Cold storage

Keeping perishable products at low temperatures in order to extend storage life. Cold storage vastly retards the processes responsible for the natural deterioration of the quality of such products at higher temperatures. Time and temperature are the key factors that determine how well foods, pharmaceuticals, and many manufactured commodities, such as photographic film, can retain properties similar to those they possess at the time of harvest or manufacture.

Food that is placed in cold storage is protected from the degradation that is caused by microorganisms. At 80°F (27°C), bacteria will multiply 3000 times in 12–24 h; at 70°F (21°C), the rate of multiplication is reduced to 15 times; and at 40°F (4°C), it is reduced to 2 times. The lower limit of microbial growth is reached at 14°F (−10°C); microorganisms cannot multiply at or below this temperature. *See* BACTERIAL GROWTH; FOOD MICROBIOLOGY.

Cold storage through refrigeration or freezing makes it possible to extend both the seasons of harvest and the geographic area in which a product is available. In the past, food products were grown locally and had to be marketed within a short period of time. Modern cold storage technology makes virtually any product available year-round on a global basis. Other technologies have been combined with refrigeration to further improve this availability. For example, in controlled-atmosphere storage of apples, controlled temperatures above freezing are maintained in a sealed room where the air is also modified to increase its nitrogen content (20.9% oxygen, 0.03% carbon dioxide, and 78.1% nitrogen with other gases) to keep apples orchard-fresh from one fall harvest through the next.

The cold storage food chain begins at the farm or packing plant where the product is chilled by three principal methods: hydrocooling (immersion in chilled water), forced-air cooling, and vacuum cooling (placing the product in a sealed chamber and creating a vacuum, causing evaporation of some of the water in the product, and subsequent cooling).

If the product is to be frozen, one of five methods is used: (1) air blast freezing (cold air at high velocity is passed over the product); (2) contact freezing (the product is placed in contact with metal plates and heat is drawn off by conduction); (3) immersion freezing (the product is immersed in low-temperature brine); (4) cryogenic freezing [the product is exposed in a chamber to temperatures below −76°F (−60°C) by using liquid nitrogen or liquid carbon dioxide]; and (5) liquid refrigerant freezing (the product is immersed and sprayed with a liquid freezant at atmospheric pressure).

The next step in the cold storage food chain is transport by railroad cars, trucks, airplanes, or boats fitted with refrigeration units that maintain temperatures to critical specifications. Electronic technology permits monitoring of temperature and location by satellite transmission from the transport vehicle to a land-based monitoring station.

Refrigerated warehouses and distribution centers maintain the temperatures required to assure continued maintenance of quality before the product makes its last commercial move to supermarkets or to food-service-industry outlets. Typically, a refrigerated warehouse is a fully insulated structure fitted with refrigeration equipment capable of precise maintenance of specific temperatures in rooms holding up to several million pounds of product. For example, individual rooms may be set to maintain refrigerated storage temperatures of 34°F (1°C) or freezer-room temperatures of 0°F (−18°C). Some food products are being marketed that may require storage temperatures as low as −20°F (−29°C) to maintain texture and to preclude separation of ingredients. *See* REFRIGERATION.

Anhydrous ammonia is the principal refrigerant used in refrigeration systems for cold storage. A number of systems had been introduced that used chlorofluorocarbon refrigerants. However, they are being phased out because of concern about the ozone layer. It is anticipated that such systems will be converted to ammonia or other refrigerants. Most engine rooms are computer-controlled in order to allow optimum use of energy and to transmit alerts if temperatures stray out of the programmed range. *See* GREENHOUSE EFFECT; HALOGENATED HYDROCARBON.

Handling of foods through distribution and cold storage is done by using pallets loaded with 1400–3000 lb (630–1350 kg) of product. Modern freezer rooms are 28–32 ft (8.5–10 m) high for conventional forklift operation, and up to 60 ft (18 m) high when automated or specialized materials-handling equipment is used. *See* FOOD MANUFACTURING; FOOD PRESERVATION; MATERIALS HANDLING.

Colemanite

One of the more common minerals of the borate group (in which boron is chemically bonded to oxygen).

Physical properties. Colemanite is white to gray with a white streak, is transparent to translucent, and has a vitreous luster. It occurs either as short highly modified prismatic crystals or as massive to granular aggregates. It has perfect cleavage in one direction, parallel to the sheet nature of its crystal structure. Colemanite has hardness of 4–$4^{1}/_{2}$ on Mohs scale and a specific gravity of 2.42. *See* HARDNESS SCALES.

Crystal structure. Colemanite is a hydroxy-hydrated calcium borate with the chemical formula $Ca[B_3O_4(OH)_3](H_2O)$. [Ca = calcium, B = boron, O = oxygen, OH = hydroxyl, H_2O = water]. The fundamental building block of the structure is a ring of one triangular ($B\phi_3$) group ($\phi = O^{2-}, OH^-$) and two tetrahedral ($B\phi_4$) groups that is conventionally symbolized as 1Δ2□:⟨Δ2□⟩. Here 1Δ2□ denotes that there is one ($B\phi_3$) group (Δ) and two ($B\phi_4$) groups (2□), the delimiters ⟨⟩ indicate the presence of a ring of linked polyhedra, specified between the delimiters (**Fig. 1**). This fundamental building block also occurs in many other borate minerals. In colemanite, the ⟨Δ2□⟩ rings share two vertices between triangles and tetrahedra of adjacent rings to form a chain extending along one axis [100]. There is one unique calcium atom coordinated by eight anions in an irregular dodecahedral arrangement.

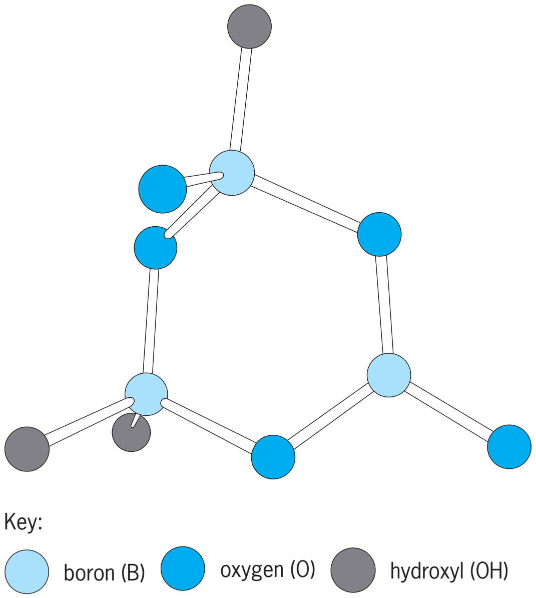

Fig. 1. Fundamental building block in the crystal structure of colemanite.

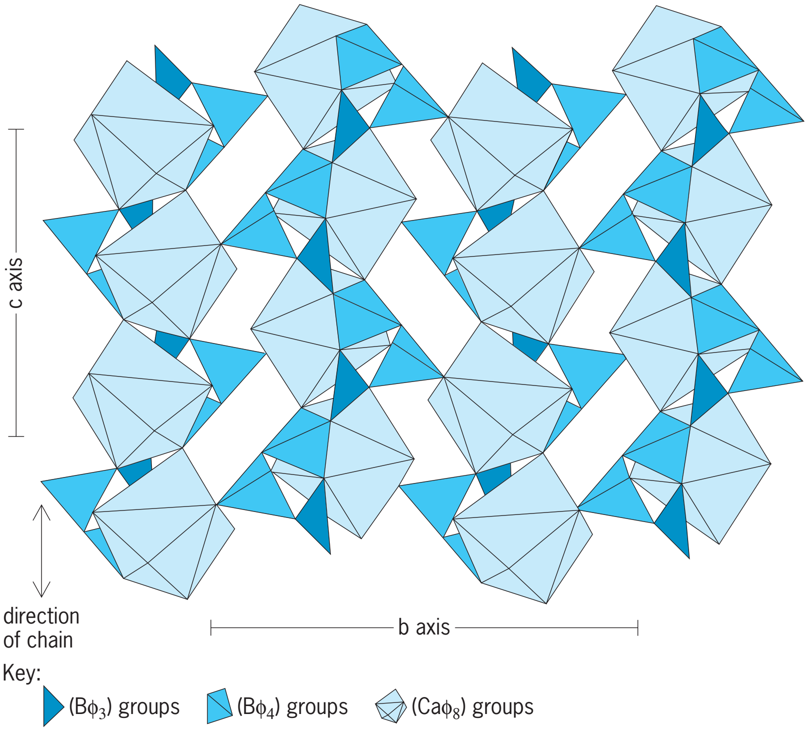

Fig. 2. Crystal structure of colemanite viewed down the *a* axis. The ⟨Δ2□⟩ rings link to form chains of borate polyhedra parallel to the *c* axis.

The (Caϕ_8) polyhedra share corners to form chains parallel to {100} (**Fig. 2**). The [Caϕ_7] chains cross-link the borate chains into a heteropolyhedral sheet of composition [$Ca_2B_3O(OH)(H_2O)$] parallel to {010}. These sheets, seen edge-on in Fig. 2, link via corner-sharing between (BO_4) tetrahedra and (Caϕ_8) dodecahedra, and through an extensive network of hydrogen bonds.

Occurrence. Colemanite typically occurs in lacustrine evaporite deposits of Tertiary age. It forms by thermal diagenesis of primary borate minerals, such as ulexite, $NaCa[B_5O_6(OH)_6](H_2O)_6$, and borax, $Na_2[B_4O_5(OH)_4](H_2O)_8$ (Na = sodium). Both ulexite and borax contain fundamental building blocks that are finite borate clusters consisting of two ⟨Δ2□⟩ rings linked together. During diagenesis, the chemical bonds between these finite borate clusters and the interstitial cations break, and the ⟨Δ2□⟩ rings then polymerize to form chains, as in colemanite. *See* BORATE MINERALS; DIAGENESIS; SALINE EVAPORITES.

Industrial uses. Colemanite is a principal source of boron, together with borax and ulexite, and is mined extensively in California and Nevada, Turkey, and Argentina. Boron is used in a wide variety of industrial commodities: soaps and washing powders, glasses and ceramics, specialty alloys, and fillers in many products. *See* BORON.

Coleoidea

The cephalopod subclass in the phylum Mollusca that includes living octopods, squids, cuttlefish, and sepiolids (bob-tail squids), and the extinct belemnites. *See* CEPHALOPODA; MOLLUSCA.

General characteristics. The group is defined by the possession of five arm pairs (which are reduced to four in octopods; see **illustration**); arm suckers or hooks with which prey are subdued; chromatophore organs in the skin; a muscular mantle that typically provides jet propulsion; and an internal shell that, although lost in most extant cephalopods, provided buoyancy to the common ancestor.

The shell of belemnites, thought to have been internal because of its unusual microstructure, has a clear buoyancy-regulating structure known as a phragmocone; its discrete chambers are sealed off as the animal grows. As they are emptied of fluid, gas fills them to allow the animal to become neutrally buoyant. The cuttlebone of cuttlefish and the internal shell of the Rams' horn squid, *Spirula spirula*, may be modified from the primitive phragmocone. Most extant coleoids, however, have further reduced the internal support; squids have a thin gladius, and among octopods, only the deep-sea finned taxa have a sizable internal fin cartilage.

Taxonomy and phylogeny. The fossil record of Coleoidea dates back to the Carboniferous. Orders of the extinct belemnite coleoids include the Aulacocerida, Belemnoteuthina, Belemnitida, Diplobelida, and Phragmoteuthida. Phylogenetic relationships among extant coleioids and between living taxa and the extinct belemnites remain unresolved. Although the greatest taxonomic and morphologic diversity of squids and octopods occur in the deep sea, these taxa remain largely unknown. Living coleoids number over 725 species, with many more suspected to remain undiscovered. Squids constitute the order Teuthida (also known as Teuthoidea), which is sometimes recognized as two orders, Myopsida (nearshore squids) and Oegopsida (oceanic squids). The three orders Spirulida (Ram's horn squid), Sepiida (cuttlefish), and Sepiolida (bob-tail

Octopus *Benthoctopus* photographed by the deep-submergence vehicle *ALVIN* at a depth of 2770 m (9140 ft), Gorda Ridge, Northeast Pacific Ocean.

squid) are sometimes treated as the single order Sepioidea. The Vampire squid constitutes the order Vampyromorpha, and order Octopoda contains deep-sea finned octopods, argonauts, midwater pelagic octopus, and the familiar benthic octopuses. *See* BELEMNOIDEA; OCTOPODA; OCTOPUS; SEPIOIDEA; TEUTHOIDEA; VAMPYROMORPHA.

Ecology. Coleoids occupy virtually every habitat in the world's oceans; they are important predators to which many animal taxa potentially fall prey, at least during part of their lives. Several factors, including well-developed brains and large eyes (which are prime examples of evolutionary convergence with vertebrates), contribute to coleiods' effectiveness as predators as well as their defense against predation.

The skin of coleoids is unique in that it contains chromatophore organs, which allow these animals to change color in milliseconds. Coleoids use camouflage to hide from potential predators as well as to sneak up on unsuspecting prey. Chromatophore organs are composed of pigments held in an enervated muscular sac. A section of the coleoid brain controls the animal's coloration by expanding or relaxing the chromatophore organs. *See* CHROMATOPHORE.

The hooks on belemnite arms, the suckers with thorny rings in squids and cuttlefish (secondarily evolved into hooks in some groups), and the muscular gripping suckers in octopods provide excellent prey-handling ability. The ancestral coleoid likely had five arm pairs of equal length. Octopods, having lost one arm pair, likely use stealth (assisted by their elaborate chromatophore-enabled camouflage) and their numerous suckers to secure their prey before injecting it with potent venom. Most other extant coleoids snatch unsuspecting prey from a distance and then draw it to their mouth by using their tentacles, a modified fourth arm pair that are highly extensible, are capable of extremely rapid movement, and have specialized hooks and/or suckers at the tips.

Reproduction and development. Intensive study of a relatively few species indicates that extant coleoids generally live short lives, typified by extremely rapid growth early in the life cycle, which slows with full sexual maturity. In most taxa, egg production occurs only near the end of the life cycle, after which both males and females begin to senesce. Although squids generally leave their eggs to survive unattended, benthic and epipelagic octopuses, such as argonauts, exhibit maternal care of their eggs through development.

Coleoptera

An order of Insecta (generally known as beetles) with a complete metamorphosis (with larva and pupa stages), the forewings forming hard protective elytra under which the hindwings are normally folded in repose, and the indirect flight muscles of the mesothorax having been lost. The head capsule is characterized by a firm ventral (gular) closure, the antennae are basically 11-segmented, and mouthparts are of the biting type with 4-segmented maxillary palpi. The prothorax is large and free. The abdomen has sternite I normally absent, sternite II usually membranous and hidden, and segment X vestigial, with cerci absent. The female has one pair of gonapophyses, on segment IX. There are four or six malpighian tubules, which are often cryptonephric. True labial glands are nearly always absent (**Fig. 1**).

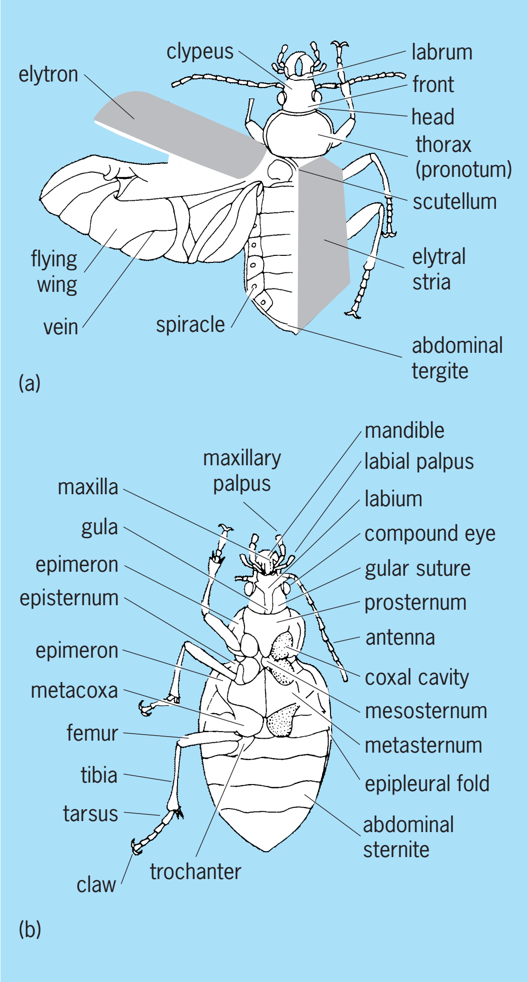

Fig. 1. Diagrammatic sketch of Carabidae member. (*a*) Dorsal view. (*b*) Ventral view.

General Biological Features

The order has well over 250,000 described species, more than any comparable group, showing very great diversity in size, form (**Fig. 2**), color, habits, and physiology. Some Ptiliidae have body lengths as small as 0.01 in. (0.25 mm), and some Cerambycidae may exceed 4 in. (100 mm). Beetles have been found almost everywhere on Earth (except as yet for the Antarctic mainland) where any insects are known, and species of the order exploit almost every habitat and type of food which is used by insects. Many species are economically important.

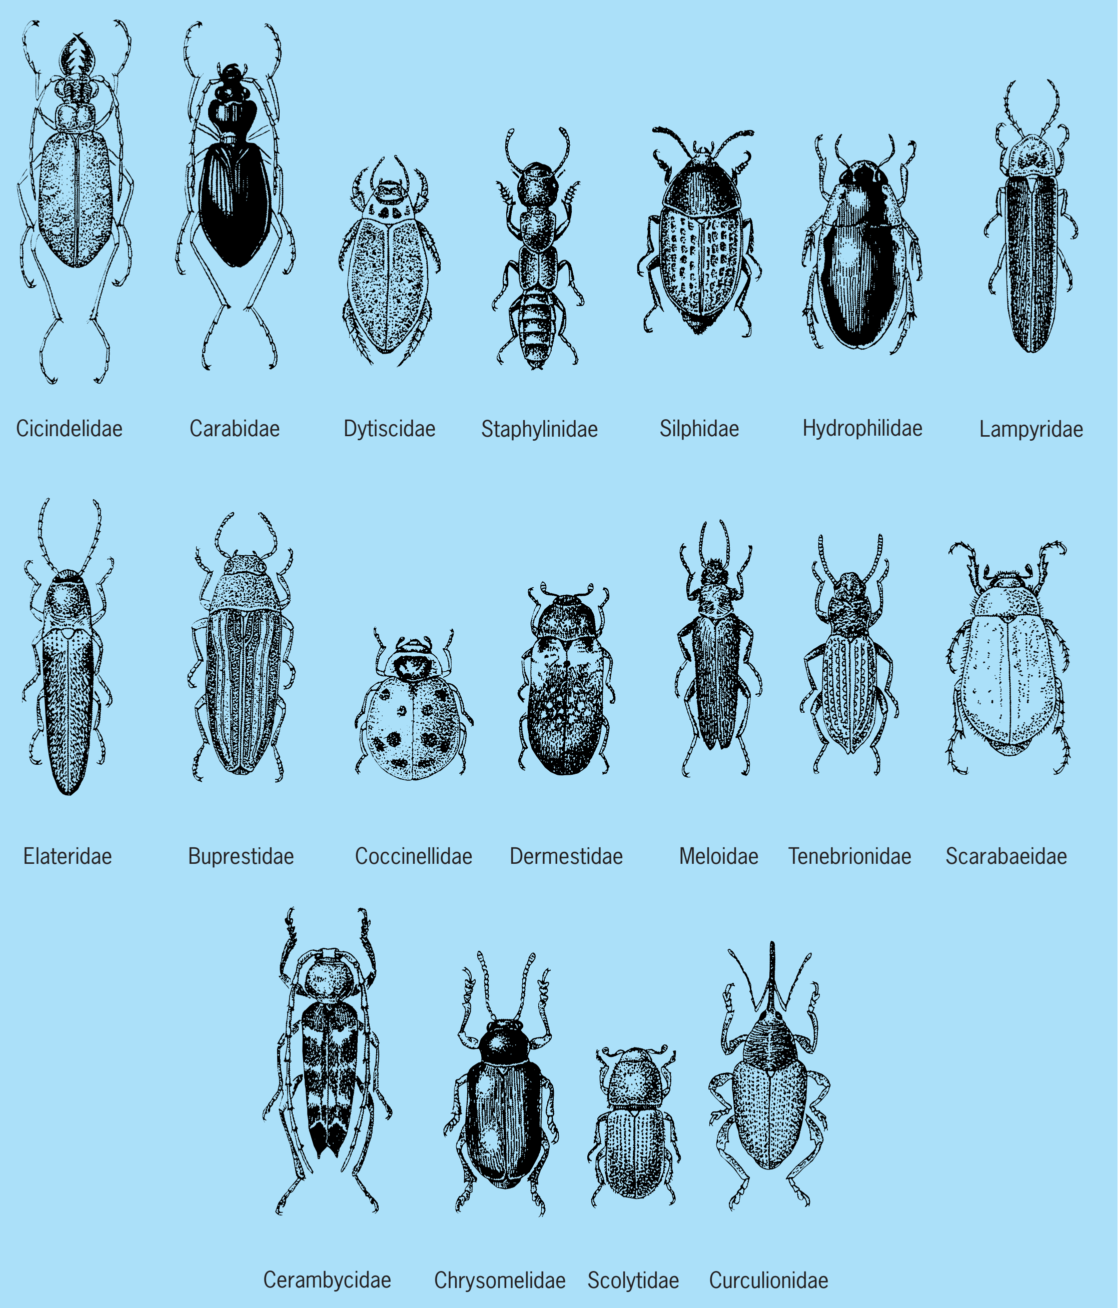

Fig. 2. Representatives of well-known families of Coleoptera. (*After T. I. Storer and R. L. Usinger, General Zoology, 3d ed., McGraw-Hill, 1957*)

A common feature is for the exoskeleton to form an unusually hard and close-fitting suit of armor, correlated with a tendency for the adults to be less mobile but longer-lived than those of other orders of higher insects. It seems to be common in a number of groups for adults to survive and breed in 2 or more successive years, a rare occurrence in other Endopterygota. Most beetles, at least in markedly seasonal climates, have a 1-year life cycle, with developmental stages adapted to specific seasons, but many larger species (particularly when larvae burrow in wood or the soil) may take 2 or more years per generation, and in suitable climates some (usually smaller) species may have more than one generation per year. Another feature unusual in Endopterygota is that many beetles have adults and larvae living in the same habitats and feeding on similar food, though many others have adult foods and habitats quite different from the larval ones. Adult beetles tend to be better runners than most other Endopterygota, and some (such as Cicindelidae) are among the fastest of running insects.

Wings and flight. The flight of most beetles is not very ready or frequent, often requiring prior climbing up onto some eminence, and in many beetles occurs only once or twice in an average life. The elytra may be held in a rigid lateral projection, as in Adephaga, or vibrate through some (usually small) angle in phase with the hindwings, as in many Polyphaga, or be held vertically upward or over the abdomen, almost in the position of repose. In a number of groups, there is evidence that the elytra contribute significantly to lift or to stability in flight. In males of Stylopidae (Strepsiptera) they are reduced to structures resembling (and probably functioning like) the halteres of Diptera. The hindwings have their insertions shifted very far forward, making the pleura of the metathorax very oblique, and their area is expanded in the anal region. Wing loading and wing-beat frequency are usually higher than in most other Pterygota, with the indirect flight muscles of the metathorax of the asynchronous type, contracting several times in response to a single nerve impulse. Wing venation is adapted to the needs of folding as well as of flight. In some groups, the wings unfold automatically if the elytra are lifted (as in Staphylinidae), but folding after flight is a more complex process, involving active participation of the flexible abdomen. In others unfolding requires considerable abdominal activity, but folding is quick and quasi-automatic, resulting from muscle pulls on the axillary sclerites of the wing base. Most beetles seem to be inherently stable (hence not very maneuverable) in flight. In a number of groups (such as Pleocomidae, Cebrionidae, Drilidae, Phengodidae, and Stylopidae), flight may be confined to the males, indicating that its prime function is to promote gene dispersal.

Cuticle. Apart from a tendency for the sclerotized layers to be thicker, the cuticle of beetles differs little from that of other insects in constitution or ultrastructure. The epicuticular wax layer shows diversity, being particularly well developed in some of the desert Tenebrionidae. Macrochaetae on the body surface may develop into scales (a trait of many Curculionidae) but are rarely plumose; in larval Dermestidae, very complex defensive hairs are developed.

The black coloring which is prevalent in many groups of beetles is produced by deposition of melanin in the process of cuticle hardening. In many groups, with adults active by day, the black is masked by a metallic structural color produced by interference in the surface cuticle layers. Pigmentary colors, mainly ommochromes, giving reddish to yellowish colors, occur in the cuticle of many species, whereas some groups, notably the tortoise beetles (Cassidinae), may have more unstable greenish pigments in the hypodermal cells beneath the cuticle. Pigmentary colors are often adapted to produce aposematic or pseudaposematic appearances, or cryptic ones. *See* PROTECTIVE COLORATION.

Defense adaptations. Special defenses against predation are common in species with long-lived adults, particularly the ground-living species of Carabidae, Staphylinidae, and Tenebrionidae. These groups commonly possess defensive glands, with reservoirs opening on or near the tip of the abdomen, secreting quinones, unsaturated acids, and similar toxic substances. In some cases, the secretion merely oozes onto the body surface, but in others may be expelled in a jet. In the bombardier beetles (Brachinini), the jet contains quinones and is expelled forcibly at nearly 212°F (100°C) through the agency of hydrogen peroxide in an explosion chamber. In other groups, toxins may be dispersed in the body, as in species of Coccinellidae, Lycidae, and Meloidae, and warning (aposematic) coloration is frequently developed.

Other common defensive adaptations include cryptic and mimetic appearances. The most frequent behavioral adaptations are the drop-off reflex and appendage retraction. Numerous Chrysomelidae, Curculionidae, and other adults will react to visual or tactile stimuli by dropping off the plant foliage on which they occur, falling to the ground with retracted appendages, and lying there for some time before resuming activity. In death feigning, the appendages are tightly retracted, often into grooves of the cuticle, and held thus for some time. In such conditions, beetles often resemble seeds and are difficult for predators to perforate or grasp.

Stridulation. Sound production (stridulation) is widespread in beetles and may be produced by friction between almost any counterposed movable parts of the cuticle. Stridulatory organs may show sex dimorphism, and in some species (such as among Scolytinae) may play an important role in the interrelations of the sexes. Elsewhere, as in species of *Cychrus, Hygrobia,* and *Necrophorus,* stridulation is a common response to molestation. Specialized sound-detecting organs, other than Johnston's organ in the antennal pedicel, are not well documented in Coleoptera.

Cryptonephrism. Cryptonephrism, in which the apical parts of the malpighian tubules are closely applied to the hindgut in the region of the rectal glands, is characteristic of a large section of Polyphaga, including all the "stored product" pests and the dominant desert beetles. This condition, not known in other adult insects, has been shown in *Tenebrio* to economize water by extracting it from the rectal contents to produce very dry feces. In cryptonephric groups, certain more or less aquatic members seem to have lost the condition secondarily.

Symbioses. Of the many types of symbiotic relations into which beetles enter with other organisms, perhaps the most ecologically important are those with fungi, which can be divided into ecto- and endosymbioses. In ectosymbiosis, the beetles carry spores or propagules of the fungi and introduce them into suitable new habitats, and are themselves nutritionally dependent (at least as larvae) on the presence of the right type of fungus in the habitat. Classic examples are in numerous bark beetles (Scolytinae) and Lymexylidae. In endosymbiosis, fungi (or sometimes bacteria) are maintained in the gut (or in mycetomes attached to it), usually of the larvae, and contribute either essential nutrients (such as steroids) or essential enzymes. Endosymbionts are usually passed externally or internally to the eggs by the ovipositing female. In endosymbiosis, it seems that as a rule the symbionts are specific to the beetles concerned, to a rather greater degree than in ectosymbionts.

Genetics. The large majority of beetles have an X-y type of chromosomal sex-determining system, with the y often small (or lost altogether) and forming a "parachute" figure with the X in meiosis. Sex ratios in natural populations are usually 50:50, and sex dimorphism, usually slight, is sometimes very marked. Thelytokous parthenogenesis, often accompanied by polyploidy, is developed in several groups. A haploid male system, like that of Hymenoptera, has been found in Micromalthidae and a few *Xyleborus* ambrosia beetles. A basic complement of nine pairs of autosomes, plus the sex pair, is maintained in many groups of beetles. *See* GENETICS.

Mating and life cycle. Mating in beetles is often a simple process, the male climbing onto the back of the female after a minimum of courtship, but in some groups (such as many Meloidae, Cerambycidae, and Scarabaeidae) more elaborate courtship is the rule. In long-lived species, individuals may copulate several times, often with different partners. Care for the young is commonly limited to the deposition of the eggs in suitable habitats under some sort of cover, but nest construction and provisioning, after the manner of solitary Aculeata Hymenoptera, develop particularly in the dung-feeding Scarabaeinae and Geotrupidae, and in a few Carabidae. Other beetles showing unusual provisions for their offspring include the ambrosia beetles or Attelabidae, some Staphylinidae-Oxytelinae, and some Lamiinae.

Beetle eggs rarely have heavily sculptured chorions or specialized caps for eclosion. Embryonic development is of typically insect types but shows considerable variation within the order. Eggs are often adapted to absorb moisture during embryonic development.

Larvae are very diverse, but usually have a well-developed head capsule with biting mouthparts, often have thoracic legs but very rarely abdominal prolegs (other than a pygopod developed from segment X), and never have true appendages on segment X. The tergite of segment IX often bears paired (sometimes articulated) posterior outgrowths known as urogomphi. First instars often differ considerably from later ones and may have toothlike egg bursters on parts of the body. The number of larval instars usually lies between 3 and 10. Pupae are usually white and exarate, resting on their backs on dorsal spines in some kind of pupal cell. They are never decticous, nor does the adult become active inside the pupal skin.

Hypermetamorphosis, in which two or more sharply different larval forms succeed during individual development, is known in several parasitic or wood-boring groups of beetles. The most common type has an active long-legged first-instar larva which seeks out a suitable feeding site and molts into a grublike type with reduced legs, as in Stylopidae, Rhipiphoridae, and Micromalthidae. The bee-parasitic Meloidae are notable in having two or even three distinct later larval stages.

Adult Anatomy

The head of beetles rarely has a marked posterior neck, and the antennal insertions are usually lateral, rather than dorsal as in most other Endopterygota, a feature possibly related to an original habit of creeping under bark. In most Curculionoidea and a few other groups, the head may be drawn out in front of the eyes to form a rostrum. Paired ventral gular sutures (sometimes partially confluent) are usually present, giving rise to a fairly normal tentorium; a frontoclypeal suture (representing an internal ridge) is often present. Two pairs of ventral cervical sclerites are found in Polyphaga only. Dorsal ocelli are rarely present, and never more than two; compound eyes range from occupying most of the head surface (as in male Phengodidae) to total absence (as in many cavernicolous or subterranean forms). Antennal forms are very various, with the number of segments often reduced, but rarely increased, from the basic 11. Mandible forms are very diverse and related to types of food.

Thorax. The prothorax commonly has lateral edges which separate the dorsal part (notum) from the ventral part (hypomeron) of the tergum. The propleuron may be fully exposed (Adephaga, Archostemata) or reduced to an internal sclerite attached to the trochantin (Polyphaga). The front coxal cavities may or may not be closed behind by inward processes from the hypomera or pleura to meet the prosternal process.

The mesothorax is the smallest thoracic segment. Dorsally, its tergum is usually exposed as a small triangular sclerite (scutellum) between the elytral bases, and ventrally, its sternite may have a median pit receiving the tip of the prosternum. The elytra of beetles develop in a different way from those of earwigs, cockroaches, and such. The first stage is the modification of wing venation to form a series of parallel longitudinal ridges connected by a latticework of crossveins (as seen in many modern Archostemata). The veins then expand to obliterate the remaining membrane, often leaving 9 or 10 longitudinal grooves or rows of punctures representing the original wing membrane and having internal pillars (trabeculae) connecting the upper and lower cuticle. There are various types of dovetailing along the sutural margins of the elytra, and their outer margins are often inflexed to form epipleura.

The form of the metathorax is affected by far-forward insertions of the hindwings and far-posterior ones of the hindlegs, so that the pleura are extremely oblique and the sternum usually long. Usually, the episterna are exposed ventrally, but the epimera are covered by the elytral edges. The metasternum commonly has a median longitudinal suture (with internal keel), and primitively, there may be a transverse suture near its hind edge. Internally, the endosternite takes diverse and characteristic forms.

Tarsi. The tarsi of beetles show all gradations from the primitive five-segmented condition to total disappearance. The number of segments may differ between the legs of an individual or between the sexes of a species. A very common feature in the order is the development of ventral lobes, set with specialized adhesive setae, on some tarsal segments. Often, strong lobes of this kind occur on the antepenultimate segments, and the penultimate one is very small and more or less fused to the claw joint. Lobed tarsi are particularly characteristic of species frequenting plant foliage.

Abdomen. Most beetles have the entire abdomen covered dorsally by the elytra in repose, and ventrally only five or six sternites (of segments III to VII or VIII) exposed; segment IX is retracted inside VIII in repose. Tergites I–VI are usually soft and flexible, those of VII and VIII more or less sclerotized. In some groups, the elytra may be truncate, leaving parts of the abdomen exposed dorsally, in which case the exposed tergites are sclerotized. Sternite IX is usually a single (internal) sclerite in males, but divided in females to form a pair of valvifers. Male gonapophyses are typically represented by a median basal piece bearing a pair of parameres (lateral lobes), and those of the female by a pair of coxites and styli attached to the valvifers. In females of many groups, an elongate ovipositor is produced by elongation into rods of sclerites of abdominal segment IX.

Elytra. A feature developed in several groups of Coleoptera, but particularly in Staphylinidae, is the abbreviation of the elytra to leave part of the abdomen uncovered in repose, but usually still covering the folded wings. One advantage of this may be to give greater overall flexibility to the body. This is probably of particular advantage to species living in the litter layer in forests, a habitat in which Staphylinidae are strikingly dominant. Perhaps surprisingly, many beetles with short elytra fly readily.

Internal anatomy. Internally, the gut varies greatly in length and detailed structure. The foregut commonly ends in a distended crop whose posterior part usually has some internal setae and may be developed into a complex proventriculus (Adephaga, many Curculionoidea); the midgut may be partly or wholly covered with small papilae (regenerative crypts) and sometimes has anterior ceca. The four or six malpighian tubules open in various ways into the beginning of the hindgut and in many Polyphaga have their apices attached to it (cryptonephric). The central nervous system shows all degrees of concentration of the ventral chain, from having three thoracic and eight abdominal ganglia distinct (as in some Cantharoidea) to having all of these fused into a single mass (as in some higher Scarabaeidae). There are two main types of testes in the males: Adephaga have each testis as a single, long, tightly coiled tube wrapped around in a membrane; Polyphaga have testes usually of several follicles. In the female, Adephaga have polytrophic ovarioles, while Polyphaga have acrotrophic ones, unlike any others known in Endopterygota.

Larval Anatomy

The head capsule in beetle larvae is usually well developed with fairly typical biting mouthparts, with or without a ventral closure behind the labium. Antennae are basically three-segmented, segment II (pedicel) usually bearing a characteristic sensory appendage beside segment III. In several groups, segment I may be divided to give four-segmented antennae (Carabidae, many Staphylinidae, Scarabaeidae), but division of segment III seems to be peculiar to Helodidae. There are up to six ocelli on each side, variously grouped. The frontal sutures (ecdysial lines) often have a characteristic inverted horseshoe form; a median coronal suture may be present. The mandibles have very diverse forms, related to types of food, and the labrum is often replaced by a toothed nasale, particularly in carnivorous types practicing extraoral digestion. The maxillae also vary considerably. In the more specialized predatory types, the cardo tends to be reduced. In some groups, maxillae and labium are more or less fused together to form a complex resembling the gnathochilarium of Millipedes. In some groups with burrowing or internal-feeding larvae, the head capsule may be largely retracted into the prothorax, with corresponding reductions of sclerotization.

Thorax. In the thorax, the prothorax is usually markedly different from the next two segments. The legs are often well developed, particularly in ground-living predatory types, and in Adephaga and Archostemata may have a separate tarsus with two claws. Reduction or loss of legs is characteristic of many burrowing or internal-feeding larvae. The first pair of spiracles is usually situated close to the front border of the mesothorax, lateroventrally; very rarely, a second thoracic spiracle is distinct.

Abdomen. Ten abdominal segments are usually visible, prolegs are rarely developed on any of the first eight segments, but segment X often forms a proleglike pygopod. The tergite of segment IX is often drawn out into posterior processes known as urogomphi, which may become articulated and movable (as in Hydradephaga, Staphylinoidea). In some aquatic larvae, segments IX and X are reduced, and the spiracles of segment VIII become effectively terminal, as in most Diptera larvae. Larval spiracles take diverse forms, which are systematically important.

Body types. The more specialized burrowers among beetle larvae may be divided into two broad types, the straight- and the curved-bodied (**Fig. 3**). Straight burrowing larvae are normal in Archostemata, Carabidae, Elateroidea, various Heteromera, Cerambycidae, and halticine Chrysomelidae, while curved larvae are the norm in Scarabaeoidea, Bostrychoidea, Chrysomelidae-Eumolpinae, and Curculionoidea. The basic difference is probably in the way in which the larva anchors itself in its burrow, using its mandibles to burrow into a resistant medium. In straight larvae, purchase may be secured by short stout legs (as in Elateridae), by terminal abdominal structures, or by protrusible asperate tuberosities (ampullae) on trunk segments (as is the case with Archostemata and Cerambycidae). In both groups, ocelli rarely number more than one and are often lost, and legs are liable to be reduced or lost. The antennae, which are always reduced in straight burrowers, may be quite long in some curved ones, such as Scarabaeoidea.

Physiology

In the basic life functions, such as digestion, respiration, excretion, circulation, muscle contraction,

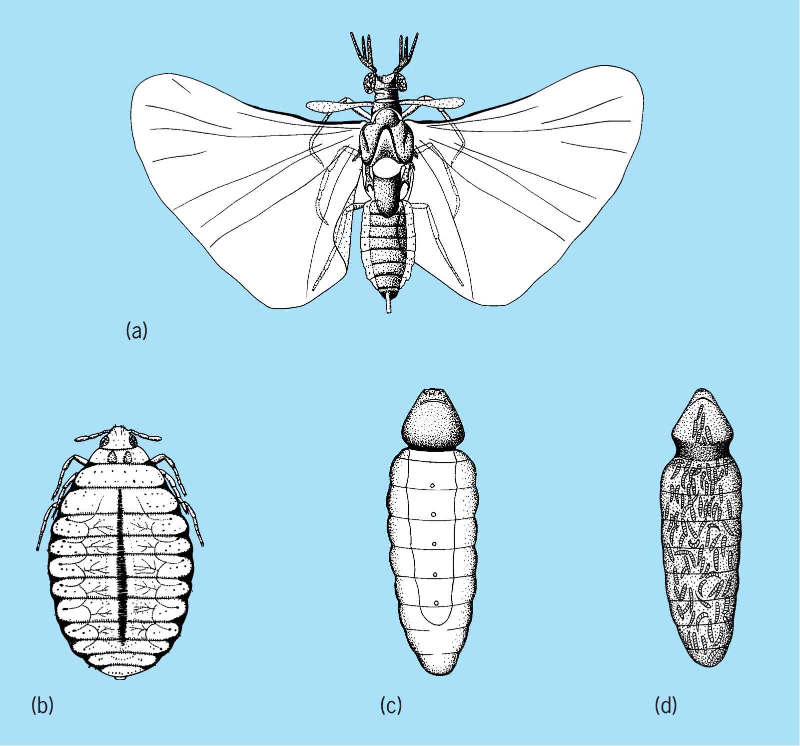

Fig. 3. Stylopidae. (*a*) *Eoxenos laboulbeni*, adult male and (*b*) adult female. (*c*) *Stylops melittae*, adult female (ventral view) and (*d*) gravid female with larvae. (*After C. P. Clausen, Entomophagous Insects, McGraw-Hill, 1940*)

nerve conduction, sense reception, and growth, most beetles show normal insect features, but certain groups are unusual in one or another of these respects. In digestion, some dermestid larvae can digest keratin, a faculty otherwise known only in some tineoid moth larvae. Some wood-boring larvae, notably in Anobiidae and Cerambycidae, have some ability to digest celluloselike substances, apparently through the aid of microorganisms carried in mycetomes associated with the midgut, and some scarabaeid larvae make similar use of microorganisms in a fermentation chamber in the hindgut. Some beetle larvae are able to live and develop normally in fungus-infested decaying wood that is very low in oxygen and high in CO_2. Some aquatic beetles and their larvae may be found living normally in hot springs at temperatures up to 111°F (44°C). In some adult Scolytinae, it has been found that the indirect flight muscles of the metathorax may be greatly reduced and absorbed during gonad development after an initial nuptial flight, yet redeveloped to become functional again with post-reproductive adult feeding. Effective color change in adults, mainly through changes in the hydration of cuticular layers, has been found in certain Scarabaeidae-Dynastinae and Chrysomelidae-Cassidinae. Something approaching homothermy during periods of adult activity has been reported in some of the larger scarabaeoid beetles, utilizing heat generation by muscles in a preliminary warm-up stage, and air-cooling of the thorax by large tracheae during high activity.

Digestion. The digestive organs and capacities of beetles, and their food requirements, are generally like those of other insects, but some groups have unusual features. In many predatory larvae, also in some adults, extraoral digestion occurs, commonly marked in larvae by the development of a rigid toothed nasale in place of the labrum. In some such larvae, particularly when aquatic, the mandibles may become tubular-channeled. In at least some staphylinine larvae, there appear to be "venom" glands developed in the mandibles.

Among herbivores and wood-borers, capacities to digest celluloses and other "difficult" carbohydrates may be developed, usually and perhaps always by the aid of symbiotic microorganisms producing suitable enzymes. Dermestid larvae have developed the ability to digest keratin, breaking its disulfide bonds in an unusually alkaline midgut and producing free hydrogen sulfide as in some tineoid larvae.

Sense organs. The sense organs of beetles, adult or larval, are generally similar in type and function to those of other insects. For vision, the adult compound eyes show great diversity in form and ommatidial structure. Some types, such as *Cicindela*, are adapted for high visual acuity in bright light, others to high sensitivity in poor light, and many show light-dark adaptations of screening pigment. Color vision seems to be restricted to certain groups in the order, notably some of the floricolous Cetoniinae. In certain beetles, specialized infrared sensitivity is evidenced, notably in the region of the vertex of the head in many Curculionidae, and in complex metasternal organs in certain Buprestidae which are attracted to burning trees in coniferous forests. *See* EYE (INVERTEBRATE).

Antennae. Antennae in bettles are mainly receptors for smell and touch, but detection of aerial vibrations (by Johnston's organ in the pedicel) may be important in some. Some of the long hairlike sensilla may detect movements in the air and serve as "wind socks" when beetles are about to fly. Many of the more actively flying groups have the antennal insertions shifted dorsally from their primitive lateral position. The olfactory sensilla, which commonly are thin-walled multiperforate setae, are often concentrated on expanded apical segments, forming a club. This arrangement probably helps in the detection of odor gradients in still air by crawling beetles. Sex dimorphism in the antennae is not uncommon in groups with short-lived adults, the males being specialized to detect female pheromones. Fairly high olfactory acuities for specific substances have been found, especially in some carrion beetles.

Taste. Taste, or contact chemoreception, is usually mediated by sensilla with a single large apical opening. These sensilla are concentrated on the palpi and other mouthparts and are often found on tibiae or tarsi of the front legs (also probably on the ovipositor in many). In water beetles, the smell-taste distinction becomes obscured.

Sound receptors. Specialized sound receptors, other than Johnston's organ, have not been much studied in Coleoptera, though many species produce sounds and in some cases (in various Scolytinae and other Curculionidae, for example) these play a significant part in courtship. The tibial spurs, in at least some species, serve to detect vibrations in the substratum. *See* ANIMAL COMMUNICATION.

Trichobothria. Very long slender hairs arising from deep cuticular pits occur in many blind cave beetles, along the outer edges of the elytra in most Carabidae, and in larvae of Staphylinidae-Paederinae. These organs are believed to register slight movements in the air, resulting from nearby activity of potential prey or predators.

Gravitational sense. A gravitational sense is evident in many burrowing bettles, which are able to sink accurately vertical burrows despite inclinations of the surface started from. Indications are that such a sense is located in the legs rather than in the antennae, though no beetles are known to have subgenual organs, which may serve this function in other insects.

Temperature sense. A temperature sense is clearly present in some beetles and larvae, but little is known of the sensilla concerned. A type of coeloconic sensillum has been shown to serve this function in palpi of Culicidae, and very similar sensilla have been found in Coleoptera (as on the head capsule of elaterid larvae), which may be sensitive to differences in soil temperature.

Biological clock. What might be called a time sense (otherwise known as a biological clock) clearly operates in many beetles that react specifically to changing daylight lengths marking the seasons in nontropical latitudes. It also manifests itself as a circadian rhythm in "wild" beetles maintained artificially in conditions of uniform temperature, illumination, and humidity. *See* INSECT PHYSIOLOGY; PHOTOPERIODISM.

Food Specialization

The biting mouthparts of many adult and larval beetles are adaptable to many types of food, and fairly widely polyphagous habits are not uncommon in the order, though most species can be assigned to one or another of a few main food categories: fungivores, carnivores, herbivores, or detritivores. Included in the last category are species feeding on decaying animal or vegetable matter and on dung. Most parasites could be included with carnivores, but those myrmecophiles and termitophiles which are fed by their hosts, and those Meloidae which develop on the food stores of bees, form special categories.

There are reasons for thinking that ancestral Coleoptera fed on fungi on dead wood, and beetles of many groups today are largely or wholly fungus eaters. Many are specialists of particular types of fungi, among whose hosts most major groups of fungi are represented. It could well be that the habit of producing fruit bodies and spores underground (as in truffles, and *Endogone*) originally coevolved in relation to the activities of burrowing beetles (such as Liodini and some Scarabaeoidea), which may still be important spore-dispersal agents for such fungi. The long-lasting fruit bodies of various Polyporaceae on dead wood are important breeding grounds for beetles of a number of families, but few beetles can complete their larval development fast enough to exploit the short-lived types of toadstool. Beetles of several families (including the Scolytinae) may serve as effective vectors, inoculating new habitats with fungi which are significant for the beetles' nutrition.

Predators. Predation, mainly on other insects, is probably the fundamental mode of life in adult and larval Adephaga, and has developed in a number of different lines of Polyphaga. Many carnivorous beetles (such as Carabidae and Staphylinidae) are fairly widely polyphagous and liable to supplement their diets with nonanimal matter to some extent, but more specialized predation also occurs (for example, among Histeridae and various Cleridae). Predacious larvae may give rise to largely herbivorous adults (such as in many Hydrophilidae and Melyridae); the converse relation, though rarer, also occurs (in some Cerambycidae, for example). Predatory beetles often do not require movement of the prey to stimulate attack and feeding behavior, and may feed extensively on eggs or pupae of other insects which escape many other predators. Predation on pupae by beetle larvae may lead to parasitic-type habits, as in Lebiini and Brachinini among Carabidae, or Aleocharini among Staphylinidae.

Herbivores. Herbivorous beetles may eat green plants of all groups, from algae to angiosperms, may attack any part of the plant, and display a great range in host plant specialization. Some, like the Colorado beetle, will feed and develop only on a few closely related species of a single genus. Others, like many of the short-nosed weevils, are highly polyphagous, and are able to live on angiosperms of many different families. Feeding on roots, or on the enclosed seeds of Angiospermae, are mainly larval habits, whereas adults usually eat stems, leaves, or flowers. Many species are injurious to crops (**Fig. 4**), and a few have been used successfully in the biological control of weeds (such as *Chrysolina* spp. against *Hypericum*). A number of beetles are effective transmitters of viruses of field crops (such as *Phyllotreta* spp. on Cruciferae); some may be useful pollinators (such as *Meligethes* spp. on Cruciferae). Many botanists believe that beetle pollination was a feature of the first

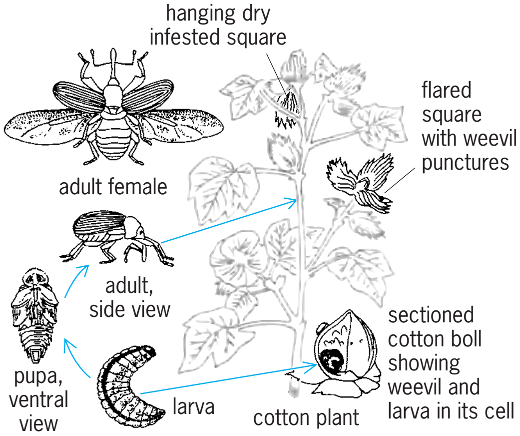

Fig. 4. Cotton boll weevil (*Anthonomus grandis* Boheman). (*After C. H. Metcalf, W. F. Flint, and R. L. Metcalf, Destructive and Useful Insects, 3d ed., McGraw-Hill, 1951*)

Angiospermae and that the enclosed carpels were developed to protect ovules against floricolous beetles.

Adults of a number of families frequent flowers, often eating pollen as well as licking nectar. Botanists distinguish cantharophilous flowers, which depend particularly on beetles for their pollination, and which include what are believed to be some of the most primitive surviving Angiospermae. Characteristic features are white flowers, either large or massed in heads, abundant pollen production, and open shapes, with nectar production often absent.

Larvae developing in flowers or buds are characteristic of Meligethinae and Cateretinae in Nitidulidae. In the latter group, larvae tend to feed on the gynoecium; in the former, on the anthers. Other groups, such as Bruchidae and various weevils, have larvae developing later, in the ripening fruits, and less typically floricolous adults. The tough exines of pollen grains are not easily permeable. For assimilation of the contents, it may be necessary either to crack the outer wall by the mandibles or to cause the grains to begin germination in the crop, as may happen in Oedemeridae and Mordellidae, for example.

Water Beetles

Beetles are unusual among the higher insects in that aquatic habits, where present, usually affect adults as well as larvae. The elytra (like the hemielytra of Heteroptera) may have been preadaptive to the invasion of water. Almost any type of fresh or brackish water body is liable to contain some types of water beetles, though very few species can live permanently in full marine salinities. Almost all aquatic beetles maintain an air reservoir, into which the second thoracic and abdominal spiracles open, under their elytra; and some, mainly small, species may have plastrons or physical gills. Aquatic larvae tend to have a last pair of abdominal spiracles that is large and effectively terminal, or tend to develop tracheal gills. Pupae are terrestrial in the large majority of water beetles, and eggs, when deposited underwater, are commonly laid in contact with airspaces in the stems of water plants, or in an air-filled egg cocoon (Hydrophilidae). Most water beetles are confined to shallow waters, and many of them are ready colonists of temporary pools, through adult flight.

Many of the adults, but fewer of the larvae, are active swimmers by means of the legs, while others rely mainly on crawling for locomotion. The whirligig beetles (Gyrinidae) are exceptional in that the adults swim very fast on the water surface, with only the ventral side submerged, by means of highly modified middle and hind legs, and are able to dive when alarmed, while the larvae are fully aquatic with long tracheal gills. The special modifications of the adults include divided compound eyes, one part for aerial, one for underwater vision; short antennae with a highly developed Johnston's organ, serving to pick up vibrations from potential prey or from the movements of other Gyrinidae in the surface film; long raptorial front legs; and a rudderlike end of the abdomen.

Aquatic larvae and more or less terrestrial adults occur in Psephenidae, some Ptilodactylidae, and the Donaciine leaf beetles; the converse relation is known in at least some Hydraenidae.

The foods of water beetles include algae (Myxophaga, Hydraenidae, many Dryopoidea), higher plants (larval Donaciinae, some Curculionidae, adults of many Hydrophilidae), other small animals (most Hydradephaga, Hydrophilid larvae), and mixed diets.

Special Habitats and Adaptations

More or less unusual adaptations and modes of life are manifest in dung and carrion beetles, ambrosia beetles, cave and subterranean beetles, desert beetles, and luminous beetles. Dung and carrion beetles exploit sporadic and very temporary food resources in which competition (particularly with Diptera larvae) tends to be fierce. Many dung beetles avoid the difficulties by burying dung stores in underground cells where their larvae can develop safely, and some beetles (Necrophorinae) adopt a similar strategy for carrion. They may also develop phoretic and symbiotic relations with specific mites preying on fly eggs.

In ambrosia beetles, the adults usually excavate burrows in wood, carrying with them spores of special fungi, which proceed to develop along the walls of the burrows and are fed on by larvae developing from eggs laid there. This type of relation between beetles, fungi, and trees exists in various forms in a number of families and may be of ecological importance if the fungi concerned are liable to kill trees.

Marginal habitats. More than one family of beetles contains highly adapted types living exclusively in deeper cave systems (cavernicolous) or the deeper layers of the soil (hypogeous). Such species are usually flightless and eyeless, poorly pigmented, and slow-moving, and of very restricted geographical distribution. In the cavernicoles, long trichobothrium-type setae are often developed on the body, and the adults may produce very large eggs singly, with a very abbreviated larval development, approaching the pupiparous condition of some Diptera.

Another marginal habitat in which beetles are the principal insect group represented is the desert, where Tenebrionidae are the dominant group. Here, too, wings are usually lost, but the cuticle tends to be unusually thick, firm, and black. Most desert beetles have burrowing larvae, and the adults also usually take refuge in the soil during the heat of the day. Elaborate adaptations for water economy and dew collection are frequent.

Another marginal habitat in which beetles may be found is hot springs. *Hydroscapha* and certain Hydrophilidae have been found breeding apparently normally in water of temperatures up to 111°F (44°C), which would be lethal for most other animals. A few water beetles are adapted to underground (phreatic) waters, showing parallel features with the cavernicolous and hypogeous terrestrial ones.

Dung and carrion beetles. Dung and carrion provide important but temporary food resources whose insect users are almost exclusively beetles and Diptera. Dung and carrion beetles are almost always good fliers, with strong antennal clubs bearing heavy concentrations of sensilla. Many of the adults are burrowers and, particularly among dung beetles, frequently make and provision underground nests, thereby removing the food supply for their larvae from the twin dangers of Diptera and drying up. Necrophorini among carrion beetles shows similar features, with the added feature of actual feeding of the larvae by adults. Another special feature of *Necrophorus* and some dung beetles is an apparently symbiotic relation with *Poecilochirus* and allied mites, which are carried on the bodies of adult beetles and which specifically attack the eggs of competing Diptera in the breeding habitat. A well-known feature of many Scarabaeine dung beetles is the formation of a ball of dung which is rolled to a nest site some distance from the dung patch.

Wood borers. One mode of life in which beetles are undoubtedly the dominant group among insects is wood boring, mainly pursued by larvae, but also by adults in some Bostrychidae, Scolytinae, and Platypodinae. Rather few beetles bore normally into the wood of healthy living trees, which are liable to drown borers in sap, but moribund, dead, or decaying timber is liable to heavy attack. Some borers can develop only in unseasoned wood, requiring remains of cell contents; others develop in seasoned wood; and many require the presence of some type of fungus for successful development. Hardwoods and softwoods have their beetle specialists, and females of some Cerambycidae restrict their oviposition to branches or trunks of some particular girth.

Parasites. More or less parasitic relations to animals of other groups have developed in a number of lines of Coleoptera. The closest parallels to Hymenoptera-Parasitica are to be seen in the families Stylopidae (Strepsiptera of many authors; Fig. 3) and Rhipiphoridae. Stylopid larvae are exclusively endoparasites of other insects, while the adult females are apterous, often legless, and remain in the host's body, while males have large fanlike hindwings and the elytra reduced to haltere-like structures. Adult mouthparts are vestigial in both sexes. The more modified of Rhipiphoridae, parasitizing cockroaches, show close parallels with the more primitive Stylopidae, while more primitive ones, probably parasitizing wood-boring beetles, resemble the allied nonparasitic Mordellidae. Larvae ectoparasitic on lignicolous beetle larvae or pupae are found in Passandridae and some Colydiidae.

A considerable variety of Coleoptera develop normally in the nests of termites and social or solitary Hymenoptera-Aculeata, some being essentially detritivores or scavengers, but most feed either on the young or the food stores of their hosts. Many of the myrmecophiles and termitophiles are highly modified structurally and behaviorally and highly host-specific. Some of these beetles appear to have successfully "broken" the chemical or tactile communication codes of their hosts.

Ectoparasitism on birds or mammals is a rare development in beetles, the best-known examples being in Liodidae-Leptininae, with adults and sometimes larvae living on the bodies of small mammals, and Staphylinidae-Amblyopinini, with apparently similar habits. A few Cryptophagidae and Languiriidae-Loberinae have been recorded as adults on bodies of rodents. In the little-known Cavognathidae of the Southern Hemisphere, in at least some species and probably in all of them, the breeding habitat is birds' nests and the larvae feed on nestling birds. *See* POPULATION ECOLOGY.

Luminescence. The beetles are notable in that some of them manifest the highest developments of bioluminescence known in nonmarine animals, the main groups concerned being Phengodidae, Lampyridae, and Elateridae-Pyrophorini, the glowworms and fireflies. In luminescent beetles, the phenomenon always seems to be manifest in the larvae and often in the pupae, but not always in the adults. *See* BIOLUMINESCENCE.

In luminous adult beetles, there is often marked sex dimorphism, and a major function of the lights seems to be the mutual recognition of the sexes of a species. In such cases, there is often a rapid nervous control of the luminescence, and a development of species-specific flash codes. In some cases, notably in adult Pyrophorini and some larval Phengodidae, an individual may carry lights of two different colors.

Another possible function of adult luminosity, and the only one seriously suggested for larvae, is as an aposematic signal. There is definite evidence that some adult fireflies are distasteful to some predators, and the luminous larvae of Phengodidae have dorsal glandular openings on the trunk segments that probably have a defensive function.

Phylogenetic History

Coleoptera are older than the other major endopterygote orders. The earliest fossils showing distinctively beetle features were found rather before the middle of the Permian Period and generally resemble modern Archostemata. By the later Permian, fossils indicate that beetles had become numerous and diverse, and during the Mesozoic Era they appear as a dominant group among insect fossils. Fossils in Triassic deposits have shown features indicative of all four modern suborders, and the Jurassic probably saw the establishment of all modern superfamilies. By early Cretaceous times, it is likely that all "good" modern families had been established as separate lines. In the Baltic Amber fauna, of later Paleogene age (about 40,000,000 years ago), about half the fossil beetle genera appear to be extinct, and the other half still-living representatives (often in remote parts of the world). Beetle fossils in Quaternary (Pleistocene) deposits are very largely of still-living species.

Beetles appear to have been the first insect wood borers, with insect borings in fossil wood of Triassic age (for example, in the Petrified Forest of Arizona) being probably the work of larval

Archostemata. Some fossil woods of slightly younger age have shown the oldest indications of a resin-secreting system, probably a defensive reaction against the attacks of wood-boring beetles. Later still, it seems that beetles may have played a major part in the evolution of the angiosperm-type of flower. The Adephaga probably evolved as ground-living predators, and their pygidial defensive glands may well have been a response to amphibian predation, much like the metathoracic glands of the roughly coeval Hemiptera-Heteroptera. Fossils clearly of adephagan water beetles are known from Lower Jurassic deposits, making a further parallel with Heteroptera-Cryptocerata.

Classification

A modern classification of beetles is given below. This system is adapted from that of Crowson (1955) and is intended to be phylogenetic in the sense of Hennig. An asterisk indicates that the family is not known in the fauna of the United States; a dagger, that the family is not known from the New World.

- Suborder Archostemata
  - Superfamily Cupedoidea
    - Family: Ommadidae†
    - Tetraphaleridae*
    - Cupedidae
    - Micromalthidae
- Suborder Adephaga
  - Superfamily Caraboidea
    - Family: Paussidae (including Ozaeninae, Metriinae, Sicindisinae)
    - Cicindelidae
    - Carabidae (including Omophroninae, Rhysodinae)
    - Trachypachidae
    - Amphizoidae
    - Haliplidae
    - Hygrobiidae†
    - Noteridae
    - Dytiscidae
    - Gyrinidae
- Suborder Myxophaga
  - Superfamily Sphaeroidea
    - Family: Lepiceridae (Cyathoceridae)*
    - Torridincolidae*
    - Hydroscaphidae
    - Sphaeridae (Sphaeriidae)
- Suborder Polyphaga
  - Series Staphyliniformia
    - Superfamily Hydrophiloidea
      - Family: Hydraenidae
      - Spercheidae
      - Hydrochidae
      - Georyssidae
      - Hydrophilidae
    - Superfamily Histeroidea
      - Family: Sphaeritidae
      - Synteliidae*
      - Histeridae (including Niponiidae)
    - Superfamily Staphylinoidea
      - Family: Ptiliidae (including Limulodidae)
      - Empelidae
      - Liodidae (including Leptininae, Catopinae, Coloninae, Catopocerinae)
      - Scydmaenidae
      - Silphidae
      - Dasyceridae
      - Micropeplidae
      - Staphylinidae (including Scaphidiinae)
      - Pselaphidae
  - Series Eucinetiformia
    - Superfamily Eucinetoidea
      - Family: Clambidae
      - Eucinetidae
      - Helodidae
  - Series Scarabaeiformia
    - Superfamily Scarabaeoidea
      - Family: Pleocomidae
      - Geotrupidae
      - Passalidae
      - Lucanidae
      - Trogidae
      - Acanthoceridae
      - Hybosoridae
      - Glaphyridae
      - Scarabaeidae
    - Superfamily Dascilloidea
      - Family: Dascillidae
      - Karumiidae*
      - Rhipiceridae (Sandalidae)
  - Series Elateriformia
    - Superfamily Byrrhoidea
      - Family Byrrhidae
    - Superfamily Dryopoidea
      - Family: Eulichadidae
      - Ptilodactylidae
      - Chelonariidae
      - Psephenidae
      - Elmidae (Elminthidae)
      - Lutrochidae
      - Dryopidae
      - Limnichidae
      - Heteroceridae
    - Superfamily Buprestoidea
      - Family Buprestidae (including Schizopidae)
    - Superfamily Artematopoidea
      - Family: Artematopidae
      - Callirhipidae
    - Superfamily Elateroidea
      - Family: Cebrionidae
      - Elateridae
      - Throscidae
      - Cerophytidae
      - Perothopidae
      - Phylloceridae†
      - Eucnemidae
    - Superfamily Cantharoidea
      - Family: Brachypsectridae
      - Cneoglossidae*

Family: Plastoceridae†
Homalisidae†
Lycidae
Drilidae†
Phengodidae
Telegeusidae
Lampyridae
Omethidae
Cantharidae
Series Bostrychiformia
Superfamily Dermestoidea
Family: Derodontidae
Nosodendridae
Dermestidae
Thorictidae†
Jacobsoniidae (Sarothriidae)*
Superfamily Bostrychoidea
Family: Bostrychidae (including Lyctinae)
Anobiidae
Ptinidae (including Ectrephini, Gnostini)
Series Cucujiformia
Superfamily Cleroidea
Family: Phloiophilidae†
Series: Peltidae
Family: Lophocateridae
Trogossitidae
Chaetosomatidae†
Cleridae
Acanthocnemidae
Phycosecidae†
Melyridae (including Malachiinae)
Superfamily Lymexyloidea
Family: Lymexylidae
Stylopidae (Strepsiptera, Stylopoidea)
Superfamily Cucujoidea
Family: Nitidulidae
Rhizophagidae (including Monotominae)
Protocucujidae*
Sphindidae
Boganiidae†
Cucujidae
Laemophloeidae
Passandridae
Phalacridae
Phloeostichidae*
Silvanidae
Cavognathidae*
Cryptophagidae (including Hypocoprinae)
Lamingtoniidae†
Helotidae†
Languriidae
Erotylidae (including Pharaxonothinae)
Biphyllidae
Cryptophilidae (including Propalticinae)†
Cerylonidae
Corylophidae
Alexiidae (Sphaerosomatidae)†
Endomychidae
Coccinellidae
Discolomidae
Merophysiidae
Lathridiidae
Byturidae
Mycetophagidae
Cisidae
Pterogeniidae†
Tetratomidae
Melandryidae
Mordellidae
Rhipiphoridae
Merycidae†
Colydiidae
Synchroidae
Cephaloidae
Pythidae
Pyrochroidae
Anthicidae
Meloidae
Aderidae
Scraptiidae (including Anaspidinae)
Oedemeridae
Cononotidae
Othniidae
Salpingidae
Inopeplidae
Mycteridae (including Hemipeplinae)
Monommidae
Zopheridae
Tenebrionidae (including Lagriinae, Nilioninae, Alleculinae)
Superfamily Chrysomeloidea
Family: Disteniidae (including Oxypeltinae, Philinae,† Vesperinae)
Cerambycidae
Megalopodidae (including Zeugophorinae)
Bruchidae (including Sagrinae)
Chrysomelidae
Superfamily Curculionoidea
Family: Nemonychidae
Anthribidae (including Bruchelinae)
Belidae*
Oxypeltidae*
Aglycyderidae (Proterhinidae)†
Allocorynidae
Attelabidae
Apionidae (including Antliarrhininae,† Ithycerinae, Nanophyinae)
Brenthidae
Curculionidae (including Scolytinae and Platypodinae)

This classification is based on a great variety of characteristics, including internal ones and those of immature stages, and takes account of the fossil evidence. Important characteristics include the structure of the propleura, the cervical sclerites, the ovarioles, larval leg segments, form of testes, wing venation and folding, number and arrangement of malpighian tubules, forms of the female and male external genitalia, presence or absence of a free larval labrum, larval spiracular structures, mode of formation of adult midgut in the pupa, form of the metendosternite, number of female accessory glands, form of adult antennae, tarsal segmentation, presence of pupal "gin traps," number of pupal spiracles, number of adult abdominal spiracles, presence of defensive glands in adults or larvae, egg bursters of the first-instar larva, form of adult tentorium and gular sutures, forms of adult coxal cavities, and internal structure of adult ommatidia.

Geographical Distribution

Almost every type of continuous or discontinuous distribution pattern which is known in any animal group could be matched in some taxon of Coleoptera, and every significant zoogeographical region or area could be characterized by endemic taxa of beetles. In flightless taxa, distributional areas are generally more limited than those of comparable winged taxa. Distinct distributional categories can be seen in those small, readily flying groups (in Staphylinidae and Nitidulidae, for example) which are liable to form part of "aerial plankton," and in those wood borers which may survive for extended periods in sea-drifted logs, both of which are liable to occur in oceanic islands beyond the ranges of most other beetle taxa. Climatic factors often seem to impose limits on the spread of beetle species (and sometimes of genera or families), and beetle remains in peats have been found to be sensitive indicators of climatic changes in glacial and postglacial times. *See* INSECTA; SOCIAL INSECTS. Roy A. Crowson

Crowson, The natural classification of the families of Coleoptera: Addenda and corrigenda, *Entomol. Mon. Mag.,* 103:209–214, 1967; S. P. Parker (ed.), *Synopsis and Classification of Living Organisms*, 2 vols., 1982.

Coliiformes

A small order of birds containing only the family Coliidae with six species (the mousebirds) restricted to Africa. Mousebirds, or colies, are small, grayish to brownish, with a crest on the head and long tail (see **illustration**). The legs are short and the feet strong, with the four toes movable into many positions, from all four pointing forward to two reversed backward. Mousebirds perch, climb, crawl, and scramble agilely in bushes and trees. They are largely vegetarian but eat some insects. They are nonmigratory and gregarious, living in flocks and sleeping in clusters, but they are monogamous in loose colonies as breeders. The nest is an open cup in a tree or bush, and the two to four young remain in the nest, cared for by both adults until they can fly.

White-headed mousebirds (*Colius leucocephalus*). (© *2004 DonGettyPhoto.com*)

The relationships of the mousebirds to other birds are obscure. Mousebirds have a surprisingly good fossil record from the Miocene of France and Germany, suggesting a wider distribution of this group. *See* AVES. Walter J. Bock

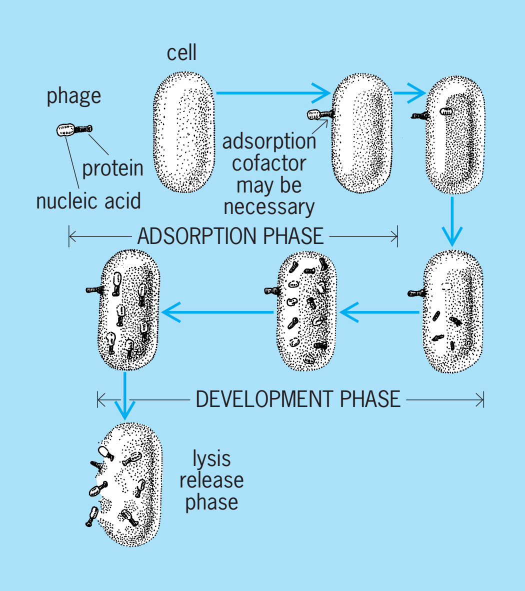
Schifter, Systematics and distribution of the mousebirds (Coliidae), in *Proceedings of the International Symposium of African Vertebrates*, 1985.

Coliphage

Any bacteriophage able to infect the bacterium *Escherichia coli*. Many are phages able to attack more than one strain of this organism. The T series of phage (T1–T7), propagated on a special culture of *E. coli*, strain B, have been used in extensive studies from which most of the knowledge of phages is derived.

A typical phage particle is shaped something like a spermatozoon. The outer skin, or shell, consists of protein and encloses contents of deoxyribonucleic acid (DNA). This DNA can be separated from the protein by osmotic shock, and it is then found that the protein shell alone can cause death of a bacterium when adsorbed to the cell surface. This does not constitute a true infection, however, since no new phage is formed.

The usual lytic infection of a *coli* B cell by a T phage proceeds as follows (see **illus.**). The phage is adsorbed, by its tail, to the cell surface. Following this adsorption, the phage DNA gains access to the cell. The protein skin has now served its purpose and, if desired, can be removed from the cell surface without affecting subsequent events. Phage in



Steps in the two phases of a lytic infection by phage. (*After E. L. Oginsky and W. W. Umbreit, An Introduction to Bacterial Physiology, Freeman, 1954*).

an infectious state no longer exists; it is now spoken of as vegetative phage and will remain in this state during its life cycle until the production of new infective particles occurs. Immediately following the injection of the DNA, the metabolic activities of the cell are profoundly altered. Normal growth ceases abruptly, although respiration continues at a steady rate. Cell enzymes still function, but their activity is now redirected and controlled by "information" supplied by the phage DNA. New protein synthesis can be detected at once; this is not bacterial protein, however, but phage protein which is to serve later as part of the new phage particles. Synthesis of bacterial ribonucleic acid (RNA) ceases. Bacterial DNA breaks down, and after about 10 min, phage DNA begins to make its appearance, formed in part from the bacterial DNA and in part from new synthesis. This new DNA is incorporated with the phage protein to make a new phage which can now be detected as an infectious unit. In another 10 min or so, lysis occurs after more phage has accumulated within the cell. The time will vary with different phages. The infectious phage, released in numbers of 100 or more particles, is able to infect susceptible bacteria. *See* BACTERIOPHAGE; LYSOGENY; LYTIC INFECTION; VIRUS.

Philip B. Cowles

Collagen

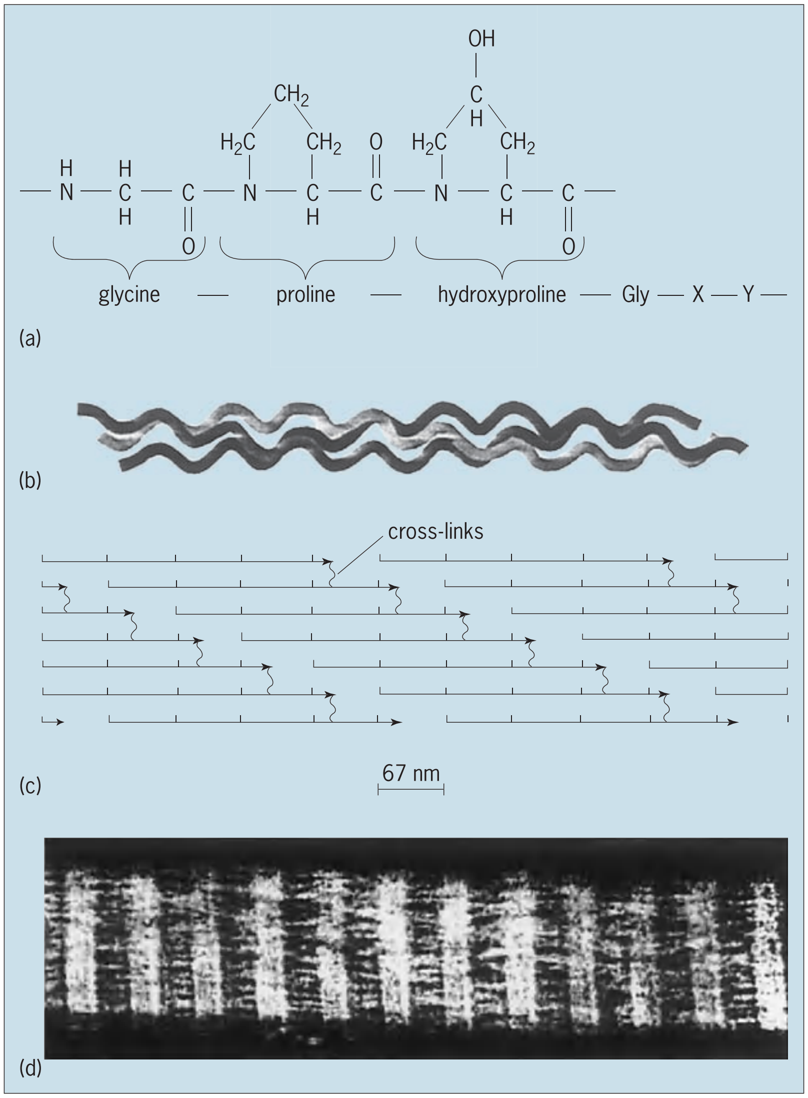
The major fibrous protein in animals. Collagen is present in all types of multicellular animals and is probably the most abundant animal protein in nature. It is estimated that collagen accounts for about 30% of the total human body protein. Collagen is located in the extracellular matrix of connective tissues. It is part of the interacting network of proteoglycans and proteins that provides a structural framework for both soft and calcified connective tissues. By self-associating into fibrils and by binding to proteoglycans and other matrix components, collagen contributes to tissue integrity and mechanical properties. Collagen interacts with cells through the integrin cell receptors and mediates cellular adhesion and migration. Important roles for collagen have been identified in development, wound healing, platelet aggregation, and aging. Its commercial importance in leather and the production of gelatin and glue have long been recognized. More recently, it is being used as a basis for biomaterials. Examples of its biomedical applications include injectable collagen to lessen facial wrinkles and defects; surgical collagen sponges to increase blood clotting; and artificial skin for the treatment of burns. *See* GELATIN; LEATHER AND FUR PROCESSING.

Structure and properties. The classification of an extracellular matrix protein as a collagen is based on the presence of a domain with the distinctive triple-helical conformation. The collagen triple helix consists of three polypeptide chains, each of which adopts an extended polyproline II–like helix. The three chains are supercoiled about a common axis and linked by hydrogen bonds. Only recently were the detailed features of this conformation determined by x-ray crystallography, confirming the general structure and showing an extensive network of ordered water hydrogen bonded to the triple helix.

The triple-helical conformation requires unique amino acid sequence features. Glycine, which is the smallest amino acid, must be present as every third residue. A high content of the sterically restricted imino acids, proline and hydroxyproline, is also necessary to stabilize the extended helix. Hydroxyproline provides additional stability through water-mediated hydrogen bonds. Collagen is the only animal protein, other than elastin, with significant amounts of hydroxyproline and hydroxylysine residues. It is easy to identify a collagen triple helix from its amino acid sequence pattern of repeating glycine-X-Y sequences, and glycine-proline-hydroxyproline is the most frequent tripeptide sequence (see **illus.**).

Types. At least 19 distinct molecules have been classified as collagens, and specific types are associated with particular tissues. The most prevalent and well-studied collagens belong to the fibril-forming or interstitial collagen family. These collagens form the characteristic fibrils seen by electron microscopy with a 67-nanometer repeating banding pattern. The banding pattern arises from the axial staggering of the collagen molecules. The molecules in a fibril are covalently cross-linked by an enzymatic mechanism to strengthen and stabilize them. Inhibition of the enzyme involved in cross-linking results in a dramatic decrease in the tensile strength of tissues, a condition known as lathyrism.

Type I is the most common fibril-forming collagen. Its fibrils make up the mineralized matrix in bone, the strong parallel bundles of fibers in tendon, and the plywoodlike alternating layers in the transparent cornea. Type II is the major fibril-forming collagen



Levels of collagen structure. (*a*) Typical amino acid repeating sequence. (*b*) Triple-helical molecular structure. (*c*) Staggered arrangement of molecules which generates the 67-nm periodic fibrils. (*d*) Electron micrograph of collagen fibril.

in cartilage, while type III is found in blood vessels and skin, together with type I. The family known as fibril-associated collagens with interrupted triple helices, or FACIT collagens, decorates the outside of the 67-nm periodic fibrils. The FACIT collagens appear to link fibrils and bind to other matrix components.

Basement membranes, which serve to separate cell layers and act as filtration barriers, contain a distinctive group of collagens, denoted as type IV collagens. Type IV collagens have many breaks in the repeating glycine-X-Y pattern of their triple helix. These collagens are organized into a network or meshlike sheet structure. In the kidney glomerulus, the network based on type IV collagen acts as a filter to determine which molecules will pass from the blood into the urine.

A number of proteins involved in host defense functions also contain collagenous amino acid sequences that adopt a triple-helical conformation. These include the complement protein C1q and mannose-binding protein. The collagenous domains of these proteins associate into hexamers or other oligomers to form the functional molecule, and are also involved in receptor and enzyme binding. *See* BONE; CONNECTIVE TISSUE; FIBROUS PROTEIN.

Biosynthesis and degradation. The genes coding for different collagen types have many exons, and the biosynthesis of collagen is a complex multistage process. The synthesis of collagen takes place in the endoplasmic reticulum. Hydroxyproline and hydroxylysine are formed by enzymes after proline and lysine are incorporated into polypeptide chains, but before the chains are folded into a triple helix. Vitamin C (ascorbic acid) is required for the hydroxylating enzymes; the failure to make hydroxyproline residues and stable collagen leads to the fragile blood vessels and skin lesions found in scurvy. After three chains associate to form the triple helix, the molecule is secreted by the cell and, following cleavage of precursor regions, fibril formation or other molecular association occurs in the matrix. Enzymes required for the posttranslational modifications of collagen include hydroxylases, enzymes involved in the attachment of sugars, proteases which cleave precursor regions, and lysyl oxidase for cross-linking.

An orderly breakdown of collagen is necessary during development and tissue remodeling. For instance, following childbirth, the uterus reduces in size, which involves a massive degradation of collagen. Collagen is resistant to degradation by most vertebrate proteases, but it is cleaved by several specific matrix metalloproteinases (collagenases). These zinc-requiring enzymes cleave fibril-forming collagens at one specific site. An abnormal increase in the degradation of cartilage collagen is seen in osteoarthritis. Collagen breakdown also appears to be essential for tumor metastases. With the recent determination of the three-dimensional structures of several matrix metalloproteinases, there are active attempts by pharmaceutical companies to develop enzyme inhibitors for use in arthritis and cancer therapies.

Diseases. Collagen is impaired in both inherited and acquired diseases involving connective tissues. A number of hereditary diseases have been shown to be due to mutations in specific collagen genes. Osteogenesis imperfecta (brittle bone) disease is characterized by fragile bones and is due to mutations in type I collagen, the major collagen in bone. Some cartilage disorders are caused by mutations in type II collagen. Ruptured arteries are found in Ehlers-Danlos syndrome type IV, which arises from mutations in type III collagen, important in blood vessels. The most common type of mutations in collagen are single-base substitutions that result in a substitution of glycine by another amino acid. Such a substitution breaks the repeating glycine-X-Y triplet pattern which is essential to form a good triple helix. Transgenic mice are being used as models for human collagen diseases.

Collard

A cool-season biennial crucifer, *Brassica oleracea* var. *acephala*, similar to nonheading cabbage. Collard is of Mediterranean origin and is grown for its rosette of leaves which are cooked fresh as a vegetable (see **illus.**). Kale and collard differ only in the form of their leaves; both have been referred to as coleworts, a name taken from the Anglo-Saxon term meaning cabbage plants.

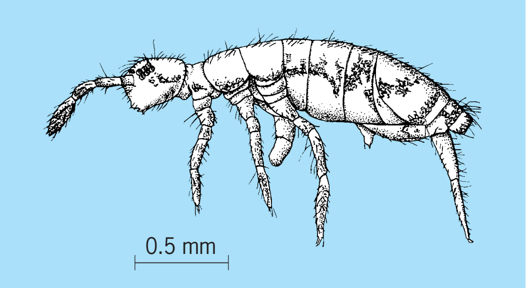
Collard (*Brassica oleracea* var. *acephala*).

Propagation is by seed. Cultural practices are similar to those used for cabbage; however, collards are more tolerant of high temperatures. Georgia and Vates are popular varieties (cultivars). Collard is moderately tolerant of acid soils. Harvesting is usually 75 days after planting. Important production centers are in the southern United States, where collards are an important nutritious green, especially during winter months. *See* CABBAGE; CAPPARALES; KALE.

H. John Carew

Collembola

An order of primitive insects, commonly called springtails, belonging to the subclass Apterygota. These tiny insects do not undergo a metamorphosis. They have six abdominal segments, some of which may be ankylosed to give an apparently smaller number (see **illus.**).



A collembolan, *Entomobrya cubensis*. (*After J. W. Folsom, Proc. U.S. Nat. Mus., 72*(6), *plate 6, 1927*).

The tarsi are united with the tibiae, and a pretarsus is present, which bears a dorsal median claw and usually a ventral clawlike appendage. The ventral tube always occurs on the first abdominal segment and connects with the mouthparts through a ventral canal consisting of two integumentary folds which overlap. Appended to the fourth abdominal segment in most of the species is a spring, or furcula. This consists of a basal piece and two apical parallel structures which end in hooks. Another pair of structures, united at the base, occur ventrally on the third abdominal segment. These bear teeth which engage with the furcula and hold it beneath the body. When released, the spring flies backward, catapulting the insect. Two families, Sminthuridae and Actaletidae, have simple tracheal systems, while the others breathe through the integument. Collembola live in humid places, often in leaf mold. Some species are active at cool temperatures, hence another common name, snowflea, is used. The earliest known insect fossil, *Rhyniella praecursor*, is thought to belong to this order.

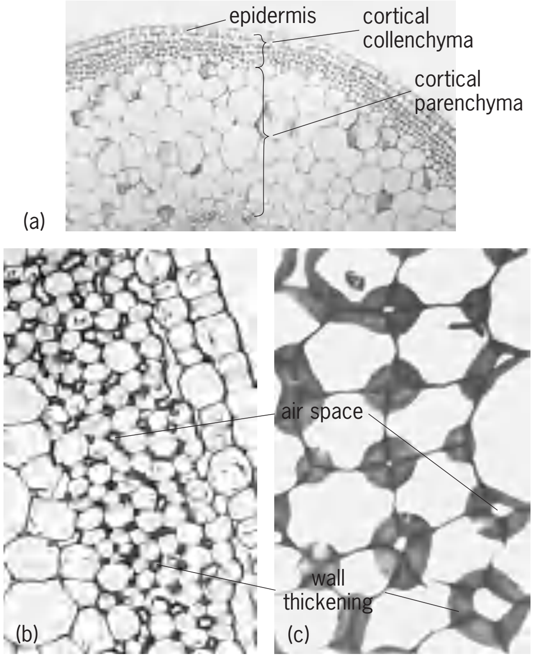
Collenchyma

A primary, or early differentiated, supporting tissue of young shoot parts appearing while these parts are still elongating. It is located near the surface, usually just under the epidermis (**illus.** *a*). When observed in transverse sections, it is characterized structurally by cell walls that are intermittently thickened, generally in the corners or places of juncture of three or more cells (illus. *b* and *c*). Collenchyma is typically formed in the petioles and vein ribs of leaves, the elongating zone of young stems, and the pedicels of flowers. *See* CELL WALLS (PLANT).

As in parenchyma, the cells in collenchyma are living and may contain chloroplasts and starch grains. The cell wall of a collenchyma cell is its most striking feature structurally and functionally. It is composed of cellulose and pectic compounds plus a very high proportion of water. In some studies collenchyma cell walls were found to contain 50–60% water by fresh weight in a variety of species examined. The cellulose and pectic compounds are present in alternating layers. A striking feature of collenchyma cell walls is their plasticity. They are capable of great



Transverse sections of Jimsonweed (*Datura stramonium*), progressively magnified. (*a*) Stem section. (*b*) Stem section, showing the corner thickenings of collenchyma cell walls and air spaces surrounded by wall thickenings. elongation during the period of growth in length of the plant. Despite this elongation, the characteristic thickening of the wall continues to increase because new wall material is added during growth. The plasticity of collenchyma is associated with a tensile strength comparable to that shown by fibers of sclerenchyma. The combination of strength and plasticity makes the collenchyma effective as a strengthening tissue in developing stems and leaves having no other supporting tissue at that time. *See* CELLULOSE; CHLOROPHYLL; EPIDERMIS (PLANT); FLOWER; LEAF; PARENCHYMA; PECTIN; STEM. Collision (physics)

Any interaction between particles, aggregates of particles, or rigid bodies in which they come near enough to exert a mutual influence, generally with exchange of energy. The term collision, as used in physics, does not necessarily imply actual contact.

In classical mechanics, collision problems are concerned with the relation of the magnitudes and direction of the velocities of colliding bodies after collision to the velocity vectors of the bodies before collision. When the only forces on the colliding bodies are those exerted by the bodies themselves, the principle of conservation of momentum states that the total momentum of the system is unchanged in the collision process. This result is particularly useful when the forces between the colliding bodies act only during the instant of collision. The velocities can then change only during the collision process, which takes place in a short time interval. Under these conditions the forces can be treated as impulsive forces, the effects of which can be expressed in terms of an experimental parameter known as the coefficient of restitution, which is discussed later. *See* CONSERVATION OF MOMENTUM; IMPACT.

The study of collisions of molecules, atoms, and nuclear particles is an important field of physics. Here the object is usually to obtain information about the forces acting between the particles. The velocities of the particles are measured before and after collision. Although quantum mechanics instead of classical mechanics should be used to describe the motion of the particles, many of the conclusions of classical collision theory are valid. *See* SCATTERING EXPERIMENTS (ATOMS AND MOLECULES); SCATTERING EXPERIMENTS (NUCLEI).

Classification. Collisions can be classed as elastic and inelastic. In an elastic collision, mechanical energy is conserved; that is, the total kinetic energy of the system of particles after collision equals the total kinetic energy before collision. For inelastic collisions, however, the total kinetic energy after collision is different from the initial total kinetic energy.

In classical mechanics the total mechanical energy after an inelastic collision is ordinarily less than the initial total mechanical energy, and the mechanical energy which is lost is converted into heat. However, an inelastic collision in which the total energy after collision is greater than the initial total energy sometimes can occur in classical mechanics. For example, a collision can cause an explosion which converts chemical energy into mechanical energy. In molecular, atomic, and nuclear systems, which are governed by quantum mechanics, the energy levels of the particles can be changed during collisions. Thus these inelastic collisions can involve either a gain or loss in mechanical energy.

Consider a one-dimensional collision of two particles in which the particles have masses m_1 and m_2 and initial velocities u_1 and u_2. If they interact only during the collision, an application of the principle of conservation of momentum yields Eq. (1), where

$$m_1u_1 + m_2u_2 = m_1v_1 + m_2v_2 \qquad (1)$$

v_1 and v_2 are the velocities of m_1 and m_2, respectively, after collision.

Coefficient of restitution. It has been found experimentally that in collision processes Eq. (2) holds,

$$e = \frac{v_2 - v_1}{u_1 - u_2} \qquad (2)$$

where e is a constant known as the coefficient of restitution, the value of which depends on the properties of the colliding bodies. The magnitude of e varies from 0 to 1. A coefficient of restitution equal to 1 can be shown to be equivalent to an elastic collision, while a coefficient of restitution of zero is equivalent to what is sometimes called a perfectly inelastic collision. From the definition of e one can show that in a perfectly inelastic collision the colliding bodies stick together after collision, as two colliding balls of putty or a bullet fired into a wooden block would do. Equations (1) and (2) can be solved for the unknown velocities υ_2 and υ_1 in the one-dimensional collision of two particles.

The concept of coefficient of restitution can be generalized to treat collisions involving the plane motion of smooth bodies—both of particles and larger bodies for which rotation effects must be considered. For these collisions, experiments show that the velocity components to be used in Eq. (2) for *e* are the components along the common normal to the surfaces of the bodies at the point where they make contact in the collision. For smooth bodies the velocity components perpendicular to this direction are unchanged. Use of this result and the principle of conservation of momentum is sufficient to solve two-dimensional collision problems of smooth bodies. For collisions of smooth spheres the velocity components to be used in Eq. (2) for *e* are those on the line joining the centers of the spheres. Velocity components perpendicular to this direction are unchanged.

Center-of-mass coordinates. A simplification of the description of both classical and quantum mechanical collisions can be obtained by using a coordinate system which moves with the velocity of the center of mass before collision. (Since for an isolated system the center of mass of the system can be shown to be unaccelerated at all times, the velocity of the center of mass of the system of particles does not change during collision.) The coordinate system which moves with the center of mass is called the center-of-mass system, while the stationary system is the laboratory system.

The description of a collision in the center-of-mass system is simplified because in this coordinate system the total momentum is equal to zero, both before and after collision. In the case of a two-particle collision the particles therefore must be oppositely directed after collision, and the magnitude of one of the velocities in the center-of-mass system can be determined if the other magnitude is known. *See* CENTER OF MASS.

Bibliography. D. Halliday, R. Resnick, and K. Krane, *Physics*, 4th ed., 1992; F. W. Sears, M. W. Zemanski, and H. D. Young, *University Physics*, 7th ed., 1987.

Colloid

A state of matter characterized by large specific surface areas, that is, large surfaces per unit volume or unit mass. The term colloid refers to any matter, regardless of chemical composition, structure (crystalline or amorphous), geometric form, or degree of condensation (solid, liquid, or gas), as long as at least one of the dimensions is less than approximately 1 micrometer but larger than about 1 nanometer. Thus, it is possible to distinguish films (for example, oil slick), fibers (spider web), or colloidal particles (fog) if one, two, or three dimensions, respectively, are within the submicrometer range.

Types of colloid dispersions

Medium	Dispersed matter	Technical name	Examples
Gas	Liquid	Aerosol	Fog, sprays
	Solid	Aerosol	Smoke, atmospheric or interstellar dust
Liquid	Gas	Foam	Head on beer, lather
	Liquid	Emulsion	Milk, cosmetic lotions
	Solid	Sol	Paints, muddy water
Solid	Gas	Solid foam	Foam rubber
	Liquid	Solid emulsion	Opal
	Solid	Solid sol	Steel

A colloid consists of dispersed matter in a given medium. In the case of finely subdivided particles, classification of a number of systems is possible, as given in the **table**. In addition to the colloids in the table, there are systems that do not fit into any of the listed categories. Among these are gels, which consist of a network-type internal structure loaded with larger or smaller amounts of fluid. Some gels may have the consistency of a solid, while others are truly elastic bodies that can reversibly deform. Another colloid system that may occur is termed coacervate, and is identified as a liquid phase separated on coagulation of hydrophilic colloids, such as proteins. *See* GEL.

It is customary to distinguish between hydrophobic and hydrophilic colloids. The former are assumed to be solvent-repellent, while the latter are solvent-attractant (dispersed matter is said to be solvated). In reality there are various degrees of hydrophilicity for which the degree of solvation cannot be determined quantitatively.

Properties. Certain properties of matter are greatly enhanced in the colloidal state due to the large specific surface area. Thus, finely dispersed particles are excellent adsorbents; that is, they can bind various molecules or ions on their surfaces. This property may be used for removal of toxic gases from the atmosphere (in gas masks), for elimination of soluble contaminants in purification of water, or decolorization of sugar, to give just a few examples. *See* ADSORPTION.

Colloids are too small to be seen by the naked eye or in optical microscopes. However, they can be observed and photographed in transmission or scanning electron microscopes. Owing to their small size, they cannot be separated from the medium (liquid or gas) by simple filtration or normal centrifugation. Special membranes with exceedingly small pores, known as ultrafilters, can be used for collection of such finely dispersed particles. The ultracentrifuge, which spins at very high velocities, can also be employed to promote colloid settling. *See* ELECTRON MICROSCOPE; SCANNING ELECTRON MICROSCOPE; ULTRACENTRIFUGE; ULTRAFILTRATION.

Colloids show characteristic optical properties. They strongly scatter light, causing turbidity such as in fog, milk, or muddy water. Scattering of light (recognized by the Tyndall beam) can be used for the observation of tiny particles in the ultramicroscope. Colloidal state of silica is also responsible for iridescence, the beautiful effect observed with opals. *See* SCATTERING OF ELECTROMAGNETIC RADIATION; TYNDALL EFFECT.

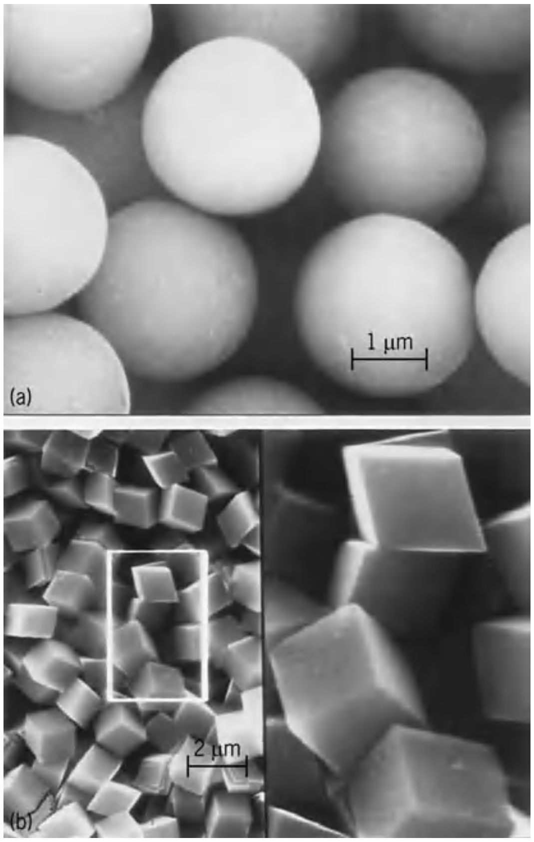
Preparation. Since the characteristic dimensions of colloids fall between those of simple ions or molecules and those of coarse systems, there are in principle two sets of techniques available for their preparation: dispersion and condensation. In dispersion methods the starting materials consist of coarse units which are broken down into finely dispersed particles, drawn into fibers, or flattened into films. For example, colloid mills grind solids to colloid sizes, nebulizers can produce finely dispersed droplets from bulk liquids, and blenders are used to prepare emulsions from two immiscible liquids (such as oil and water). *See* EMULSION.

In condensation methods, ions or molecules are aggregated to give colloidal particles, fibers, or films. Thus, insoluble monolayer films can be developed by spreading onto the surface of water a long-chain fatty acid (for example, stearic acid) from a solution in an organic liquid (such as benzene or ethyl ether). Colloidal aggregates of detergents (micelles) form by dissolving the surface-active material in an aqueous solution in amounts that exceed the critical micelle concentration. *See* MICELLE; MONOMOLECULAR FILM.

The most common procedure to prepare sols is by homogeneous precipitation of electrolytes. Thus, if aqueous silver nitrate and potassium bromide solutions are mixed in proper concentrations, colloidal dispersions of silver bromide will form, which may remain stable for a long time. Major efforts have focused on preparation of monodispersed sols, which consist of colloidal particles that are uniform in size, shape, and composition (see **illus.**). *See* PRECIPITATION (CHEMISTRY).

Dispersion stability. Dispersions of colloids (sols) are inherently unstable because they represent systems of high free energy. Particles may remain in suspended state as long as they are small enough for gravity to be compensated by the kinetic energy (brownian movement). Consequently, particle aggregation on collision must be prevented, which can be achieved by various means. *See* BROWNIAN MOVEMENT.

The most common cause for sol stability is electrostatic repulsion, which results from the charge on colloidal particles. The latter can be due to adsorption of excess ions (such as of bromide ions on silver bromide particles), surface acid or base reactions (for example, removal or addition of protons on the surface of metal hydroxides), or other interfacial chemical reactions. Alternately, sol stability can be induced by adsorption of polymers or by solvation. Stability of colloid dispersions that occur naturally may represent an undesirable state, as is the case with muddy waters whose turbidity is due to the presence of tiny particles (clays, iron oxides, and so forth). When needed, stability can be artificially induced, as in the production of paints. *See* SOLVATION.



Examples of colloid particles. (*a*) Zinc sulfide (sphalerite). (*b*) Cadmium carbonate, with an enlargement of the boxed section (*courtesy of Egon Matijević*).

Coagulation or flocculation. Processes by which a large number of finely dispersed particles is aggregated into larger units, known as coagula or flocs, are known as coagulation or flocculation; the distinction between the two is rather subtle. The concepts most commonly refer to colloidal solids in liquids (sols), although analogous principles can be employed in explaining aggregation of solid particles or liquid droplets in gases (aerosols).

Coagulation of stable sols can be accomplished by various additives (electrolytes, surfactants, polyelectrolytes, or other colloids) whose efficiency depends on their charge and adsorptivity, as well as on the nature of suspended particles to be treated. A common example of applications of coagulation is in water purification in which particulate colloid contaminants must be aggregated in order to be removed. Coagulation is also used to describe solidification of polymers (for example, proteins), which can be achieved by heating, as exemplified by boiling an egg. *See* EMULSION; FOAM; FOG; POLYMER; SMOKE. Colloidal crystals

Periodic arrays of suspended colloidal particles. Common colloidal suspensions (colloids) such as milk, blood, or latex are polydisperse; that is, the suspended particles have a distribution of sizes and shapes. However, suspensions of particles of identical size, shape, and interaction, the so-called monodisperse colloids, do occur. In such suspensions, a new phenomenon that is not found in polydisperse systems, colloidal crystallization, appears: under appropriate conditions, the particles can spontaneously arrange themselves into spatially periodic structures. This ordering is analogous to that of identical atoms or molecules into periodic arrays to form atomic or molecular crystals. However, colloidal crystals are distinguished from molecular crystals, such as those formed by very large protein molecules, in that the individual particles do not have precisely identical internal atomic or molecular arrangements. On the other hand, they are distinguished from periodic stackings of macroscopic objects like cannonballs in that the periodic ordering is spontaneously adopted by the system through the thermal agitation (brownian motion) of the particles. These conditions limit the sizes of particles which can form colloidal crystals to the range from about 0.01 to about 5 micrometers. *See* BROWNIAN MOVEMENT; KINETIC THEORY OF MATTER.

The most spectacular evidence for colloidal crystallization is the existence of naturally occurring opals. The ideal opal structure is a periodic close-packed three-dimensional array of silica microspheres with hydrated silica filling the spaces not occupied by particles. Opals are the fossilized remains of an earlier colloidal crystal suspension. Synthetic opals can be made by allowing suspensions of silica spheres to sediment and then letting the suspending medium evaporate. Colloidal crystals can also be made from suspensions of synthetic plastic (organic polymer) microspheres, formed by emulsion polymerization. Such suspensions have become important systems for the study of colloidal crystals, by virtue of the controllability of the particle size and interaction. Colloidal crystals have also been found in aqueous emulsions of oil drops in water, in which all the drops are made the same size by fractionation. Another important class of naturally occurring colloidal crystals are found in concentrated suspensions of nearly spherical virus particles, such as *Tipula* iridescent virus and tomato bushy stunt virus. *See* OPAL; VIRUS.

Crystal structure and properties. In order for colloidal crystals to form, the forces between the particles must be repulsive, since if the forces are attractive the particles will aggregate into noncrystalline clusters. The repulsion can be electrostatic, if the particles are charged (charge-stabilized), or can come from interparticle collisions (steric-stabilized). In the latter case the particle surface must be treated with an amphiphilic or polymer layer to prevent the particles from sticking together.

Similarities to atomic crystals. In colloidal crystals of spherical or nearly spherical particles, the crystal structures adopted are identical to those found in crystals formed by spherical atoms, such as the noble gases and alkali metals. The phase behavior is also quite similar.

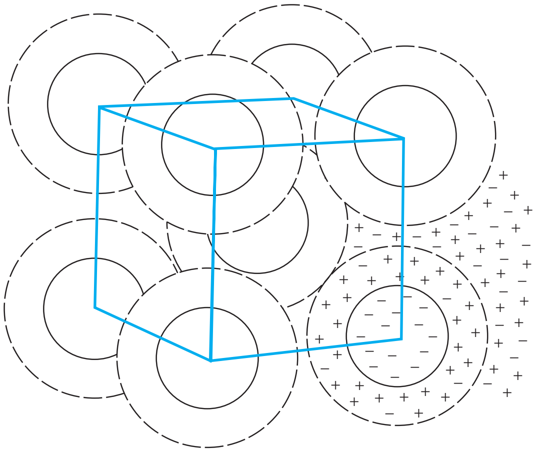

Fig. 1. Arrangement of particles and distribution of electrical charges in a charged stabilized body-centered-cubic colloidal crystal. Spheres indicated by broken lines show extent of positive counterion clouds.

For example, in suspensions of polymer spheres in organic solvents the interaction between the spheres is short-ranged, consisting only of repulsion on contact (the hard sphere limit). As with the noble gas crystals where the interatomic repulsion is short-ranged, the crystals formed are close-packed, either hexagonal or face-centered cubic, first appearing when the spheres' volume fraction is about 55%.

In aqueous suspension the particles can interact electrically, without ever actually touching. Polymer particles are readily prepared with acid surface groups which dissociate in water, leaving the particle with a large negative charge (as large as several thousand electron charges). This charge attracts positively charged small ions, which form clouds around the particles (**Fig. 1**). The spheres will repel each other if they come close enough so that their ion clouds overlap. At low concentration, the particles rarely encounter one another, executing independent brownian motion and forming the colloidal gas phase. As the concentration is increased to where the average interparticle separation is comparable to the overlap separation, the particles become strongly confined by their neighbors and form the colloidal liquid phase. If the concentration is further increased, an abrupt freezing transition to the ordered colloidal crystal phase will occur. The colloidal crystal structure found near the freezing transition is the body-centered cubic, as is found in the alkali metals, where the atomic repulsion is more long-ranged. *See* GAS; LIQUID.

Differences from atomic crystals. Despite these structural similarities, atomic and colloidal crystals are characterized by vastly different length, stiffness, and time scales.

First, particles in atomic crystals are separated by less than a nanometer compared to micrometers in colloidal crystals. This means that colloidal crystal structure can be determined by visible-light

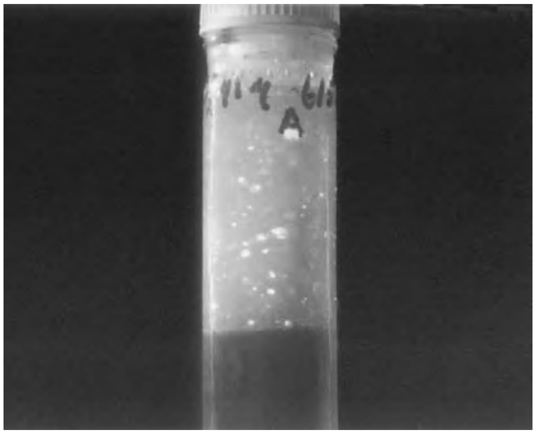

Fig. 2. Reflection of white light from a polycrystalline colloidal crystal suspension. The crystals are body-centered cubic, with a particle diameter of 0.1 μm and interparticle spacing of 1.5 μm.

techniques, as opposed to x-rays, which are required in the atomic crystal case. The spectacular iridescent appearance of opal and other colloidal crystals (**Fig. 2**) is a direct result of constructive interference in the reflection of light by the particles' periodic lattice structure; that is, the colloidal crystals Bragg-reflect visible light in the same way as atomic crystals Bragg-reflect x-rays. *See* OPALESCENCE; X-RAY CRYSTALLOGRAPHY; X-RAY DIFFRACTION.

This optical property is being developed for photonic bandgap applications, in which light of frequency in a particular range is reflected for all possible propagation directions. The search for useful photonic crystals has led to the development of inverse colloidal crystals and opals, in which a hard-sphere colloidal crystal is made (of silica particles, for example), the void space (74% of the volume for a close-packed structure) is filled with another material (a polymer, for example), and then the original particles are chemically removed (by dipping in hydrofluoric acid in the case of silica). The result is a crystal structure in which the solid material occupies only about 25% of the volume (**Fig. 3**).

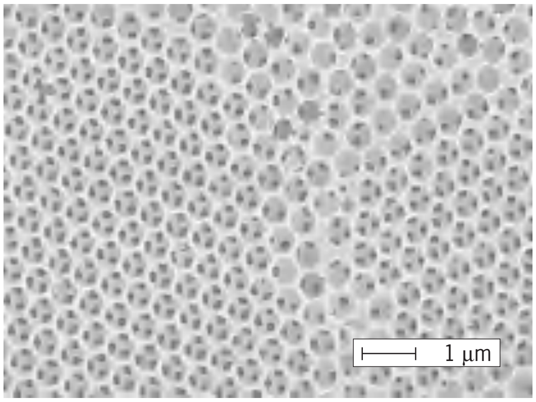

Fig. 3. Inverse opal structure formed by filling the void space of a face-centered cubic colloidal crystal emulsion of oil drops in water and then condensing silica in the aqueous void spaces. (*D.J. Pine, University of California at Santa Barbara*)

Second, colloidal crystals are about 10^8 times weaker than atomic crystals; that is, their elastic constants are 10^8 times smaller. Consequently, colloidal crystals can be melted very easily, even by a gentle shearing of the suspension.

Finally, significant atomic motions, such as the relative vibration of adjacent particles, occur in 10^{-12} s, whereas the equivalent time in a colloidal system is 10^{-2} s. Hence, it is possible to watch in detail through a microscope the motions of particles in a colloidal lattice. The distinctive properties of colloidal crystals thus provide a new avenue to the understanding of many phenomena found in atomic systems, such as lattice vibrations (sound waves), crystal dislocation and other defects, the response of crystals to large stresses (plastic flow), and crystallization itself. *See* CRYSTAL DEFECTS; CRYSTAL GROWTH; LATTICE VIBRATIONS; PLASTICITY.

Colloidal crystallization has been studied in space, taking advantage of the microgravity environment to avoid the sedimentation arising from the density mismatch between particles and suspending medium. Crystals form in space under conditions where the suspensions remain liquid on Earth.

Complex systems. In addition to the simple colloidal crystals found in bulk (three-dimensional) suspensions of spherical particles, there are a number of more exotic colloidal systems. Colloidal alloys can be formed in suspensions containing particles of several different sizes. Binary mixtures form mixed crystals, sometimes with approximately 100 particles per unit cell, analogous to the alloy structures found in binary atomic metal mixtures. Other systems include colloidal glasses, which are binary or multicomponent suspensions that exhibit shear rigidity without periodic structure; two-dimensional colloidal crystals, which are obtained by trapping a monolayer or several layers of particles; and colloidal liquid crystals, which are found in suspensions of interacting non-spherical (rod- or disk-shaped) particles such as tobacco mosaic virus. *See* ALLOY STRUCTURES; AMORPHOUS SOLID; COLLOID; CRYSTAL STRUCTURE; LIQUID CRYSTALS.

Colon

The portion of the intestine that runs from the cecum to the rectum; in some mammals, it may be separated from the small intestine by an ileocecal valve. It is also known as the large intestine. The colon is usually divided into ascending, transverse, and descending portions. In the humans a fourth section, the sigmoid, is found. The colon is longer in herbivores and shorter in carnivores, and is about 4 to 6 ft (1 to 2 m) long in humans. Although no digestive enzymes are secreted in the colon, digestion is assisted by an alkaline fluid. Much digestion (for example, all breakdown of cellulose) occurs by bacteria, of which *Escherichia coli is* the most common. Most of the fluid added to the food during digestion is reabsorbed into the body in the colon. All digestive action, water absorption, and so on, is completed before the food materials pass out of the colon into the rectum. *See* DIGESTIVE SYSTEM. Walter J. Bock

Color

That aspect of visual sensation enabling a human observer to distinguish differences between two structure-free fields of light having the same size, shape, and duration. Although luminance differences alone permit such discriminations to be made, the term color is usually restricted to a class of differences still perceived at equal luminance. These depend upon physical differences in the spectral compositions of the two fields, usually revealed to the observer as differences of hue or saturation.

Photoreceptors. Color discriminations are possible because the human eye contains three classes of cone photoreceptors that differ in the photopigments they contain and in their neural connections. Two of these, the L and M cones, are sensitive to all wavelengths of the visible spectrum from 380 to 700 nanometers. (Even longer or shorter wavelengths may be effective if sufficient energy is available.) L cones are maximally sensitive at about 570 nm, M cones at about 540 nm. The ratio L/M of cone sensitivities is minimal at 465 nm and increases monotonically for wavelengths both shorter and longer than this. This ratio is independent of intensity, and the red-green dimension of color variation is encoded in terms of it. The S cones, whose sensitivity peaks at about 440 nm, are not appreciably excited by wavelengths longer than 540 nm. The perception of blueness and yellowness depends upon the level of excitation of S cones in relation to that of L and M cones. No two wavelengths of light can produce equal excitations in all three kinds of cones. It follows that, provided they are sufficiently different to be discriminable, no two wavelengths can give rise to identical sensations.

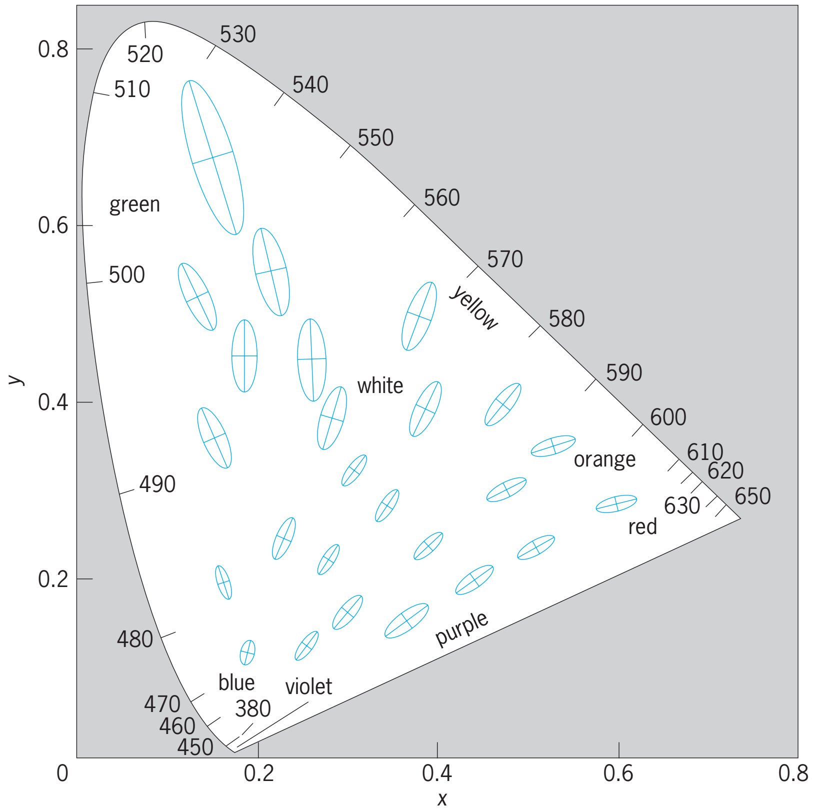
The foregoing is not true for the comparison of two different complex spectral distributions. These usually, but not always, look different. Suitable amounts of short-, middle-, and long-wavelength lights, if additively mixed, can for example excite the L, M, and S cones exactly as does a light containing equal energy at all wavelengths. As a result, both stimuli look the same. This is an extreme example of the subjective identity of physically different stimuli known as chromatic metamerism. Additive mixture is achievable by optical superposition, rapid alternation at frequencies too high for the visual system to follow, or (as in color television) by the juxtaposition of very small elements which make up a field structure so fine as to exceed the limits of visual acuity. The integration of light takes place within each receptor, where photons are individually absorbed by single photopigment molecules, leading to receptor potentials that carry no information about the wavelength of the absorbed photons. *See* EYE (VERTEBRATE); LIGHT.

Colorimetry. Although colors are often defined by appeal to standard samples, the trivariant nature of color vision permits their specification in terms of three values. Ideally these might be the relative excitations of the L, M, and B cones. Because too little was known about cone action spectra in 1931, the International Commission on Illumination (CIE) adopted at that time a different but related system for the prediction of metamers (the CIE system of colorimetry). This widely used system permits the specification of tristimulus values X, Y, and Z, which make almost the same predictions about color matches as do calculations based upon cone action spectra. If, for fields 1 and 2, $X_1 = X_2$, $Y_1 = Y_2$, and $Z_1 = Z_2$, then the two stimuli are said to match (and therefore have the same color) whether they are physically the same (isometric) or different (metameric).

The use of the CIE system may be illustrated by a sample problem. Suppose it is necessary to describe quantitatively the color of a certain paint when viewed under illumination by a tungsten lamp of known color temperature. The first step is to measure the reflectance of the paint continuously across the visible spectrum with a spectrophotometer. The reflectance at a given wavelength is symbolized as R_λ. The next step is to multiply R_λ by the relative amount of light E_λ emitted by the lamp at the same wavelength. The product $E_\lambda R_\lambda$ describes the amount of light reflected from the paint at wavelength λ. Next, $E_\lambda R_\lambda$ is multiplied by a value $\bar{x}_\lambda$, which is taken from a table of X tristimulus values for an equal-energy spectrum. The integral $\int E_\lambda R_\lambda \bar{x}_\lambda d_\lambda$ gives the tristimulus value X for all of the light reflected from the paint. Similar computations using $\bar{y}_\lambda$ and $\bar{z}_\lambda$ yield tristimulus values Y and Z.

Tables of $\bar{x}_\lambda$, $\bar{y}_\lambda$, and $\bar{z}_\lambda$ are by convention carried to more decimal places than are warranted by the precision of the color matching data upon which they are based. As a result, colorimetric calculations of the type just described will almost never yield identical values, even for two physically different fields that are identical in appearance. For this and other reasons it is necessary to specify tolerances for color differences. Such differential colorimetry is primarily based upon experiments in which observers attempted color matches repeatedly, with the standard deviations of many matches being taken as the discrimination unit.

Chromaticity diagram. Colors are often specified in a two-dimensional chart known as the CIE chromaticity diagram, which shows the relations among tristimulus values independently of luminance. In this plane, y is by convention plotted as a function of



The 1931 CIE chromaticity diagram showing MacAdam's ellipses 10 times enlarged. (*After G. W. Wyszecki and W. S. Stiles, Color Science, Wiley, 1967*)

x, where $y = Y/(X + Y + Z)$ and $x = x/(x + Y + Z)$. [The value $z = Z/(X + Y + Z)$ also equals $1 - (x + y)$ and therefore carries no additional information.] Such a diagram is shown in the **illustration**, in which the continuous locus of spectrum colors is represented by the outermost contour. All nonspectral colors are contained within an area defined by this boundary and a straight line running from red to violet. The diagram also shows discrimination data for 25 regions, which plot as ellipses represented at 10 times their actual size. A discrimination unit is one-tenth the distance from the ellipse's center to its perimeter. Predictive schemes for interpolation to other regions of the CIE diagram have been worked out.

If discrimination ellipses were all circles of equal size, then a discrimination unit would be represented by the same distance in any direction anywhere in the chart. Because this is dramatically untrue, other chromaticity diagrams have been developed as linear projections of the CIE chart. These represent discrimination units in a relatively more uniform way, but never perfectly so.

A chromaticity diagram has some very convenient properties. Chief among them is the fact that additive mixtures of colors plot along straight lines connecting the chromaticities of the colors being mixed. Although it is sometimes convenient to visualize colors in terms of the chromaticity chart, it is important to realize that this is not a psychological color diagram. Rather, the chromaticity diagram makes a statement about the results of metameric color matches, in the sense that a given point on the diagram represents the locus of all possible metamers plotting at chromaticity coordinates x, y. However, this does not specify the appearance of the color, which can be dramatically altered by preexposing the eye to colored lights (chromatic adaptation) or, in the complex scenes of real life, by other colors present in nearby or remote areas (color contrast and assimilation). Nevertheless, within limits, metamers whose color appearance is thereby changed continue to match.

For simple, directly fixated, and unstructured fields presented in an otherwise dark environment, there are consistent relations between the chromaticity coordinates of a color and the color sensations that are elicited. Therefore, regions of the chromaticity diagram are often denoted by color names, as shown in the illustration.

Although the CIE system works rather well in practice, there are important limitations. Normal human observers do not agree exactly about their color matches, chiefly because of the differential absorption of light by inert pigments in front of the photoreceptors. Much larger individual differences exist for differential colorimetry, and the system is overall inappropriate for the 8% of the population (mostly males) whose color vision is abnormal. The system works only for an intermediate range of luminances, below which rods (the receptors of night vision) intrude, and above which the bleaching of visual photopigments significantly alters the absorption spectra of the cones. *See* COLOR VISION.

Color (quantum mechanics)

A term used to describe a quantum number carried by the quarks which make up the strongly interacting elementary particles, such as the proton and neutron of the atomic nucleus. It has nothing to do with the ordinary, visual use of the word color.

The quarks which are thought to make up the strongly interacting particles have a spin angular momentum of one-half unit of $\hbar$ (Planck's constant). According to a fundamental theorem of relativity combined with quantum mechanics, they must therefore obey Fermi-Dirac statistics and be subject to the Pauli exclusion principle. No two quarks within a particular system can have exactly the same quantum numbers. *See* EXCLUSION PRINCIPLE; FERMI-DIRAC STATISTICS.

In making up a baryon, however, it often seemed necessary to violate this principle. The omega particle, for example, is made of three strange quarks, and all three had to be in exactly the same state. O. W. Greenberg was responsible for the essential idea for the solution to this paradox. In 1964 he suggested that each quark type (*u, d,* and *s*) comes in three varieties identical in all measurable qualities but different in an additional property, which has come to be known as color. The exclusion principle could then be satisfied and quarks could remain fermions, because the quarks in the baryon would not all have the same quantum numbers. They would differ in color even if they were the same in all other respects.

The color hypothesis triples the number of quarks but does not increase the number of baryons and mesons. The rules for assembling them ensures this. Tripling the number of quarks does, however, have at least two experimental consequences. It triples the rate at which the neutral π meson decays into two photons and brings the predicted rate into agreement with the observed rate.

The total production cross section for baryons and mesons in electron-positron annihilation is also tripled. The experimental results at energies up to 60 GeV are in good agreement with the color hypothesis and completely incompatible with the simple quark model without color. *See* BARYON; ELEMENTARY PARTICLE; GLUONS; MESON; QUARKS.

Color centers

Atomic and electronic defects of various types in solids which produce optical absorption bands in otherwise transparent crystals such as the alkali halides, alkaline earth fluorides, or metal oxides. They are general phenomena found in a wide range of materials. Color centers are produced by gamma radiation or x-radiation, by addition of impurities or excess constituents, and sometimes through electrolysis. A well-known example is that of the *F*-center in alkali halides such as sodium chloride (NaCl). The designation *F*-center comes from the German word *Farbe*, which means color. *F*-centers in sodium chloride produce a band of optical absorption toward the blue end of the visible spectrum; thus the colored crystal appears yellow under transmitted light. On the other hand, potassium chloride (KCl) with *F*-centers appears magenta, and potassium bromide (KBr) appears blue. *See* CRYSTAL DEFECTS.

Theoretical studies guided by detailed experimental work have yielded a deep understanding of specific color centers. The crystals in which color centers appear tend to be transparent to light and to other forms of electromagnetic radiation, such as microwaves. Consequently, experiments which can be carried out include optical spectroscopy, luminescence and Raman scattering, magnetic circular dichroism, magnetic resonance, and electromodulation. Color centers find practical application in radiation dosimeters, x-ray image storage phosphors, and tunable lasers. *See* ABSORPTION OF ELECTROMAGNETIC RADIATION.

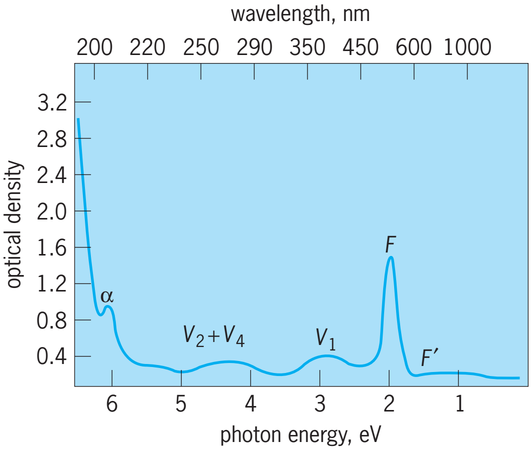

Fig. 1. Absorption bands produced in KBr crystal by exposure to x-rays at 81 K. Optical density is equal to $\log_{10}(I_0/I)$, where I_0 is the intensity of incident light and *I* the intensity of transmitted light. Steep rise in optical density at far left is due to intrinsic absorption in crystal (modified slightly by existence of *F*-centers).

Origin. **Figure 1** shows the absorption bands due to color centers produced in potassium bromide by exposure of the crystal at the temperature of liquid nitrogen (81 K) to intense penetrating x-rays. Several prominent bands appear as a result of the irradiation. The *F*-band appears at 600 nanometers and the so-called *V*-bands appear in the ultraviolet. Uncolored alkali halide crystals may be grown readily from a melt with as few imperfections as one part in 10^5. In the unirradiated and therefore uncolored state, they show no appreciable absorption from the far-infrared through the visible, to the region of characteristic absorption in the far-ultraviolet (beginning at about 200 nm in Fig. 1).

Color bands such as the *F*-band and the *V*-band arise because of light absorption at defects dispersed throughout the lattice. This absorption is caused by electronic transitions at the centers. On the other hand, colloidal particles, each consisting of many atoms, dispersed through an optical medium also produce color bands. In this case, if the particles are large enough, the extinction of light is due to both light scattering and light absorption. Colloidal gold is responsible for the color of some types of ruby glass. Colloids may also form in alkali halide crystals—for example, during heat treatment of an additively colored crystal which contains an excess of alkali metal.

Atomically dispersed centers such as *F*-centers are part of the general phenomena of trapped electrons and holes in solids. The accepted model of the *F*-center is an electron trapped at a negative ion vacancy. Many other combinations of electrons, holes,

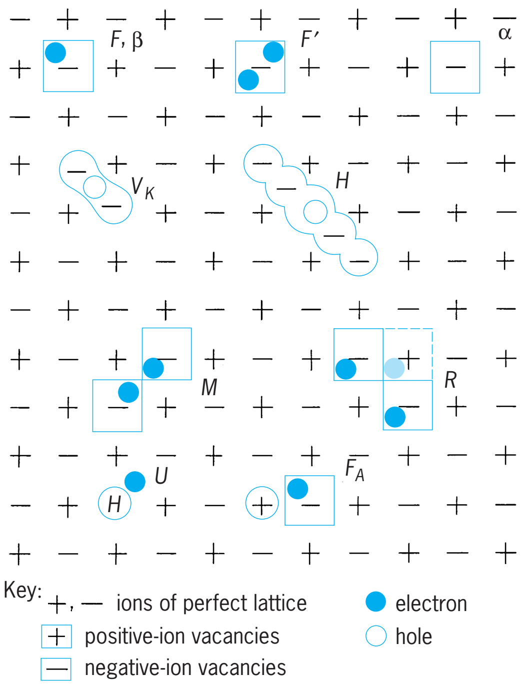

Fig. 2. Well-established models for several color centers in ionic crystal of NaCl structure. Designation β for *F*-center signifies disturbing influence of *F*-centers on tail of fundamental absorption band; characteristic absorption is also influenced by presence of vacancies, or α-centers (see Fig. 1). The V_K-center can be described as a self-trapped hole forming a Cl_2-molecule-ion, and the *H*-center can be described as a hole trapped at an interstitial halide ion. Both are stable at low temperature only. The *R*-center contains three negative-ion vacancies, one of which is in an adjacent lattice plane. *H* in circle at lower left represents hydrogen impurity, which, together with an electron, forms a *U*-center. The F_a-center is an *F*-center adjacent to a monovalent positive-ion impurity.

and clusters of lattice vacancies have been used to explain the various absorption bands observed in ionic crystals. The centers and models shown in **Fig. 2** have been positively identified either by electron spin resonance or by a combination of other types of experimental evidence. *See* HOLE STATES IN SOLIDS.

Impurities can play an important role in color-center phenomena. Certain impurities in ionic crystals produce color bands characteristic of the foreign ion. For example, hydrogen can be incorporated into the alkali halides as H^- ions substituting for halogen ions with resultant appearance of an absorption band (the *U*-band) in the ultraviolet (Fig. 2). The rate at which *F*-centers are produced by x-irradiation is greatly increased by the incorporation of hydrogen, the *U*-centers being converted into *F*-centers with high efficiency.

F-centers. *F*-centers may be produced in uncolored crystals by irradiation with ultraviolet, x-rays, gamma rays, and high-speed particles, and also by electrolysis. However, one of the most convenient methods is that of additive coloration. Alkali halide crystals may be additively colored by heating to several hundred degrees Celsius in the presence of the alkali metal vapor, then cooling rapidly to room temperature. The *F*-band that results is the same as that produced by irradiation and is dependent upon the particular alkali halide used, not upon the alkali metal vapor. For example, the coloration produced in potassium chloride is the same whether the crystal is heated in potassium or in sodium vapor. This and other evidence indicate that excess alkali atoms enter the crystal as normal lattice ions by donating an electron to accompanying negative-ion vacancies to form *F*-centers. **Figure 3** shows the position of the *F*-band in several alkali halides.

Both the width and the exact position of the *F*-band change with temperature in the manner shown in **Fig. 4**. This behavior can be explained in terms of the thermal motion of the ions surrounding the center. Thermal motion is most important at high temperatures, whereas at low temperatures the width of the absorption band becomes less and approaches a constant value which prevails down to the very lowest temperatures.

Concentration of centers. The height of the absorption maximum and the width at half maximum may be used to calculate the concentration N of absorbing centers. For potassium chloride, classical theory gives the concentration as $N = 1.3 \times 10^{16}\, AH\ \mathrm{cm}^{-3}$,

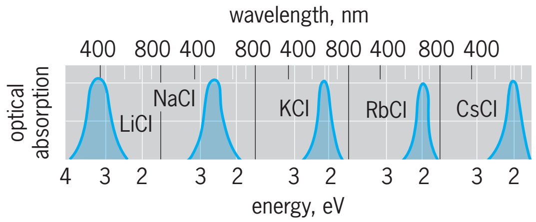

Fig. 3. *F*-bands in different alkali halide crystals.

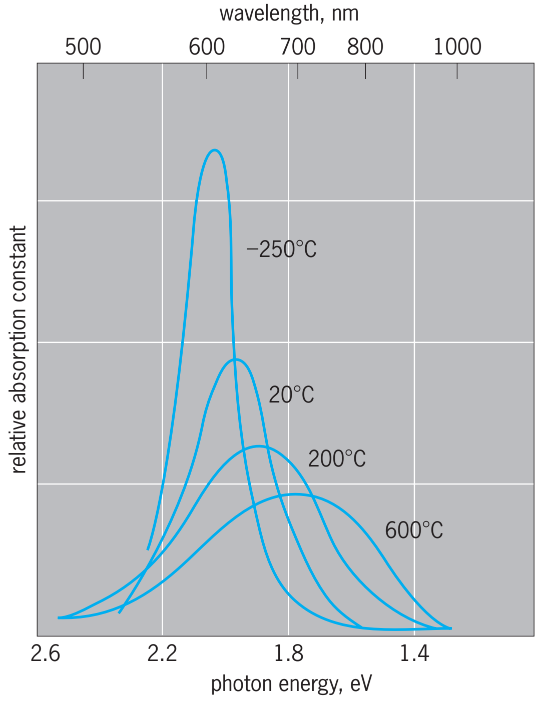

Fig. 4. Variation with temperature of the width of the *F*-band in a crystal of potassium bromide. °F = (°C × 1.8) + 32°.

where A is the maximum absorption in cm^{-1}, and H is the half width of the absorption band in electronvolts. The numerical factor in this equation depends upon the material under consideration and is given here for potassium chloride. The general relation between absorption characteristics and defect concentration is slightly more complicated but is nevertheless useful to determine concentrations below the limit of detection by chemical means.

Shape of F-band. Refined measurements of the *F*-band at low temperatures show that it is not a simple bell-shaped curve indicated in Figs. 3 and 4. In fact, it is found to contain a shoulder on the short-wavelength side, which is referred to as the *K*-band. It has been proposed that the *K*-band is in agreement with a model for the *F*-center in which an electron is trapped in a vacancy surrounded by point ions which produce the cubic crystal field of the lattice. An electron in the vicinity of a negative-ion vacancy should have a ground state and one or more excited states below the bottom of the conduction band. The main absorption peak corresponds to excitation of the electron from the 1*s*-like ground state to an excited 2*p*-like state. The *K*-band is thought to be due to transitions to the 3*p* and higher states which finally merge with the conduction band itself. *F*-center photoconductivity measurements tend to confirm the idea of discrete excited states, such as the 2*p*, which lie below the conduction band or continuum. *See* PHOTOCONDUCTIVITY.

Magnetic experiments. Some of the most detailed information on *F*-centers comes from electron spin resonance and from electron-nuclear double resonance. From these experiments the extent and character of the wave function of the electron trapped at the halogen-ion vacancy can be obtained. The electron even in the ground state is not highly localized but is spread out over the six neighboring alkali ions and to some extent over more distant neighbors. Faraday rotation studies indicated fine structure in the excited state of the *F*-center due to spin-orbit interaction. *See* MAGNETIC RESONANCE.

Lifetime of excited F-center. At low temperature an excited *F*-center decays spontaneously to the ground state with the emission of an infrared luminescent quantum. The radiative lifetime has been measured and found to be unexpectedly long, 0.57 microsecond in potassium chloride and as long as 2.0 μs in potassium iodide (KI). There are indications that this is due to a drastic change in the wave function following excitation and lattice relaxation. Lattice polarization must be taken into account in order to calculate the effect. The relaxed excited state is very spread out in the lattice, whereas the ground state is somewhat more localized.

F′-centers. When a crystal containing *F*-centers is irradiated at low temperature with light in the *F*-band itself, the *F*-absorption decreases and a new band, known as the *F′* band, appears (**Fig. 5**). Experiments have shown that for every *F′*-center created, two *F*-centers are destroyed. The *F′*-center consists of an *F*-center which has captured an extra electron. Important photoelectric effects occur during conversion of *F*- to *F′*-centers and during irradiation of alkali halides with *F*-band light.

V-centers. As Fig. 1 shows, absorption bands arise in the ultraviolet as well as in the visible portion of the spectrum when potassium bromide is irradiated while cold. These *V*-bands are apparently not present in crystals additively colored by the alkali metal vapor. Irradiation of a crystal produces both electrons and holes so that bands associated with trapped positive charges are to be expected in addition to electrons trapped at negative-ion vacancies (*F*-centers). *V*-bands can also be produced, at least in the case of potassium bromide and potassium iodide, by introduction of an excess of halogen into the crystal.

Crystals containing *V*-centers have been studied by spin resonance techniques with the result that a center not previously observed optically has been identified. This center, sometimes referred to as the V_K-center (Fig. 2), is due to a hole trapped in the vicinity of two halogen ions which have become displaced from their normal lattice position to form a Cl_2-molecule-ion (in the case of potassium chloride). It has been found in several different alkali halides, and its optical absorption and energy level structure have been correlated. The V_K-center is known to play an important role in the intrinsic luminescence of ionic crystals.

Mechanism of radiation damage. When an alkali halide crystal is exposed to ionizing radiation, such as ultraviolet light, x-rays, or beta particles, radiation damage occurs in the form of point defects. *F*-centers and *H*-centers are now known to be the primary defects formed. They are produced mainly by recombination of electron-hole pairs associated with ionizing radiation. Luminescence may also occur, depending upon temperature and upon the presence of impurities. Practical applications of these phenomena include dosimeters for detecting ionizing radiation and image plate detectors for x-rays. Analogous

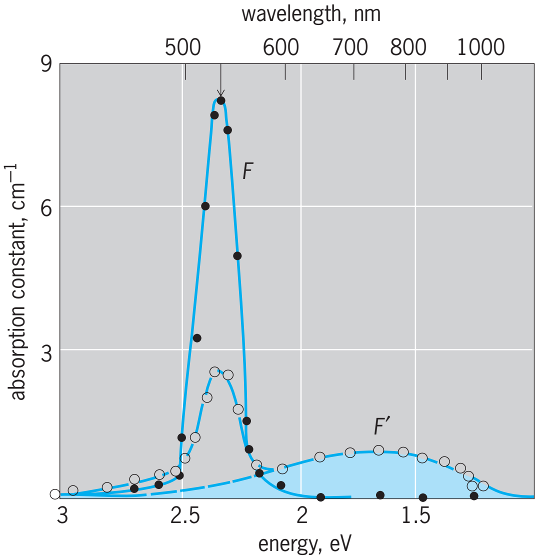

Fig. 5. ***F*- and *F′*-bands in KCl at −235°C (−391°F). *F′*-band was produced by irradiating crystal with light of wavelength shown by arrow at center of *F*-band. Such light causes the *F*-band to bleach as *F′*-band grows.**

phenomena occur in the case of crystals of the fluorite structure (CaF_2) and also in oxides such as calcium oxide (CaO) and magnesium oxide (MgO). In these cases the photolytic processes are somewhat different and apparently not as efficient as in the alkali halides. *See* DOSIMETER; ELECTRON-HOLE RECOMBINATION; PHOTOLYSIS; RADIATION DAMAGE TO MATERIALS.

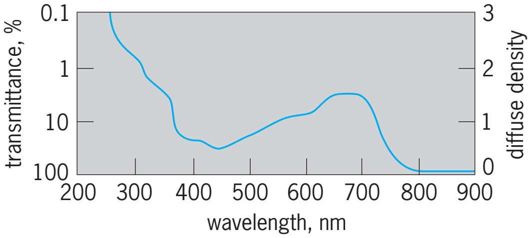
Color filter

An optical element that partially absorbs incident radiation, often called an absorption filter. The absorption is selective with respect to wavelength, or color, limiting the colors that are transmitted by limiting those that are absorbed. Color filters absorb all the colors not transmitted. They are used in photography, optical instruments, and illuminating devices to control the amount and spectral composition of the light.

Color filters are made of glass for maximum permanence, of liquid solutions in cells with transparent faces for flexibility of control, and of dyed gelatin or plastic (usually cellulose acetate) for economy, convenience, and flexibility. The plastic filters are often of satisfactory permanence, but they are sometimes cemented between glass plates for greater toughness and scratch resistance. They do not have as good quality as gelatin filters.

Color filters are sometimes classified according to their type of spectral absorption: short-wavelength pass, long-wavelength pass or band-pass; diffuse or sharp-cutting; monochromatic or conversion. The short-wavelength pass transmits all wavelengths up to the specified one and then absorbs. The long-wavelength pass is the opposite. Every filter is a band-pass filter when considered generally. Even an ordinary piece of glass does not transmit in the ultraviolet or infrared parts of the spectrum. Color filters, however, are usually discussed in terms of the portion of the visible part of the spectrum. Sharp and diffuse denote the sharpness of the edges of the filter band pass. Monochromatic filters are very narrow band-pass filters. Conversion filters alter the spectral response or distribution of one selective detector or source to that of another, for example, from that of a light bulb to that of the Sun (see **illus.**).

Neutral-density filters transmit a constant fraction of the light across the spectrum considered. They are made either by including an appropriate absorbent like carbon that is spectrally nonselective, or by a thin, partially transparent reflective layer, often of aluminum.



Transmission of a conversion filter, used to convert the spectral distribution of a light bulb (color temperature of 2360 K or 3790°F) to that of the Sun (color temperature of 5500 K or 9440°F). (*After Eastman Kodak Co., Kodak Filters for Scientific and Technical Uses, 1972*)

The transmittance of a filter is the ratio of the transmitted flux to the incident flux, expressed as either a ratio or a percentage. The density of a filter is the logarithm to base 10 of the reciprocal of the transmittance. For example, a filter with a 1% transmittance has a density of 2.

Other, closely related filters are the Christiansen, Lyot or birefringent, residual-ray, and interference filters. They use the phenomena of refraction, polarization, reflection, and interference. *See* ABSORPTION OF ELECTROMAGNETIC RADIATION; COLOR; INTERFERENCE FILTER; REFLECTION OF ELECTROMAGNETIC RADIATION; SUN.

William L. Wolfe

Color index

A quantitative measure of a star's color. Even a casual look at the night sky reveals the stars to be colored. From spectral analysis and the laws of radiation, it has been known since the 1920s that such color is closely related to temperature. Stars are reddish at about 3000 K (4940°F), orange at about 4500 K (7640°F), yellowish-white at about 6000 K (10,340°F), white at about 10,000 K (17,540°F), and bluish-white above 10,000 K. With proper calibration, color provides a means by which the temperature and spectral class can be evaluated. Visual examination is too crude, however. Instead, color must be properly defined and quantified. *See* SPECTRAL TYPE; STAR.

Color is defined through a star's various magnitude measures (m), which indicate brightness at different wavelengths. The unaided-eye stars are historically grouped into six magnitude classes, 1st magnitude being the brightest and 6th magnitude the faintest. The system was quantified in the nineteenth century so that five magnitude divisions were made to correspond to a factor of 100 in brightness. One magnitude division is then a factor of 2.512 . . . . The star Vega, with $m = 0.03$, now provides a fundamental calibration point. Telescopes extend the range to magnitude 30. *See* MAGNITUDE (ASTRONOMY).

The original magnitudes were visual, m being estimated by eye, and depended on the eye's response, which is maximized for yellow light. Photography provided a way of permanently recording starlight and of measuring magnitudes. Early photographic emulsions, however, were sensitive primarily to blue

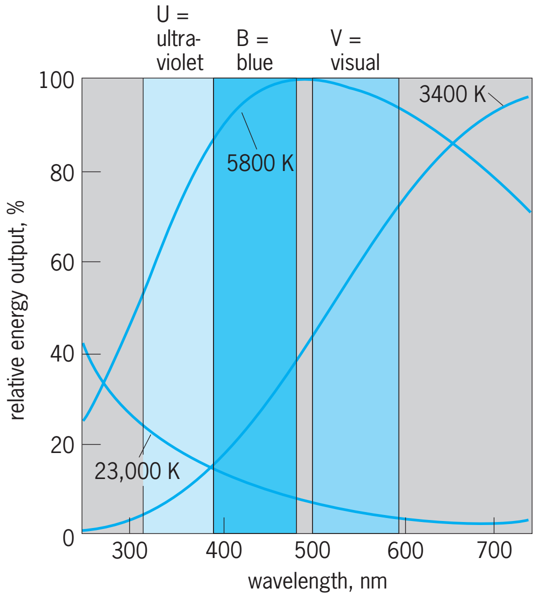


Fig. 1. Responses of the U, B (close to photographic), and V (close to visual) filters are superimposed onto blackbody curves for 3400, 5800, and 23,000 K (5660, 9980, and 40,940°F). The higher-temperature body is brighter in the blue and has a lower magnitude. (*After S. P. Wyatt and J. B. Kaler, Principles of Astronomy: A Short Version, Allyn and Bacon, 1981*)

light. As a result, blue stars look relatively brighter to the photographic plate than they do the eye, and red stars considerably fainter (**Fig. 1**). It was then necessary to establish a separate magnitude system for photography, called m_{ptg}. The original visual magnitudes were distinguished by calling them m_{vis}. The two magnitudes were set equal for white class A0-A1 stars with temperatures of 9600 K (16,820°F). Color can then be quantified by taking the difference between the two magnitudes, the color index becoming m_{ptg}-m_{vis}. Blue stars have slightly negative color indices, red stars positive ones (**Fig. 2**). *See* ASTRONOMICAL IMAGING.

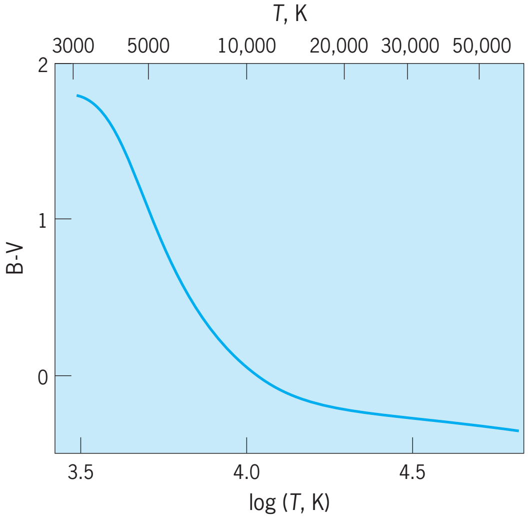

Fig. 2. Graph of the color index B-V versus the logarithm of the temperature *T* (in kelvins). As temperature climbs, the B-V color index decreases. (*After P. J. Flower, Transformations from theoretical Hertzsprung-Russell diagrams to color-magnitude diagrams: Effective temperatures, B-V colors, and bolometric corrections, Astrophys. J., 469:355–365, 1996*)

Photoelectric photometry allowed the establishment of the more precise UBV system, wherein V (yellow) and B (blue) filters respectively mimic the response of the human eye and the untreated photographic plate, and a U filter is added in the ultraviolet (Fig. 1). The traditional color index is then replaced by B-V, and the addition of U allows a second color index, U-B. Main-sequence stars trace a locus on the color-color diagram in which U-B is plotted against B-V. Deviations from the plot allow the evaluation of the degree of interstellar extinction. *See* HERTZSPRUNG-RUSSELL DIAGRAM; INTERSTELLAR EXTINCTION.

The standard system has been expanded into the red with an R filter, into the near-infrared with an I filter, and even deeper into the infrared with J, K, H, L, and M filters that go all the way to $4.75\ \mu$m. Numerous color indices are then available to examine stars that radiate primarily in the infrared. Other photometric schemes, such as the Strömgren four-color system (uvby, for ultraviolet, violet, blue, and yellow) and that used by the Sloan Survey (u′g′r′i′z′, which run from the ultraviolet to the near-infrared), allow more sophisticated color indices (for example g′-r′ instead of B-V) that are responsive not only to temperature but also to a variety of other parameters. *See* INFRARED ASTRONOMY; SLOAN DIGITAL SKY SURVEY.

Color vision

The ability to discriminate light on the basis of wavelength composition. It is found in humans, in other primates, and in certain species of birds, fishes, reptiles, and insects. These animals have visual receptors that respond differentially to the various wavelengths of visible light. Each type of receptor is especially sensitive to light of a particular wavelength composition. Evidence indicates that primates, including humans, possess three types of cone receptor, and that the cones of each type possess a pigment that selectively absorbs light from a particular region of the visible spectrum.

If the wavelength composition of the light is known, its color can be specified. However, the reverse statement cannot be made. A given color may usually be produced by any one of an infinite number of combinations of wavelength. This supports the conclusion that there are not many different types of color receptor. Each type is capable of being stimulated by light from a considerable region of the spectrum, rather than being narrowly tuned to a single wavelength of light. The trichromatic system of colorimetry, using only three primary colors, is based

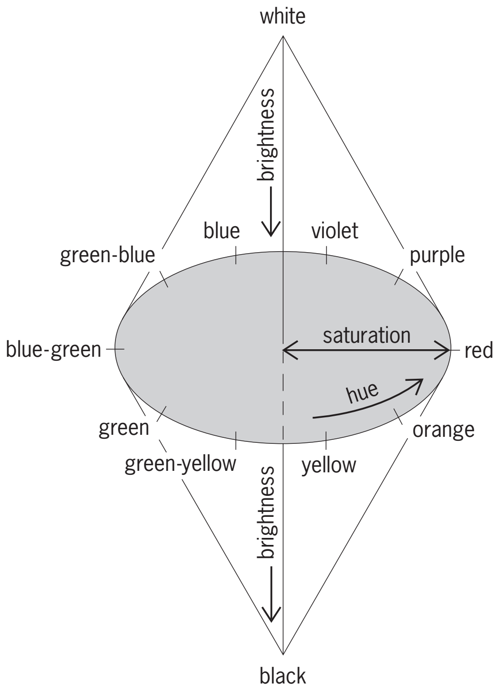

Fig. 1. **Diagram of a color solid for illustrating the appearance of surface colors. (*After N. L. Munn, Psychology, 2d ed., Houghton Mifflin, 1951*)**

on the concept of cone receptors with sensitivities having their peaks, respectively, in the long, middle, and short wavelengths of the spectrum. The number of such curves and their possible shapes have long been subjects for study, but not until the 1960s were direct measurements made of the spectral sensitivities of individual cone receptors in humans and various animals. *See* COLOR.

Color recognition. Color is usually presented to the individual by the surfaces of objects on which a more or less white light is falling. A red surface, for example, is one that absorbs most of the short-wave light and reflects the long-wave light to the eye. The surface colors are easily described by reference to the color solid shown in **Fig. 1**. The central axis defines the lightness or darkness of the surface as determined by its overall reflectance of white light, the lowest reflectance being called black and the highest, white. The circumference denotes hue, related primarily to the selective reflectance of the surface for particular wavelengths of light. The color solid is pointed at its top and bottom to represent the fact that as colors become whiter or blacker they lose hue. The distance from central axis to periphery indicates saturation, a characteristic that depends chiefly on the narrowness, or purity, of the band of wavelengths reflected by the surface. At the center of the figure is a medium-gray surface, one which exhibits a moderate amount of reflectance for all wavelengths of light. Colors that are opposite one another are called complementaries, for example, yellow and blue, red and blue-green, purple and green, and white and black.

Color mixture and contrast. Two complementaries, when added together in the proper proportions, can oppose or neutralize one another to produce a colorless white or gray. Various contrast effects also attest to the opposition of the complementaries. Staring at a bright-red surface against a gray background results in the appearance of a blue-green border around the red; this is an example of simultaneous contrast. Similarly, when a red light is turned off, there is frequently a negative afterimage that appears to have the opposite color, blue-green.

A set of primary colors can be chosen so that any other color can be produced from additive mixtures of the primaries in the proper proportions. Thus, red, green, and blue lights can be added together in various proportions to produce white, purple, yellow, or any of the various intermediate colors. Three-color printing, color photography, and color television are examples of the use of primaries to produce plausible imitations of colors of the original objects. *See* PHOTOGRAPHY; PRINTING.

Achromatic colors. Colors lying along a continuum from white to black are known as the gray, or achromatic, colors. They have no particular hue, and are therefore represented by the central axis of the color diagram in Fig. 1. White is shown at the top of the diagram since it represents the high-brightness extreme of the series of achromatic colors. With respect to the surface of an object, the diffuse, uniform reflectance of all wavelengths characterizes this series from black through the grays to white in order of increasing reflectance. Whiteness is a relative term; white paper, paint, and snow reflect some 80% or more of the light of all visible wavelengths, while black surfaces typically reflect less than 10% of the light. The term white is also applied to a luminous object, such as a gas or solid, at a temperature high enough to emit fairly uniformly light of all visible wavelengths. In the same connotation, a sound is described as white noise if its energy is nearly the same at all audible frequencies.

Gray. Gray is the term applied to all the intermediate colors in the series of achromatic colors. Gray may result from a mixture of two complementary colors, from a mixture of all primary colors, or from a fairly uniform mixture of lights of all wavelengths throughout the visible spectrum. Grayness is relative; a light gray is an achromatic color that is lighter than its surroundings, while a dark gray is so called because it is darker than its surroundings. Thus, the same surface may be called light or dark gray when carried from one situation to another. A gray color is one of minimum saturation; it corresponds to zero on a scale of excitation purity. At the other extreme on this scale is the color evoked by pure monochromatic light.

Black. The opposite extreme from white in the series of achromatic colors is black. Blackness is a relative term applied to surfaces that uniformly absorb large percentages of light of all visible wavelengths. A black object in sunlight absorbs a large percentage of the light, but it may reflect a larger absolute quantity of light to the eye than does a white object in the shade. Black may also be used to refer to invisible light; ultraviolet rays, for example, may be called black light if they fall on fluorescent materials that thereby emit visible light.

Color blindness. Color blindness is a condition of faulty color vision. It appears to be the normal state of animals that are active only at night. It is also characteristic of human vision when the level of illumination is quite low or when objects are seen only at the periphery of the retina. Under these conditions, vision is mediated not by cone receptors but by rods, which respond to low intensities of light. In rare individuals, known as monochromats, there is total color blindness even at high light levels. Such persons are typically deficient or lacking in cone receptors, so that their form vision is also poor.

Dichromats are partially color-blind individuals whose vision appears to be based on two primaries rather than the normal three. Dichromatism occurs more often in men than in women because it is a sex-linked, recessive hereditary condition. One form of dichromatism is protanopia, in which there appears to be a lack of normal red-sensitive receptors. Red lights appear dim to protanopes and cannot be distinguished from dim yellow or green lights. A second form is deuteranopia, in which there is no marked reduction in the brightness of any color, but again there is a confusion of the colors normally described as red, yellow, and green. A third and much rarer form is tritanopia, which involves a confusion among the greens and blues. *See* HUMAN GENETICS.

Many so-called color-blind individuals might better be called color-weak. They are classified as anomalous trichromats because they have trichromatic vision of a sort, but fail to agree with normal subjects with respect to color matching or discrimination tests. Protanomaly is a case of this type, in which there is subnormal discrimination of red from green, with some darkening of the red end of the spectrum. Deuteranomaly is a mild form of red-green confusion with no marked brightness loss. Nearly 8% of human males have some degree of either anomalous trichromatism or dichromatism as a result of hereditary factors; less than 1% of females are color-defective. A few forms of color defect result from abnormal conditions of the visual system brought on by poisoning, drugs, or disease.

Color blindness is most commonly tested by the use of color plates in which various dots of color define a figure against a background of other dots. The normal eye readily distinguishes the figure, but the colors are so chosen that even the milder forms of color anomaly cause the figure to be indistinguishable from its background. Other tests involve the ability to mix or distinguish colored lights, or the ability to sort colored objects according to hue.

Theories. Theories of color vision are faced with the task of accounting for the facts of color mixture, contrast, and color blindness. The schema shown in **Fig. 2** may be useful in considering the various theories of color vision. It has no necessary resemblance to the structures or functions that are actually present in the visual system.

Young-Helmholtz theory. Thomas Young, early in the nineteenth century, realized that color is not merely a property of objects or surfaces. Rather, it involves a sensory experience, the characteristics of which are determined by the nature of the visual receptors and the way in which the signals that they generate are processed within the nervous system. Young was thus led to a trichromatic theory of color vision, because he found that only three types of excitation were needed to account for the range of perceived colors. Hermann von Helmholtz clarified the theory and provided it with the idea of differential absorption of light of various wavelengths by each of three types of receptor. Hence, the theory, commonly known as the Young-Helmholtz theory, is concerned with the reception phase in the color vision schema shown. This theory assumes the existence of three primary types of color receptor that respond to short, medium, and long waves of visible light, respectively. Primary colors are those that stimulate most successfully the three types of receptor; a mixture of all three primaries is seen as white or gray. A mixture of two complementary colors also stimulates all three. Blue light, for example, stimulates the blue-sensitive receptors; hence, its complementary color is yellow, which stimulates both the red receptors and the green. Similarly, the complement of red is blue-green and the complement of green is purple (blue and red). Protanopia is explained as a condition in which no long-wave sensitive receptors are present. Deuteranopia results from loss of the green receptor.

Hering theory. The theory formulated by Ewald Hering is an opponent-colors theory. In its simplest form, it states that three qualitatively different processes are present in the visual system, and that each of the three is capable of responding in two opposite ways. Thus, this theory is concerned with the processing phase (Fig. 2), in which there is a yellow-blue process, a red-green process, and a black-white process. The theory obviously was inspired by the opposition of colors that is exhibited during simultaneous contrast, afterimages, and complementary colors. It is a theory best related to the phenomenal

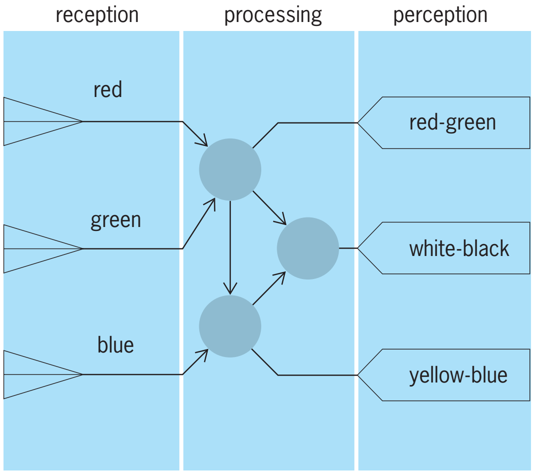

Fig. 2. **Schematic representation of the three phases of color vision which can be generally used to describe the various theories of color vision.**

and the neural-processing aspects of color rather than to the action of light on photopigments. This theory gains credibility when it is realized that opponent responses are common enough in the central nervous system. Well-known examples are polarization and depolarization of cell membranes, excitation and inhibition of nerve impulses, and reciprocal innervation of antagonistic response mechanism. The theory also maintains that there are four primary colors, since yellow appears to be just as unique perceptually, as red, green, or blue. However, it does not necessarily assume the existence of a separate yellow receptor.

Other theories. Various forms of stage theory or zone theory of color vision have been proposed. One form combines the principles of the Young-Helmholtz and Hering theories. It proposes that (1) there are three types of cone receptor; (2) the responses of red-sensitive, green-sensitive, and blue-sensitive receptors (and possibly others) are conducted to the higher visual centers; (3) at the same time, interactions are occurring at some stage along these separate conducting paths so that strong activity in a red response path inhibits, for example, the activity of the other response paths; and (4) this inhibiting effect is specific to the time and place of the strong red activity. The last point means that in neighboring regions and at subsequent times the blue and green mechanisms are less inhibited, so that blue-green afterimages and borders are commonly experienced as an opponent reaction to strong red stimulation.

Experimental evidence. Techniques of microspectrophotometry have been used to measure the absorption of light by single cone receptors from the eyes of primates, including humans. The results confirm the major assumption of the Young-Helmholtz theory, namely, that three types of visual receptor are specialized to absorb light over characteristic ranges of wavelength, with a maximum absorption at particular regions of the spectrum. Wide differences are found, from one receptor to another, in the wavelength at which this maximum absorption of light occurs. The three types of human cone receptors absorb maximally at about 420, 530, and 560 nanometers. In addition there are rod receptors sensitive to low intensities of light over a broad range of wavelengths peaking at about 500 nm. In each of the four types of receptor there is a photosensitive pigment that is distinguished by a particular protein molecule. This determines the range and spectral location of the light which it absorbs.

In other experiments, a microelectrode has been used to penetrate individual cone receptors in living retinal tissue of certain species of fish. Electrical responses are thus recorded as the receptor cell is stimulated by a beam of light. The wavelength of this test beam is varied from one end of the spectrum to the other. The result is that each cone shows an electrical response to light which presumably initiates impulses in the nerve cells of the visual system and is qualitatively the same regardless of the wavelength of the stimulating light. Quantitatively, however, the cones are found to differ widely in the size of response potential that they generate at each wavelength. In fact, they fall into three classes, responding maximally at about 460, 530, and 610 nm. This confirms, at least in the case of certain species of fish, the trichromatic aspect of the Young-Helmholtz theory.

The Hering theory has also received powerful support from electrophysiological experiments. A microelectrode may be used to record from retinal nerve cells that are close to the cone receptors described above in the fish. Electrical responses from some of these cells are again found to depend on the wavelength of the stimulating light. But, unlike the receptors themselves, these cells often have qualitatively different responses depending on wavelength of stimulation. Thus, a given cell may exhibit a positive response potential over one region of the spectrum and a negative one over another region. A retinal basis thus exists in these cells for the opponent process aspect of the Hering theory.

In monkeys having visual systems similar to that of humans, experiments have also shown opponent-color modes of responding. Cells in certain lower brain centers, for example, exhibit nerve impulses more or less continuously. Some of these cells are found to increase their activity in response to red light, for example, but decrease it in response to green. Other cells have the opposite reaction, and still others show blue-yellow opposition of the sort that is also demanded by the Hering theory.

Central nervous system factors are evident from the fact that a red light in one eye and a green light in the other can sometimes be fused to produce an appearance of yellow. Further evidence of central effects is found in the phenomenon of color constancy. The greenness of trees or the redness of bricks is only slightly less vivid when both are viewed through dark or yellow goggles; a black cat in the sunshine reflects more light to the eye than a white cat seen by indoor illumination. Color vision, like other forms of perception, is highly dependent on the experience of the observer and on the context in which the object is perceived. *See* EYE (INVERTEBRATE); EYE (VERTEBRATE); NERVOUS SYSTEM (VERTEBRATE); PERCEPTION; PHOTORECEPTION; VISION. Columbiformes

An order of birds containing the family Columbidae (worldwide; true pigeons and doves) and two smaller related families. The members of this order are characterized by an ability to drink water by "sucking" (actually lapping using the tongue) instead of the sip-and-tilt method of most birds. However, some other groups of birds are able to "suck" water by various methods. *See* CHARADRIIFORMES.

Classification. Columbiformes is here divided into the suborder Pterocletes, with the single family Pteroclidae (sandgrouse; 16 species; Old World except Australasia), and the suborder Columbae with the families Raphidae (dodos; 3 species; Mascarene Islands, western Indian Ocean) and Columbidae (pigeons and doves; 303 species; worldwide, with most groups found in Australasia to Southeast Asia). However, the relationships of the sandgrouse (Pteroclidae) are disputed; many workers argue that these birds are members of the Charadriiformes. The pigeons are divided into several subfamilies: the worldwide true pigeons (Columbinae), the pheasant-pigeon of New Guinea (Otidiphapinae), the large, crowned pigeons of New Guinea (Gourinae), the tooth-billed pigeon of Samoa (Didunculinae), and the fruit pigeons of the Old World tropics (Treroninae). Relationships of Columbiformes appear to be to the Charadriiformes in one direction and to the Psittaciformes in another. Possibly, the Columbiformes are a central stock in the evolution of birds. *See* PSITTACIFORMES.

Fossil record. The fossil record of the Columbiformes is meager, as would be expected for these terrestrial, mainly woodland and grassland birds. The extinct dodos (Raphidae), from the Mascarene Islands, are known mainly from subfossil remains.

Columbidae. Pigeons are found mainly in the tropics, but a number of species are common in temperate regions. They have a sleek plumage ranging from browns and grays to the brilliant greens, yellows, and reds of the tropical fruit pigeons (see **illustration**). They feed on seeds, fruit, and other vegetarian food. Most pigeons live in flocks but breed solitarily. Almost all are nonmigratory. The one or two young remain in the nest where they are fed by both parents, first on milk produced in the crop and then on seeds mixed with this milk. The extinct North American passenger pigeon (*Ectopistes migratorius*) lived and bred obligatorily in vast flocks, feeding largely on acorns and other mast. Although the passenger pigeon was once an abundant bird, its numbers dwindled because of overhunting and the reduction of extensive eastern forests on which it depended for food and breeding; the last individual died in captivity in 1914.

Pigeons are important game birds throughout the world. Two species of Old World origin, the rock dove (*Columba livia*) and the ring dove (*Streptopelia risoria*), have been domesticated; both have escaped and exist as feral birds throughout the world. Numerous breeds of the rock dove have been developed, which served as the primary example used by Charles Darwin in introducing his idea of evolution by natural selection. One breed of rock doves, the carrier pigeons, have served for centuries to transport messages back to their home loft. Most species of pigeons are kept and bred by aviculturists. Both domesticated species have important roles in biological research, such as studies of orientation and navigation, including work on the "magnetic compass" possessed by birds. In spite of hunting pressures, most species of pigeons are still in good numbers. A few, however, are endangered. *See* MIGRATORY BEHAVIOR.

Triangular-spotted pigeon (*Columba guinea guinea*), Fresno Zoo, California. (*Photo by Dr. Lloyd Glenn Ingles, © 2001 California Academy of Sciences*)

Raphidae. The three species of dodos and solitaires were found only in the several Mascarene Islands and were completely exterminated by the seventeenth century by sailors and released pigs. They are the symbol of extinction, with the slogan "dead as a dodo." One of the common forest trees of these islands has almost become extinct as a result; its fruits were eaten by dodos, and the hard seeds were adapted to the grinding action of the bird's stomach. The hard seed coat had to be cracked in this way so that water could reach the ovary of the excreted seed and start germination. Seeds can now be planted after cracking the seed coat artificially.

Pteroclidae. The dull-colored, ground-dwelling sandgrouse live in flocks in dry grasslands and deserts of the Old World, but depend on ponds of water to which flocks come in large numbers. The nest is generally a long distance from water, which is transported to the young by the adults by soaking their specialized belly feathers. The young drink only from these moistened feathers, and will refuse water in pans placed before them. *See* AVES. Walter J. Bock

Column

A structural member that carries its load in compression along its length. Most frequently, as in a building, the column is in a vertical position transmitting gravity loads from its top down to its base. Columns are present in other structures as well, such as in bridges, towers, cranes, airplanes, machinery, and furniture. Other terms used by both engineers and lay persons to identify a column are pillar, post, and strut. Columns of timber, stone, and masonry have been constructed since the dawn of civilization; modern materials also include steel, aluminum, concrete, plastic, and composite material. *See* COMPOSITE MATERIAL; LOADS, TRANSVERSE; STRUCTURAL MATERIALS; STRUCTURAL STEEL.

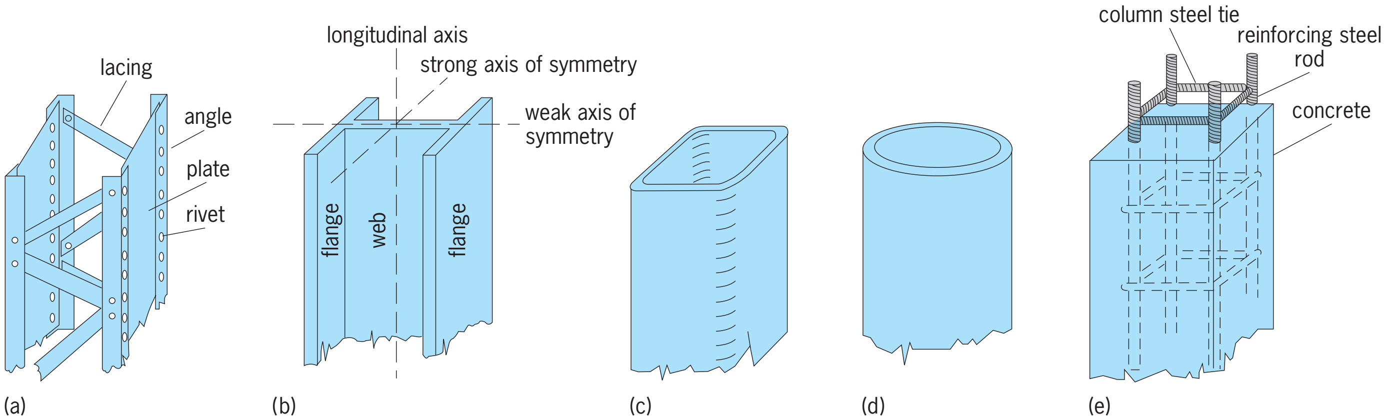
Fabrication. In the past, steel columns were built up of angle and plate elements welded or riveted together to form the desired cross-sectional shape (**illus**. *a*). Modern steel columns are made by rolling, extruding, or forming hot steel into predetermined cross-sectional shapes in the manufacturing facility (illus. *b*–*d*). Reinforced concrete columns are fabricated either in their final locations (cast-in-place concrete) or in a precast plant (precast concrete) with steel reinforcing rods embedded in the concrete (illus. *e*). Masonry columns are usually built in their final locations; they are made of brick or concrete masonry blocks; sometimes steel reinforcing rods are embedded within the masonry. *See* BRICK; CONCRETE; MASONRY; PRECAST CONCRETE; REINFORCED CONCRETE.

Classification. According to their behavior under load, columns are classified as short, slender, or intermediate. Definitions of these ranges are qualitative rather than quantitative.

A short column is one whose length is relatively short in comparison to its cross-sectional dimensions and, when loaded to its extreme, fails by reaching the compressive strength of its material. This is called failure in axial compression. A slender column is one whose length is large in comparison to its cross-sectional dimensions and, when loaded to its extreme, fails by buckling (abruptly bending) out of its straight-line shape and suddenly collapsing before reaching the compressive strength of its material. This is called a condition of instability, and it is reached at a load that depends not on the compressive strength of the material but on the stiffness of the material and the geometric properties of the column. (Stiffness is a property of materials expressed in terms of the magnitude of the load that produces a unit deformation. The greater the load required to produce a unit deformation, the stiffer the material. The geometric properties that influence the buckling of a column are the area and shape of the cross section, and the length of the column). An intermediate column falls between the classifications of short and slender. When loaded to its extreme, the intermediate column fails by a combination of compression and instability.

In addition to its length and cross section, the methods of support or fixity at the two ends of the column also influence its strength: the more effective the fixity of support, the more stable the column. (End fixity is the amount of restraint against displacement and rotation of the end of a column.)

Equilibrium, instability, and loads. As the axial load on a perfectly straight slender column with elastic material properties is increased in magnitude, this ideal column passes through three states: stable equilibrium, neutral equilibrium, and instability. The straight column under load is in stable equilibrium if a lateral force, applied between the two ends of the column, produces a small lateral deflection which disappears and the column returns to its straight form when the lateral force is removed. If the column load is gradually increased, a condition is reached in which the straight form of equilibrium becomes so-called neutral equilibrium, and a small lateral force will produce a deflection that does not disappear and the column remains in this slightly bent form when the lateral force is removed. The load at which neutral equilibrium of a column is reached is called the critical or buckling load. The state of instability is reached when a slight increase of the column load causes uncontrollably growing lateral deflections leading to complete collapse. *See* STRESS AND STRAIN; STRUCTURAL DEFLECTIONS.



Typical column configurations. (*a*) Built-up steel column. (*b*) Wide-flange steel column. (*c*) Tubular steel column. (*d*) Pipe column. (e) Reinforced concrete column.

For an axially loaded straight column with any end support conditions, the equation of static equilibrium, in the form of a differential equation, can be solved for the deflected shape and critical load of the column. With hinged, fixed or free end support conditions the deflected shape in neutral equilibrium of an initially straight column with uniform cross section throughout its length always follows a partial or composite sinusoidal curve shape, and the critical load is given by Eq. (1), where E = modulus of elasticity of the material, I = moment of inertia of the cross section, and l = length of the longest half sine wave along the deflected shape. A variant of (1) is given by Eq. (2), where L = actual length of the column between its two end supports, K = ratio of the longest half sine wave to the actual column length, and KL = effective length (length of an equivalent hinged-hinged column). From Eq. (2) it can be noted that the buckling strength of a column is inversely proportional to the square of its length.

$$P_{\text{cr}} = \frac{\pi^2 EI}{l^2} \qquad (1)$$

$$P_{\text{cr}} = \frac{\pi^2 EI}{(KL)^2} \qquad (2)$$

When the critical stress, F_{cr} ($F_{\text{cr}} = P_{\text{cr}}/A$, where A = cross-sectional area of the column), is greater than the proportional limit of the material, the column is experiencing inelastic buckling. Since at this stress the slope of the material's stress-strain curve, E_t (called the tangent modulus), is smaller than that below the proportional limit, the critical load at inelastic buckling is reduced. More complex formulas and procedures apply for such cases, but in its simplest form the critical buckling load formula is given as Eq. (3), where E_t = tangent modulus at the stress F_{cr}.

$$P_{\text{cr}} = \frac{\pi^2 E_t I}{(KL)^2} \qquad (3)$$

A column with a cross section that lacks symmetry may suffer torsional buckling (sudden twisting) before, or in combination with, lateral buckling. The presence of the twisting deformations renders both theoretical analyses and practical designs rather complex. *See* TORSION.

Eccentricity of the load, or imperfections such as initial crookedness, decreases column strength. If the axial load on the column is not concentric, that is, its line of action is not precisely coincident with the centroidal axis of the column, the column is characterized as eccentrically loaded. The eccentricity of the load, or an initial curvature, subjects the column to immediate bending. The increased stresses due to the combined axial-plus-flexural stresses result in a reduced load-carrying ability. *See* BEAM COLUMN.

Design standards. Since it is difficult, if not impossible, to construct a perfectly frictionless pin and an infinitely rigid fixity as practical column support, the theoretical formulas are only approximations for real structures. The various structural design codes and standards recognize this, and they specify adjustment factors in the form of modified effective lengths or load eccentricities. In addition, because the geometries of actual columns and the materials of which they are constructed are not perfect and since actual loadings cannot be predicted precisely, factors of safety are prescribed by design codes and standards. These are applied to the calculated capacities of ideal columns to provide margins of safety against failure.

A column that contains relatively thin plate elements, such as columns of steel, aluminum, and other metals, may fail at a load less than the critical load for the column as a whole, because one or more of the plate elements buckle locally into one or a series of short waves or wrinkles. Outstanding legs of thin angles, flanges of channels, and other such plates are elements that are susceptible to local buckling, thereby reducing the stiffness, and hence the stability, of the entire column. The likelihood of local buckling can be predicted by the mathematical theory of flat plates, and its strength reduction influence is addressed by the design codes and standards for steel, aluminum, and other metals. *See* PLATE GIRDER.

Extensions. When a column is too long to be built or transported in one piece, it has to be extended or spliced at the construction site. A reinforced concrete column is extended by having the steel reinforcing bars protrude a few inches or feet above the top of the concrete, then placing the next level of reinforcing bars to overlap, and pouring the concrete of the next level. A steel column is extended by welding or bolting splice plates on the flanges and webs or walls of the columns to provide a few inches or feet of load transfer from the upper to the lower column section. A timber column is usually extended by the use of a steel tube or wrapped-around sheet-metal plate bolted onto the two connecting timber sections.

Foundations. A column that carries the load down to a foundation must have means to transfer the load without overstressing the foundation material. Reinforced concrete and masonry columns are generally built directly on top of concrete foundations. A steel column, when seated on a concrete foundation, must have a base plate to spread the load over a larger area and thereby reduce the bearing pressure. The base plate is a thick rectangular steel plate usually welded to the bottom end of the column. *See* BUILDINGS; FOUNDATIONS. Robert T. Ratay

Combinatorial chemistry

A method in which very large numbers of chemical entities are synthesized by condensing a small number of reagents togther in all combinations defined by a small set of reactions. The main objective of combinatorial chemistry is synthesis of arrays of chemical or biological compounds called libraries. These libraries are screened to identify useful components, such as drug candidates. Synthesis and screening are often treated as separate tasks because they require different conditions, instrumentation, and scientific expertise. Synthesis involves the development of new chemical reactions to produce the compounds, while screening aims to identify the biological effect of these compounds, such as strong binding to proteins and other biomolecular targets.

Chemical Libraries

Combinatorial chemistry is sometimes referred to as matrix chemistry. If a chemical synthesis consists of three steps, each employing one class of reagent to accomplish the conversion, then employing one type of each reagent class will yield $1 \times 1 \times 1 = 1$ product as the result of $1 + 1 + 1 = 3$ total reactions. Combining 10 types of each reagent class will yield $10 \times 10 \times 10 = 1000$ products as the result of as few as $10 + 10 + 10 = 30$ total reactions; 100 types of each reagent will yield 1,000,000 products as the result of as few as 300 total reactions. While the concept is simple, considerable strategy is required to identify 1,000,000 products worth making and to carry out their synthesis in a manner that minimizes labor and maximizes the value of the resulting organized collection, called a chemical library. *See* MATRIX THEORY.

The earliest work was motivated by a desire to discover novel ligands (that is, compounds that associate without the formation of covalent bonds) for biological macromolecules, such as proteins. Such ligands can be useful tools in understanding the structure and function of proteins; and if the ligand meets certain physiochemical constraints, it may be useful as a drug. For this reason, pharmaceutical applications provided early and strong motivation for the development of combinatorial chemistry. *See* LIGAND.

Peptide libraries. In 1984 H. M. Geysen reported on the synthesis of a library of peptides and the screening of that library to probe how changes in a single amino acid in a peptide would change its association strength with an antibody. Biochemists assume that the detailed chemical structure of any ligand will affect that ligand's binding strength to a macromolecular receptor, but even with powerful modern computer modeling methods it is normally not possible to predict either the magnitude or even the direction of the effect. By synthesizing a large number of peptides, each varying from another by only one amino acid, it was possible to determine empirically which amino acid substitutions made binding stronger and which made it weaker. The synthesis of this library benefited from the fact that chemical methods for linking amino acids together to make peptides had been optimized such that little optimization of the reaction conditions was required. Instead, the challenge was how to conveniently make thousands of peptides in a format that facilitated their use in the subsequent binding studies. The solution was to synthesize the peptides on a rack of plastic pins and to test their binding ability while the peptides remained chemically attached to the pin. While solving technical challenges, perhaps more importantly this approach highlighted a philosophy in studying ligand-receptor binding problems: start with a source of molecular diversity (that is, lots of compounds) organized in a way that makes their empirical testing straightforward; then test them all and analyze the results at the end.

Because there are 20 naturally occurring amino acids, the synthesis of a linear peptide that is n amino acids long can be done in $20n$ different ways. Thus, there are 64,000,000 possible hexapeptides ($n = 6$). It would not be convenient, perhaps not even possible, to synthesize that many peptides on individual pins. In 1985 a synthesis method was reported in which the plastic used for synthesis was encased in an inert mesh resembling a tea bag. Collections of such tea-bag reactors were subjected to the chemical addition of an amino acid at the same time. After the addition, the bags were washed thoroughly and the bags (not the bag contents) mixed. The bags were redistributed to new beakers, and another amino acid was chemically added. In this method, each bag contains only one peptide. By chemically cleaving the peptide from the polymeric support, the peptide itself can be obtained. In a variant of this procedure, a mixture of reagents can be used in any given beaker such that each bag contains a mixture of peptides bound to the polymer. While the production of such mixtures complicates the subsequent assay step, it does provide for a much greater number of assays to be accomplished. Still unresolved is the question of whether the time economy afforded by using mixtures compensates for the pitfalls inherent in their testing for binding activity.

To make very large numbers of individual peptides would require very small bags for purely practical reasons. In 1988 work involving the use of polymer resin beads was reported; approximately one-tenth the width of a pinhead, these beads served as a kind of bag. By utilizing the "split-pool" approach, it was possible to synthesize extremely large peptide libraries in which each bead possessed a single peptide. The amount of peptide on one bead is only around 200 picomoles; however, this is enough both for a simple ligand-receptor binding assay and for the analytical techniques required to establish the exact chemical structure of that peptide. *See* PEPTIDE.

Organic libraries. Because much of the practical application in discovering tightly binding ligands derives from the pharmaceutical industry, the combinatorial synthesis of druglike compound libraries is of great interest. Two practical considerations make this a greater experimental challenge than the synthesis of peptide libraries.

The synthetic methods required to make druglike molecules (that is, low-molecular-weight, organic molecules) on a polymer support have not been optimized. While solid-supported peptide synthesis originated in the early 1960s and has been extensively developed since, initial experiments with organic solid-phase synthesis in the early 1970s were not followed up widely. In addition, while there are only 20 naturally occurring amino acids and therefore a finite number of reactions required to use them efficiently, an almost infinite number of organic chemical reagents exists and a very large number of reaction types. However, by the early 1990s several groups had reported the synthesis of moderately sized organic libraries by the solid-phase synthesis method. Each approach utilized a strategy like that of the Geysen pin method and thus was amenable to the parallel synthesis of hundreds to thousands of compounds.

The synthesis of much larger-membered libraries using the polymer-resin-bead approach was inhibited by the second practical issue: while 200 picomoles of an organic compound is enough for the ligand-receptor study, it is not enough to identify the structure of the ligand. The reason is that analytical methods for structure determination are both easier and more advanced for use with biological macromolecules such as polypeptides and polynucleotides. Beginning in the mid-1990s, the solution of bead tagging, or encoding, solved this issue. The strategy is simple: if the result of a chemical synthesis step cannot be easily read at low concentration, something should be added to the bead that conveniently encodes the reaction history of that bead for later analysis. The first reported methods of bead encoding involved the use of biological macromolecules themselves. After each step in the organic synthesis, either an amino acid or a nucleotide was added to a growing oligopeptide or oligonucleotide on the same bead so that the specific sequence could be read later, and from that sequence the reaction history could be elucidated. However, neither oligopeptides nor oligonucleotides are chemically inert enough to survive the conditions required for organic synthesis. Later, tags were introduced that were much more inert chemically. *See* ORGANIC SYNTHESIS.

More recent methods of encoding include the use of radio-frequency memory microchips and optical bar-coding strategies. **Figure 1** shows a scheme that uses optical-pattern encoding for the synthesis of a combinatorial library. Each of the nine chips has a different pattern written on it with a laser (a 3 × 3 matrix pattern as shown could encode for 2^9, or 512, unique chips). With the use of pattern-recognition software, the chips are sorted into appropriate reaction vessels so that chemical groups A, B, and C can be covalently added to the core organic molecule on them. After pooling the chips, optical scanning again permits sorting into appropriate reaction vessels so that a new set of three chemical groups can be added. At the end of this combinatorial synthesis involving two steps with three reagents at each, a total of 3^2, or 9, different products is obtained. Larger libraries are obtained by employing additional reaction steps, additional reagents per step, and an appropriately larger matrix pattern to enable the unique encoding of each product in the library. *See* OPTICAL INFORMATION SYSTEMS.

Major challenges in combinatorial chemistry focus on both the characterization of compounds and the screening of very large compound libraries. In addition, the use of combinatorial chemistry methods is under active study for the discovery of new catalysts, chemosensors, and other chemical substances in which prior binding of the cognate ligand (the molecule that fits into another, usually larger molecule) is necessary. *See* MOLECULAR RECOGNITION. Anthony W. Czarnik

Assaying Problems

In combinatorial chemistry, attention has been focused on the problem of how to identify the set of molecules that possess the desired combination of properties. In a drug-discovery effort, the library members that strongly bind to a particular biological receptor are of interest. In a search for new materials that behave as superconductors at relatively high temperatures, the special combination of elements yielding the best electrical properties is a goal. In each case, the library might consist of up to a million members, while the subset of target molecules might consist of several thousand contenders or just a single highly selective binder. This subset could then be studied in more detail by conventional means.

To take advantage of the parallel nature of the combinatorial chemistry strategy, rapid screening and assaying protocols are necessary. For example, gas chromatography/mass spectrometry of bead-encoded libraries is currently limited to several analyses per hour, a difficult proposition when the researcher is faced with analyzing several thousand samples. The problem is to find ways of keeping track of each library member so that parallel screening can be coupled with parallel assaying.

Spatial array. Several emerging strategies promise to address this problem. In the first case, a library is constructed in a spatial array such that the chemical composition of each location in the array is noted during the construction. The binding molecules, usually labeled with a fluorescent tag, are exposed to the entire assay. The locations that light up can then be immediately identified from their spatial location. This approach is being actively developed for libraries of proteins and nucleotides. A problem is that the chemistry required to attach various molecules to the solid surface, usually silicon, is quite tricky and difficult to generalize. The assaying strategy is intertwined with the available procedures for synthesizing the libraries themselves.

Polystyrene-bead support. A conceptually straightforward approach is to first synthesize the library by using polystyrene beads as the solid support. The product molecules are then stripped from the support and pooled together into a master solution. This complex mixture consisting of a potentially large selection of ligand molecules could then be exposed to an excess of a target receptor. The next step is to devise a method for identifying the ligand-receptor pairs that point to molecularly specific binding. One approach is to examine a part of the mixture en masse by using affinity capillary electrophoresis. With this technique, the migration times of the ligand-receptor pair are significantly longer than the

unreactive ligands, and can be interrogated by electrospray mass spectrometry.

Mass spectrometry. The mass spectrometric method often provides a direct structural identification of the ligand, either by determination of its molecular weight or by collision-induced dissociation experiments. In the latter case, the molecular ion is selected by a primary mass spectrometer and is driven into a region of high-pressure inert gas for fragmentation. The fragment ions are then used to reconstruct the original molecular structure. This direct approach to screening and assaying has the advantage that the screening is carried out in solution rather than on a solid support, and it avoids steric problems associated with resin-bound molecules. At present the approach seems limited to libraries of about 1000 compounds because of interference from unbound ligands, and limited by sensitivity issues. New strategies using mass spectrometry may eliminate this limit.

A different tack involves assaying the polystyrene beads one by one after the resin-bound molecules are exposed to a receptor. With this approach, active beads may be identified by color or by fluorescence associated with the receptor, and are subsequently indexed in standard 96-well titer plates. Identification is then possible by using a variety of spectroscopic techniques; at present, the most popular methods are electrospray mass spectrometry and matrix-assisted laser desorption ionization mass spectrometry.

Successful structure determination using mass spectrometry is often routine, particularly for protein libraries where sequencing strategies have been worked out; however, ambiguities often arise for nonpeptide libraries. Encoding strategies promise to resolve this issue. For example, it is now possible to construct the library such that the first molecule attached to the resin can be identified by its ratio of carbon-13 to carbon-12. By using isotope enrichment protocols, a particular isotope ratio can be associated with a specific molecule. Then, for a library synthesized with three steps, the molecule in the first step can be identified from its isotope ratio, the molecule in the third step is known from the synthesis, and the molecular weight is measured by mass spectrometry. Hence, the molecular weight of the molecule used in the second step can be determined by the difference. This approach has been successfully employed to assay a 1000-member library. There are many ways that this approach could be extended to larger systems.

Another advantage of the isotope-encoding strategy is that the code is actually carried with the molecule after it is cleaved from the bead. This property may have important implications when performing bioassays. This scheme appears to be functional in a practical sense. The mass spectrometry methods are generally sensitive enough ($\approx$100 femtomole) to provide a reliable assay, and robotic techniques can be developed to increase the number of assays to perhaps a few dozen per hour.

Another level of sophistication involves the assay of a single polystyrene bead by using a method such as infrared spectroscopy. The advantages of optical techniques are that they are nondestructive and can be employed without removing the target molecules from the linker. There are, however, several obvious drawbacks, including lack of specificity and sensitivity for single-bead studies. Recently, however, experiments using infrared microspectroscopy have partially overcome the sensitivity limitations. The selectivity issue has been addressed by using a carbon-deuterium stretching frequency to determine the deuterium content of a given compound. This signature can lead to identification under suitable circumstances. *See* MASS SPECTROMETRY.

Improving assaying power. It would be desirable to speed up the whole process. To fully capitalize on the elegant concept implicit in combinatorial chemistry, parallel screening methods capable of identifying large numbers of library members need to be developed. When the libraries are synthesized on beads, it would also be preferable to assay the compound without cleaving it from the polymeric resin support. This process inherently destroys the library and opens the possibility of incomplete cleaving reactions. One approach is to take advantage of a special type of mass spectrometry where it is possible to record spectra from very small areas of a solid surface. With this technique, the sample is bombarded by a focused energetic ion beam having a kinetic energy of several thousand electronvolts. The energetic particle loses some of its momentum in the top layers of the solid, causing desorption of molecular ions near the point of impact. If the energetic ion beam is formed in a short (nanosecond) pulse, the secondary ions may be measured by using time-of-flight detection. The resulting mass spectra can be recorded from an area that is much less than 1 square micrometer. Hence, it is feasible to spatially resolve the chemical components on a single resin particle that is typically in the 20–300-μm size range.

Experiments using this idea were attempted in the late 1990s. The first attempts were successful only if the covalent bonds attaching the molecules to the resin were first clipped. This was accomplished by exposing the bead to a vapor of trifluoracetic acid, a standard release agent for acid-sensitive linking moieties. After clipping, the molecules were found to remain on their respective beads, even if prior to their treatment they were essentially touching. For example, in this method, two distinct types of coated beads can be used—one with phenylalanine and one with leucine. It might be possible to extend this method to a collection of thousands of beads arrayed onto a plate.

None of the above approaches provides assaying power that satisfies the need to characterize massive combinatorial libraries. Many schemes appear to have enough sensitivity or selectivity to perform the job, but whether any will be truly practical remains to be seen. It is likely, given the high level of activity in this field, that one of the above methods (or perhaps a completely new one) will become practical. *See* ANALYTICAL CHEMISTRY; ELECTROPHORESIS.

Nicholas Winograd

Dynamic Combinatorial Chemistry

Dynamic combinatorial chemistry is in its early developmental stage. It integrates library synthesis and screening in one process, potentially accelerating the discovery of useful compounds. In the dynamic approach the libraries are not created as arrays of individual compounds, but are generated as mixtures of components, similar to natural pools of antibodies. One important requirement is that the mixture components (**Fig. 2**) exist in dynamic equilibrium with each other. According to basic laws of thermodynamics (Le Chatelier's principle), if one of the

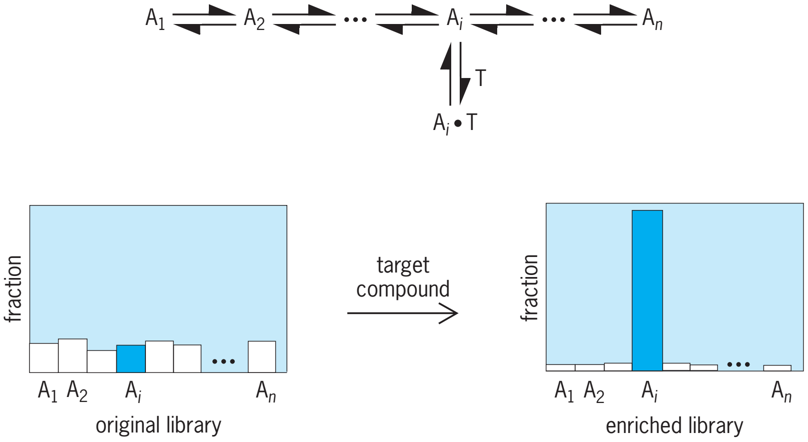

Fig. 2. Dynamic equilibrium for mixture components ($A_1 \ldots A_n$), following Le Chatelier's principle. T indicates the target.

components (A_i) is removed from the equilibrated mixture, the system will respond by producing more of the removed component to maintain the equilibrium balance in the mixture. *See* CHEMICAL EQUILIBRIUM; LE CHATELIER'S PRINCIPLE.

The dynamic mixture, as any other combinatorial library, is so designed that some of the components have potentially high affinity to a biomolecular target. These high-affinity (effective) components can form strong complexes with the target. If the target is added to the equilibrated mixture, when the effective components form complexes with the target they are removed from the equilibrium. This forces the system to make more of these components at the expense of other ones that bind to the target with less strength. As a result of such an equilibrium shift, the combinatorial library reorganizes to increase the amount of strong binders and decrease the amount of the weaker ones (Fig. 2). This reorganization leads to enrichment of the library with the effective components and simplifies their identification.

The general idea of the equilibrium shift is not new, and its combinatorial application was eventually demonstrated by several groups. As an example, researchers described a dynamic library that produced inhibitors for the enzyme carbonic anhydrase. The components of this library were formed by a reversible reaction between two series of compounds: amines and aldehydes (**Fig. 3***a*). The products of this reaction, Schiff bases, existed in the dynamic equilibrium with the starting amines and aldehydes (building blocks) and with each other. Functional groups in the building blocks (R^x and R^y) could recognize binding pockets of the target enzyme, and the best combination of those groups could make a particularly strong binder. To render the library components stable to hydrolysis, they were converted to similar amines (Fig. 3*a*) with retention of their basic target-binding properties. The researchers showed that the addition of carbonic anhydrase to the library led to the preferred formation of a sulfonamide compound (Fig. 3*b*), as compared to other library components. Structures similar to the sulfonamide compound are known to inhibit carbonic anhydrase via strong binding to its active site.

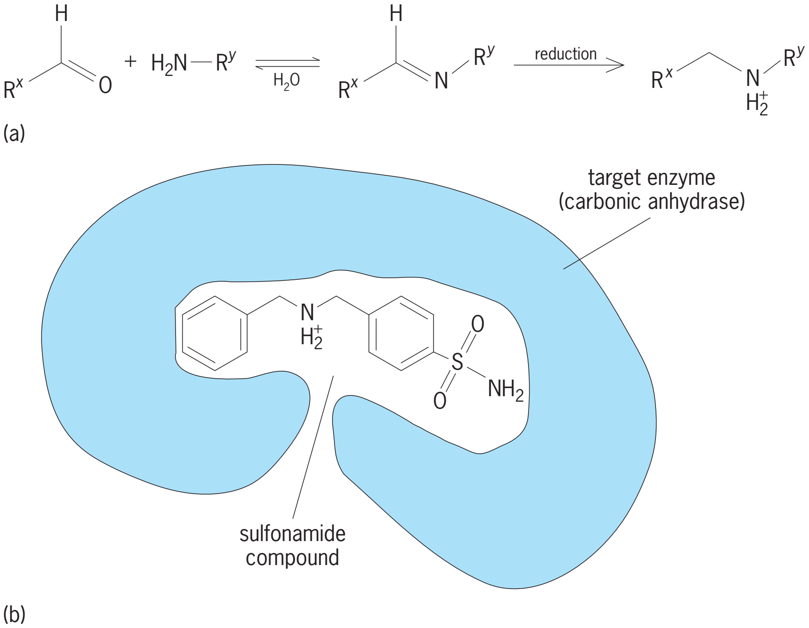

Fig. 3. Equilibrium shift utilized to produce a dynamic library. (*a*) Reversible reaction between amines and aldehydes produces a Schiff base. (*b*) Addition of the enzyme carbonic anhydrase leads to the formation of the preferred sulfonamide compound.

This example shows that the dynamic combinatorial approach requires a reversible reaction that can keep multiple components in equilibrium. A number of such reactions have been used, leading to various types of dynamic libraries. These reactions include peptide bond formation and cleavage to form libraries of peptides that bind to an antibody, photoisomerization of alkenes that changes their shape to fit a target amino acid, transesterification resulting in dynamic libraries of macrocycles that can selectively recognize metal ions, thiol-disulfide exchange that organizes a library of artificial peptide receptors, and scrambling of ligands in zinc complexes to find an effective deoxyribonucleic acid (DNA) binder.

All the above examples, dealing with relatively small libraries, were designed to prove the concept of the dynamic approach. Remarkably, however, all the systems described so far use different base reactions, target compounds, reaction media, and instrumentation. This fact indicates that numerous variations of the dynamic approach can be expected to develop in the future.

Problems. The dynamic combinatorial approach has some inherent problems. One is that it combines two intrinsically different processes: equilibrium between the library components and molecular recognition (selective binding) of the target, which generally require different conditions. One way to overcome this problem is to physically separate the equilibration and binding sites. Such separation has been accomplished by a stepwise approach to the organization of the dynamic libraries (chemical evolution). The target compound is immobilized by attachment to solid beads placed in a continuous-flow column, similar to a chromatography column (selection site). The immobilization does not allow the target to leave the column, and retains the target's properties. When the combinatorial mixture passes through the selection site, the effective components remain, bound to the target. Next, the depleted mixture enters another column (equilibration site), where special conditions, such as heating, catalysis, and irradiation, restore the equilibrium in the combinatorial mixture (**Fig. 4**). During this restoration, part of the mixture converts back into the effective components. The combinatorial mixture then returns to the selection site. After a number of such cycles, the original mixture evolves into a high-affinity subset accumulated on the target-containing beads. Later, this subset can be washed off the target and analyzed to identify the effective components.

Dynamic combinatorial chemistry is an emerging method that can potentially grow into a powerful tool for the discovery of new and useful compounds

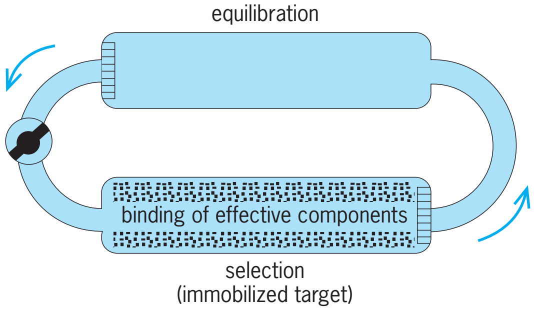

Fig. 4. Separation of equilibration and binding sites in a dynamic combinatorial experiment.

in molecular libraries. This approach may find its niche, for example, in the drug discovery process. The success of this method will depend upon the development of new reversible reactions that can be used to generate the dynamic libraries, and of analytical methods that help identify the structure of components in complex mixtures. **Alexey V. Eliseev**

Combinatorial synthesis

A method for preparing a large number of chemical compounds, commonly known as a combinatorial library, which are then screened to identify compounds having a desired function, such as a particular biological or catalytic activity. Combinatorial synthesis is an aspect of combinatorial chemistry, which allows for the simultaneous generation and rapid testing for a desired property of large numbers of chemically related compounds. One could regard combinatorial chemistry as the scientist's attempt to mimic the natural principles of random mutation and selection of the fittest. Combinatorial chemistry has already become an invaluable tool in the areas of molecular recognition, materials science, drug discovery and optimization, and catalyst development. *See* COMBINATORIAL CHEMISTRY; ORGANIC SYNTHESIS.

Combinatorial synthesis was developed to prepare libraries of organic compounds containing from a few dozen to several million members simultaneously, in contrast to traditional organic synthesis where one target compound is prepared at a time in one reaction (**Fig. 1**). Thus, a target compound AB, for example, would be prepared by coupling of the substrates A and B in a traditional (orthodox) synthesis and would be isolated after reaction processing (workup) and purification (such as crystallization, chromatography, or distillation). Combinatorial synthesis offers the potential to prepare every combination of substrates, type A_{1-m} and type B_{1-n}, providing a set of compounds, $A_{(1-m)}B_{(1-n)}$. There are two main approaches to combinatorial synthesis: parallel synthesis and split synthesis (also known as split-and-pool or mix-and-split).

Parallel synthesis. In parallel synthesis, each compound is prepared separately in an individual reaction vessel. In order to accomplish parallel combinatorial synthesis, large numbers of reactions must be carried out simultaneously and the resulting products must be isolated and purified very quickly. Recently, various automated devices, such as weighing, reaction, filtration, and chromatography machines, were developed for high-throughput parallel combinatorial synthesis. Another approach employs insoluble reagents that can be removed by filtration from a solution-phase reaction mixture. Acids, bases, reducing reagents, oxidation reagents, or various catalysts are attached to insoluble supports (such as

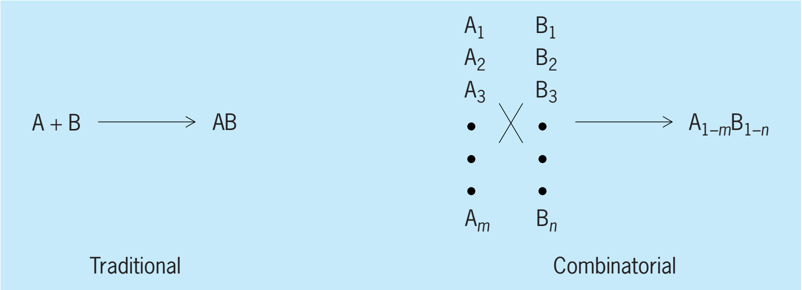

Fig. 1. Traditional synthesis versus combinatorial synthesis.

silica-gel or polymers) in this approach. Functional groups bound to insoluble supports are also applied to scavenge unreacted starting materials in solution.

Transformation of a substrate anchored to an insoluble support by treatment with a solution of reagents, generally called solid-phase synthesis, is a frequently used protocol for combinatorial synthesis. A starting substrate is first attached to a solid support by an appropriate linker group and undergoes various synthetic transformations to furnish a product on the solid support which is readily separated from the unreacted reagents and coproducts in the solution by filtration. The resulting solid-supported product can then be used in subsequent transformation steps. Solid-phase peptide synthesis is a typical example. The final products, as well as the synthetic intermediates, are detached from the solid support on demand. An example of the solid-phase parallel synthesis giving a 3 × 3 = 9-membered library is shown in **Fig. 2**. This library can be screened for optimum "hit" candidates before or after release of the supported products; however, the preferred method for biological screening is to test the compounds in solution after cleavage from the solid support. A_{1-3} and B_{1-3} could be amino acids to give dipeptides, nucleotides to give dinucleotides, or sugars to give disaccharides. *See* NUCLEOTIDE; PEPTIDE.

In both protocols—solution-phase synthesis with solid-supported reagents and solid-phase synthesis with solution-phase reagents—various polymers, glass surfaces, and silica gel are typical solid supports; cross-linked polystyrene beads having appropriate functional groups (such as NH_2, Cl, OH, and COOH) are the most frequently used.

Split synthesis. Polystyrene beads bearing a reactive functional group are also used as a starting support in split synthesis. The beads range from 10 to 200 micrometers in diameter. For example, 1 g of beads having a 100-μm diameter contains about 1 million beads. The split synthesis is illustrated in **Fig. 3** for a library of 3 × 3 × 3 = 27 possible combinations of trimeric products. Three steps of solid-phase synthesis to attach A, B, and C to the starting beads (step 1) are carried out individually to give the supported A, B, and C. The resulting three kinds of beads are suspended in a solvent, mixed by shaking, and filtered to give one portion of a mixture. The pooled mixture of beads is partitioned to three portions where each portion of beads contains A, B, and C in a statistical ratio (1:1:1). Similar manipulations (step 2) afford three portions of beads where each portion contains every combination of nine compounds (from AA to CC) in a statistical ratio. The three portions of a mixture consisting of nine compounds are subjected to coupling with X, Y, and Z (step 3) to give a nine-membered mixture having a terminal group X, a nine-membered mixture having a terminal group Y, and a nine-membered mixture having a terminal group Z, respectively. Finally, the resulting beads are all mixed together to

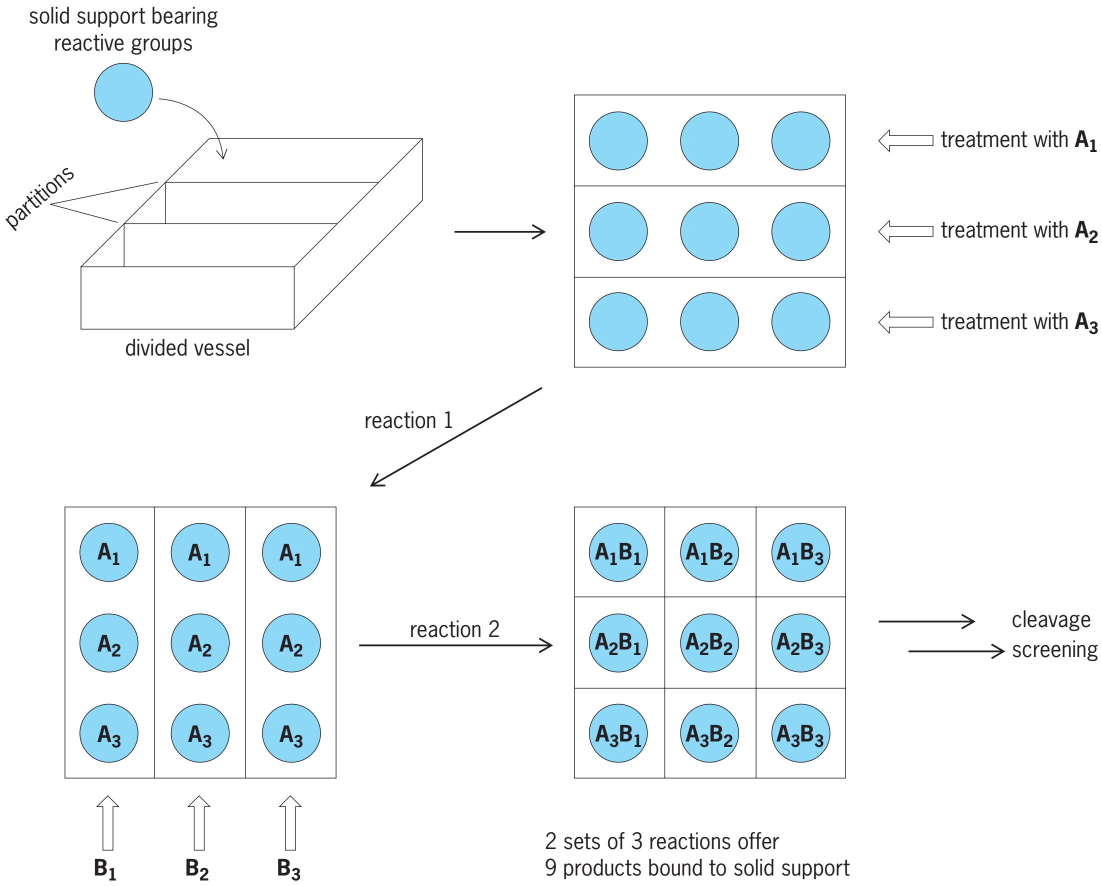

Fig. 2. Solid-phase parallel synthesis of a nine-membered library.

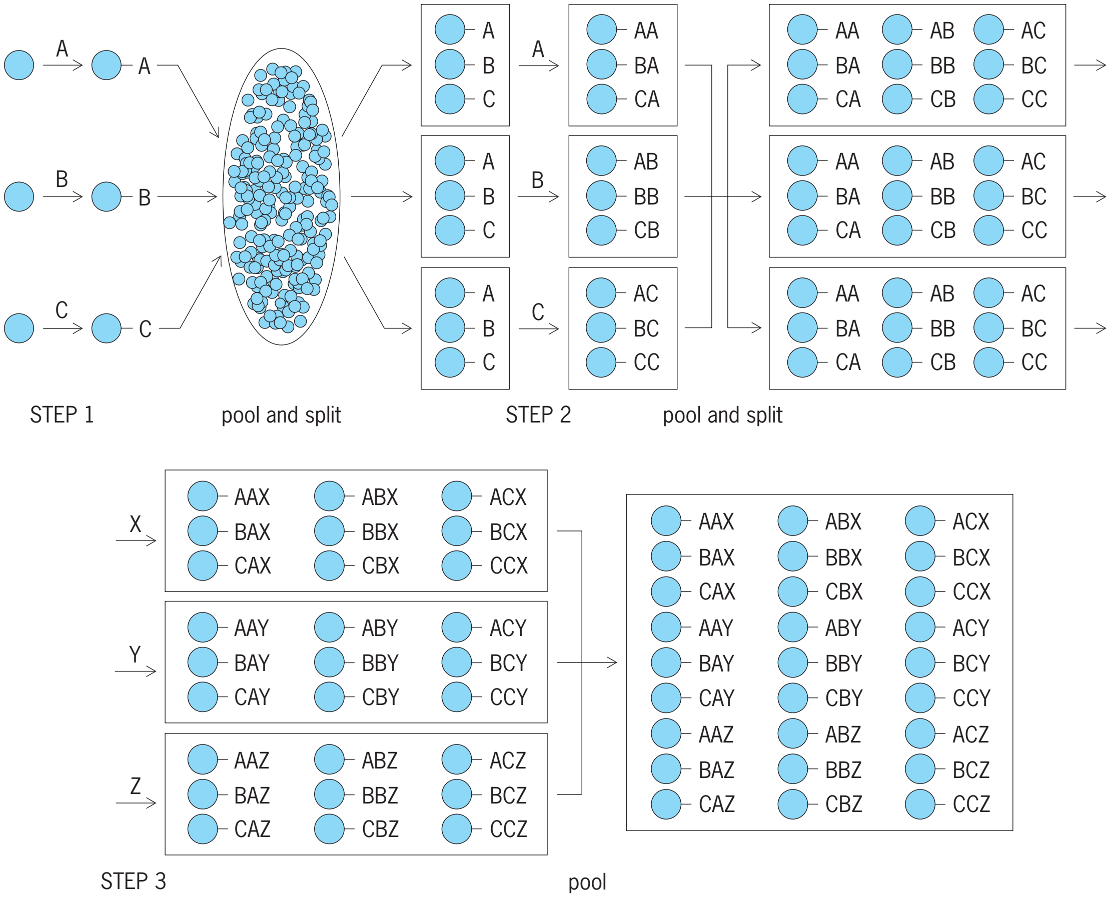

Fig. 3. Solid-phase split synthesis of a library consisting of 27 compounds.

give a library consisting of 27 compounds bound to the solid support, where three sets of three coupling reactions (3 × 3 = 9 manipulations) afford the cube of three ($3^3 = 27$) compounds. In this manner, split synthesis can offer an enormous number of combinatorial products. For example, linear coupling of 10 amino acids five times (10 × 5 = 50 manipulations) can furnish 10^5 pentapeptides. Since one bead of a library prepared by split synthesis must have one compound, the library is also referred to as the one-bead-one-compound library. Identification of the most active compound from the one-bead-one-compound library has gained in popularity with the advent of more efficient methods for one-bead spectroscopic analysis. Combinatorial theory

The branch of mathematics which studies arrangements of elements (usually a finite number) into sets under certain prescribed constraints. Problems combinatorialists attempt to solve include the enumeration problem (how many such arrangements are there?), the structure problem (what are the properties of these arrangements and how efficiently can associated calculations be made?), and, when the constraints become more subtle, the existence problem (is there such an arrangement?).

Other names for the field include combinatorial mathematics, combinatorics, and combinatorial analysis, the last term having been coined by G. W. Leibniz in his *Dissertatio de arte combinatoria* (1666) wherein he hoped for application of this field "in the entire sphere of science." Indeed, the availability today of high-speed computers which can deal with large but finite configurations seems to be bringing his prophecy near fulfillment. On the other hand, the study of combinatorial phenomena dates back to the very beginnings of mathematics. According to a Chinese legend recorded in a divinatory book of the lesser Taoists (about 2200 B.C.), the magic square

$$\begin{array}{ccc} 4 & 9 & 2 \\ 3 & 5 & 7 \\ 8 & 1 & 6 \end{array}$$

was observed on the back of a divine tortoise. Apparently, permutations were considered as early as 1100 B.C., and Rabbi Ben Ezra, in the twelfth century, probably knew the formula for the number of k-element subsets of an n-element set.

Enumeration

From the seventeenth well into the twentieth century, combinatorial theory was used primarily to solve certain problems in probability. For example, to compute the probability that exactly three heads appear in five flips of a coin, one need only count the total number of sequences of heads and tails which may occur (32) and divide this number into the number of sequences which result in three heads and two tails (10). *See* PROBABILITY.

Permutations and combinations. In enumeration of arrangements it is always essential to know which arrangements are considered the same and which different. When k objects are to be selected from a set S and different orderings on the selected objects are to be counted separately, the arrangements are called permutations or relabelings of the set of k objects. But if order is to be disregarded, so that attention is focused only on the subset consisting of the k selected elements, then the choice is termed a combination. If elements of S are allowed to be selected more than once, then the arrangements are called permutations with repetition or combinations with repetition. If S has n different elements, Eqs. (1)–(4) enumerate these

$$P(n,k) = n(n-1)(n-2)\cdots(n-k+1) = \frac{n!}{(n-k)!} \tag{1}$$

$$C(n,k) = \binom{n}{k} = \frac{P(n,k)}{k!} = C(n,n-k) \tag{2}$$

$$\overline{P}(n,k) = n^k \tag{3}$$

$$\overline{C}(n,k) = \binom{n+k-1}{k} \tag{4}$$

four basic cases. The number of k-permutations is shown in Eq. (1). In particular, $P(n, n) = n! = n(n-1)\cdots(2)\,2\cdot 1(1)$ is the number of ways to order S. The number of k-combinations (or k-element subsets of S) is shown in Eq. (2). When repetition is allowed, Eq. (3) gives the number of permutations with repetition (or k-tuples) and Eq. (4) gives the number of combinations with repetition. Formula (4), although not as widely known as formula (2), recurs throughout mathematics: for instance, it gives the number of mixed partial derivatives of order k with n variables, or the number of solutions in nonnegative integers of the equation $x_1 + \cdots + x_n = k$. *See* CALCULUS.

Generating functions. The symbol

$$\binom{n}{k}$$

in Eq. (2) is sometimes called a binomial coefficient, because it is the coefficient of x^k in the expansion of $(1+x)^n$ given in Eq. (5). When a finite or infinite

$$C(n,x) = (1+x)^n = \sum_{k=0}^{n} \binom{n}{k} x^k \tag{5}$$

sequence $(a_0, a_1, \ldots)$ is exhibited in this way as the coefficients of a polynomial or series $p(x) = \Sigma a_i x^i$, then $p(x)$ is called a generating function for the sequence. The general method of generating functions was developed by P. S. Laplace in 1812 but had already been used extensively in the eighteenth century by L. Euler. For example, substituting $x = -1$ in Eq. (5) shows that there are exactly as many even subsets of a set as odd subsets (and thus the probability of an even number of heads in n flips of a coin is $^1/_2$). *See* BINOMIAL THEOREM; SERIES.

Recursions. Algebraic identities involving generating functions are often proved from recursions (or difference equations) satisfied by the enumerating sequence. Thus the numbers $C(n,k)$ are uniquely determined by the boundary conditions $C(n,0)=1$ for all n and $C(0,k) = 0$ for all $k > 0$, and by recursion (6). The generating function defined by Eq. (5) satisfies the algebraic identity $C(n,x) = (1+x)C(n-1,x)$.

$$C(n,k) = C(n-1,\ k-1) + C(n-1,\ k) \tag{6}$$

Catalan numbers. The Catalan numbers are given in Eq. (7). They count the ways to insert parentheses in a string of n terms so that their product may be unambiguously carried out by multiplying two quantities at a time. Thus $c_4 = 5$, since *abcde* may be computed by $(ab)(cd)$, $((ab)c)d$, $(a(bc))d$, $a((bc)d)$, or $a(b(cd))$. The Catalan numbers also enumerate the ways to place nonintersecting diameters in a convex polygon with $n + 1$ vertices so that only triangular regions result. Further, c_n gives the number of ways to draw in succession all the balls from a container which originally contains $n - 1$ white balls and $n - 1$ black balls, so that at every stage there are at least as many black balls as white balls remaining in the container. Catalan numbers also appear in the theoretical measurement of preferences. Let A be a finite set, and let f be a function which assigns a real number to each element of A. Then x is said to be preferred to y if $fx \geq f(y) + 1$, and this induces a partial order on the elements of A. Thus, if $A=\{x, y, z\}$ and $f(x) = 0, f(y) = {}^1/_2$, and $f(z) = 1$, the only preference is z to x. Assignments $\{1,2,3\}$, $\{0,1,1\}$, $\{0,0,1\}$, and $\{0,0,0\}$ give the four other essentially distinct preferential orders on A, and, in general, there are $c_n + 1$ such orders on an n-element set.

$$c_n = \frac{1}{n}\binom{2n-2}{n-1} \tag{7}$$

Catalan numbers obey the recursion $c_n = c_1 c_{n-1} + c_{n-2} + \cdots + c_{n-1} c_1$ and have the generating function $c(x) = {}^1/_2\,(1 - \sqrt{1-4x})$, where the root is to be expanded by means of the series form of the binomial expansion.

Stirling numbers. If instead of selecting elements from the set S, it is desired to distribute the elements of S into r indistinguishable cells so that no cell remains empty, there results a set-partition or partition of S into r blocks, and these are counted by the Stirling number of the second kind $S(n, r)$. The Stirling numbers satisfy the boundary conditions $S(n, 1) = S(n, n) = 1$, and the recursion $S(n, r) = S(n-1, r-1) + rS(n-1, r)$ [which may be established by distinguishing within the family of partitions between the distributions for which the first $n-1$ elements of S leave a cell unoccupied which must be filled by the last element and those for which the first $n-1$ elements occupy every cell]. In addition, they satisfy formula (8), where $(x)_r$ stands for falling factorial

$$x^n = \sum_{r=1}^{n} S(n, r)(x)_r \tag{8}$$

$x(x-1)(x-2)\cdots(x-r+1)$. The Bell number, given by Eq. (9), is the total number of partitions

$$B(n) = \sum_{r=1}^{n} S(n, r) \tag{9}$$

of an n-element set. These numbers also give the number of rhyme schemes for a poem of n lines. There are $B(4) = 15$ ways to rhyme a quatrain: *abcd*, *aabc*, *abac*, . . . , *aabb*, . . . , *abbb*, *aaaa*. The Stirling numbers of the first kind, $s(n, r)$, are defined as the coefficients of the generating function of $(x)_n$.

Fibonacci numbers. The Fibonacci numbers are defined by the elementary recursion $f_{n+2} = f_n + f_{n+1}$; $f_0 = 0, f_1 = 1$. Each f_n counts, for example, the number of sequences of $n-2$ zeros and ones with no consecutive zeros. The generating function $f(x)$ of the Fibonacci numbers satisfies the identity $(1 - x - x^2)f(x) = x$, from which the closed form $f_n = (\tau^n - (1-\tau)^n)/\sqrt{5}$; where $\tau = (1+\sqrt{5})/2$, may readily be deduced.

Asymptotic formulas. Occasionally, only a rough estimate of the number of arrangements of a certain kind is desired (for example, to estimate how long a computer will take to list all such arrangements), and then an asymptotic enumeration formula is sought. Thus, $n!$, which is the number of (complete) permutations $P(n,n)$, obeys for large n Stirling's formula (10), where $e = 2.71828\ldots$ [here $f(n) \approx$

$$n! \approx \sqrt{2\pi n}\left(\frac{n}{e}\right)^n \tag{10}$$

$g(n)$ means that as n grows without bound the ratio $f(n)/g(n)$ approaches 1]. *See* E (MATHEMATICS).

Integer partitions. An integer partition of n is a nonincreasing sequence of positive integers whose sum is n; the number of these partitions is denoted by $p(n)$. Thus $p(4) = 5$, since 4, $3+1$, $2+2$, $2+1+1$, and $1+1+1+1$ all partition 4. No usable formula for $p(n)$ is known, but Euler discovered an elegant expression for the generating function: $p(x) = (1-x)^{-1}(1-x^2)^{-1}\cdots(1-x^{m)})^{-1}\ldots$. Asymptotically, $p(n)$ obeys formula (11), where e^x is the exponential

$$p(n) \approx \left(\frac{1}{4n\sqrt{3}}\right) e^{\pi\sqrt{2n/3}} \tag{11}$$

function which uses the base e. Thus $p(n)$ is eventually greater than any polynomial function of n but is eventually less than a^n for any $a > 1$.

If the requirement that the sequence be nondecreasing is removed, so that, for example, the partition $1+3$ is considered distinct from the partition $3+1$, then the number of such partitions of n is much easier to count and is 2^{n-1}. If $\overline{p}(n)$ denotes the number of partitions of n into distinct parts, then $\overline{p}(x) = (1+x)(1+x^2)(1+x^3)\cdots$, and if $\overline{p}_k(n)$ is the number of partitions of n into distinct parts whose largest part is at most k, then $\overline{p}_k(x) = (1+x)(1+x^2)\cdots(1+x^k)$.

Partially ordered sets. Results in asymptotic enumeration include a formula for the number of partially ordered sets with n elements. The asymptotic estimate of approximately $2^{n^2/4}$ for the number of partially ordered sets with n elements results from the observation that as n becomes large the partially ordered sets which contain four elements w, x, y, z such that $w < x < y < z$ become asymptotically inconsequential (in the sense that the probability that a random partially ordered set contains a four-element chain approaches zero). *See* LATTICE (MATHEMATICS).

Probabilistic method. A nonconstructive proof technique termed the probabilistic method guarantees the existence of certain configurations by showing that the probability of their occurrence is positive. For any i and j, the existence of a graph all of whose circuits have at least i edges but whose chromatic number is at least j can be demonstrated by this technique. *See* GRAPH THEORY.

Ferrer's diagrams. Associated with an integer partition $n = a_1 + \cdots + a_k$ is an array of dots called its Ferrer's diagram, whose ith row contains a_i dots. Thus $4 = 3 + 1$ gives rise to the diagram $\begin{smallmatrix}\bullet&\bullet&\bullet\\ \bullet&&\end{smallmatrix}$.

A reflection of the diagram through its main diagonal interchanges rows and columns, converting $4 = 3 + 1$ into its dual partition $4 = 2 + 1 + 1$. This correspondence proves a number of identities, such as the number of partitions of n into k parts equals the number of partitions of n which have greatest part k.

Möbius inversion. Another useful counting technique exploits the relationship between a pair of functions f and g defined on a lattice L. Suppose that g satisfies Eq. (12), and that the values of g are known;

$$g(s) = \sum_{s \le t} f(t) \tag{12}$$

then the values of f can be found if the calculation in Eq. (12) can be "inverted" to define f in terms of g. The principle of Möbius inversion states that there is a function $\mu(s, t)$, called the Möbius function of the lattice, defined for pairs of elements (s,t) in L and which depends only on the lattice, such that Eq. (13) holds.

$$f(s) = \sum_{s \le t} \mu(s,t)g(t) \tag{13}$$

For example, assume that the lattice in question is the boolean algebra on the two points H and P. Let the subset $\{H\}$ stand for the property that a specific card in a deck is a heart, $\{P\}$ for the property that it is a picture card, $\{P,H\}$ for the property that it is both a heart and a picture card, and ϕ, the zero of the lattice, for the property that it is neither. As t varies over these four subsets, let $f(t)$ denote the number of cards in the deck which have precisely the property (or properties) t (and no others), and let $g(t)$ denote the number which have at least the property (or properties) t. Then clearly $g(\phi) = 52$, $g(\{H\}) = 13$, $g(\{P\}) = 12$, and $g(\{P,H\}) = 3$, and g and f stand in the relation given by Eq. (12). For boolean algebras the Möbius function is given as follows: $\mu(s,t) = 0$ if s is not a subset of t, and $\mu(s,t) = (-1)^p$ otherwise, where p is the number of elements in t but not in s. [Thus, for all $s \subseteq t$, $\mu(s,t) = 1$ if the difference in sizes of s and t is even and $\mu(s,t) = -4$ if it is odd.] In our example, $f(\phi) = g(\phi) - g(\{H\}) - g(\{P\}) + g(\{P,H\}) = 30$ cards which are neither hearts nor picture cards. *See* BOOLEAN ALGEBRA.

For a general boolean algebra, the Möbius inversion formula for $f(\phi)$ is more often called the principle of inclusion-exclusion, or sieve formula, because at various stages of the summation the correct number is alternately overcounted and then undercounted. Assume S has $n = g(0)$ elements each of which may have some of the properties $P_1, \ldots, P_r$. Further, let $g(i_1, i_2, \ldots, i_k)$ be the number of elements with (at least) properties $P_{i1}, P_{i2}, \ldots, P_{ik}$. Again Eq. (12) is satisfied, so by Eq. (13), one arrives at formula (14) for $f(0) = f(\phi)$.

$$\begin{aligned} f(0) = n - \sum_{1 \le i_1 \le n} g(i_1) + \cdots \\ + (-1)^p \sum_{1 \le i_1 < \cdots < i_p \le n} g(i_1, \ldots, i_p) + \cdots \end{aligned} \qquad (14)$$

Derangements. The derangement numbers D_n count complete permutations (without repetition) subject to the additional constraint that every element be "wrongly labeled." That is, if $S = \{1, \ldots, n\}$, then D_n is the number of ways to order S into sequences $a_1, \ldots, a_n$ such that $a_i \ne i$ for $i = 1, \ldots, n$. If the property P_i of a permutation is that $a_i = i$, then the sieve formula may be applied to prove Eq. (15). In probabilistic terms, Eq. (15) implies that no matter what the size of the decks is, the probability is approximately $1/e$ that two identical and randomly shuffled decks of cards will never have the same card in the same place.

$$\begin{aligned} D_n &= P(n,n) - C(n,1)P(n-1,n-1) \\ &\quad + C(n,2)P(n-2,n-2) - \cdots \\ &= n!\left(1 - 1 + \frac{1}{2!} - \frac{1}{3!} + \cdots \right. \\ &\quad \left. + \frac{(-1)^n}{n}\right) \approx \frac{n!}{e} \end{aligned} \qquad (15)$$

Gaussian coefficients. The Möbius function has been computed for other lattices which arise in enumeration, such as the lattice of all positive divisors of a given integer n (with elements ordered by divisibility), a lattice of integer partitions, the lattice of partitions of an n-element set (ordered by refinement: $s \le t$ if every block of s is contained in a block of t), and the lattice of all subspaces of a vector space of dimension n over a finite field with q elements. The number of subspaces of dimension k in such a vector space is expressed in formula (16) for gaussian coefficients. This apparent rational function of q is, in fact, a polynomial which is the generating function for the numbers $p_{m,k}(n)$ of integer partitions of n into at most m parts whose largest part is at most k, Eq. (17). An easy fact, established from the Ferrer's diagram, is that $p_{m,k}(N) = p_{m,k}(mk - n)$. A much harder result is that the sequence of coefficients is unimodal: $p_{m,k}(n+1) \ge p_{m,k}(n)$ for all $n < mk/2$. *See* LINEAR ALGEBRA.

$$\begin{bmatrix} n \\ k \end{bmatrix}_q = \frac{(q^n - 1)(q^{n-1} - 1)\cdots(q^{n-k+1} - 1)}{(q^k - 1)(q^{k-1} - 1)\cdots(q - 1)} \qquad (16)$$

$$\begin{bmatrix} m+k \\ k \end{bmatrix}_q = \sum_{q=0}^{mk} p_{m,k}(n) q^n \qquad (17)$$

The lattices for boolean algebras, subspaces, and set-partitions show striking similarities [such as the similarity between Eqs. (2) and (16)], which are studied in the general theory of geometric lattices or combinatorial geometries. For example, the methods applied to set partitions to study the four-color theorem of graph theory, when applied to the lattice of subspaces, provide a way to attack the problem of finding efficient error-correcting codes. *See* INFORMATION THEORY.

Magic squares. A (generalized) magic square is an n by n matrix of (not necessarily distinct) nonnegative integers all of whose row and column sums are equal to a prescribed number x. Thus $x = 15$ in the 3×3 magic square given earlier. The number of such magic squares is 1 when $n = 1$, $x + 1$ when $n = 2$, and in general is a polynomial of the form $a_m x^m + a_{m-1}x^{m-1} + \cdots + a_1 x + 1$, where $m = (n-1)^2$. Although the coefficients a_i are not given explicitly in this formula, for each n they may be computed by the method of undetermined coefficients, so that a computer search of magic squares for small values of x will also determine the number of such squares for all values of x. *See* MATRIX THEORY.

Pólya counting formula. If the number of ways to paint the faces of a cube with red and blue is to be computed, formula (3) would seem to give $2^6 = 64$; however, it is reasonable to assume that all six arrangements in which exactly one face is blue are identical, since for all such arrangements a rotation of the cube will make the top face blue. Under the condition that two coloring patterns are to be assumed equivalent if one can be transformed into the other by a rotation, the number of configurations is 10. This number can be derived by exhausting all cases or by the Pólya counting formula. The Pólya formula counts the number of functions from a set D (in the example, the faces of the cube) to a set R (the colors red and blue), with two functions f and g assumed to be the same if some element of a fixed group G of (complete) permutations of D (in this case, the 24 rotations of a cube) takes f into g. Actually, the

Pólya formula provides a way to compute the generating function, with variables $x_1,\ldots,x_k$ corresponding to the elements of R, for which the coefficient of $x_1^{a1} \cdots x_k^{ak}$ is the number of functions which use each x_i value exactly a_i times. (For the painted cube, if x_i = red and x_2 = blue, then the generating function is given by $x_1^6 + x_1^5x_2 + 2x_1^4x_2^2 + 2x_1^3x_2^3 + 2x_1^2x_2^4 + x_1x_2^5 + x_2^6$.) The proof of the Pólya theorem depends on a special case proved earlier by W. Burnside: if G is a group consisting of m (complete) permutations of S, then the number of inequivalent permutations of S is

$$\frac{1}{m}\sum_{\sigma\in G} f(\sigma)$$

Here two permutations π_1 and π_2 are regarded as equivalent if there is some σ in G such that the relabeling that σ effects on the sequence π_1 gives the sequence π_2; and for each σ in G, $f(\sigma)$ denotes the number of permutations of S which do not change when relabeled by σ. *See* GROUP THEORY.

Application of Lefschetz theorem. A wide range of techniques is employed in enumeration theory. For example, the hard Lefschetz theorem from algebraic geometry was used to show that if A is any set of n distinct positive real numbers, and if for any subset B of A, $s(B)$ is the sum of its members, then $s(B)$ is constant on at most $g(n)$ subsets B, where $g(n) = \bar{p}_n([(n + 1)(n)/4])$, the number of partitions of $[(n + 1)(n)/4]$ into distinct parts whose largest part is at most n. Thus $g(n)$ is the middle coefficient of the polynomial $(1 + x)(1 + x^2)(1 + x^3) \cdots (1 + x^n)$ and $g(n)$ is achieved by letting A be the arithmetic progression $\{1,2,\ldots, n\}$ and setting the sum equal to $[(n + 1)(n)/4]$.

Properties of Arrangements

An arrangement is primarily a family of subsets of a set S. An alternate way of formulating this concept is as an incidence system, also called a relation, which specifies when a particular element s of S is in a subset S_i of the family, for example, by means of the incidence matrix $M = [m_{ij}]$ of the family: the rows of the incidence matrix are indexed by the elements $s_1,\ldots, s_n$ of the set S, the columns of the matrix are indexed by the subsets $S_1,\ldots,S_m$ in the family, $m_{ij} = 1$ if s_i is in S_j, and $m_{ij} = 0$ otherwise. For example, if $S = \{s_1,s_2,s_3,s_4\}$, $S_1 = \{s_1, s_2\}$, $S_2 = S_4 = \{s_1,s_3,s_4\}$, and $S_3 = \{s_2\}$, the incidence of matrix of this arrangement is

$$\begin{bmatrix} 1 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 0 & 1 & 0 & 1 \end{bmatrix}$$

Systems of distinct representatives. If $n = m$ in an incidence system, a system of distinct representatives for the sets is a permutation $a_1,\ldots, a_n$ of S such that a_i is in S_i for $i = 1, 2, \ldots,n$. (In a congressional committee S, where each S_j might denote a particular cause or coalition, it might be desirable to find a system of distinct representatives so that each cause or coalition would have a different proponent.) In the above example, s_1,s_2,s_3,s_4 is such a system.

Marriage theorem. A system of distinct representatives certainly cannot exist unless any k of the subsets S_i together contain at least k distinct elements, and in fact it can be shown that this condition is also sufficient. This theorem is whimsically called the marriage theorem, since if S consists of a collection of n boys and each subset S_i consists of the boys acquainted with a particular girl g_i, then the conditions of the theorem guarantee that each girl could marry a boy of her acquaintance.

Algorithms for finding systems. Algorithms for computers exist which find systems of distinct representatives with reasonable efficiency: as n increases, the time a computer needs to find a system increases as the square of n. *See* DIGITAL COMPUTER.

Permanent. To enumerate the systems of distinct representatives, it is enough to compute the permanent of the incidence matrix defined by $\Sigma m_{1,a\,1}m_{2,a2} \cdots m_{n,an}$, where the sum is taken over all $n!$ permutations $(a_1, a_2, \ldots, a_n)$ of the set of column indices.

Maximal systems. When a complete system of distinct representatives does not exist, the size of a largest possible system is equal to the smallest possible value of the function $n - k + s_{i1\ldots,ik}$ for all possible combinations $S_{i1},\ldots, S_{ik}$ of subsets in the family, where $s_{i1,\ldots,ik}$ is the number of elements in $S_{i1} \cup \cdots \cup S_{ik}$. A related theorem asserts that the minimum number of blocks into which a partially ordered set may be partitioned subject to the constraint that any pair of elements x and y in the same block be related ($x \le y$ or $y \le x$) is equal to the maximum possible size of a set S of pairwise unrelated elements. It is always possible to find such a set S with the further property that any (complete) permutation π which preserves the partial order [if $x \le y$, then $\pi(x) \le \pi(y)$] must take members of S to other members of S. This fact can be used to show that in a boolean algebra the maximum size of S is $C(n, [n/2])$. This number is the middle (largest) binomial coefficient and corresponds to the set S of all subsets of size $[n/2]$.

Assignment problem. Suppose it is desired to assign n workers to do n jobs, and entry a_{ij} of a matrix A measures how well the ith worker does the jth job. An assignment would be a permutation $j_1,\ldots, j_n$ of the jobs so that the ith worker performs the job j_i. The assignment problem requires that one find an assignment maximizing the total utility T, given by Eq. (18).

$$T = \sum_{i=1}^{n} a_{ij_i} \qquad (18)$$

The problem may be solved by introducing auxiliary row and column numbers $u_1,\ldots, u_n$ and $v_1,\ldots,v_n$ subject to the condition $u_i + v_j \ge a_{ij}$ for all i and j. Then Eq. (19) is valid for any assignment,

$$T = \sum_{i=1}^{n} a_{ij_i} \le \sum_{i=1}^{n} u_i + \sum_{j=1}^{n} v_j = R \qquad (19)$$

since in an assignment each row and column is used exactly once. The marriage theorem shows that the maximum utility M of T is equal to the minimum m of R. Further, an algorithm is known which systematically changes the u's and v's to reduce R, arriving at numbers u_i and v_j for which the set of a_{ij}'s such that $a_{ij} = u_i + v_j$ admits a complete system of distinct representatives. For an assignment derived from such a system, $T = R$ and so M is achieved for this T. This method is practical in that the algorithm leads directly to a solution; and since the number of possible assignments is usually very large (for example if $n = 25$, this number is $25! > 10^{25}$), without some guidance there is no practical way to search for the optimal assignment or to recognize it when it is found. Another application of the marriage theorem is to prove topological fixed-point theorems. *See* TOPOLOGY.

Doubly stochastic matrices. A doubly stochastic matrix, a matrix of nonnegative real numbers such that every row sum and every column sum is equal to one, is a real-number analog of a magic square. The set of all n by n doubly stochastic matrices is convex in the sense that if $M_1, \ldots, M_k$ are all doubly stochastic and $a_1, \ldots, a_k$ are nonnegative numbers whose sum is one, then the convex combination

$$\sum_{i=1}^{k} a_i M_i$$

is also doubly stochastic. These matrices in fact form a convex polytope (a generalization of the notion of convex polygon) in euclidean space $\mathbf{R}^{n^2}$, in that their entries are bounded and there are a finite number of vertices (a minimal set of matrices such that every doubly stochastic matrix is a convex combination of elements of this set). The marriage theorem can be used to prove that the $n!$ permutation matrices with exactly one 1 in each row and column are the vertices of the convex polytope of doubly stochastic matrices.

By a theorem in linear programming, linear functions are optimized on the vertices of a convex polytope. For the assignment problem this means that for a more general assignment in which the ith worker spends a fraction m_{ij} of the work time on the jth job and each job is always being worked on (so that the matrix $M = [m_{ij}]$ is doubly stochastic), a maximum utility is obtained when each worker spends all the work time at one job. *See* LINEAR PROGRAMMING.

Upper-bound problem. In a typical problem in linear programming, polytopes in $\mathbf{R}^m$ occur which are defined by n linear constraints, such as those given by (20), where the x_j's are the variables (corresponding to vectors in $\mathbf{R}^m$.

$$\sum_{j=1}^{m} a_{ij} x_j \le b_i \qquad i = 1, \ldots, n \tag{20}$$

Algorithms to maximize linear functions on these polytopes usually involve proceeding from one vertex to another at which the function is greater. [An algorithm was given in 1979 using different (nonlinear) techniques, which guarantees that the number of steps needed to solve any such linear program is no more than a polynomial function of mn, but for most practical applications it has been found that a vertex-to-vertex method such as the simplex algorithm gives a faster answer.] It is important when allocating computer time to place an upper bound on the number of vertices. In 1970 it was shown that the number of vertices of a polytope in $\mathbf{R}^m$ defined by n linear constraints is at most $M(m,n)$, given by Eq. (21).

$$M(m, n) = \binom{n - \left[\frac{m+1}{2}\right]}{n - m} + \binom{n - \left[\frac{m+2}{2}\right]}{n - m} \tag{21}$$

Existence and Construction

In the 1920s R. A. Fisher noted that "the design and analysis of statistical experiments requires the construction of orthogonal Latin squares and balanced incomplete block design." *See* STATISTICS.

Orthogonal Latin squares. A Latin square is a square n by n matrix with entries from the set $N = \{0, 1, \ldots, n-1\}$ so that each number occurs exactly once in each row and exactly once in each column. Two Latin squares are said to be orthogonal if when they are superposed the n^2 cells contain each of the n^2 pairs of numbers from N exactly once. For $n = 3$ one has the superposed orthogonal squares

$$\begin{matrix} 00 & 11 & 22 \\ 12 & 20 & 01 \\ 21 & 02 & 10 \end{matrix}$$

where the first digits form the first square, and the second digits the second square. This square may be used to design an agricultural experiment which tests the interaction of three varieties of grain with three types of fertilizers. A field is divided into nine plots in each of which the choice of grain is made according to the first digit and the choice of fertilizer according to the second digit. The Latin squares assure the even distribution of the varieties of grain and fertilizer in both directions, so that effects such as the variation of the soil are mimimized, and the orthogonality allows the experimenter to try each fertilizer with each variety of grain.

For $n \le 10$ each of these arrays can be viewed as a particular type of magic square whose entries are distinct two-digit numbers and such that each row and column sum is $11n(n-1)/2$ (33 for $n = 3$ and 495 for $n = 10$).

If n is odd, it is easy to construct two orthogonal squares A and B. One takes $A = [a_{ij}]$ and and $B = [b_{ij}]$ where $a_{ij} = i + j$, $b_{ij} = i + 2j$, reducing these sums by n or $2n$ if necessary to put them in the range $0, \ldots, n-1$. If n is a multiple of 4, it is not much more difficult to make a construction. But for n of the form $4m + 2$ it is considerably harder. It is clearly impossible when $n = 2$, and, by an exhaustive trial, G. Tarry showed it to be also impossible for $n = 6$. Euler had

Fig. 1. Two orthogonal Latin squares for $n = 10$. (*Courtesy of Thomas Brylawski*; *Karl Petersen*, *photographer*)

conjectured in 1782 that no pair of orthogonal Latin squares existed for any n of the form $4m + 2$, but in 1959 orthogonal Latin squares were found for every $4m + 2$ greater than or equal to 10 (**Fig. 1**).

Block designs. T. Kirkman posed the following puzzle in the 1850s: Is it possible for 15 schoolchildren to go for walks in 5 groups of 3 every afternoon, so that in seven afternoons every child shall have walked with every other child? This arrangement is indeed possible and the following is a solution, the girls being represented by letters $a, \ldots, o$:

The cited design is a special case of a balanced incomplete block design or (b, v, r, k, λ)-design: an arrangement of v elements or treatments x_i, $i = 1, \ldots, v$, into b subsets or blocks B_j, $j = 1, \ldots, b$, so that each B_j contains exactly k distinct elements, each element occurs in r blocks, and every combination of two elements $x_u x_v$ occurs together in exactly λ blocks.

Counting the total number of plots (incidences of x_i in B_j or symbols in the above arrangement) in two ways—first summing over the blocks and then summing over the treatments, the constraint (22) is obtained.

$$bk = vr \qquad (22)$$

By considering all two-element subsets which contain x, constraint (23) is obtained. The two technical constraints (24) imply that the blocks are incomplete in that none of the blocks contains all or all but one of the treatments and none consists of a single treatment.

$$r(k-1) = \lambda(v-1) \qquad (23)$$

$$2\rangle k\rangle v-1, \lambda\rangle 0 \qquad (24)$$

Steiner triple systems. When $\lambda = 1$ and $k = 3$, such (b, v, r, k, λ)-designs are known as Steiner triple systems, and in this case constraints (22) and (23) imply that v is of the form $6m + 1$ or $6m + 3$. Kirkman himself proved that triple systems exist for all such v.

The schoolchild arrangement has the additional property that the blocks themselves are partitioned into r families called parallel classes of v/k blocks each such that every element occurs in exactly one block of each parallel class. Such designs are termed resolvable. A resolvable Steiner triple system is called a Kirkman triple system, and clearly in this case v must be divisible by three. In 1968 Kirkman triple systems (resolvable balanced incomplete block designs with block size three) were shown to exist for all $v = 6m + 3$.

An application of Steiner triple systems might arise in testing taste preferences among v products if every pair of products is to be compared, but each taster can efficiently taste only three products per day. A Kirkman system will, in addition, give an efficient schedule in which each product is used exactly once each day.

Fisher's inequality. Fisher's inequality states that $b \geq v$ in every design. If $b = v$, then necessarily $k = r$ and the design is called a symmetric (v, k, λ)-design. It is a property of these designs that every two blocks intersect in λ elements, and hence the transpose of the incidence matrix of a (v, k, λ)-design is itself a (v, k, λ)-design. Elementary matrix theory may be used to show that if v is even, then a symmetric design with parameters v, k, λ exists only if $k - \lambda$ is a perfect square; and deep results in number theory have been used to show that when v is odd, there must exist integers c, y, and z not all zero such that Eq. (25) holds.

$$x^2 = (k-\lambda)y^2 + (-1)^{(v-1)/2}\lambda z^2 \qquad (25)$$

See NUMBER THEORY.

Existence for fixed k. If k is fixed, then, for all but finitely many sets of parameters b, v, r, k, λ satisfying Eqs. (22), (23), and (24), there exists a block design having those parameters. When $k \leq 5$, all sets of parameters for which a block design exists have been determined. (A design is simple when $\lambda = 1$.)

Projective planes. When a symmetric design has $\lambda = 1$, condition (23) shows that if $k = n + 1$, then $v = n^2 + n + 1$. In analogy with the points (treatments) and lines (blocks) of a plane in projective geometry, such configurations are called projective planes. In this case, condition (25) states that if the parameter n, called the order of the plane, is of the form $4m + 1$ or $4m + 2$, then integers u and v exist with $n = u^2 + v^2$. Thus an infinite number of possible values of n are excluded, beginning with 6, 14, and 21. Whenever n is a power of a prime (and thus the size of a finite field), a plane exists, namely, the projective plane coordinatized over the field (but these are not the only planes which exist for prime-power orders). In the early part of the twentieth century, planes were constructed over many algebraic systems in which linear equations could be solved, but which were not associative. Planes coordinatized over such systems are different from those coordinatized over fields. The smallest of these planes has order 9 and thus has 91 points. *See* ALGEBRA; PROJECTIVE GEOMETRY.

Non-Desarguesian planes. The theorem of G. Desargues (which states that if corresponding vertices of two triangles lie on three concurrent lines, then the three points of intersection of respective sides of those triangles will lie on a line) holds in general only for those planes which arise from fields, and hence the term non-Desarguesian plane is used for the others. No (necessarily non-Desarguesian) projective plane has been found for any n that is not a prime power [and no n has been excluded except those not satisfying condition (19)]. Whether a projective plane exists for an n that is not a power of a prime is an important unsolved problem in existence theory and projective geometry. Orthogonal Latin squares and projective planes are related in that the existence of a projective plane of order n is equivalent to the existence of a set of $(n - 1)$ n by n Latin squares every pair of which is orthogonal. This would mean that for the first unresolved case, $n = 10$, nine pairwise orthogonal Latin squares must be found to produce a projective plane of order 10. No one has found more than two such squares.

Friendship theorem. Only for trivial projective planes can all the points be paired with all the lines in such a way that the incidence system is dualized, and each line is paired with a point not on that line. Stated differently, this is the friendship theorem: Among n people, if every pair of people has exactly one common friend, then there is someone who knows everyone else.

t-Designs. The concept of a block design in which every pair of elements is in the same number of blocks can be generalized to t-designs with parameters $t - (v, k, \lambda)$, in which each t-element subset of a v-element set is in a fixed number λ of k-element blocks. Every t-design is an s-design for all s such that $0 \leq s \leq t$ where the λ_s are given by Eq. (26), and

$$\lambda_s = \frac{\lambda P(v - s, t - s)}{P(k - s, t - s)} \tag{26}$$

these numbers must all be integers. Formulas (22) and (23) are special cases of Eq. (26), with $\lambda_0 = b$, the number of blocks, and $\lambda_1 = r$, the replication number.

Designs are only known for relatively small values of t. For $t = 3$, there are the inversive planes which, like finite projective planes, combine classical geometry and finite fields. Let P be the points of a finite affine plane coordinatized by a field F with q elements. These points are in correspondence with the elements of an extension field F' with q^2 elements, where each point (r,s) is paired with the element $r + sx$, with x the root of an irreducible quadratic equation (like $\sqrt{-1}$ over the real numbers). An ideal point at infinity, ∞, is added giving $v = q^2 + 1$ points. The blocks are then the images of the set B_0 consisting of the line $\{(s,0)$: s element of $F\}$ along with ∞ under all linear fractional transformations, given by Eq. (27). Here ∞ acts like 1/0 so that Eq. (28)

$$y \to \frac{ay + b}{cy + d} \qquad (a,b,c,d \text{ elements of } F',\ ad = bc) \tag{27}$$

$$\frac{a^{\infty} + b}{c^{\infty} + d} = \frac{a}{c} \tag{28}$$

holds. The blocks (all with $q + 1$ elements) are then called circles (with the original lines in the affine plane corresponding to circles through ∞). Circles have the property that every triple of points determines a unique circle ($\lambda = 1$), and further that if C is a circle which contains p but not q, there is a unique circle which contains q and is “tangent” to C at p.

The construction of t-designs has been closely related to the study of multiply transitive groups. The Mathieu groups give two designs for $t = 5$. One has parameters $5 - (12,6,1)$, and the other has parameters $5 - (24,8,1)$. In the first case, the blocks which contain a fixed three-element subset of points form a design isomorphic to the affine plane of order three, and in the second the blocks through three fixed points form a projective plane of order four.

At present no simple designs are known for $t > 5$. Steiner quadruple systems [designs with parameters $3 - (v,4,1)$] have been constructed for all v congruent to 2 or 4 modulo 6.

Error-correcting codes. The following matrix is the incidence system of a projective plane of order 2 (and symmetric Steiner triple system):

$$\begin{matrix}
1 & 0 & 0 & 0 & 1 & 0 & 1 \\
1 & 1 & 0 & 0 & 0 & 1 & 0 \\
0 & 1 & 1 & 0 & 0 & 0 & 1 \\
1 & 0 & 1 & 1 & 0 & 0 & 0 \\
0 & 1 & 0 & 1 & 1 & 0 & 0 \\
0 & 0 & 1 & 0 & 1 & 1 & 0 \\
0 & 0 & 0 & 1 & 0 & 1 & 1
\end{matrix}$$

Since $k = 3$ and $\lambda = 1$, each row has exactly three 1’s and any two rows overlap in only one of these columns. Thus, any two rows differ in four of their entries. This matrix is an example of a binary block code of distance $m = 4$ and length $n = 7$: a set of codewords, each consisting of a sequence of n binary digits (zeros and ones), such that any two codewords differ in at least m places. If seven messages are coded by rows of the above matrix and one is transmitted to a receiver, the original message can be decoded—even if during transmission one of the 1’s were changed to a 0 or conversely—by choosing the codeword closest to the received sequence. For example, if 1001011 were received, the last codeword was transmitted. On the other hand, if two digits were changed, resulting for example in a received message 1000110, the receiver could not tell whether the intended message corresponded to the first codeword or the second. Such a code will then

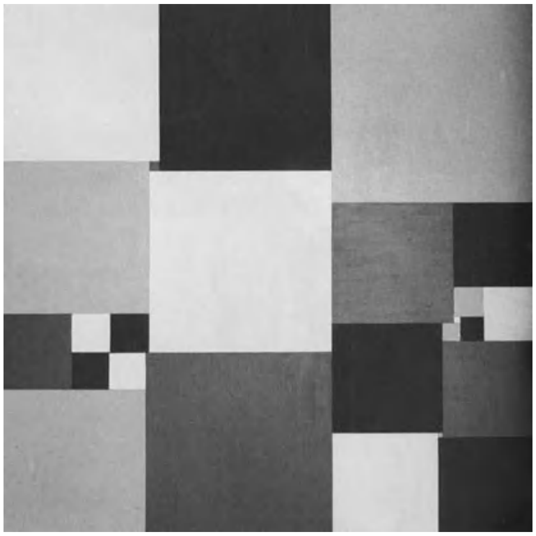

Fig. 2. Subdivision of a square into 26 smaller squares; no two of which are the same size. (*Courtesy of Thomas Brylawski*; *Karl Petersen*, *photographer*)

"correct" one transmission error and decide if an intended codeword with up to three such errors has been correctly transmitted.

In general, a block code will correct up to $[(m-1)/2]$ errors. The fundamental problem in coding theory is to construct codes with a large number of words and large distance but small length. In the example, the size of the code may be increased without decreasing the distance by adding a 1 to the end of all seven codewords, adjoining a new word of eight 1's, and then forming the eight additional words constructed from each of the others by interchanging all 0's and 1's.

Subdivision of square. An elegant combinatorial application of the theories of electrical networks and three dimensional convex polytopes led in the 1940s to the construction of a square subdivided into n smaller squares no two of which are the same size (**Fig. 2**, where $n = 26$). The least number of unequal squares into which a square can be divided is 21, and that, up to symmetry, there is only the following subdivision. A square of length 112 is partitioned into squares of length 50, 35, 27, 8, 19, 15, 17, 11, 6, 24, 29, 25, 9, 2, 7, 18, 16, 42, 4, 37, and 33, respectively, where each square enters the big square as far north as possible and then as far west as possible.

Pigeonhole principle. The pigeonhole (or Dirichlet drawer) principle states that: if a very large set of elements is partitioned into a small number of blocks, then at least one block contains a rather large number of elements. From this result it follows, for example, that any permutation of the numbers from 1 to $mn + 1$ must contain either an increasing subsequence of length $m + 1$ or a decreasing subsequence of length $n + 1$. To see this, associate with each number in the permutation P the pair of numbers (i,d), where i (respectively d) is the length of the longest increasing (respectively decreasing) subsequence in which it is the first element. Then no two numbers in P are associated with the same pair (since if p precedes q, P initiates a longer increasing subsequence if $p < q$ and a longer decreasing subsequence if $p > q$), so that not every number can be associated with one of the mn pairs (i, d), $i = 1, \ldots, m$; $d = 1, \ldots, n$. One can do no better than $mn + 1$, since if the numbers from 1 to mn are arranged sequentially in an n by m array and read off from left to right starting at the bottom, then the longest increasing subsequence has length m and the longest decreasing subsequence has length n. This construction belongs to the field of extremal combinatorial theory, a branch of combinatorics which constructs counterexamples of size n for theorems which hold for all $k \geq n + 1$.

Ramsey's theorem. Ramsey's theorem, proved in the 1930s, generalizes the pigeonhole principle as follows: For any parameters $(r; r_1, \ldots, r_k)$ with each $r_i \geq r$, there exists a number N such that for all $n \geq N$, if S is an n-element set all

$$\binom{n}{r}$$

whose r-element subsets are partitioned into blocks $A_1, \ldots, A_k$, then there is some r_i-element subset S' of S such that all

$$\binom{r_i}{r}$$

of the r-element subsets of S' are in the block A_i. For a given set of parameters, one then asks for the Ramsey number, or smallest N for which the theorem is true. When $r = 1$, by the pigeonhole principle $N = r_1 + \cdots + r_k - k + 1$. For the parameters (2;3,3), the theorem can be interpreted as follows: When the edges and diagonals of a regular polygon with a sufficiently large number N of vertices are all colored red or blue, there are three vertices of the polygon which are also the vertices of a triangle all of whose edges are the same color. One can always find a monochromatic triangle in a hexagon, and the extremal configuration consisting of a pentagon whose edges are red and whose five diagonals are blue shows that the Ramsey number for these parameters is 6.

Analogs of Ramsey's theorem have been proved for graphs, vector spaces, configurations in the Euclidean plane, and (with infinite cardinals as parameters) in set theory. However, very few Ramsey numbers have been computed. For example, when the edges and diagonals of a polygon are colored with four colors, the smallest N which guarantees a monochromatic triangle [that is, for (2;3,3,3,3)] is known only to be between 51 and 63.

Many asymptotic results are known and have interpretations in graph theory. For example, the Ramsey number $(2;3,t)$ is known to be at most $ct^2/\log t$, where c is an absolute constant not depending on t. This means that in any graph with $ct^2/\log t$ vertices and no triangles, there is a subset of t vertices, no two of which are connected by an edge. **Thomas Brylawski**

Combining volumes, law of

The principle that when gases take part in chemical reactions the volumes of the reacting gases and those of the products, if gaseous, are in the ratio of small whole numbers, provided that all measurements are made at the same temperature and pressure. The law is illustrated by the following reactions:

1. One volume of chlorine and one volume of hydrogen combines to give two volumes of hydrogen chloride.
2. Two volumes of hydrogen and one volume of oxygen combine to give two volumes of steam.
3. One volume of ammonia and one volume of hydrogen chloride combine to give solid ammonium chloride.
4. One volume of oxygen when heated with solid carbon gives one volume of carbon dioxide.

It should be noted that the law applies to all reactions in which gases take part, even though solids or liquids are also reactants or products.

The law of combining volumes was put forward on the basis of experimental evidence, and was first explained by Avogadro's hypothesis that equal volumes of all gases and vapors under the same conditions of temperature and pressure contain identical numbers of molecules. *See* AVOGADRO'S NUMBER.

The law of combining volumes is similar to the other gas laws in that it is strictly true only for an ideal gas, though most gases obey it closely at room temperatures and atmospheric pressure. Under high pressures used in many large-scale industrial operations, such as the manufacture of ammonia from hydrogen and nitrogen, the law ceases to be even approximately true. *See* GAS. Thomas C. Waddington

Combustion

The burning of any substance, in gaseous, liquid, or solid form. In its broad definition, combustion includes fast exothermic chemical reactions, generally in the gas phase but not excluding the reaction of solid carbon with a gaseous oxidant. Flames represent combustion reactions that can propagate through space at subsonic velocity and are accompanied by the emission of light. The flame is the result of complex interactions of chemical and physical processes whose quantitative description must draw on a wide range of disciplines, such as chemistry, thermodynamics, fluid dynamics, and molecular physics. In the course of the chemical reaction, energy is released in the form of heat, and atoms and free radicals, all highly reactive intermediates of the combustion reactions, are generated. *See* FLAME; FREE RADICAL; REACTIVE INTERMEDIATES.

Processes. The physical processes involved in combustion are primarily transport processes: transport of mass and energy and, in systems with flow of the reactants, transport of momentum. The reactants in the chemical reaction are normally a fuel and an oxidant. In practical combustion systems the chemical reactions of the major chemical species, carbon and hydrogen in the fuel and oxygen in the air, are fast at the prevailing high temperatures (greater than 1200 K or 1700°F) because the reaction rates increase exponentially with temperature. In contrast, the rates of the transport processes exhibit much smaller dependence on temperature and are, therefore, lower than those of the chemical reactions. Thus, in most practical flames the rate of evolution of the main combustion products, carbon dioxide and water, and the accompanying heat release depends on the rates at which the reactants are mixed and heat is being transferred from the flame to the fresh fuel-oxidant mixture injected into the flame. However, this generalization cannot be extended to the production and destruction of minor species in the flame, including those of trace concentrations of air pollutants such as nitrogen oxides, polycyclic aromatic hydrocarbons, soot, carbon monoxide, and submicrometer-size inorganic particulate matter. *See* TRANSPORT PROCESSES.

Nitrogen oxides are formed by the capture of atmospheric nitrogen and the oxidation of organically bound nitrogen in fossil fuels in the flame. Both their oxidative formation, and their destruction in high-temperature fuel-rich flame zones are controlled by the chemistry of the interconversions of the nitrogen species in the flame. The oxidation reaction of the trace combustible species may slow down in the tail end of the flame because of the reduced temperature, or it may get quenched in the flow close to cooled walls of the combustion chamber. Hence, the emission of these trace species strongly depends on the rate of their oxidative destruction.

The fine inorganic particulate matter originates from the vaporization of a small fraction of fuel ash, mainly metals in coal and oil ash, and its subsequent condensation to form an aerosol as the combustion products cool down. The chemical transformation of the ash in the course of combustion (for example, the formation of suboxides of reduced melting temperature) has a strong influence on the aerosol formation and emission. *See* AEROSOL.

Types. When the fuel and oxidant are both gaseous, the combustion is called homogeneous. The combustion reactions will commence as the reactants are heated beyond a critical (ignition) temperature. Such a temperature is dependent on the types of the fuel and the oxidant and their mixture ratio, and also on the physical characteristics of the surroundings.

Liquid fuels are usually prepared for combustion by atomization; they are injected into the flame in the form of a spray of fine droplets. The drops vaporize, and the fuel vapor burns in a manner similar to a fuel gas. However, there are two phases present, liquid and gas, and the combustion is called heterogeneous. *See* ATOMIZATION.

The heavy residual fuel oils used in large industrial and utility boilers are not fully vaporizable, and a small fraction (about 10%) of the fuel oil burns in the form of small coke particles in the tail of the flame. Because of the higher carbon-to-hydrogen ratio of petroleum fuels compared to natural gas (the latter being mainly methane), oil flames, with higher concentrations of soot, tend to be more luminous than gas flames. The soot particles, although performing the useful function of increasing the radiating ability of the flame, ought to be completely burned within the combustion chamber to ensure a clean exhaust.

Solid fuels (coal, wood, and agricultural and municipal waste) are often burned on grates, with the fuel lying on the grate as a bed of solids and the air admitted through the openings in the grate. The grate can be stationary or moving, the feed being correspondingly periodic or continuous.

Coal, the most abundant fossil fuel, is burned predominantly in large industrial and utility boilers in pulverized form. After fine grinding, the pulverized coal is pneumatically transported by a fraction of the combustion air or an air–flue-gas mixture to the burner through which it is injected into the combustion chamber. Boiler combustion chambers equipped for burning pulverized coal are large so as to provide ample time for burning even the largest coal particles completely and for cooling the flyash particles below their softening temperature before they leave the combustion chamber. *See* COMBUSTION CHAMBER; FOSSIL FUEL.

Technology. In the early years of the development of modern combustion technology, after World War II, the objectives were to complete combustion in the smallest possible combustion space and with a minimum of air in excess of that which was stoichiometrically required. Environmental concerns changed this agenda, emphasizing the reduction of combustion-generated pollution. This includes emissions of the acid rain precursors, that is, nitrogen oxides and sulfur oxides, and air toxics such as polycyclic aromatic hydrocarbons, soot, and submicrometer-size inorganic particulates. Methods for reducing such emissions include fuel treatment (for example, desulfurization), combustion process modification, and postcombustion fuel-gas cleanup. Of these, the suitable modification of the combustion process is the most cost effective but also the most challenging. Notable examples of the achievements of this method are the significant reduction (up to 95%) of nitrogen oxide emissions from boilers and industrial furnaces obtained by the combination of staged admission of the fuel and the air into the combustion process, the use of flue-gas recirculation, and the use of very fuel lean premixed mixtures in industrial gas turbine combustors. In order to allay environmental concerns and to satisfy tight regulations, it is necessary to combine combustion modifications with fuel treatment and post-combustion cleanup to reduce pollutant emissions further. *See* ACID RAIN; AIR POLLUTION.

Applications. Combustion applications are wide ranging with respect to the fields in which they are used and to their thermal input, extending from a few watts for a candle to hundreds of megawatts for a utility boiler. Combustion is the major mode of fuel utilization in domestic and industrial heating, in production of steam for industrial processes and for electric power generation, in waste incineration, and in propulsion in internal combustion engines, gas turbines, or rocket engines.

Although the specific conditions of the individual applications impose different constraints on technologically acceptable solutions for the common goal of high thermal efficiency with minimal pollutant emission, basic studies of combustion science are a unifying source relevant to the development of clean combustion technologies in diverse fields of practical applications. János M. Beér

Combustion chamber

The space at the head end of an internal combustion engine cylinder where most of the combustion takes place. *See* COMBUSTION.

Spark-ignition engine. In the spark-ignition engine, combustion is initiated in the mixture of fuel and air by an electrical discharge. The resulting reaction moves radially across the combustion space as a zone of active burning, known as the flame front. The velocity of the flame increases nearly in proportion to engine speed so that the distance the engine shaft turns during the burning process is not seriously affected by changes in speed. *See* INTERNAL COMBUSTION ENGINE; SPARK PLUG.

For high efficiency the mixture should burn as quickly as possible while the piston is near top center position (constant-volume combustion). Short burning time is achieved by locating the spark plug in a central position to minimize the distance the flame front must travel. The chamber itself is made as compact as possible for the required volume, to keep the flame paths short (**Fig. 1**). A compact chamber presents less wall area to the enclosed volume, thereby reducing the heat loss from the flame front. Because motion of the flame depends upon transferring heat from the flame to the adjacent layers of unburned mixture, the reduced heat loss increases the flame velocity. One method for increasing flame velocity is to provide small-scale turbulence in the cylinder charge, often by designing the chamber so that part of the piston head comes close to the cylinder head at top center position (Fig. 1*a*). The squish that results forces the mixture in this region into the rest of the combustion chamber at high velocity. The turbulence so produced increases the rate of heat transfer from the flame to the unburned mixture, greatly increasing the flame velocity. Other engines may use high swirl in the intake port and combustion chamber or an auxiliary or precombustion chamber to accomplish the same result (Fig. 1*e*). When a prechamber is used, combustion begins in the richer mixture around the spark plug in the prechamber.

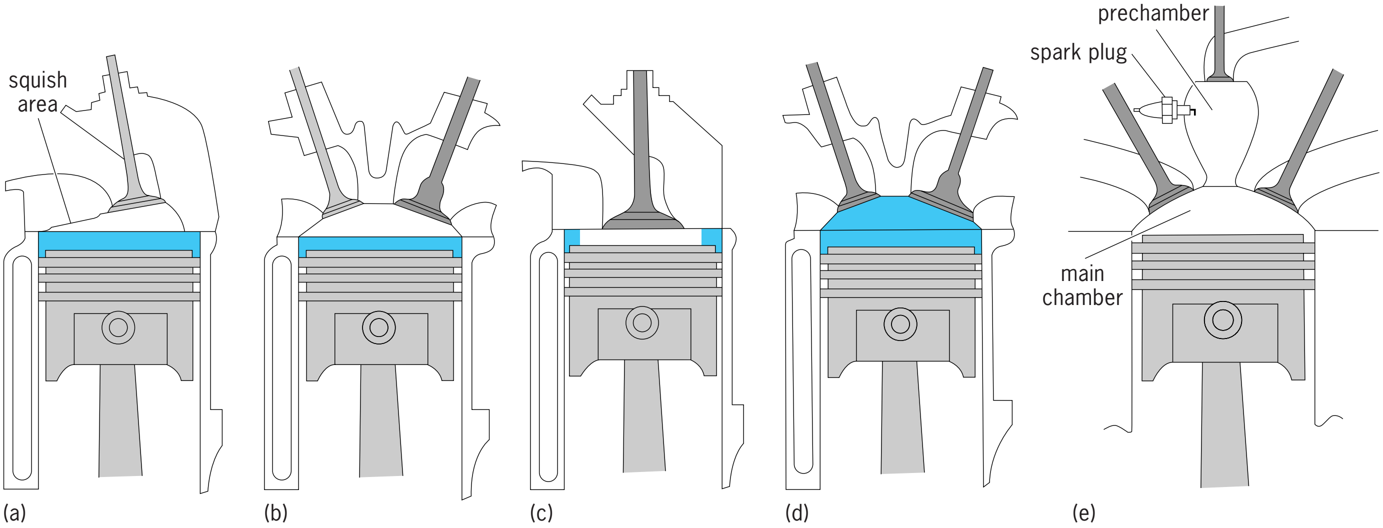

Fig. 1. Various combustion chambers used in spark-ignition engines. (*a*) Wedge. (*b*) Hemispheric (open). (*c*) Bowl-in-piston (cup). (*d*) Crescent (pent-roof). (*e*) Prechamber. (*Automotive and Technical Writing*, *Charlottesville*)

The burning mixture then enters the main chamber, which is filled with a leaner mixture, where combustion is completed. This process is known as stratified charge.

Occasionally a high burning rate, or too rapid change in burning rate, gives rise to unusual noise and vibration called engine roughness. Roughness may be reduced by using less squish or by shaping the combustion chamber to control the area of the flame front. A short burning time is helpful in eliminating knock because the last part of the charge is burned by the flame before it has time to ignite spontaneously. *See* SPARK KNOCK.

For high power output, the shape of the combustion chamber must permit the use of large valves with space around them for unrestricted gas flow. In many engine designs, three and four valves per cylinder are used to provide higher volumetric efficiency. *See* VALVE TRAIN.

Pockets or narrowed sections in the combustion chamber that trap thin layers of combustible mixture between adjacent surfaces interfere with combustion and increase the unburned fuel hydrocarbons normally present in the exhaust gases. Because unburned hydrocarbons are one of the constituents of smog-forming air pollution, the newer combustion chambers have less squish and less surface area per unit of volume. *See* AIR POLLUTION; SMOG.

Compression-ignition engine. In compression-ignition (diesel) engines, the fuel is injected late in the compression stroke into highly compressed air. Mixing must take place quickly, especially in smaller high-speed engines, if the fuel is to find oxygen and burn while the piston remains near top center. After a short delay, the injected fuel ignites from contact with the hot air in the cylinder. There is no flame front travel to limit the combustion rate. Injection may be into either an undivided combustion chamber (direct injection) or a divided combustion chamber (indirect injection) [**Fig. 2**].

During direct injection into an undivided chamber, mixing can be improved by producing a swirl in the intake air so that it is moving relative to the fuel spray (Fig. 2*a*). Swirl velocity increases with higher inlet velocities present at high engine speeds. Therefore, mixing becomes more rapid as the time available for mixing becomes less. Another type of undivided combustion chamber is formed by a narrow cavity in the piston head (Fig. 2*b*). For rapid

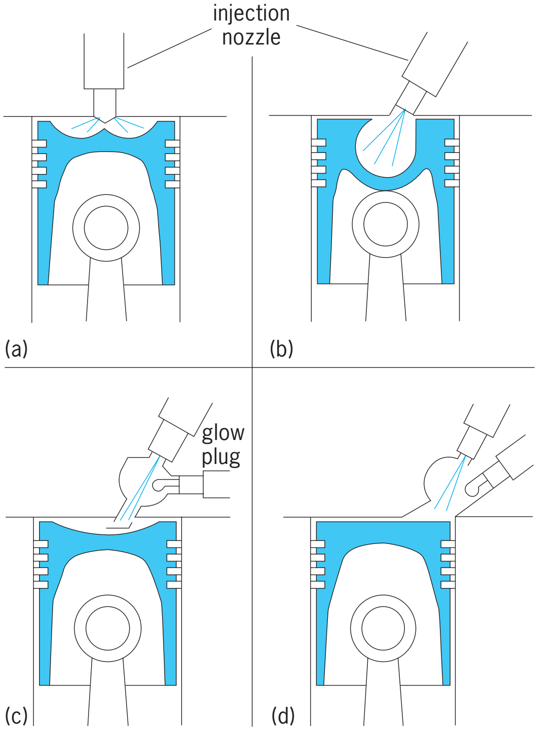

Fig. 2. Various combustion chambers used in compression-ignition (diesel) engines. (*a*) Direct injection. (*b*) MAN M system (German manufacturer). (*c*) Prechamber. (*d*) Swirl chamber. (*Robert Bosch Corp.*)

vaporization, the fuel is sprayed against the hot wall of the combustion chamber in the direction of the swirling air. Smooth combustion with relatively little exhaust smoke results.

Most high-speed diesel engines have indirect injection, in which the combustion chamber is divided into a main and a connected auxiliary chamber. Fuel is sprayed into the auxiliary chamber, where rapid mixing and combustion takes place (Fig. 2*c* and *d*). The burning mixture then issues into the main chamber, where any remaining fuel is burned.

If mixing of fuel and air is too thorough by the end of the delay period, high rates of pressure rise result, and the operation of the engine is rough and noisy. To avoid this condition, the auxiliary chamber in most compression-ignition engines operates at high temperature so that the fuel ignites soon after injection begins. This reduces the amount of fuel present and the degree of mixing at the time that ignition takes place.

High rates of pressure rise can also be reduced by keeping most of the fuel separated from the chamber air until the end of the delay period. Rapid mixing must then take place to ensure efficient burning of the fuel while the piston is near top center. *See* DIESEL ENGINE. Augustus R. Rogowski; Donald L. Anglin

Comet

One of the major types of objects that move in closed orbits around the Sun. Compared to the orbits of planets and asteroids, comet orbits are more eccentric and have a much greater range of inclinations to the ecliptic (the plane of the Earth's orbit). Physically, a comet is a small, solid body which is roughly 2 mi (3 km) in diameter, contains a high fraction of icy substances, and shows a complex morphology, often including the production of an extensive atmosphere and tail, as it approaches the Sun. *See* ASTEROID; PLANET.

About 10 reasonably bright comets are discovered or rediscovered each year. On the average, one per year is bright enough to be visible to the unaided eye and to generate much interest among the public as well as among comet workers.

Astronomers consider comets to be worthy of detailed study for several reasons: (1) They are intrinsically interesting, involving a large range of physical and chemical processes. (2) They are valuable tools for probing the solar wind. (3) They are considered to be remnants of the solar system's original material and, hence, prime objects to be studied for clues about the nature of the solar system in the distant past. (4) Comets may be required to explain other solar system phenomena.

Present knowledge of comets is heavily influenced by the Halley's Comet campaign in 1986, which included images of the nucleus obtained by spacecraft sent to intercept the comet, and by the extensive studies of the very large Comet Hale-Bopp in 1997. While the data obtained from these comets are invaluable, comets are believed to be highly individualistic. *See* HALLEY'S COMET.

Fig. 1. Comet West as photographed on March 9, 1976, showing the general appearance of a bright comet. The fan-shaped structure emanating from the head or coma is the dust tail, while the single straight structure is the plasma tail. The tails are some 30° in length. (*S. M. Larson*, *Lunar and Planetary Laboratory*, *University of Arizona*)

Appearance. As seen from Earth, comets are nebulous in appearance, and the tail is usually the most visually striking feature. This tail can in some cases stretch along a substantial arc in the sky (**Fig. 1**). Some fainter comets, however, have little or no tail.

The coma or head of a comet is seen as the ball of light from which the tail or tails emanate. Within the coma is the nucleus, the origin of the material in the tail and coma.

Discovery and designation. Comets are discovered by both amateur and professional astronomers. The fainter ones are often discovered by professionals on wide-field images taken for other purposes. In particular, searches for near-Earth objects and other asteroids have dramatically increased the discovery rate of fainter comets. Comets are also being discovered by space-borne solar coronagraphs. Amateurs usually carry out systematic searches of the sky using wide-field binoculars or telescopes. Discoveries are communicated to the Bureau for Astronomical Telegrams, Smithsonian Astrophysical Observatory, Cambridge, Massachusetts, and are then announced by the International Astronomical Union.

In the system for comet designations in use since January 1, 1995, objects are recorded by a letter for the half-month in which they are found; note that the letters I and Z are not used. Thus, the second comet discovered during the second half of February 1995 would be designated C/1995 D2; the C (for comet) is replaced by P if the comet is periodic. The naming of comets carries on the tradition of naming them for their discoverers while striving for fairness and simplicity. For example, Comet C/1995 O1 (Hale-Bopp) was independently discovered by A. Hale and T. Bopp on July 23, 1995, and was the first comet discovered in that half-month period. Comets discovered prior to 1995 retain their old system designation, where the comets in a given year were assigned a letter in order of their discovery. The letter was later replaced by a roman numeral indicating order of perihelion passage. Halley's Comet at its last appearance was first called Comet 1982i, and later became Comet 1986III. Halley's Comet also illustrates the exceptional case of a comet being named after the person who computed its orbit.

Oort Cloud and comet evolution. A major step in understanding the origin of comets was taken in 1950 by J. Oort. He developed the idea that comets are in effect "stored" in a Sun-centered spherical cloud of radius approximately 50,000 AU from the Sun (1 AU is the distance from the Sun to the Earth, 9.3×10^7 mi or 1.50×10^8 km). Occasionally, gravitational perturbations by passing stars or clouds of interstellar gas send comets into the inner solar system, where they are discovered and their phenomena are observed. This process, of course, leads to the eventual destruction of the comet, because passages near the Sun cause a loss of material which is not recovered by the comet. Very rough estimates indicate that a comet loses 0.1% to 1% of its mass at each perihelion passage. Thus, a comet with radius of 0.6 mi (1 km) would lose a layer approximately in the range 1–10 ft (0.3–3 m) thick on each passage. The origin and evolution of comets are discussed in more detail below.

The current view considers the Oort Cloud as a steady-state reservoir which loses comets as just described and gains them from an inner cloud of comets located between the orbit of Neptune and the traditional Oort Cloud. Some comets can enter the inner solar system directly from the innermost part of the inner cloud, called the Kuiper Belt, discussed below. These discoveries mark a trend to expand the study of comets to bodies both larger and smaller than the traditional range. Ideas that periodic comet showers could result from a tenth planet in the inner cloud or a faint solar companion, called Nemesis, are novel but not generally accepted.

Observations. Observations of comets run the gamut of modern observing techniques. These include images in visual and ultraviolet wavelengths, photometry (accurate brightness measurements) in visual and infrared wavelengths, spectral scans in many wavelength regions, radio observations, and observations in extreme ultraviolet wavelengths and x-rays from rockets and orbiting spacecraft above the Earth's atmosphere. Visual wavelength spectra of comets show considerable variation. Ultraviolet spectra, obtained regularly with the *International Ultraviolet Explorer* satellite during its lifetime, have been found to be rather similar. Observations of meteors also contribute to the understanding of comets. *See* ASTRONOMICAL SPECTROSCOPY.

Measurements. The advent of space missions to comets has added an entirely new dimension to obtaining cometary information. A wide variety of direct measurement techniques have already been applied. Mass spectrometers have determined the properties of neutral gases, plasmas, and dust particles (via impact ionization). Dust counters have recorded the fluxes of dust and determined the mass distribution. Magnetometers have measured the strength and orientation of the magnetic field. Further plasma properties have been determined by plasma wave detectors. In addition, detailed imaging of the nucleus was made possible by the space missions. *See* HALLEY'S COMET.

Near-Sun and near-Earth comets. Most comets are observed under so-called normal circumstances; that is, the comet is between 0.5 and 1.5 AU from the Sun and a few tenths of an AU from Earth. Two specific exceptions are discussed here.

While comets have been observed at distances from the Sun of less than 0.1 AU for decades, only in 1979 was it learned that comets occasionally impact the Sun (**Fig. 2**). This fact was determined from a satellite (*SOLRAD*) used to monitor the Sun's corona; hence, the cometary discovery was not planned. The instrument carries an occulting disk which blocks out the bright glare of the Sun's surface, producing

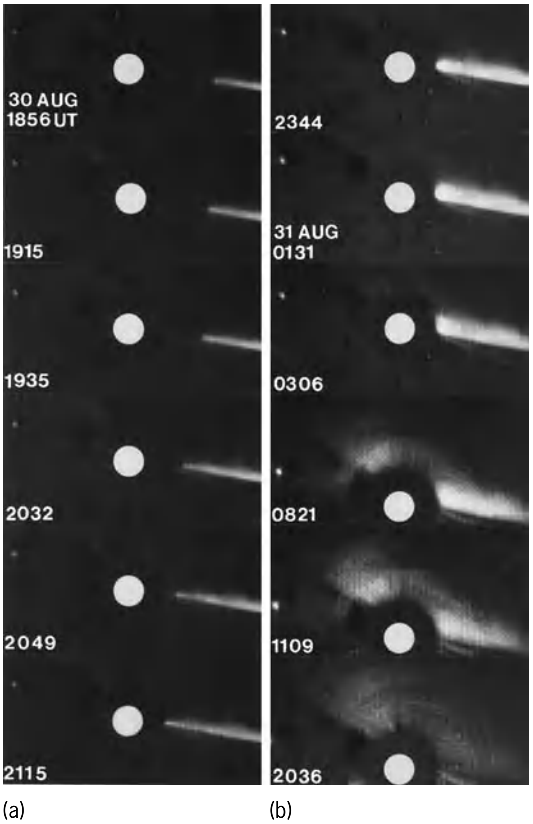

Fig. 2. Sequence of photographs obtained from a *SOLRAD* satellite showing Comet Howard-Koomen-Michels hitting the Sun in August 1979. Captions give date and universal time (Greenwich mean time) of each photograph. (*a*) Before impact. (*b*) After impact. (*Naval Research Laboratory*, *Washington*, *DC*)

a dark circle with an apparent diameter of 5 solar radii. Comet Howard-Koomen-Michels hit the Sun on August 30, 1979; the estimated time of impact was 22^h29^m Greenwich mean time. The comet was clearly photographed (Fig. 2) approaching the Sun, but its reappearance, which would have produced a cometary image on the *SOLRAD* photographs, did not occur. Instead, a brightening of a major portion of the corona was observed which then slowly faded away. The brightening was presumably caused by cometary debris ultimately blown away by the Sun's radiation pressure following the disintegration of the nucleus.

Analysis of the data from this solar monitoring satellite and from other satellites, such as the *Solar Maximum Mission* (*SMM*) and the *Solar and Heliospheric Observatory* (*SOHO*), has turned up many more cometary impacts with the Sun. These results imply that solar impacts by relatively small comets are quite frequent. Observations by *SOHO* led to discovery of many comets and are providing a database for studying cometary phenomena near the Sun.

Comets very near the Earth are rare, but provide unique opportunities for new discoveries. Comet IRAS-Araki-Alcock was another example of a comet being first discovered by a satellite, in this case the *Infrared Astronomical Satellite* (*IRAS*), which also discovered additional comets. This comet passed within 0.031 AU of Earth on May 11, 1983. This distance was only about 12 times the average distance from the Earth to the Moon. Comet Hyakutake passed relatively close to Earth in late March and early April of 1996, thus providing spectacular naked-eye views.

The small distance to Comet IRAS-Araki-Alcock also provided a perfect opportunity to bounce radar waves off the nucleus. The experiment was successful, and the echoes provided evidence for the existence of a solid cometary nucleus with diameter of 0.6 mi (1 km).

The discovery of small comets hitting the Sun and the comets discovered by *IRAS* (including Comet IRAS-Araki-Alcock) imply that small comets are more numerous than had been generally believed. As the details for the origin of comets are worked out, it will be necessary to account for this fact. There has been increasing interest in small comets or comet-like objects, and the number of these objects in the inner solar system may be much larger than previously thought. In the past, the total population of comets might have been an important source of atmospheres for the terrestrial planets as well as a possible source of moderately complex organic molecules necessary for the initial development of life on Earth.

The proposal that the Earth is constantly being bombarded by very large numbers of house-size, icy objects has received considerable public attention. These objects have been called comets, but they are not comets because they do not sublimate. Their origin is unclear, and if they existed, they would have to have extraordinary properties. In sum, their existence is highly unlikely.

Kuiper Belt objects. Observations since 1992 have revealed a major population of large comets in a vast region beyond the orbit of Neptune. This discovery was anticipated about 1950 when K. E. Edgeworth and Gerard Kuiper, working independently, noted that the distribution of mass in the solar system dropped precipitously beyond the orbit of Neptune. They postulated that the missing mass was in a ring of undiscovered bodies in the trans-Neptunian region. These are commonly called Kuiper Belt objects.

Many of these objects, which continue to be discovered, are not small by cometary standards, and they are numerous. Credible estimates place roughly 100,000 objects with diameters larger than 60 mi (100 km) in a ring extending from 30 to 50 AU. Clearly, this is a major, largely unexplored population of cometary objects in this region. *See* KUIPER BELT.

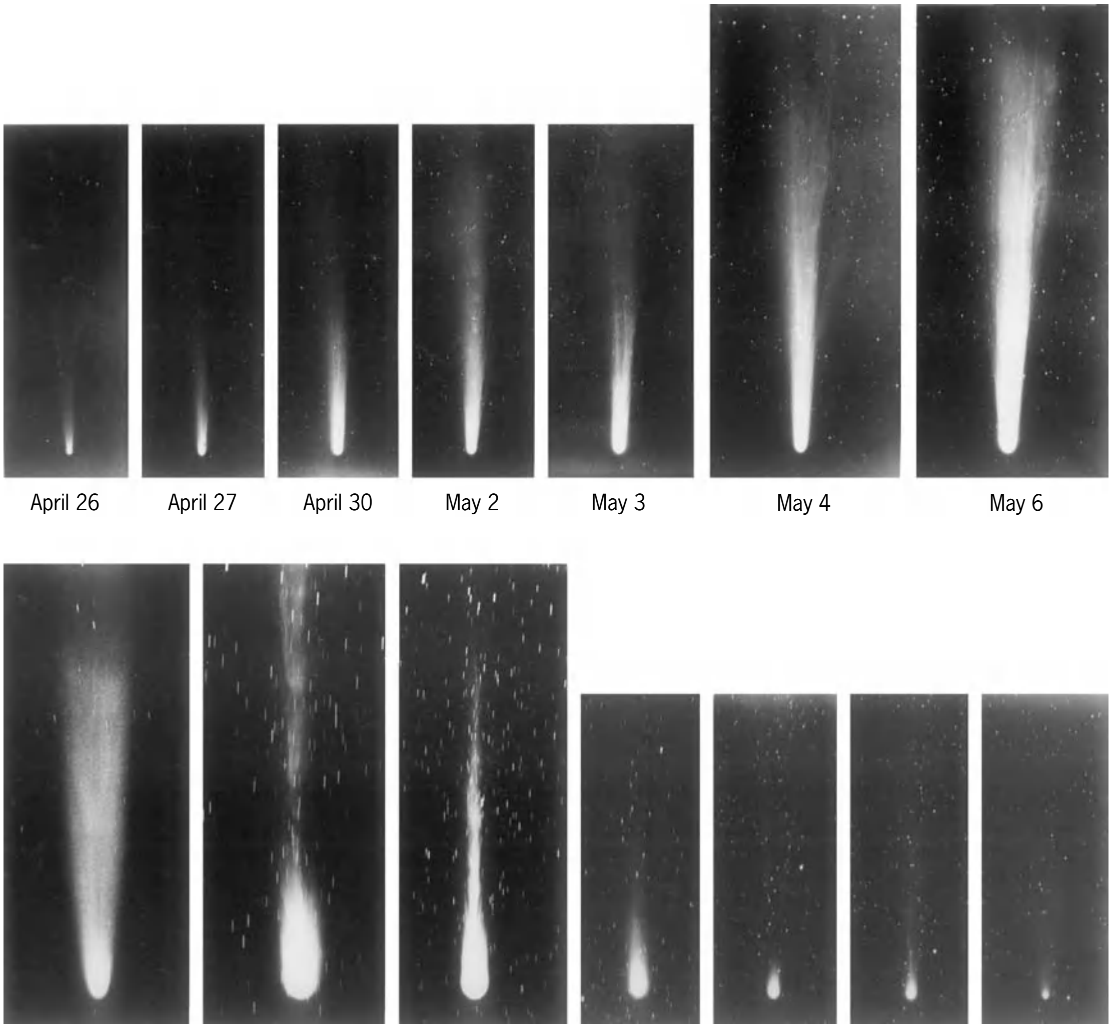
Orbits. The first closed comet orbit to be calculated was Edmond Halley's elliptical orbit for the comet of 1680. This work indicated that comet orbits were ellipses with the Sun at one focus. In subsequent work, Halley noticed the striking similarity of the orbits of what were thought to be three different comets observed in 1531, 1607, and 1682. In 1705 he concluded that these were the same comet with a period of 75 or 76 years, and predicted its return in 1758. This comet is the one bearing Halley's name. It made an appearance in 1910 (**Fig. 3**), and again in 1985 and 1986.

The second comet to have its return successfully predicted was named after J. F. Encke. This comet has the shortest known period, 3.3 years. At its 1838 return, Encke's Comet showed another common property of comets, that is, a steadily changing period. This phenomenon is now known to result from the so-called nongravitational forces which must be explained by any successful comet model.

Six parameters are necessary to describe completely the orbit of a comet. They specify the orientation of the orbital plane in space, the orientation of the orbit in this plane, the size and shape of the ellipse, and the position of the comet along the orbit. In principle, three observations of position on the celestial sphere are sufficient, because each observation consists of independent measures of two coordinates. In practice, definitive orbits are derived from many observations, often hundreds.

While comet orbits are represented by ellipses to a good approximation, there are departures caused by the nongravitational forces and by the gravitational perturbations of the planets. When orbital parameters are listed for a comet, they refer to an ellipse which exactly matches the comet's position and motion at a specific time. Such an osculating orbit, as it is called, forms the starting point for studies of orbital evolution and for accurate predictions of the time and location of a comet's appearance in the sky. *See* CELESTIAL MECHANICS.

Currently, orbital parameters have been determined for roughly 1000 individual comets. Most are classified as long-period comets, that is, comets with



April 26 April 27 April 30 May 2 May 3 May 4 May 6

May 15 May 23 May 28 June 3 June 6 June 6 June 11

Fig. 3. Sequence of photographs showing the changing appearance of Halley's Comet in 1910. (*Carnegie Observatories*)

orbital periods greater than 200 years. The orbital planes of the long-period comets have approximately random inclinations with respect to the ecliptic. This means that there are as many comets with direct orbits (revolving around the Sun in the same sense as the planets) as with retrograde orbits (revolving in the sense opposed to the planets' motion). Careful examination of the original (that is, inbound) orbits of the long-period comets shows none that are hyperbolas; that is, no interstellar comets have yet been observed. This fact strongly implies that the cloud of comets is gravitationally bound to the Sun and therefore is a part of the solar system.

The short-period comets are mostly in direct orbits with inclinations of less than 30°. The distribution of periods shows a peak between 7 and 8 years, and the majority have an aphelion (point of greatest distance from the Sun) near the orbit of Jupiter.

Composition. The many spectroscopic studies and direct spacecraft measurements on the composition of comets have observed numerous species of atoms, molecules, and ions (see **table**). Fairly complex molecules such as polymerized formaldehyde [$(H_2CO)_n$] and methyl cyanide (CH_3CN) are present.

Observations of the gas composition in Halley's coma have found these values by number of molecules: water, approximately 80%; carbon monoxide, roughly 10%; carbon dioxide, approximately 3.5%; complex organic compounds such as polymerized formaldehyde, a few percent; and trace substances, the remainder. These values were obtained from direct measurements, except for that of carbon monoxide, which was determined from a rocket

Atomic and molecular species observed in comets*

experiment. These values are for the outer layers of a comet which has passed through the inner solar system many times. The values of a new comet or the interior of Halley may be different with a higher fraction of carbon dioxide likely.

Measurements of dust composition were made by instruments on the spacecraft sent to Halley's Comet. Some of the particles contain essentially only the atoms hydrogen, carbon, nitrogen, and oxygen; these are the "CHON" particles. Other particles have a silicate composition, that is, they resemble rocks found throughout the solar system. The dominant dust composition is a mixture of these two and resembles carbonaceous chondrites enriched in the light elements hydrogen, carbon, nitrogen, and oxygen.

Structure. The main components of a comet are the nucleus, coma, hydrogen cloud, and tails (**Fig. 4**).

Nucleus. Strong evidence points to the existence of a central nuclear body or nucleus for all comets from which all cometary material, both gas and dust, originates. In the early 1950s, F. L. Whipple proposed an icy conglomerate model of the nucleus. In this model, the nucleus is not a cloud of particles as had previously been thought (the "sandbank" model), but a single mass of ice with embedded dust particles, commonly called a dirty snowball. Such a nucleus could supply an adequate amount of gas to explain cometary phenomena and last through many apparitions because only a relatively thin surface layer would be eroded away (by sublimation) during each passage near the Sun.

The nucleus of Halley's Comet has been directly observed. Its shape was highly irregular, the surface exhibited features and structure, and the albedo (fraction of reflected light) was very low. While the confirmation of the existence of a single, nuclear body is important, Halley is just one comet and generalizations from it may not be valid. *See* ALBEDO.

Fortunately, images of three more nuclei have been obtained. The image of the nucleus of Comet Borelly was taken by the *Deep Space 1* spacecraft on September 22, 2001. The close-up view of the nucleus (**Fig. 5***a*) shows considerable detail and an irregular shape about 5 mi (8 km) long. The image shows smooth terrain around the central part of the nucleus, which is also the part of the nucleus with active jets. The remainder of the terrain is generally inactive and has features identified as pits, troughs, and ridges. The albedo over the surface varies from 0.01 to 0.03; in other words, the surface is very dark.

The image of the nucleus of Comet Wild 2 was taken by the *Stardust* spacecraft on January 2, 2004. The close-up view of the nucleus (Fig. 5*b*) shows detail including an apparent impact crater, and a rounded body with a typical dimension of 2.5 mi (4 km). The albedo is 0.03±0.015; that is, it is also very dark. The surface has high-angle slopes which indicate that the body is cohesive and self-supporting. The images of Comet Wild 2 serve to emphasize the differences with Comets Halley and Borrelly. The diversity of comets is clearly very important.

The generic nuclear body (**Fig. 6**) is irregular, with radius ranging from around 1000 ft (300 m) to 12 mi (20 km). Masses would range in order of magnitude from 10^{11} to 10^{16} kg (10^{11} to 10^{16} lb), with roughly equal parts of snow and dust. The average density would be in the range 0.2 to 2 g/cm^3 (0.2 to 2 times that of water). The interior is probably porous, which means that there are significant voids along with the regions of solid material. Nuclei of comets sometimes split into two or more pieces; Comet West (1976 VI) is an example.

Coma. The coma is observed as an essentially spherical cloud of gas and dust surrounding the nucleus. The principal gaseous constituents are neutral molecules (see table), and the dust composition has

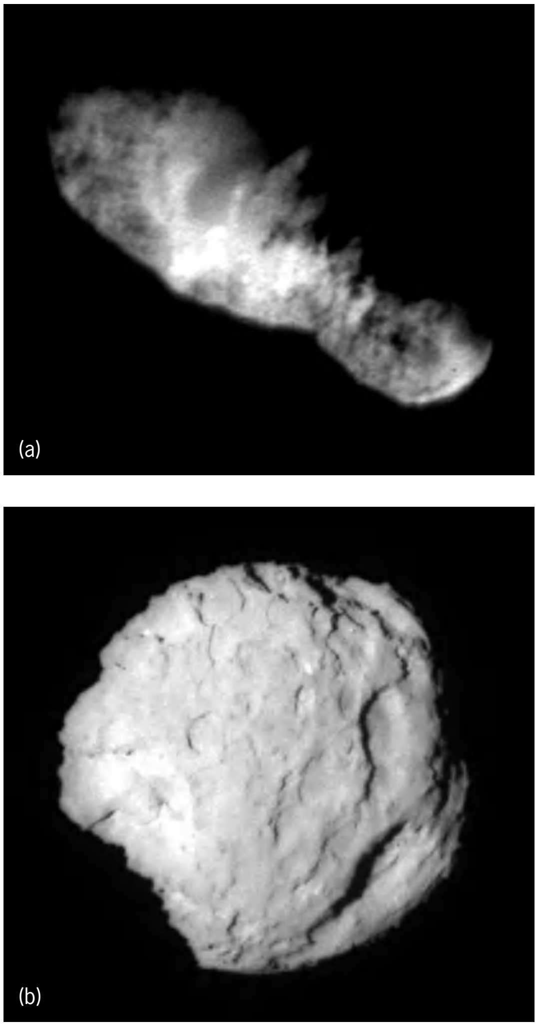

Fig. 5. Images of comet nuclei. (*a*) Close-up image of Comet Borrelly's nucleus taken on September 22, 2001, by the *Deep Space 1* spacecraft (*NASA/JPL*). (*b*) Image of Comet Wild 2's nucleus taken on January 2, 2004, just after closest approach by the *Stardust* spacecraft (*NASA; Stardust mission team*).

been described above. The coma can extend as far as 10^5 to 10^6 km (10^5 to 10^6 mi) from the nucleus, and the material is flowing away from the nucleus at a typical speed of 0.6 mi/s (1.0 km/s). As the gas flows away from the nucleus, the dust particles are dragged along. For comets at heliocentric distances greater than 2.5 to 3 AU, the coma is not normally visible and is presumed not to be present. An exception is Halley's Comet, which displayed an outburst and comalike activity at 14.4 AU.

Hydrogen cloud. In 1970, observations of Comet Tago-Sato-Kosaka and Comet Bennett from orbiting spacecraft showed that these comets were surrounded by a giant hydrogen cloud that extends to distances on the order of 10^7 km (10^7 mi), or a size larger than the Sun. The observations were made in the resonance line of atomic hydrogen at 121.6 nm. Hydrogen clouds have since been observed for many other comets. Fairly bright comets (such as Bennett) have a hydrogen production rate by sublimation from the nucleus at heliocentric distance of 1 AU in the range 3 to 8×10^{29} atoms/s. The size of the hydrogen cloud depends on the velocity of the outflowing hydrogen atoms, and 5 mi/s (8 km/s) has been derived. This velocity would arise (from energy balance considerations) if most of the hydrogen in the cloud were produced by the photodissociation of the hydroxyl radical (OH).

Tails. Photographs of bright comets generally show two distinct types of tails (Fig. 1): the dust tails and the plasma tails. They can exist separately or together in the same comet. In a color photograph, the dust tails appear yellow because the light is reflected sunlight, and the plasma tails appear blue from emission due to ionized carbon monoxide, CO^+.

Studies of features in plasma tails led L. Biermann in 1951 to postulate the existence of a continuous outflow of ionized material from the Sun, which he called the solar corpuscular radiation, now called the solar wind. The interaction of the solar wind and its magnetic field, as suggested by H. Alfvén in 1957, plays an important role in cometary physics and in the formation of plasma tails. The direct measurements on the sunward side by the spacecraft sent to Halley's Comet, on the tailward side by the *International Cometary Explorer* mission to Comet Giacobini-Zinner in 1985, by the *Giotto* spacecraft passing Comet Grigg-Skjellerup in 1992, and by the *Deep Space 1* spacecraft passing Comet Borrelly in 2001 have confirmed these views. *See* SOLAR WIND.

The plasma tails are generally straight and have lengths that range in order of magnitude from 10^7 to 10^8 km (10^7 to 10^8 mi). The Great Comet of 1843 had a plasma tail extending over 2 AU in length. The plasma in these tails is composed of electrons and molecular ions (see table). The dominant visible ion is CO^+. The zone of production for the molecular plasma appears to be in the coma near the sunward side of the nucleus. The material in the plasma tails is concentrated into thin bundles or streamers, and additional structure is found in the tail in the form of knots and kinks. These features appear to move along the tail away from the head at speeds of 6 mi/s (10 km/s) to 120 mi/s (200 km/s). Plasma tails are generally not observed beyond heliocentric distances of 1.5 to 2 AU; an exception is Comet Humason, which showed a spectacular, disturbed plasma tail well beyond normal distances.

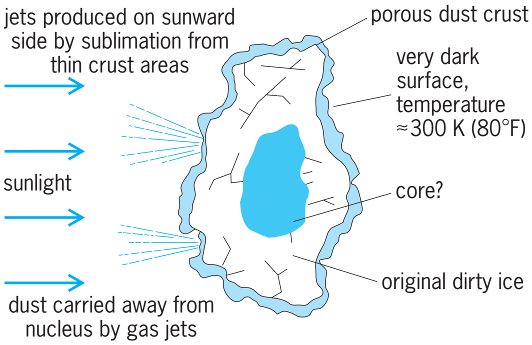

Fig. 6. Schematic model of the cometary nucleus.

The dust tails are usually curved and have lengths that range in order of magnitude from 10^6 to 10^7 km (10^6 to 10^7 mi). Normally, the dust tails are relatively homogeneous; an exception, Comet West, is shown in Fig. 1. Observations indicate that the dust particles are typically 1 micrometer in diameter and are probably silicate in composition. Occasionally dust tails are seen which appear to point in the sunward direction, the so-called antitails. Examples are Comet Arend-Roland in 1957 and Halley's Comet in 1986. These are not truly sunward appendages but are the result of projection effects.

Observations of the bright comet Hale-Bopp have revealed gas tails in the element sodium. One of these is long and narrow (Fig. 4). The other is a diffuse sodium gas tail superimposed on the dust tail. The sodium tails are probably present in all comets but were made more easily visible by Comet Hale-Bopp's large size.

Modern theory. The goal of modern comet theory is to explain the facts about comets outlined above. The broad, theoretical approach appears to be in reasonably good shape and has survived the tests of direct exploration by spacecraft (**Fig. 7**).

Sublimation from nucleus. The cornerstone of the current best ideas is F. L. Whipple's icy conglomerate model of the nucleus. As a comet approaches the Sun on its orbit, sunlight supplies radiant energy to the surface of the nucleus. The energy received heats the nucleus when it is far from the Sun. As the comet

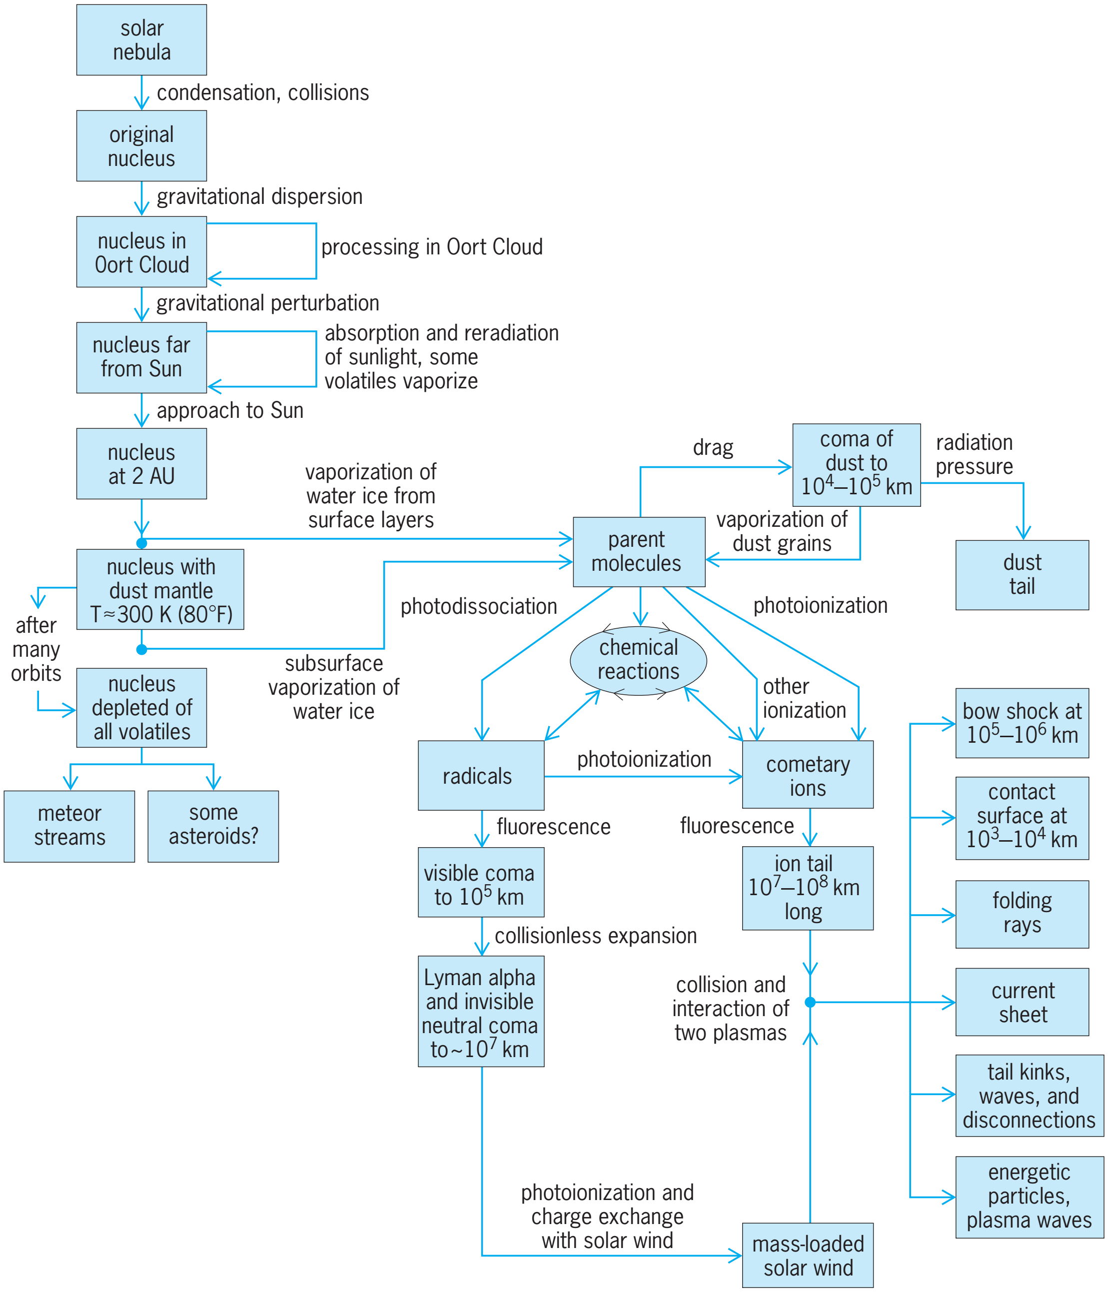

Fig. 7. Summary of processes involved in the formation of comets and the interaction with sunlight and the solar wind. 1 km = 0.6 mi.

continues toward the Sun, the temperature of the surface layers increases to a value, determined by the thermodynamic properties of the ice, where sublimation (passage from the solid state directly to the gaseous state) occurs. Then, most of the incident energy goes to the sublimation of ices. The situation has at least one additional complexity. Sublimation of ice from a dust–ice mixture probably leaves a dust crust which is heated to temperatures higher than the sublimation temperature of water ice. The heat is conducted inward to the ice layers, and the sublimated gases then pass outward through the dust crust. The jets of material seen on Halley's Comet originate in areas of minimal dust crust.

The onset of activity in comets at 2.5 to 3 AU is entirely consistent with water ice as the dominant ice constituent of the nucleus. But a problem still exists. Most other possible constituents are predicted from theory to begin sublimation much farther from the Sun than water ice, but, for example, molecular emissions from CN are visible essentially at the onset of activity.

The solution to this problem lies in the dominant form of water ice found in comets, amorphous ice. Models for the formation of comets treat the process as occurring under low-temperature and low-pressure conditions. When ices form under these conditions, energy is not available to convert the amorphous ice to crystalline ice (a minimum energy state). The transition to crystalline ice takes place at temperatures much higher than the formation temperature. Also, minor constituents are trapped in the amorphous ice. They are partially released when the amorphous ice crystallizes, and the rest is released when the ice sublimates. Some minor constituents may not be trapped in the amorphous ice, and these could be vaporized and released from comets beyond 3 AU, particularly on a comet's first approach to the Sun.

Origin of nongravitational forces. The nongravitational forces have a ready explanation if the cometary nucleus is rotating. The result of radiant energy producing sublimation of ices in an ice-dust mixture is to leave a crust of dusty material. Thus, there is a time lag while the heat traverses the dust layer between maximum solar energy received and maximum loss through sublimation. If the nucleus were not rotating, the maximum mass loss would be directly toward the Sun. For a rotating nucleus, the mass loss occurs away from the sunward direction, toward the afternoon side of the comet. The analogous situation on Earth (that is, the time lag between cause and effect) produces the warmest time of day in the afternoon, not at noon. The mass loss under these circumstances produces a force on the nucleus via the rocket effect (reaction force), and this force can accelerate or retard the motion of the comet in its orbit. Detailed studies of the nongravitational forces in comets show that they are entirely consistent with water ice as the controlling substance.

A possible alternative origin of nongravitational forces is still based on water as the controlling substance. For some comets, simply having a larger mass loss before perihelion compared to after perihelion would produce the nongravitational effects.

Formation of coma. The sublimated gases, mostly neutral molecules, flow away from the nucleus, dragging some of the dust particles with them to form the coma. Close to the nucleus, the densities are high enough that chemical reactions can occur between molecular species. Photodissociation is also important. Thus, the molecules observed spectroscopically far from the nucleus often are not the same as the initial composition.

Formation of dust tails. The dust particles carried away from the nucleus by the flow of coma gases are blown in the antisolar direction by the Sun's radiation pressure to form the dust tails. The detailed theory has been developed through the years, and good agreement can usually be obtained with the observed shapes and sizes of the tails if the emission of dust from the nucleus has a peak before perihelion. The larger particles liberated from the nucleus can orbit the Sun and reflect sunlight to produce the zodiacal light. *See* ZODIACAL LIGHT.

Formation of plasma tails. The gas flowing away from the nucleus has a more involved fate. Under normal circumstances, when a comet's heliocentric distance is about 1.5 to 2 AU or less, significant ionization of the coma molecules occurs (probably by solar radiation), and this triggers a reaction with the solar wind. At the Earth, the solar wind, a fully ionized proton-electron gas, flows away from the Sun at 250–310 mi/s (400–500 km/s) and has an embedded magnetic field. Because of the magnetic field, the ionized cometary molecules cause the solar-wind field lines to slow down in the vicinity of the comet while proceeding at the full solar-wind speed away from the comet. This situation causes the field lines and the trapped plasma to wrap around the nucleus like a folding umbrella, to form the plasma tail. This picture has been completely confirmed by the spacecraft measurements. In addition, the folding can be seen and photographed because of the emission from the trapped ions (such as CO^+) which serve as tracers of the field lines (**Fig. 8**). Thus, while the ionized molecules are indeed swept in the antisolar direction by the solar wind, the plasma tail should be thought of as a part of the comet attached to the near-nuclear region by the magnetic field captured from the solar wind.

Exceptions occur at times apparently when the polarity of the solar-wind magnetic field changes. In terms of solar-wind structure, this polarity reversal takes place when the comet crosses the heliospheric current sheet (HCS). This can disrupt the magnetic connection to the near-nuclear region and literally causes the old plasma tail to disconnect while the new tail is forming. This process is quite common (**Fig. 9**). While the physics of this phenomenon is complex, the observational and theoretical basis is sound.

Fate of comets. When the process of sublimation has been carried out over an extensive period of time, as would be the case for the short-period comets, the ices will be exhausted and the inactive or "dead"

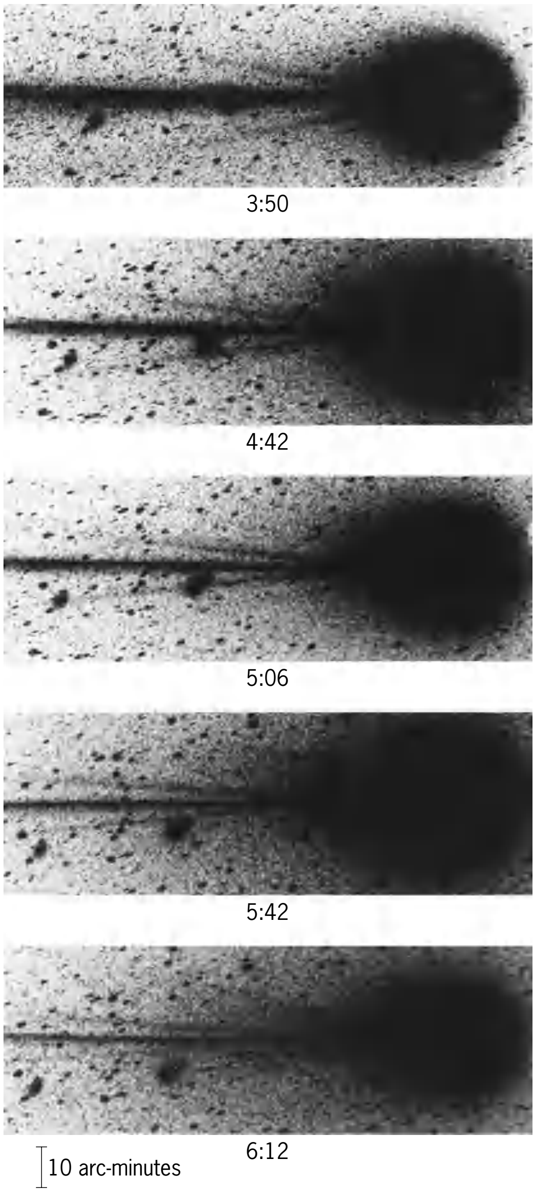

Fig. 8. Sequence of photographs of Comet Kobayashi-Berger-Milon on July 31, 1975, showing the capture of magnetic field from the solar wind. The dominant pair of tail streamers visible on either side of the main tail lengthen and turn toward the tail axis in this sequence. (*Joint Observatory for Cometary Research*, operated by *NASA–Goddard Space Flight Center and New Mexico Institute of Mining and Technology*)

comet should consist of dust particles and larger-sized rocky material. These remnants are dispersed along the comet's orbit by perturbations, and are the particles responsible for producing meteors when they enter the Earth's atmosphere. Small particles, very probably of cometary origin, have been collected by high-flying aircraft. *See* METEOR.

Comet Shoemaker-Levy 9 and Jupiter. Images of Comet Shoemaker-Levy from the Hubble Space Telescope in 1993 and early 1994 show a string of many bright points (**Fig. 10*a***). The comet then consisted of pieces from a larger body torn apart by a close encounter with Jupiter in 1992. This comet's life ended with a spectacular collision with Jupiter over a period of a few days around July 22, 1994 (Fig. 10*b*). These events dramatically illustrate disruption and collisions with other solar system bodies as fates for cometary bodies. *See* JUPITER.

Comet Hyakutake. In late March 1996, Comet Hyakutake came within about 0.1 AU of Earth, providing spectacular views. On the evening of March 25, the plasma tail stretched from near Polaris well to the south. A length of 55° was easily observed, and experienced observers in dark sites reported lengths of 100°, that is, the tail extended more than halfway across the sky.

The comet was very low in dust content, and the plasma was conspicuous. On March 24–25, a superb disconnection event took place (Fig. 9); the disconnected part of the tail could be traced to a distance of at least 35° from the head. The disconnection event and the disturbed appearance of the plasma tail are characteristic of a comet in the stormy equatorial region of the solar wind. The appearance of Comet Hyakutake contrasted with that of Comet Hale-Bopp (**Fig. 11**).

A major unexpected discovery was that Comet Hyakutake is a bright and variable source of x-rays. Searches of databases of satellites observing in x-rays subsequently showed that x-ray emission is a common property of comets. The x-rays are produced when a highly ionized species in the solar wind (such as oxygen ionized six times) exchanges charge (an electron) with neutral molecules in the coma. The

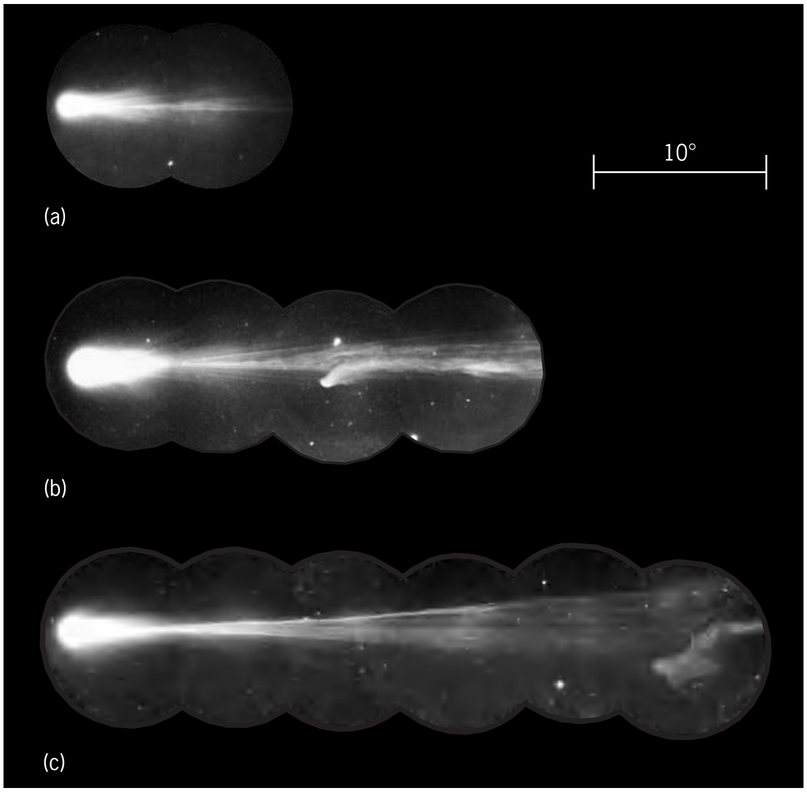

Fig. 9. Photographs of Comet Hyakutake (C/1996 B2) taken on three successive days in March 1996 by Shigemi Numazawa of Niigata, Japan. A spectacular disconnection event is clearly shown, and a new plasma tail immediately forms. (*a*) March 24. (*b*) March 25. (*c*) March 26. (*Courtesy of Sky and Telescope*)

Fig. 10. Comet Shoemaker-Levy 9. (*a*) Mosaic of three *Hubble Space Telescope* images taken in January 1994. Twenty comet fragments are visible (*H. A. Weaver and T. E. Smith, Space Telescope Science Institute, NASA*). (*b*) Sequence of *Hubble Space Telescope* images of Jupiter showing evolution of impact site of fragment "G," the largest fragment of the comet. From lower left to upper right, the images show the impact plume visible just off the limb about 5 minutes after impact on July 18, 1994; the fresh impact site about 1.5 hours after the impact; the evolved "G" impact site and other impact sites on July 21; and the view on July 23 (*R. Evans, J. Trauger, H. Hammel, HST Comet Science Team, NASA*)

result is a species with reduced ionization (in the previous example, oxygen ionized five times) but in an excited state. These ions spontaneously emit photons in the x-ray wavelength range.

Comet Hale-Bopp. Comet Hale-Bopp provided spectacular views in March and April 1997. Because of the observing circumstances, the comet was often both an evening and a morning object. Its intrinsic brightness can be appreciated by the fact that the comet was never closer to the Earth than 1 AU. Comet Hale-Bopp is clearly the largest comet studied with modern technology, even though no spacecraft was sent to the comet. An extensive body of data was gathered.

Because of the comet's great intrinsic brightness, a large nucleus was suspected. The brightness profile obtained from Hubble Space Telescope images showed a sharp peak that could be identified with light from the nucleus itself. A diameter of about 25 mi (40 km) was inferred. This is a very large nucleus, with roughly 65 times the volume of Comet Halley's nucleus.

Fig. 11. Photograph of Comet Hale-Bopp taken on April 8, 1997, by H. Mikuz and B. Kambik at the Crni Vrh Observatory, Slovenia. The image shows the smooth, white dust tail (right) and the blue plasma tail (left); the latter shows some filamentary structure but is relatively undisturbed. (*Ulysses Comet Watch*)

A wide-field image of Comet Hale-Bopp (Fig. 11) shows large dust and plasma tails. The dust tail was expected because this was a very dusty comet. The appearance of the plasma tail is unusual because of the inclination of the comet's orbit to the plane of the ecliptic of 89.4°. This means that the orbit is almost exactly perpendicular to the Earth's orbit. Comet Hale-Bopp spent months in the calm polar solar wind and was the best-documented comet in the polar region. The relatively undisturbed, almost serene appearance of the plasma tail is a direct consequence of the calm polar-region environment.

Origin. For years, it seemed likely that the population of short-period comets could be produced from the population of the long-period comets—those in Oort's Cloud—by their gravitational interaction with Jupiter. It is now understood that they originate in a ring of comets in the vicinity of the orbits of Neptune and Uranus, and beyond.

The Oort Cloud is the source of the long-period comets. The evidence from the statistics of cometary orbits indicates an essentially spherical cloud of comets with dimensions in the range 10^4 to 10^5 AU. Gravitational perturbations from passing stars and gas clouds have several effects on the cloud. They limit its size and tend to make the orbits random (as observed). Most importantly, the perturbations continually send new comets from the cloud into the inner solar system, where they are observed. Thus, the Oort Cloud can be considered as a steady-state reservoir for new comets. Evidence is mounting for the view that the Oort Cloud is supplied by an inner cloud of comets.

The current consensus on the origin of comets holds that they condensed from the solar nebula at the same time as the formation of the Sun and planets. In other words, although the details are sketchy, comets are a natural by-product of the solar system's origin. They may be remnants of the formation process, and their material may be little altered from the era of condensation to the present time. *See* SOLAR SYSTEM.

The consensus scenario for the origin is as follows. Generally accepted models of the solar nebula have temperature and density conditions suitable for the condensation of cometary materials at solar distances around the orbits of Uranus and Neptune. The condensate could coalesce to produce a ring of comets or cometesimals. Gravitational perturbations by the major planets would disperse the ring of comets, sending some into the inner cloud or Oort's Cloud and sending some inward to become short-period comets.

Some scenarios for formation and evolution assign additional roles to the comets. They may have been a major source of the atmospheres of the terrestrial planets and might even have provided the organic molecules necessary for the evolution of life on Earth. While some of these ideas are speculative, they help show why comets are objects of keen interest and active study, and why several space agencies have launched deep-space probes to comets beginning in the 1980s.

Space missions to comets. Interest in sending a spacecraft to a comet was heightened by the appearance of Halley's Comet in 1985 and 1986. The first mission was the diversion of the third *International Sun-Earth Explorer* (*ISEE 3*) from Earth orbit to pass through the tail of Comet Giacobini-Zinner in September 1985. The spacecraft, renamed *International Cometary Explorer* (*ICE*), measured the properties of the tail, including the magnetic field, and the general plasma environment. For a discussion of the missions to Halley's Comet, also called the Halley armada, *see* HALLEY'S COMET.

One Armada spacecraft, *Giotto*, was diverted to intercept Comet Grigg-Skjellurup in July 1992.

The *Deep Space 1* spacecraft encountered Comet Borrelly in September 2001 and obtained imaging and plasma data, as mentioned above.

The *Stardust* mission was launched in February 1999 and encountered Comet Wild 2 in January 2004. Besides imaging of the nucleus and coma, the mission plan is to bring samples of cometary dust back to Earth. This has been accomplished.

The *Deep Impact* mission to Comet Tempel 1 was launched in January 2005. On July 4, 2005, it sent an 820-lbm (370-kg) impactor spacecraft (mostly copper) into the comet's nucleus. **Figure 12** shows the scene shortly after the impact. Because of the large amount of dust in the plume, the expected crater cannot be seen with certainty. Studies of the plume indicate that the outer layer of the comet (down to tens of meters) consists of fine powdery dust only loosely bound by the gravity of the nucleus.

The *Rosetta* mission to Comet Churyumov-Gerasimenko was launched in March 2004. The journey to the comet takes approximately 10 years, and the plan is highly ambitious. Part of the spacecraft will spend about 2 years near the comet and part will land on the comet's nucleus. The nominal mission end is in 2015.

Fig. 12. Image of Comet Tempel 1, 67 s after the impact, taken from the *Deep Impact* flyby spacecraft. The nucleus and the plume of material from the impact are clearly visible. (*NASA/JPL-Caltech/University of Maryland*)

Comets and the public. There is no scientific evidence for the belief that comets are harbingers, omens, or actual producers of evil, disasters, or natural calamities. Some facts about comets can be distorted to provide an apparent basis for some fears. There are toxic gases in comets, but the amount is very small and, moreover, the cometary gas would not penetrate the Earth's atmosphere. The only real problem would be an impact of a comet on the Earth's surface. The odds of an impact are very small, and studies indicate that the somewhat fragile cometary nucleus would break up high in the Earth's atmosphere. Thus, the Tunguska event, which took place in central Siberia on June 30, 1908, and which produced substantial devastation, is no longer believed to have a cometary origin.

The opportunities for much of the public to view bright comets are becoming increasingly rare due to the combination of atmospheric pollution and bright city lights. In January 1974 there was general public disappointment over the poor visibility of Comet Kohoutek, particularly as viewed from cities in the populous northeastern United States, although it was a conspicuous object to astronomers at mountaintop observatories in the southwestern United States. Halley's Comet was not a spectacular object for public viewing in 1985 and 1986. In part, this was due to the circumstances of the comet's orbit, which led to the comet's times of greatest intrinsic brightness occurring well away from the Earth in contrast to the situation in 1910. The march of light pollution is inexorable, and the interested viewer of comets will require an observing site well away from urban population centers. John C. Brandt

Comfort heating

The maintenance of the temperature in a closed volume, such as a home, office, or factory, at a comfortable level during periods of low outside temperature. Two principal factors determine the amount of heat required to maintain a comfortable inside temperature: the difference between inside and outside temperatures and the ease with which heat can flow out through the enclosure. *See* CONDUCTION (HEAT).

Heating load. The first step in planning a heating system is to estimate the heating requirements. This involves calculating heat loss from the space, which in turn depends upon the difference between outside and inside space temperatures and upon the heat transfer coefficients of the surrounding structural members.

Outside and inside design temperatures are first selected. Ideally, a heating system should maintain the desired inside temperature under the most severe weather conditions. Economically, however, the lowest outside temperature on record for a locality is seldom used. The design temperature selected depends upon the heat capacity of the structure, amount of insulation, wind exposure, proportion of heat loss due to infiltration or ventilation, nature and time of occupancy or use of the space, difference between daily maximum and minimum temperatures, and other factors. Usually the outside design temperature used is the median of extreme temperatures.

The selected inside design temperature depends upon the use and occupancy of the space. Generally it is between 66 and 75°F (19 and 24°C).

The total heat loss from a space consists of losses through windows and doors, walls or partitions, ceiling or roof, and floor, plus air leakage or ventilation. All items but the last are calculated from $H_l = UA(t_i - t_o)$, where heat loss H_l is in British thermal units per hour (or in watts), U is overall coefficient of heat transmission from inside to outside air in Btu/(h)(ft^2)(°F) (or J/s · m^2 · °C), A is inside surface area in square feet (or square meters), t_i is inside design temperature, and t_o is outside design temperature in °F (or °C).

Values for U can be calculated from heat transfer coefficients of air films and heat conductivities for building materials or obtained directly for various materials and types of construction from heating guides and handbooks.

The heating engineer should work with the architect and building engineer on the economics of the completed structure. Consideration should be given to the use of double glass or storm sash in areas where outside design temperature is 10°F (−12°C) or lower. Heat loss through windows and doors can be more than halved and comfort considerably improved with double glazing. Insulation in exposed walls, ceilings, and around the edges of the ground slab can usually reduce local heat loss by 50–75%. **Table 1** compares two typical dwellings. The 43% reduction in heat loss of the insulated house produces a worthwhile decrease in the cost of the heating plant and its operation. Building the house tight reduces the large heat loss due to infiltration of outside air. High heating-energy costs may now warrant 4 in. (10 cm) of insulation in the walls and 8 in. (20 cm) or more in the ceiling.

Humidification. In localities where outdoor temperatures are often below 36°F (2°C), it is advisable to provide means for adding moisture in heated spaces to improve comfort. The colder the outside air is, the less moisture it can hold. When it is heated to room temperature, the relative humidity in the space becomes low enough to dry out nasal membranes, furniture, and other hygroscopic materials. This results in discomfort as well as deterioration of physical products.

Various types of humidifiers are available. The most satisfactory type provides for the evaporation of the water to take place on a mold-resistant treated material which can be easily washed to get rid of the resultant deposits. When a higher relative humidity is maintained in a room, a lower dry-bulb temperature or thermostat setting will provide an equal sensation

TABLE 1. Effectiveness of double glass and insulation*

		Heat loss, Btu/h†	
Heat-loss members	Area, ft^2 (m^2)	With single-glass weather-stripped windows and doors	With double-glass windows, storm doors, and 2-in. (5.1-cm) wall insulation
Windows and doors	439 (40)	39,600	15,800
Walls	1952 (181)	32,800	14,100
Ceiling	900 (84)	5,800	5,800
Infiltration		20,800	20,800
Total heat loss		99,000	56,500
Duct loss in basement and walls (20% of total loss)		19,800	11,300
Total required furnace output		118,800	67,800

*Data are for two-story house with basement in St. Louis, Missouri. Walls are frame with brick veneer and 25/32-in. (2.0-cm) insulation plus gypsum lath and plaster. Attic floor has 3-in. (7.5-cm) fibrous insulation or its equivalent. Infiltration of outside air is taken as a 1-h air change in the 14,400 ft^3 (408 m^3) of heating space. Outside design temperature is −5°F (−21°C); inside temperature is selected as 75°F (24°C).

†1 Btu/h = 0.293 W.

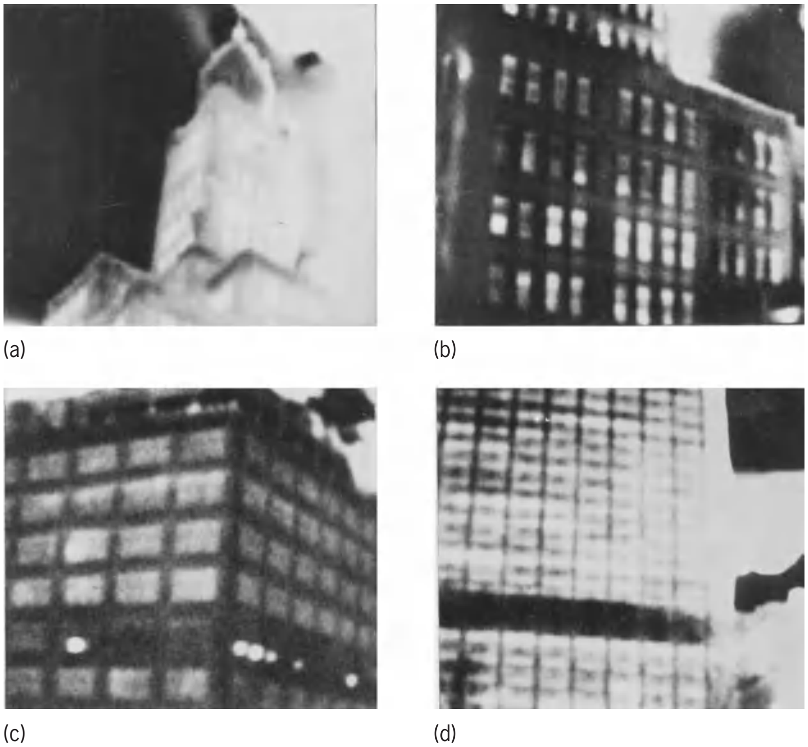
of warmth. This does not mean, however, that there is a saving in heating fuel, because heat from some source is required to evaporate the moisture.

Some humidifiers operate whenever the furnace fan runs, and usually are fed water through a float-controlled valve. With radiation heating, a unitary humidifier located in the room and controlled by a humidistat can be used.

Insulation and vapor barrier. Good insulating material has air cells or several reflective surfaces. A good vapor barrier should be used with or in addition to insulation, or serious trouble may result. Outdoor air or any air at subfreezing temperatures is comparatively dry, and the colder it is the drier it can be. Air inside a space in which moisture has been added from cooking, washing, drying, or humidifying has a much higher vapor pressure than cold outdoor air. Therefore, moisture in vapor form passes from the high vapor pressure space to the lower pressure space and will readily pass through most building materials. When this moisture reaches a subfreezing temperature in the structure, it may condense and freeze. When the structure is later warmed, this moisture will thaw and soak the building material, which may be harmful. For example, in a house that has 4 in. (10 cm) or more of mineral wool insulation in the attic floor, moisture can penetrate up through the second floor ceiling and freeze in the attic when the temperature there is below freezing. When a warm day comes, the ice will melt and can ruin the second floor ceiling. Ventilating the attic helps because the dry outdoor air readily absorbs the moisture before it condenses on the surfaces. Installing a vapor barrier in insulated outside walls is recommended, preferably on the room side of the insulation. Good vapor barriers include asphalt-impregnated paper, metal foil, and some plastic-coated papers. The joints should be sealed to be most effective. *See* HEAT INSULATION.

Thermography. Remote heat-sensing techniques evolved from space technology developments related to weather satellites can be used to detect comparative heat energy losses from roofs, walls, windows, and so on. A method called thermography is defined as the conversion of a temperature pattern detected on a surface by contrast into an image called a thermogram (see **illus.**). Thermovision is defined as the technique of utilizing the infrared radiation from a surface, which varies with the surface temperatures, to produce a thermal picture or thermogram. A camera can scan the area in question and focus the radiation on a sensitive detector which in turn converts it to an electronic signal. The signal can be amplified and displayed on a cathode-ray tube as a thermogram.

Normally the relative temperature gradients will vary from white through gray to black. Temperatures from −22 to 3540°F (−30 to 2000°C) can be measured. Color cathode-ray tubes may be used to display color-coded thermograms showing as many as 10 different isotherms. Permanent records are possible by using photos or magnetic tape.



(a)
(b)
(c)
(d)

Thermograms of building structures: (*a-c*) masonry buildings; (*d*) glass-faced building. Black indicates negligible heat loss; gray, partial loss; and white, excessive loss. (*Courtesy of A. P. Pontello*)

Infrared thermography is used to point out where energy can be saved, and comparative insulation installations and practices can be evaluated. Thermograms of roofs are also used to indicate areas of wet insulation caused by leaks in the roof.

Infiltration. In **Table 2**, the loss due to infiltration is large. It is the most difficult item to estimate accurately and depends upon how well the house is built. If a masonry or brick-veneer house is not well caulked or if the windows are not tightly fitted and weather-stripped, this loss can be quite large. Sometimes, infiltration is estimated more accurately by measuring the length of crack around windows and

TABLE 2. Infiltration loss with 15-mi/h (24 km/h) outside wind

Building item	Infiltration, $ft^3/(ft)(h)$
Double-hung unlocked wood sash windows of average tightness, non-weather-stripped including wood frame leakage	39
Same window, weather-stripped	24
Same window poorly fitted, non-weather-stripped	111
Same window poorly fitted, weather-stripped	34
Double-hung metal windows unlocked, non-weather-stripped	74
Same window, weather-stripped	32
Residential metal casement, $^{1}/_{64}$-in. (0.4-mm) crack	33
Residential metal casement, $^{1}/_{32}$-in. (0.8-mm) crack	52

doors. Illustrative quantities of air leakage for various types of window construction are shown in Table 2. The figures given are in cubic feet of air per foot of crack per hour.

Design. Before a heating system can be designed, it is necessary to estimate the heating load for each room so that the proper amount of radiation or the proper size of supply air outlets can be selected and the connecting pipe or duct work designed. *See* AIR REGISTER; CENTRAL HEATING AND COOLING; HOT-WATER HEATING SYSTEM; OIL BURNER; RADIATOR; STEAM HEATING; WARM-AIR HEATING SYSTEM.

Heat is released into the space by electric lights and equipment, by machines, and by people. Credit to these in reducing the size of the heating system can be given only to the extent that the equipment is in use continuously or if forced ventilation, which may be a big heat load factor, is not used when these items are not giving off heat, as in a factory. When these internal heat gain items are large, it may be advisable to estimate the heat requirements at different times during a design day under different load conditions to maintain inside temperatures at the desired level.

Cost of operation. Design and selection of a heating system should include operating costs. The quantity of fuel required for an average heating season may be calculated from

$$F = \frac{Q \times 24 \times \mathrm{DD}}{(t_i - t_o) \times \ \mathrm{Eff} \ \times H}$$

where F = annual fuel quantity, same units as H
Q = total heat loss, Btu/h (or J/s)
t_i = inside design temperature, °F (or °C)
t_o = outside design temperature, °F (or °C)
Eff = efficiency of total heating system (not just the furnace) as a decimal
H = heating value of fuel
DD = degree-days for the locality for 65°F (19.3°C) base, which is the sum of 65 (19.3) minus each day's mean temperature in °F (or°C) for all the day's of the year

If a gas furnace is used for the insulated house of Table 1, the annual fuel consumption would be

$$F = \frac{56,500 \times 24 \times 4699}{[75-(-5)] \times 0.80 \times 1050} = 94,800\ \mathrm{ft}^3 \ \ (2684\mathrm{m}^3)$$

For a 5°F (3°C), 6–8-h night setback, this consumption would be reduced by about 5%. *See* THERMOSTAT.

Comfort temperatures

Air temperatures adjusted to represent human comfort or discomfort under prevailing conditions of temperature, humidity, radiation, and wind. Theoretical formulas attempt to compare the rate of heat loss to surroundings with rate of heat production by work and metabolism. Most modern empirical relations, based on relative comfort expressed by human subjects under differing atmospheric combinations, attempt to indicate the temperature at which air at some standard humidity, air motion, and radiation load would be just as uncomfortable (or comfortable). Many former indices, however, had arbitrary scales.

Heat is produced constantly by the human body at a rate depending on muscular activity. For body heat balance to be maintained, this heat must be dissipated by conduction to cooler air, by evaporation of perspiration into unsaturated air, and by radiative exchange with surroundings. Air motion (wind) affects the rate of conductive and evaporative cooling of skin, but not of lungs; radiative losses occur only from bare skin or clothing, and depend on its temperature and that of surroundings, as well as sunshine intensity.

As air temperatures approach body temperature, conductive heat loss decreases and evaporative loss increases in importance. Hence, at warmer temperature, humidity is the second-most important atmospheric property controlling heat loss and hence comfort, and the various sensible temperature formulas incorporate some humidity measure. *See* BIOMETEOROLOGY.

Temperature and humidity. Almost a century ago, wet-bulb temperature was thought to indicate human comfort under warm conditions, especially in deep mines, ship engine rooms, and steel mills and other factories, on the assumption that sweaty skin approximated a wet bulb. It was superseded after 1923 by the effective temperature, which combined dry- and wet-bulb temperatures, at constant low-ventilation rate, as evaluated by 300 trained subjects walking between controlled-environment rooms. In the 1950s this was approximated by the discomfort index, soon renamed temperature-humidity index (THI) and used by the Weather Bureau (now National Weather Service) for several years. In Canada it was called humidity index. It is calculated by either Eq. (1) or Eq. (2), where the air

$$\mathrm{THI} = 15 - 0.4(t_a + t_w) \qquad (1)$$

$$\mathrm{THI} = t_a - 0.55(1 - \mathrm{RH})(t_a - 58) \qquad (2)$$

and wet-bulb temperatures—t_a and t_w respectively—are expressed in °F and relative humidity (RH) is expressed as a decimal fraction. Except in saturated air (RH = 1.0, that is, 100%), the temperature-humidity index is usually lower than air temperature. A different temperature-humidity index was used in 1980 by another National Weather Service office to compute a heat wave index, ranging from 0 (mild) to 15 (extreme).

A simple average of air temperature in °F and relative humidity in percent was called humiture in 1937, and was changed in 1959 to a simple average of dry- and wet-bulb temperatures in °F. Later, this was further changed to an average of air temperature in °F and excess vapor pressure e, above 10 millibars, with the saturation vapor pressure at 45°F. This index is called humidex in Canada. The originator of humidex opposed raising the threshold to 21 mb (saturation at 65°F), which was being used by at least one television weatherperson. No two of these formulations are equivalent, but each is usually less than air temperature. *See* AIR TEMPERATURE; HUMIDITY; PSYCHROMETRICS.

Wind and radiation. Meanwhile, more refined measurements led to more elaborate formulas involving all aspects of heat loss. Operative temperature modifies effective temperature to include radiation at constant wind speed, and standard operative temperature considers also temperature and heat conduction of skin. The 1955 heat stress index, essentially the ratio of evaporation needed to maintain a stable body temperature to the evaporation possible under existing conditions and working rate, has been evaluated by a detailed computer program. The 1979 apparent temperature, a very complete formulation, is calculated by use of a nomograph or computer as the heat index of the National Oceanic and Atmospheric Administration (see **illus.**). It is a nonlinear combination of air temperature and relative humidity, adjusted for wind.

A less detailed graphic computation yields a similar but not equivalent value known as humisery. Another approach uses the shaded comfort-factor thermometer, which is a large bulb half-covered by a wetted cloth so that air temperature, wet-bulb temperature, wind, and radiation are integrated into a single number similar to a Fahrenheit temperature; most people are said to be comfortable at values from 63 to 72.

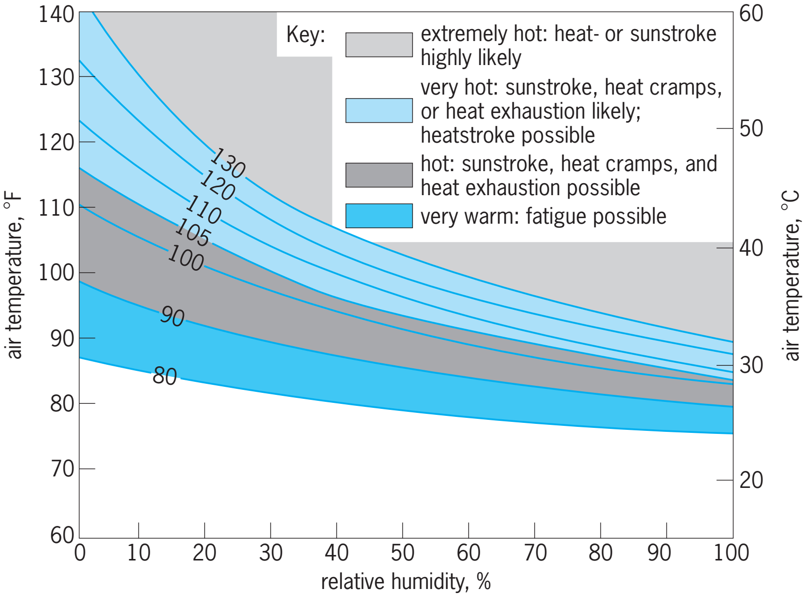
Cold conditions. Under cold conditions, atmospheric moisture is negligible and wind becomes important in heat removal. Wind chill, given by Eq. (3),

$$H = (10.45 + 10\sqrt{v} - v)(33 - t) \qquad (3)$$

where H represents heat loss in kcal/(m^2)(h^2), does not estimate sensible temperature as such, but rather heat loss in kcal/(m^2)(h) for wind speed v in m/s and air temperature t in °C.

The formula was based on the rate of freezing, at various temperature-wind combinations during the Antarctic winter, of water in a plastic cylinder, not on responses of human subjects. It has never been validated by the latter approach. Nevertheless, the temperature at which the estimated heat loss at some reference wind speed equals that at the existing temperature-wind combination is the wind chill temperature. The reference wind speed is variously 3 mi/h, 3 knots, or 4 mi/h, and in a revised formulation is 0.

Arnold Court



Heat index used by the National Weather Service, National Oceanographic and Atmospheric Administration. The numerical values on each curve represent a heat index, that is, apparent temperature in °F.

Commelinales

An order of flowering plants, division Magnoliophyta (Angiospermae), which is included in the subclass Commelinidae in the class Liliopsida (monocotyledons). It consists of 4 families and about 1000 species, the bulk of which is in the families Commelinaceae (about 700 species) and Xyridaceae (about 200 species). The order is marked by its flowers that ordinarily have the perianth well differentiated into sepals and petals but do not have nectaries or nectar. The ovary is consistently superior and the fruit capsular. The wandering Jew (species of *Tradescantia* and *Zebrina* in the Commelinaceae) belongs to this order. *See* COMMELINIDAE; LILIOPSIDA; MAGNOLIOPHYTA; PLANT KINGDOM.

Arthur Cronquist; T. M. Barkley

Commelinidae

A subclass of the class Liliopsida (monocotyledons) of the division Magnoliophyta (Angiospermae), the flowering plants, consisting of 7 orders, 16 families, and nearly 15,000 species. The orders include Commelinales, Eriocaulales, Restionales, Juncales, Cyperales, Hydatellales, and Typhales. For further information see separate articles on each order.

These monocotyledons are syncarpous (the carpels are united in a compound ovary) or pseudomonomerous (reduced to a single carpel from a syncarpous ancestry). The endosperm is usually starchy, and the perianth is either well differentiated into sepals and petals or more or less reduced and not petallike. The stomates have two or more subsidiary cells, the pollen is either binucleate or more often trinucleate, and the endosperm may be nuclear. Many of the families have well-developed vessels in all vegetative organs. Several of the orders of Commelinidae have often been treated as a single order Farinosae or Farinales. *See* LILIOPSIDA; MAGNOLIOPHYTA; PLANT KINGDOM.

Arthur Cronquist; T. M. Barkley

Common cold

An acute infectious disorder characterized by nasal obstruction and discharge that may be accompanied by sneezing, sore throat, headache, malaise, cough, and fever. The disorder involves all human populations, age groups, and geographic regions; it is more common in winter than in summer in temperate climates. Most people in the United States experience at least one disabling cold (causing loss of time from work or school or a physician visit) per year. Frequencies are highest in children and are reduced with increasing age.

Most, or possibly all, infectious colds are caused by viruses. More than 200 different viruses can induce the illness, but rhinoviruses, in the picornavirus family, are predominant. Rhinoviruses are small ribonucleic acid–containing viruses with properties similar to polioviruses. Other viruses commonly causing colds include corona, parainfluenza, influenza, respiratory syncytial, entero, and adeno. *See* ADENOVIRIDAE; ENTEROVIRUS; PARAINFLUENZA VIRUS; RHINOVIRUS.

Cold viruses are spread from one person to another in either of two ways: by inhalation of infectious aerosols produced by the sneezing or coughing of ill individuals, or by inoculation with virus-containing secretions through direct contact with a person or a contaminated surface. Controlled experiments have not shown that chilling produces or increases susceptibility to colds. Infection in the nasopharynx induces symptoms, with the severity of the illness relating directly to the extent of the infection. Recovery after a few days of symptoms is likely, but some individuals may develop a complicating secondary bacterial infection of the sinuses, ear, or lung (pneumonia).

Colds are treated with medications designed to suppress major symptoms until natural defense mechanisms terminate the infection. Immunity to reinfection follows recovery and is most effective in relation to antibody in respiratory secretions. There is no established method for prevention of colds; however, personal hygiene is recommended to reduce contamination of environmental air and surfaces with virus that may be in respiratory secretions. *See* PNEUMONIA.

Communications cable

A cable that transmits information signals between geographically separated points. The heart of a communications cable is the transmission medium, which may be optical fibers, coaxial conductors, or twisted wire pairs. A mechanical structure protects the heart of the cable against handling forces and the external environment. The structure of a cable depends on the application.

Optical communications cables. These cables are used in both terrestrial (**Fig. 1**) and undersea (**Fig. 2**) systems. Optical communications cables for terrestrial use may be installed aerially, by direct burial, or in protective ducts. The terrestrial and undersea cables differ in several respects. First, the terrestrial cable requires only enough longitudinal strength to support its own weight over relatively short pole-to-pole spans, or to allow installers to pull the cable into ducts or lay it in a trench. For the undersea

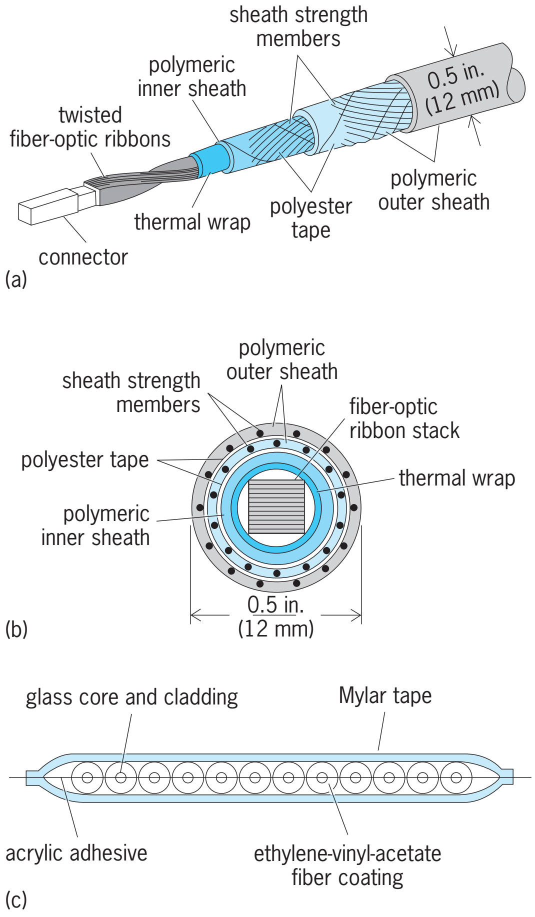

Fig. 1. Multifiber cable for terrestrial use (144 fibers maximum). (*a*) Cutaway view. (*b*) Cross section of cable. (*c*) Cross section of single optical fiber ribbon (12 fibers).

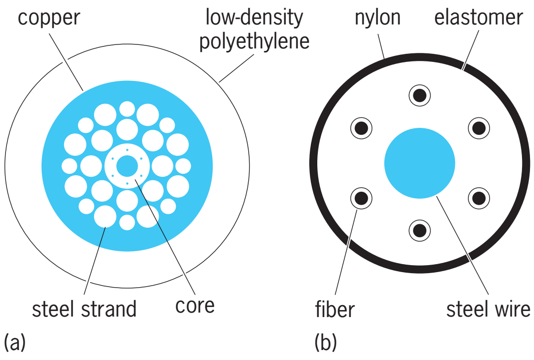

Fig. 2. Optical-fiber cable for undersea systems. (*a*) Cross section. (*b*) Detail of cross section of core.

TABLE 1. Principal characteristics of the first transoceanic fiber-optic United States-to-Europe undersea cable system

Characteristic	Value
Line rate	295.6 megabits/s
Number of service fibers	4
Number of protection fibers	2
Regenerators per repeater	6
Number of voice channels	8000
Number of conversations (with digital circuit multiplication equipment)	40,000
Optical wavelength	1310 nm

cable, the high-strength steel strand allows it to be laid and recovered in ocean depths up to 4.5 mi (7315 m). A second difference is that the undersea cable must deliver as much as 1.6 amperes of direct current to the spaced, series-connected repeaters. Repeaters for the terrestrial system are generally located in buildings, and are powered from locally available sources. A third difference is due to the environment. Terrestrial cables are often installed in ducts. Hence, only limited protection is required against local hazards. The undersea cable, on the other hand, must withstand moderately severe handling in laying, and it sustains the full pressure of ocean depths. At 4.5 mi (7315 m) depth, this pressure is 10,700 lb/in.^{2} (73.8 megapascals). To withstand this pressure, the cable is a filled design (no voids). The thick polyethylene outer layer provides electrical insulation for the power-carrying copper conductor, and is tough enough to resist severe handling. In addition to providing longitudinal strength, the steel strand overlaid with copper acts as a pressure cage to protect the core and fibers. *See* ELECTRICAL INSULATION; POLYOLEFIN RESINS; SUBMARINE CABLE.

Optical communications cables are often used to carry input and output data to computers, or to carry such data from one computer to another. Then they are generally referred to as optical data links or local-area networks. The links are generally short enough that intermediate regeneration of the signals is not needed. *See* FIBER-OPTIC CIRCUIT; LOCAL-AREA NETWORKS.

Optical fibers. Signals in these cables are carried by light pulses which are guided down the optical fiber. In most applications, two fibers make up a complete two-way signal channel. The guiding effect of the fiber confines light to the core of the glass fiber and prevents interference between signals being carried on different fibers. The guiding effect also delivers the strongest possible signal to the far end of the cable. Exceptionally pure silica glass in the fiber minimizes light loss for signals passing longitudinally through the glass fiber. Developers have realized fiber losses of 0.27 dB or less per statute mile (0.17 dB per kilometer), at a wavelength of 1550 nanometers. For such a fiber, the signal can travel 11 mi (18 km) before losing half its power, and can travel 75 mi (120 km) or more before requiring electronic regeneration or amplification. Coaxial cable systems require regeneration at much closer intervals. In the L5 and T4M Coaxial Cable systems, for example, signals are amplified or regenerated every mile (every 1.6 km). *See* OPTICAL FIBERS.

Signal regeneration. Optical cable systems are usually digital. Thus, information is coded into a train of off-or-on light pulses. These are detected by a photodetector at the far end of a cable span and converted into electronic pulses which are amplified, retimed, recognized in a decision circuit, and finally used to drive an optical transmitter. In the transmitter, a laser converts the electric signals back into a train of light pulses which are strong enough to traverse another cable span. By placing many spans in tandem, optical cable systems can carry signals faithfully for thousands of miles.

In TAT-8, the first transoceanic fiber-optic cable, which entered service in 1988 (**Table 1**), six regenerators are mounted in a repeater housing (**Fig. 3**). Thus, the repeater regenerates signals in three pairs of fibers.

Optical-fiber amplifiers. Rather than undersea regenerators, current optical-fiber cable systems use erbium-doped fiber amplifiers (EDFAs) to boost the optical signal on long spans. Conversion from optical to electronic modes and back again is then not needed in the undersea repeaters. Systems using optical amplifiers are simple and reliable, but still deliver a near-perfect, low-noise signal because of signal regeneration at the receiving terminal. With careful design, it is possible to carry a 5-gigabit/s signal across the Pacific Ocean, a 5500-mi (9000-km) distance, with EDFAs before regeneration on shore. Such systems deliver the signal to the distant shore with a bit-error ratio of better than 10^{-10}.

Repeaterless undersea cables. The trend toward lower fiber loss allows the linking of mainland to offshore islands without undersea electronics and optics. Cable systems of over 155 mi (250 km) are feasible (**Table 2**), with future capability trending toward 190 mi (300 km).

Advantages. Optical communications cables have five key advantages over earlier metallic cables: noise- and error-free transmission; greater repeater spacings; enormous information capacity (many individual voice, data, or television channels); immunity

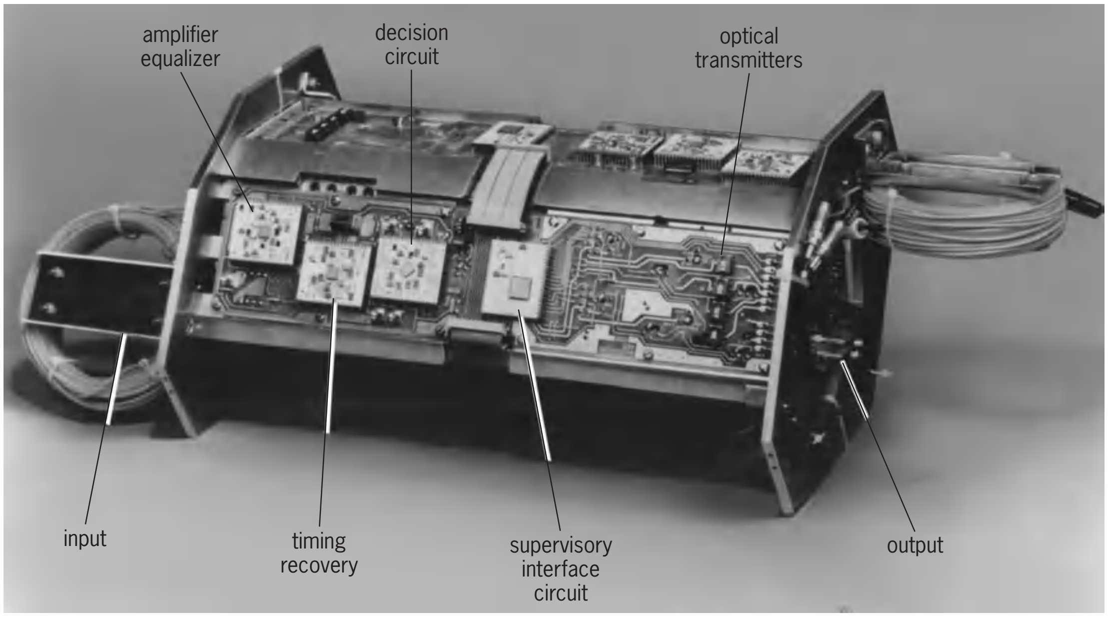

Fig. 3. Regenerator for SL-280 optical undersea cable communications system used in TAT-8.

from outside interference (other signals or noise); and smaller size and lower weight.

Because of these advantages and because optical cable technology is in its infancy, many additional applications can be expected to develop, and the cost of such communications cables can be expected to continue to decrease. *See* OPTICAL COMMUNICATIONS.

Coaxial cable communications systems. Coaxial communication systems evolved before optical systems. Most of these systems are analog in nature. Signals are represented by the amplitude of a wave representing the signal to be transmitted. In a multichannel system, each voice, data, or picture signal occupies its unique portion of a broadband signal which is carried on a shared coaxial conductor or "pipe." In the transmitting terminal, various signals are combined in the frequency-division transmitting multiplex equipment. At the receiving end of a link, signals are separated in the receiving demultiplex equipment. This combining and separation operates much as broadcast radio and television do, and the principles are identical. *See* AMPLITUDE MODULATION; ELECTRICAL COMMUNICATIONS; FREQUENCY MODULATION.

TABLE 2. Repeaterless cable system

Characteristic	Value
System length	188 mi (300 km) maximum
Fiber type	SL, dispersion shifted
Fiber proof stress	200,000 lb/in.^{2} (1.38 GPa)
Cable design	SL, embedded core
Optical wavelength	1.55 μm
Optical source	Buried-heterostructure multiple quantum well laser and EDFA*
Optical detector	EDFA and avalanche photodiode
Line data rate	5 gigabits/s
Line coding	Nonreturn to zero (NRZ)

*EDFA = erbium-doped fiber amplifier.

In order to carry as many channels as possible, the multiplexing and demultiplexing use single-sideband (SSB) transmission. The fixed carrier signals, which do not convey useful information, are suppressed in the transmitting multiplex and reintroduced in the receiving multiplex. This avoids unnecessary load on the system. *See* SINGLE SIDEBAND.

Terrestrial cables. The channel capacity of terrestrial coaxial systems increased dramatically over the years to meet increased long-distance calling (**Table 3**). This resulted in decreased cost per channel, which stimulated still further demand. While demand was the driving force, it is improving technology which allowed such tremendous increases in capacity.

The L1 and L3 systems used electron tubes as the amplifying device, while all later systems used transistors. The L5 system benefited by the use of thin-film integrated circuits. These advances were responsible for the 22-fold increase in the number of channels per coaxial pair (Table 3). Because the number of coaxial pairs per cable was also increased, the total route capacity was increased by a factor of 73 over the 30-year period. *See* ELECTRON TUBE; INTEGRATED CIRCUITS; TRANSISTOR.

Repeater spacing decreases as the capacity rises (Table 3). Multiplying channel capacity by 22 has meant going to higher frequencies, since each additional channel requires another 4 kHz of spectrum. At higher frequencies the cable has higher loss, and therefore such signals must be amplified at closer intervals.

Undersea cables. The history of undersea communications goes back to 1858, when the first transatlantic telegraph cable was completed by C. W. Field. This cable had no repeaters and thus was capable of carrying only a single slow-speed telegraph signal. Nevertheless, it allowed news to be communicated

TABLE 3. L-system characteristics

Characteristic	L1	L3	L4	L5	L5E
Service date	1946	1953	1967	1974	1976
Repeater spacing, mi (km)	8 (12.9)	4 (6.4)	2 (3.2)	1 (1.6)	1 (1.6)
Voice-band channel capacity per 3/8-in. (9.5-mm) coaxial pair	600	1860	3600	10,800	13,200
Coaxial pairs	4	6	10	11	11
Working pairs	3	5	9	10	10
Channel capacity	1800	9300	32,400	108,000	132,000

between North America and Europe without the long delay of surface mail. While telegraph cables were improved over the years, the next major breakthrough occurred in 1956, when the first transatlantic telephone cable was completed from Nova Scotia to Newfoundland, and then across the Atlantic to Scotland.

With the completion of TAT-1 (Transatlantic Telephone-1), callers could for the first time talk across the Atlantic Ocean as easily as they could within the continents. The response was a dramatic increase in use of overseas calling. Since 1956, cables have been installed throughout the world. England, France, Japan, and the United States have been active in designing and installing undersea communications cables.

Low delay is one respect in which undersea cables have a significant edge over satellites in a geosynchronous orbit. Delay is usually evaluated in terms of round-trip message time. For a telephone conversation, it is the extra time added between question and answer because of the transmission time. For the satellite connection, this delay is about 0.5 s. For a 4000-statute-mile (6400-km) undersea cable link, delay is only 0.06 s. Longer delay has two effects: it makes echo more bothersome to voice communications, and it requires more complex and less efficient protocols for data communications. *See* COAXIAL CABLE; TELEPHONE SERVICE; TELEPHONE SYSTEMS CONSTRUCTION. Communications satellite

An artificial device that circumnavigates the Earth, receiving and retransmitting radio-frequency signals to multiple points on Earth. The communications hardware includes antennas, receivers, signal processing, and power amplifiers. The performance is predicted by calculating the power received by the satellite and by the receiving ground station. The satellite has solar arrays and batteries to provide electrical power, thrusters to keep the satellite in the desired position and orientation, and radiators to dissipate heat. The equipment is designed to operate unattended for many years. Many communications satellites are put in a special circular orbit high above the equator.

Communications satellites provide worldwide exchange of voice, text, data, and images to both fixed stations and mobile stations in support of aeronautical, land, and maritime services. With the advent of more powerful satellites and smaller, less powerful, and even portable terminals, satellite broadcasts are accessible to users in both highly populated and remote areas of the world. Applications are proliferating—from distributing network programming to television and radio stations or directly to subscribers, to providing essential communications for disaster relief or medical treatment, supporting Internet access and e-mail, or even to connecting travelers on handheld phones. By providing reliable communications among diverse and geographically distant populations, satellites have helped to make the world a global community. Communications satellites represent at least 40% of the total number of satellites and 30% in cost.

For a communications satellite to provide continuous service 24 h every day, it must remain above the Earth station's horizon, and preferably remain stationary in one spot in the sky so that antennas on the ground do not have to be repointed. As the Earth turns, the satellite moves in a circle, and the center of this circle must be at the center of the Earth. This can happen only if the satellite is above and perpendicular to a spot on the Equator. The height of the satellite is also critical. If the satellite is too low, the attraction of gravity is too strong and the satellite will accelerate toward the Earth. If the satellite is too high, the gravitational attraction is too weak and the satellite will accelerate away from the Earth. If the satellite is 35,786 km (22,237 mi) above the Earth's surface, the attraction of gravity is exactly right. Except for a few small disturbing forces, the satellite will remain at that height, over a point on the Earth's Equator. Such a satellite is called a geostationary satellite and, as the Earth turns, it traverses a path called a geostationary orbit. To an observer on Earth, the satellite remains stationary in the sky.

Basic configuration. Most communications satellites are active repeaters. That is, they receive a signal from an Earth station, amplify it, and retransmit it to one or more earth stations (**Fig. 1**). The signal

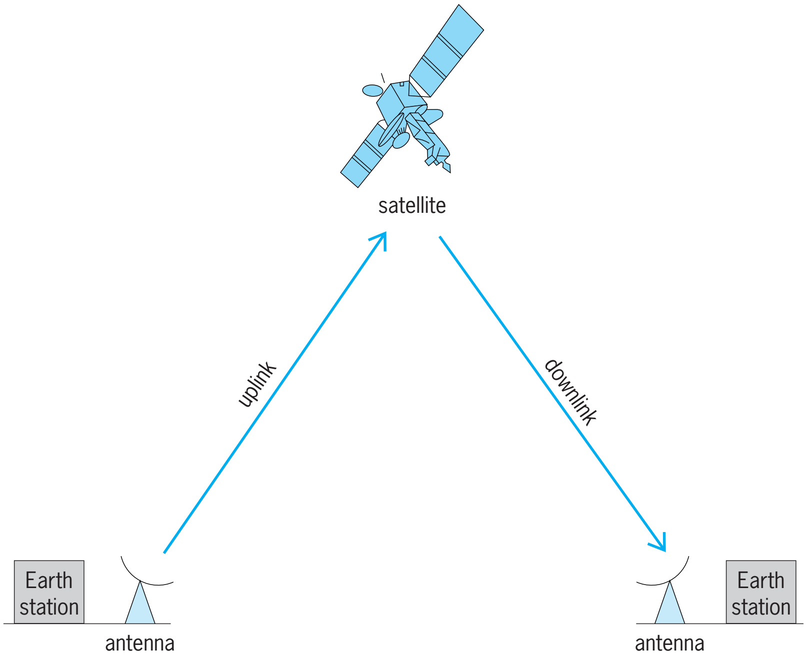

Fig. 1. Communications to and from a satellite.

from the first Earth station to the satellite is called the uplink, and the signal from the satellite back to another Earth station is the downlink. In the satellite, the equipment used to handle the signals is the communications subsystem. The signal is received by an antenna, amplified, processed through many stages, and immediately transmitted through an antenna back to Earth.

A typical communications satellite has a compact, rectangular body, with antennas and solar arrays unfolded in space (**Fig. 2**). The large antennas are used for both transmitting and receiving communications. A smaller antenna is often used to receive commands and to send information about the satellite's status. Before launch, the solar panels are folded next to the body. After launch, they are extended into two long arrays. Other external parts include the thrusters for propulsion, sensors to detect orientation, and radiators to dissipate excess heat.

Inside the satellite, the communications subsystem includes the receiver, the processing equipment, and the power amplifier. The receiver includes a low-noise amplifier to minimize the noise added to the signal, and a downconverter to shift the carrier frequency to another frequency. The processing equipment may include switches, attenuators, and multiplexers. The power amplifiers provide the maximum power to be transmitted.

To support communications, the satellite has several specialized components. These provide the electric power (solar array, batteries, and power conditioning equipment), orientation (sensors and wheels), propulsion (propellant tanks, fuel, and thrusters), structure, and thermal control. Telemetry provides information about the satellite, the command subsystem is used to control the satellite, and tracking is used to help determine its orbit. Since ordinary repairs cannot be done after a satellite is launched, high reliability is essential. Frequently, duplicate equipment is available in the satellite, and used if the primary equipment fails.

Communications Subsystem

The function of a communications satellite is accomplished by the communications subsystem, which receives, amplifies, processes, and transmits

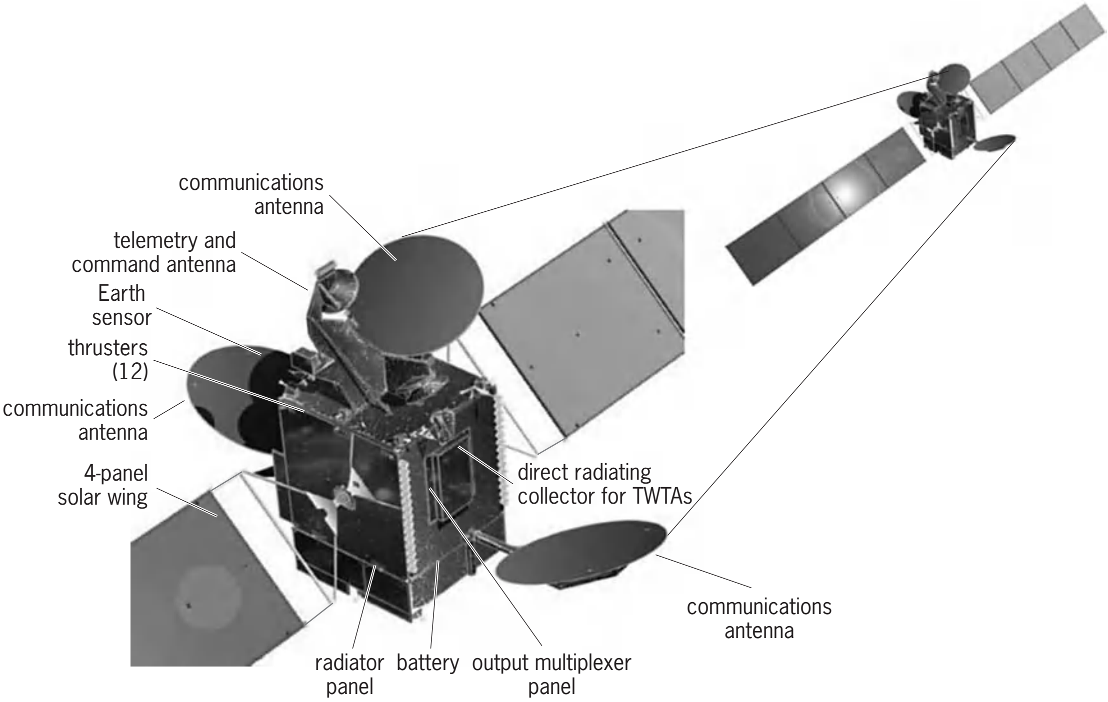

Fig. 2. Typical communications satellite. TWTA = traveling-wave-tube amplifier. (*Space Systems/Loral*)

TABLE 1. Frequencies allocated to communications satellites*

Frequency range, GHz	Letter designation	Typical service usage
1.0–2.0	L-band	Mobile satellite service
1.55–3.9	S-band	Mobile satellite service, digital audio radio service
3.7–6.2	C-band	Fixed satellite service, very small aperture terminal
8.0–12.0	X-band	Military/satellite imagery
11.7–14.5	Ku-band	Fixed satellite service, direct broadcast satellite, very small aperture terminal
17.7–21.2	Ka-band	Fixed satellite service “broadband,” intersatellite link
27.5–31.0	Ka-band	Fixed satellite service “broadband,” intersatellite link

*From Richard Barnett.

information. Hardware includes antennas, receivers, frequency converters, multiplexers, and power amplifiers. The properties of these components depend on the radio frequencies used, and the way the information is imposed on the carrier frequency.

Radio frequencies. A variety of frequencies are received and transmitted by communications satellites (**Table 1**). The fixed satellite service (FSS) provides the major communications between fixed Earth stations. The mobile satellite service (MSS) communicates with ships, vehicles, and airplanes. Direct broadcast satellite (DBS) transmits television directly to homes. Digital audio radio service (DARS) provides continuous radio programs to vehicles. Very small aperture terminals (VSATs) provide communications to very small antennas, often used by businesses. And intersatellite links carry communications from one satellite to another. *See* SATELLITE RADIO; SATELLITE TELEVISION BROADCASTING.

Communications satellites use frequencies above 1 GHz (1,000,000,000 Hz or 1,000,000,000 cycles per second). The commonly used radio frequencies are lower. The AM radio band is around 1000 kHz (or 0.001 GHz) and the FM radio band is around 100 MHz (or 0.1 GHz). Frequencies from 0.3 to 3 GHz are also called ultrahigh frequencies (UHF), and frequencies from 3 to 30 GHz are called superhigh frequencies (SHF).

The amount of radio spectrum (bandwidth) available for space communications is limited. Bandwidth is a measure of how much information can be transmitted. A telephone call, or a modem connection to the Internet, takes only about 10 kHz. A television channel, or a high-speed connection to the Internet for transmission of pictures, requires much more bandwidth. The demand for satellite communications continues to increase, and the lower frequencies are in high demand. The higher frequencies (above 15 GHz) are more available, but are also more attenuated by rain, which can both decrease the signal power and increase the receiver noise level. *See* BANDWIDTH REQUIREMENTS (COMMUNICATIONS); RADIO-WAVE PROPAGATION.

There are different ways to conserve bandwidth by reusing frequencies in a single satellite. One way is to use narrow antenna beams on a satellite. If one beam covers Europe and the other covers North America, different signals can be sent on the different beams at the same frequency, using the antenna directivity for isolation. Another way is to use polarized beams, with the same frequency used for two different polarizations. Antennas can discriminate against an undesired signal, just as polarizing sunglasses can reduce the glare from horizontal surfaces. In each of these ways, the equipment is designed so that the unwanted signal is no more than 1/1000 of the desired signal.

Multiple satellites can use the same frequencies—if the Earth station antennas can discriminate between adjacent satellites. The Earth station antenna must have a beam that includes only a single satellite. This applies to both the uplink and the downlink. The signal from the ground must be received by only one satellite, and the signal to the ground must be received from only one satellite. In geostationary orbit, some neighboring satellites, using identical frequencies, are operated with only a 2° separation, which is 1470 km (915 mi).

Finally, another method, called compression, packs more information into less bandwidth. This technique takes advantage of redundancy in the signal. Voice activation uses a voice channel only when a person is speaking, typically only 40% of the time. Early television compression made use of the time it took an electron beam to return to the start of another scanning line. More compression is possible using the time between frames. With digital data, more efficient modulation methods allow more information bits per unit of time. Packet switching, used in the Internet, allows a variety of different signals originating and destined for different users to share the same communications channel. With many different technical improvements, a single communications satellite can now broadcast a hundred different television channels to small home antennas. Earlier satellites could broadcast only a few channels to Earth stations with large antennas. *See* DATA COMPRESSION; PACKET SWITCHING.

The International Telecommunications Union (ITU), working with various national agencies such as the Federal Communications Commission (FCC), controls the use of radio frequencies by specifying the frequency ranges and imposing limitations on power. Some frequencies used by satellites were first used by microwave relay systems, which transmit a signal through a series of relay towers, typically on the tops of hills. Since microwave relay systems preceded satellites, satellites must limit the power per area incident on these towers to avoid causing harmful interference. *See* RADIO SPECTRUM ALLOCATIONS.

Modulation, multiplexing, and multiple access. To send a signal through a communications satellite, the information must be superimposed on a high-frequency (RF) signal (carrier). This is called modulation. If the carrier is not modulated, no information is transmitted and only a constant signal is received. A satellite will normally relay many signals from an Earth station. Multiplexing is used to combine these signals and demultiplexing to separate them. Finally, a satellite often handles signals from more than one Earth station; this is called multiple access.

There are several methods of modulation, multiplexing, and multiple access that may be used in various combinations. Multiplexing and multiple access require sharing the satellite resources to carry various signals. These resources can be shared by using different frequencies, by taking turns (time division), by using different antenna beams, or by using different polarizations. Signals such as telephone and television may be analog or digital. Theoretically, any method can be used for either type of signal. In practice, time division is easier with digital signals, while frequency division is easier with analog signals.

Modulation. There are three basic modulation methods, which change the amplitude, frequency, or phase of a carrier. In amplitude modulation (AM), the amplitude of the carrier is varied in proportion to the input signal. In frequency modulation (FM), the frequency of the carrier is varied in proportion to the input signal. FM is less susceptible to noise and interference than AM. In phase modulation (PM), also called angle modulation, the phase of the carrier is varied in proportion to the input signal. This also varies the frequency of the carrier, but much less than FM, since the variation is never more than one cycle.

Phase-shift keying (PSK) is a digital version of phase modulation in which the phase of the carrier is changed depending on certain bit sequences. This is the most common form of modulation used on communications satellites today. *See* AMPLITUDE MODULATION; FREQUENCY MODULATION; MODULATION; PHASE MODULATION.

Multiplexing. Most communications satellites handle many signals. Multiplexers are used to combine signals before they reach an Earth station, at the Earth station, or in the satellite. The most common forms of multiplexing used in satellite communications are frequency-division multiplexing (FDM) and time-division multiplexing (TDM). As a simple illustration, in the case of a radio or television receiver, different broadcast stations are transmitted at different frequencies (FDM), while different programs may be on one station, but received at different times (TDM).

Frequency-division multiplexing is often used to combine telephone channels. This may be done before the signals reach the Earth station, and then the resulting trunks may be multiplexed together at the station. Each signal is converted to an assigned frequency band, and then the signals can be combined. For example, if two phone channels have frequencies of 0–10 kHz, one channel can stay at the same frequency and another channel can be converted to 10–20 kHz. These two channels can be combined into one 0–20 kHz signal. Many other channels can be converted to other frequency bands and combined. The combination can then be sent up to a satellite and down to another Earth station, where demultiplexers reverse the process and separate the different telephone channels.

Time-division multiplexers were introduced in telephone networks when voice calls were digitized. At 64,000 bits/second, the voice signal can be sampled 8000 times per second, and each sample digitized to 8-bit accuracy. These digitized voice signals can be multiplexed with other voice channels to form digital streams with many more bits/second, extending to standardized streams as high as billions of bits per second, for use in communications satellites, as well as fiber optic and microwave services. Once information is digitized, it can be multiplexed with any other type of digitized information.

Multiple access. Several Earth stations can send signals, including voice, data, teletype, facsimile, television, and digitized data, simultaneously to the same satellite. This is called multiple access. Multiple access is similar to multiplexing signals into a satellite, but the different Earth stations must coordinate their transmissions. There are several ways to share access to a satellite: dividing the frequency band (frequency-division multiple access or FDMA); dividing access in time (time-division multiple access or TDMA); dividing access in space (space-division multiple access or SDMA) via spot beams or polarizations, for example; or by using different codes to divide the access (code-division multiple access or CDMA).

In FDMA, each Earth station has exclusive use of an assigned bandwidth between specified frequencies. The strength of the signals must be balanced, so that a strong signal at one frequency does not interfere with a weak signal at a neighboring frequency. Individual carriers may also have different power, bandwidth, and quality requirements, which all must be balanced so that each station is satisfied.

In TDMA, each Earth station has an assigned time to use the entire bandwidth or a portion of it. A prearranged schedule is used to avoid overlapping transmissions so that at any time the satellite has only one signal present within each TDMA channel. TDMA systems are flexible, and can accommodate traffic variations among stations by increasing or decreasing the duration of each station's bursts to match the traffic flow.

Random multiple access (RMA) is a variation of TDMA in which the available time is not assigned to individual stations. This system, also called ALOHA, was devised at the University of Hawaii. It allows small, inexpensive Earth stations to communicate through a satellite with a minimum of protocols and no network supervision. When a station needs to transmit, it sends a burst of data pulses, and then watches the downlink. If it sees a corrupted signal, it knows that another station is transmitting. It then waits a short, random time before trying again. If there is not too much traffic, the signal is eventually transmitted with no interference.

In CDMA, the transmitting Earth station uses a unique digital code to spread each signal over a bandwidth much wider than is actually needed. The receiving station uses the same code to retrieve the information. Other networks may operate simultaneously within the same bandwidth, as long as different, noninterfering (orthogonal) codes are used for different signals. *See* MULTIPLEXING AND MULTIPLE ACCESS.

Antennas. Antennas are passive devices used to collect the signal (radio-frequency power) incident on a satellite, and to radiate an amplified signal from the satellite. Inside the satellite, radio-frequency power is often guided by waveguides, or hollow metal pipes with circular or rectangular cross section. If a waveguide is open at one end, it will radiate some power, but not very efficiently. If the open end is flared out like a cone, it will be more efficient as a radiator. *See* WAVEGUIDE.

If an antenna is a good radiator, it is also a good receiver. Its properties are reciprocal. At the same frequency, it has the same pattern for transmitting and receiving. If it transmits a lot of power in a certain direction, it will also be good at receiving power from that same direction.

Types of antennas. A horn is an open waveguide designed to radiate maximum power. Close to the radiating end, the opening increases in size. The angles and surfaces (smooth, steps, or corrugations) are chosen for maximum performance. A horn is simple and reliable. Communications satellites use horns for global beams, which radiate over the entire Earth, facing the satellite. Horns may also be used for telemetry and command signals, which radiate in many directions.

A parabolic antenna is the type most commonly used in communications satellites. It has a feed, similar to a horn, and a parabolic reflector. The feed radiates a wide beam, aimed toward the reflector. The reflector surface has the shape of a paraboloid, made by rotating a parabola around its axis. The feed is at the focus of the parabola so that the reflector focuses the radiation into a narrow beam. Like the reflecting telescopes used by astronomers, parabolic reflectors work over a wide range of frequencies. That is, they have the same focus for different colors (they are free of chromatic aberration).

For Earth stations, large parabolic antennas usually have an on-axis feed located in the reflected beam (**Fig. 3***a*). Since the feed is small compared to the reflector diameter, it obstructs only a small part of the reflected beam. On small antennas, an offset feed may be placed outside of the reflected beam (Fig. 3*b*). The reflector is still part of a paraboloid, and the feed is still at the focus, but the reflector is part of one side of a paraboloid.

Antenna gain. The gain of an antenna is the ratio of how much better it radiates in one direction (beam center) than an ideal isotropic radiator, which radiates equally in all directions. The antenna gain G of a parabolic reflector is given by Eq. (1), where A is

$$G = 4\pi \eta A/\lambda^2 \qquad (1)$$

the physical area of the reflector, η is the antenna efficiency, and λ is the wavelength. The antenna efficiency accounts for imperfections in the antenna, and is always less than unity. The gain can also be calculated as $109\eta D^2 f^2$, where the diameter, D, is in meters (m), and the frequency, f, is in gigahertz (GHz). Thus, the gain of a parabolic antenna is higher for larger reflectors and for higher frequencies. As an example, an INTELSAT Earth station may have a 30-m (98-ft) antenna, transmitting at 6 GHz, with an efficiency of 0.60. Its antenna gain, G, is a ratio greater than 2,000,000.

Antenna beamwidth. A good antenna focuses the power in one direction, but only at the expense of power in other directions. The antenna is a passive device. It does not amplify the total power. With a good parabolic antenna, the power decreases rapidly as the angle from the beam axis increases. A useful definition of beamwidth is the angle over which the power has dropped to one-half of the peak value. This is called a half-power beamwidth. An approximate, but useful, equation for the half-power beamwidth of a parabolic antenna (in degrees) is given by Eq. (2), where, again, frequency, f, is in

$$\theta = 21/(fD) \qquad (2)$$

gigahertz and antenna diameter, D, is in meters. The number 21 is not a true constant, but may vary somewhat for different antennas. The INTELSAT antenna just described would have a beamwidth of 0.1°.

Antenna coverage. An Earth station antenna usually transmits to and receives from a single satellite. The maximum gain is desired in one direction, and a simple parabolic antenna often provides excellent performance. However, a satellite antenna often communicates with several Earth stations. In this case, the aim is to achieve a minimum gain anywhere in a given region. This region may be a country, a group of

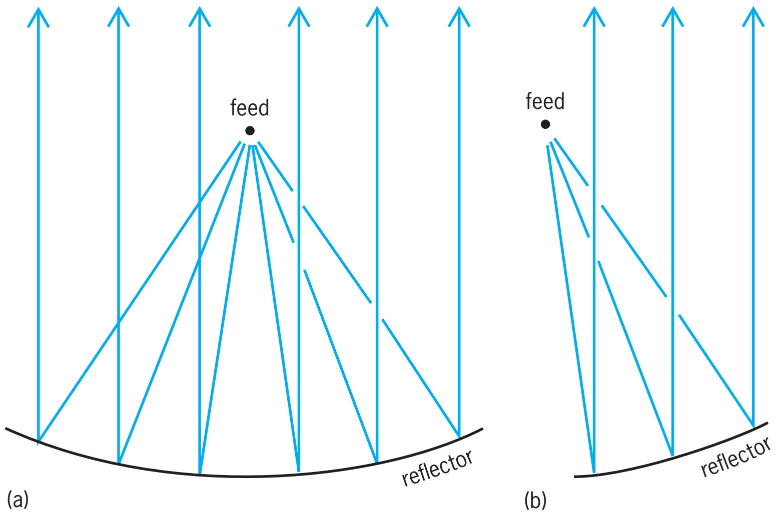

Fig. 3. Parabolic antennas. (*a*) On-axis feed. (*b*) Offset feed.

countries, or a time zone within a country. Because the power outside the desired region is wasted, it should be minimized. Circular and elliptical patterns can be generated with a single feed and a reflector. More complicated patterns can be generated with a single parabolic reflector and several feeds, or a single feed and a specially distorted reflector. In the case of a multifeed antenna, the designer often varies the number of feeds, their location, the power in each feed, and the phase. A computer is used to calculate the pattern for each variation, and the variables are adjusted until a near-optimum pattern is obtained. *See* ANTENNA (ELECTROMAGNETISM).

Receivers. The signal from the Earth station enters the satellite receive antenna and is amplified by the satellite receiver. Because the received signal is at a very low power level, the first few stages should amplify the signal without introducing additional noise. These initial amplifier stages are called a low-noise amplifier. After the signal has been amplified by the initial stages, its higher power level is less likely to be affected by noise.

The receiver also shifts the carrier frequency of the received signal. In a satellite it must be shifted to a different frequency before it is transmitted. Otherwise, the high-power transmitter would overwhelm the sensitive receiver. In an Earth station the frequency is often shifted to a lower frequency for ease of handling. It is most efficient to shift the frequency of the signal at low power levels. After the initial amplification stages, the frequency is changed, followed by additional amplification.

Power amplifiers. Traveling-wave tubes (TWTs) are often used in satellites to generate the high levels of radio-frequency power required. The power output of a traveling-wave tube increases as the power input is increased. As in any amplifier, the power output has a practical maximum; at this maximum, the traveling-wave tube is operating in a nonlinear mode called saturation. In satellite communications, maximum power is often desired, but it sometimes does not result in the best performance. For some operations, it is necessary to "back off" from the maximum, to find a linear portion of the output versus input curve. This decreases the distortion near saturation, and reduces crosstalk, when one user's communications cross over to a different user's channel at a different frequency. *See* CROSSTALK; SATURATION; TRAVELING-WAVE TUBE.

Solid-state power amplifiers (SSPAs) are also used in satellites when they can supply the desired power output. SSPAs have several stages of amplification. The maximum power is often limited by the heat dissipated by the amplifier. This heat can be conducted to larger surfaces and then radiated away. If enough heat cannot be dissipated, the temperature increases and may lead to failure of the amplifier. *See* POWER AMPLIFIER; MICROWAVE SOLID-STATE DEVICES.

Satellite Performance (Link Budget)

A communications satellite is built to be operated with specified Earth stations. Its communications performance, described in terms of a link budget, is evaluated as the power of the received signal relative to the sources of noise in the link between two Earth stations. The total link budget represents both parts of the link: the uplink from Earth station to satellite and the downlink from satellite to a second Earth station.

For each link a "good" signal must be received. The system designer must decide whether to spend more money for a more powerful transmitter, larger antennas, or a better receiver. To find the best system, the designer must work with a budget for each of the two links. One example of a downlink budget starts with a transmitter power of 180 W (**Fig. 4**, right). An antenna increases the power to an apparent 180,000 W, a loss in space drops this to 4×10^{-16} W, and the Earth station antenna increases this to a received power of about 10^{-12} W. A similar calculation is made for the uplink budget (Fig. 4, left). The other part of the calculation for each link, is to see if this is a "good" signal, that is, if it is larger than the noise by a sufficient margin.

Decibels. In both the uplink and the downlink, the power transmitted, P, is a large number of watts, and the carrier power received, C, is usually a very small number of watts. It is easier to express these numbers in decibels rather than in absolute quantities. Ratios were first expressed as decibels in measurements of sound intensity. The bottom of the scale was determined (the minimum intensity that can be heard), and any measured sound intensity could then be expressed in decibels, as an absolute measurement.

To express a quantity in decibels, the common logarithm of the absolute quantity is taken, and the result multiplied by ten, that is, $10 \log_{10}(\ )$. There are two main reasons for using decibels: (1) decibel notation makes it easy to write and understand very small and very large numbers, and (2) it is easier to calculate the cumulative effects of gains and losses along the link path by addition rather than multiplication.

In calculating link budgets, the unit abbreviation is attached to "dB." For example, 10 million watts, or 10^7 W, is expressed as 70 dBW. In calculating satellite performance, not only are many numbers expressed in decibels, but equations are often written in decibel format, with addition and subtraction symbols, instead of multiplication and division notation. *See* DECIBEL; LOGARITHM.

Transmitter performance. The start of any radio-frequency transmission in space is the output of the power amplifier from either the satellite or the Earth station. The transmitter should transmit the maximum power in the direction of the intended receiver. This is done by using an amplifier with maximum output power, P, and a transmit antenna with maximum antenna gain, G_t. The product of the transmitter power (in watts) and the antenna gain (as a ratio) is known as the equivalent isotropically radiated power or EIRP (in watts or dBW). From the receiver's point of view, the transmitter appears to be radiating this amount of power (and, it would be radiating this amount of power if it were radiating equally in all directions).

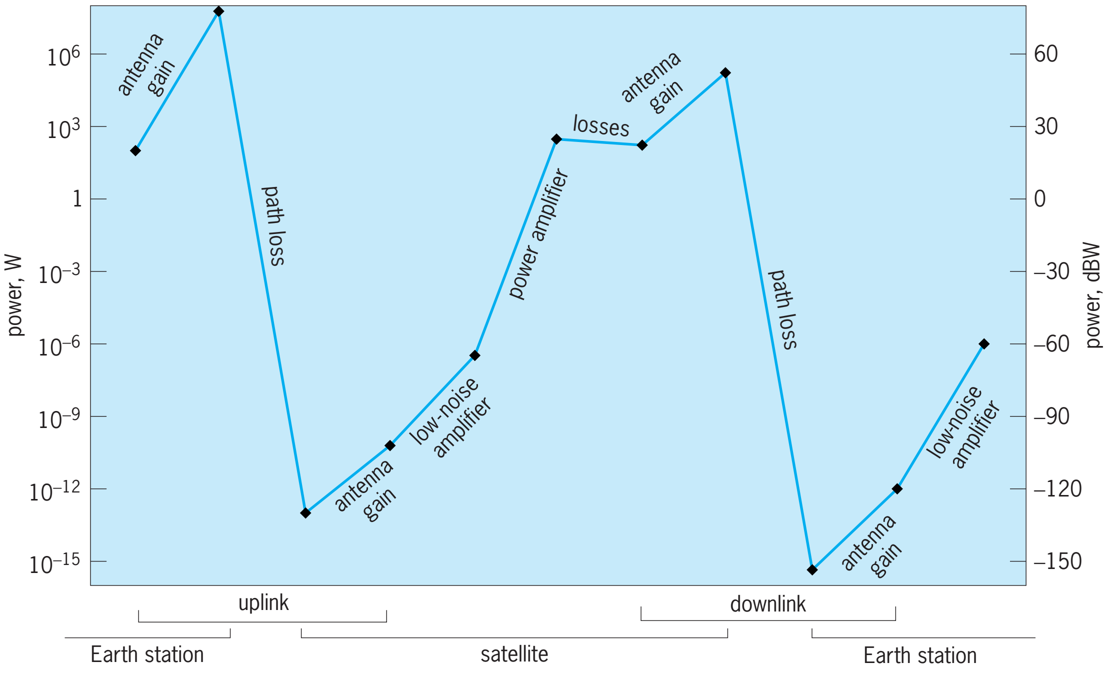

Fig. 4. Power levels for a broadcast satellite (link budget). (*Data from Space Systems/Loral*)

Free-space path loss. In almost any transmission of radio frequencies, most of the power is lost in space. In transmission to and from communications satellites, the distances are larger, so the losses are larger. The distance S from an Earth station to a satellite is enormous—more than 35,000 km (22,000 mi) for a geostationary satellite. The power will spread over a large area of $4\pi S^2$, and the receive antenna only intercepts a small area A, reduced by the receive antenna efficiency η. The received carrier power C is then given by Eq. (3). If the value of ηA from Eq. (1)

$$C = \frac{PG_t\eta A}{4\pi S^2} \tag{3}$$

is substituted in Eq. (3), the received carrier power C can be written as Eq. (4), where P is the transmitter power, and G_t and G_r are the gains of the transmit antenna and receive antenna. The transmitter power, P, is increased by the two antenna gains, and reduced by the loss in space. The free-space path loss, L, is found to be $(4\pi S)^2/\pi^2$. Since the wavelength λ of the carrier is very small and the distance S is very large, the free-space path loss is a very large ratio.

$$C = PG_t(1/L)G_r \tag{4}$$

The reason for introducing the receive antenna gain G_r into Eq. (3) is to treat both antennas in the same way. Antennas are reciprocal: an antenna used to receive has the same gain as it would to transmit, providing that gain is measured at the same frequency. A numerical example of Eq. (4) is given at the top of **Table 2**. The transmitter power per channel is 180 W. The transmit antenna increases this by a factor of 1000. The reciprocal of the free-space path loss is a factor of 2.3×10^{-21}, which with a receive antenna gain of 2500 results in a carrier power received of 1.04×10^{-12} W.

TABLE 2. Performance of the downlink, from a broadcast satellite[*]

Symbol	Description	Number	In decibels[†]
P	Transmitter power per channel	180 W	22.5 dBW
G_t	Transmitter antenna gain	1000	30.0 dB
$1/L$	1/Free space path loss[‡]	2.3×10^{-21}	−206.3 dB
G_r	Receiver antenna gain	2500	34.0 dB
C	**Carrier power received**	**1.04×10^{-12} W**	**−119.8 dBW**
T_s	Noise temperature	125.0 K	21.0 dBK
k	Boltzmann's constant	1.381×10^{-23} W/Hz-K	−228.6 dBW/Hz-K
B	Bandwidth	24,000,000 Hz	73.8 dBHz
kT_sB	**Noise received**	**4.1×10^{-14} W**	**−133.8 dBW**
C/kT_sB	Carrier-to-noise ratio	25	14.0 dB

[*] Data from Space Systems/Loral.
[†] Decibels are explained in the text. Example: $10 \log_{10}(180\text{W}) = 22.5$ dBW.
[‡] Path is 39,500 km (22,544 mi) from satellite to Earth; radio frequency is at 12.5 GHz.

Noise. The carrier power received is important only when compared to the noise present in the system. Without additional information, it is difficult to determine whether the received carrier power of 1 trillionth of a watt is sufficient. If no noise is present, the signal can be amplified to any desired power; however, if there is too much noise present, the received signal is useless. The noise may come from many sources. The noise may be directly incident on the antenna (such as the Sun in the antenna beam axis), it may leak in from the sides (from antenna sidelobes), it may be added between the antenna and receiver (waveguides may not be perfect), or it may be inherent in the receiver (from the "low-noise amplifier").

In satellite communications, the noise power is often expressed as a system noise temperature T_s, equivalent to that radiated by a blackbody at the specified temperature. This noise is usually present over a broad band of frequencies, and most of it can be filtered out. However, the desired signal occupies a narrow band, and the noise in that band cannot be filtered out. For an audio signal the bandwidth might be only 10 kHz, while for a television channel it might be 24 MHz. When the noise temperature, T_s, the bandwidth, B, and Boltzmann's constant, k (a fundamental physical constant), are multiplied together, the result is the noise received, in watts. In the example in Table 2, the noise temperature is 125 K ($-148°$C), and the bandwidth is 24 MHz, so the noise power received is 4.1×10^{-14} W. Usually, the noise temperature is lower for a downlink, since the receive antenna on the ground "sees" cold space as background, while in an uplink, the receive antenna "sees" the warmer earth. *See* BOLTZMANN CONSTANT; HEAT RADIATION.

The values in the right column of Table 2 are in decibel notation. To calculate the carrier power received, the first four numbers are added instead of multiplied. To find the noise power, the decibel values of T_s, k, and B are added. The final carrier-to-noise ratio, 14.0 dB, is determined by subtracting the noise (-133.8 dBW) from the carrier power (-119.8 dBW).

In this example, the ratio of carrier to noise is 25, which means that the signal is 25 times stronger than the noise. The minimum ratio required depends on the specific application. During the design phase, if the ratio is too low, some changes must be made in the link to achieve an acceptable value. For example, the transmitter power or the size of one of the antennas might be increased.

System performance. Usually, a communications satellite receives a signal from an Earth station and sends it back to another Earth station. The system performance depends on the uplink (Earth to satellite), and the downlink (satellite to Earth). To combine the two ratios, the noise per carrier for each link must be added. Therefore, the reciprocals of the carrier-to-noise ratios must be added, and then the reciprocal taken of the result. If the uplink carrier-to-noise ratio (C/N_u) is 240 and the downlink carrier-to-noise ratio (C/N_d) is 25, then the total carrier-to-noise ratio (C/N_t) is 22.6. In general, the combined ratio is less than that of either of the links.

Losses. In addition to free-space path loss, there may be many other losses in power. Some are negligible, while others are significant. The transmitter and the transmit antenna are usually connected with a waveguide that may have losses. Similarly, there may be losses between the receive antenna and the receiver; to minimize these, the receiver is mounted as close to the antenna as possible.

Geometric loss results from spreading the signal over a large area. Additional losses may be incurred in going through the Earth's atmosphere. At certain frequencies, especially above 10 GHz, there are absorption bands from oxygen and water vapor in the air. For low-elevation angles from the Earth station to the satellite, these bands produce more absorption because the beam has a longer path in the atmosphere. The presence of raindrops in the atmosphere can increase both the attenuation and the noise level in the signal. Both the decrease in the carrier signal and the increase in the noise result in a decrease of the all-important ratio of carrier to noise power.

Margin. Some losses are fixed, some slowly increase with time, and others fluctuate with time. Some losses are known, and some are unknown. To compensate for all these losses, a system is designed with a margin. This means that the system has more capability (a higher total carrier-to-noise ratio) than needed. When a loss is larger than expected, the margin decreases, but the system continues to operate according to specifications. The power of Earth station transmitters can usually be adjusted, especially when several stations are transmitting to one satellite at the same or adjacent frequencies. The satellite transmitted power can also be adjusted by ground-controlled attenuators.

Space Technology

Much of the space technology used in communications satellites is also used in many other satellites in near-Earth orbit. This section deals primarily with the technology specially for communications satellites. *See* SPACE PROBE; SPACE TECHNOLOGY.

Orientation. Many communications satellites are three-axis body-stabilized, that is, they have one axis pointed north, one axis pointed toward Earth, and the third more or less parallel to the velocity vector along the orbit. The orientation is measured with Sun sensors (the simplest method), Earth sensors (or horizon sensors), or radio-frequency sensors. Any error in attitude is corrected by actuating wheels with rotational inertia. The simplest arrangement to visualize is three reaction wheels, each used to correct for errors around the three axes. For redundancy, four reaction wheels may be used, with each axis at the same angle from the other three (109.5°). Some satellites have either a fixed momentum wheel or a gimballed momentum wheel that always turns in the same direction. Note that gyroscopes are wheels used only as sensors, reaction wheels rotate in either direction, and momentum wheels rotate always in the same direction. When a wheel reaches its maximum allowed rotation speed, a thruster is fired to exert a torque that causes the wheel to slow down. *See* GYROSCOPE.

Structure. A typical communications satellite has a compact rectangular body, with various antennas, thrusters, and solar arrays mounted on external surfaces. After launch, the two solar arrays are unfolded (deployed) in the north and south directions, and mounted so that they can rotate around this north-south axis to face the Sun continually. Usually, there is no correction for the annual north- south motion of the Sun. The structure needs to be light, strong enough to withstand the acceleration and vibration of launch, and stiff enough to keep antennas pointed accurately. Therefore, it is made of light metals (aluminum, beryllium, magnesium, or titanium) or a composite (boron/epoxy or graphite/epoxy). *See* SPACECRAFT STRUCTURE.

Propulsion. Thrusters are used for both attitude control (satellite orientation) and station keeping (satellite positioning). The most common propellant is hydrazine (N_2H_4). This monopropellant needs no oxidizer; when heated, it decomposes and generates more heat. The simplest system has pressurized nitrogen inside the tank with the hydrazine to expel the fuel from the tank (blow-down system). There is no apparent gravity in orbit, so either a bladder or a surface tension system is needed to ensure that fuel rather than nitrogen comes out of the tank. *See* HYDRAZINE; ROCKET PROPULSION; SPACECRAFT PROPULSION.

Electric power. A communications satellite uses most of the available power for the power amplifiers: either traveling-wave tubes or solid-state power amplifiers. Primary electrical power is provided by solar cells mounted on solar arrays, and secondary power is provided by rechargeable batteries. These components must be connected with appropriate regulation, conversion, and distribution. Deployed solar arrays get cold during eclipse, and generate excess voltage when they come out of eclipse. Batteries require a higher voltage during charge, and provide a lower voltage during discharge. Solid-state power amplifiers need only a few volts. Traveling-wave tubes require a few volts for the filament heater, but over 1000 V for acceleration of the electron beam. Because solar arrays lose power due to particle radiation in space over many years, they are built with excess power. Some batteries have a limited life, but with careful construction, testing, and operation, they provide excellent service. *See* RADIATION DAMAGE TO MATERIALS; SPACE POWER SYSTEMS.

Thermal control. In many communications satellites, the majority of the electric power is used by the power amplifiers. While these amplifiers generate lots of radio-frequency power, they are not 100% efficient, so they also generate heat. Dissipation of this heat is a key element in the thermal control of communications satellites. The north and south faces are often used for heat dissipation, since they receive less sunlight than the other surfaces. These surfaces have low absorptivity to visible light, including sunlight, and high thermal emissivity to radiate the heat into space. The heat is conducted to these faces with solid metal or with heat pipes. The power amplifiers are mounted on or near the inside of these surfaces. With solid-state power amplifiers, the small integrated circuit chip is mounted on a metal heat sink that absorbs and spreads the heat to limit the chip temperature.

Telemetry and command. The objective of the telemetry subsystem is to provide information about the spacecraft for operational use, failure analysis, and prediction of spacecraft performance. The command subsystem receives commands from the spacecraft control center and executes them. Some commands are used to reconfigure the communications subsystem, to fire thrusters, and to switch to redundant equipment when needed.

Since telemetry and command are essential for failure recovery, the antenna coverage must be nearly omnidirectional. This enables recovery even when control of orientation has been lost, and the main antennas no longer point at the Earth. If the available power decreases, other equipment is turned off automatically so that the telemetry and command subsystems will still have power. *See* TELEMETERING.

Tracking. The location of a satellite can be measured by determining its distance from two or three Earth stations. The distance is determined from the transit time of radio signals. This measurement is independent of the processing of telemetry and command signals, but uses the same command receiver and telemetry transmitter. The transit times may be measured by transmitting tones of different frequencies and finding the phase relations of the returned signals. The transit times can also be measured by transmitting a pseudorandom series of bits, and measuring the time delay for which there is most correlation between the transmitted and received signal—when they match. From a series of measurements, the location of the satellite at various times can be determined. Thruster firings are then scheduled to keep the satellite in the desired location.

Reliability. Large velocity changes are needed to launch satellites into space. Once launched, satellites are difficult to repair and expensive to replace. Therefore, satellites must function when they are first launched, and continue to perform for many years. This task is similar to building a car that will go over 200,000 km (over 125,000 mi) without maintenance or repair. Satellites achieve a long life by having inherently reliable components, redundant subsystems, and a rigorous test schedule before launch.

Communications satellites have an excellent record. The launch reliability, including both the launch vehicle and initial operation of the satellite, may be 75% for early launch vehicles and new programs and as high as 95% for mature operations. The probability of their reaching a design lifetime of 12 or 15 years may be calculated as 75%, and is often exceeded. This excellent record, in addition to larger satellites handling lots of traffic, has drastically reduced the cost of communications, including overseas phone calls. For example, a computer

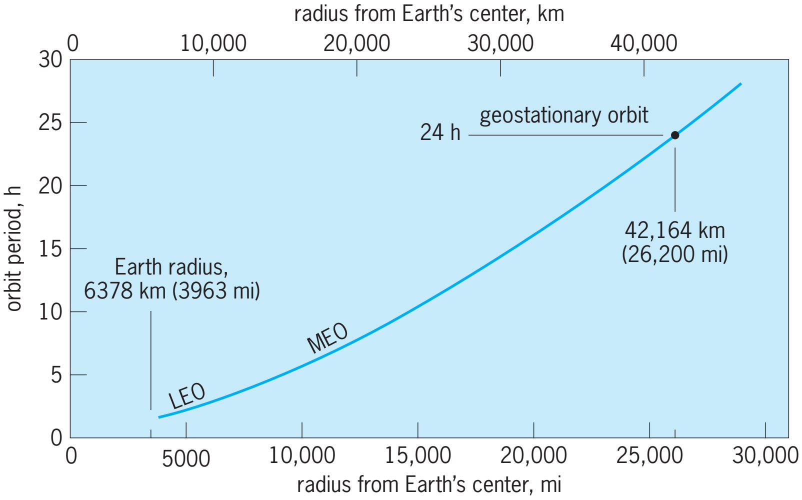

Fig. 5. Orbit periods of circular orbits.

may be purchased at a nearby store, but the technical assistance may be halfway around the world, via satellite. *See* RELIABILITY, AVAILABILITY, AND MAINTAINABILITY.

Orbits

Communications satellites circumnavigate the Earth in a path called an orbit. The majority are in a very special orbit, called a geostationary orbit. Other orbits are also used, due to advantages in launching the satellite, keeping the satellite in place (stationkeeping), or communicating with desired earth stations.

Geostationary orbit. The first characteristic of a geostationary orbit is that the path is circular (eccentricity is near zero), so the satellite is always the same distance (radius) from the center of the Earth. When the radius is larger, the time to go around increases, both because of the larger distance and because the satellite has a smaller velocity (**Fig. 5**). The second characteristic is that the geostationary orbit have a period of rotation exactly equal to the time it takes the Earth to rotate around its axis (23 h, 56 min, 4.1 s). This occurs for a satellite 35,786 km (22,237 mi) above the Earth's surface, or 42,164 km (26,200 mi) from the center of the Earth. For low Earth orbits (LEO), the period is only a few hours; for medium Earth orbits (MEO) it is longer. For a very large radius of 384,300 km (238,860 mi), the orbit period would be 27.3 days, which corresponds to the Moon's orbit around the Earth.

A third characteristic of a geostationary orbit is that the orbit must be in the equatorial plane. Otherwise, the satellite would have a north-south oscillation. Since the satellite orbit period is the same as the time it takes for the Earth to complete a rotation, the satellite is always over the same point (longitude) on the Equator. And, most importantly, since the satellite is always at the same height over the same point on the Equator, it appears to be stationary in the sky to an observer on the Earth. Once an Earth station antenna is pointed at the satellite, it will remain pointed at the satellite.

Different points along the Equator can be identified by their longitude. Longitudes may range from 0 to 360° E, or they can be written from −180° to +180° E. Negative east longitudes are simply west longitudes (west from the Greenwich meridian). The longitude of a geostationary satellite is the longitude of the point on the equator directly underneath the satellite.

Azimuth and elevation. To point an antenna at a satellite, it is useful to know the satellite's azimuth and elevation as seen by an observer on Earth. The azimuth is the direction of the satellite, measured in the horizontal plane from geographic north in a clockwise direction (starting eastward). The elevation is the angle between a satellite and the observer's horizon plane.

For an observer in the Northern Hemisphere, geostationary (GEO) satellites appear placed in an arc in the southern sky, as shown in **Fig. 6**. The top curve in the figure is for an observer at 10° N latitude. Satellites are shown for differences of 2° longitude (satellite longitude minus station longitude). The lower curves are for observers at other latitudes (30° N, 50° N, and 70° N), with satellites having 10° spacing. The azimuths are between 90° and 270°. For an observer in the Southern Hemisphere, the geostationary arc appears in the northern sky, and the azimuths are in the ranges 270° to 360°, and 0° to 90°.

If the longitude of the satellite is equal to the longitude of the observer (Earth station), then an observer in the Northern Hemisphere would find the satellite directly south (azimuth = 180°). When the longitudes of the satellite and observer are different, then the elevations are lower, and the azimuth (direction) is no longer due south.

Stationkeeping. If the Earth were perfectly spherical and there were no other perturbing forces, a satellite inserted into geostationary orbit would remain there indefinitely. But there are perturbing forces, and over time the orbit of a satellite changes. For a communications satellite to perform its mission, small thrusters must be used to counteract these forces and keep the satellite in its desired location. This is called stationkeeping. Without these thrusters, a geostationary satellite would have significant longitudinal drift, north-south oscillations, east-west oscillations, and radial oscillations.

The longitudinal drift is caused by irregularities in the Earth's shape around the Equator, unknown until artificial satellites were launched. Specifically, the equatorial cross section is not circular. This causes a change in the longitudinal drift, which can be a longitude acceleration of as much as 0.002 (degree)/(day)^2. This is small, but over many days the satellite would move to a different longitude. The change in longitude can be pictured as a weight sliding downhill, as in **Fig. 7**. The figure shows two low points, around 75°E and 252°E. A satellite at one of these stable longitudes will stay there, and a satellite near that longitude will oscillate about that longitude. The first commercial communications satellite, *Early Bird*, was stationed at 310°E and kept there by use of its thrusters. When it ran out of fuel, it "slid down the hill" to 252°E, and up the other side to 200°E. Around 200°E, it reversed,

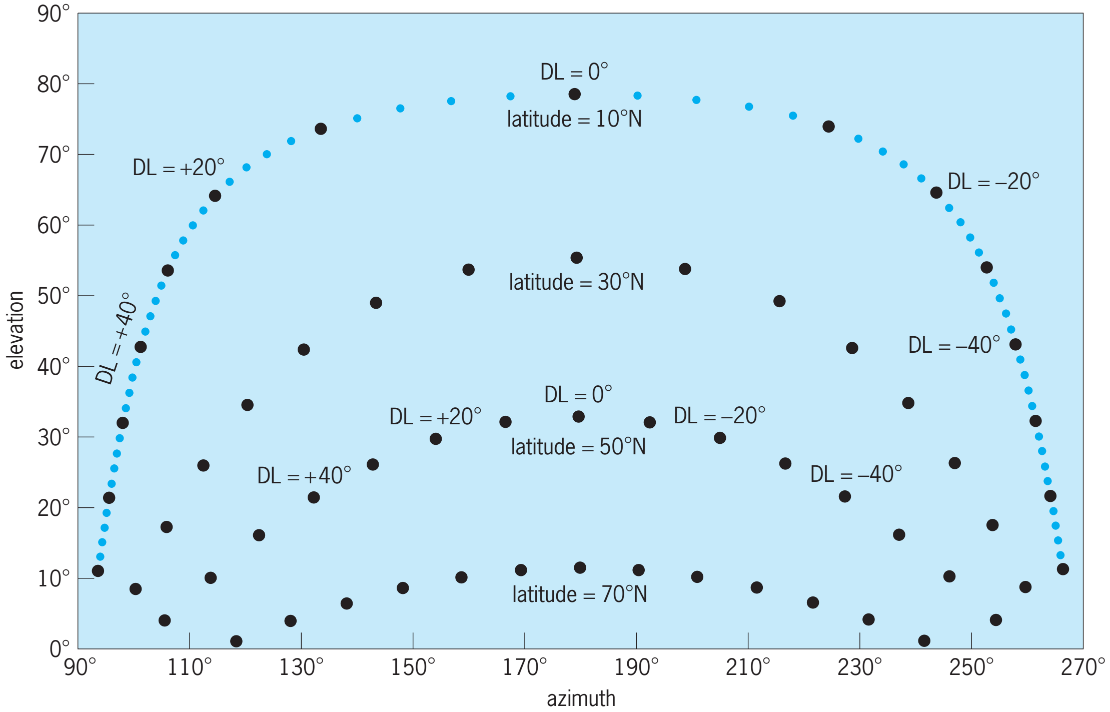

Fig. 6. Azimuth and elevation of geostationary satellites. DL = satellite east longitude − station east longitude.

and came back to 310°E. It continues to go back and forth every 3 years. *See* EARTH, GRAVITY FIELD OF.

The daily north-south oscillations of the satellite are caused by gravitational attractions of the Sun and Moon. These cause the orbit plane to tip with respect to the equatorial plane. Instead of remaining over one spot on the Equator, the satellite shows a daily cycle of going into the Northern Hemisphere and then the southern hemisphere. If unchecked, this north-south oscillation will increase to 15° in about 26 years, and then return to zero. In practice, controlling these north-south oscillations takes the major part of a satellite's fuel. Near the end of the satellite's life, the fuel may be reserved for longitudinal control, and the north-south oscillations allowed to increase.

The daily east-west oscillations of a satellite are caused by solar radiation pressure, which is 4.57×10^{-6} N/m^2 (6.6×10^{-10} psi) at the Sun-to-Earth distance. On one side of the orbit, the force increases the velocity, and on the other side it decreases it. These forces change an initially circular orbit into an elliptical orbit. On one side the satellite is going faster than the Earth, and the satellite moves eastward in longitude, and on the other side, 12 h later, the satellite is moving westward. The eccentricity would continue to increase, except that after 6 months the sunlight comes from the opposite direction, and the effect is reversed. Satellite maneuvers are usually not done just to control eccentricity. When thrusters are fired to control the mean longitude, they also affect the orbit eccentricity. Choosing the best time of day for these maneuvers usually allows the orbit eccentricity to be kept within acceptable limits.

Daily radial oscillations also take place with eccentric orbits, as the distance between the satellite and the center of Earth varies. In terms of actual distance (kilometers or miles), the daily radial oscillation is exactly one-half of the east-west oscillation. For antenna pointing, the radial oscillations are usually not important. In a few applications, involving digital communications, radial oscillations may become significant, as both the frequency received and the time delay have a daily variation.

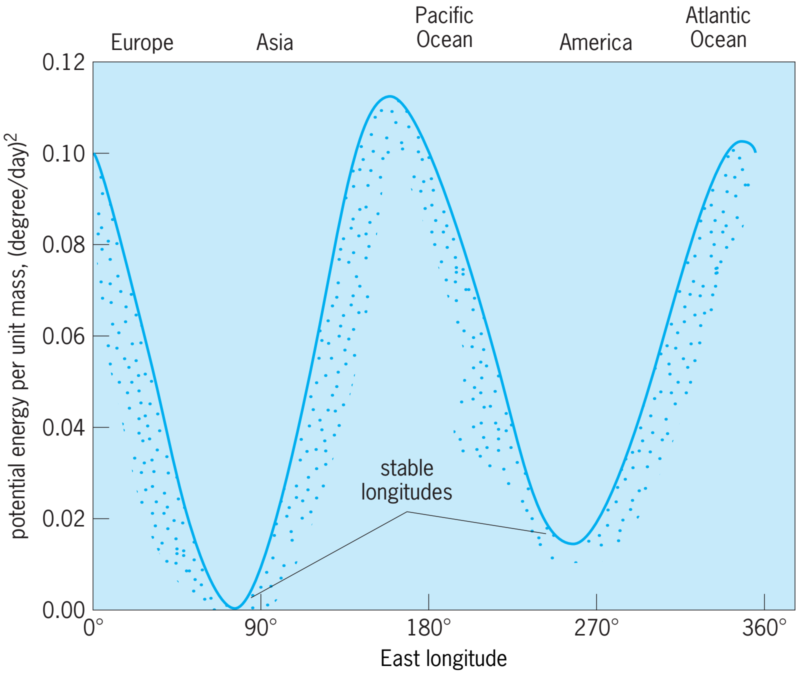

Fig. 7. Longitudinal acceleration pictured as hills and valleys. A satellite tends to "slide downhill." (The vertical scale, which is the potential energy per unit mass, is also the integral of the longitude acceleration with respect to longitude.)

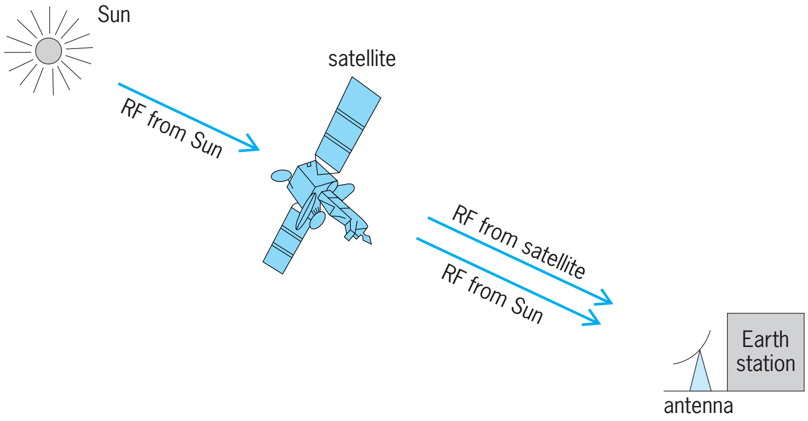

Fig. 8. Sun-station interference. Radio-frequency (RF) signals from the Sun interfere with those from the satellite.

Satellite link delays. A signal goes from Earth to a satellite at the speed of light, which is 299,792 km/s (186,282 mi/s). This means that there is a time delay between sending and receiving a signal. The distance to a communications satellite in geostationary orbit can vary from 35,786 km (22,237 mi) to 41,679 km (25,898 mi), so the time delay is from 0.12 to 0.14 s. The usual phone conversation through a satellite includes an uplink and a downlink from one speaker to another, and then a return through another uplink and downlink. Therefore, there are four time delays in sequence. The total delay is about half a second. This time delay can be a problem when the two speakers start speaking at the same time. It also produces an echo if equipment is not operating properly. Suppressing the echo requires special equipment because local phones have only a pair of wires to transmit and receive. Lower-altitude satellites, not in geostationary orbit, will have less time delay.

Sun, Earth, and Moon effects. The Sun emits radio-frequency radiation at microwave frequencies. This radiation can produce noise in a communications downlink, when the Sun is in the beam of the Earth station antenna receiving the satellite signal. The worst interference occurs when the satellite is directly between the Earth station and the Sun (**Fig. 8**). At different times, this condition may affect the downlink of every geostationary communications satellite to any Earth station. This Sun-generated noise may be a minor annoyance, or may completely overwhelm the transmitted signal. However, interference occurs only a few consecutive days in the spring and a few days in the fall, and it lasts only several minutes each day.

The Earth casts a shadow into space. Except for a few minutes at the start and end of the shadow period, these are total eclipses. When a geostationary satellite is in the shadow, the solar array output drops to zero. To continue operation, power is furnished by rechargeable batteries. These eclipses occur in two 6-week periods in the spring and in the fall. The duration of the eclipse increases to a maximum of 70 min (which occurs on the vernal and autumnal equinox), and then decreases again to zero over that period.

The Moon also casts a shadow in space. When a satellite is in the shadow, the solar array output also drops. These eclipses are mostly partial eclipses (the satellite is in the penumbra). The occurrences are irregular, and can occur during any month of the year. Most last less than an hour. A very small number of eclipses are much longer. On September 23, 2014, for example, an unusual partial eclipse on a geostationary satellite at 180° E will last over 3 h. A few similar eclipses of long duration occur every 18.6 years (when the Moon's orbit plane is closest to the equatorial plane). *See* ECLIPSE; MOON.

Launching into geostationary orbit. A communications satellite is often launched into geostationary orbit in three steps, which requires three firings of rockets or thrusters. The first step is a launch into a parking orbit, a low circular orbit. The second step is from the parking orbit into a transfer orbit, which has a high point (apogee) near geostationary orbit, and a third step circularizes the orbit and puts the satellite into geostationary orbit. Each rocket firing starts with an initial velocity, produces a change in velocity (called Delta-V), and ends with a final velocity (**Table 3**). The change in velocity is related to the mass ratio, that is, the ratio of the combined rocket, fuel, and satellite masses to the rocket and satellite mass after the fuel mass is used up. The actual numbers depend on various factors, including the launch site, launch vehicles, and height of the parking orbit. If a 1000-kg (2200-lb) satellite is needed in geostationary orbit, the mass in parking orbit is about five times as much, or 5000 kg (11,000 lb).

Constellations of satellites at lower altitudes. Compared to satellites in geostationary orbit, satellites at lower altitudes have smaller orbit periods. This means they cannot continuously communicate with an Earth station. Eventually they will disappear below the horizon. With a number of satellites, it is possible to always have one or more above the horizon. The Earth station can maintain continuous communications by switching from one satellite to another, just as a cell phone in a car switches from one tower to another. *See* MOBILE RADIO.

TABLE 3. Launching into geostationary orbit, from Kennedy Space Center (Florida)

	Initial velocity, km/s (mi/s)	Final velocity, km/s (mi/s)	Delta-V, km/s (mi/s)	Mass ratio
Achieve parking orbit	0.4 (0.25)	7.7 (4.8)	7.3 (4.5)	10 to 1
Perigee firing	7.7 (4.8)	10.1 (6.3)	2.4 (1.5)	5 to 2
Apogee firing*	1.6 (1.0)	3.1 (1.9)	1.8 (1.1)	2 to 1

*Cape Kennedy launch requires extra Delta-V of 0.3 km/s (0.2 mi/s) for 30° orbit plane change.

The advantages of these constellations include ease of communication to a satellite that is closer, ease of launch to lower altitudes, and antenna beams that can focus on smaller areas (thus serving higher-density populations). The major disadvantages are the large number of satellites required, and the large initial cost of manufacturing and launching all the satellites. Many different constellations of satellites have been studied. Usually a symmetrical constellation is planned, with each satellite carefully positioned with respect to the others.

One system, called Globalstar, uses 48 satellites. There are eight circular orbits, each with six satellites. The orbits are inclined at 52° to the Equator, and the ascending nodes (where the satellites pass the Equator going from south to north) are separated by 45°. In each orbit, there are six satellites equally spaced around the orbit. Each satellite provides communications between a handheld phone and a base station that connects to landlines, undersea cables, or satellites that handle international traffic. Technically, this system has been successful, but in the initial phases it has not generated the expected traffic and revenue. Another similar system, Iridium, included intersatellite links, so that any communications path could be established through a series of these satellites to any point in the world.

Other orbits. To meet special needs, other orbits are used by some communications satellites. The former Soviet Union established *Molniya* satellites in a Molniya orbit. This elliptical orbit is inclined 62.9° to the Equator, with a high point (apogee) at the most northern latitude. Special parameters were chosen so that the apogee did not precess to the Southern Hemisphere. Also, the orbit period was one-half of a sidereal day (11 h, 58 min), so every other apogee would always be at the same longitude. Earth stations usually had two tracking antennas, so that they could switch between satellites without a break in communications. The *Molniya* orbit has high-elevation-angle coverage of the Northern Hemisphere, and advantages of long dwell times and economical launches. During the Cold War, there were two hotlines between Washington and Moscow, one using a *Molniya* satellite, the other using a geostationary satellite.

More recently, variations on the Molniya orbit have been proposed for certain communications satellites. These all have in common the use of an inclined, elliptical orbit, with the satellites dwelling at the apogee over the geographic area they are intended to serve. In ITU terminology, they are referred to as HEO (highly elliptical orbit) satellites. Some systems have their orbit period as a submultiple of a sidereal day in order to keep the apogee at an constant Earth longitude. For continuous service, more satellites are required in the constellation because the orbit period is reduced (for example, three satellites for an 8-h orbit).

Satellites for mobile communications are sometimes designed without north-south stationkeeping. These are sometimes called geosynchronous satellites because, while the orbit period is equal to a sidereal day, the orbit inclination results in a daily north-south excursion of several degrees. This reduces consumption of satellite fuel. These orbits are applicable to mobile communications because the beamwidth of the mobile Earth stations tends to be wider, and able to encompass the north-south movement of the satellite without losing signal strength. Mobile applications with narrow-beamwidth Earth-station antennas must be equipped to constantly repoint their antennas because the mobile user may move in different directions and sometimes with pitch and roll. In this case, the additional movement of the satellite by a few degrees in a north-south direction can be easily accommodated. The *Marisat* satellite, for example, started with an inclination of several degrees (resulting in north-south oscillations of several degrees), which over the years first decreased to zero and then started increasing.

Stations in polar regions cannot use geostationary satellites. For those very close to a pole, the satellites are below the horizon, and for those a little farther away, it is difficult to communicate with a satellite at a low elevation. After 25 years, the *Marisat* satellite has an inclination of 15°, so each day it is above the horizon for a few hours. It has outlived its design lifetime, but still has some communications capability. Therefore, the research station at the South Pole can use it for a few hours each day, and other similar satellites at other times. *See* CELESTIAL MECHANICS; ORBITAL MOTION.

History and Present-Day Satellites

During World War II, the development of rockets and radar (using microwaves) made satellite communications a feasible concept. Launch vehicles would be required to place the satellites into orbit, and microwave components to make wideband communications possible. In 1945, Arthur C. Clarke wrote about the possibility of communications satellites in geostationary orbit. Transistors had not yet been invented, so he thought "in terms of large manned space stations. . . perhaps half a century" latter. In 1958, a battery-operated tape recorder (project SCORE) transmitted the first satellite message to the whole world—a Christmas message by President Eisenhower from a low-orbit satellite.

Active repeater satellites. In 1962, the first repeating communications satellites were launched: *Telstar* and *Relay*. These satellites received a signal, amplified it, and retransmitted it. For the first time, television signals could be transmitted across the Atlantic Ocean, but these satellites were in low orbit, and after 20 or 30 min disappeared below the horizon. Then *Syncom I* was launched into geosynchronous orbit. Due to launch constraints, it was in a 33° inclined orbit, so that each day the subsatellite point (the point directly under the satellite) oscillated between 33° N and 33° S.

Led by COMSAT, a multinational consortium of nations, the International Telecommunications Satellite (INTELSAT) Organization, was formed to establish global commercial satellite communications. In 1965, *Early Bird* was launched by COMSAT into a geostationary orbit, in which it remained stationed over the mouth of the Amazon River. It could thus

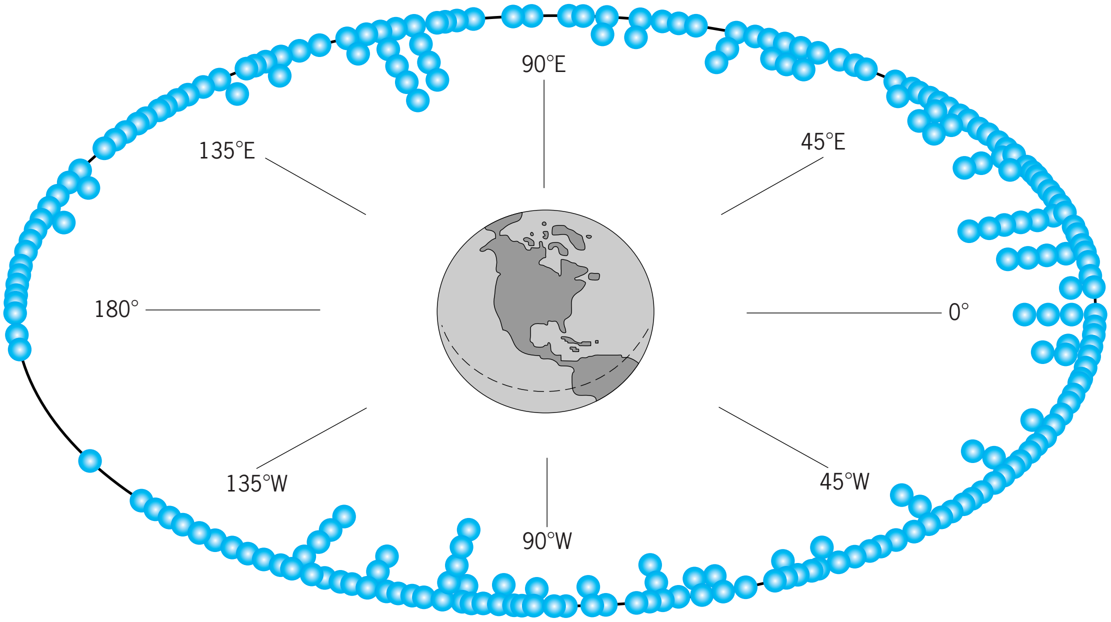

Fig. 9. Commercial communications satellites in geostationary orbit. (*Boeing Company*)

provide continuous communications between the eastern United States and western Europe 24 h a day. An INTELSAT satellite launched in 1967 brought commercial service to the Pacific area. Additional satellites later provided more communications to achieve a commercial global system.

Meanwhile, the U.S. Department of Defense developed the Initial Defense Communications Satellite Program (IDCSP), whose satellites were in near synchronous orbits. The Soviet Union launched communications satellites into Molniya orbits, which provided better coverage at high latitudes (far from the equator). Many Communist countries used the system initiated by the Soviet Union called Intersputnik.

Technical progress. Early earth stations were large and powerful so that they could communicate with small and weak satellites. As the capabilities of satellites increased, the Earth terminals could be smaller and less powerful. From specialized sites they moved to business premises and to homes. From communications to ships they progressed to other mobile communications, with airplanes, cars, and handheld phones. Satellite antennas became larger, with higher gains. Low-noise amplifiers made it easier to detect faint signals. Traveling-wave tubes and solid-state power amplifiers became more powerful. Silicon solar cells tripled in efficiency. Nickel-cadmium batteries were replaced by nickel-hydrogen and other batteries.

The number of active commercial communications satellites in geostationary orbit is now over 200 (**Fig. 9**), not including communications satellites in lower orbit or military communications satellites in geostationary orbit. With a variety of methods of frequency reuse, there is still room for more satellites.

Communications satellites are designed for specific missions, but have many common features (**Table 4**). A large, modern communications satellite may communicate with large fixed Earth stations (INTELSAT), it may broadcast to a large number

TABLE 4. Characteristics of a few communications satellites in use*

Spacecraft type:	Fixed satellite service	Broadcast	Mobile	Ka-band spot	Military
					Spacecraft name:	INTELSAT IX	Echostar 9	Thuraya 2	iPSTAR	Wideband Gapfiller
Launch year	2001 to 2003	2003	2003	2005	2007
Procurement agency	INTELSAT	EchoStar	Thuraya/Etisalat	Shin	U.S. Military
Satellite contractor	Space Systems/Loral	Space Systems/Loral	Boeing	Space Systems/Loral	Boeing
Launch vehicle	Ariane-44L, Ariane 5, Proton-M	Zenit-3SL	Zenit-3SL	Ariane-5GS	Delta-4M + (5,4)
Orbital slot	64°E to 34.5°W	121°W	44°E	120°E	
Satellite mass, kg (lb)	4725 (10,395)	4737 (10,421)	5177 (11,389)	6775 (14,905)	5987 (13,171)

of television users (Echostar and Direct TV), or it may communicate directly with handheld telephones (Thruraya). Satellites may be launched from the Kennedy Space Center in the United State (using the Delta or Atlas launch vehicle), Korou in French Guiana (Ariane), or Russia (Zenit or Proton). Many have a mass of around 5000 kg (10,000 lb), 50 to 100 power amplifiers (transponders), and design lifetimes of 12–15 years.

Since the beginnings of communications satellites in the 1960s, advances in communications have included fiber-optic cables and cellular telephones. However, these technologies are unlikely to completely replace satellites since these services complement each other. Satellites can never provide adequate cell phone service for large cities, but cellular phone towers may never be built in sparsely populated areas, and certainly not in ocean regions. Satellites are well suited to mobile communications, including aeronautical, maritime, and land applications. Fiber-optic cables are ideal for wideband communications from point to point, but when undersea cables break, satellites are often used to restore traffic. And satellites are particularly useful for broadcasting to a large number of points, whether for distributing network programs to television stations, or directly to television subscribers. Satellites also have the flexibility to switch their capability from one area to another. Spot beams can be repositioned to accommodate changing traffic needs for coverage of special events such as the Olympics or compelling news, such as disasters and other national and international developments. Communications scrambling

The methods for ensuring the privacy of voice, data, and video transmissions. Various techniques are commonly utilized to perform such functions.

Voice. Analog methods typically involve splitting the voice frequency spectrum into a number of sections by means of a filter bank and then shifting or reversing the sections for transmission in a manner determined by switch settings similar to those of a combination lock; the reverse process takes places at the receive end. The strength of these methods depends on the number of switch settings available (often called the key size) and the rate at which the switch settings are changed. *See* ELECTRIC FILTER.

Digital methods first convert the analog voice to digital form by a number of digital coding techniques such as pulse code modulation (PCM), delta modulation, or linear predictive coding (LPC). The digital voice data are then scrambled or encrypted by one of the many methods discussed below and are transmitted digitally. After the data are received, they are descrambled or deciphered and then converted back to analog form by the appropriate voice decader. *See* ANALOG-TO-DIGITAL CONVERTER; DIGITAL-TO-ANALOG CONVERTER; MODULATION; PULSE MODULATION.

Data. A simple data-scrambling method involves the addition of a pseudorandom number sequence to the data at the transmit end. The same sequence must be subtracted at the receive end to recover the data. The strength of the method depends on the period of the sequence and the way the sequence is generated, as well as the number of different pseudorandom number sequences available. Devices using this method are known as stream ciphers. Typically, the pseudorandom number sequences are in binary form; and the addition and subtraction are performed in binary form also.

A second method partitions the data into blocks. Data within a block may be permutated bit by bit or substituted by some other data in a manner determined by the switch setting, which is often called a key. At the receive side, the reverse permutation or substitution is performed to recover the data. Devices using this method are known as block ciphers. An example of block ciphers is the Data Encryption Standard (DES), accepted as a standard by the National Bureau of Standards in 1977. DES, which uses both permutation and substitution iteratively, is approved for nonmilitary, nondiplomatic governmental use.

The National Security Agency established a commercial communication security endorsement program under which encryption devices suitable for different applications are developed and certified by the government. *See* CRYPTOGRAPHY.

Video. Typical video scrambling devices used for cable television applications involve modifying the amplitude or polarity of the synchronization signals, thereby preventing the normal receiver from detecting the synchronization signals. A device capable of undoing the modifications is used to recover the signal. Some devices also invert the polarity of the video signal so that the black and white levels are reversed. *See* CLOSED-CIRCUIT TELEVISION.

A more sophisticated technique, used in satellite transmission, introduces a random delay to the active video signal on a line-by-line basis which is determined by a pseudorandom number sequence. Knowing the sequence, the receiver can compensate for the delay and recover the signal. An even more advanced technique called cut-and-rotate has been proposed. This method selects a random point of time in a scan line and cuts the line into two sections. The second section of the line is transmitted first, followed by the first section. By knowing exactly where the cut takes place, the receive side can perform the reverse process and reconstruct the signal.

Video signals can also be digitized by a number of coding techniques and then scrambled by any of the data-scrambling techniques discussed above to achieve high security. *See* TELEVISION. Lin-Nan Lee

Communications systems protection

The protection of wire and optical communications systems equipment and service from electrical disturbances. This includes the electrical protection of lines, terminal equipment, and switching centers, and inductive coordination, or the protection against interference from nearby electric power lines.

Sources of disturbance. The principal sources of destructive electrical disturbances on wire communications systems are lightning and accidental energization by power lines. Lightning that directly strikes aerial or buried communication cable may cause localized thermal damage and crushing. Simultaneously, it energizes the communication line with a high-level voltage transient that is conducted to terminal equipment. Indirect strikes are more common than direct strikes and, although they normally do not cause mechanical damage, they propagate electrical transients along the line. The rate of occurrence of these transients is geographically dependent, increasing with the level of thunderstorm activity (keraunic level) and earth resistivity. The distance over which a buried cable collects a lightning strike, and the resulting voltage produced within a cable, both increase as resistivity of the earth increases. The duration of the lightning-caused voltage transient on shielded communication cable is typically less than 1 or 2 milliseconds. The magnitude of the voltage between conductors and shield of a cable can reach several thousand volts. In regions of high thunderstorm activity and earth resistivity, a communication line several miles long may experience annually more than 1000 voltage transients of magnitude greater than 250 V. The accompanying current surge usually is less than 100 A, but much higher currents can result from a direct strike to the cable. *See* LIGHTNING.

During fault conditions on commercial power lines, high voltages may occur in nearby communication lines by several mechanisms. The most common is magnetically induced voltage caused by the high unbalanced currents of a phase-to-ground power-line fault. During such an event, an aerial or buried communication line that is parallel to the faulted power line intercepts its time-varying magnetic field, incurring a high longitudinal voltage. In effect, the system is a one-turn to one-turn air-core transformer. This inductively coupled voltage may be several hundred volts, with current limited by the impedance of the communication line and its terminations. Another source of high voltage is a damaged aerial power line that falls and directly contacts an aerial communication cable, or a digging machine that simultaneously contacts power and communication cable jointly buried in a common trench. In these cases, currents conductively enter the communication lines and are limited in magnitude only by fusing capabilities. Finally, communication lines near a power station or transmission-line tower may be subjected to high voltages from the rise in ground potential as power fault currents return through the ground mat of the power station. In each of these mechanisms, power-line fault-clearing devices are intended to limit duration of conduction to a few seconds. However, if the power-line fault impedance is high, the automatic clearing devices may not operate, and the overvoltage can last indefinitely. *See* ELECTRIC POWER SYSTEMS; ELECTROMAGNETIC INDUCTION; GROUNDING; TRANSFORMER; TRANSMISSION LINES.

In city centers, the diversion of lightning strikes by steel-framed buildings, and the shielding effect of the many underground metallic utility systems, considerably reduce the probability of high-voltage transients from lightning or induction from power lines. Since communication and power facilities are routed in separate conduits, the possibility of a power contact is remote. *See* ELECTRICAL INTERFERENCE; ELECTRICAL NOISE.

Electrical protection. The components of a communications system requiring electrical protection include both metallic and optical-fiber lines, terminal equipment, and switching centers.

Metallic lines. Metallic communication lines often are made up of many closely spaced pairs of wires arranged as a cable. A grounded circumferential metallic shield on the cable reduces the magnitude of electrical transients from nearby lightning strikes, and also can intercept a low-current direct strike, minimizing damage to the internal conductors. The effectiveness of the shield is improved if its resistance per unit length is low and if the dielectric strength of the insulation between the shield and the internal conductors is high. Frequent grounding of the shield eases the return of lightning currents to earth, thereby reducing voltages in the cable. Voltage breakdown within the cable can be avoided by installing surge protective devices between the pairs and shield at stress points along the cable. The devices may be air gaps consisting of carbon electrodes separated by a few thousandths of an inch (about 0.1 mm), or gas tube surge arresters, which use metallic electrodes separated by a gap in an enclosed discharge medium. They limit voltages at their terminals to the capabilities of the cable insulation, and are used principally in areas of high lightning activity. *See* COMMUNICATIONS CABLE; ELECTRICAL SHIELDING; GAS TUBE; LIGHTNING AND SURGE PROTECTION; SURGE SUPPRESSOR.

A special case for this type of protection arises on lines that serve antennas of wireless telecommunications systems. Lightning striking an antenna tower propagates voltage surges along the cable. If the cable is not well shielded and insulated, damage can occur, sometimes at considerable distance from the tower. Surge protectors placed between lines and shield at several locations within about a mile (1–2 km) of the tower help avoid this damage.

The localized damage caused by a direct strike to buried shielded cable can be reduced or eliminated by the burial of one or more wires at least 1 ft (0.3 m) above the cable. These shield wires divert all or much of the lightning current from the cable.

Damage to cable plant from a power-line contact is minimized by providing frequent bonds between the cable shield or aerial support strand and the neutral conductor of the power line. These bonds create low-resistance paths for fault currents returning to the neutral, and hasten deenergization by power-line fault-clearing devices. Closely spacing the bonds limits the length of communication cable that is damaged by the contact.

The outer metallic shields of belowground cables may be attacked by electrolytic action and require protective measures against corrosion. Electrolysis occurs where direct current leaves the shield. Severe sources of electrolytic currents include stray direct current from electrified railways and from industries using large amounts of direct current in grounded circuits. An effective remedial measure is to install a gap, known as an insulating joint, in the cable shield to interrupt the current. This gap can hinder the electrical protection and noise mitigation function of the shield unless it is bridged with a capacitor that provides a bypass for lightning and power-frequency currents. *See* CORROSION.

Optical-fiber lines. Optical-fiber communication lines are enclosed in cables that may contain metallic components to provide mechanical strength, waterproofing, local communications, or a rodent barrier. Though the cables otherwise would be immune to the effects of lightning or nearby power lines, such metallic components introduce a measure of susceptibility that is made all the more important by the high information rates carried by the fibers. A direct lightning strike to a metallic component of buried optical-fiber cable can cause localized thermal damage, arcing, and crushing that together may damage the fibers. Electrical protection is provided by cable designs that withstand these effects. As with metallic lines, the probability of this damage can be reduced by burying one or more shield wires at least 1 ft (0.3 m) above the cable.

Alternating currents may be conducted on the metallic sheath components of optical-fiber cables during an accidental contact with power-line conductors. Cable damage is minimized in extent by bonding the sheath to the neutral conductor of the power line, and by providing enough conductivity to carry the currents without damage to the fibers. *See* OPTICAL COMMUNICATIONS; OPTICAL FIBERS.

Some networks provide high-speed data via optical lines between a communication center and a pedestal near the served premises, and then use metallic lines to enter the premises (fiber-to-curb system). Often the power for equipment in the pedestals comes from a centralized powering node over metallic lines. Surge protectors are placed at each end of these powering lines to help avoid equipment damage. Because the power on these lines may exceed those of ordinary telephony, care should be taken to ensure that the protectors can reset after conducting a surge. These protectors, and the protectors on the lines between pedestal and premises, should not have too low a limiting voltage or they may needlessly cause data disturbances during thunderstorms or power-line malfunctions.

Terminal equipment. To protect the users, their premises, and terminal equipment, communication lines that are exposed to lightning or contacts with power lines are usually provided with surge protectors. Article 800 of the National Electrical Code requires that communication lines exposed to contact with power lines of voltages greater than 300 V be equipped with a protector at the entrance to the served premises. Interbuilding lines that are exposed to lightning also have protectors. Although not required, it is common practice to minimize equipment damage by so equipping communication lines in an area of significant lightning exposure even if there is no power-contact hazard. Article 830 extends similar requirements to coaxial circuits that provide network-powered broadband communications. *See* ELECTRICAL CODES.

For the most part, the protector contains a voltage-limiting device, such as a gap-type or solid-state surge protector, connected between each wire of the line and a local ground electrode. Any voltage surge on the wires thereby is limited with respect to local ground. Voltages between the communication lines, power lines, and other grounded systems within the premises are limited by bonds between the protector ground, the power neutral, and other metallic systems.

Sparking between communication lines and nearby objects, and electric shock hazard to the user, are minimized if the insulation of the lines and terminal equipment withstands voltages at least as great as the limiting voltage of the protector (plus an allowance for voltage drop of grounding conductors). Service interruptions are avoided if electronic circuits within the equipment also are able to withstand these surge voltages. Within some equipment, surge immunity is achieved by applying additional voltage limiters, such as varistors, avalanche diodes, or special low-voltage gas tubes. *See* MICROWAVE SOLID-STATE DEVICES; VARISTOR.

Sustained currents from power-line contacts can overheat the network-side wires connected to the protector unless interrupted by a current-limiting device. A short length of fine-gage wire in series with the communication line, or a fuse at the protector, is usually installed for that purpose. If the terminal equipment contains an internal voltage limiter, an additional fuse may be needed to protect the premises wire connecting the equipment to the protector. *See* FUSE (ELECTRICITY).

Switching centers. Switching centers contain electronic equipment that routes communications to their proper destinations. This equipment is protected from the effects of electrical transients appearing at interfaces with external communication lines in a similar way as for terminal equipment. In addition to these effects at external interfaces, communication equipment within centers may be subjected to transient voltages resulting from lightning strikes to nearby objects or from direct strikes to the building. Such events cause rapidly varying currents in metallic structural members and in the grounding system. These currents can be conductively and magnetically coupled to wires interconnecting equipment in the building. Depending on the relative paths taken by the lightning currents and the wiring, transient differences in voltage may appear between nearby ground and conductors that extend between internal locations.

One method of controlling these voltages is to bond, as often as possible, all metallic equipment frame members and grounded circuits to the floor ground of the building. This technique, known as an integrated ground (or mesh bonding network), reduces potential differences, but permits surge currents to circulate throughout the system. Sensitive electronics can be damaged by the local potential differences caused by these circulating currents, so some designs avoid circulating currents by isolating the entire system from ground except at one location, which is deliberately grounded. This system, known as the isolated ground plane (or isolated bonding network), has found effective use in many switching centers. *See* ELECTRIC PROTECTIVE DEVICES; ELECTROMAGNETIC COMPATIBILITY; ELECTRONIC EQUIPMENT GROUNDING; SWITCHING SYSTEMS (COMMUNICATIONS).

Inductive coordination. Inductive coordination refers to measures that reduce the magnitudes and effects of steady-state potentials and currents induced in metallic communication lines from paralleling power facilities. Where power and communication lines are parallel for long distances, normal-load power currents returning to the power generator via the neutral conductor or earth induce voltages into the communication lines. Malfunction of terminal equipment may result. The induced voltages appear equally in each wire of a pair; electrical asymmetries in the lines or terminal equipment convert them to a voltage between the wires of a pair and may cause background noise or data errors. Remedial measures that reduce the induction effect are (1) balancing the power-line currents to reduce the neutral component returning to the generator; (2) using a grounded metallic shield on the communication cable so that shield currents partly cancel the field from the disturbing power line; (3) using well-balanced communication line and terminal equipment to minimize conversion to voltages between wires; (4) installing reactive components in the communication line to reduce induced currents; and (5) using terminal equipment that is tolerant of induced voltages. *See* INDUCTIVE COORDINATION.

Solar magnetic storms. Solar magnetic storms, which occur with varying intensity over an 11-year cycle, produce strong currents in a predominantly east-west direction of the earth surface. They cause a voltage difference between a conductor and the earth that increases at higher latitudes and with earth resistivity. The voltage typically lasts for several minutes and is low frequency (below 0.1 Hz); it can be treated as a direct-current voltage on telecommunication and power-line circuits.

Long-distance metallic lines are susceptible to these storms to the extent that they have conductive connections to earth, either deliberately or by means of surge protective devices that are operated by the storm. The increasing use of optical-fiber lines for long-distance telephony largely removes this threat. Where protectors are used on long metallic lines, they should be capable of continuously conducting up to 1.0 A without posing a fire hazard. Short metallic lines are unlikely to experience enough voltage to operate surge protectors. If terminals on these lines have conductive connections to earth, ability to operate in the presence of 3-V direct current between ends of the line accommodates all but extreme magnetic storms.

Power utilities have had widespread outages during magnetic storms, and this loss of utility power poses a threat to metallic and optical-fiber communication systems. Reserve power systems using batteries in conjunction with engine alternators help provide uninterrupted telecommunications service for the duration of an extended power outage. *See* GEOELECTRICITY; GEOMAGNETIC VARIATIONS; UNINTERRUPTIBLE POWER SUPPLY.

Nuclear electromagnetic pulse. A nuclear burst at altitudes higher than about 25 mi (40 km) generates an electromagnetic field pulse over a large area of the earth surface; a burst at 300 mi (500 km) would illuminate most of the contiguous United States. The magnitude of the electric field would peak at tens of kilovolts per meter in a few nanoseconds and would last a few hundred nanoseconds. It would affect communication systems by causing high-voltage transients on wires that enter electronic equipment at telecommunications centers. The field would couple to the wires by two mechanisms: direct penetration through walls of the building into the wiring; and coupling of current pulses onto conductors that enter the building (such as power lines, telecommunications cables, and antenna leads), which in turn couple surges to the internal wiring. The surges, though brief, may be much larger than normal signal levels and can cause malfunctions or damage. The protection measures summarized here are among those considered to be reasonable and practical for public communication networks.

Direct field penetration through the structure is reduced by enhancing its shielding. This is done by selecting construction methods with electrically interconnected components in walls, floors, and roof. Poured concrete with interconnected steel reinforcement is preferred. The interconnected steel should be bonded to the common bonding network of the building. Where this construction is unavailable, interior metallic structures, such as cable racks, supports, raceways, and equipment cabinets, should be interconnected and bonded to the common bonding network. Critical equipment and its wiring should be distant from unshielded windows.

The effect of surge currents entering via penetrating conductors is best reduced by diverting to ground much of the surge current before it enters the building. This is largely done by directly bonding to the grounding system all entering telecommunication cable shields and antenna lead-ins, and by installing surge protectors on mains conductors at the service entrance. Because these means do not completely remove penetrating currents, critical equipment and its wiring should be separated from penetrating conductors. *See* ELECTROMAGNETIC PULSE (EMP). Michael Parente

Commutation

The process of transferring current from one connection to another within an electric circuit. Depending on the application, commutation is achieved either by mechanical switching or by electronic switching.

Mechanical switching. Commutation was conceived over a century ago through the invention of the direct-current (dc) motor. When direct current is supplied to a winding on a rotor that is subjected to a stationary magnetic field, it experiences a rotational force and resulting output torque. As the stator north and south poles are reversed relative to the rotating winding, the rotor current is reversed by a commutator in order to maintain the unidirectional torque required for continuous motor action. *See* DIRECT-CURRENT MOTOR; WINDINGS IN ELECTRIC MACHINERY.

The principle is illustrated in **Fig. 1**. In its simplest form, a single rotor winding is connected between two segments of a cylindrical copper commutator which is mounted axially on the rotor. Connection to the external dc supply is through sliding carbon contacts (brushes). The segments have small insulated gaps at *A* and *B*. As *A* and *B* pass the brushes, the current in the rotor winding reverses. In the short interval where the brushes short-circuit the segments, the rotor current decays before building up in the reverse direction. The angular position of the brushes is selected to reverse the current at the appropriate rotor position. *See* COMMUTATOR.

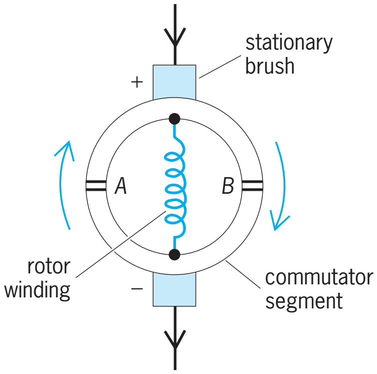

Fig. 1. Basic commutator for a dc motor.

Commutation not only reverses the current but automatically synchronizes the timing of the reversal with the rotor position, irrespective of motor speed. The process can also be considered as a mechanical alternating-current/direct-current converter with the frequency of the rotor current being matched to the speed. The same commutation permits the reverse conversion in a dc generator where alternating-current (ac) voltages induced in a driven rotor are converted to a dc output voltage. *See* DIRECT-CURRENT GENERATOR.

Practical dc motors and generators typically incorporate several winding sections positioned around the rotor and connected to a correspondingly increased number of commutator segments to produce smoother performance.

The same principle of commutation applies to the ac commutator motor and universal ac/dc motor, which are common in variable-speed kitchen appliances and electric hand tools. The commutator still reverses the connection to the rotor to accommodate rotor position. When ac voltage is supplied to both commutator and stator winding, current reversals in the ac waveform are common to both the rotor and the stator thus torque remains unidirectional. *See* ALTERNATING-CURRENT MOTOR; UNIVERSAL MOTOR.

Electronic commutation. The equivalent of mechanical commutation occurs in solid-state converter circuits such as those used for rectifying ac to dc or inverting dc to ac. **Figure 2** shows a three-phase converter widely used in industry. For simplicity, the ac supply network is represented by equivalent phase voltages in series with the effective supply inductance. (Often this inductance is mainly the inductance per phase of a converter transformer that interfaces the converter and the three-phase supply.) Usually, supply resistance is relatively low and plays a negligible role in the converter action. As shown, thyristors 1 and 2 are conducting the dc current from phase *a* to phase *c*. A smooth dc current does not produce a voltage across the inductance *L* in each phase.

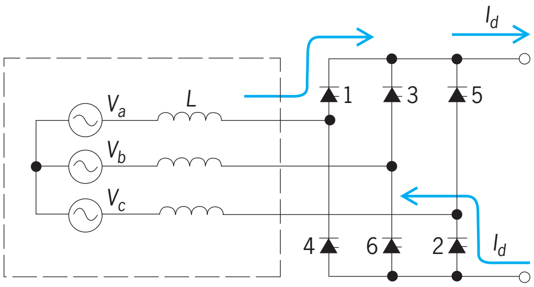

Fig. 2. Three-phase converter.

In the cyclic conduction sequence, the dc current is commutated from phase *a* and thyristor 1 to phase *b* and thyristor 3. To achieve this, thyristor 3 is gated in a region of the ac waveform when its forward voltage is positive. Turning it on applies a reverse voltage to thyristor 1 (phase *b* being more positive than phase *a*), which ceases conduction to complete the commutation of the dc current. This is repeated in sequence for the other thyristors in each ac cycle. *See* CONVERTER; SEMICONDUCTOR RECTIFIER.

In practice, the commutation is not instantaneous because of the inductance, which is referred to as commutation inductance or commutation reactance when considered as an ac impedance. The buildup of current in the incoming phase matches the reduction of current in the outgoing phase over a certain electrical angle until commutation is complete. The angle is referred to as the overlap or commutation angle and may typically be 20–30 electrical degrees. *See* INDUCTANCE.

Meanwhile the dc waveform, which is composed of segments of the ac waveform as selected by the switching action, is affected by the overlap because of the transient commutation voltage drop in the inductances. On average, with consideration of six commutations per ac cycle, the dc voltage may be reduced by several percent, sufficient for commutation to be incorporated into conversion calculations. The overlap angle is a variable and becomes larger for a larger dc current to be commutated, for a larger commutation reactance, and for a smaller ac voltage. It also depends on the actual values of ac voltage at the point-on-wave at which a thyristor is gated to turn on.

Artificial (forced) commutation. The ac supply voltages in Fig. 2 provide a natural commutation voltage. In some other circuits, additional circuit means are necessary to provide a reverse voltage for the outgoing thyristor (or other solid-state switching device). They include charged capacitors, voltage reversals from resonant inductance–capacitance circuits, and additional thyristors.

Electrical noise. Commutation, whether natural or forced, creates abrupt transitions in the converter waveforms, with high-frequency components as an unwanted by-product. This is a factor in assessing radio-frequency interference in the vicinity of power electronic equipment and supply leads. *See* ELECTRICAL INTERFERENCE; ELECTRICAL NOISE.

Commutation with dc converter stations. Converters at the very high power levels of dc transmission are based on natural commutation of the converters shown in Fig. 2. As for many industrial applications of the same circuit, the timing of the commutation process is determined by real-time automatic control. In controlling the dc voltage and current, the commutation must be confined to points in the ac waveform for which the commutating voltage is conducive to successful completion of the commutation. Theoretically, the gating of a thyristor can be delayed by a half cycle (180°) from the point-on-wave where its voltage becomes positive, in order to have a controlled transition from full dc voltage as a rectifier to full reverse dc voltage as an inverter. In practice, commutation imposes constraints at both extremes of control: delay with a minimum value of 5–7° provides a sufficient commutation voltage to avoid hesitant thyristor turn-on; at the other extreme, the delay must still leave sufficient time for the overlap angle together with a period for the outgoing thyristor to recover its ability to hold off conduction. *See* DIRECT-CURRENT TRANSMISSION.

In establishing the maximum permitted delay (firing angle) for inverter operation, the control has to take into account variations in the overlap angle (as noted previously) to maintain the recovery period referred to as the extinction or commutation margin angle, typically 15–18°. Should a delayed commutation extend into this margin, there is the prospect of commutation failure, which implies that the orderly converter switching is disturbed, resulting in a collapse of the converter dc voltage. This power interruption is temporary if the control returns the firing angle to a safe region. A disturbance in the ac system adjacent to a converting station may depress the ac voltage to a level at which commutation cannot be completed. This is also designated as a commutation failure. The recovery of the converter to the previous power level commences when the voltage is restored. John Reeve

Commutator

That part of a dc motor or generator which serves the dual function, in combination with brushes, of providing an electrical connection between the rotating armature winding and the stationary terminals, and of permitting the reversal of the current in the armature windings. For explanation of the necessity of this function *see* COMMUTATION.

A commutator (**Fig. 1**) is composed of copper bars assembled to form a drumlike cylinder which is concentric with the axis of rotation. Insulation, commonly mica, to provide exceptional mechanical and electrical stability, is placed between commutator bars and between the bars and the shaft.

Conducting brushes (**Fig. 2**), commonly carbon, sufficient in size and number to carry the current, are spaced at intervals of 180 electrical degrees about the surface of the commutator and held in contact with the surface of the commutator by spring tension. In special cases, as when only the top or bottom half of a dc motor is accessible, only one positive brush set and one negative brush set are used when the armature is wave-wound. This is permissible, as wave windings characteristically have two parallel paths between any two commutator bars separated 180 electrical

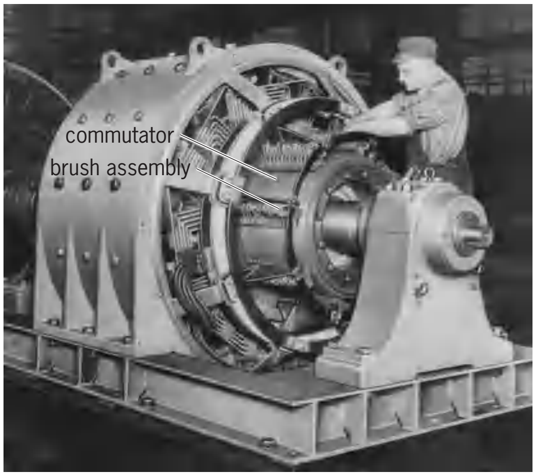

Fig. 2. Direct-current generator showing the typical brush assembly. (*Allis-Chalmers*)

degrees. Machines employing commutators are usually restricted to voltages below the kilovolt range because flashover between the closely spaced commutator segments may result from deposition of carbon dust from the brushes and from uneven voltage distribution between commutator bars under heavy loading. For machines using commutators *see* DIRECT-CURRENT GENERATOR; DIRECT-CURRENT MOTOR; REPULSION MOTOR; UNIVERSAL MOTOR; WINDINGS IN ELECTRIC MACHINERY.

Arthur R. Eckels

Compact disk

A system for data storage in which digitally encoded information in the form of microscopic pits on a rotating disk is accessed by optical readout. The compact disk was originally developed as a music carrier providing high fidelity, random access, convenience, durability, and low cost. Its attributes made it suitable for storing diverse data such as video programs and computer software, and improvements allowed recordability and erasability. Greater storage capacity and more sophisticated integration of features is provided in the DVD optical disk format.

Operating Principles

An acoustic signal waveform is stored on the disk in the form of a binary code, as a series of 0's and 1's. This is done by forming pits along spiral tracks on a transparent plastic disk, overlaying this with a reflective coating, and covering this coating with a protective layer. The light from a semiconductor laser is focused onto the pits from below (**Fig. 1**). The presence or absence of pits within the laser spot changes the intensity of the reflected beam (pits diffract the light, reducing reflected intensity). The reflected light strikes a light-detecting photodiode that converts the varying-intensity light beam into a binary electrical signal. *See* LASER.

With the light focused on the pits, the outer lower surface of the transparent disk is out of focus; hence dust, fingerprints, and minor scratches on this surface are blurred and do not affect the detection process. Even more important, the use of an optical pickup means that there is no mechanical contact and hence no wear on pickup or disk.

Because the focused laser spot size is extremely small, a considerable amount of information can be placed on the data surface. Adjacent tracks of the spiral of pits are nominally 1.6 micrometer apart (track pitch), and hence about 22,200 such tracks are placed across a 35.5-mm radius on a 120-mm-diameter (4.75-in.) disk. The track is optically scanned at a nominal constant linear velocity of about 1.4 m/s. The pits, and the separations between pits along a track, vary in length from about 0.97 to 3.56 μm (**Fig. 2**). Smaller track pitch and lower linear velocities (and shorter pit and land lengths) may be used for greater storage capacity.

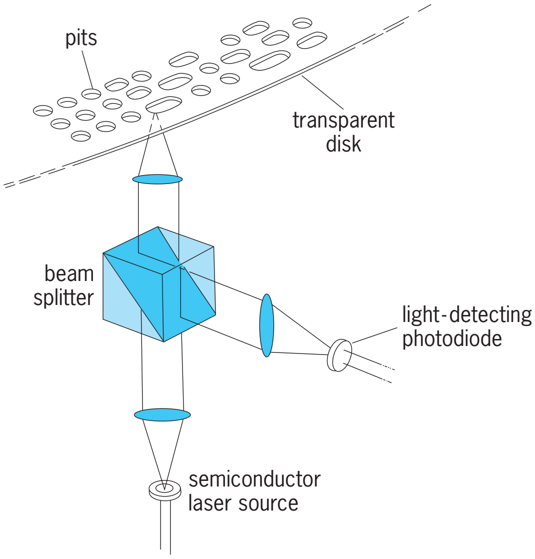

Fig. 1. Optical readout system for an audio compact disk.

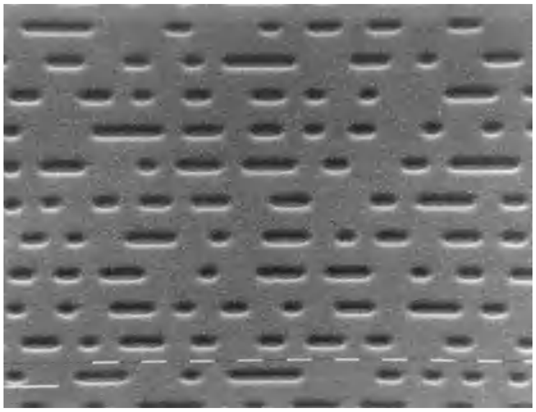

Fig. 2. Pits on an audio compact disk. (*From M. G. Carasso et al., Compact disc: Digital audio, Philips Tech. Rev., 40(6):151–180, 1982*)

Digitally encoded waveform. The human ear is insensitive to sounds with frequencies higher than about 20,000 Hz. The Shannon (or Nyquist) sampling theorem specifies that a waveform can be exactly reproduced from samples taken at a uniform rate of at least twice that of the highest signal frequency. The standard sampling rate for audio compact disks is 44.1 kHz; thus, the highest audio frequency encoded is 22.05 kHz. The amplitude of each sample is represented by a 16-bit binary word. Thus, the amplitude of each original audio sample is approximated to the nearest of 2^{16} (65,536) equally spaced levels in a process known as quantization. With stereo channels, the data rate stored on the disk is $2 \times 16 \times 44{,}100 = 1{,}411{,}200$ bits/s. *See* INFORMATION THEORY; PULSE MODULATION.

An important audio performance figure is the signal-to-noise ratio. If it is assumed that all unwanted noise and interference have been eliminated, the remaining noise will be that due to the quantization process, with an amplitude of the order of one-half of a quantization level. The theoretical signal-to-noise ratio, the amplitude of the largest undistorted signal to the amplitude of the noise, is $S/N = 6.02(16) + 1.76 = {\sim}98$ dB. This is comparable, for example, to the figure of 90 dB for the dynamic range of a symphony orchestra. As a comparison, the best signal-to-noise ratio figure for professional magnetic tapes is about 80 dB, and acceptable signal-to-noise ratios for conventional audio systems are about 70–80 dB.

Disk mastering and replication. In the disk mastering and replication process (**Fig. 3**), a glass disk is covered by a uniform coating of photoresist material. A laser exposes portions of the photoresist where pits are to be formed. The photoresist is then developed and washed, leaving the master recording. A nickel mother is derived from this master and is then used as a mold to produce multiple copies of the disk in transparent polycarbonate plastic. These substrates are coated with a thin metallic reflecting layer (usually aluminum), with a protective plastic coating on top of that.

Data is coded on a compact disk using an EFM (eight-to-fourteen modulation) code. In EFM, single binary 1's are represented by both the beginning and end of a pit length; otherwise the signal is a sequence of 0's. This correspondence between the channel bit stream (the signal represented on the disk) and the cross section of a disk is shown in Fig. 3*e* and *f*.

Electromechanical control. Advanced control systems in the compact disk player are designed to retrieve data from the disk surface reliably. The laser spot on the pit track must stay focused to within $+/-0.5\ \mu$m. But since the vertical movement of the disk might be as much as 1000 times this, automatic focusing must be provided. In some designs, this is accomplished by inserting a cylindrical lens in the path of the reflected beam and allowing the beam to impinge on a four-quadrant segmented photodiode. The changing ellipticity of the focused spot is registered as a differential signal between two opposite pairs of photodiode segments, which provides the control signal for the focusing servomechanism. *See* SERVOMECHANISM.

The laser spot must track the pits with a tolerance of $\pm 0.1\ \mu$m. However, track eccentricity might be 100 μm or more. Thus, an automatic tracking system

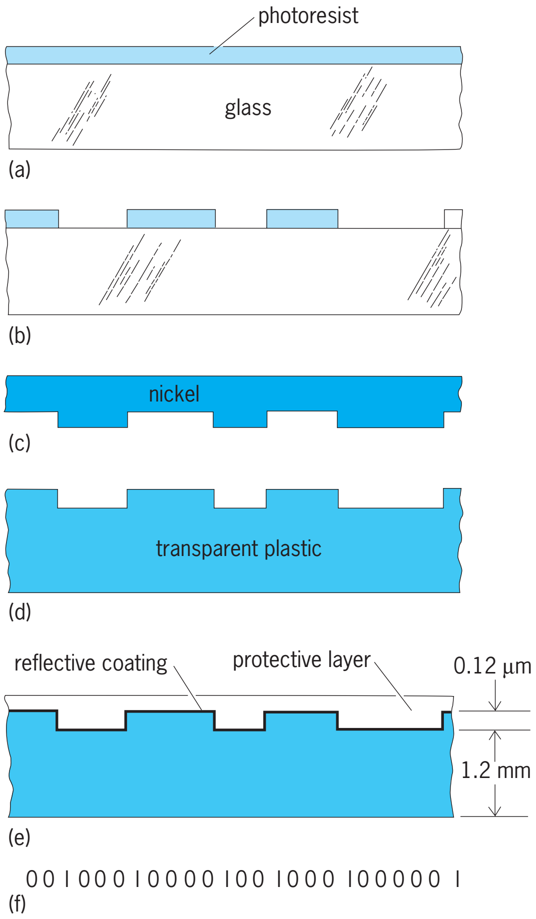

Fig. 3. Mastering and replication process for an audio compact disk. (*a*) Glass disk covered by a uniform layer of photoresist. (*b*) Pits formed by a focused laser in the photoresist, which is developed and washed away, giving the master. (*c*) Nickel mother, formed from the master. (*d*) Transparent plastic disk stamped from the nickel mother. (*e*) Disk with the reflective coating and the protective layer added. (*f*) Associated binary electrical signal (channel bit stream).

is required. In some designs, lateral tracking control is achieved by generating two tracking laser spots, with one straddling each edge of the track when the main spot is properly centered. The differential signal from two photodiodes positioned to pick up the reflection from the tracking spots provides the lateral position control signal.

The constant linear velocity of the beam along the track is ensured by synchronizing the data read off the disk with a quartz-crystal oscillator. *See* OSCILLATOR.

Signal processing. Since the information that is read off the disk is in digital form, as a sequence of 0's and 1's, it can be processed in many ways that are not possible with analog systems. To enable this, information can be passed through a buffer memory, and then output at a rate that is controlled by the player's quartz-crystal (oscillator) clock, hence entirely eliminating the wow and flutter of conventional systems.

Error correction. Errors in the information read off the disk fall into two broad categories: (1) An error in an individual bit may be due to an imperfectly formed pit or random imperfection formed in the plastic disk during the molding process. (2) A burstlike error produced by severe scratches or dirt on the outer layer of the transparent disk affects many adjacent tracks.

In principle, the detection and correction of errors is achieved by adding extra check bits known as parity bits. The bit stream can be divided into blocks and the bits in a block arranged in the form of a rectangular grid or matrix. If a parity bit is assigned to every row and every column, then, on the assumption that only one bit per block is in error, it is possible to identify precisely which bit is in error, and hence to correct it. In practice, extensions of this idea are used in the detection and possible correction of compact disk data errors, but implementation is more complex. In particular, an algorithm known as the cross interleave Reed-Solomon code (CIRC) is used.

Conversion of signal to analog form. To recreate the original music signal, the binary data on the disk must be passed through a digital-to-analog (D/A) converter and a low-pass filter. The digital-to-analog converter accepts each 16-bit sample and outputs a voltage corresponding to its value. The series of samples forms a staircase waveform that is applied to a low-pass filter that removes all frequencies above the half-sampling frequency. In this way, the filter reconstructs the original waveform. A steep (high-order) analog filter can be used, with a flat amplitude to the half-sampling frequency, at which point the amplitude falls to zero. *See* DIGITAL-TO-ANALOG CONVERTER; ELECTRIC FILTER.

In practice, low-pass filtering is accomplished using a technique called oversampling, in which the output sampling rate is increased by a factor of, say, 8, from 44.1 to 352.8 kHz, with a digital filter. This technique has the effect of requiring only a mild (low-order) analog filter while the audio bandwidth remains limited to 20 kHz. Oversampling yields an output signal characteristic with essentially flat frequency response and phase linearity.

Diverse Formats

The compact disk was originally designed as a music carrier. Subsequently, the format was extended to include the CD-ROM (read-only memory) format for computer applications. Newer formats that use the compact disk as their basis include the recordable CD-R and erasable CD-RW formats, and the multimedia DVD format.

CD-R. The CD-R (recordable) format allows users to record audio or other digital data on a compact disk; it is also called the CD-WO (write-once) format. The recording is permanent and may be read indefinitely, but cannot be erased. CD-R disks with up to 80 min (or about 700 megabytes) of playing time are available. A recording is complete when a leadin area (with table of contents), user data, and leadout area have been written.

CD-R disks are built on a polycarbonate substrate and contain a reflective layer and a protective top layer. Sandwiched between the substrate and the reflective layer is a recording layer composed of an organic dye polymer, generally either cyanine or phthalocyanine. To achieve appropriate reflectivity, a gold or silver reflective layer is used. Unlike regular compact disks, CD-R disks are manufactured with a pregrooved track, which is used to guide the recording laser. This practice simplifies recorder hardware design and promotes disk compatibility. The organic dye recording layer is a photoabsorption surface that absorbs energy from the recording laser as heat. The laser passes through the polycarbonate substrate and heats this layer, causing the substrate layer to expand into the absorption layer and mix with the dye materials there. The polycarbonate mixed with dye, which has been decomposed from the heat, acts to form a pit in the substrate. These pits create the change in reflectivity required by compact disk player pickups. During readout, the same laser, reduced in power, is reflected from the pits and its changing intensity is monitored at a photodiode. In this way, CD-R disks can be played in most CD audio and CD-ROM drives.

CD-RW. The CD-RW (rewritable) format allows data to be written, read, erased, and rewritten. A CD-RW drive can read, write, and erase CD-RW media, read and write CD-R media, and read CD audio and CD-ROM media. The data can comprise computer programs, text, pictures, video files, or audio files. Altogether, five layers are built on a transparent polycarbonate substrate: a dielectric layer, a recording layer, another dielectric layer, a reflective metal (aluminum) layer, and a top acrylic protective layer. As in the CD-R, the writing and reading laser follows a pregroove across the disk radius. However, whereas the CD-R uses a dye recording layer, the CD-RW format employs a phase-change mechanism. The recording layer is composed of an alloy of silver, indium, antimony, and tellurium, which exhibits a reversible crystalline-amorphous phase change when recorded at one temperature and erased at another. Data are recorded by directing a laser to heat an area of the crystalline layer to a temperature slightly above its melting point. When the area solidifies rapidly, it becomes amorphous, and the decreased change in reflectivity can be detected. Because the crystalline form is more stable, the material will tend to change back to this form. Thus, when the area is heated again (at a slightly lower laser power) and cooled gradually, it will return to a crystalline state, providing rewritability. A very low power laser is used to read data.

This phase-change recording technology allows thousands of rewrite cycles. The disk capacity is 650 megabytes. Since the reflectivity of CD-RW disks is only about 15 and 25% in the amorphous and crystalline states respectively, they cannot be played in conventional compact disk players. A CD-RW drive is required, or a multiread drive capable of reading lower-reflectivity disks. The CD-UDF (universal disk format) specification modifies the CD Red Book file format so that nonaudio data can be written in data packets. With CD-UDF-compliant drives, CD-R and CD-RW disks can be used in a personal-computer environment much like other storage media; in addition to audio recording, nonaudio data files can be dragged and dropped from the personal computer to disk storage.

DVD. The DVD (digital video disk or digital versatile disk) standard includes formats for video, audio, and computer applications. DVD-video was the first DVD format to be developed. One disk digitally stores a complete feature film with digital audio sound tracks. As with compact disks, DVD-video disks use a pit-and-land structure to store data. The track pitch is 0.74 μm, compared to 1.6 μm on a compact disk. The pits and lands are as short as 0.4 μm, compared to 0.83 μm on a compact disk. These reduced dimensions are possible because the laser beam uses a visible red wavelength of 635 or 650 nanometers, compared with 780 nm in a compact disk. The standard specifies a lens with a numerical aperture of 0.6, compared with 0.45 in the compact disk standard. These specifications provide a large storage capacity.

Data storage. A DVD-video disk is the same diameter (120 mm or 4.75 in.) and thickness (1.2 mm or 0.05 in.) as a compact disk. Whereas a compact disk uses a single polycarbonate substrate, a DVD-video disk employs two 0.6-mm substrates, bonded together, with the data layers placed near the internal interface.

A single-layer, single-sided DVD-video disk uses one substrate with a data surface, and one blank substrate; the disk holds 4.7 gigabytes of data. Two substrates with data surfaces can be bonded together to form a single-layer, double-sided disk holding 9.4 gigabytes of data; the disk is turned over to access the opposite layer.

The DVD-video standard also allows data to be placed on two layers in a substrate, one embedded beneath the other to create a dual-layer disk that is read from one side. The layers are separated by a semitransparent (semireflective) metal layer. Both layers can be read from one side by focusing the reading laser on either layer. The beam either reflects from the lower semireflective layer or passes through it and reflects from the top reflective layer. Together, the dual layers hold 8.5 gigabytes of data. The DVD-video standard allows for a double-sided, double-layer disk, in which two dual-layer substrates are bonded together, creating a capacity of 17 gigabytes.

Data compression. A motion picture may comprise 200 gigabytes of data; to fit this program on a single disk, data reduction must be employed. The DVD-video standard uses the MPEG-2 (Motion Picture Experts Group-2) algorithm to encode its video program. Image data that are redundant, not perceived, or marginally perceived are removed or coarsely quantized. This analysis is carried out for both individual video frames and series of frames. MPEG-2 allows for a variable bit rate. Simple pictures are given a low bit rate, and complex pictures a high bit rate. The maximum output bit rate is 10.08 megabits per second, and the average bit rate might be 4.7 megabits per second, in contrast to the compact disk's fixed rate of 1.41 megabits per second. With MPEG-2, a single-layer DVD-video disk can store up to 133 min of high-quality digital video with digital audio sound tracks; longer motion pictures can use the dual-layer disk design. The video program is stored at 4:2:0 component video; 4:2:0 refers to the ratios of frequencies used to record the different video components (one luminance and two color-difference), and the luminance and color-difference data are kept separate for higher fidelity. *See* DATA COMPRESSION.

Audio. The audio portion of the DVD-video standard provides both multichannel and stereo sound tracks. DVD-video disks can accommodate three independent 5.1-channel sound tracks, each with five main channels and a low-frequency effects channel. The DVD-video standard recognizes two multichannel formats. Disks can carry a digital sound track with a sampling frequency of 48 kHz; using audio data compression, the normal output bit rate is 384 kilobits per second. Disks also carry linear pulse-code-modulation (PCM) digital stereo sound tracks employing sampling rates of either 48 or 96 kHz, and word lengths of 16, 20, or 24 bits. Up to eight independent pulse-code-modulation channels are permitted.

Features. A DVD-video player is often connected to a home theater system and can also play CD music disks. DVD-video disks cannot be played in compact disk players. The DVD-video standard provides features such as normal (4:3) and wide-screen (16:9) aspect ratios, an automatic pan-scan feature, up to nine camera angles and interactive story lines, up to eight language tracks, and up to 32 sets of subtitles. These features are options, and implementation is left to the content provider. The DVD-video format also uses copy protection to prevent digital or analog dubbing of disks. Disks and players are tagged with regional flags so that players will play only disks intended for certain geographical markets.

Formats. In addition to the DVD-video format (formally known as Book B), the DVD family includes

DVD-read only (Book A), DVD-audio (Book C), DVD-write once (Book D), and DVD-rewritable (Book E) as well as other formats and extensions. The DVD format uses the UDF file structure. The DVD-audio format is used to store high-quality multichannel music programs at a variety of sampling frequencies and quantization word lengths. In addition, the DVD-audio format can employ lossless audio data compression to increase storage capacity effectively without degrading audio file content. The other DVD formats are employed in computer applications; Books A and E are often called DVD-ROM and DVD-RAM (random access memory), respectively. DVD-ROM and DVD-RAM drives are connected to personal computers, and function much like CD-ROM drives.

Other optical disk formats under development provide greater capacity and performance. The compact disk and the DVD will further integrate audio and video technologies with the technology of the computer. *See* COMPUTER STORAGE TECHNOLOGY; OPTICAL RECORDING.

Comparator

An electronic circuit that produces an output voltage or current whenever two input levels simultaneously satisfy predetermined amplitude requirements. A comparator circuit may be designed to respond to continuously varying (analog) or discrete (digital) signals, and its output may be in the form of signaling pulses which occur at the comparison point or in the form of discrete direct-current (dc) levels.

Linear or analog comparator. A linear comparator operates on continuous, or nondiscrete, waveforms. Most often one voltage, referred to as the reference voltage, is a variable dc or level-setting voltage and the other is a time-varying waveform. When the signal voltage becomes equal to the reference voltage, a discrete output level is obtained. If the time-varying (signal) voltage approaches the reference voltage from a more negative level the output voltage is of one polarity; if it approaches the reference from a more positive value the output is of the opposite polarity.

Operational-amplifier voltage comparator. A very high-gain operational amplifier whose output is inverting with respect to one input terminal and noninverting with respect to the other and whose output voltage is limited at upper and lower levels (usually at voltages near the supply voltage levels, $+V_{\text{supply}}$) may be used as a voltage comparator (**Fig. 1**). The upper and lower output levels are designated as V_{OH} and V_{OL}, respectively. When the input signal υ_i equals V_{REF}, the output is approximately in the center of this range. The change in input voltage around V_{REF} required to drive the output to its respective limits is given by Eq. (1), where A is the voltage gain of the

$$\Delta \upsilon_i = \frac{V_{OH} - V_{OL}}{A} \qquad (1)$$

amplifier. If A is very large, $\Delta \upsilon_i$ approaches 0; as υ_i approaches V_{REF} from the negative side, the output switches abruptly from V_{OL} to V_{OH} as soon as υ_i becomes bigger than V_{REF}; and as υ_i approaches V_{REF} from the positive side, the output switches abruptly to V_{OL} as soon as υ_i becomes less than V_{REF}. If υ_i and V_{REF} are interchanged, the output polarity shifts are reversed.

Comparators are often designed with a built-in offset voltage; that is V_{OH} and V_{OL} need not be symmetrical about V_{REF}. For example, high and low output levels may be designed as $V_{OH} = +5$ V and $V_{OL} = 0$, which would be compatible with standard saturated logic levels; or as $V_{OH} = 0$ and $V_{OL} = 15$ V, for outputs compatible with standard emitter-coupled logic levels. *See* LOGIC CIRCUITS.

The high-gain operational-amplifier comparator used in the open-loop mode is designated as a nonregenerative comparator because there is no positive feedback path from the output back to the input.

An operational-amplifier comparator connected in a positive-feedback mode (**Fig. 2**) is referred to as a regenerative comparator. If the voltage gain A is

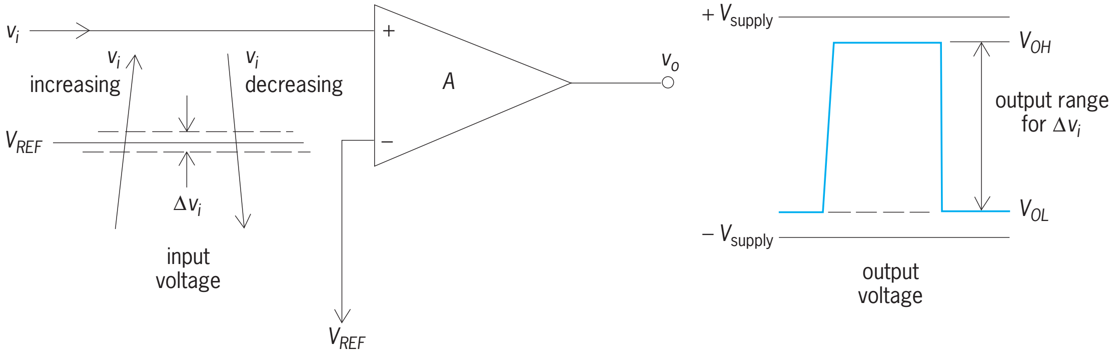

Fig. 1. High-gain nonregenerative operational amplifier as voltage comparator.

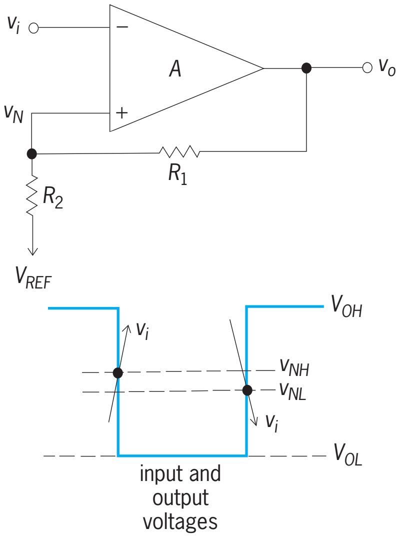

Fig. 2. Regenerative operational amplifier as comparator (Schmitt trigger). The input and output voltages are superimposed, showing hysteresis.

very high, then the feedback voltage v_N is given by Eq. (2) when the output voltage is $v_o = V_{OH}$; and

$$v_N = v_{NH} = \frac{R_2 V_{OH} + R_1 V_{REF}}{R_1 + R_2} \qquad (2)$$

when $v_o = V_{OL}$ the feedback voltage is given by Eq. (3).

$$v_N = v_{NL} = \frac{R_2 V_{OL} + R_1 V_{REF}}{R_1 + R_2} \qquad (3)$$

For this circuit there is a difference between the input levels which will cause the output to switch, given by Eq. (4).

$$v_{NH} - v_{NL} = \frac{R_2}{R_1 + R_2}(V_{OH} - V_{OL}) \qquad (4)$$

This difference in input levels is referred to as the hysteresis of the circuit. Such regenerative comparators are generically referred to as Schmitt triggers. Historically, they were first implemented as discrete two-vacuum-tube devices, which were later replaced by transistors and then by the operational amplifier feedback circuit. *See* AMPLIFIER; FEEDBACK CIRCUIT; HYSTERESIS; OPERATIONAL AMPLIFIER.

Digital comparator. The term digital comparator has historically been used when the comparator circuit is specifically designed to respond to a combination of discrete level (digital) signals, for example, when one or more such input signals simultaneously reach the reference level which causes the change of state of the output. Among other applications, such comparators perform the function of the logic gate such as the AND, OR, NOR, and NAND functions. More often, the term digital comparator describes an array of logic gates designed specifically to determine whether one binary number is less than or greater than another binary number. Such digital comparators are sometimes called magnitude or binary comparators.

Applications. Comparators may take many forms and can find many uses, in addition to those which have been discussed. For example, the electronically regulated dc voltage supply uses a circuit which compares the dc output voltage with a fixed reference level. The resulting difference signal controls an amplifier which in turn changes the output to the desired level. In a radio receiver the automatic gain control circuit may be thought of broadly as a comparator; it measures the short-term average of the signal at the output of the detector, compares this output with a desired bias level on the radio-frequency amplifier stages, and changes that bias to maintain a constant average level output from the detector. *See* AUTOMATIC GAIN CONTROL (AGC).

Regenerative comparators (Schmitt triggers) are often used as the key element in the voltage-controlled oscillator (VCO), which in turn is the control element in the phase-locked loop (PLL). Nonregenerative comparators are often used in parallel analog-to-digital converters where a number of comparators (equal to the desired bit rate) are used at a succession of higher V_{REF} levels. *See* ANALOG-TO-DIGITAL CONVERTER; PHASE-LOCKED LOOPS.

Complement

A group of proteins in the blood and body fluids that are sequentially activated by limited proteolysis and play an important role in humoral immunity and the generation of inflammation. When activated by antigen–antibody complexes, or by other agents such as proteolytic enzymes (for example, plasmin), complement kills bacteria and other microorganisms. In addition, complement activation results in the release of peptides that enhance vascular permeability, release histamine, and attract white blood cells (chemotaxis). The binding of complement to target cells also enhances their phagocytosis by white blood cells. The most important step in complement system function is the activation of the third component of complement (C3), which is the most abundant of these proteins in the blood. *See* IMMUNITY.

There are two mechanisms for the activation of C3, the classical and the alternative pathways. The classical pathway requires calcium and is activated when the C1q component binds to immunoglobulin antibodies IgG or IgM. In contrast, activation of the alternative pathway requires magnesium and is not dependent on antibodies. The activation of C3 by either pathway results in the cleavage of C3 to a small fragment, C3a, and a large fragment, C3b. The latter binds to a bimolecular enzyme, and a new trimolecular complex is formed which cleaves C5 into a small fragment, C5a, and a large fragment, C5b. This is the final enzymatic step in complement activation; the rest of the activation process is nonenzymatic. An amphiphilic macromolecular complex is formed by the binding of one molecule of C5b to one molecule each of C6, C7, and C8, and 12 or more molecules of C9. This so-called membrane attack complex invades the membrane of target cells and kills them. At first these complexes become embedded in target-cell membranes without inflicting any damage. After a molecule of C8 binds to the C5b,6,7 complex, a transmembrane channel (pore) is formed, and the complex can destroy target cells, although very slowly. The process is much accelerated by polymerization of C9 into the complexes, forming a cylindrical structure. The top of the cylinder is hydrophilic and capped by a ring or annulus that remains outside the target cell. The other end is lipophilic; it becomes embedded in the cell membrane and forms large transmembrane channels which coalesce into so-called leaky patches. The target cell loses potassium, imbibes sodium and water, swells, and bursts. This is called cell lysis, or hemolysis in the case of a red blood cell.

As mentioned earlier, several small fragments are enzymatically generated during complement activation, and these act to release histamine from mast cells. The C5a fragment is potent in chemotaxis and in activating phagocytes. The C2b fragment contains a peptide that, upon release by further proteolysis, markedly enhances vascular permeability. Phagocytes and red blood cells have a receptor for fragments C4b and C3b, called complement receptor (CR1), which appears to play an important role in clearing immune complexes from blood. Phagocytes also have a complement receptor 3 (CR3) which, when engaged, stimulates phagocytes to produce superoxide and enhances phagocytic killing of ingested bacteria. A third complement receptor (CR2) is found only on B lymphocytes. *See* ALLERGY; CELLULAR IMMUNOLOGY; HISTAMINE.

Genetic deficiencies of certain complement subcomponents, including properdin, have been found in humans, rabbits, guinea pigs, and mice. All are inherited as autosomal recessives, except for properdin deficiency, which is X-linked recessive, and C1 inhibitor deficiency, which is autosomal dominant. Certain deficiencies lead to immune-complex diseases, such as systemic lupus erythematosus; other deficiencies result in increased susceptibility to bacterial infections, particularly those of the genus *Neisseria* (for example, gonorrhea and meningococcal meningitis), and hereditary angioneurotic edema. *See* COMPLEMENT-FIXATION TEST.

Bibliography. R. D. Campbell et al., Structure, organization, and regulations of the complement genes, *Annu. Rev. Immunol.*, 6:161–196, 1988; H. J. Muller-Eberhard, The membrane attack complex of complement, *Annu. Rev. Immunol.*, 4:503–528, 1986.

Complement-fixation test

A sensitive reaction used in serology for the detection of either antigen or antibody, as in the diagnosis of many bacterial, viral, and other diseases, including syphilis. It involves two stages: stage I is the binding or fixation of complement if certain antigen-antibody reactions occur, and stage II is detection of residual unbound complement, if any, by its hemolytic action on the sensitized erythrocytes subsequently added. This is shown in the **illustration**. *See* ANTIBODY; ANTIGEN; COMPLEMENT.

In the first stage either the antigen or the antibody must be supplied as a reagent, with the other of the pair as the test unknown. Fresh guinea pig serum is normally used as a complement source. Sheep erythrocytes which are coated with their corresponding antibody (amboceptor or hemolysin) are used in the second stage.

The controls A, B, and C in the illustration demonstrate that sufficient complement is present to effect hemolysis of the sensitized indicator cells and that

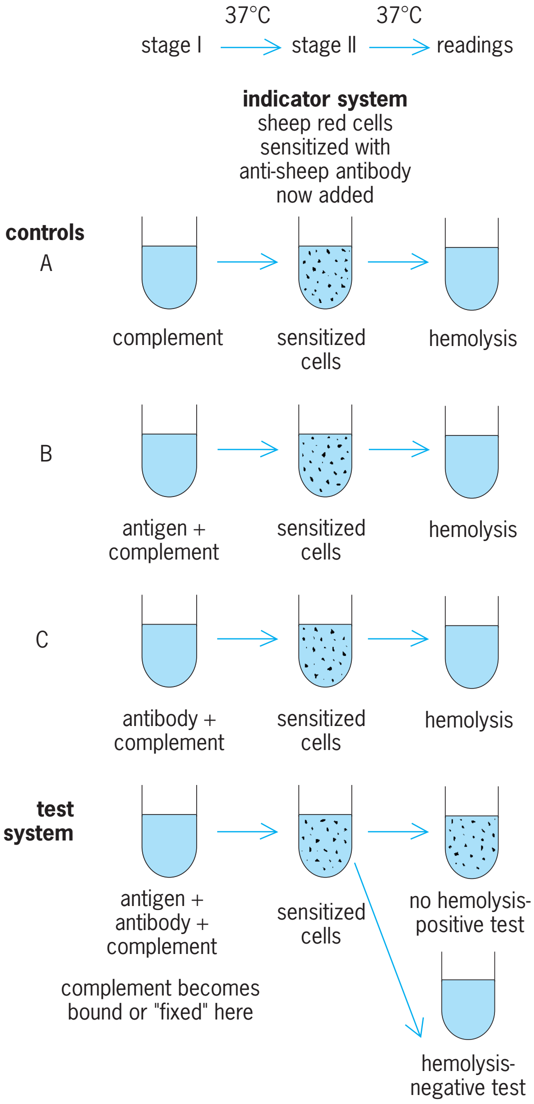

Diagram of the complement-fixation reaction. 37°C = 98.6°F.

neither antigen nor antibody added alone will interfere with this by binding complement. In the test system the combination of a suitable antigen and antibody in the presence of complement will bind the complement to the complex so that the complement becomes unavailable for the hemolysis of the indicator cells added in stage II. If either antigen or antibody is added as a reagent in stage I, then the presence of the other in the test unknown that is added can be detected through its ability to complete the antigen-antibody system. A lack of hemolysis denotes that the complement is bound. This result is termed a positive complement-fixation reaction and, if the system is controlled against false reactions, implies that the antigen (or antibody) assumed to be in the test unknown was actually present. Conversely, complete hemolysis of the sensitized erythrocytes implies, ultimately, absence of antigen or antibody and is termed a negative complement-fixation reaction. In its most sensitive form the microcomplement-fixation test can distinguish the minute antigenic difference that results from the shift in a single amino acid between hemoglobins A and S. *See* IMMUNOLOGY; LYTIC REACTION; SEROLOGY. **Henry P. Treffers**

Complementation (genetics)

The correction of a cellular defect caused by mutations in a gene by the addition of the normal gene or its product (protein). In cell cultures, complementation can be accomplished by transfer of deoxyribonucleic acid (DNA) or messenger ribonucleic acid (mRNA) that encodes this protein. Another way to "complement" a cellular defect is by joining two chromosome sets in the same cell, each defective due to a different mutation but together able to correct the cellular defect. This principle is used in somatic cell hybridization (or cell fusion), in which cells are fused to generate hybrid cells that possess all chromosomes from both fusion partners. Such hybrids are usually viable and can be examined for the presence of the cellular deficiency via complementation analysis. *See* CHROMOSOME; DEOXYRIBONUCLEIC ACID (DNA); MUTATION.

Complementation analysis. Complementation analysis is used to study the relationships between different genes or alleles which individually cause functional defects in the organism when mutated but in combination restore the wildtype phenotype. It has been very helpful in elucidating the genetic heterogeneity of hereditary diseases, such as Zellweger syndrome, which is caused by malfunctioning peroxisomes (intracellular organelles involved in the metabolism of hydrogen peroxide); xeroderma pigmentosum, which is associated with defective repair of DNA damage caused by ultraviolet light; and Fanconi anemia, a blood disorder associated with chromosomal breakage and a high susceptibility to cancer. These are recessive diseases, which means that both copies of the disease gene are defective; patients inherit a defective copy from each parent, who themselves are carriers of only one defective copy and are asymptomatic.

A condition for carrying out complementation analysis is that a specific disease feature should be recognizable at the cellular level. In the case of Fanconi anemia, for example, this feature is the hypersensitivity of patient cells to DNA cross-linking agents (which promote the joining of two DNA strands or a DNA strand with a protein strand) such as mitomycin C (MMC). When cell lines derived from two unrelated patients with Fanconi anemia are fused, the resulting hybrid cell line may continue to show MMC sensitivity (indicating a lack of complementation), or the cell line may show MMC resistance (indicating that complementation has taken place). *See* PEROXISOME; SOMATIC CELL GENETICS.

Complementation groups. Patients whose cell lines—when combined in a fusion hybrid—fail to complement each other's defect are said to belong to the same "complementation group," whereas when complementation does occur, the cell lines belong to different groups (**Fig. 1**). When multiple complementation groups exist for a disease, each group is thought to represent a distinct disease gene. The explanation is that certain proteins may function as essential components of a specific biochemical pathway and that a defect in any one of these components may cause disruption of that pathway, each defect having essentially the same consequence for the organism. In the case of Fanconi anemia, 12 complementation groups have been distinguished. The disease gene has been identified for 11 of these groups. Eight of these genes encode proteins that aggregate into a multi-subunit complex that protects the cell against certain types of DNA

Patel, The emerging genetic and molecular basis of Fanconi anaemia, Nature Rev. Genet., 2(6):446–457,* © *2001 Macmillan Magazines Ltd.*]

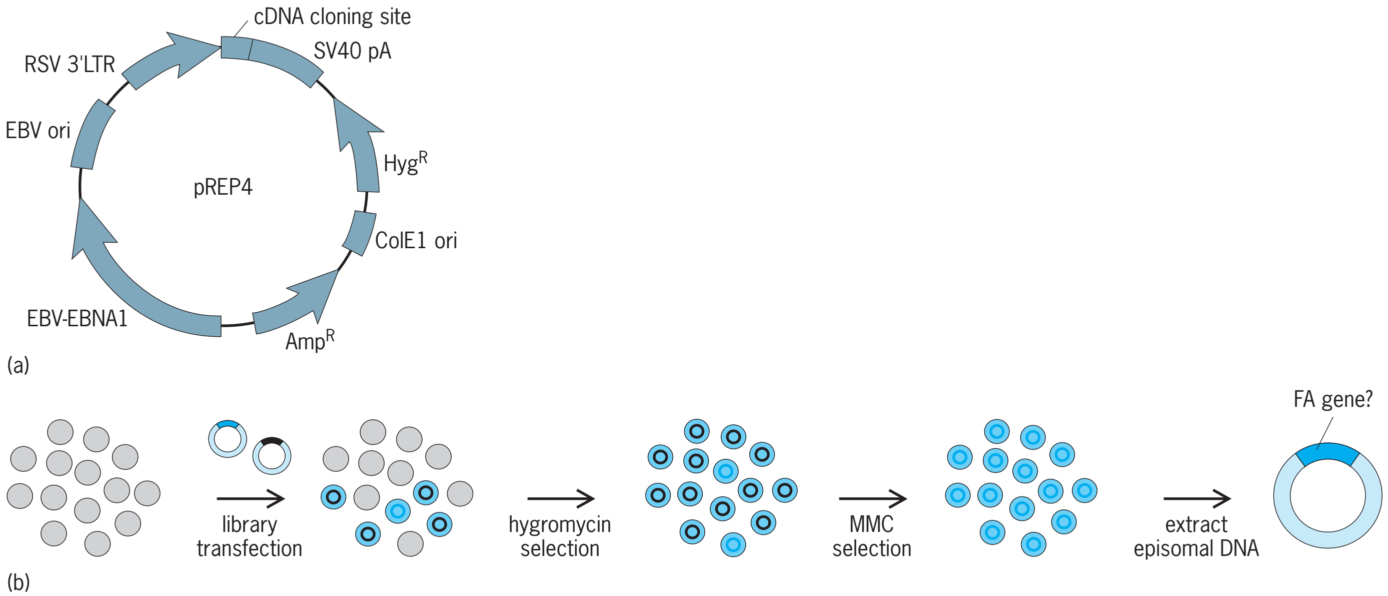

Fig. 2. Example of complementation cloning of an FA gene. (*a*) The vector containing various cDNAs. (*b*) The plasmid with the various inserts is introduced into lymphoblasts derived from a patient with FA (library transfection). Selection with hygromycin causes only cells that contain a plasmid to survive. Selection with MMC causes cells to survive that are complemented for the FA defect. The cDNA present in the plasmid extracted from surviving cells is likely the gene that is defective in the lymphoblasts. [*Reproduced with permission from Nature Reviews Genetics (http://www.nature.com/reviews): H. Joenje and K. J. Patel, The emerging genetic and molecular basis of Fanconi anaemia, Nature Rev. Genet., 2(6):446–457, © 2001 Macmillan Magazines Ltd.*]

damage. Each protein is important for the function of this complex, which explains why defects in any one of them cause Fanconi anemia.

Complementation cloning. A procedure known as complementation cloning has been instrumental in the identification of most of the genes underlying Fanconi anemia. This method makes use of an expression plasmid (a vector that expresses the gene) that is able to replicate in bacteria as well as in human cells (**Fig. 2**). When introduced into human B lymphoblasts (white blood cells), the plasmid is constructed in such a way that it cannot be integrated into the cellular DNA. A wide variety of human genes (cDNAs) are placed into multiple copies of this plasmid, which ensures expression of all these individual genes. After the plasmids with the inserted human genes are introduced into lymphoblasts from a patient with Fanconi anemia, the cells are selected for plasmid uptake by using a selection marker present in the plasmid. Further selection with a concentration of MMC that kills Fanconi anemia cells but not wild-type cells (normal functioning cells) allows survival of cells that have been complemented for the defect. These complemented cells are likely to harbor a plasmid that expresses the gene that is defective in the lymphoblasts. Extraction of the plasmid allows the identification of its insert, which is a candidate for representing the defective gene. Finding pathogenic mutations in this gene in patients belonging to the same complementation group finally should provide proof of identity for this disease gene.

Intragenic complementation. Sometimes combinations of different defects in a single gene may lead to partial or complete complementation (intragenic complementation). This might occur when the protein functions exclusively by forming a homodimer. In such cases, deficiencies in different regions of the individual proteins may be compensated in the dimeric structure, resulting in a preserved function. *See* GENE; GENE ACTION; HUMAN GENETICS.

Complex numbers and complex variables

A natural and extremely useful extension of the familiar real numbers. They can be introduced formally as follows. Consider the two-dimensional real vector space consisting of all ordered pairs (a_1, a_2) of real numbers. Geometrically this space can be identified with the ordinary euclidean plane, viewing the real numbers a_1, a_2 as the coordinates of a point in the plane.

The addition of vectors is defined by $(a_1, a_2) + (b_1, b_2) = (a_1 + b_1, a_2 + b_2)$ and is just the usual addition of vectors by the parallelogram law (**Fig. 1**). The multiplication of a vector (a_1, a_2) by a real number c is defined by $c(a_1, a_2) = (ca_1, ca_2)$, and is just the uniform dilation of the plane by the factor c. It

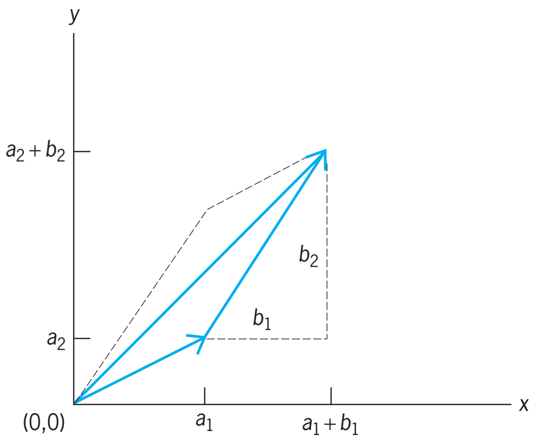

Fig. 1. Vector addition of two complex numbers by the parallelogram law.

may be asked whether it is possible to define a multiplication of one vector by another in such a manner that this multiplication is linear and satisfies the same formal rules as multiplication of real numbers. That is to say, it may be asked whether it is possible to associate to any two vectors (a_1, a_2) and (b_1, b_2) a product vector $(a_1, a_2) \cdot (b_1, b_2)$ in such a manner that:

1 The multiplication is linear in the sense that

$$(a_1, a_2) \cdot [(b_1, b_2) + (c_1, c_2)] = (a_1, a_2) \cdot (b_1, b_2) + (a_1, a_2) \cdot (c_1, c_2)$$

2 It is associative,

$$(a_1, a_2) \cdot [(b_1, b_2) \cdot (c_1, c_2)] = [(a_1, a_2) \cdot (b_1, b_2)] \cdot (c_1, c_2)$$

3 It is commutative,

$$(a_1, a_2) \cdot (b_1, b_2) = (b_1, b_2) \cdot (a_1, a_2)$$

4 There is an identity vector (e_1, e_2) such that

$$(e_1, e_2) \cdot (a_1, a_2) = (a_1, a_2)$$

for all vectors (a_1, a_2).

5 For each vector (a_1, a_2) other than (0, 0) there is a vector (b_1, b_2) for which

$$(b_1, b_2) \cdot (a_1, a_2) = (e_1, e_2)$$

There does exist such a multiplication, given by Eq. (1), and it is essentially unique in the sense that

$$(a_1, a_2) \cdot (b_1, b_2) = (a_1 b_1 - a_2 b_2, a_1 b_2 + a_2 b_1) \quad (1)$$

any multiplication satisfying all the desired properties can be reduced to Eq. (1) by a suitable choice of coordinates in the plane. The plane with the ordinary addition and scalar multiplication of vectors and with the vector multiplication in Eq. (1) is the complex number system. It is not possible to introduce a corresponding multiplication on vector spaces of higher dimensions, although, for example, if the commutativity condition is dropped, there is a multiplication satisfying the remaining conditions on the four-dimensional vector space (the quaternions).

Geometric interpretation. The multiplication in Eq. (1) can be interpreted most easily geometrically by introducing polar coordinates in the plane and writing $(a_1, a_2) = (r \cos \theta, r \sin \theta)$, where r is the length of the vector (a_1, a_2), or the modulus of the complex number (a_1, a_2), defined by $r^2 = a_1^2 + a_2^2$, and θ is the angle between the vector (a_1, a_2) and the first coordinate axis, or the argument of the complex number (a_1, a_2), defined by $\tan \theta = a_2/a_1$. It follows immediately from Eq. (1), by using the familiar addition formulas for the sine and cosine functions, that

$$(r_1 \cos \theta_1, r_1 \sin \theta_1) \cdot (r_2 \cos \theta_2, r_2 \sin \theta_2) = [r_1 r_2 \cos (\theta_1 + \theta_2), r_1 r_2 \sin (\theta_1 + \theta_2)]$$

Thus multiplication of complex numbers amounts to multiplying their moduli and adding their arguments (**Fig. 2**). *See* TRIGONOMETRY.

Real and imaginary parts. Introducing the basis vectors $l = (1, 0)$ and $i = (0, 1)$, any vector (x, y) can be written uniquely as the sum $(x, y) = xl + yi$. Since the multiplication given by Eq. (1) is linear, the product of any two vectors is determined by giving the multiplication table for the basis vectors l and i. It follows readily from Eq. (1) that $l \cdot l = l$, $l \cdot i = i \cdot l = i$, and $i \cdot i = -l$, so that in particular the vector l is the identity element for the multiplication of complex numbers. Furthermore, the addition and multiplication of vectors of the form xl for all real numbers x reduce to the ordinary addition and multiplication of real numbers. There is consequently a natural imbedding of the real numbers into the complex numbers by associating to any real number x the complex number xl. The complex number l can be identified with the ordinary real number 1, and reflecting this identification the notation can be simplified by writing a complex number $z = (x, y) = xl + yi$ merely as $z = x + iy$. The component x is called the real part of the complex number

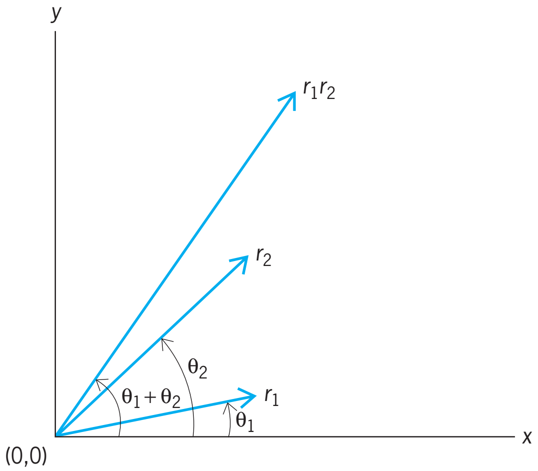

Fig. 2. Multiplication of complex numbers.

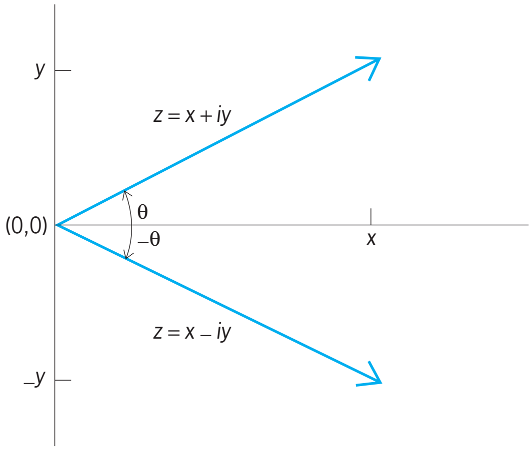

Fig. 3. Complex conjugate numbers.

z, and the component y is called the imaginary part. The modulus of the complex number z is denoted by $|z|$.

Complex conjugates. The vectors l and $-i$ are also a basis and satisfy exactly the same multiplication table as the vectors l and i, so the mapping which associates to any complex number $z = x + iy$ the complex number $\bar{z} = x - iy$ is a one-to-one mapping preserving the algebraic structure of the complex number system; thus $\overline{(z_1 + z_2)} = \bar{z}_1 + \bar{z}_2$ and $\overline{(z_1 \cdot z_2)} = \bar{z}_1 \cdot \bar{z}_2$. The complex number $\bar{z}$ is called the conjugate of z. It has the properties that $z = \bar{z}$ precisely when z is a real number, that $z \cdot \bar{z} = x^2 + y^2 = |z|^2$, and that in polar coordinates $\bar{z}$ is a complex number with the same modulus as z but with the negative argument (**Fig. 3**).

Polynomials. An ordinary real polynomial function $f(x) = x_n + a_1x^{n-1} + \cdots + a_n$ can be extended to a function of a complex variable z in the obvious manner, merely setting $f(z) = z^n + a_1z^{n-1} + \cdots + a_n$ and using the algebraic operations as defined for complex numbers. The advantage of this extension is that the fundamental theorem of algebra then holds: a nontrivial polynomial function over the complex numbers always has a root α, a complex value for which $f(\alpha) = 0$. The same result is true for polynomials with complex coefficients $a_1, \ldots, a_n$. A simple consequence of this result is that any polynomial function of degree n can be written as a product $f(z) = (z - \alpha_1)(z - \alpha_2) \cdots (z - \alpha_n)$ where the complex numbers $\alpha_1, \alpha_2, \ldots, \alpha_n$ are precisely the roots of this polynomial repeated according to multiplicity. Thus passing from the real to the complex number system simplifies the analysis of polynomial functions and clarifies many of their properties. This was in a sense the original motivation for introducing the complex number system.

Power series. In a somewhat similar manner, passing from the real to the complex number system simplifies and clarifies the analysis of more general functions than polynomials. Many of the familiar functions treated in elementary calculus have convergent Taylor series expansions and so can be written for all real numbers x sufficiently near a real number a in the form of a convergent infinite series

$$f(x) = \sum_{n=0}^{\infty} a_n(x - a)^n$$

where $n!a_n = f^{(n)}(a)$. If this series converges when the real number x is replaced by nearby complex numbers z, there results a natural extension of the function f to a complex-valued function of the complex variable z.

The question of convergence can be handled rather easily. A series of the form

$$\sum_{n=0}^{\infty} a_n(z - a)^n$$

where a_n, a, z are complex numbers is called a complex power series centered at the point a. For any such series there is a value r, a nonnegative real number or ∞, such that the power series converges for all complex numbers z satisfying $|z - a| < r$ and diverges for all complex numbers z satisfying $|z - a| > r$; r is called the radius of convergence of the power series. If $r = 0$, the power series diverges for all complex numbers z other than $z = a$, while if $r = \infty$, the power series converges for all complex numbers. Otherwise, the series converges for all complex numbers lying within a circle of radius r centered at the point a and diverges for all complex numbers outside that circle. The series may or may not converge at complex numbers on the circle itself. The radius of convergence can be determined by Hadamard's formula: $1/r = \limsup_{n\to\infty} |a_n|^{1/n}$. Alternatively and generally more simply the radius of convergence satisfies

$$\liminf_{n\to\infty} |a_n|/|a_{n+1}| \leq r \leq \limsup_{n\to\infty} |a_n|/|a_{n+1}|$$

If r is the radius of convergence of a power series, then that series converges absolutely and uniformly on the set of all complex numbers z satisfying $|z - a| \leq \rho$ whenever $\rho < r$.

Using these observations it is easy to see, for example, that the exponential function can be extended to a complex-valued function of the complex variable z defined for any z by

$$e^z = \sum_{n=0}^{\infty} z^n/n!$$

Among the trigonometric functions the sine and cosine functions also can be defined for arbitrary complex numbers z by their Taylor series. Moreover, these functions satisfy the identity $e^{iz} = \cos z + i \sin z$ for all complex numbers z, an interesting relation among the elementary functions only apparent when passing to complex numbers. *See* SERIES.

Analytic functions. A complex-valued function f of a complex variable defined on some region Ω in the complex plane is analytic or holomorphic in Ω if for each point a in Ω the values of the function at all points z sufficiently near a are given by a power series expansion

$$f(z) = \sum_{n=0}^{\infty} a_n (z - a)^n$$

This power series then must be the Taylor series expansion of the function f at the point a and must converge in at least the largest circle centered at a and contained in Ω. An analytic function in a region Ω is necessarily a continuous function in Ω moreover, as a function of the two real variables (x, y), an analytic function has partial derivatives of all orders.

Characterization by differentiability. There are a number of alternative characterizations of analytic functions, all of which are useful. The most common and perhaps the most surprising characterization, which is often taken as the definition of an analytic function, is that a function f is analytic in Ω precisely when the limit given by (2) exists at all points a in Ω. This limit is

$$\lim_{z\to a}\frac{f(z)-f(a)}{z-a} \tag{2}$$

the complex analog of the ordinary derivative and is therefore called the complex derivative and written $f(a)$. If the power series

$$f(z)=\sum_{n=0}^{\infty}a_n(z-a)^n$$

converges in a disc Δ centered at a, then

$$f'(z)=\sum_{n=0}^{\infty}na_n(z-a)^{n-1}$$

and this series also converges in the disc Δ. *See* CALCULUS.

Cauchy-Riemann equation. If f is analytic near a point a, then the complex derivative (2) can be calculated by letting z approach a through a sequence of points having the same imaginary value as a, hence $f'(a) = \partial f/\partial x$. Alternatively, the complex derivative can be calculated by letting z approach a through a sequence of points having the same real value as a, hence $f'(a) = -i\,\partial f/\partial y$. Upon comparing these two results it follows that an analytic function f must satisfy the Cauchy-Riemann equation

$$\frac{\partial f}{\partial x}+i\frac{\partial f}{\partial y}=0$$

which is sometimes written $\partial f/\partial\bar{z}=0$. Conversely if f is a complex-valued function defined in a region Ω of the complex plane, and if f has continuous first partial derivatives with respect to the real coordinates x and y, and if they satisfy the Cauchy-Riemann equation at all points of Ω, then f is analytic in Ω. It is not enough merely to require the existence of the first partial derivatives, and so this is not such a clean characterization of analytic functions as the preceding one, but it is nonetheless very useful. Weaker regularity conditions than the continuity of the first partial derivatives are possible. For instance, if the function f has first partial derivatives in the sense of distributions and if they satisfy the Cauchy-Riemann equation, then f is analytic.

Relation to harmonic functions. Setting $f(x, y) = u(x, y) + iv(x, y)$, where u and $v$are real-valued functions, the Cauchy-Riemann equation can be written equivalently as the pair of equations

$$\frac{\partial u}{\partial x}=\frac{\partial v}{\partial y},\quad \frac{\partial u}{\partial u}=-\frac{\partial v}{\partial x}$$

It follows immediately from this that $\partial^2u/\partial x^2 + \partial^2v/\partial y^2 = 0$ and similarly for v, so that the real and imaginary parts of an analytic function are harmonic functions. Conversely if u is harmonic in a simply connected region Ω of the complex plane, the pair of real Cauchy-Riemann equations determines a harmonic function v such that $u + iv$ is analytic in Ω, and v is unique up to an additive constant; if Ω is not simply connected, the function v may not be single-valued. *See* DIFFERENTIAL EQUATION; LAPLACE'S DIFFERENTIAL EQUATION.

Morera's theorem. If f is an analytic function in a region Ω of the complex plane, then it follows from the Cauchy-Riemann equation that, using the terminology and notation of differential forms, the differential form $fdz = fdx + ifdy$ is closed, since

$$d(f\,dx+i\,f\,dy)=\left(i\frac{\partial f}{\partial x}-\frac{\partial f}{\partial y}\right)dx\wedge dy=0$$

Therefore

$$\int_{\gamma} f\,dz=0$$

for any closed path γ homologous to zero in Ω. Conversely Morera's theorem asserts that if f is a continuous complex-valued function in Ω and if

$$\int_{\gamma} f\,dz=0$$

for all closed paths γ homologous to zero in Ω, then f is necessarily analytic in Ω. From this characterization of analyticity it follows immediately that the limit of a uniformly convergent sequence of analytic functions is also analytic.

Conformal mapping. An analytic function f in a region Ω of the complex plane can be viewed as a mapping from the plane region Ω into the complex plane. If $f(z) = u(z) + iv(z)$, this mapping is described in real terms by the pair of functions $u(x, y)$, $v(x, y)$. It follows readily from the Cauchy-Riemann equation that the jacobian determinant of this real mapping is

$$\det\begin{pmatrix}u_x\ u_y\\ v_x\ v_y\end{pmatrix}=u_x^2+v_x^2=\left|f'(z)\right|^2 \tag{3}$$

Since the jacobian determinant is thus always nonnegative, the mapping always preserves orientation. Moreover, the mapping is locally one-to-one whenever $f'(z) \neq 0$, and its inverse is readily seen also to satisfy the Cauchy-Riemann equation and therefore to be analytic. By analyzing further the condition imposed by the Cauchy-Riemann equation it follows that if $f'(a) \neq 0$, if γ_1 and γ_2 are two differentiable paths through the point a, and if the tangent vectors to γ_1 and γ_2 at the point a are at an angle θ apart, then the tangent vectors to the paths $f(\gamma_1)$ and $f(\gamma_2)$ at the point $f(a)$ are also at an angle θ apart. The mapping

Fig. 4. A conformal mapping that preserves angles at a.

f thus preserves angles at a, and is therefore said to be conformal at a (**Fig. 4**). Conversely any continuously differentiable conformal mapping is an analytic function with a nonzero complex derivative, thus providing a very geometric characterization of analytic functions. *See* CONFORMAL MAPPING; PARTIAL DIFFERENTIATION.

For completeness, something should be said about the mapping property of an analytic function at a point at which the complex derivative is zero. The analytic function $f(z) = z^n$, for example, has a zero derivative at $z = 0$ whenever $n > 1$. The mapping is not conformal but increases angles at the origin by a factor of n (**Fig. 5**) and so can be viewed as a mapping which wraps each circle about the origin in its domain n times about the origin in its range. Now if f is any analytic function at the origin with $f(0) = f'(0) = 0$, then this function can be written in the form $f(z) = g(z)^n$ for some integer $n > 1$, where g is analytic at the origin, $g(0) = 0$ but $g'(0) \neq 0$. Therefore the change of variable $w = g(z)$ reduces the function f to the form $f(w) = w^n$ just considered. It is clear from this that an analytic function takes open sets to open sets even when its derivative is zero and that any analytic function satisfies the maximum modulus theorem: if f is analytic at a and $|f(a)| \geq |f(z)|$ for all points z in some neighborhood of a, then f must actually be a constant. This seemingly simple property has a considerable range of applications.

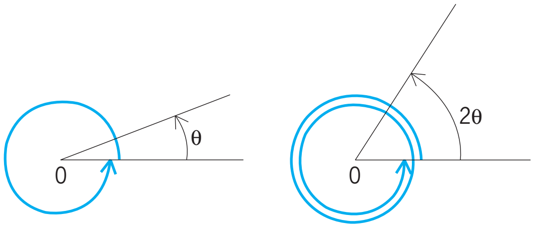

Fig. 5. The mapping z^2 at the origin.

Cauchy integral formula. An integral representation formula due to A. Cauchy plays a fundamental role in complex analysis and is traditionally the principal tool used in proving the equivalence of some of the alternative characterizations of analytic functions given above. The formula asserts that if γ is the smooth boundary curve of a finite region Ω in the complex plane (**Fig. 6**) and if f is analytic in an open neighborhood of the closed region $\Omega \cup \gamma$ (the union of Ω and γ), then

$$\frac{1}{2\pi i}\int_\gamma \frac{f(\zeta)d\zeta}{\zeta - z} = \begin{cases} f(z) & \text{whenever } z \text{ is a member of } \Omega \\ 0 & \text{whenever } z \text{ is not a member of } \Omega \cup \gamma \end{cases} \quad (4)$$

This shows, for example, that the values of the analytic function f in Ω are completely determined by the values of that function on the boundary of Ω. Equation (4) can be differentiated under the integral sign to yield the companion formula (5)

$$f^{(n)}(z) = \frac{n!}{2\pi i}\int_\gamma \frac{f(\zeta)\,d\zeta}{(\zeta - z)^{n+1}} \quad (5)$$

for the derivatives of the function f at any point z in Ω. In particular, if Ω is a disk of radius r centered at a point a and if $|f(z)| \leq M$ on the boundary γ of Ω, then (5) implies that $|f^n(a)| \leq Mr^{-n}n!$. Thus the derivatives of an analytic function cannot grow faster than $r^{-n}n!$ for some r as n tends to infinity. An immediate consequence of this estimate is Liouville's theorem, the assertion that the only functions analytic and bounded in the entire plane are the constant functions.

Relation to Green's integral theorem. The Cauchy integral formula (4) can be considered as a special case of a more general integral representation formula, following fairly directly from Green's integral theorem. If Ω and γ are as before and if f is any continuously differentiable complex-valued function of the real variables (x, y) in an open neighborhood of the closed region $\Omega \cup \gamma$, then

$$f(z) = \frac{1}{2\pi i}\int_\gamma f(\zeta)\frac{d\zeta}{\zeta - z} + \frac{1}{2\pi i}\int\int_\gamma \frac{\partial f(\zeta)}{\partial\bar{\zeta}}\frac{d\zeta \wedge d\bar{\zeta}}{\zeta - z} \quad (6)$$

is valid for all z in Ω. Since analytic functions are characterized by the Cauchy-Riemann equation $\partial f/\partial\bar{z} = 0$, it is evident that (6) reduces to (4) for analytic functions. The more general formula (6) is useful in investigating solutions of the partial differential equation $\partial f/\partial\bar{z} = g$ for a given function g. This equation has many applications in complex analysis.

Relation to Poisson integral formula. The Cauchy integral formula (4) is also closely related to the Poisson integral formula for harmonic functions, which can be

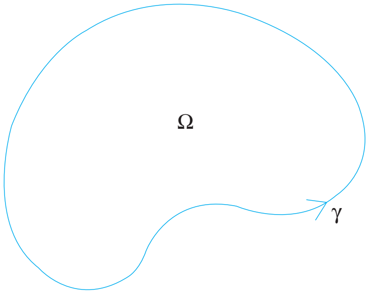

Fig. 6. The geometric situation in which the Cauchy integral formula holds.

derived from Eq. (4). The Poisson formula is useful in solving boundary-value problems for harmonic functions. For any continuous function on the smooth boundary γ of a bounded region Ω, there exists a harmonic function u in Ω with the given boundary values. If Ω is simply connected, the function u is the real part of an analytic function in Ω, so there thus exists a holomorphic function in Ω with an arbitrarily specified real part on γ. The imaginary part of this analytic function is determined uniquely up to an additive constant by the real part, so there cannot exist an analytic function in Ω with arbitrarily specified values on the boundary curve γ. On the other hand, if g is any sufficiently smooth function on γ, the integral

$$\int_\gamma \frac{g(\zeta)}{\zeta - z} d\zeta$$

represents an analytic function $f_i(z)$ at all points z in Ω and another analytic function $f_0(z)$ at all points outside $\Omega \cup \gamma$. These functions have well-defined boundary values on γ, and $f_i(z) - f_0(z) = 2\pi i g(z)$ whenever z is on γ; the function $f_0(z)$ vanishes only when g is the boundary value on γ of an analytic function in Ω.

Isolated singularities. If a function f is analytic at all points of a disk Δ centered at a, except perhaps at the point a itself, a is called an isolated singularity of the function f. There are three mutually exclusive possibilities for the nature of such a singularity.

1. It may happen that $|f(z)|$ remains bounded near the point $a(14)$. In that case the function can be extended to an analytic function even at the point a by suitably choosing the value of $f(a)$; the point a is then called a removable singularity.

2. It may happen that $\lim_{z\to a}|f(z)| = \infty$. In that case a is a removable singularity for the function $g(z) = 1/f(z)$, so that $f(z) = 1/g(z)$ where $g(z)$ is an analytic function vanishing at the point a; and if $g(z) = (z - a)^k g_0(z)$, where $g_0(z)$ is analytic and $g_0(a) \neq 0$, then $f(z) = (z - a)^{-k} f_0(z)$ where $k > 0$ and $f_0(z)$ is analytic and $f_0(a) \neq 0$. The function $f(z)$ is said to have a pole of order k at the point a. The function $f_0(z)$ has a Taylor expansion at the point a as usual, so the function $f(z)$ has an expansion given by Eq. (7).

$$f(z) = a_{-k}(z-a)^{-k} + \cdots + a_{-1}(z-a)^{-1} + a_0 + a_1\,(z-a) + a_2\,(z-a)^2 + \cdots \quad (7)$$

The portion

$$\sum_{n=-k}^{-1} a_n(z-a)^n$$

of this expansion is called the principal part or singular part of the function $f(z)$ at the point a, while the remainder of the series represents an analytic function near a.

3. If neither of the two preceding cases arises, the function $f(z)$ is said to have an essential singularity at the point a. A function having an essential singularity admits a Laurent series expansion near the point a of the form

$$f(z) = \sum_{n=-\infty}^{+\infty} a_n(z-a)^n \quad (8)$$

in which infinitely many terms involving negative powers of the variable $(z - a)$ appear. Singularities of this type can occur and do so frequently. For example, whenever $f(z)$ has a pole at a point a, then $e^{f(z)}$ has an essential singularity at the point a. The behavior of a function near an essential singularity is rather complicated. A theorem of K. Weierstrass asserts that in any neighborhood of an essential singularity the values taken by the function come arbitrarily near any complex value. A much deeper theorem of E. Picard asserts that in any neighborhood of an isolated singularity a function actually takes all complex values with at most one possible exception.

Global properties. The zeros of an analytic function are isolated, in the sense that if f is analytic near a point a and $f(a) = 0$, then f has no other zeros in some neighborhood of a. That leads quite easily to the identity theorem: if $f(z)$ and $g(z)$ are analytic in a connected-region Ω and if $f(a_n) = g(a_n)$ for an infinite sequence of points a_n having a limit point inside Ω, then $f(z) = g(z)$ at all points z in Ω. On the other hand, if a_n is any sequence of points in Ω having no limit point inside Ω, there are analytic functions in Ω having zeros precisely at the points a_n. This result is particularly easy in case that Ω is the entire complex plane. Indeed, in that case any analytic function having zeros at the points a_n can be written as a product given

$$f(z) = z^m e^{h(z)} \prod_n \left(1 - \frac{Dz}{a_n}\right) e^{P_n(z)} \quad (9)$$

where $h(z)$ is an analytic function in the entire plane and $P_n(z)$ are suitably chosen polynomials ensuring that the product converges when there are infinitely many points a_n. There is a good deal of quite detailed information relating the growth of the function $f(z)$, the distribution of the zeros a_n, and the canonical product formula (9). This area of investigation is called the theory of entire functions. The infinite product expansions of even the elementary functions are quite interesting. For example, the expansion of $\sin \pi z$ is given by

$$\sin \pi z = \pi z \prod_{n=1} \left(1 - \frac{z^2}{n^2}\right) \quad (10)$$

Meromorphic functions. A function analytic in a region Ω of the complex plane, except possibly for poles at some points of Ω, is called a meromorphic function in Ω. The points at which the function has poles can of course have no limit point inside Ω. Near any pole a function can be written as the quotient of two analytic functions, as already noted. There is an analogous global result: any meromorphic function in Ω can be written as the quotient of two functions each analytic in Ω. If $a_1, a_2, \ldots$ is any sequence of points in Ω having no limit point inside Ω and if

$f_1(z), f_2(z), \ldots$ are principal parts of poles at these points, so that

$$f_v = \sum_{n=-kv}^{-1} a_{v,n}(z - a_v)^n$$

There exists a meromorphic function $f(z)$ in Ω having poles with the specified principal parts at the specified points and no other singularities. This is the analog of the familiar partial fraction expansion for quotients of polynomials. The resulting expansions of even the elementary functions are quite interesting, as for example the expansion

$$\pi \cot \pi z = \frac{1}{z} + \sum_{n=1}^{\infty} \frac{2z}{z^2 - n^2} \tag{11}$$

Rational functions. Those functions that have at most finitely many zeros and poles in the entire complex plane, and that either have a well-defined limit or tend to infinity as the variable approaches infinity, are rational functions; that is, they are quotients of polynomial functions. These functions extend naturally to the Riemann sphere, the set that arises by adjoining to the complex plane a single point at infinity. The change of variable $\zeta = 1/z$ transforms the complement of a large circle in the plane of the variable z to the interior of a small circle in the plane of the variable ζ; the point at infinity in the variable z corresponds to the origin in the variable ζ, and that makes it possible to speak of the behavior of a rational function at the point at infinity. The rational functions are precisely those functions that are meromorphic on the entire Riemann sphere, including the point at infinity. Although they are in some senses the simplest of analytic functions, their study leads to extremely complicated problems. Any such function can be viewed as a mapping of the Riemann sphere to itself; and this mapping can be iterated, beginning with the function $f(z)$ and then passing to the iterates $f^2(z) = f(f(z))$, and so on. The behavior of the iterates can be very complicated even for the simplest such functions, second-degree polynomials. The sphere can be decomposed into two disjoint sets: the Fatou set, an open subset of the Riemann sphere on which the iterates form an equicontinuous family of functions and generally converge; and the Julia set, usually a very complicated closed set, even a fractal set, on which the iterates form a family exhibiting the phenomenon of chaos (**Fig. 7**). *See* CHAOS; FRACTALS.

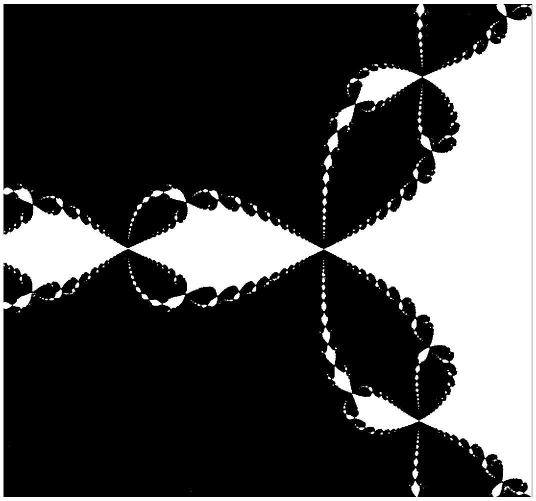

Fig. 7. $z \mapsto z^3 - 1$**. Fractal image. (*Reprinted with permission from H.-O. Peitgen and P. H. Richter, The Beauty of Fractals, Springer-Verlag, New York, 1986*)**

Analytic functions of several variables. A complex-valued function depending on several complex variables $f(z_1, \ldots, z_n)$ is called analytic at a point $(a_1, \ldots, a_n)$ if the values of that function at all points z_j sufficiently near a_j are given by a multiple power series expansion

$$f(z_1, \ldots, z_n) = \sum_{i_1=0}^{\infty} \cdots \sum_{i_n=0}^{\infty} a_{i_1 \ldots i_n}(z - a_1)^{i_1} \cdots (z - a_n)^{i_n} \tag{12}$$

If this series converges at a point $(z^0{}_1, \ldots, z^0{}_n)$ with $|z^0{}_1 - a_i| = r_i > 0$, then it is absolutely and uniformly convergent on the set of all points $(z_1, \ldots, z_n)$ for which $|z_i - a_i| \leq \rho_i$ whenever ρ_i are any positive constants such that $\rho_i < r_i$. This series thus converges to the same value for any ordering of the terms. For example, it can be rewritten as the power series

$$f(z_1, \ldots, z_n) = \sum_{i_n=0}^{\infty} a_{i_n}\left(z_1, \ldots, z_{n-1}\right) \cdot (z_n - a_n)^{i_n} \tag{13}$$

in the variable z_n with coefficients which are analytic functions of the variables $z_1, \ldots, z_{n-1}$. Hence holding $z_1, \ldots, z_{n-1}$ constant, the function $f(z_1, \ldots, z_n)$ is analytic in the variable z_n alone, or more generally the function $f(z_1, \ldots, z_n)$ is analytic in each variable separately. Conversely a surprisingly nontrivial theorem of F. Hartogs asserts that a function $f(z_i, \ldots, z_n)$ that is analytic in each variable separately at all points of a region Ω is an analytic function of all n variables $z_1, \ldots, z_n$ in Ω.

It follows from this result that analytic functions of several variables can be characterized in many of the same ways as are analytic functions of one variable, since it suffices to show that a function is analytic in each variable separately. Thus, if a function of several complex variables has a complex derivative in each variable separately, or satisfies the Cauchy-Riemann equations in each variable separately, then it is analytic. It is convenient to extend the Cauchy-Riemann characterization by associating to any function f of n complex variables the differential form

$$\bar{\partial} f = \sum_{i=1}^{n} \frac{\partial f}{\partial \bar{z}_i} d\bar{z}_i$$

A function of n complex variables that is continuously differentiable in the underlying real variables is analytic if $\bar{\partial} f = 0$. The analysis of this differential operator plays a significant role in a great deal of research on properties of analytic functions of several variables.

Extension of results from one variable. Some results extend quite directly from one to n complex variables: the uniform limit of analytic functions is analytic; the maximum modulus theorem holds; and there is an extension of the Cauchy integral formula, asserting that if $f(z_1, \dots, z_n)$ is analytic whenever z_j is a member of $\Omega_j \cup \gamma_j$ where Ω_j is a plane domain with smooth boundary γ_j, then

$$f(z_1, \dots, z_n) = \left(\frac{1}{2\pi i}\right)^n \int_{\zeta_1 \epsilon \gamma_1} \cdots \int_{\zeta_n \epsilon \gamma_n} \frac{f(\zeta_1, \dots, \zeta_n)}{(\zeta_1 - z_1) \cdots (\zeta_n - z_n)} d\zeta_1 \cdots d\zeta_n \qquad (14)$$

holds whenever z_j is a member of Ω_j for all indices j. However, for the most part, the theory of analytic functions of several complex variables is far from being merely an extension of the standard results of the classical theory of functions of a single complex variable, by considering one variable at a time. Indeed, the theory of functions of several complex variables has quite a distinctive character with a considerable variety of results which perhaps are not the expected generalizations of the classical results but which shed new light on the familiar theory of analytic functions of a single variable.

Integral formulas. In addition to the direct extension of the classical Cauchy integral formula from one to several variables in (14), there are a variety of other integral representation formulas that reflect the higher-dimensional situation and that have significant applications. Some of these formulas, such as those due to André Weil and Stefan Bergman, follow the extended Cauchy integral formula (14) in that they involve integration over only part of the boundary of the domain. Others, such as those of Salomon Bochner and E. Martinelli, involve an integration over the full boundary, and are particularly useful for examining the behavior of functions on smoothly bounded domains. Yet others, such as those due to W. Koppelman and I. Lieb, extend the analysis to functions that are not complex analytic, by providing explicit solutions f of the system of partial differential equations $\bar{\partial} f = \phi$, where ϕ is a differential form. These solutions also are important in the analysis of the boundary values of analytic functions of several variables. The integral formulas themselves are rather complicated.

Analytic continuation. An examination of the extended Cauchy integral formula (14) indicates some of the differences between the cases $n = 1$ and $n > 1$. When $n = 1$, either formula (14) or (4) expresses the values of an analytic function inside a domain Ω in terms of the values of the analytic function on the boundary of Ω, whereas when $n > 1$, formula (14) expresses the values of an analytic function inside a domain $\Omega_1 \times \cdots \times \Omega_n$ in terms of the values of the analytic function on a very small piece of the boundary. For example, when $n = 2$ the domain $\Omega_1 \times \Omega_2$ can be viewed as an open set of the four-dimensional euclidean space, its boundary is the three-dimensional subset $(\Omega_1 \times \gamma_2) \cup (\gamma_1 \times \Omega_2)$, but the integration in (14) is extended across the two-dimensional part $\gamma_1 \times \gamma_2$ of the boundary. This difference is not superficial; it reflects the greater possibilities for analytic continuation of functions of $n > 1$ variables than of functions of a single variable.

For any domain Ω in the complex plane there are functions which are analytic in that domain but which cannot be extended as analytic functions across any part of the boundary of Ω. For example, there exist nontrivial analytic functions vanishing at any infinite sequence of points $a_1, a_2, \dots$ of Ω having no limit point inside Ω, and if every boundary point of Ω is a limit of a subsequence of these points $a_1, a_2, \dots$ then such an analytic function cannot be continued across any boundary point. However, there are domains Ω in the space of $n > 1$ complex variables such that any function analytic in Ω extends to an analytic function in a properly larger domain. For example, it was shown by Hartogs that if Ω is an open neighborhood of the boundary of a compact subset K in the space $n > 1$ complex variables, then every function analytic in Ω extends to a function analytic in the union of K and Ω (**Fig. 8**).

Thus in the study of functions of $n > 1$ complex variables there arise the problems of characterizing the natural domains of existence of analytic functions (called domains of holomorphy) and of determining for those domains which are not domains of holomorphy the largest domains to which all analytic functions can be extended (called the envelopes of holomorphy). Both problems have been extensively studied, the first one particularly so. Perhaps the most surprising result is that the domains of holomorphy can be characterized purely locally: a domain Ω in the space of n complex variables is a domain of holomorphy if and only if each point on the boundary of Ω has an open neighborhood $\cup$ such that the intersection of $\cup$ and Ω is a domain of holomorphy. The determination of the envelope of holomorphy of a domain is generally rather difficult, the situation being complicated by the fact that the envelope of holomorphy may not be realizable as a domain in the space of n complex variables.

Zeros and singularities. Another and not entirely unrelated difference between functions of $n > 1$ and functions of one complex variable is that in the case $n > 1$ the zeros and singularities of an analytic function are never isolated. The set of zeros of an analytic function of $n > 1$ variables is a set of topological dimension $2n - 2$ and is in most places locally euclidean but can have very complicated singularities. Strange spaces, such as the exotic seven spheres,

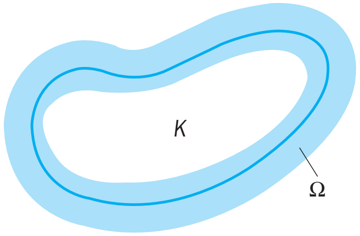

Fig. 8. Analytic continuation in $n > 1$ dimensions according to the theorem of Hartogs.

manifolds which are topologically but not differentiably equivalent to the ordinary seven-dimensional sphere, arise in this context. Even the purely local study of functions of several complex variables thus presents a considerable challenge. *See* TOPOLOGY.

Applications. The general theory of analytic functions of several complex variables has a wide range of applications in other parts of mathematics. It is a standard tool in the examination of function algebras and of special spaces of functions, the subject of harmonic analysis. The techniques also arise in geometric problems in various parts of differential geometry. *See* DIFFERENTIAL GEOMETRY. Robert C. Gunning

Complexity theory

The theory of complex systems. Complexity theory arises from the need to understand the richness in structure and behavior often seen in large systems. The property that distinguishes complex systems from systems that are large but simple is the emergence of global features from local interactions, as captured in the popular saying "the whole is greater than the sum of its parts." For example, a flock of birds emerges when individual birds coordinate their behavior with each other.

Complexity often appears as unpredictability, or as a tendency for a system to undergo sudden, rapid change. Typically, it arises within systems that have strong interrelationships between components. For instance, the coordinated action of millions of individual cells, all tightly bound together, produces the action of muscles in the body. Epidemics emerge from the spread of infection from individual to individual.

Complexity theory has its roots in many fields of research, including biology, computer science, ecology, engineering control systems, nuclear physics, and operations research. In physics, for instance, there is a need to understand properties that emerge within large ensembles of atoms and other particles. General systems theory, developed by the biologist Ludwig von Bertalanffy in the 1950s, identified the role of internal interactions and processes in self-organization. In the 1960s, W. Ross Ashby and Norbert Wiener developed cybernetics, which concerned communications and feedback in the control of systems. Complexity theory came into its own during the late 1980s, as increasing computing power made large-scale simulation studies practical. The formation of specialist research centers, such as the Santa Fe Institute, did much to promote the new science during the 1990s. *See* CYBERNETICS; ECOLOGY; NUCLEAR STRUCTURE; OPERATIONS RESEARCH.

Several fields of research have become closely linked to complexity theory. The link to graph theory is assured by the network model of complexity (discussed below). The relevance of chaos theory arises because complexity in dynamic systems often leads to nonlinear and chaotic behavior. Another related field is artificial life (Alife), which concerns lifelike features found in artificial systems. By addressing complexity in living systems, this field has influenced the development of theory in evolution, ecology, and sociobiology. Evolutionary computing concerns computational processes that address complex problems by mimicking species evolution. The best-known example is the genetic algorithm, introduced by John Holland in 1975. This solves complex optimization problems by treating key parameters as genes within a population of potential solutions. Complex adaptive systems (CAS) are systems, such as brains or societies, composed of interacting elements that adapt or change in response to experience. *See* CHAOS; EVOLUTIONARY COMPUTATION; GENETIC ALGORITHMS; GRAPH THEORY.

Network model. In most cases, complexity can be understood in terms of networks. This model treats systems as sets of objects ("nodes") with connections ("edges") linking them. For instance, within a flock of birds the nodes would be birds and their interactions would be the edges. In a nuclear chain reaction, the nodes would be atoms and the edges would be moving neutrons. The network model also applies to processes and behavior. In a game of chess, for instance, each arrangement of pieces on the board is a node in a network of board arrangements, and moves by the players provide the edges that link different arrangements. In many games, for instance, a general strategy is to restrict your opponent's moves while maximizing the number of possible moves that you can make.

Strictly speaking, a set of nodes linked by edges forms a graph (for example, people who are neighbors of each other). A directed graph is a graph in which each edge has direction (for example, descendants in a family), and a network is a graph in which the nodes or edges have attributes associated with them (for example, people have names).

In any network, some features arise from the nature of the objects and their relationships, and some emerge from the underlying network. A network is connected if there is a path (a sequence of edges) leading from any one node to any other. For example, the edges A-B, B-C, C-D form a path between nodes A and D. Attributes that are often used to express the structure of different networks include:

Connectivity (the number of edges that must be removed to break the network apart).

Edge density (the number of edges as a fraction of the total number possible).

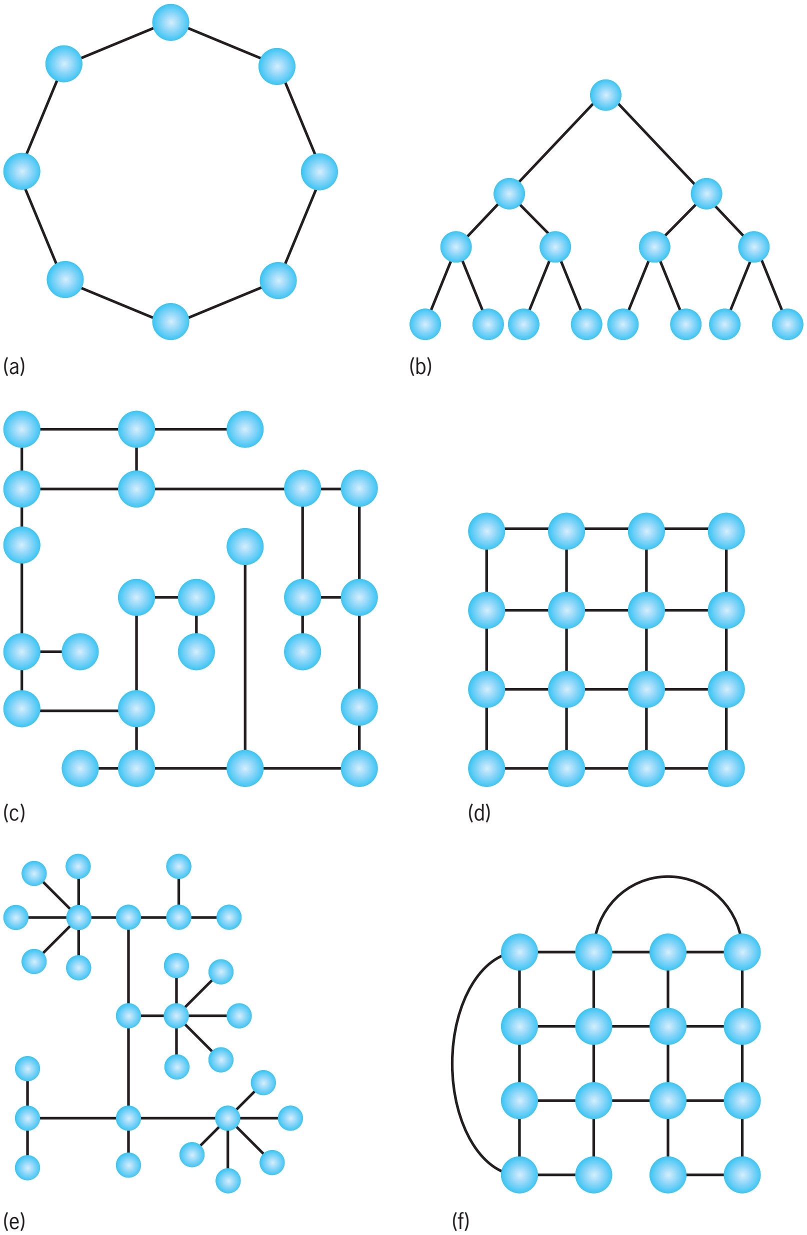

Fig. 1. Structure of some common kinds of networks. (*a*) Cycle. (*b*) Tree. (*c*) Random. (*d*) Regular. (*e*) Scale-free. (*f*) Small world.

Clustering (the density of links between sets of nodes linked to a given node).

Diameter (the greatest separation between pairs of nodes, where separation is taken to mean the shortest path between a given pair of nodes).

Several kinds of network structure are common because they confer important properties:

1. Cycles or circuits (**Fig. 1*a***) are regular networks in which a single path joins every node. The sequence of edges A-B, B-C, C-D, D-A forms a cycle linking the nodes A, B, C, and D.

2. Trees (Fig. 1*b*) are connected networks that contain no cycles. Hierarchies are trees with a root node, a node that all edges lead away from (for example, a common ancestor in a family tree). In computing, objects can form hierarchies in two ways: whole-part hierarchies (for example, in a whole book, the parts are chapters), and gen-spec hierarchies (for example, a novel is a special kind of book, and a book is a special kind of publication).

3. Random networks (Fig. 1*c*) are networks in which edges are distributed randomly between nodes.

4. Regular networks (Fig. 1*d*) are connected networks in which the edges form a pattern (for example, a lattice or grid).

5. Scale-free networks (Fig. 1*e*) form when new nodes in a growing network attach preferentially to existing nodes with highest connectivity. The resulting distribution of links per node obeys an inverse power law. That is, some nodes have many connections, but most have few. Web sites on the Internet, connected by hypertext links, provide a good example.

6. Small worlds (Fig. 1*f*) are connected graphs that contain both local clusters and long-range interactions. They fall between random networks at one extreme and regular networks at the other. Social networks often take this form.

Phase transitions. Complex systems have a tendency to undergo sudden change. Examples include crystallization, water freezing, and epidemics. In all cases, these phase changes occur at a fixed value (the critical point) of some order parameter (for example, water freezes at a temperature of 0°C). Phase transitions can usually be understood as connectivity avalanches in an underlying network (**Fig. 2**). If a network is formed by adding edges at random to a set of N nodes, then a phase change (connectivity avalanche) occurs when the number of edges reaches the critical density $N/2$ (**Fig. 3**): the nodes become absorbed into a unique giant component. This connectivity avalanche translates into many physical processes. In crystallization, for instance, it involves small crystal seeds merging to form large structures. In all epidemic phenomena, the process requires a certain critical level of interaction to sustain itself. Nuclear fission, for instance, starts when the fuel reaches a critical mass. *See* CRITICAL MASS; CRITICAL PHENOMENA; CRYSTALLIZATION; EPIDEMIC; PHASE TRANSITIONS.

Automata whose state spaces lie close to the phase change in connectivity (the so-called edge of chaos) often exhibit interesting behavior, leading to speculation that only these automata are capable of universal computation and the ability to evolve.

Self-organized criticality occurs when internal processes maintain a system in a critical state (for example, a sand pile). Characteristically, the frequency (f) of events in such a system (for example, the sand pile collapses) follows an inverse power law $f(s) = s^{-\tau}$, where s is the size of the event and τ is a self-similarity exponent.

Encapsulation. Encapsulation involves grouping nodes in a network into modules that are highly connected internally, but with limited connections to the rest of the network. In both natural and artificial systems, encapsulation is the most common way of coping with complexity. It appears in many different guises. In human activity, large tasks are usually

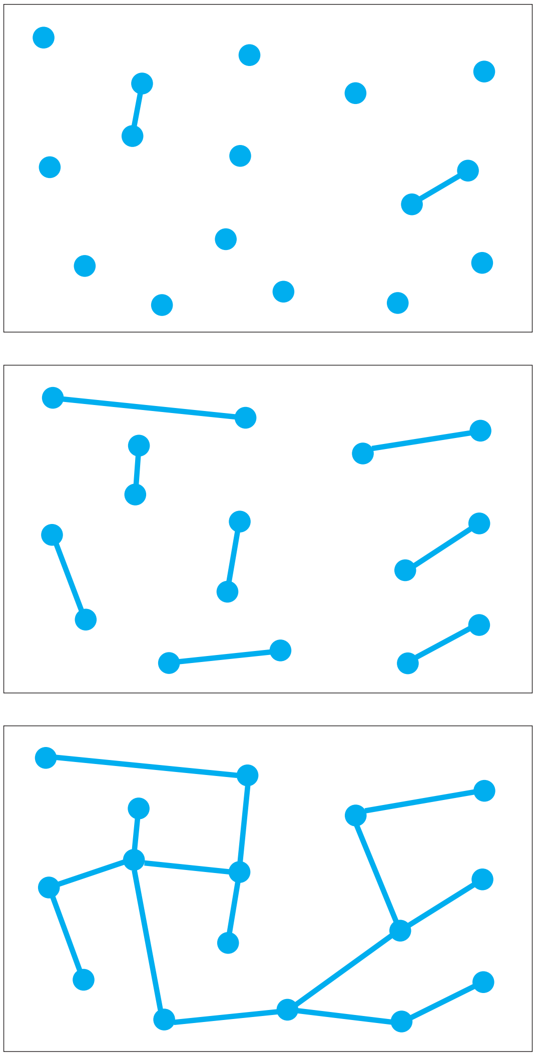

Fig. 2. Formation of a unique giant component as edges are added to a random network.

broken down into managable parts: Large corporations are typically divided into work units such as divisions, departments, and sections. Likewise, filing systems are divided into cabinets, drawers, files, and folders.

Modular design simplifies construction. Computer software typically consists of self-contained, reusable objects and modules. Living trees grow by the repeated addition of modules, such as buds, leaves, and branches. Engineering systems are often designed around modular components. A motor car, for instance, has electrical, fuel, and steering systems, and so on.

Encapsulation reduces complexity by eliminating long-range connections. In a human organization, for instance, specialization reduces the scope of problems that each person needs to deal with. On the other hand, modular designs can be brittle, often failing when long-range connections occur, such as by placing a library book back on the wrong shelf.

Modular structures often form into hierarchies of organization. A book, for instance, is a hierarchy of modules consisting of chapters, sections, paragraphs, sentences, and words. In management, hierarchies arise from the dual desires to simplify complex tasks and to control complex organizations ("divide and rule").

Self-organization. Internal interactions can lead to the emergence of order within complex systems, even in the absence of external influences. Several processes are known to promote self-organization. Ilya Prigogine introduced the term "dissipative systems" to describe systems (including living things) that are far from equilibrium and share energy with their environment. He argued that in dissipative systems local irregularities can grow and spread, allowing large-scale patterns and order to emerge. Crystal growth is an example. *See* CRYSTAL GROWTH.

Feedback plays an important role in self-organization. It occurs where the output of a system is fed back as input to the same system. Negative feedback dampens disturbances and stabilizes local patterns and behavior. Familiar examples include thermostats, speed governors, and other control devices that maintain systems in a steady state (sometimes called homeostasis). Positive feedback amplifies local effects, allowing them to grow and spread. Control systems are designed to avoid positive feedback because of its destabilizing effect. In contrast, positive feedback plays an important role in natural systems by contributing to the formation of large-scale order. In interstellar gas clouds, for instance, gravity leads to the formation of large centers of mass. These centers gather material faster, and at the expense of smaller ones, eventually forming stars and planets. Within an ant colony, piles of food, eggs, and waste grow in a similar way. Eventually this sorting of materials creates the order seen in ant colonies. Firing of a laser occurs when groups of atoms synchronize their outputs by "enslaving" other atoms. *See* CONTROL SYSTEMS; HOMEOSTASIS; LASER; MOLECULAR CLOUD.

Other processes that promote self-organization include encapsulation, adaptation, and evolution within living systems.

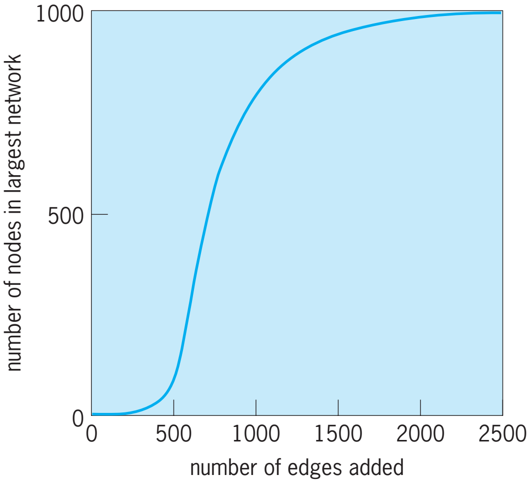

Fig. 3. Connectivity avalanche. Edges, each joining a pair of nodes, are added at random to a set of 1000 nodes. The avalanche begins when about 500 edges are added.

Emergence. In a system of objects, interactions lead to self-organization, which results in the emergence of large-scale features. An ant colony emerges from the joint activity of thousands of individual ants interacting with each other and with their environment. Emergent properties are not predictable from the properties of the individuals, but often involve the imposing of constraints on individuals. In module formation, for instance, individual interactions with the outside could disrupt the module's integrity.

Module formation is a crucial mechanism in the emergence of order in many complex systems. In a growing embryo, for instance, cells differentiate at a very early stage of development, forming modules that grow into separate limbs and organs. *See* CELL DIFFERENTIATION.

A related problem is the paradox of self-replication. This originated during the seventeenth century with attempts to explain human reproduction. Human eggs or sperm were thought to contain homunculi, tiny bodies from which children would grow. However, this idea led to a paradox: a single homunculus would need to have nested within it smaller homunculi from which future generations would spring. The paradox of self-replication arises because some part a self-replicating system apparently needs to contain a copy of the whole system. How is it possible, for instance, for a plant or animal to reproduce without including a complete description of itself? The paradox is resolved by observing that only information about the process of replication needs to be embedded within the system, not the entire system itself. The rest of the information can be derived from interaction of the system with its environment. John von Neumann suggested that there is a threshold of complexity below which automata are too simple to be capable of self-replication. However, later researchers, such as Lionel and Roger Penrose, demonstrated that even certain simple block structures could replicate themselves. Tom Ray's Tierra model provided a practical demonstration of a computational environment within which programs emulated organisms by containing code for reproducing themselves.

Computational complexity. In computing, the complexity of a problem is measured by the time (or space) required to solve it, and the way that time increases as the size of the input increases. For instance, given a list of the locations of n towns, the time needed to find the most northerly town increases in proportion to n [denoted $O(n)$], but the time required to find the shortest distance between pairs of towns increases in proportion to n^2 [denoted $O(n^2)$].

In problem solving, an important advantage of modularity is to reduce combinatorial complexity. In a rail network linking, say, 100 stations, separate fares for every pair of stations would require a table with 4950 entries, but grouping the stations into, say, 3 zones would reduce the table to no more than 6 different fares.

Problems are often classified according to their computational complexity. Conventional terminology defines the class P to consist of all problems that can be solved by a deterministic algorithm for which the time complexity is a polynomial function of the input (for example, the towns examples above). The class NP consists of problems that a nondeterministic machine can solve in polynomial time. An unresolved theoretical question is whether the classes P and NP are identical. *See* CRYPTOGRAPHY.

Hard problems occur when the time complexity increases faster than any polynomial of the input. In the traveling salesman problem, for instance, a salesperson needs to find a route that minimizes the total distance traveled while visiting a number of towns (without doubling back). The solution involves checking all possible orderings of a list of the towns.

Attempts to link complexity to thermodynamics and information theory led to the Kolmogorov-Chaitin definition of algorithmic complexity, which is the length of the shortest program needed to compute a given pattern. For example, a table of sports scores in general contains more or less random entries and cannot be compressed. In contrast, a table of logarithms can be condensed to a formula that calculates all the entries. Describing the path of a flock of birds greatly reduces the detail needed to describe the paths of all the individual birds. These ideas extend into many aspects of computing. Methods such as minimum message length (MML) adapt them to provide practical methods of classification and problem solving. Data compression algorithms typically employ a fixed program and reduce a file to the data needed to regenerate the original pattern. Fractals may be regarded as patterns that are produced by repeating a given algorithm on different scales. *See* DATA COMPRESSION; FRACTALS; INFORMATION THEORY.

As information technology has spread throughout society, the idea of natural computation has been increasingly influential. This idea treats natural processes as forms of computing. For instance, scientific studies sometimes employ computational analogies (for example, animals as programmed robots) to understand complex processes in natural systems. Likewise, computing has borrowed ideas from nature, which has evolved ways of solving complex problems. This practice has resulted in a proliferation of biological terms such as cellular automata, genetic algorithms, neural networks, and swarm intelligence. *See* NEURAL NETWORK.

Role of simulation. Complex systems usually behave in nonlinear fashion. They are often mathematically intractable, and the richness of their behavior can make them inherently unpredictable. Simulation models provide a practical way of representing them. Certain representations are widely used to simulate specific kinds of complex systems, notably cellular automata, spin glasses, and agent-based models.

Cellular automata are grids of cells, each of which is an automaton that interacts with its neighbors. First introduced by John von Neumann, cellular automata became popular during the 1970s as a result of John Conway's cellular automaton Game of Life.

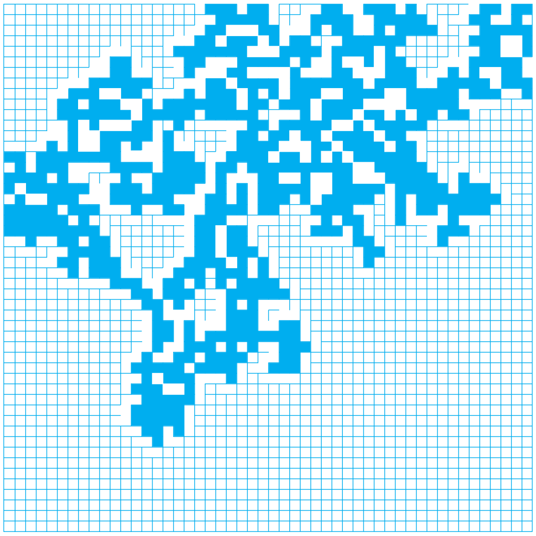

Fig. 4. Cellular automaton simulation of epidemic spread through a landscape. The cells represent areas of the land surface. Filled cells have been infected.

They have been applied to many physical processes, such as flows and spread of epidemics (**Fig. 4**). In a simple cellular automaton model of disease spread, for instance, each cell would denote an area within a landscape, and the cell's state at any given time might be "susceptible," "infected," or "immune." The epidemic would spread from infected cells to neighboring susceptible cells. The virulence of the disease would determine the chances of a susceptible cell becoming infected; otherwise it would become immune. *See* CELLULAR AUTOMATA.

Spin glasses (regular lattices, in which each node has a "spin") have been used to study processes, such as glass formation, involving transitions from incoherent to coherent configurations of spin states in magnetic materials. *See* SPIN GLASS.

Agent-based models consist of many independent agents (for example, people, animals, or companies) that interact with one another and behave according to defined sets of rules. Cellular automata are a subclass of agent-based models. Early examples of this approach included Paulien Hogeweg's work on the emergence of social order within bumblebee colonies and Craig Reynold's "boids" models of flocking behavior in birds.

Simulation models provide several practical advantages for dealing with complexity. One is the potential to perform "virtual experiments" for problems where real-world experiments are impractical. Another is the ability to explore "what-if" scenarios when complexity makes prediction impossible. *See* SIMULATION.

Future challenges. Complexity theory is becoming more important as the problems faced by science and society grow more complex. Is it possible to evolve designs to specification for huge networks that are both robust and efficient? The Internet, for instance, poses enormous challenges as a self-organizing system for gathering, storing, and distributing information. *See* INTERNET.

In biology perhaps the greatest challenge at present is to understand how genetic regulatory networks control growth and development. During the 1970s, Stuart Kauffmann proposed a switching model of genetic control that was based on Boolean networks. Research has increasingly pointed to modular organization within the genome. Development of the eye, for instance, is encoded by a set of genes whose activity is controlled by a single "eyeless gene." *See* DEVELOPMENTAL GENETICS; MOLECULAR BIOLOGY.

One far-reaching impact of communications and globalization is that the world is increasingly rich in interactions. Cascading interactions often mean that events in one part of the world can affect events on the other side of the globe.

Composite beam

A structural member composed of two or more dissimilar materials joined together to act as a unit. An example in civil structures is the steel-concrete composite beam in which a steel wide-flange shape (I or W shape) is attached to a concrete floor slab (**Fig. 1**). The many other kinds of composite beam include steel-wood, wood-concrete, and plastic-concrete or advanced composite materials–concrete. Composite beams as defined here are different from beams made from fiber-reinforced polymeric materials. *See* COMPOSITE MATERIAL.

There are two main benefits of composite action in structural members. (1) By rigidly joining the two parts together, the resulting system is stronger than the sum of its parts. A simple example is a pair of timber 2 by 4 in. (5 by 10 cm) studs joined by

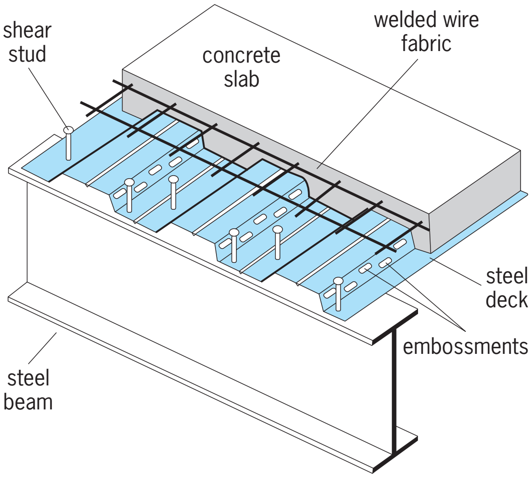

Fig. 1. Typical composite floor system.

nails. The two timber pieces connected together are far stronger and more rigid than the two individual pieces stacked together. A key feature of this system is the connecting elements, nails in this case, which provide the transfer of horizontal (shear) forces in the system. (2) Composite action can better utilize the properties of each constituent material. In steel-concrete composite beams, for example, the concrete is assumed to take most or all of the compression while the steel takes all the tension. Since concrete is very strong in compression but weak in tension (the ratio of tensile to compressive strength being approximately 1:10), and steel is prone to instability (buckling) in compression, the composite beam represents the most efficient use of these two materials. *See* CONCRETE; SHEAR; STEEL.

In general, it is assumed that these composite beams are loaded primarily in flexure and that the steel beam carries all of the tension and the slab part or all of the compression. The bending forces on the beam give rise to large horizontal (shear) forces at the interface of the materials. To transfer this force, several mechanisms can be considered, including adhesion, friction, and bearing. The first two are generally disregarded because of their lack of reliability, and in most composite systems the shear connection is provided by steel elements welded to the steel beam. These elements transfer the shear forces by bearing against the concrete. The most common type of shear connector is a shear stud, which resembles a bolt but has no threads and a smaller head (Fig. 1). Shear studs typically range from $\frac{1}{2}$ to $\frac{3}{4}$ in. (13 to 19 mm) in diameter, and from $3\frac{1}{2}$ to 5 in. (8 to 13 cm) in length. A typical $\frac{3}{4}$ -in. shear stud can transfer about 20 kips (90 kilonewtons) of horizontal force (1 kip = 1000 lb or 454 kg load). The shear stud requires a head to resist any tendency of the slab and beam to separate vertically. The studs typically are distributed evenly along the length of the beam, with spacing ranging from 6 to 16 in. (150 to 400 mm). Because typical steel decks have troughs at 12 in. (150 mm) spacing, this is the most common spacing for shear studs. It is also common to see several studs side by side in the direction perpendicular to the main axis of the beam. This arrangement is necessary in steel bridges, because the size of the steel beam is large and thus the shear forces are large. *See* STRESS AND STRAIN.

There are numerous reasons why steel-concrete composite beams have long been recognized as one the most economical structural systems for both multistory steel buildings and steel bridges. Buildings and bridges require a floor slab to provide a surface for occupants and vehicles, respectively. Concrete is the material of choice for the slab because its mass and stiffness can be used to reduce deflections and vibrations of the floor system and to provide the required fire protection. The supporting system underneath the slab, however, is often steel because it offers superior strength-weight and stiffness-weight ratio, ease of handling, and rapid construction cycles. Since both the steel and concrete are already present in the structures, it is logical to connect them together to better utilize their strength and stiffness. The typical steel-concrete composite beam is 60 to 80% stronger and stiffer than the steel beam alone. The stiffness and strength gains are greater for shallow beams [16 to 24 in. (40 to 60 cm) in depth] and less for deeper sections.

Three important developments have contributed to the widespread use of steel-concrete composite beams. (1) Automated systems were developed to provide the connection between the steel beam and the concrete. This connection was originally provided by welding steel channels, spirals, or serpentines to the top of the steel beam. In the 1950s a system utilizing shear studs that could be welded with a portable system (stud gun) was developed, and is in almost universal use today. (2) In the 1960s and 1970s, steel floor decking was developed. Steel decking consists of thin corrugated metal sheets that are laid between the steel beams and used as the formwork to cast the concrete. This made concrete casting much simpler, as the formwork was left in place to provide much of the tensile capacity of the slab. (3) Alternative types of steel beams were developed. Due to height limitations and the need for complex HVAC (heating, ventilation, and air conditioning), electrical, and communication installations, several variations on the traditional composite beam have been developed. They include composite joists, composite trusses, and stub-girders (**Fig. 2**). These systems are intended to provide high span/depth ratios while retaining flexibility in relocating building services. Systems using joists and trusses are popular since they avoid the need to make expensive penetrations in the beam web. *See* CONCRETE SLAB.

Composite beams in buildings have spans ranging typically from about 20 to 40 ft (6 to 12 m) for traditional beams but can be as large as 80 to 100 ft (24 to 30 m) for systems using trusses rather than I sections for the steel portion. Until recently, most

composite beams were designed for full interaction, meaning that enough studs were provided to transfer the full capacity of the steel beam or concrete slab, whichever was lower. Today, composite beams are often designed for partial interaction; that is, they use fewer studs than needed to transfer the full capacity of the steel or concrete. Unlike composite beams in buildings, where the design of the shear connection is controlled by strength, the design of shear studs for composite beams in bridges is controlled by the fatigue capacity of the studs.

Composite laminates

Assemblages of layers of fibrous composite materials (**Fig. 1**) which can be tailored to provide a wide range of engineering properties, including inplane stiffness, bending stiffness, strength, and coefficients of thermal expansion.

The individual layers consist of high-modulus, high-strength fibers in a polymeric, metallic, or ceramic matrix material. Fibers currently in use include graphite, glass, boron, and silicon carbide. Typical matrix materials are epoxies, polyimides, aluminum, titanium, and alumina. Layers of different materials may be used, resulting in a hybrid laminate. The individual layers generally are orthotropic (that is, with principal properties in orthogonal directions) or transversely isotropic (with isotropic properties in the transverse plane) with the laminate then exhibiting anisotropic (with variable direction of principal properties), orthotropic, or quasi-isotropic properties. Quasi-isotropic laminates exhibit isotropic (that is, independent of direction) inplane response but are not restricted to isotropic out-of-plane (bending) response. Depending upon the stacking sequence of the individual layers, the laminate may exhibit coupling between inplane and out-of-plane response. An example of bending-stretching coupling is the presence of curvature developing as a result of inplane loading. *See* COMPOSITE MATERIAL; METAL MATRIX COMPOSITE; POLYMERIC COMPOSITE.

Lamination theory. Classical lamination theory describes the mechanical response of any composite laminate subjected to a combination of inplane and bending loads. The laminate in Fig. 1 uses a global x-y-z coordinate system with z perpendicular to the plane of the laminate and positive downward. The origin of the coordinate system is located on the laminate midplane. The laminate has N layers numbered from top to bottom. Each layer has a distinct fiber orientation denoted θ_k. The z coordinate to the bottom of the kth layer is designated z_k with the top of the layer being z_{k-1}. The thickness, t_k, of any layer is then $t_k = z_k - z_{k-1}$. The top surface of the laminate is denoted z_0, and the total thickness is $2H$.

Assumptions. It is assumed that (1) there is perfect bonding between layers; (2) each layer can be represented as a homogeneous material with known effective properties which may be isotropic, orthotropic, or transversely isotropic; (3) each layer is in a state of plane stress; and (4) the laminate deforms according to the Kirchhoff (1850) assumptions for bending and stretching of thin plates: (a) normals to the midplane remain straight and normal to the deformed midplane after deformation, and (b) normals to the midplane do not change length.

Strain-displacement relationships. The Kirchhoff assumptions require the out-of-plane strains ε_z, γ_{zx}, and γ_{zy} to be identically zero. The nonzero strains, $\{\varepsilon\}$, at any z location can then be expressed in terms of the midplane strains, $\{\varepsilon^0\}$, and curvatures, $\{\kappa\}$, in Eq. (1).

$$\{\varepsilon\} = \{\varepsilon^0\} + z\{\kappa\} \tag{1}$$

Stresses. The stresses, $\{\sigma\}^k$, at any z location in the kth layer are now determined from the strains [Eq. (1)] and the stress-strain constitutive equations expressed in terms of the stiffness matrix $[\overline{Q}]^k$ of the kth layer. The result is shown in Eq. (2).

$$\{\sigma\}^k = [\overline{Q}]^k(\{\varepsilon^0\} + z\{\kappa\}) \tag{2}$$

Inplane forces per unit length. The inplane forces per unit length $\{N\}$ (**Fig. 2**) are defined as the through-thickness integrals of the planar stresses in the laminate. After integration, the results are shown in Eq. (3), where $[A]$ and $[B]$ are coefficient matrices

$$\{N\} = [A]\{\varepsilon^0\} + [B]\{\kappa\} \tag{3}$$

that are functions of the layer material properties and laminate stacking sequence. The $[A]$ matrix represents the inplane stiffness, and the $[B]$ matrix defines the bending-stretching coupling. $[A]$ is a function of the layer thicknesses, but is independent of the stacking sequence of the layers. In contrast, $[B]$ is dependent on both the layer thicknesses and the stacking sequence of the individual layers. If the laminate

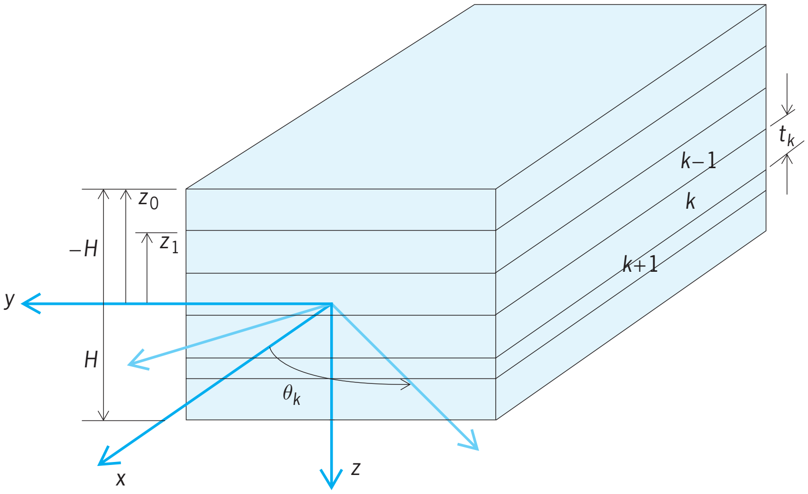

Fig. 1. Composite laminate consisting of layers with varying thickness.

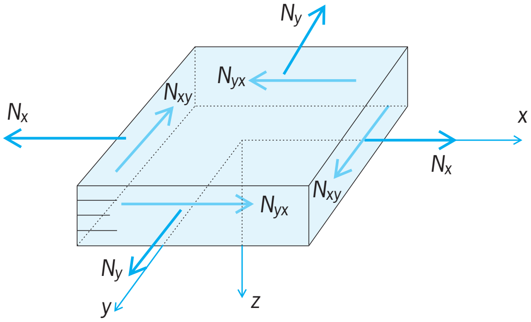

Fig. 2. Inplane forces per unit length, {*N*}.

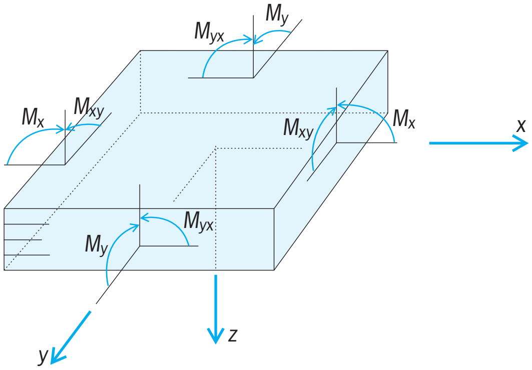

Fig. 3. Moments per unit length, {*M*}.

stacking sequence is symmetric about the laminate midplane, then $[B] = 0$.

Moments per unit length. The moments per unit length, $\{M\}$ (**Fig. 3**), are defined as the integrals of the differential forces, $\sigma_i dz$, times the moment arm, z, integrated over the laminate thickness, resulting in Eq. (4). Here the stacking sequence–dependent

$$\{M\} = [B]\{\varepsilon^0\} + [D]\{\kappa\} \tag{4}$$

bending stiffness matrix, $[D]$, is a coefficient matrix similar to $[A]$ and $[B]$.

Laminate constitutive relations. Equations (3) and (4) can be combined to give the fundamental equations of lamination theory, Eqs. (5) and (6). Equations (5)

$$\{N\} = [A]\{\varepsilon^0\} + [B]\{\kappa\} \tag{5}$$

$$\{M\} = [B]\{\varepsilon^0\} + [D]\{\kappa\} \tag{6}$$

and (6) exhibit coupling between the bending and stretching response of a laminate through the $[B]$ matrix. If $[B] = 0$, then the inplane (stretching) response is decoupled from the bending response. Indeed, there is no bending-stretching coupling for laminates which are symmetric about their midplane since $[B] = 0$ for symmetric laminates.

Laminate engineering constants. Expressions for the effective engineering constants of symmetric laminates can be determined from consideration of inplane forces applied individually. The laminate compliance, $[a^*]$, is defined in Eq. (7), where $[A]^{-1}$

$$[a^*] \equiv 2H[A]^{-1} \tag{7}$$

is the inverse of the $[A]$ matrix and $2H$ is the total thickness of the laminate. The engineering constants of symmetric laminates can be expressed as functions of the individual coefficients of the laminate compliance.

Examples demonstrating the variability of the effective engineering constants as a function of fiber orientations and laminate stacking sequence are provided in the following paragraphs for unidirectional off-axis and symmetric angle-ply laminates. A unidirectional laminate (also called a lamina) consists of layers all having the same fiber orientation. A symmetric angle-ply laminate has an equal number of layers at $+\theta$ and $-\theta$ fiber orientations located symmetrically about the laminate midplane. These results demonstrate one of the major advantages of fibrous composite materials, namely, the ability to tailor the material properties through the choice of fiber orientations, layer thicknesses, and materials. Most of the results discussed are for a typical carbon-epoxy composite, T300/5208. This composite consists of T300 carbon fibers in an epoxy matrix (5208).

Axial modulus. Predictions for the effective axial modulus (stiffness in the direction of 0° fiber orientation) E_x of angle-ply laminates are compared to the predictions for unidirectional off-axis lamina. The angle-ply laminate has higher stiffness than the off-axis lamina for fiber angles ranging from 0° to approximately 60°. Experimental results for T300/5208 angle-ply laminates exhibit very good correlation with the theoretical predictions. The higher axial stiffness for the angle-ply laminate is a result of the constraining effect (and resulting multiaxial state of stress) that the adjacent layers of the laminate have on each other.

Axial Poisson's ratio. The coupling between the transverse strain (strain perpendicular to the direction of applied stress) and the strain in the direction of applied stress is called Poisson's ratio. It is an important engineering material property. The comparison of Poisson's ratios (**Fig. 4**) is one of the most interesting

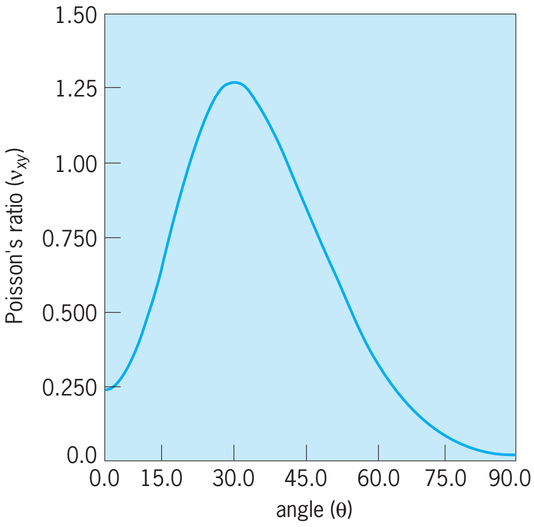

Fig. 4. Poisson's ratio comparisons for the composite laminate T300/5208.

and surprising results for laminated fibrous composites. There is a very large increase in Poisson's ratio when an off-axis ply is laminated with another off-axis ply of opposite sign. This is the case for a wide range of fiber orientations. The angle-ply laminate exhibits a maximum Poisson's ratio in excess of 1.25 (for this particular carbon/epoxy) at an angle of approximately 27°. That the Poisson's ratio can be in excess of 1.0 is very surprising to those accustomed to working with metals, where the maximum Poisson's ratio is 0.5. The high Poisson's ratio in these laminates is due to the internal state of stress in the individual layers. The laminates behave more like structures with variable internal mechanisms as compared with homogeneous materials with uniform stress states. *See* STRESS AND STRAIN.

Through-thickness Poisson's ratio. The ratio of the strain through the thickness of the laminate with that in the direction of the applied stress is called the through-thickness Poisson's ratio. For the unidirectional lamina, the through-thickness Poisson's ratio increases monotonically from the axial value to the transverse value as the fiber orientation angle increases. In sharp contrast, the through-thickness Poisson's ratio for angle-ply laminates initially decreases with increasing angle, passing through zero at approximately 13°, attains a minimum negative value at approximately 25°, then passes through zero again at approximately 40° as it increases to the transverse value at 90° (**Fig. 5**). This is another example of the variety of material properties that are possible with fibrous composites. The minimum value and the angles corresponding to zero through-thickness Poisson's ratios can be altered by modification of the laminate configuration.

Shear modulus. Shear modulus is a measure of the materials resistance (stiffness) to shear loading. The angle-ply laminate is much stiffer than the unidirectional lamina for essentially all fiber orientations. At $\theta = 45^\circ$ where the shear stiffnesses of both the lamina and the laminate are largest, the stiffness of the laminate is more than 3.5 times that of the lamina for the carbon/epoxy under consideration. The results clearly indicate that ±45° fiber orientations are desired in structures requiring high shear stiffness. *See* SHEAR.

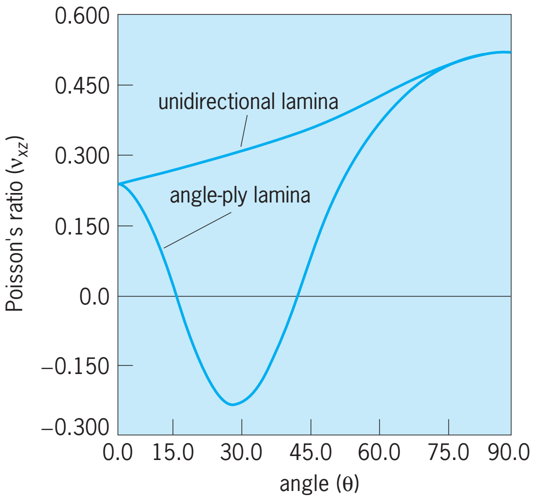

Fig. 5. Through-thickness Poisson's ratios for composite laminate T300/5208.

Coefficients of mutual influence. For anisotropic materials such as fibrous composites, there are additional important engineering properties that describe material behavior. These properties are called coefficients of mutual influence. They are similar to Poisson's ratios in that they provide an indication of the coupling between normal and shear components of strain. This type of coupling is not present in isotropic materials. One of the coefficients of mutual influence for unidirectional off-axis lamina of two different materials (T300/5208 carbon/epoxy and SCS6/Ti-15-3, a metal matrix composite) is the ratio of shear strain to axial strain for applied stress in the axial direction. The most significant features of the results are that the coefficient exhibits vary large gradients and magnitudes for the carbon/epoxy in the vicinity of $\theta = \pm 12^\circ$, and that there is a major difference in maximum values between the two materials. The coefficient of mutual influence can be nearly twice as large as Poisson's ratio. Thus the coupling between axial and shear response can be twice as large as the coupling between axial and transverse response for unidirectional lamina. The effective coefficient of mutual influence is zero for angle-ply laminates because the $+\theta$ and $-\theta$ fiber orientations have the effect of offsetting one another.

Laminate design. A wide variety of effective material properties can be obtained with one type of fibrous composite simply through changes in the stacking arrangement (layer thicknesses and fiber orientations of the individual layers) of the laminate. For example, changing the type of composite provides even more variety in the properties. Thus, material properties of the laminate can be tailored. This is a very important feature of fibrous composites because the material can be designed to have specific material properties.

Coefficient of thermal expansion. The wide variety of coefficients of thermal expansion are possible through changes in the stacking arrangement of a given carbon/epoxy. The coefficient of thermal expansion is the strain associated with a change in temperature of 1°. Most materials have positive coefficients of expansion and thus expand when heated and contract when cooled. The effective axial coefficient of thermal expansion of the carbon/epoxy can be positive, negative, or zero, depending upon the laminate configuration. Laminates with zero coefficient of thermal expansion are particularly important because they do not expand or contract when exposed to a temperature change. Composites with zero (or near zero) coefficient of thermal expansion are therefore good candidates for application in space structures where the temperature change can be 500°F (from −250 to +250°F) [278°C (from −157 to +121°C)] during an orbit in and out of the Sun's proximity. There are many other applications where thermal expansion is a very important consideration.

Composite material

A material system composed of a mixture or combination of two or more macroconstituents that differ in form or material composition and are essentially insoluble in each other. This definition is considered to be too broad by some engineers because it includes many materials that are not usually thought of as composites. For example, in many of the particulate-type composites, such as dispersion-hardened alloys and cermets, the composite structure is microscopic rather than macroscopic. Also, this definition does not draw the line between composite materials and composite structures. However, instead of trying to establish a distinction between materials and structures, it is more useful to make a distinction between mill composites (such as nonmetallic laminates, clad metals, and honeycomb) and specialty composites (such as tires, rocket nose cones, and glass-reinforced plastic boats).

Constituents and Construction

In principle, composites can be constructed of any combination of two or more materials—metallic, organic, or inorganic; but the constituent forms are more restricted. The matrix is the body constituent, serving to enclose the composite and give it bulk form. Major structural constituents are fibers, particles, laminae or layers, flakes, fillers, and matrices. They determine the internal structure of the composite. Usually, they are the additive phase.

Because the different constituents are intermixed or combined, there is always a contiguous region. It may simply be an interface, that is, the surface forming the common boundary of the constituents. An interface is in some ways analogous to the grain boundaries in monolithic materials. In some cases, however, the contiguous region is a distinct added phase, called an interphase. Examples are the coating on the glass fibers in reinforced plastics and the adhesive that bonds the layers of a laminate together. When such an interphase is present, there are two interfaces, one between the matrix and the interphase and one between the fiber and the interface.

Interfaces are among the most important yet least understood components of a composite material. In particular, there is a lack of understanding of processes occurring at the atomic level of interfaces, and how these processes influence the global material behavior. There is a close relationship between processes that occur on the atomic, microscopic, and macroscopic levels. In fact, knowledge of the sequence of events occurring on these different levels is important in understanding the nature of interfacial phenomena. Interfaces in composites, often considered as surfaces, are in fact zones of compositional, structural, and property gradients, typically varying in width from a single atom layer to micrometers. Characterization of the mechanical properties of interfacial zones is necessary for understanding mechanical behavior.

Nature and performance. Several classification systems for composites have been developed, including classification by (1) basic material combinations, for example, metal-organic or metal-inorganic; (2) bulk-form characteristics, such as matrix systems or laminates; (3) distribution of the constituents, that is, continuous or discontinuous; and (4) function, for example, electrical or structural.

There are five classes under the classification by basic material combinations: (1) fiber composites, composed of fibers with or without a matrix; (2) flake composites, composed of flat flakes with or without a matrix; (3) particulate composites, composed of particles with or without a matrix; (4) filled (or skeletal) composites, composed of a continuous skeletal matrix filled by a second material; and (5) laminar composites, composed of layer or laminar constituents.

There is also a classification based on dimensions. The dimensions of some of the components of composite materials vary widely and overlap the dimensions of the microstructural features of common conventional materials (**Fig. 1**). They range from extremely small particles or fine whiskers to the large aggregate particles or rods in reinforced concrete. *See* CRYSTAL WHISKERS; REINFORCED CONCRETE.

The behavior and properties of composites are determined by the composition, form and arrangements, and interaction between the constituents. The intrinsic properties of the materials of which the constituents are composed largely determine the general order or range of properties of the composite. Structural and geometrical characteristics—that is, the shape and size of the individual constituents, their structural arrangement and distribution, and the relative amount of each—contribute to overall performance. Of far-reaching importance are the effects produced by the combination and interaction of the constituents. The basic principle is that by using different constituents it is possible to obtain combinations of properties and property values that are different from those of the individual constituents.

A performance index is a property or group of properties that measures the effectiveness of a material in performing a given function. The values of performance indices for a composite differ from those of the constituents.

Fiber-matrix composites. Fiber-matrix composites have two constituents and usually a bonding phase as well.

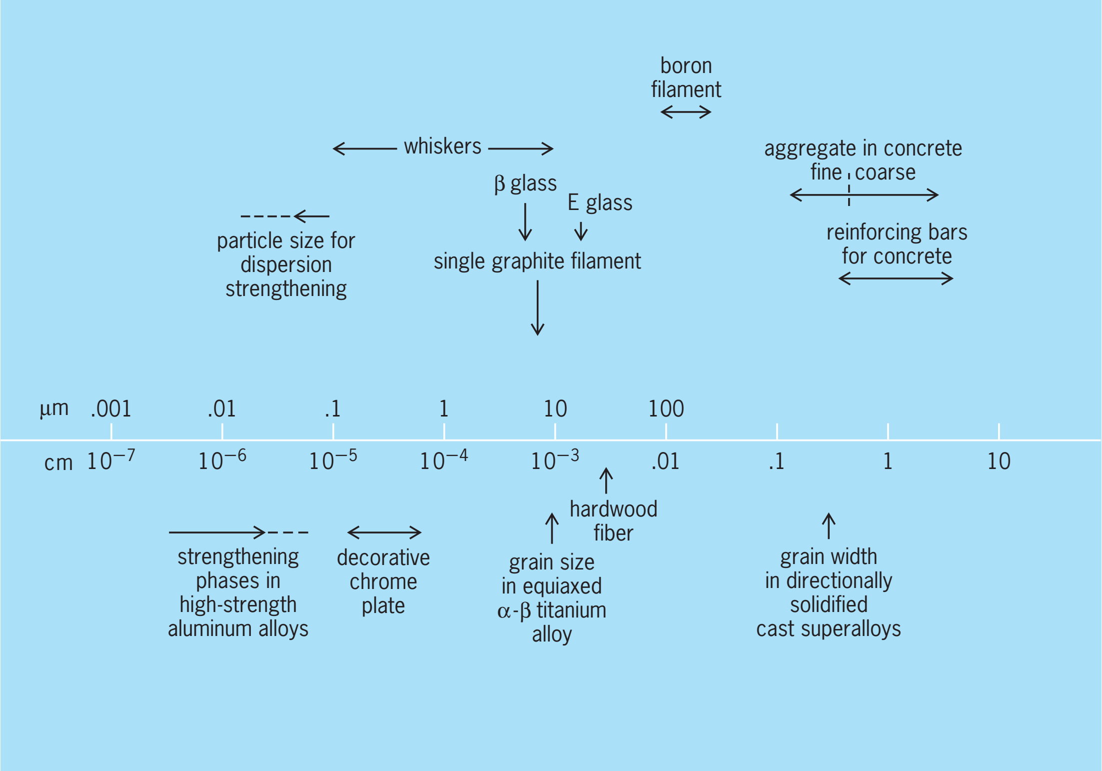

Fig. 1. Dimensional range of microstructural features in composite and conventional materials. Filament and fiber dimensions are diameters. 1 cm = 0.39 in.

Fibers. The performance of a fiber-matrix composite depends on orientation, length, shape, and composition of the fibers; mechanical properties of the matrix; and integrity of the bond between fibers and matrix. Of these, orientation of the fibers is perhaps most important.

Fiber orientation determines the mechanical strength of the composite and the direction of greatest strength. Fiber orientation can be one-dimensional, planar (two-dimensional), or three-dimensional. The one-dimensional type has maximum composite strength and modulus in the direction of the fiber axis. The planar type exhibits different strengths in each direction of fiber orientation; and the three-dimensional type is isotropic but has greatly decreased reinforcing values. The mechanical properties in any one direction are proportional to the amount of fiber by volume oriented in that direction. As fiber orientation becomes more random, the mechanical properties in any one direction become lower.

Fiber length also impacts mechanical properties. Fibers in the matrix can be either continuous or short. Composites made from short fibers, if they could be properly oriented, could have substantially greater strengths than those made from continuous fibers. This is particularly true of whiskers, which have uniform high tensile strengths. Both short and long fibers are also called chopped fibers. Fiber length also has a bearing on the processibility of the composite. In general, continuous fibers are easier to handle but have more design limitations than short fibers.

Bonding. Fiber composites are able to withstand higher stresses than their individual constituents because the fibers and matrix interact, resulting in redistribution of the stresses. The ability of constituents to exchange stresses depends on the effectiveness of the coupling or bonding between them. Bonding can sometimes be achieved by direct contact of the two phases, but usually a specially treated fiber must be used to ensure a receptive adherent surface. This requirement has led to the development of fiber finishes, known as coupling agents. Both chemical and mechanical bonding interactions occur for coupling agents.

Voids (air pockets) in the matrix are one cause of failure. A fiber passing through the void is not supported by resin. Under load, the fiber may buckle and transfer stress to the resin, which readily cracks. Another cause of early failure is weak or incomplete bonding. The fiber-matrix bond is often in a state of shear when the material is under load. When this bond is broken, the fiber separates from the matrix and leaves discontinuities that may cause failure. Coupling agents can be used to strengthen these bonds against shear forces. *See* SHEAR.

Reinforced plastics. Probably the greatest potential for lightweight high-strength composites is represented by the inorganic fiber–organic-matrix composites, and no composite of this type has proved as successful as glass-fiber-reinforced plastic composites. As a group, glass-fiber–plastic composites have the advantages of good physical properties, including strength, elasticity, impact resistance, and dimensional stability; high strength-to-weight ratio; good electrical properties; resistance to chemical attack and outdoor weathering; and resistance to moderately high temperatures (about 260°C or 500°F).

A critical factor in reinforced plastics is the strength of the bond between the fiber and the polymer matrix; weak bonding causes fiber pullout and delamination of the structure, particularly under adverse environmental conditions. Bonding can be improved by coatings and the use of coupling agents. Glass fibers, for example, are treated with silane (SiH_4) for improved wetting and bonding between the fiber and the matrix.

Generally, the greatest stiffness and strength in reinforced plastics are obtained when the fibers are aligned in the direction of the tension force. Other properties of the composite, such as creep resistance, thermal and electrical conductivity, and thermal expansion, are anisotropic. The transverse properties of such a unidirectionally reinforced structure are much lower than the longitudinal. Seven mechanical and thermal properties are of direct interest in assessing the potential of a new composite: density, modulus, strength, toughness, thermal conductivity, expansion coefficient, and heat capacity; others, such as fracture toughness and thermal diffusivity, are calculated from them.

Advanced Composites

Advanced composites comprise structural materials that have been developed for high-technology applications, such as airframe structures, for which other materials are not sufficiently stiff. In these materials, extremely stiff and strong continuous or discontinuous fibers, whiskers, or small particles are dispersed in the matrix. A number of matrix materials are available, including carbon, ceramics, glasses, metals, and polymers. Advanced composites possess enhanced stiffness and lower density compared to fiber-glass and conventional monolithic materials. While composite strength is primarily a function of the reinforcement, the ability of the matrix to support the fibers or particles and to transfer load to the reinforcement is equally important. Also, the matrix frequently dictates service conditions, for example, the upper temperature limit of the composite.

Reinforcements. Continuous filamentary materials that are used as reinforcing constituents in advanced composites are carbonaceous fibers, organic fibers, inorganic fibers, ceramic fibers, and metal wires. Reinforcing inorganic materials are used in the form of discontinuous fibers and whiskers. *See* STRENGTH OF MATERIALS.

Carbon and graphite fibers offer high modulus and the highest strength of all reinforcing fibers. These fibers are produced in a pyrolysis chamber from three different precursor materials—rayon, polyacrylonitrile (PAN), and pitch. High-modulus carbon fibers are available in an array of yarns and bundles of continuous filaments (tows) with differing moduli, strengths, cross-sectional areas, twists, and plies. *See* CARBON; GRAPHITE.

Almost any polymer fiber can be used in a composite structure, but the first one with high-enough tensile modulus and strength to be used as a reinforcement in advanced composites was an aramid, or aromatic polyamide, fiber. Aramid fibers have been the predominant organic reinforcing fiber; graphite is a close second. *See* MANUFACTURED FIBER; POLYMER.

The most important inorganic continuous fibers for reinforcement of advanced composites are boron and silicon carbide, both of which exhibit high stiffness, high strength, and low density. Continuous fibers are made by chemical vapor deposition processes. Other inorganic compounds that provide stiff, strong discontinuous fibers that predominate as reinforcements for metal matrix composites are silicon carbide, aluminum oxide, graphite, silicon nitride, titanium carbide, and carbon carbide. *See* BORON.

Polycrystalline aluminum oxide (Al_2O_3) is a commercial continuous fiber that exhibits high stiffness, high strength, high melting point, and exceptional resistance to corrosive environments. One method to produce the fibers is dry spinning followed by heat treatment.

Whiskers are single crystals that exhibit fibrous characteristics. Compared to continuous or discontinuous polycrystalline fibers, they exhibit exceptionally high strength and stiffness. Silicon carbide whiskers are prepared by chemical processes or by pyrolysis of rice hulls. Whiskers made of aluminum oxide and silicon nitride are also available. Particulates vary widely in size, characteristics, and function; and since particulate composites are usually isotropic, their distribution is usually random rather than controlled. *See* PYROLYSIS.

Organic-matrix composites. In many advanced composites the matrix is organic, but metal matrices are also used. Organic matrix material are lighter than metals, adhere better to the fibers, and offer more flexibility in shaping and forming. Ceramic matrix composites, carbon-carbon composites, and intermetallic matrix composites have applications where organic or metal matrix systems are unsuitable.

Materials. Epoxy resins have been used extensively as the matrix material. However, bismaleimide resins and polyimide resins have been developed to enhance in-service temperatures. Thermoplastic resins, polyetherketone, and polyphenylene sulfide are in limited use.

The continuous reinforcing fibers for organic matrices are available in the forms of monofilaments, multifilament fiber bundles, unidirectional ribbons, roving (slightly twisted fiber), and single-layer and multilayer fabric mats. Frequently, the continuous reinforcing fibers and matrix resins are combined into a nonfinal form known as a prepreg.

Fabrication. Many processes are available for the fabrication of organic matrix composites. The first process is contact molding in order to orient the unidirectional layers at discrete angles to one another. Contact molding is a wet method, in which the reinforcement is impregnated with the resin at the time of molding. The simplest method is hand lay-up, whereby the materials are placed and formed in the mold by hand and the squeezing action expels any trapped air and compacts the part.

Molding may also be done by spraying, but these processes are relatively slow and labor costs are high, even though they can be automated. Many types of boats, as well as buckets for power-line servicing equipment, are made by this process.

Another process is vacuum-bag molding, where prepregs are laid in mold to form the desired shape. In this case, the pressure required to form the shape and achieve good bonding is obtained by covering the lay-up with a plastic bag and creating a vacuum. If additional heat and pressure are desired, the entire assembly is put into an autoclave. In order to prevent the resin from sticking to the vacuum bag and to facilitate removal of excess resin, various materials are placed on top of the prepreg sheets. The molds can be made of metal, usually aluminum, but more often are made from the same resin (with reinforcement) as the material to be cured. This eliminates any problem with differential thermal expansion between the mold and the part.

In filament winding, the resin and fibers are combined at the time of curing. Axisymmetric parts, such as pipes and storage tanks, are produced on a rotating mandrel. The reinforcing filament, tape, or roving is wrapped continuously round the form. The reinforcements are impregnated by passing them through a polymer bath. However, the process can be modified by wrapping the mandrel with prepreg material. The products made by filament winding are very strong because of their highly reinforced structure. For example, filament winding can be used directly over solid-rocket-propellant forms.

Pultrusion is a process used to produce long shapes with constant profiles, such as rods or tubing, similar to extruded metal products. Individual fibers are often combined into a tow, yarns, or roving, which consists of a number of tows or yarns collected into a parallel bundle without twisting (or only slightly so). Filaments can also be arranged in a parallel array called a tape and held together by a binder. Yarns or tows are often processed further by weaving, braiding, and knitting or by forming them into a sheetlike mat consisting of randomly oriented chopped fibers or swirled continuous fibers held together by a binder.

Weaving to produce a fabric is a very effective means of introducing fibers into a composite. There are five commonly used patterns (**Fig. 2**). Although weaving is usually thought of as a two-dimensional process, three-dimensional weaving is often employed.

Knitting is a process of interlooping chains of tow or yarn. Advantages of this process are that the tow or yarn is not crimped as happens in weaving, and higher mechanical properties are often observed in the reinforced product. Also, knitted fabrics are easy to handle and can be cut without falling apart.

In braiding, layers of helically wound yarn or tow are interlaced in a cylindrical shape, and interlocks can be produced at every intersection of fibers. During the process, a mandrel is fed through the center of a braiding machine at a uniform rate, and the yarn or tow from carriers is braided around the mandrel at a controlled angle. The machine operates like a maypole, the carriers working in pairs to accomplish the over-and-under sequencing. The braiding process is most effective for cylindrical geometries. It is used for missile heat shields, lightweight ducts, fluid-sealing components such as packings and sleevings, and tubes for insulation.

Carbon-carbon composites. A carbon-carbon composite is a specialized material made by reinforcing a carbon matrix with continuous carbon fiber. This type of composite has outstanding properties over a wide range of temperatures in both vacuum and inert atmospheres. It will even perform well at elevated temperatures in an oxidizing environment for short times. It has high strength, modulus, and toughness up to 2000°C (3600°F); high thermal conductivity; and a low coefficient of thermal expansion. A material with such properties is excellent for rocket motor nozzles and exit cones, which require high-temperature strength as well as resistance to thermal shock. Carbon-carbon composites are also used for aircraft and other high-performance brake applications that take advantage of the fact that carbon-carbon composites have the highest energy-absorption capability of any known material. If a carbon-carbon composite is exposed to an oxygen-containing atmosphere above 600°C (1100°F) for an

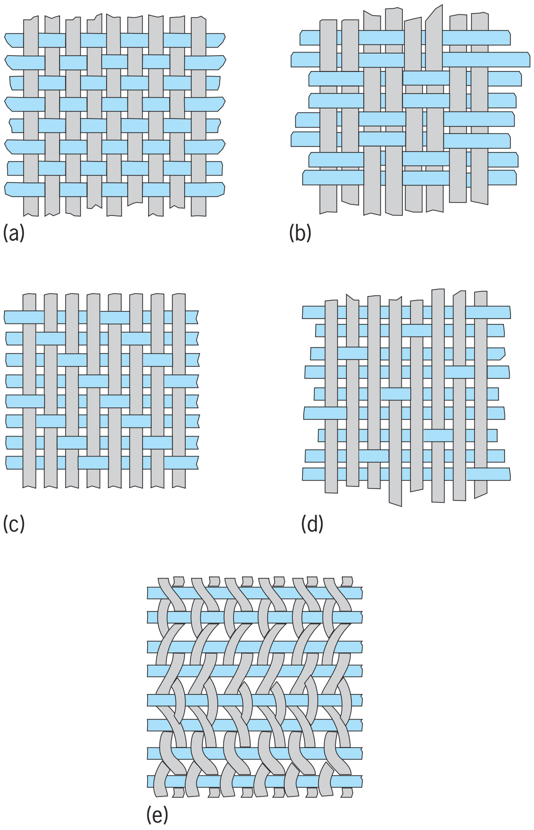

Fig. 2. Common weave patterns: (*a*) box or plain weave, (*b*) basket weave, (*c*) crowfoot, (*d*) long-shaft, and (*e*) leno weave.

appreciable time, it oxidizes, and therefore it must be protected by coatings.

Metal-matrix composites. Metal-matrix composites are usually made with alloys of aluminum, magnesium, or titanium; and the reinforcement is typically a ceramic in the form of particulates, platelets, whiskers, or fibers, although other systems may be used. Metal-matrix composites are often classified as discontinuous or continuous, depending on the geometry of the reinforcement. Particulates, platelets, and whiskers are in the discontinuous category, while the continuous category is reserved for fibers and wires. The type of reinforcement is important in the selection of a metal-matrix composite, because it determines virtually every aspect of the product, including mechanical properties, cost, and processing method. The primary methods for processing of discontinuous metal-matrix composites are powder metallurgy, liquid metal infiltration, squeeze or pressure casting, and conventional casting; however, most of these methods do not result in finished parts. Therefore, most discontinuously reinforced metal-matrix composites require secondary processing, which includes conventional wrought metallurgy operations such as extrusion, forging, and rolling; standard and nonstandard machining operations; and joining techniques such as welding and brazing. *See* BRAZING; MACHINING; METAL CASTING; POWDER METALLURGY; WELDING AND CUTTING OF MATERIALS. Mel M. Schwartz

Ceramic-matrix composites. In general, ceramics are brittle engineering materials with limited reliability. Brittleness is connected with the structure and chemical bonding of the main constituents, and reliability is connected with the stochastic character of main phases and defect distribution within the polycrystalline ceramic body. In spite of the generally high strength, hardness, and chemical and shape stability of ceramics, these two negative properties disqualify their wider application in industry. Ceramic-matrix composites are designed as materials with higher fracture resistance (less brittleness), higher reliability, and in particular cases higher strength compared to monolithic ceramics. These attributes are required for high technologies, especially in the aircraft, automotive, engineering, and energy industries. *See* BRITTLENESS; CERAMICS.

Ceramic composites are materials with at least two constituents, the ceramic-matrix phase and reinforcing-toughening filaments. The filaments cover a wide range of dimensions, from nanoinclusions, through micro-whiskers, to fibers that are several centimeters to a few meters long.

Ceramic nanocomposites. These composites have at least one of the main constituents at the nanometer scale (from one to several hundred nanometers). Typical examples of such ceramic nanocomposites are silicon carbide–silicon nitride (SiC/Si_3N_4) and silicon carbide–alumina (SiC/Al_2O_3). Benefits from the design of these materials are better mechanical properties at room temperature or high temperature, as well as improved electric and magnetic properties. *See* NANOSTRUCTURE.

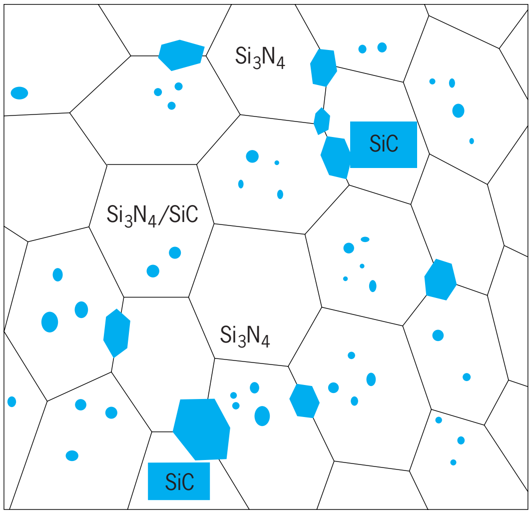

Fig. 3. Schematic of a SiC/Si_3N_4 nanocomposite. This microstructure consists of silicon carbide inclusions within silicon nitride grains, and silicon carbide grains located at the grain boundaries.

Examples of some properties of nanocomposites are as follows: A SiC/Si_3N_4 nanocomposite containing 20 vol % SiC has a bending strength greater than 1 GPa (10000 atm) up to 1400°C (2552°F), and a fracture toughness of 7 $MPa \cdot m^{1/2}$. Silver–ferrite oxide nanocomposite (Ag/Fe_2O_3) exhibits a superparamagnetic state at temperatures greater than 100 K (−173°C; −280°F).

Based on distribution of nanograins within the matrix, ceramic nanocomposites can be formally divided into intra type, inter type, intra/inter type, and nano/nano type. The SiC/Si_3N_4 nanocomposite (**Fig. 3**) can be considered an intra/inter type, because of distribution of SiC grains at grain boundaries as well as within the Si_3N_4 grains.

Whisker/platelet-reinforced composites. This ceramic composite contains whiskers or platelets. The whiskers are randomly distributed within the composite matrix. Silicon carbide or silicon nitride whiskers are usually embedded in a silicon carbide, silicon nitride, or alumina matrix. Improvement of the mechanical properties of these composites is reached by dissipation of the crack tip energy on a whisker or platelet. Whisker length varies between several micrometers and hundreds of micrometers. A typical parameter that determines a whisker shape is the aspect ratio, or the length-to-thickness ratio. Platelets are single crystals of flake shape. Their aspect ratio is the diameter-to-thickness ratio. Despite lower effectivity of platelets in dissipating crack tip energy compared to the whiskers, their application is forced due to the environmental unacceptability of whiskers. The bending strength of Si_3N_4/Si_3N_4 ceramics is 0.8–1 GPa (8000–10,000 atm), and fracture toughness is 6 $MPa \cdot m^{1/2}$ at room temperature.

Ceramic fiber-matrix composites. In principle, these composites are similar to fiber-matrix composites. The difference is in the composition of fibers, the matrices, and the processing routes.

The typical examples of fibers are the silicon carbide or alumina fibers. Fibers are polycrystalline materials with high tensile strength. Silicon carbide fiber tensile strength for Hi-Nicalon-S fiber is greater than 3 GPa (30,000 atm).

Silicon carbide, silicon nitride, and alumina ceramics are typically used as the matrices. Carbon as a constituent of these composites is also used either in the form of fibers or as a matrix.

There are several processes of embedding the continuous fibers into the ceramic matrix: polymer impregnation and pyrolysis, slurry impregnation and hot pressing, and chemical vapor infiltration.

These materials exhibit a high tensile strength when the fibers are oriented in the direction of the tensile force, and a very high work of fracture, which means a high fracture toughness. For example, the tensile strength of a SiC/Si_3N_4 composite is 0.5 GPa (5000 atm), and the fracture toughness is 26.5 $MPa{\cdot}m^{1/2}$.

Laminate/layered ceramic composites. These ceramic composites consist of two or more different ceramic sheets which are repeated several times through the ceramic body. These materials are usually produced by tape casting in order to built the ceramic "green" body, which is densified by hot pressing or gas pressure sintering. The properties of this type of ceramics are highly anisotropic in different directions, parallel and perpendicular to the layer area. The layers can differ by composition or by microstructure. Mechanical properties of silicon nitride–based layered composite are in particular cases exceptional; for example, a bending strength of 1.2 GPa (12,000 atm) and a fracture toughness of 10 $MPa{\cdot}m^{1/2}$ are reported. *See* SINTERING.

Layered materials offer a possibility to design materials with multifunctions, exhibiting excellent mechanical properties and improved electrical, thermal, or magnetic properties. Pavol Šajgalík

Applications

The use of fiber-reinforced materials in engineering applications has grown rapidly. Selection of composites rather than monolithic materials is dictated by the choice of properties. The high values of specific stiffness and specific strength may be the determining factor, but in some applications wear resistance or strength retention at elevated temperatures is more important. A composite must be selected by more than one criterion, although one may dominate.

Components fabricated from advanced organic-matrix–fiber-reinforced composites are used extensively on commercial aircraft as well as for military transports, fighters, and bombers. The propulsion system, which includes engines and fuel, makes up a significant fraction of aircraft weight (frequently 50%) and must provide a good thrust-to-weight ratio and efficient fuel consumption. The primary means of improving engine efficiency are to take advantage of the high specific stiffness and strength of composites for weight reduction, especially in rotating components, where material density directly affects both stress levels and critical dynamic characteristics, such as natural frequency and flutter speed.

Composites consisting of resin matrices reinforced with discontinuous glass fibers and continuous-glass-fiber mats are widely used in truck and automobile components bearing light loads, such as interior and exterior panels, pistons for diesel engines, drive shafts, rotors, brakes, leaf springs, wheels, and clutch plates.

The excellent electrical insulation, formability, and low cost of glass-fiber-reinforced plastics have led to their widespread use in electrical and electronic applications ranging from motors and generators to antennas and printed circuit boards.

Composites are also used for leisure and sporting products such as the frames of rackets, fishing rods, skis, golf club shafts, archery bows and arrows, sailboats, racing cars, and bicycles.

Advanced composites are used in a variety of other applications, including cutting tools for machining of superalloys and cast iron and laser mirrors for outer-space applications. They have made it possible to mimic the properties of human bone, leading to development of biocompatible prostheses for bone replacements and joint implants. In engineering, composites are used as replacements for fiber-reinforced cements and cables for suspension bridges. *See* MATERIALS SCIENCE AND ENGINEERING. Mel M. Schwartz

Composition board

A wood product in which the grain structure of the original wood is drastically altered. Composition board may be divided into several types. When wood serves as the raw material for chemical processing, the resultant product may be insulation board, hardboard, or other pulp product. When the wood is broken down only by mechanical means, the resultant product is particle board. Because composition board can use waste products of established wood industries and because there is a need to find marketable uses for young trees, manufacture of composition board is one of the most rapidly developing portions of the wood industry. *See* PAPER.

Fiberboard. One form of fiberboard is produced by loading a batch of wood chips into a chamber which is then heated and pressurized by steam. After about 2 min, the 1000-lb/in.^{2} (6.9-megapascal) pressure is abruptly released to hydrolyze and fluff the chips into a brown fiber. The fiber is refined, washed, and felted into a mat on a wire conveyor so that some of the water can drain out, and then the mat is cut to length for loading on a screen into a press. At controlled temperature in the press, the lignin rebonds the material while water is driven off as steam through the screen. The finished reconstituted wood product is a hard isotropic board as a consequence of the felting of the fibers and the ligneous bonding, possibly augmented by synthetic adhesive.

Alternatively, a similar board is produced by a continuous process. A screw feed delivers wood chips from a hopper to a steam preheater where the chips partially hydrolyze in the vicinity of 150 lb/in.^{2} (0.11 MPa). The hot chips pass between grinding disks to discharge as pulp, which is then formed into sheets essentially as described above. The wood chips may also be processed entirely by grinding. A further variation is to deliver the pulp slurry into a deckle box, in which case most of the water is removed by suction applied below the box before the mat is compressed into the finished sheet.

Instead of conveying the wet fiber or pulp to the mat, it can be dried sufficiently to be conveyed by air; it is then introduced between chrome-plated cauls and pressed. Because of the low-moisture content, no screen is needed; the finished sheet is smooth on both sides. Most new plants use variants of the dry process.

In any of the foregoing methods synthetic resin may be added as a binder before the board is formed. After the board is formed, it may be impregnated with drying oils and heated in a kiln at 300°F (150°C) until the oils are completely polymerized to produced tempered board. *See* DRYING OIL; RESIN.

If insulating board is required instead of hardboard, the material is less compacted, the degree of compaction being described by the specific gravity of the finished board.

Particle board. When formed from wood particles that retain their woody structure, the product is termed particle board. Properties of such boards depend on the size and orientation of the particles, which may be dimensioned flakes, random-sized shavings, or splinters. After the particular type of particles are produced, they are screened to remove fines and to return oversizes for further reduction. Graded particles are dried, mixed with synthetic adhesive and other additives such as preservatives, and delivered to the board-forming machine.

Forming machines are basically of two types. In one type mixed materials are metered by weight or volume onto an open flat tray, prepressed at room temperature, and finally consolidated under heat at high pressure to the finished dimension. Whether carried out as a batch or a continuous process, this flat-press method tends to orient the particles with their long dimensions approximately parallel to the face of the board. In the second type of machine the mixed materials are extruded under pressure between heated platens. Thick boards made this way may have hollow cores produced by rods fixed in the aperture ahead of the platens. Particles in extruded boards are randomly oriented. Boards formed by either method may be layered, with different-sized particles at the surfaces from those in the center, which are also usually coarser.

Characteristics. Hardboards produced by a continuous process can be formed to great length, although a finished length of 16 ft (5 m) is usual stock maximum. Standard thicknesses range from $^1/_8$ to $^5/_{16}$ in. (3.2 to 7.9 mm); standard densities range from a specific gravity of 0.80 to 1.15, with boards up to 1.45 available if needed.

Tensile strength parallel to the face ranges from 1000 lb/in.^{2} (6.9 MPa) for untreated board to 5500 lb/in.^{2} (37.9 MPa) for tempered hardboard; perpendicular to the face it ranges from 125 to 400 lb/in.^{2} (0.86 to 2.76 MPa). Compression strength parallel to the face ranges from 2000 to 5300 lb/in.^{2} (13.8 to 36.5 MPa).

Lengths and widths of particle boards are similar to those of hardboards; thicknesses range from $^1/_4$ to 1 in. (6 to 25 mm); thicker sheets are most economically produced by laminating sheets of standard thicknesses. Properties of flat-pressed particle board vary more than do those of hardboard. They have low density: 0.4–1.2 specific gravity. Tensile strength parallel to their faces ranges from 500 to 5000 lb/in.^{2} (3.4 to 34.5 MPa) and perpendicular from 40 to 400 lb/in.^{2} (276 kPa to 2.76 MPa). Extruded particle board has low bending strength; it is used chiefly as the core of plywood-type panel. Development of adhesives specifically for composition boards has extended their utilitarian value, and variety of textures has increased their esthetic appeal. *See* WOOD PRODUCTS.

Frank H. Rockett

Compound (chemistry)

A substance composed of two or more elements that do not vary in composition from sample to sample, and that have fixed and definite physical properties, such as density and refractive index. The elements in compounds cannot be separated by simple physical or mechanical means, but only by chemical treatment. When compounds are formed from their elements, heat is generated or absorbed. These properties distinguish them from mixtures.

For example, if iron filings and sulfur powder are mixed together, the two elements can be separated, either by removing the iron filings with a magnet or by dissolving the sulfur in an appropriate solvent, and the individual particles of each element are distinguishable under a magnifying glass. If iron filings and sulfur are heated together, a chemical reaction takes place and a new substance is formed, iron sulfide, with properties totally different from iron or sulfur. *See* DENSITY; ELEMENT (CHEMISTRY).

Most chemical compounds are formed in fixed and definite proportions by weight from their elements, and they obey the laws of chemical combination. However, a number of solid compounds, known as nonstoichiometric compounds, exhibit departures from the law of definite proportions. *See* DEFINITE COMPOSITION, LAW OF; EQUIVALENT WEIGHT; INORGANIC CHEMISTRY; MULTIPLE PROPORTIONS, LAW OF; NONSTOICHIOMETRIC COMPOUNDS; ORGANIC CHEMISTRY. Thomas C. Waddington

Compressible flow

Flow in which density changes are not negligible. Pressure changes normally occur throughout a fluid flow, and these pressure changes, in general, induce a change in the fluid density. In a compressible flow, the density changes that result from these pressure changes have a significant influence on the flow. The changes in the flow that result from the density changes are often termed compressibility effects. All fluids are compressible. However, compressibility effects are more frequently encountered in gas flows than in liquid flows.

Compressibility. The compressibility of a fluid is defined by Eq. (1), where ρ is the density, and $\Delta\rho$ is the

$$\tau = \frac{\Delta\rho/\rho}{\Delta p} \qquad (1)$$

density change that results from a pressure change of Δp. From Eq. (1) it follows that the relative density change is given by Eq. (2). If the product $\tau\,\Delta p$ is very

$$\frac{\Delta\rho}{\rho} = \tau\,\Delta p \qquad (2)$$

small, then the change in density, $\Delta\rho$, will be negligible and the effect of the density changes on the flow can be neglected. Such flows that are effectively at constant density are termed incompressible flows. For a flow in which the product $\tau\,\Delta p$ is moderate or large, the changes in density in the flow cannot, in general, be neglected. Such flows in which the density changes are significant are termed compressible flows. As a rough guide, if the density changes by less than 5% in the flow, that is, $\Delta\rho/\rho < 0.05$, the flow can be treated as incompressible. The speed of sound in the fluid, a, is approximately given by Eq. (3). Using this in Eq. (1) gives Eq. (4). The larger the

$$a^2 = \frac{\Delta p}{\Delta\rho} \qquad (3)$$

$$\tau = \frac{1}{\rho a^2} \qquad (4)$$

value of ρa^2, the less compressible is the fluid. Thus a liquid, which has a large value of ρa^2, will have a much smaller compressibility than a gas, which has a small value of ρa^2. For example, water has a value of ρa^2 that is about 15,000 times greater than that of air and so is much less compressible than air. *See* SOUND.

Mach number. An important dimensionless parameter in compressible flows is the Mach number, M. This is defined by Eq. (5), where a is the speed of

$$M = \frac{V}{a} \qquad (5)$$

sound and V is the velocity of the flow. For a gas, the speed of sound is given by Eq. (6), where R is the

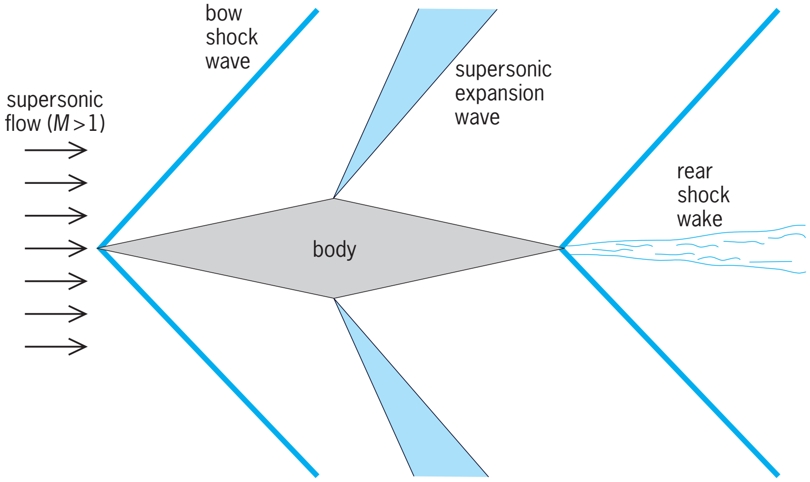
$$a = \sqrt{kRT} \qquad (6)$$

gas constant, $k = c_p/c_v$, c_p and c_v being the specific heats at constant pressure and constant volume respectively, and T is the temperature. If $M < 0.3$ in a flow, the density changes in the flow will usually be negligible; that is, the flow can be treated as incompressible. Compressible flows are, therefore, as a rough guide, associated with Mach numbers greater than 0.3.

When $M < 1$, the flow is said to be subsonic; when $M = 1$, the flow is said to be sonic; when M varies from slightly below 1 to slightly above 1, the flow is said to be transonic; and if $M > 1$, the flow is said to be supersonic. When the Mach number is very high, this usually being taken to mean $M > 5$, the flow is said to be hypersonic.

Properties. Compressible flows can have features that do not occur in low-speed flows. For example, shock waves and expansion waves can occur in supersonic flows (*see* **illus.**). Another important phenomenon that can occur due to compressibility is choking, where the mass flow rate through a duct system may be limited as a result of the Mach number being equal to 1 at some point in the flow. *See* CHOKED FLOW; SHOCK WAVE; SONIC BOOM.

Another effect of compressibility is associated with the acceleration of a gas flow through a duct. In incompressible flow, an increase in velocity is associated with a decrease in the cross-sectional area of the duct, this in fact being true as long as $M < 1$. However, when $M > 1$, that is, when the flow is supersonic, the opposite is true; that is, an increase in the velocity is associated with an increase in the cross-sectional area. Therefore, in order to accelerate



Waves in supersonic flow over a double-wedge body.

a gas flow from subsonic to supersonic velocities in a duct, it is necessary first to decrease the area and then, once the Mach number has reached 1, to increase the area, that is, to use a so-called convergent-divergent nozzle. An example is the nozzle fitted to a rocket engine. *See* FLUID FLOW; MACH NUMBER; NOZZLE; SUPERSONIC FLOW. Patrick H. Oosthuizen

Bibliography. J. D. Anderson, Jr., *Modern Compressible Flow: With Historical Perspective*, 3d ed., McGraw-Hill, 2003; P. H. Oosthuizen and W. E. Carscallen, *Compressible Fluid Flow*, McGraw-Hill, 1997.

Compression ratio

In a cylinder, the piston displacement plus clearance volume, divided by the clearance volume. This is the nominal compression ratio determined by cylinder geometry alone. In practice, the actual compression ratio is appreciably less than the nominal value because the volumetric efficiency of an unsupercharged engine is less than 100%, partly because of late intake valve closing. In spark ignition engines the allowable compression ratio is limited by incipient knock at wide-open throttle. Knock in turn depends on the molecular structure of the fuel and on such engine features as the temperature of the combustible mixture prior to ignition, the geometry and size of the combustion space, and the ignition timing. For example, isooctane, benzene, and alcohol can be burned at much higher compression ratios than *n*-heptane. In compression ignition engines critical compression ratio is that necessary to ignite the fuel and depends on fuel and cylinder geometry. *See* COMBUSTION CHAMBER; DIESEL ENGINE; INTERNAL COMBUSTION ENGINE; SPARK KNOCK; VOLUMETRIC EFFICIENCY. Neil MacCoull

Compressor

A machine that increases the pressure of a gas or vapor (typically air), or mixture of gases and vapors. The pressure of the fluid is increased by reducing the fluid specific volume during passage of the fluid through the compressor. When compared with centrifugal or axial-flow fans on the basis of discharge pressure, compressors are generally classed as high-pressure and fans as low-pressure machines.

Compressors are used to increase the pressure of a wide variety of gases and vapors for a multitude of purposes (**Fig. 1**). A common application is the air compressor used to supply high-pressure air for conveying, paint spraying, tire inflating, cleaning, pneumatic tools, and rock drills. The refrigeration compressor is used to compress the gas formed in the evaporator. Other applications of compressors include chemical processing, gas transmission, gas turbines, and construction. *See* GAS TURBINE; REFRIGERATION.

Characteristics. Compressor displacement is the volume displaced by the compressing element per unit of time and is usually expressed in cubic feet per minute (cfm). Where the fluid being compressed flows in series through more than one separate compressing element (as a cylinder), the displacement of the compressor equals that of the first element. Compressor capacity is the actual quantity of fluid compressed and delivered, expressed in cubic feet per minute at the conditions of total temperature, total pressure, and composition prevailing at the compressor inlet. The capacity is always expressed in terms of air or gas at intake (ambient) conditions rather than in terms of arbitrarily selected standard conditions.

Air compressors often have their displacement and capacity expressed in terms of free air. Free air is air at atmospheric conditions at any specific location. Since the altitude, barometer, and temperature may vary from one location to another, this term does not mean air under uniform or standard conditions. Standard air is at 68°F (20°C), 14.7 lb/in.^{2} (101.3 kilopascals absolute pressure), and a relative humidity of 36%. Gas industries usually consider 60°F (15.6°C) air as standard.

Types. Compressors can be classified as reciprocating, rotary, jet, centrifugal, or axial-flow, depending on the mechanical means used to produce compression of the fluid, or as positive-displacement or dynamic-type, depending on how the mechanical elements act on the fluid to be compressed. Positive-displacement compressors confine successive volumes of fluid within a closed space in which the pressure of the fluid is increased as the volume of the closed space is decreased. Dynamic-type compressors use rotating vanes or impellers to impart velocity and pressure to the fluid.

Reciprocating compressors are positive-displacement types having one or more cylinders, each fitted with a piston driven by a crankshaft through a connecting rod. Each cylinder also has intake and discharge valves, and a means for cooling the mechanical parts (**Fig. 2**). Fluid is drawn into the cylinder during the suction stroke. At the end

Fig. 1. Mobile air compressor unit which is driven by engine in the forward compartment. (*Ingersoll-Rand*)

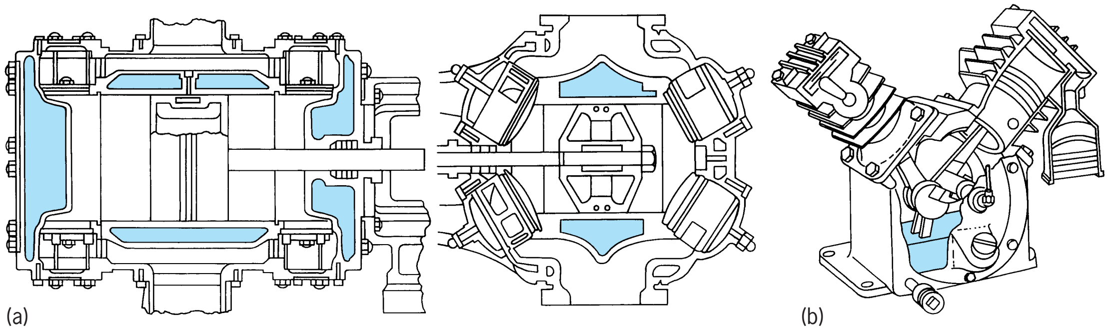


Fig. 2. Compressor cylinders, (*a*) water-cooled and (*b*) air-cooled.

of the suction stroke, motion of the piston reverses and the fluid is compressed and expelled during the discharge stroke. When only one end of the piston acts on the fluid, the compressor is termed a single-acting unit. When both ends of the piston act on the fluid, the compressor is double-acting. The double-acting compressor discharges about twice as much fluid per cylinder per cycle as the single-acting.

Single-stage compressors raise the fluid pressure from inlet to discharge on each working stroke of the piston in each cylinder. Two-stage compressors use one cylinder to compress the fluid to an intermediate pressure and another cylinder to raise it to final discharge pressure. When more than two stages are used, the compressor is called a multistage unit.

Some reciprocating compressors provide variable displacement. Instead of use of a crankshaft, the length of the piston stroke is controlled by a rotating swash plate, or wobble plate, that can change angle while the compressor is running. This design allows the compressor to operate continuously while providing only the displacement needed.

Vertical and horizontal compressors may be single-cylinder or multicylinder units. The angle type is multicylinder with one or more horizontal and vertical compressing elements (**Fig. 3**). Single-frame (straight-line) units are horizontal or vertical, double-acting, with one or more cylinders in line with a single frame having one crank throw, connecting rod, and crosshead. The V or Y type is a two-cylinder, vertical, double-acting machine with cylinders usually at a 45° angle with the vertical. A single crank is used. Semiradial compressors are similar to V or Y type, but have horizontal double-acting cylinders on each side. Duplex compressors have cylinders on two parallel frames connected through a common crankshaft. In duplex-tandem steam-driven units, steam cylinders are in line with air cylinders. Duplex four-cornered steam-driven compressors have one or more compressing cylinders on each end of the frame and one or more steam cylinders on the opposite end. In four-cornered motor-driven units, the motor is on a shaft between compressor frames.

Reciprocating compressors are built to handle fluid capacities ranging to 100,000 ft^3/min (2800 m^3/min); pressures range to over 35,000 lb/in.^{2} (240 megapascals). Special units can be built for larger capacities or higher pressures. Water is the usual coolant for cylinders, intercoolers, and aftercoolers, but other liquids, including refrigerants, may also be used.

Compressor thermodynamics. Compression efficiency in any compressor is compared against two theoretical standards—isothermal and adiabatic. Neither occurs in an actual compressor because of unavoidable losses. Isothermal compression has perfect cooling—air remains at inlet temperature while being compressed. The work input to the compressor is the least possible. Adiabatic compression has no cooling; the temperature rises steadily during compression. Discharge pressure is reached sooner than with isothermal compression. Since air pressure is higher during every part of the piston's stroke, more work input is needed. *See* THERMODYNAMIC PROCESSES.

If compression is divided into two or more steps or stages, air can be cooled between stages. This intercooling brings the actual compression efficiency closer to the isothermal standard.

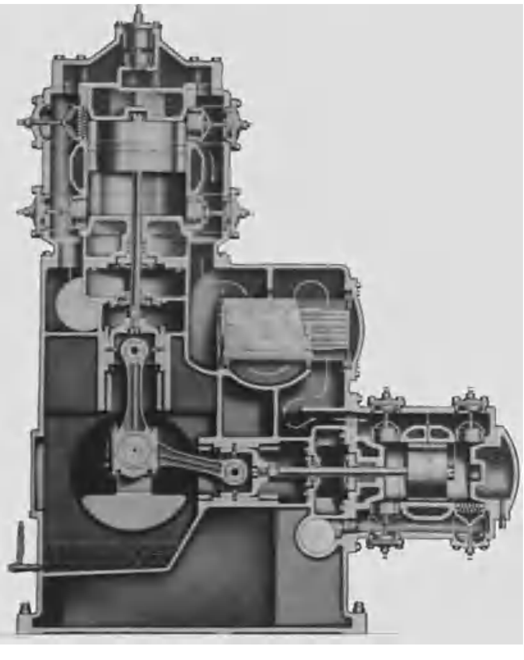

Fig. 3. Cross section of stationary angle-type compressor with first stage vertical and second stage horizontal.

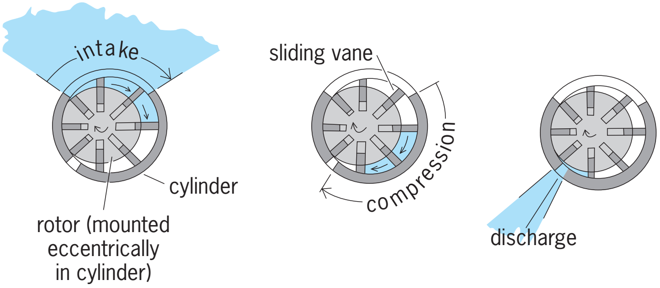

Fig. 4. Operation of sliding-vane rotary compressor.

Water vapor in air entering the compressor leaves as superheated vapor, because its temperature is in excess of that corresponding to its pressure. It can be converted to water only by cooling to a temperature below the saturation temperature corresponding to its pressure. Immediate cooling of air after it leaves the compressor proves best, because this prevents vapor from reaching the distribution system. Either air- or water-cooled heat exchangers, called aftercoolers, are used for this.

The usual single-stage reciprocating compressor is built for pressures to about 150 lb/in.^{2} (1.0 MPa); two-stage types for up to about 500 lb/in.^{2} (3.4 MPa); three-stage for up to about 2500 lb/in.^{2} (17 MPa); four- and five-stage for up to 15,000 lb/in.^{2} (100 MPa), and higher.

Rotary compressors. Other forms of positive-displacement compressor are the rotary types.

Sliding-vane type. In the sliding-vane rotary compressor, fluid is trapped between vanes as the rotor passes the inlet opening (**Fig. 4**). Further rotation of the rotor reduces the volume of the space in which the fluid is trapped. Fluid pressure rises until the discharge port is reached, when discharge occurs.

Depending on design, the compressor may be cooled with atmospheric air, oil, or water. For low pressures one stage of compression is used; for higher pressures, two stages. Capacities range to about 5000 ft^3/min (140 m^3/min). Some compressors of this type have rings around the vanes to keep them from bearing on cylinder walls. Others have vanes bearing against the cylinder.

Lobe type. In the lobed rotary compressor, fluid is trapped between two or more rotors held in fixed relationship to each other. Rotation of the impellers reduces the volume in which the fluid is trapped, producing a pressure rise. Fluid is discharged when the rotors pass the outlet port. Either two or three rotors are used. Capacities range about 5–50,000 ft^3/min (0.1–1400 m^3/min). Pressures above about 15 lb/in.^{2} (100 kPa) are obtained by operating two or more lobe-type compressors in series. Rotors are straight or slightly twisted.

Liquid-piston type. In the liquid piston rotary compressor, a round multiblade rotor revolves in an elliptical casing partly filled with liquid, usually water. When the rotor turns, it carries liquid around with it, the blades forming a series of buckets. Because the liquid follows the casing contours, it alternately leaves and returns to the space between blades (twice each revolution). As the liquid leaves the bucket, the fluid to be compressed is drawn in. When the liquid returns, it compresses the fluid to discharge pressure.

Liquid-piston compressors handle up to about 5000 ft^3/min (40 m^3/min). Single-stage units can develop pressures to about 75 lb/in.^{2} (520 kPa); multistage designs are used for higher pressures. Water or almost any other low-viscosity liquid serves as the compressant. For exacting services, the compressor may be sealed with chilled water to prevent condensation in lines.

Radial-flow units. Dynamic-type centrifugal compressors use rotating elements to accelerate the fluid radially. By diffusing action, velocity is converted to static pressure. Thus, the static pressure is higher in the enlarged section. Centrifugal compressors usually take in fluid at the impeller eye (or central inlet of the circular impeller) and accelerate it radially outward. Some static-pressure rise occurs in the impeller, but most of the pressure rise occurs in the diffuser section of the casing, where velocity is converted to static pressure. Each impeller-diffuser set is a stage of the compressor. Centrifugal compressors are built with from 1 to 12 or more stages, depending on the final pressure desired and the volume of fluid to be handled. The pressure ratio, or compression ratio, of a compressor is the ratio of the absolute discharge pressure to the absolute inlet pressure. *See* BERNOULLI'S THEOREM; DIFFUSER.

In the typical compressor, centrifugal action of the impeller produces a pressure rise and a large increase in air velocity. In the diffuser, velocity energy is converted to static pressure.

Pressure delivered by a centrifugal compressor is practically constant over a relatively wide range of capacities. Pumping limit, also called surge point or pulsation point, is the lower limit of stable operation. Percentage stability is 100 minus the pumping limit in percent of design capacity.

Multistage centrifugal compressors handle from 500 to more than 150,000 ft^3/min (14 to 4300 m^3/min) at pressures as high as 5000 lb/in.^{2} (35 MPa), but are limited to compression ratios in the order of 10.

Axial-flow units. Compressors that accelerate the fluid in a direction generally parallel to the rotating shaft consist of pairs of moving and stationary blade-rows, each pair forming a stage. The pressure rise per stage is small, compared with a radial-flow unit. Therefore, the usual axial-flow compressor has more stages than a centrifugal compressor working through the same pressure range. Single-stage axial compressors have capacities from a few to more than 100,000 ft^3/min (2800 m^3/min) at pressures from less than 1 to several pounds per square inch. Multistage axial-flow compressors compress air to 150 lb/in.^{2} (1 MPa) or more. Some special machines handle over 2,000,000 ft^3/min (60,000 m^3/min). Pressure rise per stage is generally relatively small, so units for higher pressures frequently have a considerable number of stages—20 or more.

While centrifugal machines deliver practically constant pressure over a considerable range of capacities, axials have a substantially constant delivery at variable pressures. In general, centrifugals have a wider stable operating range than axials. Because of their more or less straight-through flow, axials tend to be smaller in diameter than centrifugals and to be longer. Efficiency of axials usually runs slightly higher.

To prevent surging at extremely low loads, large-capacity axials are sometimes fitted with a blowoff system that discharges excess air to the atmosphere. Then there is always enough air passing through the machine to keep it in its stable range.

Because of difficulty in accurately predicting the performance curves of centrifugal and axial compressors, only one capacity and one discharge-pressure rating, together with corresponding power input, are normally guaranteed. Shape of the curve may be indicated but is never guaranteed. *See* FAN; PUMPING MACHINERY. Tyler G. Hicks; Donald L. Anglin

Compton effect

The increase in wavelength of scattered electromagnetic radiation that is determined by the angle of scattering when gamma rays or energetic x-rays are scattered by electrons. When the scattering electron is assumed to be unbound and at rest, analysis leads to a wavelength increase approximated by Eq. (1).

$$\Delta\lambda = \lambda_2 - \lambda_1 = \frac{h}{m_0 c}(1 - \cos\phi) \qquad (1)$$

Here, λ_1 is the wavelength of the incident radiation, λ_2 is the wavelength of the radiation scattered at the angle ϕ, h is Planck's constant, m_0 is the rest mass of the electron, c is the speed of light, and ϕ is the angle by which the scattered radiation deviates from the direction of the incident radiation.

The quantity $h/m_0c = 2.426310 \times 10^{-12}$ m is called the Compton wavelength of the electron. The Compton wavelengths of other particles are defined in terms of their rest masses in an analogous manner. Thus, for example, the Compton wavelength of the proton is 1.321410×10^{-15} m.

There is a near consensus that the Compton effect provides the most persuasive evidence from any physical phenomenon in support of the photon description of electromagnetic radiation. The evidence provided by the angular dependence of the wavelength shift is not in itself sufficient to establish the reality of photons. However, when supplemented by the experimental evidence that a single scattering electron suffices to conserve both energy and momentum in a binary collision with a photon, it provides compelling support for the photon picture.

A. H. Compton's measurements, carried out in the era of the old quantum theory, challenged the validity of J. J. Thomson's theory of coherent scattering by electrons, which was based on the Maxwell equations of electromagnetism and the wavelike nature of x-rays. The wavelike properties of x-rays were established by the use of crystalline solids as diffraction gratings, leading to the development of wavelength-dispersive x-ray spectrometry. Compton's mastery of this new technology led him to the proof that x-rays also display particlelike properties. *See* MAXWELL'S EQUATIONS; X-RAY DIFFRACTION; X-RAY SPECTROMETRY.

The modern picture of coherent scattering differs from that of Thomson. His calculated differential cross section for unpolarized radiation is given by Eq. (2). Here $d\Omega$ is the solid scattering angle, and r_e is

$$d\sigma = \frac{r_e^2}{2}(1 + \cos^2\phi)d\Omega \qquad (2)$$

the classical electron radius, equal to e^2/m_0c^2, where e is the charge on the electron. This result must be multiplied by the square of an atomic form factor, $f(\phi)$, because the electrons in an atom scatter in a cooperative manner. The resulting Rayleigh cross section depends very strongly on both the atomic number Z and the energy E. Data from low-Z targets such as graphite have the simple form that leads to the Compton analysis. Higher-Z targets such as iron or copper produce data dominated by Rayleigh scattering, showing little shift in wavelength. For example, markedly different energy spectra are obtained when

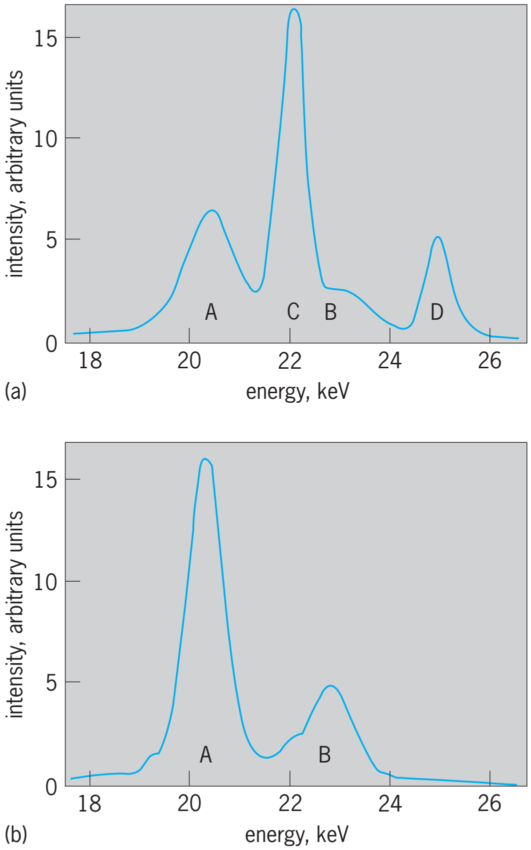

Fig. 1. Energy spectra of K x-rays of silver after scattering at about 170° from targets of (*a*) copper and (*b*) polyethylene (CH_2). The peaks labeled A and B are from Compton scattering; those labeled C and D are from Rayleigh scattering.

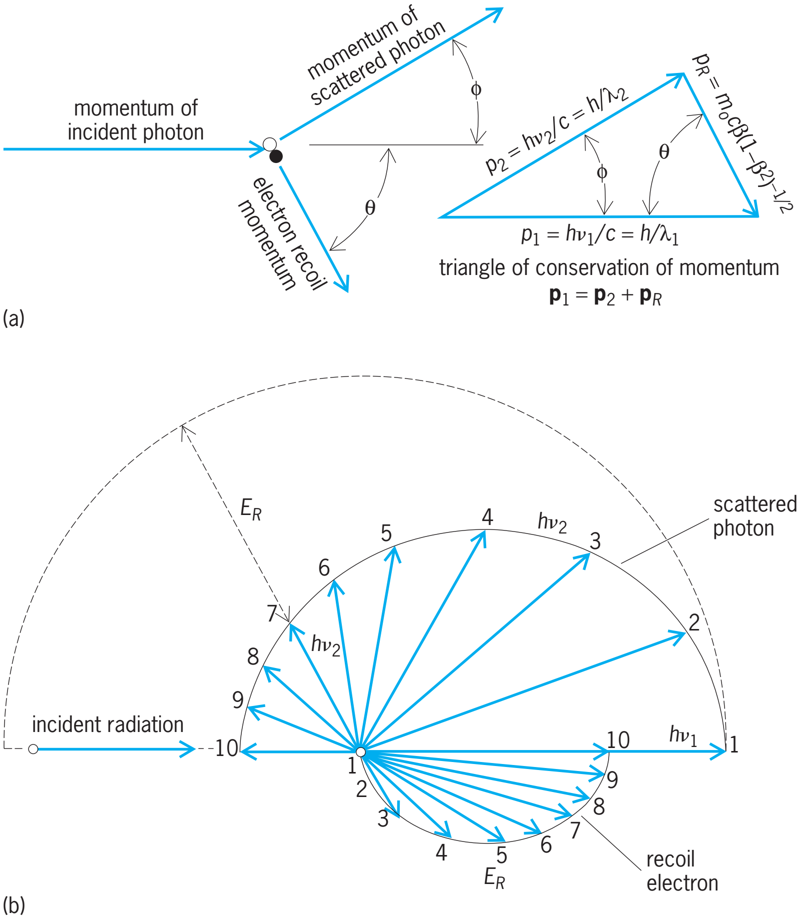

Fig. 2. Geometry of Compton scattering. (*a*) Diagrams for applying energy and momentum conservation to the collision of a photon with an electron, initially at rest. Symbols defined in text. (*b*) Relation of energy and direction of scattered photon, $h\nu_2$, and of recoil electron, E_R, in the special case that initial photon energy, $h\nu_1 = m_0c^2$. Photon and electron energy and direction are plotted for 10 photon scattering angles varying from 0 to 180°. Paired arrows mean, for example, that when the secondary photon goes in direction 5 in the upper half of the diagram, recoil electron follows arrow 5 in the lower half. (*After B. R. Wheaton, The Tiger and the Shark, Cambridge University Press, 1983*)

the K x-rays of silver (with energy of 22.1 keV) are backscattered from polyethylene (CH_2) and copper (**Fig. 1**). These spectral differences, easily revealed by a modern germanium detector, are hidden and unsuspected causes of inconsistency if a detector of low resolving power is used. *See* SCATTERING OF ELECTROMAGNETIC RADIATION.

Theory. The essential break with a classical theory of scattering is to adopt a model pioneered by A. Einstein, in which photons of frequency ν travel as discrete quanta with energy hν and linear momentum hν/c. Compton's analysis applies the photon concept to a collision with an unbound electron at rest. The photon transfers some energy and momentum to the electron so the scattered photon must have less energy, $h\nu_2$, than the primary, $h\nu_1$. Since $\nu = c/\lambda$ for a wave of speed c, the wavelength of the scattered photon, λ_2, must exceed the initial wavelength λ_1. *See* PHOTOEMISSION; PHOTON; QUANTUM MECHANICS.

In an elastic collision, both the energy and the linear momentum must be conserved. Application of these two principles to determine the wavelength shift expected for a given scattering angle leads to what is now known as the Compton equation, Eq. (1). *See* COLLISION (PHYSICS); CONSERVATION LAWS (PHYSICS); CONSERVATION OF ENERGY; CONSERVATION OF MOMENTUM.

Scattering process. Compton's analysis applies to the scattering process for a collision between an incident photon of linear momentum p_1 and wavelength λ_1 and a resting, unbound electron (**Fig. 2***a*). After the collision, the scattered photon moves at an angle ϕ and the electron recoils at an angle θ, both angles being with respect to the direction of the incident photon.

Compton's decisive x-ray data were produced at such low energies that the recoil electron traveled at nonrelativistic speeds, but both Compton and P. Debye treated the problem generally. The principle of conservation of energy yields Eq. (3), where β is

$$h\nu_1 = h\nu_2 + m_0c^2\left(\frac{1}{\sqrt{1-\beta^2}} - 1\right) \qquad (3)$$

V/c and V is the speed of the recoil electron. Conservation of linear momentum yields two equations, Eq. (4), for the horizontal component and Eq. (5)

$$\frac{h\nu_1}{c} = \frac{h\nu_2}{c}\cos\phi + \frac{m_0V}{\sqrt{1-\beta^2}}\cos\theta \qquad (4)$$

$$0 = \frac{h\nu_2}{c}\sin\phi - \frac{m_0V}{\sqrt{1-\beta^2}}\sin\theta \qquad (5)$$

for the vertical component. By squaring these equations and substituting $\nu = c/\lambda$, the electron velocity can be eliminated and Eq. (1) is obtained for the shift in wavelength. *See* RELATIVITY.

Many tests of the theory, particularly those using modern energy-dispersive detectors, are checked by reverting to frequency. Equation (1) can be rewritten to give the energy of the scattered photon, and can be recombined with Eq. (3) to obtain an expression for the recoil energy of the initially stationary electron. Following Debye, the nature of these solutions can be illustrated compactly for the important special case that $h\nu_1 = m_0c^2$ by plotting the energy and direction of both the scattered photon and the recoil electron for various scattering angles (Fig. 2*b*). The resulting diagram emphasizes that while the photons may scatter backward as well as forward, the recoil electron is always projected forward in a much narrower cone.

Compton profile. The assumption that the scattering electron is at rest in the laboratory frame of reference is not consistent with the real situation in experiments. The photons are scattered by electrons whose speeds are typically 1% of the speed of light for valence electrons and 10% for core electrons, causing substantial Doppler shifts. Analysis shows that a second term should be added to the right-hand side of Eq. (1) for the wavelength shift. This second term is proportional to the projection of the electron's initial momentum on the scattering vector. Accurate measurement of the complete

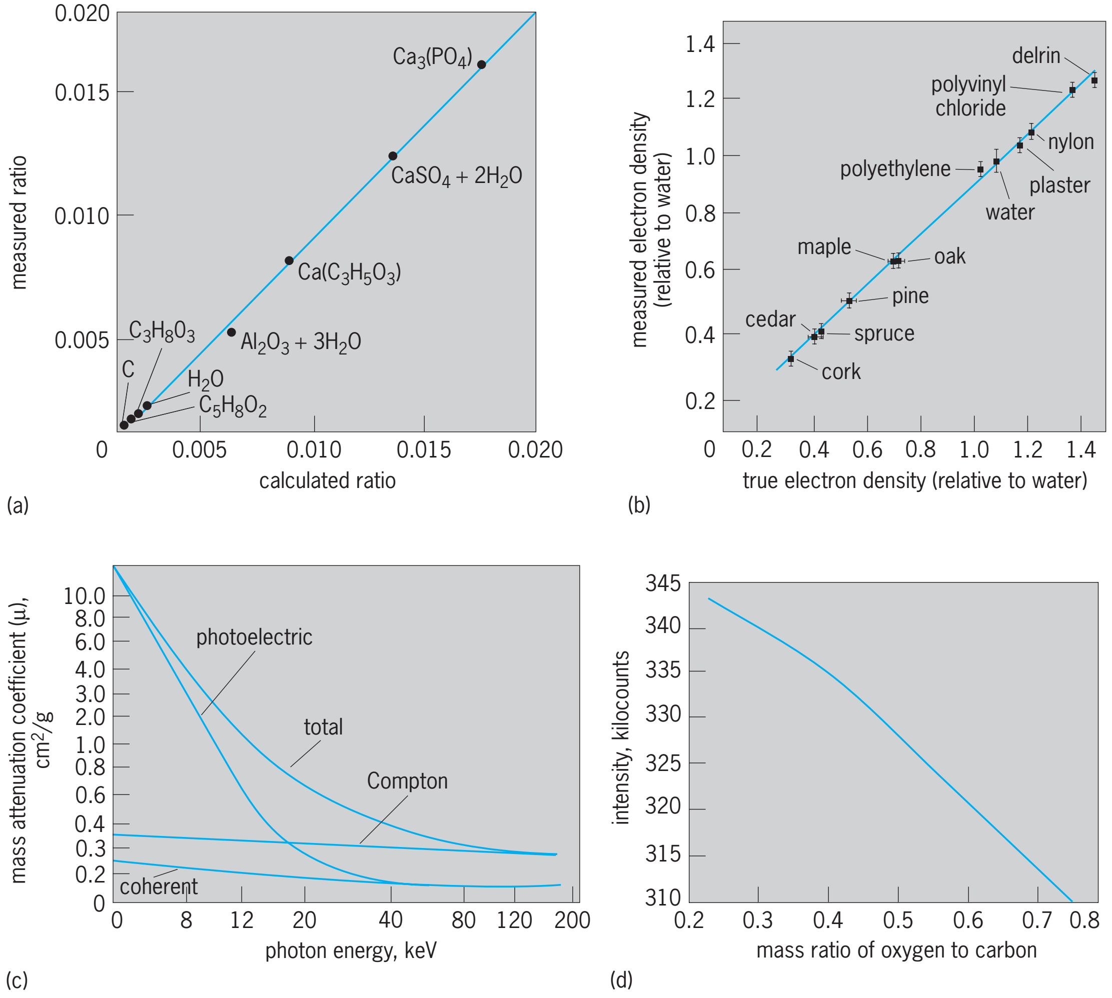

Fig. 3. Examples of nondestructive analysis of low-*Z* compounds using Compton scattering. (*a*) Comparison of measured and calculated Rayleigh-Compton ratios at an energy of 60 keV. Calculated ratio is based on assigning an effective atomic number to the compound. Diagonal line represents equality of measured and calculated ratios. (*b*) Comparison of Compton-measured electron density and true electron density of compounds for energies (662 keV) where Compton effect is totally dominant. Diagonal line represents equality of measured and true densities. (*c*) Energy dependence of the linear attenuation coefficient for the main interactions in soft tissue. Coefficients for total attenuation and components due to photoelectric effect, Compton effect, and coherent scattering are shown. (*d*) Dependence of backscatter intensity on the carbon-oxygen ratio in methanol-water mixtures (which simulate proportions of fat and lean meat) for the L x-rays of neptunium (∼ 17 keV). This dependence results from competition of Compton scattering with photoelectric absorption. (*Parts a, b, c after R. Cesareo, ed., Nuclear Analytical Techniques in Medicine, Elsevier Science, 1988*)

spectrum of scattered wavelengths gives a distribution of one cartesian component of the velocity of the scattering electrons. With a beryllium target, this technique was used to demonstrate that electrons follow Fermi-Dirac rather than Boltzmann statistics. If the incident radiation in this method is provided by ordinary x-ray generators, then the intensity of the scattered radiation is so low as to make most experiments impractical, because of the need to define the scattering angle by collimators. However, the advent of highly luminous synchrotron x-ray sources has made this an active research area. It permits accurate determination of directional variations of velocity spectra in single-crystal specimens and opens new research opportunities in the study of molecular bonds. *See* DOPPLER EFFECT; FERMI-DIRAC STATISTICS; SYNCHROTRON RADIATION.

Intensity distribution. Thomson's theory of x-ray scattering by electrons makes predictions not only of the wavelength shift but also of the intensity as a function of scattering angle. However, his expression depends on the distance of the photon from the scatterer, and Compton's model makes no prediction of this distance. That prediction requires the use of quantum mechanics in its relativistic form, due to P. A. M. Dirac. The result, known as the Klein-Nishina formula, contains the Thomson expression as a first term but goes on to include large frequency- and angle-dependent corrections. *See* RELATIVISTIC QUANTUM THEORY.

Applications. The Compton effect often plays a major nuisance role, producing most of the background in x-ray diffraction and in the field of gamma-ray spectroscopy, where interest focuses on producing energy spectra with narrow lines whose intensity and mean energy can be estimated accurately. Compton scattering of x-rays by materials of low atomic number is so dominant that it forces the versatile technique of x-ray fluorescence to employ extremely thin targets, thus removing it from the list of nondestructive analytical techniques. However, the development of high-resolution silicon and germanium semiconductor radiation detectors in the 1960s opened new areas for applications of Compton scattering. Those related to the measurement of Compton profiles are discussed above. *See* JUNCTION DETECTOR; X-RAY FLUORESCENCE ANALYSIS.

Noninvasive analysis. Semiconductor detectors make it possible to measure the separate probabilities for Rayleigh and Compton scattering. An effective atomic number has been assigned to compounds that appears to successfully correlate theory with Rayleigh-Compton ratios (**Fig. 3***a*).

Average density can be measured by moving to higher energies where Compton scattering does not have to compete with Rayleigh scattering. At these energies, Compton scattering intensity has been successfully correlated with mass density (Fig. 3*b*). An appropriate application is the measurement of lung density in living organisms.

At low energies and low atomic numbers, the main competition for photon attenuation is between Compton scattering and photoelectric absorption (Fig. 3*c*). This competition can be used to analyze very low Z mixtures such as fat-lean ratios (Fig. 3*d*). *See* NONDESTRUCTIVE EVALUATION.

Gamma-ray astronomy. The ability to put large detectors in orbit above the Earth's atmosphere has created the field of gamma-ray astronomy. This field is now based largely on the data from the Compton Gamma-Ray Observatory, all of whose detectors make use of the Compton effect (although not exclusively). The information produced by this observatory on gamma-ray bursters may change the estimated age of the universe by a factor of 2. *See* GAMMA-RAY ASTRONOMY; GAMMA-RAY DETECTORS; GAMMA RAYS; X-RAYS.

Computational chemistry

A branch of theoretical chemistry that uses a digital computer to model systems of chemical interest. In this discipline, the essential physics that determines molecular behavior is captured in mathematical models and programmed for digital computers. The models are imperfect but have proven remarkably useful.

The domain of computational chemistry is vast. In principle, almost any quantity that can be measured can be computed. In practice, programs are available that calculate properties of individual molecules, including geometries, charge distributions, and modes of vibration for both ground and excited electronic states. Changes in those properties can also be calculated as the computer transforms compounds from reactants to products during the simulation of a chemical reaction. Properties, such as absorption and emission spectra which involve the interaction of molecules with electromagnetic radiation, can also be computed. Where possible, computational procedures are validated by comparison with experiment, and the confidence gained from such comparisons often encourages application to properties that are at or beyond what can be measured experimentally. Computations can thus provide information about the geometries of short-lived high-energy species or molecules that may be only a glimmer in the eye of a creative chemist.

In addition to estimates of important quantities, computations also provide deep insight into the reasons that chemicals behave as they do. For example, electronic structure calculations provide information about bonding electrons that can explain structural preferences and foretell chemical reactivity. In favorable cases, this information can be used proactively to design molecules to user specifications or aid in the design of catalysts that promote the production of a desired compound.

Because of the increasing power of computers and the simultaneous development of well-tested and reliable theoretical methods, computational chemistry and experimental chemistry are becoming interdependent partners. In addition to the more traditional use of computational chemistry as a tool to explain experimental outcomes, computations are increasingly used to develop plausible hypotheses that are then tested in the laboratory. Hypothetical molecules conceived by a molecular designer are often synthesized and evaluated in the computer long before they are ready to be tested in the laboratory.

The practice of computational chemistry can involve either the application of existing computational tools to new molecules or the development of new computational methods. New software developments are constantly pushing back the frontiers of what is computable. Breakthroughs may involve the incorporation of better physics into the underlying mathematical models, the implementation of algorithms that better utilize computing resources, or the use of time-saving approximations. Popular approximate methods include semiempirical methods that rely partially on experiment to estimate model parameters, and methods that partition a large complex system into two parts, with one part being the focus of the calculation that is treated rigorously and the other being the surroundings that is treated with less rigor. Such approaches coupled with improvements in hardware have made it possible to perform calculations, which required supercomputing capabilities just a few years ago, on a desktop workstation or even a personal computer. *See* ALGORITHM.

Before a computational study is begun, an effective method must first be identified that balances the computational cost against a combination of factors, including accuracy, scalability, interpretability, response speed, and ease of implementation and use.

While keeping this balance in mind, a practitioner's first decision is often between two fundamentally different mechanical treatments of molecules: quantum mechanics and molecular mechanics.

Quantum mechanics. One active area of computational chemistry involves the calculation of molecular properties based on Schrödinger's wave equation

$$H\Psi = E\Psi$$

where H is the Hamiltonian operator for a molecule's electrons as they move in the field of the fixed nuclei, Ψ is a function of the electron coordinates, and E is a constant identified as the electronic energy of the molecule. H typically includes operations that evaluate the kinetic energy of the electrons in terms of the curvature of Ψ, and multiplication operations that account for potential energy. In order for a function Ψ to be a suitable wavefunction, the Hamiltonian operations when applied to Ψ must return Ψ multiplied by the constant E. Solutions of the Schrödinger equation exist for only certain quantized values of E, the lowest of which corresponds to the ground electronic state of the molecule. This energy will change as the positions of the nuclei are moved, and most electronic structure programs feature gradient methods to locate nuclear configurations that correspond to minima in the energy E. The wavefunction Ψ has no physical meaning, but its square is interpreted as the electron density and indicates where the electrons are likely to be found in a molecule. Electron density plays a profound role in determining the physical and chemical properties of a molecule. *See* QUANTUM MECHANICS; SCHRÖDINGER'S WAVE EQUATION.

Regrettably, the Schrödinger equation cannot be solved exactly for any but the simplest molecular systems. Fortunately, useful approximations abound. One popular and successful approximation is to partition Ψ into factors known as molecular orbitals (MOs). Each MO is expressed as a linear combination of atom-centered basis functions known as atomic orbitals (AOs). The coefficients of the AOs in the MOs are determined by an energy minimization process that attributes an orbital energy to each of the MOs and assigns electrons usually in pairs to those MOs that have the lowest energy. *See* MOLECULAR ORBITAL THEORY.

Molecular orbital calculations can take from a few seconds of computer time to many hours, depending on the level of approximation. Computing time is also a steep function of molecular size, increasing roughly as the fourth or fifth power of the number of basis functions (atomic orbitals) used to express the MOs. High-level ab initio calculations can rival the accuracy of experiment in determining ground- and excited-state molecular geometries, electronic-transition frequencies, vibration frequencies, and heats of formation.

Density functional theory is another quantum-mechanical method that has been applied to molecules. Originally developed for problems in solid-state physics, these calculations express the total energy of the system as a function of the ground-state electron density rather than of the molecular wave function. Since the computer time increases only as the cube of the number of basis functions, density functional methods can be used for larger molecules than molecular orbital methods, while often maintaining comparable accuracy. *See* QUANTUM CHEMISTRY.

Electronic structure calculations have been used productively in many chemical disciplines. In the life sciences, electronic structure calculations provide plausible explanations for the biological activity of known molecules, and guidance for the design of new molecules with desired properties. For example, calculated charge distributions for the transition state of an essential biochemical transformation can serve as a template for the design of drugs which act by inhibiting the enzyme responsible for catalyzing this transformation in a pathogenic organism.

Molecular mechanics. The molecular-mechanics model treats the atoms and bonds in a molecule much like a collection of balls joined by springs. Because of its relative simplicity, it can be applied to proteins and other large molecules, where quantum-mechanical methods are impractical. Molecular-mechanics programs can adjust the molecular structure until a conformation of minimum energy is determined. The spring force constants and atomic sphere parameters that define a force field are typically preadjusted by developers so that their programs produce results that nearly agree with a "training set" of experimentally measured or reliably calculated quantities. These parameter values are often assumed to be valid for other molecules and molecular conformations that are outside of the training set. *See* BOND ANGLE AND DISTANCE; CHEMICAL BONDING; MOLECULAR MECHANICS.

Force fields differ mainly by the inclusion of additional terms for interactions such as hydrogen bonding or coupling between the springs. Some force fields have been customized for families of compounds such as proteins and nucleic acids. At one time or another, missing or inappropriate force-field parameters are the bane of every practitioner of molecular mechanics, especially when treating molecules and conformations that are far different from those represented in the training set used to fix the parameters of the force field. In spite of limitations, satisfactory accuracy for many applications and modest computer demands have made molecular mechanics–based methods popular, especially for large molecules.

Gradient techniques used in either molecular or quantum mechanics assure that a low-energy structure at the bottom of an energy well containing the starting point will be found. If the energy surface is complex, other lower-energy structures are likely to exist at remote locations and may not be found unless algorithms that promote broader exploration are exercised. One technique used for broader sampling of potential-energy surfaces is molecular dynamics. *See* CHEMICAL DYNAMICS.

Molecular-dynamics calculations simulate atomic motion by integration of Newton's equations.

Acceleration is directed by the negative gradient of the potential energy, which is calculated with the underlying molecular-mechanics model. The method requires large amounts of computer time just to simulate a few hundred picoseconds to nanoseconds of atomic motion. Various approximations have been developed to decrease the amount of computer time required, while maintaining the accuracy of the calculations. Large systems may be simulated by the imposition of periodic boundary conditions. This means that the box containing the particles is considered to be replicated in all three dimensions, similar in the manner by which strips of wallpaper continue a pattern around a room. The influence of explicit molecules can be replaced by a solvation function whose magnitude depends on the type and fractional exposure of solute atoms to the solvent. In Monte Carlo methods, each particle movement is determined randomly and selectively accepted, based on certain energy criteria. In Langevin dynamics methods, forces between nearby particles are treated exactly, and those due to remote particles, including solvent, are treated stochastically. Software is available for computer simulations of small molecules moving in a variety of solvents, of solutes permeating through lipid membranes, and for various motions of proteins and nucleic acids. *See* MONTE CARLO METHOD; STOCHASTIC PROCESS.

Many important structural and thermodynamic quantities may be computed from simulations of sufficient length by averaging over the ensemble of molecular conformations, which are sampled during the simulation. In order to evaluate the free-energy change associated with a chemical reaction, advantage is often taken of the principle that free energy is a function of state. Consequently in a reaction, changes in free energy F are independent of the path taken to get from the reactants to the products. This principle enables the calculation of the free-energy change of a reaction from the known change for a closely related reference reaction. For example, if the free-energy change ΔF_3 for binding ligand B to a protein receptor R has been measured experimentally (see **illustration**), the free energy change for binding ligand A to the same receptor (ΔF_1) can be estimated as $\Delta F_1 = \Delta F_2 + \Delta F_3 + \Delta F_4$. Molecular simulations can be used to calculate the free-energy changes associated with the kind of structural morphing involved in steps 2 and 4. These transformations, which are an alchemist's dream come true, may be impossible in the laboratory, but are readily simulated in a computer using advanced algorithms based on thermodynamic perturbation or integration theories. In the hands of experienced computational chemists, simulations of this type can be used to find analogs of a reference compound that alter receptor-binding characteristics in a desired fashion. *See* FREE ENERGY; SIMULATION.

$$\begin{tikzcd}
R + A \arrow[r, "\Delta F_1"] \arrow[d, "\Delta F_2"'] & RA \\
R + B \arrow[r, "\Delta F_3"'] & RB \arrow[u, "\Delta F_4"']
\end{tikzcd}$$

Thermodynamic cycle to calculate free energy of binding of ligand A to a receptor based on a known value for binding ligand B.

Interactive computer graphics. Graphical methods are not necessarily based on a mechanical model, but are often used in conjunction with the mechanical methods described above. Interactive graphics has become so prevalent in the chemical community that it is almost impossible to conceive of calculations without associated molecular manipulation and visualization. Here a picture is worth millions of numbers. When seated at a molecular graphics terminal, the chemist is essentially working with a sophisticated set of molecular models that are stored in the computer memory and displayed on a screen. Molecular orbitals, electron densities, and normal-mode vibrations can be viewed from a variety of perspectives. The sequence of conformations from computer simulations, displayed one frame after another, in effect creates a movie of the thermal motion of the molecules. Moving a mouse or turning a dial moves atoms about the screen as easily as tangible models can be moved physically.

Seeing in three dimensions is often essential for understanding the behavior of a molecule. A sense of depth is produced when a pair of computer-generated left- and right-eye images is seen through one of several types of viewers that aid in merging the images. Stereoscopic viewing is most useful when comparing the structures of two molecules or when studying interactions between them. Structural comparisons in three dimensions enable the user to discern similarities and differences between molecules that might escape a reader of the printed page. Unlike physical models, these graphical renderings of molecules can be easily overlaid in order to further enhance comparisons. Computer graphics can also be used to dock models of small guest molecules into cavities within larger host molecules. This is particularly important for drug designers. For example, when the structure of a target protein is available, computer graphics can be used to study the fit of a drug candidate into potential binding sites in the protein and to anticipate the influence of such binding on the protein's function. Alterations can then be made on the small molecule with the goal of improving the fit to the binding site. The potential of this technology continues to increase as the number of available crystal structures of important enzymes or receptors rises. *See* COMPUTER GRAPHICS; CONFORMATIONAL ANALYSIS; STEREOCHEMISTRY.

Computational fluid dynamics

The numerical approximation to the solution of mathematical models of fluid flow and heat transfer. Computational fluid dynamics is one of the tools (in addition to experimental and theoretical methods) available to solve fluid-dynamic problems. With the advent of modern computers, computational fluid dynamics evolved from potential-flow and boundary-layer methods and is now used in many diverse fields, including engineering, physics, chemistry, meteorology, and geology.

Computational methods. The fundamental model of fluid flow, known as the Navier-Stokes equations, is derived from the conservation of mass, momentum, and energy. For example, if the fluid is incompressible, the Navier-Stokes equations can be written as Eqs. (1) and (2), where u, v, and w are the cartesian

$$\text{Continuity}: \quad \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \tag{1}$$

Momentum :

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} + w\frac{\partial u}{\partial z} = -\frac{1}{\rho}\frac{\partial p}{\partial x} + \frac{1}{\mu}\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2}\right) \tag{2a}$$

$$\frac{\partial v}{\partial t} + u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y} + w\frac{\partial v}{\partial z} = -\frac{1}{\rho}\frac{\partial p}{\partial y} + \frac{1}{\mu}\left(\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} + \frac{\partial^2 v}{\partial z^2}\right) \tag{2b}$$

$$\frac{\partial w}{\partial t} + u\frac{\partial w}{\partial x} + v\frac{\partial w}{\partial y} + w\frac{\partial w}{\partial z} = -\frac{1}{\rho}\frac{\partial p}{\partial z} + \frac{1}{\mu}\left(\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2} + \frac{\partial^2 w}{\partial z^2}\right) \tag{2c}$$

components of velocity, ρ the fluid density, p the pressure, and μ the fluid viscosity. The compressible form of the Navier-Stokes equations, which is of slightly different form because of the variable fluid properties, additionally contains the energy equation, which couples the temperature, velocity, and pressure fields. The complete formulation requires initial and boundary conditions and thermodynamic relations for fluid properties. Numerical solution of this set of nonlinear coupled partial differential equations presents many difficulties, including application of boundary conditions, particularly for free and moving surfaces; grid generation for complex geometries; turbulence modeling; pressure-velocity coupling for incompressible flows; and resolution of shock waves in supersonic flows. A hierarchy of approaches is available for simplifying Eqs. (1) and (2) [see **table**]. *See* DIFFERENTIAL EQUATION; NAVIER-STOKES EQUATION.

Computational fluid dynamics is associated with field-equation solutions of the Euler and Navier-Stokes equations instead of other computational techniques such as boundary-element methods for inviscid flows and momentum-integral methods for boundary-layer flows. The crucial elements of computational fluid dynamics are discretization, grid generation and coordinate transformation, solution of the coupled algebraic equations, turbulence modeling, and visualization.

Discretization. Numerical solution of partial differential equations requires representing the continuous nature of the equations in a discrete form. Discretization of the equations consists of a process where the domain is subdivided into cells or elements (that is, grid generation) and the equations are expressed in discrete form at each point in the grid by using finite difference, finite volume, or finite element methods. The finite difference method requires a structured grid arrangement (that is, an organized set of points formed by the intersections of the lines of a boundary-conforming curvilinear coordinate system), while the finite element and finite volume methods are more flexible and can be formulated to use both structured and unstructured grids

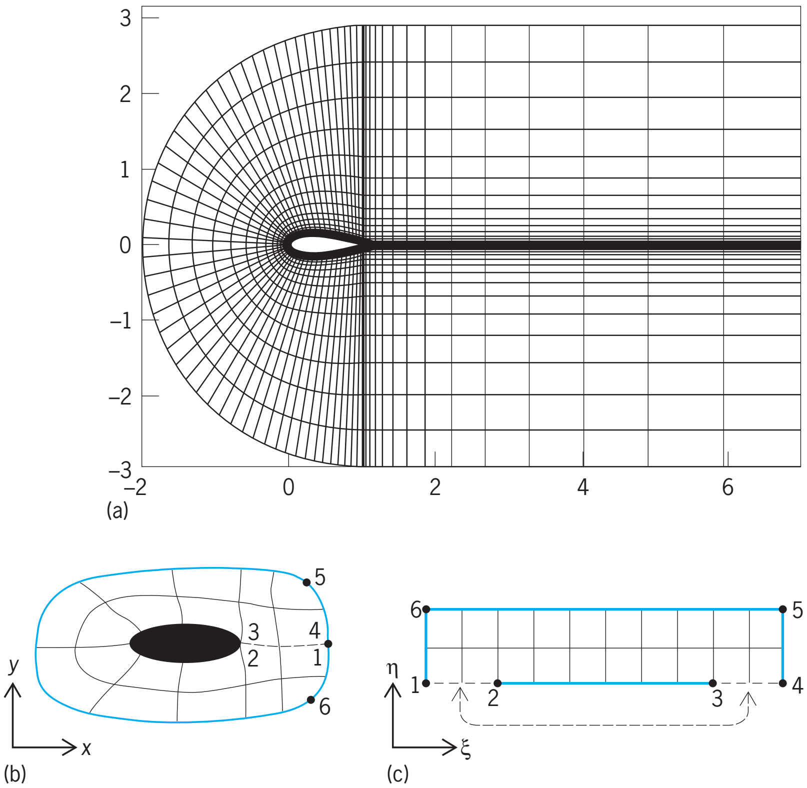

Fig. 1. **Computational grid for numerical analysis of flow about a hydrofoil. (*a*) Structured grid. (*b*) Schematic of physical domain. (*c*) Schematic of computational domain.**

Hierarchy of approaches to fluid-flow problems*

Mathematical basis	Type of partial differential equation	Physical problems
Laplace equation	Elliptic	Inviscid and irrotational flow
Euler equation	Hyperbolic	Inviscid flow
Boundary-layer equations	Parabolic	Thin viscous layer
Navier-Stokes equations	Mixed	Laminar flow
Reynolds-averaged Navier-Stokes (RaNS) equations + turbulence model	Mixed	Turbulent flow
Large-eddy simulation (Navier-Stokes equations + subgrid model)	Mixed	Turbulent flow
Direct numerical solution (Navier-Stokes equations + grid resolving all length scales)	Mixed	Turbulent flow

*Listed in order of increasing complexity of numerical solution.

(that is, a collection of triangular elements or a random distribution of points). Complex shapes necessitate nonuniform, boundary-conforming grids with grid points concentrated in regions of high gradients, such as inside boundary layers or near shock waves. Structured grids are usually generated by using algebraic interpolation functions or elliptic partial differential equations. For finite difference methods, the equations are rewritten in generalized nonorthogonal coordinates and evaluated on a so-called computational domain, which is defined by the transformation between the boundary-conforming curvilinear-coordinate system in the so-called physical domain and an orthogonal grid with uniform spacing (**Fig. 1**). *See* FINITE ELEMENT METHOD.

Finite difference discretization of Eqs. (1) and (2) is based on the algebraic representation of derivatives by using Taylor-series expansions. For example, the temporal derivative in Eq. (2*a*) expressed as a first-order backward difference is Eq. (3), where (i, j, k) is

$$\frac{\partial u}{\partial t} = \frac{u^{n}_{i,j,k} - u^{n-1}_{i,j,k}}{\Delta t} + \vartheta\,[(\Delta t)] \tag{3}$$

the location of the grid point, (n) is the current time level, $(n-1)$ is the previous time level, Δt is the time step between (n) and $(n-1)$, and $\vartheta(t)$ represents the truncated terms in the Taylor-series approximation of the partial derivative $\partial u/\partial t$. (Dropping these terms introduces a source of error, known as a truncation error, which is of an order of magnitude equal to that of the time step Δt.) Due to advantageous stability characteristics, in comparison to central differencing, an upstream-backward difference is typically used for the convective terms. Assuming that the grid is uniform and orthogonal, the first-order upstream difference for the x-component convective term of Eq. (2*a*) is given by Eq. (4), where Δx or the

$$u\frac{\partial u}{\partial x} = u^{n-1}_{i,j,k}\,\frac{u^{n}_{i,j,k} - u^{n}_{i-1,j,k}}{\Delta x} + \vartheta\,[(\Delta x)] \tag{4}$$

grid spacing, and the grid point locations (i,j,k), are given by a numerical molecule (**Fig. 2**). Usually, the viscous terms in the momentum equations are evaluated by using a central difference. For example, the second-order central difference of the second partial derivative of u in the x direction [from Eq. (2*a*)] is given by Eq. (5).

$$\frac{\partial^2 u}{\partial x^2} = \frac{u^{n}_{i+1,j,k} - 2u^{n}_{i,j,k} + u^{n}_{i-1,j,k}}{(\Delta x)^2} + \vartheta\,[(\Delta x)^2] \tag{5}$$

Solution of equations. The assembly of the finite difference equations for each grid point results in a large implicit system of algebraic equations for each of the velocity components (u, v, w). For example, the equation for the u component of velocity at the point (i, j, k) is Eq. (6), where A is a matrix of co-

$$\begin{aligned} &A_{i,j,k}u^{n}_{i,j,k} + A_{i+1,j,k}u^{n}_{i+1,j,k} + A_{i-1,j,k}u^{n}_{i-1,j,k} \\ &\quad + A_{i,j+1,k}u^{n}_{i,j+1,k} + A_{i,j-1,k}u^{n}_{i,j-1,k} \\ &\quad + A_{i,j,k+1}u^{n}_{i,j,k+1} + A_{i,j,k-1}u^{n}_{i,j,k-1} = C^{n-1} \end{aligned} \tag{6}$$

efficients related to the grid and the transformation relations (between the physical and computational domains) and C is a known column vector including pressure, body-force, and velocity terms from the previous time step. Equation (6) is usually solved by iterative schemes, such as the alternating direction implicit (ADI) method, which is based upon splitting Eq. (6) into three tridiagonal systems that correspond to sweeps along each of the index (i,j,k) directions. If Eq. (4) and Eq. (5) are evaluated at time level $(n-1)$ instead of (n), the system of finite difference equations is explicit and the solution at each point can be directly evaluated. However, explicit formulations have restrictions on the ratio of the time step to the grid spacing, which are significant for viscous flows

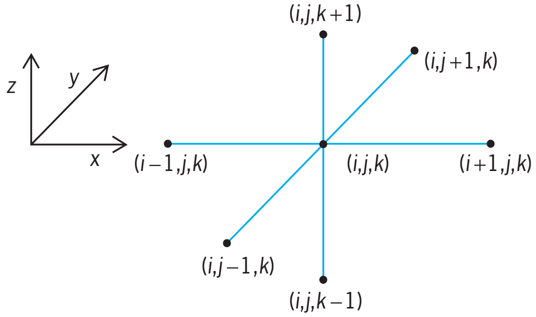

Fig. 2. Numerical molecule, showing nomenclature for neighboring grid points in finite difference discretization.

because of the fine near-wall grid spacing required to resolve the boundary layer. *See* MATRIX THEORY.

For either implicit or explicit approaches, efficient use of computers is required. Current-generation supercomputers are based on vector processors, which are most efficient with large arrays (vectors) of numbers. Optimizing a program, or vectorization, is accomplished by following programming rules so that the compiler can translate the code into vector instructions. *See* SUPERCOMPUTER.

Complete solution of the Navier-Stokes equations requires, for compressible flow, an equation of state such as the ideal gas equation, which relates temperature and density. In contrast, the solution of the incompressible equations presents the problem that the system of equations is lacking an equation for the direct solution of the pressure field. Typically, an equation for pressure is derived which satisfies continuity, and an algorithm must be incorporated which iteratively couples the pressure and velocity fields.

Turbulence modeling. There are a variety of approaches for resolving the phenomena of fluid turbulence. The Reynolds-averaged Navier-Stokes (RANS) equations, which are derived by decomposing the velocity into mean and fluctuating components, contain additional turbulent Reynolds-stress terms which are unknown. Closure of the RANS equations can be accomplished by using the Boussinesq assumption, which relates the Reynolds stresses to the mean rate of strain or the Reynolds-stress equations, which can be solved directly with additional modeling assumptions. An alternative to the RANS equations is large-eddy simulation, which solves the Navier-Stokes equations in conjunction with a subgrid turbulence model. The most direct approach to solving turbulent flows is direct numerical simulation, which solves the Navier-Stokes equations on a mesh that is fine enough to resolve all length scales in the turbulent flow. Unfortunately, direct numerical simulation is limited to simple geometries and low-Reynolds-number flows because of the limited capacity of even the most sophisticated supercomputers. *See* TURBULENT FLOW.

Visualization. The final step is to visualize the results of the simulation. Powerful graphics workstations and visualization software permit generation of velocity vectors, pressure and velocity contours, streamline generation, calculation of secondary quantities (such as vorticity), and animation of unsteady calculations. Despite the sophisticated hardware, visualization of three-dimensional and unsteady flows is still particularly difficult. Moreover, many advanced visualization techniques tend to be qualitative, and the most valuable visualization often consists of simple x-y plots comparing the numerical solution to theory or experimental data. *See* COMPUTER GRAPHICS.

Applications. Computational fluid dynamics has wide applicability in such areas as aerodynamics, hydraulics, and geophysical flows, with length and time scales of the physical processes ranging from millimeters (fractions of an inch) and seconds to kilometers (miles) and years.

Vehicle aerodynamics and hydrodyamics, which have provided much of the impetus in the development of computational fluid dynamics, are primarily concerned with the flow around aircraft, automobiles, and ships where the goal is the determination of the lift and drag forces and the moments resulting from these forces. Furthermore, computational fluid dynamics is being applied to explicate basic physics and to examine complete vehicle configurations. *See* AERODYNAMIC FORCE; AERODYNAMICS; HYDRODYNAMICS.

Hydraulics and environmental fluid dynamics also find many applications of computational fluid dynamics. The prediction of pollutant dispersion in rivers, lakes, and estuaries and riverine morphology, including river-bed formation and sediment deposition, have been studied by using computational fluid dynamics. Detailed analysis of hydraulic structures by using computational fluid dynamics can provide data which are useful in new designs and in the modernization of aging facilities. *See* HYDRAULICS; RIVER ENGINEERING; WATER POLLUTION.

The study of atmospheric and oceanic dynamics finds prolific use of computational fluid dynamics. Although long-term prediction of weather is not possible, because of its random nature and the multiplicity of length and time scales, the study of smaller problems (such as thunderstorms and ocean circulation) and low-resolution global-scale phenomena (for example, global climate models) is possible. *See* CLIMATE MODELING; DYNAMIC METEOROLOGY; FLUID FLOW; FLUID-FLOW PRINCIPLES; NUMERICAL ANALYSIS; OCEAN CIRCULATION; SIMULATION; WEATHER FORECASTING AND PREDICTION.

Computational intelligence

An approach to designing intelligent systems using mathematical algorithms. It consists of the fields of neural networks, evolutionary computation, and fuzzy sets. The term was first used as an alternative to artificial intelligence in the 1980s. The current popular use of the term as defined above results from an effort by James Bezdek in the early 1990s to differentiate the fields of neural networks, evolutionary computation, and fuzzy sets from classical artificial intelligence (AI). There is significant continuing research in the area of computational intelligence, as well as a number of examples of practical, everyday systems that make use of computational intelligence approaches.

Computational intelligence has been used to enable a car to autonomously navigate from Washington, DC, to San Diego with a human driver intervening only a few times; to support automatic transmissions and antilock braking systems; and to determine whether one might grant credit card purchase requests. One of the best checkers-playing computer programs developed so far uses a computational intelligence approach.

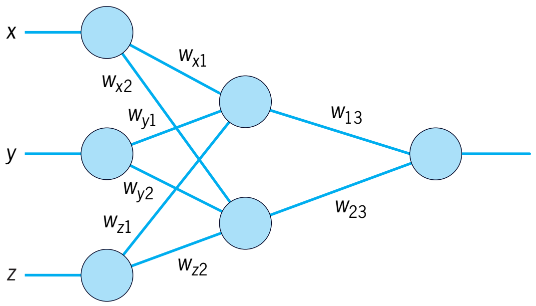
In the classical approach to intelligent systems, known as artificial intelligence, all reasoning may be done using high-level symbols. For example, one can use rules such as: if it is raining, bring an umbrella. These types of rules (called heuristic rules) may also be used in fuzzy systems with the difference being that approximate matches are allowed. So one might still bring an umbrella on a cloudy overcast day where it was not quite raining at the moment. *See* ARTIFICIAL INTELLIGENCE.

Systems that are described by the term "computational intelligence" make use of lower-level computational features even when they may have a high-level interpretation. For example, in the case of fuzzy systems, which may be expressed as heuristic rules, there will be an underlying mathematical description of sets as well as conjunction, disjunction, and inference operators. Fuzzy rules have been successfully used in the control of antilock brakes.

Fuzzy systems. A fuzzy system is one that makes use of approximate reasoning using the mathematical basis of fuzzy logic. The concept of fuzzy logic is concerned with membership in the classes of true or false. For example, a person with some bald spots might be said to be balding. However, he would completely belong neither to the class of bald people nor to the class of people with hair.

To see how this differs from probability, consider that you have the opportunity to acquire one of two lottery tickets after the winning tickets from the lottery have been chosen. The first is described as having a 90% chance of having won a lot of money, and the second one is described as having a 0.9 membership in the class of tickets which have won a lot of money. In the first case you have a 90% chance of winning a lot of money and a 10% chance of winning nothing. In the second case, you will have approximately won a lot of money. This is likely to translate into something between a lot of money and a fair amount of money. If you had to put a probability distribution on the likely winnings in the second case, you might have a probability of 0 of winning no money and a probability of 0 of winning the entire lottery, but a probability of 80% of being runner-up, 10% of being second runner-up, and 10% of being third runner-up. Most people would choose the ticket with the 0.9 membership in the class of tickets which have won a lot of money because they would be guaranteed a good sum of money. Of course, some gamblers would choose the all-or-nothing route. *See* FUZZY SETS AND SYSTEMS.

Neural networks. Perhaps the most widely used technology within the computational intelligence approaches is that of neural networks. Neural networks are inspired by the underlying processing done in the human brain. There are nodes which correspond (loosely) to neurons in the brain and have interconnections which correspond (loosely) to the synapses that connect neurons in the brain. A simple three-layer neural network is shown in the **illustration**.



Feedforward neural network with three inputs, one output, and one hidden layer of two nodes. The connection weights are denoted by w_{ij}.

A neural network learns from a set of labeled examples to produce intelligent responses. Neural networks are also used to intelligently group unlabeled data into clusters. Thus, a neural network is one attempt to mimic the underlying learning processes of the human brain. Clearly, a system that can learn to improve its performance will be quite valuable. There are many approaches to training a neural network. Many of them rely on the feedforward–backpropagation approach which was popularized in the mid-1980s. In this approach, examples are presented to the neural network, and the connection weights between nodes are updated to make the outputs of the network closer to those of the examples. The connection weights loosely correspond to the synaptic strengths of connections between neurons in the human brain.

Neural networks have a powerful property of universal approximation. This means that they can arbitrarily closely approximate any function, in theory. This has been proven mathematically. In practice, the theorems do not show how to configure the network, what type of functions should exist within a node to determine its output or, perhaps most importantly, do not guarantee that the appropriate weights can be learned. So it is known that there is a neural network that arbitrarily closely approximates a particular function, but it is not known if this network can ever be discovered.

Consider the function that emulates a person who decides whether a credit card transaction should be allowed. Given what is known about neural networks, it would be possible to develop one that was as good as any human expert if we knew how to do so. It is unknown if this can actually be done, but in practice systems for making such decisions (with capabilities that do not necessarily match those of a human) have been built. The function to be approximated is the binary human decision of whether to grant credit or not grant credit. A highly accurate system will, clearly, save money for the credit card company, and it will have the side effect of preventing people from getting in too much debt.

Fuzzy systems and neural networks have been combined to produce neuro-fuzzy systems. Under certain conditions they have been shown to be universal approximators, also. Typically, a set of fuzzy rules can be extracted from a neuro-fuzzy system which may provide an explanation capability that is lacking in a typical neural network where all information is stored as a set of weights. The extent of the explanation capability will depend on the complexity of the fuzzy rules. There is, typically, a trade-off between complexity and accuracy. So more understandable but less complex rules will be less accurate than the more complex rules in the usual case. *See* NEURAL NETWORK.

Evolutionary computation. Evolutionary computation embodies a set of methods to evolve solutions to problems. Evolutionary computation has typically been applied to optimization problems. For example, excellent solutions to the classical traveling salesman problem have been evolved. This problem is to minimize the distance traveled by a salesperson who has to make calls in a set of cities.

Evolutionary computation considers potential solutions to a problem as members of a population. Mimicking how natural evolution is considered to work, members of the population can be chosen to mate. They then produce offspring, typically with the use of a crossover operator in which parts of each solution become a part of the offspring. After crossover, a mutation operator is often applied to the child which may randomly change some of its characteristics. The offspring compete for survival to the next generation based upon a fitness function. Those that are more fit survive.

There are at least three major paradigms within evolutionary computation. Genetic algorithms, which merge parts of solutions to form new solutions and then apply random mutation to them, can be applied to both binary bit strings and real-valued solutions. Evolutionary strategies make heavy use of the mutation operator. There is also genetic programming in which computer programs are evolved, typically in the Lisp language. The latter approach provides a computer-executable solution to a problem. *See* GENETIC ALGORITHMS.

Evolutionary computation has been used to evolve the weights, and sometimes the structure, of neural networks. It has also been used to evolve fuzzy systems and fuzzy neural networks. Thus, these approaches are complementary. An interesting application of evolutionary computation was in evolving an expert checkers-playing program that did not require any human knowledge. The system evolved weights for a neural network which served as a board evaluation function. After evolution, it was able to beat an expert-level checkers player. *See* EVOLUTIONARY COMPUTATION.

In summary, all the computational intelligence approaches discussed here can be used alone or together to produce systems that exhibit human expertise or intelligence. Lawrence O. Hall

Computer

A device that receives, processes, and presents information. The two basic types of computers are analog and digital. Although generally not regarded as such, the most prevalent computer is the simple mechanical analog computer, in which gears, levers, ratchets, and pawls perform mathematical operations—for example, the speedometer and the watt-hour meter (used to measure accumulated electrical usage). The general public has become much more aware of the digital computer with the rapid proliferation of the hand-held calculator and a large variety of intelligent devices, ranging from typewriters to washing machines, and especially with exposure to the Internet and the World Wide Web. *See* CALCULATORS; INTERNET; WORLD WIDE WEB.

In the 1950s and 1960s the definition of "computer" included only the provision of input and output, and the ability to process the input to produce the output. Since then, the common understanding of the term (in particular, for digital computers) has come to include storage, and even the ability to store the program of instructions, allowing decision making based on previously computed results. *See* COMPUTER PROGRAMMING; COMPUTER STORAGE TECHNOLOGY.

Analog computer. An analog computer uses inputs that are proportional to the instantaneous value of variable quantities, combines these inputs in a predetermined way, and produces outputs that are a continuously varying function of the inputs and the processing. These outputs are then displayed or connected to another device to cause action, as in the case of a speed governor or other control device. *See* CONTROL SYSTEMS.

Small electronic analog computers are frequently used as components in control systems. Inputs come from sensing devices which output an electrical signal (transducers). These electrical signals are presented to the analog computer, which processes them and provides a series of electronic outputs that are then displayed on a meter for observation by a human operator or connected to an electrical action device to ring a bell, flash a light, or adjust a remotely controlled valve to change the flow in a pipeline system. If the analog computer is built solely for one purpose, it is termed a special-purpose electronic analog computer.

In any analog computer the key concepts involve special versus general-purpose computer designs, and the technology utilized to construct the computer itself, mechanical or electronic. An analog computer is often combined with a digital computer to form a hybrid computer. *See* ANALOG COMPUTER.

Digital computer. In contrast, a digital computer uses symbolic representations of its variables. The arithmetic unit is constructed to follow the rules of one (or more) number systems. Further, the digital computer uses individual discrete states to represent the digits of the number system chosen.

Electronic versus mechanical computers. The most prevalent special-purpose mechanical digital computers used to be the supermarket cash register, the office adding machine, and the desk calculator. Each of these has been universally replaced by electronic devices allowing much greater logical decision making and greatly increased speed. For example, most products now carry a bar code, the Universal Product Code (UPC). The code is scanned by a light-sensitive device, bringing information about each product into the point-of-sale (POS) terminal that has replaced the mechanical cash register. The POS terminal then computes total charges and provides a receipt for the customer. It may also communicate with a centralized computer system that controls inventory, accounts payable, salaries and commissions, and so on. While a mechanical cash register could carry out only a small number of operations each minute, and some electromechanical devices might handle several hundred operations per second, even a small general-purpose electronic computer can carry out its computations at millions of operations per second.

Stored program operation. A digital computer works with a symbolic representation of variables; consequently, it can easily store and manipulate numbers, letters, images, sounds, or graphical information represented by a symbolic code. Typically, a general-purpose electronic digital computer operates on numbers by using both decimal and binary number systems, and on symbolic data expressed in an alphabet. It contains both an arithmetic unit and a storage unit. As the digital computer processes its input, it proceeds through a series of discrete steps called a program. The storage unit serves to retain both the values of the variables and the program to process those variables. The arithmetic unit may operate on either variables or coded program instructions interchangeably, since both are usually retained in the storage unit in the same form. Thus, the digital computer has the capability to be adaptive, because processing can be determined by the previously prepared program, by the data values supplied as input to the computation, and by the values generated during the course of the computation. Through the use of the stored program, the digital computer achieves a degree of flexibility unequaled by any other computing or data-processing device.

Applications. In the past, most digital computers were confined to standard applications, such as bookkeeping, accounting, engineering design, and test data reduction. However, the advent of the relatively inexpensive and readily available personal computer, and the combination of the computer and communications, such as by the use of networks, have dramatically altered that pattern. The most common application now is probably text and word processing, followed by electronic mail. *See* ELECTRONIC MAIL; LOCAL-AREA NETWORKS; MICROCOMPUTER; WORD PROCESSING.

Ready access to national networks has fostered the growth of communities of computer users who communicate easily and effectively on the World Wide Web, including an explosion of commerce via online communications. The convergence of computers and network communications also has encouraged the development of network computers, smaller and simpler computers that depend on the availability of software and data from around the world arriving via networks in order to accomplish their tasks.

The ability of even modest computer systems to store, organize, and retrieve very large amounts of information has brought about radical changes in the very nature of many business offices. Indeed, many industrial, academic, and governmental processes have been irrevocably changed by the computer. It is often said that the Manhattan Project, although managed by paper and pencil in the 1940s, simply could not have been accomplished at all today without using computers. That is, there has been a change in the very thought processes that people use to accomplish tasks, in order to accommodate computer-based solutions for those tasks.

Personal workstations, used in engineering design and other applications requiring intense computation and sophisticated graphics, have become more powerful than earlier, very large computer systems. This has moved computation, and even the storage of many large data files, directly onto each person's desk, and in many cases, into handheld computers. In addition, applications that were once considered esoteric have led to industrial applications, such as the use of robots on manufacturing assembly lines. Many of the heuristic techniques employed by these robots are based on algorithms developed in such artificial-intelligence applications as virtual reality. *See* ARTIFICIAL INTELLIGENCE; COMPUTER-AIDED DESIGN AND MANUFACTURING; COMPUTER-AIDED ENGINEERING; COMPUTER GRAPHICS; ROBOTICS; VIRTUAL REALITY.

Computers have begun to meet the barrier imposed by the speed of light in achieving higher speeds. This has led to research and development in the areas of parallel computers (in order to accomplish more in parallel rather than by serial computation) and distributed computers (taking advantage of network connections to spread the work around, thus achieving more parallelism). Continuing demand for more processing power has led to significant changes in computer hardware and software architectures, both to increase the speed of basic operations and to reduce the overall processing time. *See* COMPUTER ARCHITECTURE; CONCURRENT PROCESSING; DISTRIBUTED SYSTEMS (COMPUTERS); MULTIPROCESSING; SUPERCOMPUTER.

In the hardware domain, clock rates approaching gigahertz speed have led to ever smaller computers, since electronic pulses cannot travel further than 1 ft (0.3 m) per nanosecond; instruction and video caches have been enlarged for faster processing and display; and central processing units are continually being redesigned to enable more parallelism (and to avoid the "von Neumann bottleneck" inherent in a serial architecture). In the software domain, parallelism is being achieved both locally via multithreading and multiprocessor operating systems, and globally via distributed computation. *See* COMPUTER PERIPHERAL DEVICES; DATABASE MANAGEMENT SYSTEM; DIGITAL COMPUTER; HUMAN-COMPUTER INTERACTION. Bernard A. Galler; John H. Sayler

Computer-aided circuit design

The application of specialized computer software to the design, simulation, and physical layout of electronic circuits on semiconductor chips and circuit boards. *See* INTEGRATED CIRCUITS; PRINTED CIRCUIT.

Designing integrated circuits is extremely challenging because of the large amount of detailed technical data associated with circuits containing many transistors and their interconnections. Competition in the integrated circuit marketplace requires that integrated circuit products be optimal in some respect to be profitable. Thus, the integrated circuit design task is necessarily coupled with an optimization task. Readily available transistors make many alternative circuit implementations possible, and optimization means choosing the circuit that maximizes (or minimizes) an objective function of interest, such as performance, power consumption, area, or ease of testing. Because of this complexity, computer-aided design software has evolved into the principal tool used by most designers of high-performance analog and digital electronic devices and systems. Only computer programs can choose optimal designs, can evaluate these designs before prototypes are built, and can simulate circuit performance under realistic component tolerances and environmental conditions.

Classical "breadboarding" and bench testing of design prototypes are infeasible when circuits containing anywhere from hundreds to millions of transistors are involved. Even for circuits containing few components, conventional breadboarding techniques may not evaluate circuit performance adequately. Component positioning on the circuit board, component interconnect routing, and board material properties all can have a significant effect on circuit performance, and if the breadboard does not faithfully replicate all of these final product physical characteristics, its results may be of little use. *See* BREADBOARDING.

Once an analog or digital circuit design has been completed and extensive simulation has shown its performance to be satisfactory, the myriad details required to prepare the device or electronic system for manufacture must be conveyed to the appropriate fabrication facility. Comprehensive computer-aided design systems contain software to generate computer files that describe the physical structure and layout of the circuit components and the routing of their interconnections. *See* COMPUTER-AIDED DESIGN AND MANUFACTURING.

In semiconductor manufacturing, these files are used to create integrated circuit mask sets. Microelectronic circuits are manufactured using a photolithographic process, by which patterns corresponding to transistors and connection wires are transferred onto a silicon wafer, which is then customized by local physical or chemical reactions. These patterns are contained in a mask set, a detailed draft of the geometries of the transistors and wires on several layers.

In circuit board fabrication, data files are used to generate conductor path-etching masks and to provide positioning data for drilling via and component mounting holes. This software also can generate circuit schematic drawings and prepare component parts lists. Philip V. Lopresti

Design of Digital Circuits

Most digital electronic products employ very large scale integration (VLSI) circuits, often called microelectronic circuits. Such circuits may have over 1 million transistors. This large scale of integration is made possible by advances in semiconductor technologies that allow the manufacture of transistors and wires with dimensions much smaller than 1 micrometer. Raising the scale of circuit integration is advantageous, because increasingly complex functions can be realized on a single integrated circuit, with a corresponding increase in reliability and decrease in overall cost.

There are four stages in the creation of a digital integrated circuit: design, fabrication, testing, and packaging (**Fig. 1**). Design is the refinement of a functional specification into the geometries needed for fabrication. Fabrication means manufacturing semiconductor dies, that is, the unpackaged circuits. Testing means checking for manufacturing defects that may lead to erroneous operation. Working dies are placed into ceramic or plastic packages. Computer-aided-design tools support design and testing, while computer-aided-manufacturing tools support the remaining stages.

Major design tasks. Circuit design can be split into three major tasks: conceptualization and modeling, synthesis and optimization, and validation. Conceptualization consists of casting an idea into a model that captures the function the circuit will perform. Synthesis consists of refining the model from an abstract one to a detailed one with all the features required for fabrication. Validation consists of verifying the consistency of the models used during design, as well as some properties of the original model.

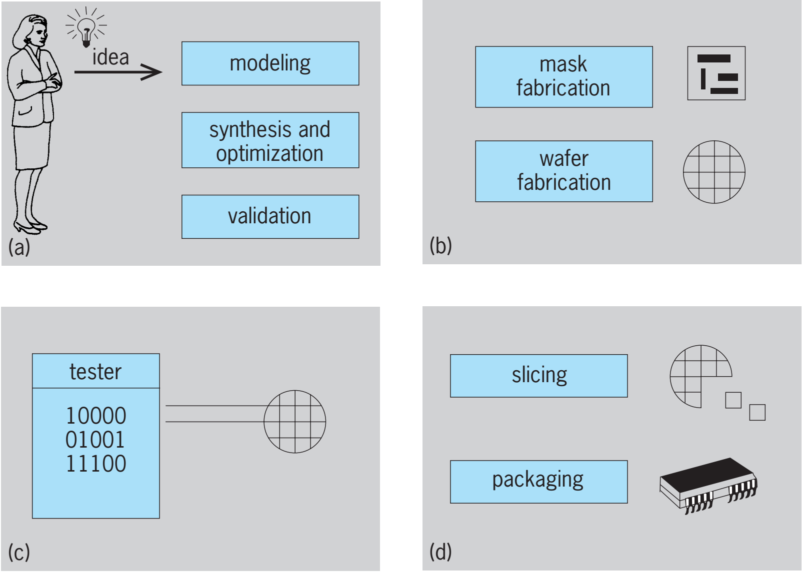

Fig. 1. Four phases in creating a microelectronic chip. (*a*) Design. (*b*) Fabrication. (*c*) Testing. (*d*) Packaging. (*After G. De Micheli, Synthesis and Optimization of Digital Circuits, McGraw-Hill, 1994*)

Modeling. Circuit modeling plays a major role in microelectronic design, because it represents the vehicle used to convey information. Modeling must be rigorous as well as general, transparent to the designer, and machine-readable. Most modeling is now done using hardware description languages (HDLs). Graphic models are sometimes used, such as flow and schematic diagrams. The very large scale nature of the problem forces the modeling style, both textual and graphical, to support hierarchy and abstractions, allowing a designer to concentrate on a particular portion of the model at any given time.

Synthesis. The overall goal of circuit synthesis is to generate a detailed model of a circuit, such as a geometric layout, that can be used to fabricate the chip. This objective is achieved through a stepwise refinement process, during which the original abstract model provided by the designer is iteratively detailed. As synthesis proceeds in refining the model, more information is needed regarding the technology and the desired design implementation style. A functional model of a circuit may be fairly independent from the implementation details, while a geometric layout model must incorporate all technology-dependent specifics, such as wire widths.

Circuit synthesis is usually layered in three stages, related to the modeling abstraction level involved: high-level synthesis, logic-level synthesis, and physical design (**Fig. 2**). High-level synthesis, also called architectural-level synthesis, consists of generating the macroscopic structure of a circuit. This activity corresponds to determining an assignment of the circuit functions to operators, called resources, as well as their interconnection and the timing of their execution. Logic-level synthesis is the task of generating the gate-level structure of a circuit. It entails the manipulation of logic specifications to create logic models as interconnections of logic primitives. Logic design is often eased by the use of libraries of logic gates. The task of transforming a logic model into an interconnection of instances of library cells, that is, the back end of logic synthesis, is often referred to as library binding or technology mapping. Physical design consists of creating the geometric layout of the circuit. It entails the specification of all geometric patterns defining the physical layout of the chip, as well as their position on the die.

Circuit optimization is often combined with synthesis. It entails the selection of some particular choices in a given model, with the goal of raising one or more figures of merit of the design. The role of optimization is to enhance the overall quality of the circuit. Most designers equate quality with circuit performance. Performance involves the time required to process some information, as well as the amount of information that can be processed in a given time period. Circuit performance is essential to competitive products in many application domains. Power consumption is an important quality measure for microelectronic circuits to be used for portable applications, where the autonomous operation time depends on the battery capacity and discharge rate. Another measure of circuit quality is the overall circuit area. An objective of circuit design is to minimize the area, for three main reasons: (1) smaller circuits allow more dies to be placed on each wafer, and therefore enable lower manufacturing costs to be achieved; (2) the manufacturing yield decreases with an increase in chip area; and (3) large chips are more expensive to package. The circuit quality also involves the circuit testability, that is, the ease of testing the chip after manufacturing. Testable chips are clearly desirable because earlier detection of malfunctions in electronic systems enables overall costs to be lowered. *See* OPTIMIZATION.

Validation. Circuit validation consists of acquiring a reasonable certainty level that a circuit will function correctly, under the assumption that no manufacturing fault is present. Circuit validation is motivated by the need to remove all possible design errors before proceeding to expensive chip manufacturing. It can be performed by simulation and by verification

methods. Digital circuit simulation consists in analyzing the circuit variables over an interval of time for one specific set (or more sets) of input patterns. Simulation can be applied at different levels, corresponding to the model under consideration. Simulated output patterns must then conform to the expected ones. Even though simulation is the most commonly used way of validating circuits, it is often ineffective for large circuits except for detecting major design flaws. Indeed, the number of relevant input pattern sequences needed to analyze a circuit grows with the circuit size, and designers must be satisfied with monitoring a small subset. Verification methods, often called formal verification methods, consist of comparing two circuit models and detecting their consistency. Another facet of circuit verification is checking some properties of a circuit model, such as whether there are deadlock conditions. *See* SIMULATION.

Testing. Microelectronic circuits are tested after manufacturing to screen fabrication errors. Thus, testing is the verification of correct manufacturing. Since impurities are unavoidable in the air of manufacturing plants, particles from the air can cause defects in random positions on some circuits. There are several testing techniques, and their relation to design is important. In particular, circuits may be designed with a self-testing feature. After manufacturing, the circuit can be set in testing mode, where it will generate, apply, and analyze testing patterns to check proper operation.

Design for testability means addressing the ease of testing during the design stage. Circuit testability affects the circuit quality. A circuit that is not fully testable is less valuable than another one that is, because faulty units may be released on the market. Enhancing testability can be done by appropriate logic and architectural synthesis techniques.

Hardware/software codesign. Digital microelectronic circuits may contain complex building blocks, such as processors, controllers, and memories. Processors and controllers may be designed to execute specific programs stored in memory, which are referred to as embedded software. For integrated circuits containing programmable components executing software, hardware/software codesign techniques are needed to exploit the synergism between hardware and software to achieve the design objectives. Computer-aided codesign tools support a variety of tasks, including performance analysis of hardware/software systems, support for deciding on the hardware/software implementation of system functions, and support for developing software compilers that are retargetable to various processor architectures. Giovanni De Micheli

Design of Analog and Radio-Frequency Circuits

To meet the challenges of delivering high performance at low power, and to avoid the high cost of multiple design prototyping, designers of analog and radio-frequency circuits utilize very specialized simulation and extraction tools that equate physical design to electrical performance. Mixed analog, radio-frequency, and digital circuit design needs detailed process-dependent active device and passive interconnect characterization data as well as robust circuit simulation tools to accurately predict proper circuit operation under all operating conditions.

Integrated-circuit design process. The analog-integrated circuit design process may be broken down into four principal areas involving multiple design and design support teams. The first area is dedicated to model development and computer-aided design or electronic design automation (EDA) tool support. Team activity focuses on active device model parameter extraction (usually through measurement on actual devices), passive component model extraction (usually through electromagnetic simulation), and component library development and maintenance, including the implementation of parametrized layout structures or “cells.” A second design area is dedicated to system-level architectural design and block partitioning. At this high level, designers are responsible for meeting overall system requirements (both digital and analog) and specifying the requirements for individual functional blocks or subcircuits. The third principal design activity is devoted to detailed circuit design and to follow-on system integration. This group uses the electrical models and associated layout information provided by the modeling group. The fourth design team is involved in design testing and verification. This area concerns itself with validating the actual hardware, accounting for physical measurements, test fixturing, and electrical packaging. Sophisticated tool infrastructure and model databases are required to tie together the data flowing among these four design teams.

At high frequencies, component material and geometric attributes play a strong role in electrical performance. Therefore, reliable schematic-to-layout modeling is critical to successful design. Sophisticated design environments that provide a user interface for synchronized schematic and layout capture are fully integrated within several modern analog and radio-frequency simulators. Many of these environments also support parameter tuning, optimization, statistical analysis, and result generation.

Behavioral versus circuit models. In early design phases involving definition of the system architecture and block partitioning, a top-down approach using a high-level behavior model representation is common, since behavior model simulation requires much less computational effort than is needed for transistor-level circuit simulation. Computer models for various function blocks, such as low-noise amplifiers, mixers, voltage-controlled oscillators, or in-phase and quadrature demodulators, typically are used to support early system development.

Behavior model parameters will supply performance simulation accuracy to only a second order of parameter analysis and simulation accuracy within the radio-frequency system. Modern systems are complex and behavioral models may not predict the integrated circuit behavior sufficiently accurately under a wide range of specified operating conditions.

Some of the lost critical circuit detail includes the device terminal impedances, bias and temperature dependencies, transient response times, and signal feedback conditions.

Working with more detailed circuit information can overcome these deficiencies, but doing so comes at the cost of increased characterization effort. Proven existing netlist-based circuit models are an alternative to behavioral models, but circuit-level modeling requires a simulator that can analyze circuits containing a very large number of transistors. These simulators also need to contain libraries of commercial components and manufacturer's device models for standard transistors, diodes, resistors, capacitors, and inductors. The simulator also should be able to support cosimulation with functional blocks described by other circuit or behavioral models, and should include utilities to speed the process of transmission-line design, matching network extraction, and filter synthesis for both lumped and distributed radio-frequency designs.

To address characterization of a wide range of on-chip or packaged physical, analog and radio-frequency/microwave circuit designers rely heavily on a variety of electromagnetic simulation technologies. These tools are used to extract electrical behavior from the structure in the form of transmission-line parameters or equivalent SPICE (Simulation Program with Integrated Circuit Emphasis) models. The resulting extracted electrical models are then inserted into the complete network for cosimulation with transistor-level circuits or high-level behavioral models.

Linear circuit simulation. Linear analysis is used to compute the frequency response of passive circuits or circuits which operate under small-signal conditions. In active circuits operating under small signal conditions, signal level and termination values do not influence the operation of circuit components and the superposition principle holds true. Most high-frequency circuit designers rely on linear analysis to develop circuits to (1) match impedances between cascaded components to ensure optimum power transfer, (2) suppress unwanted signal transmission at specific frequencies, and (3) deliver optimum load terminations for active devices.

Linear simulation results are offered in a wide range of representations including scattering, impedance, and admittance (S,Z,Y) network parameters at specific excitation frequencies. For two-port (terminal) networks, linear analysis also can determine stability, voltage and power gain, noise, and matching element parameters. If there are nonlinear devices in the circuit, a bias-point analysis must first be performed, in which case each device is linearized at its bias point, and linear analysis in the frequency domain proceeds.

Extended linear analysis results may include group delay (delay of the propagation of energy at a given frequency), or even steady-state time-domain responses for impulse, step, and modulated pulses, and nodal voltages at internal circuit nodes. In this case the frequency-domain results from linear-network analysis are transformed into the time domain via the fast Fourier transform (FFT), which presents steady-state (periodic) information about network parameters in the time domain. *See* FOURIER SERIES AND TRANSFORMS.

Harmonic balance analysis (HBA). Harmonic balance analysis supports the large-signal simulation of nonlinear devices and is performed using a spectrum of harmonically related frequencies, similar to measured signals on a spectrum analyzer. This analysis type involves the periodic steady-state response of a fixed circuit to a given predetermined set of fundamental tones. This analysis is limited to periodic responses because the basis set chosen to represent the physical signals in the circuit are sinusoids, which are periodic. *See* SPECTRUM ANALYZER.

In harmonic balance, the circuit is usually divided into two subcircuits connected by wires forming multiports. One subcircuit contains the linear components of the circuit and the other contains the nonlinear device models. The linear subcircuit response is calculated in the frequency domain at each harmonic component and is represented by a multiport Y (admittance) matrix. This is the function performed by linear analysis. The nonlinear subcircuit contains the active devices whose models compute the voltages and currents at the intrinsic ports of the device. (Parasitic elements are linear and absorbed by the linear subnetwork.)

For circuits operating under large signal conditions, device nonlinearity will generate harmonically related signals. Analysis parameters, such as the number of harmonics, specify which combinations of these harmonically related signals will be considered and set the fundamental frequencies used in the analysis of the network. Harmonic balance analysis is often used to examine the compression characteristics and spurious output of radio-frequency circuits such as amplifiers, mixers, and frequency converters.

Since harmonic balance analysis supports frequency domain linear models such as transmission lines as well as nonlinear device models such as transistors, it is well suited to simulate high-frequency networks operating under steady-state conditions.

Transient analysis. Many of today's communication devices, however, as a result of fast switching and on/off states, operate under non-steady-state conditions. Transient circuit analysis is required to understand circuit behavior under nonperiodic conditions. Radio designers, for example, often use transient analysis to investigate the transient performance of oscillators and phase-locked-loop synthesizers.

Transient analysis discretizes time and uses numerical integration methods to solve the circuit equations over each time increment. The equations are derived from the circuit interconnections and circuit device models. The analysis begins with vectors of initial values for the node voltages and branch currents. At the beginning of each iteration, the simulator linearizes the circuit around the solution calculated in the previous iteration, and calculates the matrix associated with the linearization point. The simulator then uses a matrix solver to calculate a new vector of unknowns. At the end of each iteration, the analysis updates the solution and checks to see if the new solution satisfies the specified tolerances. If the result is within tolerance, the loop terminates. Otherwise, the loop uses the new result to start the next iteration.

Time-domain simulators have waveform sampling requirements that can lead to excessively long run times for certain applications or that can introduce simulation errors. For a device operating under multitone excitation, a time-domain simulator must have a sample rate twice the highest frequency rate, yet must take enough samples to capture the lowest frequency of interest. High sampling rates continuing for a long sampling period result in a lengthy simulation. Capturing the intermodulation products of a radio-frequency circuit under multitone drive, for example, can require prohibitive simulation run times. It also has been shown that the black-box S-parameter and SPICE models used in these simulators has inadequately modeled high-frequency time-domain effects in a number of cases.

High-frequency passive modeling. One of the most fundamental impairments in a radio-frequency circuit or a high-speed channel is the attenuation of the transmitted signal across the printed circuit board caused by transmission line loss. Printed circuit boards with dielectric substrates composed of FR4 (Flame Retardant 4, a fiber glass-epoxyresin combination that is widely used in printed circuit boards) were not originally intended to support signals at multigigabit speeds, and their dielectric loss is very pronounced at high frequency. Typical microstrip differential transmission lines on FR4 exhibit an insertion loss of roughly 0.5 dB/in. at 5 GHz and 0.9 dB/in. at 10 GHz. This loss effectively performs a low-pass filtering on transmitted radio-frequency or digital signals and hence severely limits the distance that they can propagate on printed circuit board transmission lines.

Passive models for integrated circuit components (spiral inductors, for example) and interconnects (transmission lines, vias, and packages) are having increasing impact on the circuit performance of many high-frequency designs. Circuit designers can employ models for these passive components ranging from simple single lumped elements to rigorous measurement or electromagnetic-based broadband response representations.

Electromagnetic simulation is a cost-effective alternative to physical prototyping and is therefore used throughout the high-frequency modeling community. It is employed to both extract electrical behavior and optimize component performance through optimization. Parametric optimization is often used to reduce the electrical losses associated with silicon-based designs.

Various types of electromagnetic simulation such as finite-element (for full-wave three-dimensional extraction), method of moments (for two-dimensional surface currents), and quasistatic solvers (for lower frequencies) are available to characterize the parasitic effects of transmission media operating at various frequencies. The outputs of these solvers are extracted RLGC (resistance, inductance, conductance, capacitance) models (limited bandwidth), w-elements, or S-parameters. (The w-elements are a set of physical parameters needed for the electromagnetic field analysis of circuit conductors. S-parameters essentially provide the expected broadband transmission and reflection properties of the signal propagating through the given structure.) The outputs are represented by data tables with terminal nodes defining the connection points for input/output signals.

Convolution. Properly addressing linear frequency domain models such as transmission lines and S-parameters in transient time-domain simulations requires a time-domain representation of the linear components or network. One method involves a technique known as convolution.

Direct convolution is a relatively slow mathematical process, even at today's computational speeds. Theoretically, in order for the convolution technique to obtain correct results, the sampling range should be set to infinity. However, this is not practical simulation. A finite sampling range will also lead to excessive computation times. For example, if convolution analysis will calculate the spectral components of the impulse response to be at a bandwidth of 0–200 GHz with a resolution of 100 MHz, the number of frequency sampling points is 2000 and the number of time sampling points is 4000 (0–10 ns with a step of 2.5 ps).

Therefore, an alternate method that does not have the computational burden of direct convolution is desired. Such an alternative mathematical method must still recognize the physical behavior of the frequency-dependent losses that the simulator is attempting to model. One option is to select a "state space" representation for the frequency-dependent model in the time domain, in which a set of rational polynomial functions in the time domain provide a least-squares fit to the frequency-domain behavior after a Fourier transform. Thus, performance of the transient simulation does not call upon convolution. The same technique can be applied for obtaining a usable model from frequency-dependent S-parameter inputs, to avoid demanding convolution during the transient simulation to follow.

One challenge for representing frequency-based models in the time domain is preserving causality. Causality requires that "effects" happen after "causes," which means the impulse response for time $t < 0$ must be zero. Beyond proper handling of losses to conform to causality, a state-space conversion of a transmission-line model can become just as numerically intense as direct convolution if not handled properly. For instance, a given transmission-line model might contain a large number of signal conductors to account for the behavior of each line and the crosstalk between them. Computing state-space models for such transmission matrices without extracting out consistent behavior between like terms would be exceedingly wasteful. This means first capturing the modal delay or propagation delay from the line behavior, before generating the polynomials that represent the loss behavior.

Validation. As the number and complexity of integrated circuit performance metrics continue to proliferate, accurate design verification becomes a greater challenge and is further complicated by the effects of high-density input-output packaging. System metrics such as bit error rate (BER), error vector magnitude (EVM), or intersymbol interference (ISI) must be characterized by exact standards and specifications: Design details of the integrated circuit, the advanced package, or both must now be incorporated in a simulation. For integrated circuit verification, a high-level system test bench environment is often employed to define complex excitations and derive these figures of merit. In such system test benches, complex modulated communication waveforms may be applied directly to the circuit design. Additionally, package effects and test fixture contributions may also be included, either through electromagnetic simulation or direct measurement of existing hardware. David Vye

Computer-aided design and manufacturing

The application of digital computers in engineering design and production. Computer-aided design (CAD) refers to the use of computers in converting the initial idea for a product into a detailed engineering design. The evolution of a design typically involves the creation of geometric models of the product, which can be manipulated, analyzed, and refined. In CAD, computer models and graphics replace the sketches and engineering drawings traditionally used to visualize products and communicate design information.

Engineers also use computer programs to estimate the performance and cost of design prototypes and to calculate the optimal values for design parameters. These programs supplement and extend traditional hand calculations and physical tests. When combined with CAD, these automated analysis and optimization capabilities are called computer-aided engineering (CAE). *See* COMPUTER-AIDED ENGINEERING; OPTIMIZATION.

Computer-aided manufacturing (CAM) refers to the use of computers in converting engineering designs into finished products. Production requires the creation of process plans and production schedules, which describe how the product will be made, what resources will be required, and when and where these resources will be deployed. Production also requires the control and coordination of the necessary physical processes, materials, equipment, and labor. In CAM, computers assist managers, manufacturing engineers, and production workers by automating many production tasks. Computers are used to develop process plans, order and track materials, and monitor production schedules. They also control the machines, industrial robots, test equipment, and systems that move and store materials in the factory.

Advantages of automation. CAD/CAM can improve productivity, product quality, and profitability. Computers can eliminate redundant design and production tasks; improve the efficiency of workers; increase the utilization of equipment; reduce inventories, waste, and scrap; decrease the time required to design and make a product; and improve the ability of a factory to produce different products. Today most manufacturers employ CAD/CAM to varying degrees. *See* AUTOMATION; PRODUCTIVITY.

Several factors account for the rapid development of CAD/CAM technology since the 1960s. First, advances in computer technology produced faster, more capable, smaller, and less expensive machines. Together with improved techniques for software engineering, this makes CAD/CAM increasingly cost-effective even for small companies. Second, world markets for manufactured goods are more competitive. CAD/CAM has become an essential tool for economic success. Third, the design life cycle of many products has been compressed. New products must be developed quickly and brought to market at high levels of quality, reliability, and safety. *See* SOFTWARE ENGINEERING.

Computer-integrated manufacturing. The deployment of CAD/CAM in the manufacturing industry has led to new ideas about organization and production. Traditionally, manufacturing companies, especially large companies, have been organized into functional units such as marketing, design, engineering, quality, and production. These departments were coordinated by a higher level of management, often without a great deal of direct communication among the units themselves.

The fact that CAD, CAE, and CAM work best together has led to the breakdown of many of the traditional barriers between functional and manufacturing units. The goal of computer-integrated manufacturing (CIM) is a database, created and maintained on a factory-wide computer network, that will be used for design, analysis, optimization, process planning, production scheduling, robot programming, materials handling, inventory control, maintenance, quality assurance and control, and marketing. Although many technical and managerial obstacles must be overcome, computer-integrated manufacturing appears to be the future of CAD/CAM. *See* COMPUTER-INTEGRATED MANUFACTURING; DATABASE MANAGEMENT SYSTEM.

Developing disciplines in CAD/CAM integration include concurrent engineering, design for manufacture and assembly (DFM/A), and factory modeling. In concurrent engineering, interdisciplinary product development teams consider all phases of a product life cycle during the design process. DFM/A software allows a design team to assess the effort and costs involved in the production of a part or assembly and to consider ways to redesign the product for ease of production. Discrete event simulation programs have been developed to model and optimize the processes, equipment, and layout of the factories in which the design will be produced. *See* SIMULATION.

CAD technology. Initially, CAD workstations were terminals connected to a mainframe computer. They allowed graphic displays of the product model and included devices (mouse, joystick, trackball, light pen, and stylus and tablet) for interacting with both the model and its display. Today a CAD workstation can be a personal computer or a graphics workstation (**Fig. 1**), and may be stand-alone or a link on a network. Large machines (mainframes or supercomputers) are often necessary for creating, manipulating, and analyzing complex models and assemblies. Raster graphics (cathode-ray tubes) permit displays of models in full color, immediate updates as the model is changed, sophisticated rendering, and even animation. Interactive devices include the mouse and keyboard, but for manipulating a three-dimensional (3D) model in all its degrees of freedom, a spaceball or other 3D input device is helpful. Virtual reality and gaming environments have led to useful 3D interactive devices (such as data gloves, body suits, control sticks, and steering wheels). Output devices, such as printers, plotters, and various media and storage devices, can also be linked to the computer. *See* COMPUTER PERIPHERAL DEVICES; MICROCOMPUTER; SUPERCOMPUTER; VIRTUAL REALITY.

The CAD system allows the designer to create a geometric model of the product design, display different views of the model, modify it as desired, save different models in a database for later recall, and make printed copies of design notes, engineering drawings, and rendered images as needed.

The appropriate computer model depends on the type of product. In the design of printed wiring assemblies, for example, two-dimensional models are used to lay out circuits and electronic components on the face of a circuit board. In mechanical and civil engineering design, three-dimensional, geometric models represent parts, devices, assemblies, and structures.

Several types of geometric models are possible, including solid models, wire-frame (line) drawings, and surface representations, such as planes, patches, or sculptured drawings. Solids modeling is the basis for most current CAD systems, because the information in the model database represents a distinct solid object, completely and unambiguously. There are several modeling schemes for producing complete solid models: boundary representation (b-rep), constructive solid geometry (CSG), cell decomposition, spatial enumeration (octrees), and primitive instancing. Boundary representations define an object in terms of its bounding faces, edges, and vertices, and their relationships. Constructive solid geometry builds complicated solid models by adding or subtracting simpler geometric shapes (cubes, slabs, cylinders, spheres, and cones), called primitives. In cell decomposition, a solid model is composed of a collection of nonoverlapping geometric entities called hyperpatches. Spatial enumeration maps an object into a defined spatial grid and represents whether elements in the grid are filled or empty. Primitive instancing involves parametrized shapes that can be transformed into particular instances. Most commercially available CAD systems are based on boundary representation and constructive solid geometry schemes. Newer solid modelers incorporate design by features, parametric and variational modeling, and constraint-based systems.

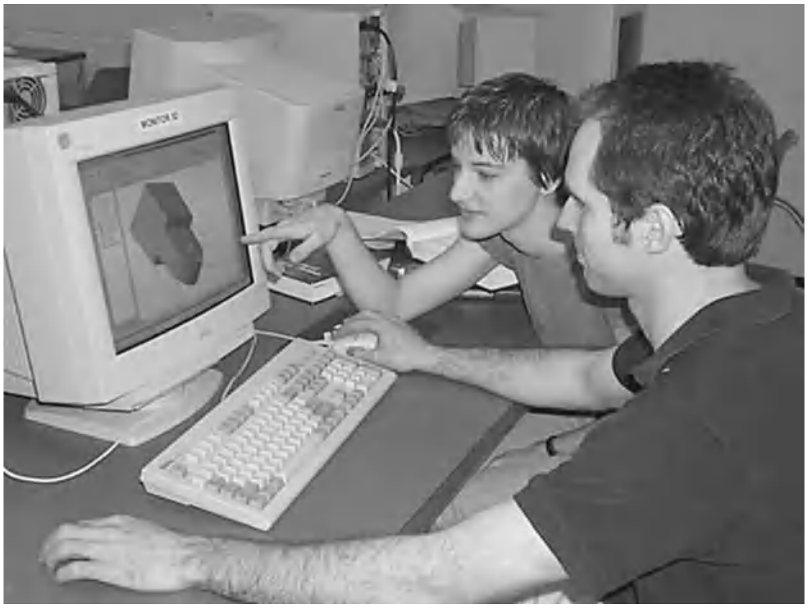

Fig. 1. Computer-aided design workstation where the designer creates and refines a geometric model of a product. (*Center for Computer-Aided Engineering*, *University of Virginia*)

Many CAD systems are still used as electronic drafting devices. Although this has many time- and labor-saving advantages, the true benefits of CAD arise from 3D modeling systems. In the traditional drafting environment, several views of a single object must be drawn to capture its geometry, whereas with 3D CAD a single solid model is created from which any particular view can be derived automatically. As the design evolves, each change does not require an entirely new model. In the future, as CAD, CAE, and CAM are integrated in CIM, the CAD model will become part of a common database for the entire design and manufacturing cycle. *See* COMPUTER GRAPHICS; DRAFTING; ENGINEERING DRAWING.

Analysis programs. A CAD model can be coupled with various analysis programs to predict the behavior of an object or assembly in its operating environment. Finite element analysis (FEA) determines the internal response of an object to applied loads or forces; computational fluid dynamics (CFD) is concerned with flow analysis and visualization; mechanical dynamics programs simulate the behavior of multibody systems (mechanical assemblies) over time; and ergonomic and human factors models assess how people interact with vehicles, machines, and structures. *See* COMPUTATIONAL FLUID DYNAMICS; FINITE ELEMENT METHOD; HUMAN-FACTORS ENGINEERING.

(*Automated Manufacturing Research Facility*, *National Institute of Standards and Technology*)

CAM and numerically controlled machines. The origin of automated manufacturing predates CAM and is usually associated with the introduction of numerically controlled machine tools in the mid-1950s. Machine tools, such as drills, lathes, saws, and milling machines, are used to cut and shape parts from stock. Numerically controlled machine tools use precoded information to operate the machine, rather than a human machinist.

The precoded information, called a program of instructions, contains a detailed set of directions, in symbolic form, that instructs the machine which operations to perform. The program may be punched on paper tape, recorded on magnetic tape, or manually input to the controller unit by a human operator. The more sophisticated numerically controlled systems used in CAM employ direct numerical control, where the program is transmitted electronically to the controller unit over a direct link with the computer.

The numerical controller unit reads the program, interprets the symbols, and sends the appropriate control signals to servomotors and other physical controls on the machine itself. Various sensors send information back to the controller unit. The purpose of this closed-loop or feedback system is to ensure that the actual process is following the program. Most modern numerical control systems are computer–numerically controlled, and the control unit is based on a microprocessor. Microprocessors are also used to monitor and control other types of equipment and processes. The microprocessor control units are called programmable controllers. *See* MICROPROCESSOR; PROGRAMMABLE CONTROLLERS.

Machining centers and cells. Numerically controlled machines vary in complexity from simple, open-loop, tape-controlled drill presses to versatile, multifunction machining centers. A horizontal numerical control machining center is shown in **Fig. 2**, as one component of a still more complex and versatile group of automated machines called a machining workstation or cell. The machining center can perform a variety of functions, such as drilling, boring, reaming, tapping, and milling. The tools required for these operations are stored in a circular tool drum. When the controller calls for a new tool, an automated tool changer removes the current tool from the spindle chuck and returns it to the drum. The drum rotates the new tool to the position in front of the changer, and the changer inserts the new tool in the chuck. The machining center also controls the position and orientation of the part being made, so that it can be machined on all sides.

Automated part programming. Preparing numerically controlled programs is called part programming. Manual part programming is tedious and difficult, because the programmer must calculate and record a long list of the relative positions of tools and parts for each movement along the tool path. Computer-assisted part programming simplifies this task. The

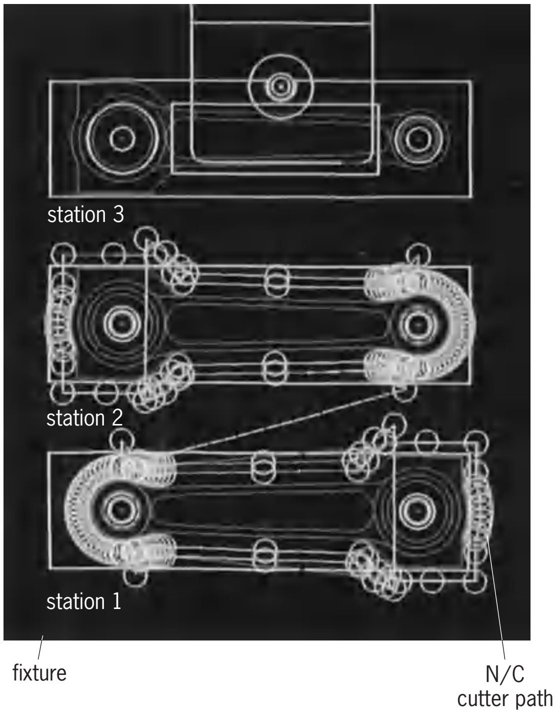

Fig. 3. Computer-aided design and manufacturing display on a system that allows the part programmer to create a cutter location file and preview the cutter path before machining. (*Control Data Corp.*)

programmer specifies the part geometry and machining information (tool sizes, speed, feed rates, and tolerances) in a high-level programming language. The module creates the part program. **Figure 3** shows the display of a numerically controlled machine tool creating a part program for a connecting rod; **Fig. 4** shows this rod being cut out of stock. Automation significantly reduces the time required for part programming and program verification, especially for complex parts with many machining steps. In integrated CAD/CAM systems, the part geometry is specified in the CAD database and does not need to be reentered during programming.

Advances in manufacturing. The development of CAD software for creating true solid models caused designers and manufacturing engineers to think about product models in new ways. They now recognize three approaches to the production of parts: subtractive, additive, and net shape production. Traditional manufacturing relies largely on processes that shape and remove material. Parts are created by subtracting material from stock. Rapid prototyping involves a set of manufacturing techniques based on additive processes; the techniques build up to the desired shape. Several distinct rapid prototyping methods have been developed into commercial systems, including stereolithography (**Fig. 5***a*), selective laser sintering, laminated object manufacturing, ballistic particle manufacturing, fused deposition modeling, (Fig. 5*b*), and 3D printing (Fig. 5*c*). These systems create physical models of parts directly from a CAD database. Such models (prototypes) may be used for presentation, communication, and understanding; as masters for the production of secondary tooling; or for making actual production-quality parts.

The first rapid prototyping system was developed in 1986. The stereolithography apparatus (Fig. 5*a*) uses a CAD driven laser beam to draw individual layers of a part by transforming liquid polymer into solid material using ultraviolet light. It defines the industry standard for rapid prototyping.

Net shape manufacturing techniques produce engineering materials to finish or near-finish dimensions from the start. Working from the CAD model, the goal is to produce a part as close as possible to the final version on the first pass. A variety of fabrication techniques are available: melt processing, shaping from powder, and forming from sheets or billets. Net shape production conserves resources and can reduce costs.

Robotics. Industrial robots are general-purpose, programmable manipulators that perform a variety of production tasks. Robots can move material, load and unload parts on other machines, assemble components, spray paint, and spot-weld. The first industrial robot was installed in a United States automotive diecasting facility in 1961. Figure 2 shows a type of robot that loads and unloads parts and changes tools in a tool drum at a machining center. To spare humans the tasks, robots can do unpleasant, boring, fatiguing, or dangerous jobs, such as working in areas contaminated by fumes, acid, or radiation.

Robots can be reprogrammed for different tasks as needed. In walk-through and lead-through training, the robot arm and end effector (hand or specialized tool) are moved through the desired sequence, and that sequence is recorded in the robot's memory. With a more sophisticated technique, the robot program is created on an off-line computer using a high-level programming language, and then loaded into the robot memory when needed. This eliminates the loss of production time during robot training, and

allows a repertoire of programs to be stored and used interchangeably.

Robots also can be equipped with humanlike senses (vision, touch, and hearing) to perform more complicated tasks. For example, a video camera and a computer equipped with image-processing hardware and software are used for robot vision. This allows the robot to discern objects in the camera field and recognize the position and orientation of familiar objects. In this way the robot can retrieve randomly oriented parts, recognize specific parts in the presence of other objects, perform visual inspections, and assemble products requiring precise alignment. Similarly, touch, force (stress), and proximity sensors let the robot sense contact with another object, gage and control the force of contact (for example, its grip strength), and sense the presence of nearby objects it has not touched. *See* COMPUTER VISION; ROBOTICS.

Automated materials handling. Materials handling refers to the movement, storage, retrieval, and tracking of raw materials, work in process, and completed products. Conveyor belts, hand trucks, fork lifts, and cranes are familiar equipment used to move materials. Shelves, bins, pallets, and silos are used for storage. Inventory sheets, traveler cards, parts lists, and fixed storage locations aid in tracking and retrieving materials.

In CAM, the goal is to automate all materials handling under computer control. Mobile robots, called automated guided vehicles, follow routes on the factory floor defined by wires or tape. Combined with automated pickup and delivery stands, automated guided vehicles move bins or trays of material without human intervention. A typical automated storage and retrieval system uses conveyors and lifts to move bins into and out of specialized inventory shelving. The computer automatically assigns entering bins to empty shelf locations, recording the bin number and shelf location for future retrieval. The bins are labeled with bar codes and can be identified automatically by optical scanners. Large-scale software systems, such as manufacturing resource planning, assist managers in determining what raw materials and components will be required during the current production period. These systems also help the managers to decide when materials and components must be ordered or manufactured to maintain production schedules. *See* MATERIALS HANDLING.

Flexible manufacturing systems. Flexible manufacturing systems are a form of computer-integrated manufacturing used to make small to moderate-sized batches of parts. A typical flexible manufacturing system comprises a cluster of numerical control machine tools, served by an automated materials-handling system and controlled by a central computer. A typical flexible manufacturing system can make from 4 to 100 different kinds of parts in volumes of 40–2000 parts per year, all with minimal human intervention. Such a system is efficient because it is highly automated and requires little downtime for changeovers for making batches of different parts. The flexible manufacturing system is in contrast to the familiar assembly line, which depends for its efficiency on making a single product in very large numbers. *See* FLEXIBLE MANUFACTURING SYSTEM.

Globally distributed manufacturing. With the evolution of the Internet and the World Wide Web, globally distributed manufacturing is possible. Virtual corporations can be established involving participants from around the world. Design, production, and assembly can occur wherever is most convenient and cost-effective for the enterprise. Developments in CAD/CAM, including advances in product data models and international standards, have made this possible. *See* COMPUTER PROGRAMMING; DIGITAL COMPUTER; ENGINEERING DESIGN; INTERNET; WORLD WIDE WEB.

Computer-aided engineering

Any use of computer software to solve engineering problems. With the improvement of graphics displays, engineering workstations, and graphics standards, computer-aided engineering (CAE) has come to mean the computer solution of engineering problems with the assistance of interactive computer graphics. *See* COMPUTER GRAPHICS.

CAE software is used on various types of computers, such as mainframes and superminis, grid-based computers, engineering workstations, and even personal computers. The choice of a computer system is frequently dictated by the computing power required for the CAE application or the desired level and speed of graphics interaction. The trend is toward more use of engineering workstations. *See* DIGITAL COMPUTER; MICROCOMPUTER.

Design engineers use a variety of CAE tools, including large, general-purpose commercial programs and many specialized programs written in-house or elsewhere in the industry. Solution of a single engineering problem frequently requires the application of several CAE tools. *See* ENGINEERING DESIGN.

A typical CAE program is made up of a number of mathematical models encoded by algorithms written in a programming language. The natural phenomena being analyzed are represented by an engineering model. The physical configuration is described by a geometric model. The results, together with the geometry, are made visible via a user interface on the display device and a rendering model (graphics image). *See* ALGORITHM; COMPUTER PROGRAMMING; MODEL THEORY; PROGRAMMING LANGUAGES.

CAE allows for many more iterations of the analysis-design cycle than was possible by hand computation, especially when the CAE is coupled with optimization systems that drive this cycle automatically. The benefits are translated into improved productivity and quality of design.

Program structure. A CAE program usually consists of a series of mathematical models and a data structure. **Figure 1** illustrates a simplified view of a typical CAE program operating in an engineering workstation environment. First, a mathematical description of the physical phenomena being analyzed is written. This engineering model may consist of equations such as Newton's second law to describe the dynamics of a system or the Navier-Stokes equations to analyze a fluid flow field. Next, a model of the physical configuration is created. This geometric model may consist of two- or three-dimensional (2D or 3D) curves, surfaces, faceted approximations to surfaces, or solid elements. The results of the engineering analysis are frequently displayed on the geometric model by color fringing to show the variation of a scalar parameter. Large amounts of data are created during this modeling phase, and the need for a data structure to store and retrieve them is greater than for the engineering model. *See* DATA STRUCTURE.

Although the engineering and the geometry are fully described, they cannot be viewed on the display until a model for rendering has been formulated and coded. A mathematical description of the lighting conditions, the approximate intensities of

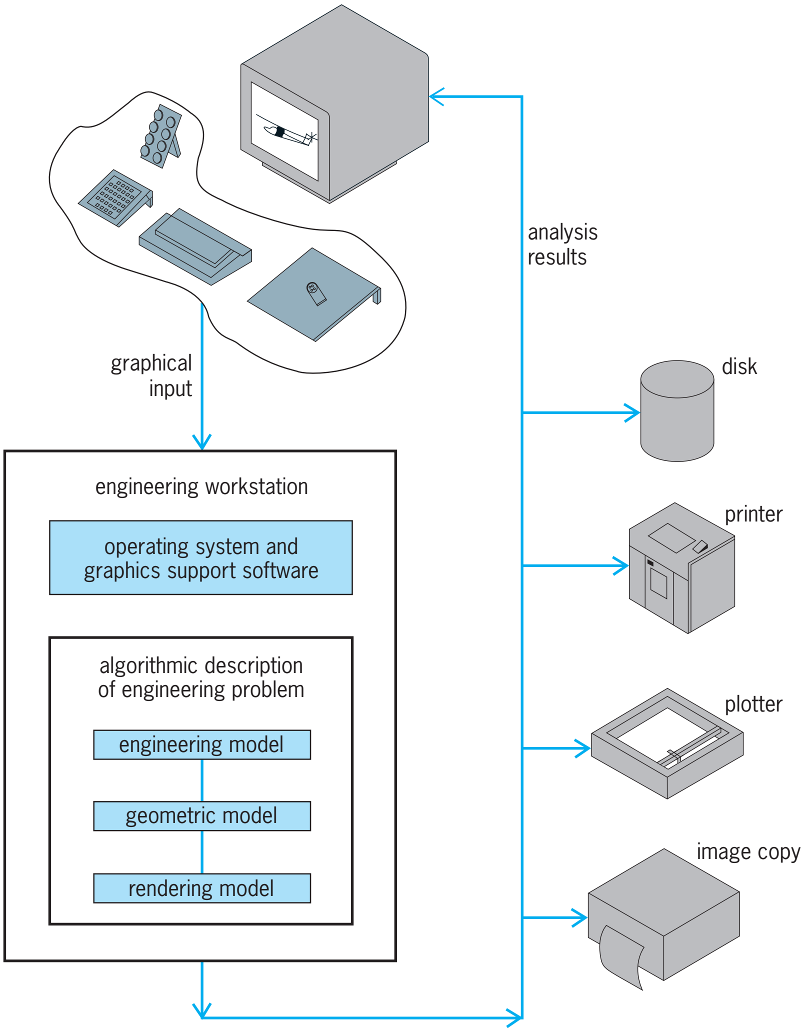

Fig. 1. CAE program in an engineering workstation environment.

light reflected by the nodes of the geometric model, and the corresponding shades of color provide the graphics data necessary for the model to be realistically shaded. Before viewing, the graphics data are transformed from geometric model coordinates to a normalized coordinate system. Parameters are set for an orthographic or perspective projection from 3D model coordinates to 2D coordinates for final transformation to the display screen in device coordinates. The CAE applications programmer accomplishes most of these tasks with the help of precoded algorithms provided by graphics-support software. Interactive communication with the graphics image and the geometric and engineering models occurs through a user interface written with the assistance of the graphics software or windowing software provided with the workstation.

In the past, CAE programs have been predominantly coded in the FORTRAN programming language. The present trend is toward the C, C++, and Java programming languages together with the UNIX and Windows operating systems. *See* OPERATING SYSTEM.

Graphics standards. Portability, the ability to move programs easily from one computer to another, is important for CAE software. Although it has long been possible to make a computational program code portable by using standard programming languages, this was not previously possible for CAE software because of the lack of graphics standards. A proposed 3D graphics standard (CORE), introduced to the American National Standards Institute (ANSI), was superseded by the adoption in 1985 of the 2D Graphical Kernel System (GKS) as an international standard by the International Organization for Standardization (ISO).

A new 3D device-independent graphics standard, the Programmer's Hierarchical Interactive Graphics System (PHIGS), was proposed by ANSI in 1985 and adopted as an international standard by ISO in 1988. Where possible, the concepts and nomenclature of GKS have been used in PHIGS.

The principal limitation to CAE software portability has been the wide variety of graphics hardware and the direct dependence of CAE software on this hardware. Both GKS and PHIGS give the programmer device-independent graphics primitives and coordinate systems as well as a set of logical graphics input devices to replace the wide variety of input hardware. For example, the pick action (selection of a graphics entity on the screen) could be physically accomplished by a light pen, a cursor and tablet, or a mouse. Using graphics standards, the CAE programmer will always specify a logical pick device regardless of the physical device used to achieve the pick.

PHIGS has several important advantages over GKS for CAE software. It is a full 3D system for viewing and modeling transformations, and allows both graphics and nongraphics data to be stored in its data structure. The data structure can invoke other structures and store transformations as attributes. The result is a hierarchical graphics data structure well suited for animation and representation of entities with multiple components. A number of extensions to PHIGS, called PHIGS PLUS (PHIGS+), were adopted as a separate international standard in 1990. PHIGS+ provides support for most of the rendering model and some of the geometric model in a CAE program. PHIGS+ routines address lighting, shading, hidden surface elimination, transparency, nonuniform rational B-spline (NURBS) curves and surfaces, and improved user interaction and control. PHIGS and PHIGS+ were merged into a single international standard, PHIGS, in 1997.

The emergence of PHIGS+ was in response to dramatically improved computer graphics hardware capabilities in the late 1980s and early 1990s, and that were rapidly being incorporated into the new breed of CAE workstations. Vendors did not wait for international committees to address these new capabilities in their standards, but deployed their own proposed extensions in the interim. While this made these new capabilities available to the CAE software developers, it also prevented the CAE software from easily being ported from one hardware platform to another, which is the main purpose of a standard.

Taking advantage of this noncompliance to the adopted international standard and the slow rate at which new technologies and capabilities were addressed by these standards, an industry consortium was established in 1992 to support a new graphics standard known as OpenGL. The aim of OpenGL is to provide a timely integration of new technologies and capabilities as they emerge and to avoid the problem of partial conformance to the standard. GKS, PHIGS, and other standards have been plagued by partially conforming deployments, which makes portability between platforms difficult and defeats a key purpose of standards. The OpenGL Architecture Review Board, which draws its membership from nine leading computer graphics hardware vendors, avoids this problem by permitting only the term OpenGL to be applied to products that conform completely to the OpenGL standard. OpenGL is today the most widely used and supported 2D and 3D graphics application programming interface (API).

Hardware. Computer systems ranging from workstations to mainframe computers are used for CAE software. For example, the aerospace and automotive industries make wide use of very large mainframe computers and large grid-based computer systems to support computer-intensive CAE software such as finite element analysis and computational fluid dynamics. These large computational resources are connected by high-speed data transmission lines to file servers holding the model and resulting data. The precomputation model description and the postcomputation interrogation of the results, and frequently the computations themselves, are usually performed on ultra-high-end workstations capable of managing these vast amounts of data. These workstations are typically 64-bit multiprocessor systems, with 12 to 24 gigabytes (GB) of shared memory

(RAM) and a UNIX operating system, which are connected to the file servers via one or more 1- or 10-gigabit/second network connections. Ultra-high-end workstations are necessary when working with large, complex models and datasets, such as the solid modeling of a complete automobile or aircraft.

For less complex models and datasets, or for subsets of the larger models and datasets, it is typical to use high-end engineering workstations. These workstations are typically 32-bit single- or dual-processor systems with up to 4 GB RAM running a Windows or UNIX operating system, the former being more common. These engineering workstations distinguish themselves from personal computers by having more RAM and faster central processing units (CPU), graphical processing units (GPU), hard disks, network connections, and internal interconnects and data transfer rates. These high-end engineering workstations cost two or three times more than a typical personal computer and are commonly used by engineers. In contrast, ultra-high-end workstations typically cost three to five times more than a high-end engineering workstation, and consequently are less used.

Computer-intensive engineering problems are frequently distributed across multiple CPUs. These CPUs can be connected in a grid structure where each CPU has its own RAM and where communications between these CPUs and their RAM takes place over a computer network. Occasionally these grids are composed of regular personal computers and engineering workstations that are accessed whenever they are idle, such as during nighttime hours. The bottlenecks of such systems are the limited bandwidth between the CPUs and the personnel time required to configure and manage these grids. Grid systems tend to be most successful when the computations can be easily parallelized and when there is minimal need to communicate and move data between the CPUs. Computational problems that do not fall into this category are best performed on large multiprocessor, shared-memory systems with high-speed, high-bandwidth interconnects between the CPUs. Examples of such systems include mainframes and the ultra-high-end workstations described earlier. The advantages of these systems include the flexibility of how data can be accessed simultaneously by multiple CPUs without having to be moved across a network, and the reduced need for manually managing the distribution of the computational resources within the system. *See* MICROPROCESSOR; MULTIACCESS COMPUTER; MULTIPROCESSING; SUPERCOMPUTER.

These large centralized computational resources are often connected to networks of from 10 to 100 client workstations that act as display terminals with local controllers (**Fig. 2**). When a large number of CAE users invoke computer-intensive programs, a significant delay in response usually occurs. For this reason, as well as initial cost considerations, most companies today deploy high-end engineering workstations on a two- or three-year upgrade cycle. Though many small CAE applications programs are written for personal computers, of which most engineering companies have a wide array, most large, commercial CAE programs do not perform effectively or at all on personal computers. Engineering workstations, on the other hand, have the necessary computer power and local resources, and usually run only one CAE program at a time and serve only one user. As a result of this independence, a demanding CAE code at one workstation node in a computer network will not affect the response time for other users. *See* DISTRIBUTED SYSTEMS (COMPUTERS); LOCAL-AREA NETWORKS.

Fig. 2. Solid modeling and simulation on a mainframe via a CAE workstation.

The personal-computer gaming industry has been instrumental to the recent widespread availability of affordable, high-quality graphical processing units that are capable of supporting the heavy demands of CAE graphics processing. These graphical processing units contain a number of specialized high-speed, parallel graphics engines, display list memory, image memory, buffer memory, and alpha memory to permit the real-time generation of color-shaded images desired for CAE applications. The graphics engines perform graphics modeling and viewing transformations, lighting and shading computations, and scan conversion of models for raster-scan display. Display list memory retains the rendering model structure. The z-buffer provides fast hardware support for hidden surface elimination, whereas alpha memory allows fast hardware-assisted transparency computations. The final rasterized image is stored in one of two image memories for fast transmission to the display screen. Most graphical processing units support the OpenGL graphics standard by performing its operations directly in hardware as opposed to computing them in software. *See* COMPUTER ARCHITECTURE.

The graphical processing unit used in a typical personal computer accounts for approximately 2–4% of the personal computer cost. In contrast, in a high-end engineering workstation, the graphical processing unit typically accounts for 20% of the hardware cost. Where ultra-high-end workstations are also used for graphics processing and visualization, it is increasingly common to use multiple high-end graphical processing units working in parallel, with each unit capable of computing 750 million triangles per second or 8 billion pixels per second.

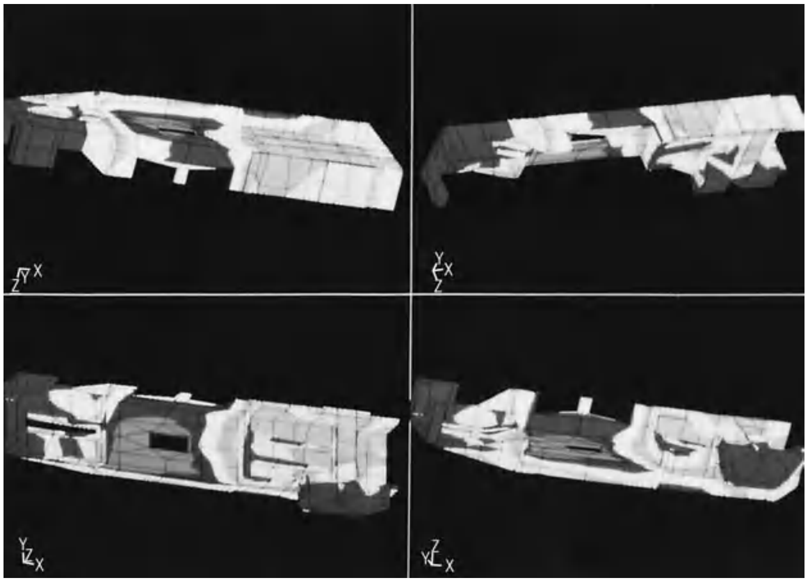

Fig. 3. Finite-element stress analysis using commercial CAE software.

A wide variety of output devices are available for CAE images. The most popular are ink-jet and laser printers for color images and line drawings on paper and Mylar. Others include wall projection and stereovision display systems, often combined with positional and orientation input from the observer. Many types of graphics input devices are available for workstations and mainframe displays. Cursor and tablet, mouse, joystick, ball, glove, function key box, and dial box are the most widely used. Light pens are generally in use on older-technology displays. *See* COMPUTER PERIPHERAL DEVICES.

Commercial CAE software. Most companies use a combination of a few commercial CAE programs and a number of smaller, specialized CAE applications programs typically written in-house or elsewhere in the industry. There are several classes of commercial CAE software. The first large commercial programs used for CAE were dynamic simulation systems, which usually had no graphical output or at best a printer-plotter output of graphs. They required the engineer to give input in the form of ordinary differential equations or building-block elements to describe the dynamic behavior of a real system, in many ways similar to the patching (programming) of analog computers. These systems numerically integrate the set of coupled differential equations, thereby simulating the dynamic behavior of the particular system. Simulation systems are still widely used, and although the graphics output has improved considerably, the description of the input has not changed greatly. *See* ANALOG COMPUTER; NUMERICAL ANALYSIS; SIMULATION.

A need to solve detailed problems, such as stress or deformation analysis, for components of systems led to the development of the finite-element method or finite-element analysis. In this method, a complex object is broken down into simpler elements. With these, a set of equations is formulated which, when solved, predict the behavior of the object as modeled by the set of elements. The modeling of the object is known as finite-element preprocessing, and the validity of the solution is largely dependent on the skill of the modeling engineer. Although very advanced methods of interactive graphics are used in finite-element preprocessing, it is still a very tedious and expensive operation. The solution of the equations is highly computer-intensive. Finite-element methods are applicable for a wide variety of physical phenomena, including mechanical stress and strain, fluid flow, acoustics, heat transfer, and electrical fields. **Figure 3** illustrates the solution of a finite-element stress analysis problem with a commercial CAE code running on a mainframe computer. *See* FINITE ELEMENT METHOD.

Computer-aided design and manufacturing. CAD/CAM systems were created by the aerospace industry in the early 1960s to assist with the massive design and documentation tasks associated with producing airplanes. By the late 1970s, these codes were being distributed to other industries. CAD/CAM systems have been used primarily for detail design and drafting along with the generation of numerical control instructions for manufacturing. Gradually, more CAE functions are being added to CAD/CAM systems. A trend toward open architecture with flexible geometry interfaces is stimulating the addition of more analysis and manufacturing functions. Modeling with CAD/CAM systems has become fairly sophisticated. Most popular commercial systems support 2D and 3D wireframe, surface models, and solid models. Rendered surface models differ from solid models in that the latter have full information about the interior of the object. For solid models, a combination of three types of representation is commonly used: constructive solid geometry, boundary representation, and sweep representation. Complex systems require significant amounts of processing power, primary memory space, and disk space. *See* COMPUTER-AIDED DESIGN AND MANUFACTURING.

Integration of CAE software. Frequently, all of these CAE tools are needed together with specialized CAE applications programs to solve a single engineering problem. The integration of these tools or the communication of data between them is a challenging problem. To successfully integrate these programs, a centralized database is necessary. Data from the various CAE tools are processed into and retrieved from this database through a database management system. If the CAE software is proprietary and the data structure not easily accessible, the proprietary programming interfaces may be used or, sacrificing of functionality and interactivity, a data interchange standard may be used. *See* DATABASE MANAGEMENT SYSTEM.

The Initial Graphics Exchange Specification (IGES) was developed under the leadership of the National Bureau of Standards (today known as the National Institute of Science and Technology) and was accepted as a standard by ANSI in 1981 (Y14.26M-1981). The goal of IGES is to allow the transfer of geometric data between dissimilar CAD systems. IGES is widely available and is generally capable of providing the translation of a snapshot of the model in one CAD system into a static model that cannot be edited in another CAD system.

The standard for exchange of product model data (STEP) has been adopted as an international standard by the International Organization for Standardization (ISO 10303). The aim of STEP is to provide a neutral, computer-interpretable representation and description of product data throughout the life cycle of a product that is independent from any particular system. It can be used for both data exchange and for archiving data over time. The latter is an important issue when the product life cycle exceeds the life span of the software and hardware that created the product data. Given this extremely broad objective, ISO 10303 is not a single standard but a collection of interrelated documents that form a multipart standard. A number of these documents have been adopted as an international standard, while many others are still in development. The **table** lists of some of the documents that have been adopted as part of ISO 10303.

The software industry's support for adopted ISO 10303 documents has been significantly slower than was the case for PHIGS (graphics standards). In the case of STEP, the software vendors have been hesitant to support the standard, both because of the high up-front cost associated with complying with the complexity of the standard, and because of their desire to provide a comprehensive yet proprietary solution for the customer in which the customer's data is locked into. Thus far, it is primarily the large mechanical CAD/CAM/CAE vendors serving the automotive industry that have given into customer pressure and competition to provide support for STEP (AP 203, AP 214). Recently it appears that AP 210 and AP 212 have also started to receive some initial vendor support.

Adopted ISO 10303 documents

Document number	Title
STEP AP 201	Explicit Draughting
STEP AP 202	Associated Draughting
STEP AP 203	Configuration Controlled Design
STEP AP 204	Mechanical Design using Boundary Representation
STEP AP 207	Sheet Metal Die Planning & Design
STEP AP 209	Composite and Metallic Structural Analysis and Related Design
STEP AP 210	Electronic Assembly, Interconnection and Packaging Design
STEP AP 212	Electrotechnical Design and Installation
STEP AP 214	Core Data For Automotive Mechanical Design Processes
STEP AP 215	Ship Arrangement
STEP AP 216	Ship Moulded Forms
STEP AP 218	Ship Structures
STEP AP 224	Process Planning Using Machining Features
STEP AP 225	Building Elements Using Shape Rep
STEP AP 227	Plant Spatial Configuration
STEP AP 232	Technical Data Packaging: Core Info & Exch.

Applications. The CAE methods for electrical and electronics engineering are well developed. The geometry is generally two-dimensional, and the problems are primarily linear or can be linearized with sufficient accuracy. Chemical engineering makes extensive use of CAE with process simulation and control software. The fields of civil, architectural, and construction engineering have CAE interests similar to mechanical CAE with emphasis on structures. Aerospace, mechanical, industrial, and manufacturing engineering all make use of mechanical CAE software together with specialized software.

An example of CAE is the design of an aircraft landing-gear mechanism. The first step is definition of the problem and creation of a set of performance specifications. Next, the conceptual design phase may be aided by specialized programs to determine a size estimate of the landing gear based on specified loads and deflections. Commercial CAE programs are available for kinematic synthesis of mechanisms based on specified motion requirements, but this landing-gear mechanism will be designed with an in-house program written for the purpose. *See* LANDING GEAR.

The next phase is preliminary design. An applications program is used to analyze the deflection and response of a shock-absorbing, energy-dissipating strut. Dynamic analysis of the guiding mechanism and complete assembly is determined by a commercial code. When the dynamic loads are determined, a finite-element stress analysis of each link of the mechanism is done by using commercial finite-element-method software. Following the stress analysis, some links are changed in size and the dynamic analysis repeated to determine new loads. Using the new loading, another iteration of the finite-element-method software is made to verify that the stresses fall below the strength limits.

The next phase is the final design. All components of the assembly are drawn in 2D on a CAD/CAM system and detailed, giving dimensions, material specifications, and other instructions. An assembly drawing is created from the components, and mating of components are verified. An alternative approach is to create a solid model of each component, assemble the solid components, and run an automatic interference-clearance check; 2D drop-offs are then automatically made of each component and manually detailed (at the workstation) by a drafter. From the final part geometry, instructions for numerically controlled machine tools are generated to produce the part. Some systems may support tooling design and process planning. Finally, a design release is made to the manufacturing department.

Computer architecture

The art or practice of designing computer systems. Just as the architecture of a building describes its overall structural concept and principal features, the architecture of a computer system consists of a description of the overall layout and major features of a computer system. In both cases, we are concerned with how the object, whose architecture we are describing, appears to the user. In computer architecture, the user is not the final user of the system, but the person who writes computer programs to be run on the system. Compared to the architecture of buildings, which is largely an issue of esthetics, the architecture of a computer system is principally about efficiency and economy of operation. There may be an esthetic dimension to computer architecture, but when present it is distinctly lower in importance.

At present, computer architecture is the highest level of the closely related field of computer design. The field has evolved from being the top level of the design process used by the early developers of computers into a separate area of specialization within the overall hierarchy of computer designers and engineers. Underneath computer architecture are the fields of computer organization and implementation, and computer engineering. *See* COMPUTER; DIGITAL COMPUTER.

Computer organization and implementation. Closely related to the field of computer architecture is a subsidiary discipline known as computer organization and implementation. It is difficult to define precisely where computer architecture stops and computer organization and implementation begins. In general, computer architecture is concerned with the principal design parameters, while computer organization and implementation is concerned with the subsidiary points of design of the system, including the composition of the logic circuits that make up each structural component of the system and the implementation of each of those logic circuits as an arrangement of specific electrical circuits of some particular type or types. Computer organization focuses on issues such as whether an adder circuit will be implemented as a ripple-carry adder or as a carry-lookahead adder and whether the underlying electrical circuits will be implemented in TTL (transistor-transistor logic), bipolar transistors, CMOS (complementary metal-oxide semiconductors), or gallium arsenide (GaAs). *See* INTEGRATED CIRCUITS; LOGIC CIRCUITS.

Major issues. There are several major issues in the design of a computer system covering all or nearly all of the architectural considerations. *See* MICROCOMPUTER.

Instruction-set architecture. Traditionally, the instruction-set architecture—the detailed design of the set of machine instructions implemented in the processor—has been the core issue in defining the architecture of a computer system. For example, how many machine instructions will there be, will the instructions be of uniform length or variable in length, and how many fields will the machine instruction contain. *See* MICROPROCESSOR.

Registers. The typical central processor contains several special-purpose registers (storage units), including an instruction register, a program counter or instruction pointer, a processor status register, perhaps one or more separate index registers, segment (base) registers, one or more general-purpose registers to hold integer or fixed-point data (integer registers), and either the same or a distinct set of registers to hold floating-point data. Although integer registers, a single instruction register, and the program counter or instruction pointer have traditionally been of the same width (number of bits), there is no law requiring such. Floating-point registers may or may not be of different width from integer registers. *See* COMPUTER STORAGE TECHNOLOGY.

Native data types. These are the data types that will be separately and distinctly represented and recognized by the computer hardware. Some computers may natively represent and carry out arithmetic on decimal integers via an underlying binary representation. Floating-point representation may or may not be present. *See* NUMBERING SYSTEMS.

Word size. The most commonly encountered number of bits contained in a single word of memory (word width) are 32 and 64. *See* SEMICONDUCTOR MEMORIES.

Memory addressing scheme. There are two principal issues under the topic of memory addressing scheme. The first is the smallest unit of addressable memory, which is usually the byte, although there are several machines of major significance that are not byte-addressable but word-addressable. The second issue is the order in which the bytes are stored for the several bytes that constitute a single word. In the scheme known as big-endian, the leftmost byte (that is, the byte with the numerically smallest address) contains the most-significant bits of the word content, while the byte containing the bits of least significance possesses the numerically highest address. The opposite arrangement is known as little-endian.

Maximum size of memory. A major issue for the modern computer architect is how large the memory address space should be, since memory has been getting cheaper at a prodigious rate. For every doubling of size of the memory address space, the width of an address increases by one bit. Therefore, the designer is not free to increase the memory address space by an arbitrary amount, as every increase in address width has much wider implications for instruction set architecture, as well as imposing requirements affecting lower levels of computer organization and implementation. On the other hand, insufficiency of memory address space has been one of the principal factors causing an architecture to become outmoded.

Number of buses and their relationship. A modern computer typically has a frontside bus and a backside bus, as well as one or more subsidiary busses. The backside bus connects the registers in the central processing unit (CPU) with the main memory and with the various levels of cache memory. The frontside bus constitutes the main conduit between the CPU and peripheral devices, and one or more subsidiary buses interconnect various groups of peripheral devices. Each subsidiary bus is designed to accommodate the needs of peripheral devices within a particular speed range. A simpler and therefore cheaper computer uses a smaller number of subsidiary buses, and each such bus may operate at a lower efficiency while it is communicating with a peripheral device that is considerably slower than the maximum speed that the bus is capable of. *See* COMPUTER PERIPHERAL DEVICES.

Datapath width. This is the number of bits involved in a single transfer of data within or between units within the central processor, such as its internal registers.

CISC versus RISC. Historically, the mainstream of computer architecture was monopolized by complex instruction-set computers (CISC). During the evolution of CISC machines, a lot of the ingenuity of the designer lay in coming up with a larger repertoire of machine instructions, of which the more recently developed tended to be instructions of ever-greater capability and complexity. However, there is a price to pay for the existence of the extra, more powerful instructions. A more elaborate decoding circuitry is required in the central processing unit to interpret these instructions, or there must be a distinctly longer and wider within-processor special-purpose memory to represent the microprograms for all of the instructions contained in the machine's instruction set architecture (ISA).

During the early 1960s, research carried out at IBM suggested that an alternative approach in which the size of the instruction set was actually diminished to a central core of frequently used instructions might be more efficient. In a reduced instruction-set computer (RISC), the area of the processor chip that is saved by omitting either the extra decoding circuitry or the extra length and width of the microprogramming store necessitated by the presence of the omitted more complex instructions is used instead to increase the number of registers. As a result, there are two forms of time savings involved in the execution of the remaining instructions. First, the smaller size and simplified circuitry of the arithmetic logic unit (ALU) enables this component to significantly faster execute the remaining instructions. Second, the presence of a much larger number of registers enables intermediate data to be retained in a register for significantly longer periods of time, reducing both the number of write operations from registers to memory and read operations from memory to registers, compared to the numbers of such operations that must be performed in a CISC processor because of the need temporarily to vacate a register to enable it to do something else. In fact, a great part of the savings in processing time for the RISC processor is due to the substantial reduction in transfers to and from main memory that is occasioned by the much larger number of registers present in the RISC processor. Among the CISC instructions that are omitted in the RISC processor are those that operate directly upon or that write out their results directly to memory. Instead, there are only two instructions provided to accomplish memory transfer operations: a LOAD instruction and a STORE instruction. For this reason, a RISC processor is sometimes referred to as a Load/Store processor. As with any other design decision, a price must be paid performance-wise in exchange for the gain in execution speed. The remaining, "core" instructions that are still present in the RISC processor are executed with a dramatically improved speed. However, the omitted instructions, when they otherwise would have been called for by the source program, must each be emulated by the compiler by means of a series of shorter instructions. As a result, the execution time for one of these instructions omitted from the processor's instruction set will be dramatically longer than it otherwise would have been. For some source code programs, such as those that used very few of the omitted instructions, and those relatively rarely, there will be a net time savings. But for other source code programs, such as those that used relatively heavily and frequently the instructions that have been omitted, the performance will be slower. *See* COMPUTER PROGRAMMING.

RISC remained largely out of the mainstream of computer architecture until the 1990s, when it began to compete seriously with CISC computers. Some of the pioneers in this area include the IBM RS/6000 and the Digital Equipment Corporation Alpha, followed by a number of other products by these and other vendors. Currently, the CISC and RISC streams of processor development have shown some convergence, with microprocessors of predominantly one or the other design incorporating some features previously associated with the other stream.

It should be noted that the earliest supercomputers designed by the famous computer architect and designer Seymour Cray used some of the same principles of design that we know today as RISC. *See* SUPERCOMPUTER.

Pipelining. Pipelining is a design approach to increase the rate of instruction execution. The traditional operation of a computer processor was described as the fetch-execute cycle or more precisely as the fetch-decode-execute cycle. In the first or fetch portion of the cycle, the instruction pointed to by the instruction pointer is copied into the instruction register. Once it has been copied, electronic circuitry within the processor decodes the instruction, that is, determines what sequence of steps must be performed in order to execute the instruction. An example of such a sequence is to (1) copy the contents of memory location A to register temp01, (2) copy the contents of memory location B to register temp02, (3) add the contents of temp01 and temp02 and write the result to register temp02, and

(4) copy the contents of register temp02 to memory location C. Once the sequence of actions has been identified, it must be carried out. This is the execute portion of fetch-decode-execute. In a pipeline machine, these three phases of executing a machine instruction can be done on three or more instructions in parallel. That is, while the first instruction of a sequence of machine instructions is being executed after having first been fetched and decoded, the second instruction, having previously been fetched, is simultaneously undergoing decoding, while the third instruction in the sequence is being fetched. In addition, the execution of a single instruction usually involves several component steps, and therefore a pipeline can be constructed with more than three stages, thus making it possible for more than three instructions to be present simultaneously in the pipeline at various stages of processing. This last technique is known as super-pipelined architecture.

Other techniques for increasing the processing speed. In addition to instruction pipelining, several techniques can be used to increase the processor speed, principally by increasing the extent to which different machine instructions are executed in parallel. These include branch prediction, speculative execution, and superscalar architecture.

Multiprocessor core. In the competition for higher processor speeds, one of the more recent design techniques is to include within the processor more than one core unit capable of carrying out arithmetic-logic operations in parallel. A substantial speedup is possible, even though the presence of other structures within the overall framework of the processor might not allow the various cores each to operate at full speed, making one or more of the processor cores have to wait for some commonly used resource to become available. *See* CONCURRENT PROCESSING; MULTIPROCESSING.

Compiler as adjunct to processor. All of the techniques that are used for increasing the parallelism of instruction execution possess a common restriction on their application; that is, they can succeed in producing an improvement in performance only with the active cooperation of the compiler to define precisely where in the program each of them can be applied. For example, pipelined processing is successful in increasing processor speed only for those parts of the program where the precise order of instruction execution is certain. When it happens, as on occasion it must, that an unexpected branch of program execution must occur, then many of the instructions already in the pipeline, some of which might have already been partially executed, must all be flushed from the pipeline, and the pipeline must be reloaded from the point to which the program has unexpectedly branched. In fact, in some number of instances it might even be necessary for already executed instructions or parts of instructions to be undone. Thus, there are distinct limits to the extent to which parallel processing can be successfully deployed to increase processor throughput. As the degree of parallelism within the processor has increased with the development of more advanced architectural techniques, the role of the compiler in using the additional opportunities for parallelism has become ever more important. Thus, the modern computer architect must be knowledgeable in the design and construction of compilers as well as of computer hardware.

Economics. What drives computer design more than any other factor is economics. It is always possible to make improvements in the design of a computer. But the main factor that architects and designers must consider is the importance of being able to build a machine for a price that will return a reasonable profit in the market for which it is targeted.

Historically significant computer architects. There have been many computer architects of distinction. John Vincent Atanasoff invented the stored-program computer in something akin to its current form. Even so, the computer architecture he originated is often referred to as the "von Neumann" architecture. J. Prosper Eckert and John W. Mauchly were the designers of the electronic integrator and computer (ENIAC) built at Aberdeen, Maryland, in 1946. They also designed the binary automatic computer (BINAC), the first machine to use magnetic tape instead of punched cards; and the first model of the universal automatic computer (UNIVAC), which was the first machine able to handle both characters and numeric information. Seymour Cray was the inventor of an entire genre, the supercomputer, and was certainly one of the most prolific computer architects of all time. Gene M. Amdahl, in addition to having originated the law of computer architecture that bears his name, was the principal architect for the IBM Series 360 series of mainframes, which to date is the longest-lived computer architecture. The first machines of this series were introduced in 1963, were extended to become the System 370 and the System 390, and are still being produced. Gordon Bell was the principal architect of many members of the PDP series at Digital Equipment Corporation and oversaw the development of its VAX series of machines.

Computer-based systems

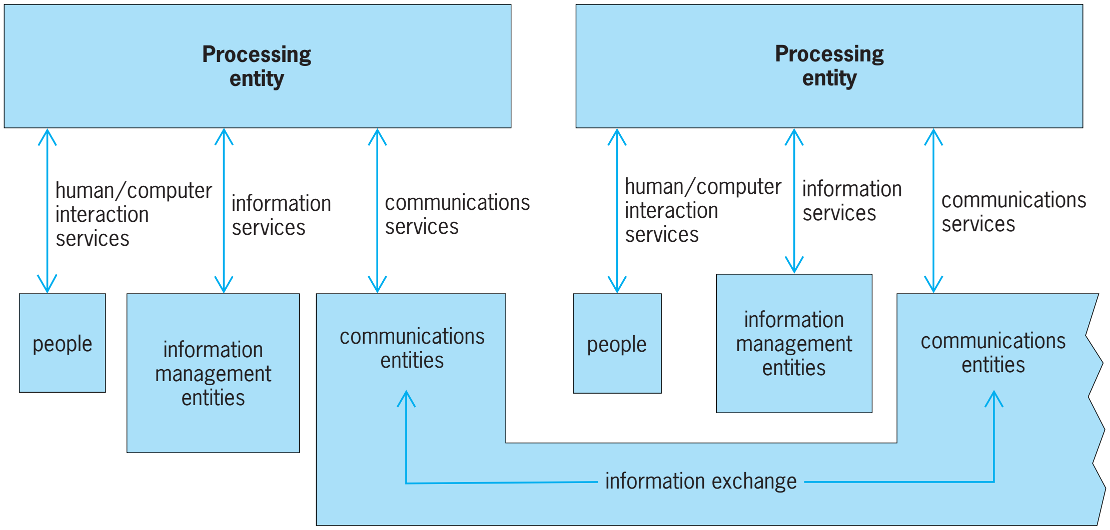
Complex systems in which computers play a major role. While complex physical systems and sophisticated software systems can help people to lead healthier and more enjoyable lives, reliance on these systems can also result in loss of money, time, and life when these systems fail. Much of the complexity of these systems is due to integration of information technology into physical and human activities. Such integration dramatically increases the interdependencies among components, people, and processes, and generates complex dynamics not taken into account in systems of previous generations. Engineers with detailed understanding of the application domain and computer electronics, software, human factors, and communication are needed to provide a holistic approach to system development so that disasters do not occur.

Complex computer-based systems can contain distributed processing and databases, internal communication systems, heterogeneous processing components, and sophisticated human-machine interfaces. Processing components by themselves can constitute a system, or they may be embedded in a physical system such as an automobile, aircraft, or medical diagnostic system. Both the encompassing system and the processing system are known as computer-based systems. *See* DISTRIBUTED SYSTEMS (COMPUTERS); EMBEDDED SYSTEMS; HUMAN-COMPUTER INTERACTION.

Such systems are normally built by people from diverse disciplines. Each discipline uses terminology, problem structuring, and techniques specific to its field, which prevents information from being shared, increases integration difficulties, and makes interdisciplinary optimization extremely difficult. The lack of communication and interdisciplinary understanding makes it more difficult to keep the parts and interfaces consistent, and to analyze system-level aspects such as security, performance, and safety. In real-time systems, meeting performance requirements is as important as meeting functional requirements. Delayed timing can cause catastrophic results in control systems such as digital flight systems or nuclear power plants.

Engineering activities. The computer-based systems engineer develops a system within a system; the properties of the former have pervasive effects throughout the larger system. The computer-based system consists of all components necessary to capture, process, transfer, store, display, and manage information. Components include software, processors, networks, buses, firmware, application-specific integrated circuits, storage devices, and humans (who also process information). Embedded computer-based systems interact with the physical environment through sensors and actuators, and also interact with external computer-based systems (see **illus.**). The computer-based systems engineer must have a thorough understanding of the system in which the computer-based system is embedded, for example an automobile, medical diagnostic system, or stock exchange.

Computer-based systems engineering is analogous to traditional systems engineering, but the focus and necessary skills are different. To better understand the differences, it is useful to look at how these disciplines work together to develop a sophisticated vehicle. The systems engineer has primary responsibility for specifying and allocating requirements for the vehicle. The computer-based systems engineer works with the systems engineer on system-level requirements that relate to the distributed processing system. One such requirement is "the vehicle operator shall be able to navigate." The systems engineer and the computer-based systems engineer make decisions concerning the system boundary; for example, they decide which navigation functions the system automates and which navigation functions the vehicle operator performs. They also make design decisions; for example, they might decide that the system will include maps and that a global positioning system will provide location coordinates. To architect the



Model of a distributed computer-based system.

computer-based system, the computer-based systems engineer must understand the global positioning system and how the operator will use it, together with the maps, to navigate the vehicle.

The computer-based systems engineer must also determine what is done in software, hardware, and firmware, and make decisions with respect to resources and allocation. These decisions determine the types of processors, communication links, and storage devices that are needed, such as a signal processor for processing data from the proximity sensor and a CD-ROM (compact disk–read-only memory) for storing the map database. Based on dependability needs, the computer-based systems engineer chooses fault tolerance features such as dual buses, standby processors, fault-tolerant operating systems, and software recovery blocks. The computer-based systems engineer also optimizes both the number of standard parts in the computer-based system (commonality) and the system's affordability. Standard software and hardware parts and standard interfaces reduce development and maintenance costs. *See* FAULT-TOLERANT SYSTEMS.

After considering various trade-offs, including those involving processing allocation, the systems engineer and computer-based systems engineer define the subsystems and interfaces. Interfaces should be minimal for ease of change and good maintainability. Software engineers work with computer-based systems engineers to define software requirements and allocate them to processing resources. In the example, some software will be allocated to the signal processor, and other software will be allocated to data processors. Such allocation decisions can be difficult to make and can seriously affect performance. Tools that simulate software functionality running dynamically on different hardware configurations support these trade-offs. *See* SOFTWARE ENGINEERING; SYSTEMS ENGINEERING.

Model-based development. Models are necessary in systems engineering as they support interdisciplinary communication, formalize system definition, improve analysis of trade-offs and decision making, and support optimization and integration. The use of models can reduce the number of errors in the design and thus the system, reduce engineering effort, and preserve knowledge for future efforts. Maintaining models with up-to-date knowledge is a major problem as most systems are not generated from models, although this should be an industry goal. During the later stages of system development and testing, significant schedule pressure makes it difficult to keep the models and manually developed software consistent.

Model types are numerous, and include domain models, process models, data models, system dynamics models, dependability models, and communication models. Integrating diverse models is a major issue in systems engineering science. The Unified Modeling Language (UML) attempts to address this problem. This language is object-oriented and integrates scenario models, state models, and information models. Scenario models describe interactions between the system and its environment, including people who use the system. State models describe system dynamics, changes that occur in the system because of events that occur externally or internally. Information models define the data in the system. *See* OBJECT-ORIENTED PROGRAMMING.

Integrated design environments support tool integration, and are a necessity for integrating the tools that support diverse models. Although integrated design environments are in their infancy, standards such as Computer-Aided Systems and Software Engineering Data Interchange Format (CDIF) are contributing to their development. Computer graphics

A branch of computer science that deals with the theory and techniques of computer image synthesis. Computers produce images by analyzing a collection of dots, or pixels (picture elements). Computer graphics is a mature discipline with a growing range of applications. It is used to enhance the transfer and understanding of information in science, engineering, medicine, education, and business by facilitating the generation, production, and display of synthetic images of natural objects with authentic realism almost indistinguishable from photographs. Computer graphics facilitates the production of images that range in complexity from simple line drawings to three-dimensional reconstructions of data obtained from computerized axial tomography (CAT) scans in medical applications. Images of three-dimensional anatomical surfaces can be constructed from the two-dimensional slices generated by computerized tomography or magnetic resonance imaging. These images help physicians to understand the complex anatomy present in the slices, and to evaluate and plan the treatment and even surgery of complex anatomical abnormalities (**Fig. 1**). *See* COMPUTERIZED TOMOGRAPHY; MEDICAL IMAGING.

Scientific data visualization combines computer graphics and data analysis techniques to allow visualization and analysis of large data sets in scientific and engineering computations and thus offer insights that would be difficult or impossible to extract from numerical results. The creation and interaction that is afforded by computer graphics has become an indispensable tool in automobile, aircraft, and architectural design. New products can be simulated from conception to testing, thereby bypassing several steps and weeks of the traditional design and test cycle. Molecular modeling (**Fig. 2**) and user interaction facilitates and speeds the design of new drugs.

(*a*) Visualization of brain and skull utilizing the VOXEL-MAN system. (*b*) Post-operative computerized tomography study. (*IMDM, University of Hamburg*)

User interaction can be increased through animation, which conveys large amounts of information by seemingly bringing to life multiple related images. Animation is widely used in entertainment, education, industry, flight simulators, scientific research, and heads-up displays (devices which allow users to interact with a virtual world). Virtual-reality applications permit users to interact with a three-dimensional world, for example, by "grabbing" objects and manipulating objects in the world.

Digital image processing is a companion field to computer graphics, which also deals with images. However, image processing, unlike computer graphics, generally begins with some image in image space, and performs operations on the components (pixels) to produce new images that exhibit some desired feature. *See* IMAGE PROCESSING.

Image presentation and display hardware. Computers are equipped with special hardware to display images. Several types of image presentation or output devices convert digitally represented images into visually perceptible pictures. They include pen-and-ink plotters, dot-matrix plotters, electrostatic or laser-printer plotters, storage tubes, liquid-crystal displays (LCDs), active matrix panels, plasma panels, and cathode-ray-tube (CRT) displays. Images can be displayed by a computer on a cathode-ray tube in two different ways: raster scan and random (vector) scan. *See* CATHODE-RAY TUBE; COMPUTER PERIPHERAL DEVICES.

Liquid-crystal and plasma displays. Liquid-crystal and plasma panel displays are frequently employed in laptop computers. Plasma panels comprise an array of tiny neon bulbs which emit orange light ("in the on" or "intensified" state) under an applied voltage. It remains in this state until it is changed, and thus does not need to be refreshed. Plasma panels typically have about 50–125 cells per inch (20–50 per centimeter) and employ raster technology. The screens are flat, flicker-free, and rugged, making them ideal for military and industrial applications.

A liquid-crystal display is made up of six layers sandwiched together to form a thin panel. The front layer is a vertical polarizer plate. Next is a layer with thin vertical grid wires electrodeposited on the surface adjoining the crystal. This is followed by the thin liquid-crystal layer, a layer of horizontal grid wires, and a horizontal polarizer. The final layer is a reflective layer.

Active matrix panels are liquid-crystal-display panels that have transistors at each grid point. The transistors are used to make the crystals change their state quickly and to control the degree to which the state has been changed. These properties make active-matrix panels attractive display devices for miniature television sets with continuous-tone images. The crystal can also be dyed to provide color. *See* FLAT-PANEL DISPLAY DEVICE; LIQUID CRYSTALS.

Vector displays. In the 1960s, random scan (vector) displays became a popular technique for generating graphics on a screen without using large amounts of computer memory. Vector images are specified as a series of lines maintained in a list. The lines are specified by the coordinates of their end points. These are stored in a display buffer, a contiguous memory containing all of the information required to draw the picture on a cathode-ray-tube screen. The computer cycles through the list, redrawing each line 30 times a second to maintain a flicker-free picture on the screen. One drawback of most random scan displays is that they do not allow for patterned shading except when it is defined as a series of lines.

Raster-scan displays. The most common display for raster scan images is the cathode-ray tube. The raster scan is very similar to a television set. The beam in this system traces a regular pattern on the screen. It usually starts at the upper left corner of the screen and is directed across the screen in the horizontal direction. After completing one pass across the screen, it moves down and traces the next line. Each line is referred to as a scan line. Images are composed of continuous shaded rows and columns of discrete pixels. Thus horizontal and vertical line segments are represented as a group of adjacent pixels in a row or column. The area of computer graphics that is responsible for converting a continuous figure such as a line segment into its discrete representation is called scan conversion.

Raster-scan systems normally refresh the entire screen with the display pattern 30–60 times a second, recreating a pattern that is stored as a bit map in a special high-speed video memory. Every pixel in the display corresponds to one or more bits of memory. The total number of pixels in an image is a function of the size of the image and the number of pixels per unit length; the latter number is referred to as the resolution of the image. A 2 by 1 in. (5 by 2.5 cm) image at a resolution of 300 pixels per inch (120 pixels per centimeter) would have a total of 180,000 pixels.

The quality of an image is determined by its spatial and contrast resolution. The spatial resolution (sharpness) is determined by the number of rows and columns of pixels. For example, a high-resolution image might consist of about 1000 by 1000 pixels. The contrast resolution is the number of different shades of gray in a monochromatic display or the number of possible colors in a color display. The control over the intensity or color of each pixel is obtained by storing multiple bits for each pixel. For example, three bits will yield eight intensity levels. These bits are then used to control not only intensity but color. Higher-resolution images require more data to represent the image and more solid-state memory to store the image. For color images, three times as many bits are needed, one for each of the three additive primary colors from which the image is made; for example, 8 bits for each of the colors red, blue, and green (yield a total of 24 bits in a so-called full-color system. Systems with 24 bits per pixel of color provide for up to 2^{24} or 16,777,216 different colors to produce the smooth shades required of realistic images.

A need for only a small number of colors in a given image is often coupled with a need to change colors from image to image. A look-up table can be employed in such situations. This display device facilitates reductions in storage requirements that never the less satisfy the need to support a sufficient number of simultaneous colors. The look-up table has as many entries as there are pixel values. A pixel's value is not used to control the beam intensity directly but rather as an index into the look-up table. The entry in the table is then used to control the beam's intensity or the color of the screen. For example, a pixel value of, say, 92 is used to access entry number 92 in the table, and the value stored in that entry is then used to control the beam.

Color displays use a shadow-mask cathode-ray tube, which is similar to the television picture tube. Here, the inside of the tube's viewing surface is covered with closely spaced groups of red, blue, and green phosphor dots. The dot groups, arranged in a triad, are so small that light emanating from the individual dots is perceived as a mixture of the three colors. Very high resolution displays require masks to be fine spaced. The triads are placed on about 0.20-mm centers, whereas home television sets are placed on about 0.60-mm centers. This distance is called the pitch of the tube. *See* ELECTRONIC DISPLAY; PICTURE TUBE.

Interactive techniques. Interaction with the object takes place via devices attached to the computer, starting with the keyboard and the mouse. Each type of device can be programmed to deliver various types of functionality. The area of computer graphics that deals with effective use of interactive devices and the protocols that facilitate computer-human interaction is called interactive techniques.

The quality and ease of use of the user interface often determines whether users enjoy a system and whether the system is successful. In critical applications such as air-traffic control and command/control or in "situation display" problems, a poorly designed user interface can contribute to accidents.

Interactive graphics aids the user in the creation and modification of graphical objects and the response to these objects in real-time. The most commonly used input device is the mouse. It is a small hand-held device whose relative motion across a surface can be measured. The roller ball on the underside of the mechanical mouse is converted into digital values that determines its movement in two orthogonal (x, y) directions. The mouse typically specifies locations in image space. Here, the cursor is often displayed as visual feedback to allow the user to see the locations being specified. It could also be used to select an item in a pull-down or pop-up menu. Often in this case the item selected is highlighted or framed in a filled rectangle, since the location of the cursor becomes irrelevant.

Other kinds of interaction devices include the joystick, trackball, light pen, and data tablet. The trackball is often described as an upside-down mouse. The user operates the trackball by dragging the palm across it. The motion of the ball rotating freely within a housing is measured by potentiometers or shaft encoders. Mice are "relative" devices that have no absolute origin—only changes from previous positions are reported—and thus they can be moved, lifted, and moved again. However, the joystick is homed in a center position from which it can be moved left, right, backward, or forward. Here again potentiometers sense the movements. *See* POTENTIOMETER.

A data tablet is a flat surface, from 6 by 6 in. (15 by 15 cm) to 4 by 6 ft. (1.2 by 1.8 m) or larger in size, which is capable of detecting the position of a movable stylus held by the user. Most tablets use magnetic signals generated by electrical pulses applied to a patterned grid which is embedded in the tablet to sense the position of the stylus. The tablet is an absolute device as there is a frame of reference or origin to which the position of the stylus is referred. Through this device, the physical movement of a user's hand can be converted into the movement of a cursor of an object on the display screen.

Voice recognition systems, which free the user's hands for other activities, provide other means of interaction. They analyze the waveforms created when users speak. These systems must, however, be trained to recognize the waveform of a speaker.

Some of these two-dimensional (2D) devices can be modified to extend to three dimensions (3D). The space ball (**Fig. 3**), an example of a three-dimensional device, is a rigid sphere containing strain gages. The user can pull or push the space ball in any direction

Fig. 3. Space ball motion-control input device, which resolves fingertip pressure into translation in three dimensions and rotation, providing six-degrees-of-freedom control. (*Labtec, Inc.*)

to provide three-dimensional translation and orientation. The data glove is a device capable of recording hand movements. It records both the position of the hand and its orientation as well as finger movements. The data glove is capable of a simple gesture recognition and general tracking of hand orientation.

Computer graphics and image processing complement each other. Remarkable visual effects can be achieved by using a combination of these technologies.

Image representation. The representation and description of objects requires the creation of geometric models. Geometric objects have important characteristics such as size, shape, and orientation and certain spatial relationships to each other.

The surfaces of objects in an image can be described as a collection of polygons or patches that are stitched together to make up the scene. This method is called geometric or shape modeling. Polygons work reasonably well for objects that have flat surfaces, like buildings. When surfaces are highly curved, it is generally necessary to cover the surface with many small polygons, which require increases in storage and in execution time. Patches are very efficient at representing surfaces of objects to a given accuracy. Often fewer patches are required, but the equations require more computation than those used for polygons.

The production of a computer-generated image requires additional steps. The designer has to specify the objects in the image and their shapes, positions, orientations, and surface colors or textures. Further, the viewer's position and direction of view (camera orientation) must be specified. The software should calculate the parts of all objects that can be seen by the viewer (camera). Only the visible portions of the objects should be displayed (captured on the film). (This requirement is referred to as the hidden-surface problem.) The rendering software is then applied to compute the amount and color of light reaching the viewer eye (film) at any point in the image, and then to display that point. Some modern graphics work stations have special hardware to implement projections, hidden-surface elimination, and direct illumination. Everything else in image generation is done in software.

Solid modeling is a technique used to represent three-dimensional shapes in a computer. The importance of solid modeling in computer-aided design and manufacturing (CAD/CAM) systems has been increasing. Engineering applications ranging from drafting to the numerical control of machine tools increasingly rely on solid modeling techniques. Solid modeling uses three-dimensional solid primitives (the cube, sphere, cone, cylinder, and ellipsoid) to represent three-dimensional objects. Complex objects can be constructed by combining the primitives. *See* COMPUTER-AIDED DESIGN AND MANUFACTURING; COMPUTER-AIDED ENGINEERING.

Color models. Color specification using the RGB (red, green, and blue) color model is an additive process. The appropriate primary color component is added to black to yield a desired color. This method matches closely the working principles of the display monitor. The complementary color model, called the CMY (cyan, magenta, and yellow) model, defines colors using a subtractive process. This model matches the working principles of the printer. It begins with white, and the appropriate color is subtracted to yield the desired color. *See* COLOR.

Image synthesis. The creation of images by simulating a model of light propagation is often called image synthesis. The goal of image synthesis is often stated as photorealism, that is, the criterion that the image look as good as a photograph. Rendering is a term used for methods or techniques that are used to display realistic-looking three-dimensional images on a two-dimensional medium such as the cathode-ray-tube screen. A three-dimensional image has to be projected before it is displayed on a two-dimensional display medium. The display of a wire-frame image (**Fig.** 4*a*) is one way of rendering the object. The most common method of rendering is shading. Generally, rendering includes addition of texture, shadows, and the color of light that reaches the observer's eye from any point in the image. The specification of this color (as determined by each of the red, green, and blue color components) is computed by the rendering software that is used to generate the image.

The concept is somewhat related to operation of a camera that is used to photograph an object that is illuminated by a light source, albeit simplified in the

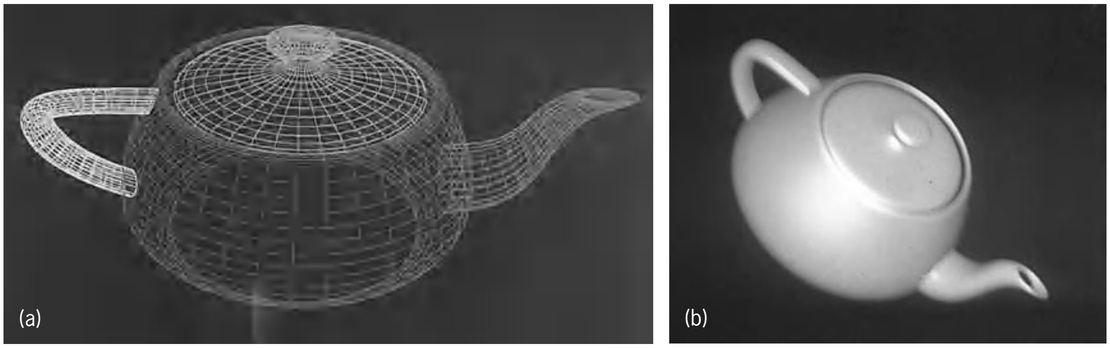

Fig. 4. Renderings of a teapot. (*a*) Wire-frame model with 512 polygons. (*b*) Smooth shading (non-shiny). (*A. Tokuta, Technical Report, Department of Computer Science and Engineering, University of South Florida*)

Fig. 5. Animation frame showing both reflections from and refraction through Geri's eyeglasses in Pixar's Geri's Game. (*Pixar Animation Studios*)

model. Light energy emanating from the source interacts with the physical environment, is reflected off the surface of the object through the camera lens, and is registered on the film, forming an image of the object. The parts of the object closer to the light source should appear brighter, while the parts farther away or directed away from the light source should appear darker. The mathematical model that is used for these types of optical phenomena is called a local illumination model. It tracks the light energy coming directly from the light source to a particular object surface but does not fully account for the energy arriving at the surface. Light energy is also reflected from other objects in the environment, and energy can pass through transparent and translucent objects in the environment (**Fig. 5**). Models of computation that strive to account for the accurate transportation of light are referred to as global illumination models.

Producing realistic images involves both physics and psychology. The psychology of visual perception is extensively documented. The amount of light propagation can be computed by the rendering software, based on simple models. Shading techniques (constant, Gourad, or Phong) can be applied to evaluate the illumination model at various locations. In constant shading, a single color is computed for an entire polygon, based on the position of the light source. This method of shading tends to produce poor results because the human visual system exaggerates changes in intensities that may exist between adjacent polygons that may have different shading.

Consequently, some form of interpolation is often used. For the Gourad shading, the evaluation of the model is done once for each vertex. The intensities are then interpolated across the polygon. The direction of the normal to the surface must be taken into account in the calculation of the intensities; here, the vertex normal that is used is the computed average of the adjacent surface normals. In the case of Phong shading (Fig. 4*b*), the evaluation of intensity is done once for each pixel. The normal vector that is used in the evaluation is computed, however, as the interpolated values of normals at the vertices. This has the added advantage of preserving specular highlights.

The character of the light that is reflected from a surface of an object depends on the composition, direction, and geometry of the source, the orientation of the surface, and the surface properties of the object. It is also characterized as either diffusely or specularly reflected. An ideal mirror reflects light that strikes it, and each ray that hits a point on the surface is reflected in one direction. An observer who happens to be located in that direction, and is looking at the point, should see a reflection of the light source in its original color and not the surface itself. This ideal reflection is called specular. Specular reflection is directional; that is, it depends on the angle of incident light. An ideal dull surface reflects light in all directions because the microfacets constituting the surface are considered to be pointing in different directions. Thus an observer perceives the same light, intensity to be reflected from a given point regardless of the observer's position. This type of reflection is called diffuse. Each point on a surface is thus considered to emit three types of light: diffuse light, specularly reflected light, and transmitted or refracted light. Each ray leaving a surface comprises the sum of these three contributions. Modeling of shadows, requires additional computation. *See* ILLUMINATION; REFLECTION OF ELECTROMAGNETIC RADIATION.

Ray tracing is a technique that is used to produce realistic images but is view-dependent. This means that the entire computation must be repeated when the observer's position is changed. This method, however, interleaves the determination of visibility, illumination, and shading at each pixel. The basic idea is to trace the paths of rays, from the viewpoint of an observer looking through each pixel in the screen into the image. If the ray hits a surface, reflected and possibly refracted rays are spawned, which in turn are traced to see if they intersect any other surfaces. The final color and intensity of each pixel are determined as the summation of the contributions from each spawned ray.

The radiosity method is view-independent. The radiosity of a surface is the rate at which energy leaves the surface, and is the sum of the rates at which the surface emits energy and reflects or transmits it from that surface. Given an image, the calculations are done only once, even before the visible-surface determination is performed from a desired viewpoint of the observer. Once the global illumination has been determined, it is easy to move the observer to different viewpoints and thus create a series of images. This method uses the principle of conservation of energy (by modeling energy equilibrium in a system of surfaces) to compute the light intensity for each surface in the image, and assumes ideal diffuse surfaces composed as either light sources or reflecting surfaces. *See* CONSERVATION OF ENERGY.

Natural and synthetic objects. Computer-generated images are used extensively in the entertainment world and other areas. Realistic images have become essential tools in research and education. Conveying realism in these images may depend on the convincing generation of natural phenomena. A fundamental difficulty is the complexity of the real world. Existing models are based on physical or biological concepts.

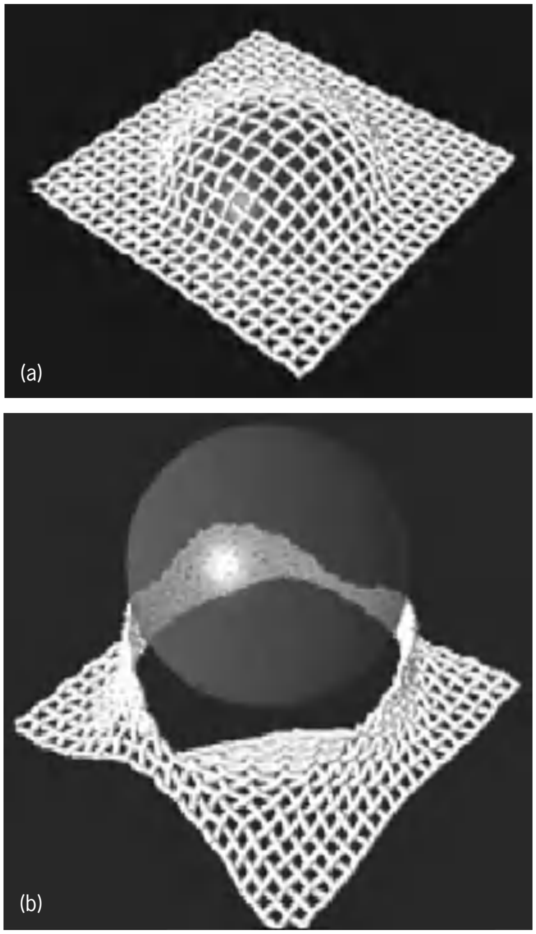

Fig. 6. Example of realistic images based on physical properties. (*a*) Net falling over a physical obstacle. (*b*) Fracture developing in the net. (*D. Terzopoulos and K. Fleischer, Schlumberger Palo Alto Research*)

The behavior of objects can be determined by physical properties or chemical and microphysical properties. (**Fig. 6**).

Many natural phenomena are not efficiently represented by geometric or solid models. Procedural models, fractals, grammar-based models, and particle systems have been used to model a variety of things. Procedural models describe objects that can be modeled from a procedure and a parameter set. The appearances of textured surfaces from wood to marble, and woven material to fur, have been simulated by use of procedural texturing techniques.

Clouds and mountain terrain are examples of objects that have been modeled using fractals. The term "fractal" was introduced by Benoit Mandelbrot to describe a particular attribute of certain natural phenomena. For example, an aerial view of a coastline tends to exhibit a so-called recurrent pattern that is not dependent on the scale of the image. *See* FRACTALS.

Grammar-based models can describe the structure of certain plants and trees. Work in this area is based on a parallel graph grammar called L-system. This system specifies the construction of a plant or tree as a sentence in the language that the grammar generates.

Particle systems have been used to model fuzzy objects such as fire and clouds. An object is represented by a set of particles that evolve over time—each is born, evolves in space, and dies or is extinguished, all at different times.

Volume rendering. Volume rendering combined with animation is a major tool used in visualization. Visualization offers a method to see the unseen. It enables researchers to observe their simulations and computations, thus enriching the process of scientific discovery. A major application of this area is medical imaging (Fig. 1), where volume data are available from positron emission tomography (PET) scanners, for example. *See* SIMULATION.

Computer-integrated manufacturing

A system in which individual engineering, production, and marketing and support functions of a manufacturing enterprise are organized into a computer-integrated system. Functional areas such as design, analysis, planning, purchasing, cost accounting, inventory control, and distribution are linked through the computer with factory floor functions such as materials handling and management, providing direct control and monitoring of all process operations.

Computer-integrated manufacturing (CIM) may be viewed as the successor technology which links computer-aided design (CAD), computer-aided manufacturing (CAM), robotics, numerically controlled machine tools (NCMT), automatic storage and retrieval systems (AS/RS), flexible manufacturing systems (FMS), and other computer-based manufacturing technology. Computer-integrated manufacturing is also known as integrated computer-aided manufacturing (ICAM). Autofacturing includes computer-integrated manufacturing, but also includes conventional machinery, human operators, and their relationships within a total system. *See* COMPUTER-AIDED DESIGN AND MANUFACTURING; FLEXIBLE MANUFACTURING SYSTEM; ROBOTICS.

Agile manufacturing and lean manufacturing. Flexible manufacturing has been subsumed by the concept of agile manufacturing, which presumes that all operations can be virtually instantly reconfigured to satisfy a changing market demand. For example, only cars with certain options are selling, but the marketing department has directed the manufacturing department to gear up to produce models with other options. Agile manufacturing could efficiently reconfigure operations to satisfy the new requirement, or it could create a virtual manufacturing facility by electronically combining the operations of many different locations into the optimum configuration required to meet new market demands.

Lean manufacturing reorganizes and reduces operations to the minimum required to produce certain parts or products at the absolutely lowest cost. Lean manufacturing typically focuses on either market-niche-type products or seeks a virtual monopoly on large-volume low-variability products.

Modern manufacturing enterprise. The CIM factory integrates the traditional hard or process-based technology factory (departments) with software of systems-based technology (nondepartments).

Effectiveness, efficiency, and economy. Manufacturing companies seek the optimal combination of effectiveness, efficiency, and economy. Efficiency is most often associated with transfer-line or assembly-line technology. The best-known developer of this technology was Henry Ford. His Model T factory could produce cars at an unprecedented rate for that time, but the consumer had no choice at all about the specifications of the product. Flexibility is most often associated with robotics and other reprogrammable automation. Effectiveness is usually associated with the soft technology and organizational support structure of the enterprise.

Optimization of the CIM factory is based on specific criteria. By considering efficiency, flexibility, and effectiveness, the CIM factory enables economy of scope. In economy of scope, flexibility is at least as important as efficiency, because the factory is seen to be an ever-changing dynamic environment which must always respond quickly to the needs of the marketplace, if not actually lead the need. The traditional factory with both rigid transfer-line technology and a rigid organizational structure cannot satisfy this objective; it strives for maximum volume of each product. In the ideal case, the CIM factory provides for profit with an order quantity of one, that is, when no two products are identical. Within the manufacturing enterprise, the CIM factory combines agility during manufacturing planning and leanness during production.

Organization. The CIM factory concept includes both soft and hard technology. Soft technology can be thought of as the intellect or brains of the factory, and hard technology as the muscles of the factory. The type of hard technology employed depends upon the products or family of products made by the factory. For metalworking, typical processes would include milling, turning, forming, casting, grinding, forging, drilling, routing, inspecting, coating, moving, positioning, assembling, and packaging. For semiconductor device fabrication, typical processes would include layout, etching, lithography, striping, lapping, polishing, and cleaning, as well as moving, positioning, assembling, and packaging. More important than the list of processes is their organization.

Whatever the products, the CIM factory is made up of a part fabrication center, a component assembly center, and a product assembly center. Centers are subdivided into work cells, cells into stations, and stations into processes. Processes comprise the basic transformations of raw materials into parts which will be assembled into products. In order for the factory to achieve maximum efficiency, raw material must come into the factory at the left end and move smoothly and continuously through the factory to emerge as a product at the right end. No part must ever be standing; each part is either being worked on or is on its way to the next workstation.

In the part fabrication center, raw material is transformed into piece parts. Some piece parts move by robot carrier or automatic guided vehicle (AGV) to the component fabrication center. Other piece parts (excess capacity) move out of the factory to sister factories for assembly. There is no storage of work in process and no warehousing in the CIM factory. To accomplish this objective, part movement is handled by robots or conveyors of various types. These materials handlers serve as the focus or controlling element of work cells and workstations (**Fig. 1**). Each work cell contains a number of workstations. The station is where the piece part transformation occurs from a raw material to a part, after being worked on by a particular process.

Components, also known as subassemblies, are created in the component assembly center. Here materials handlers of various types, and other reprogrammable automation, put piece parts together. Components may then be transferred to the product assembly center, or out of the factory (excess capacity) to sister factories for final assembly operations there. Parts from other factories may come into the component assembly center of this factory, and components from other factories may come into the product assembly center of this factory. The final product moves out of the product assembly center to the product distribution center or in some cases directly to the end user. *See* AUTOMATION.

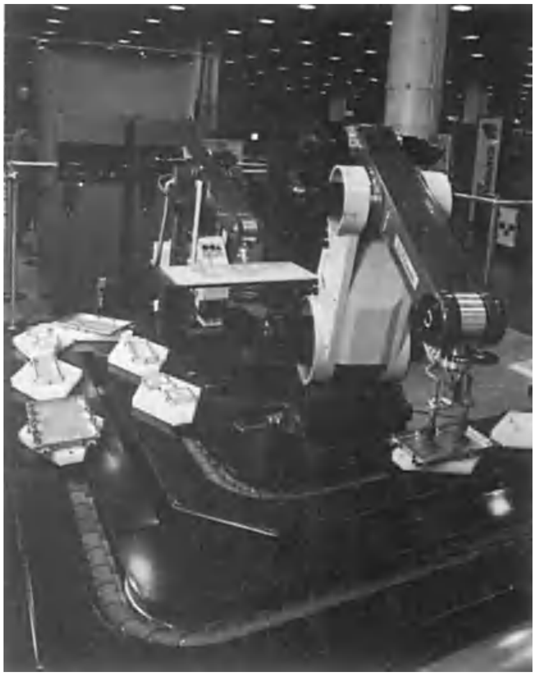

Fig. 1. Typical CIM workstation.

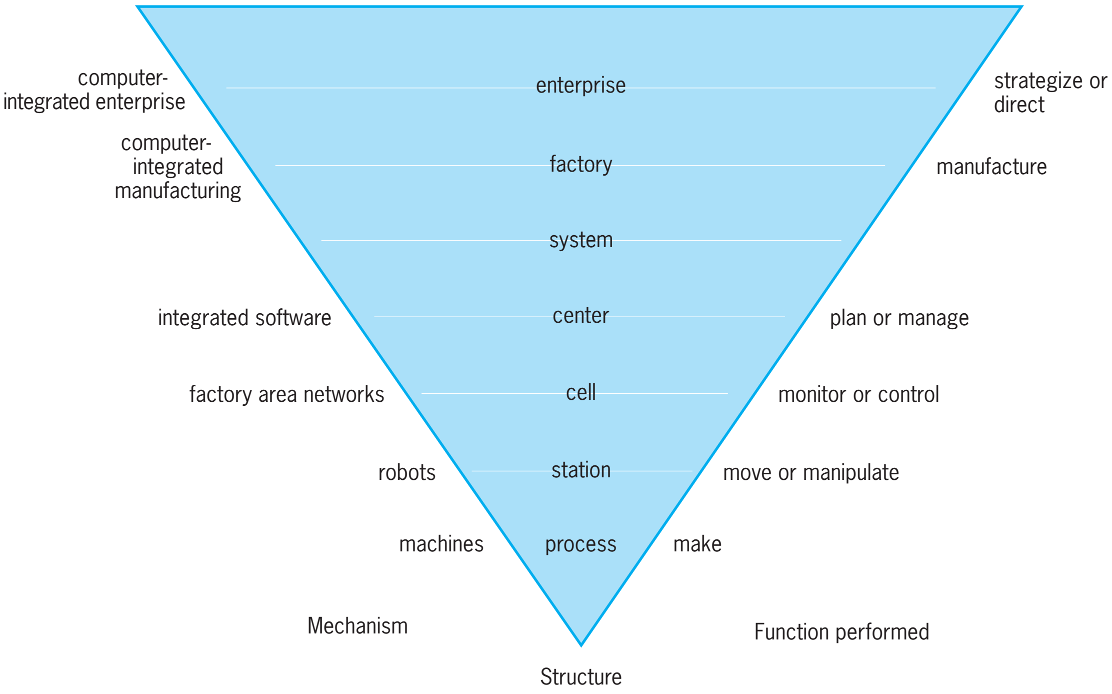

Fig. 2. Diagram of the architecture of manufacturing.

Integration. The premise of CIM is that a network is created in which every part of the enterprise works for the maximum benefit of the whole enterprise. Independent of the degree of automation employed, for example, whether it is robotic or not, the optimal organization of computer hardware and software is essential. The particular processes employed by the factory are specific to the product being made, but the functions performed can be virtually unchanged in the CIM factory no matter what the product. These typical functions include forecasting, designing, predicting, controlling, inventorying, grouping, monitoring, releasing, planning, scheduling, ordering, changing, communicating, and analyzing.

It must be recognized that independent, optimum performance of the individual functions is not as important as their integration with one another, or their integration with the factory floor itself. This integration is brought about in two ways. The first is through an architecture of manufacturing which specifies precisely how and when each function is integrated with the other (**Fig. 2**). The second is through a controller and networks.

For example, a cell controller ensures integration of data between each machine, robot, automatic guided vehicle, and so forth, of the cell. The cell network (**Fig. 3**) actually performs this communication within the cell, and connects cells together into centers. In the cell network, communication is possible between each machine of the network and between different networks. The cell controller itself serves to perform such tasks as downloading part programs or recipes from the CAD system or planning system to each machine in the cell, monitoring actual performance of each machine and comparing this performance to the plan, selecting alternate routing for a part if a machine is not operable, notifying operators of pending out-of-tolerance conditions, archiving historical performance of the cell, and transmitting to the center level on an exception basis the cell performance compared to plan. Typically, the human interface with factory floor operations and intermachine communications is accomplished through networked programmable controllers, personal computers running soft logic, machine and robot controllers, display devices, and programmable logic controllers (PLCs) communicating through Wireless Application Protocol (WAP) devices. These interactions are managed through personal computer–based technology integrated in real time through various communications protocol standards. *See* PROGRAMMABLE CONTROLLERS.

The center level of the CIM factory is all of the policies and procedures that run the factory. These are embodied in computer software, which is in turn based upon an overall integration plan or CIM architecture.

The purpose for the architecture is to provide a blueprint for employing CIM. While there are as many variations of the details of the architecture of the CIM factory as there are factories, the structure of the architecture is generic. The focus is the agile manufacturing system (AMS), which is made up of cells, stations, and processes. The information to be fed back to functions where decisions are made is as important as the product itself. In this example, the functions are defined very broadly and are used only to illustrate the absolute necessity for interaction between functions if the CIM factory is to be made to work efficiently, flexibly, and effectively.

In CIM, as decisions are made, they are tested on a computerized model of the CIM architecture to

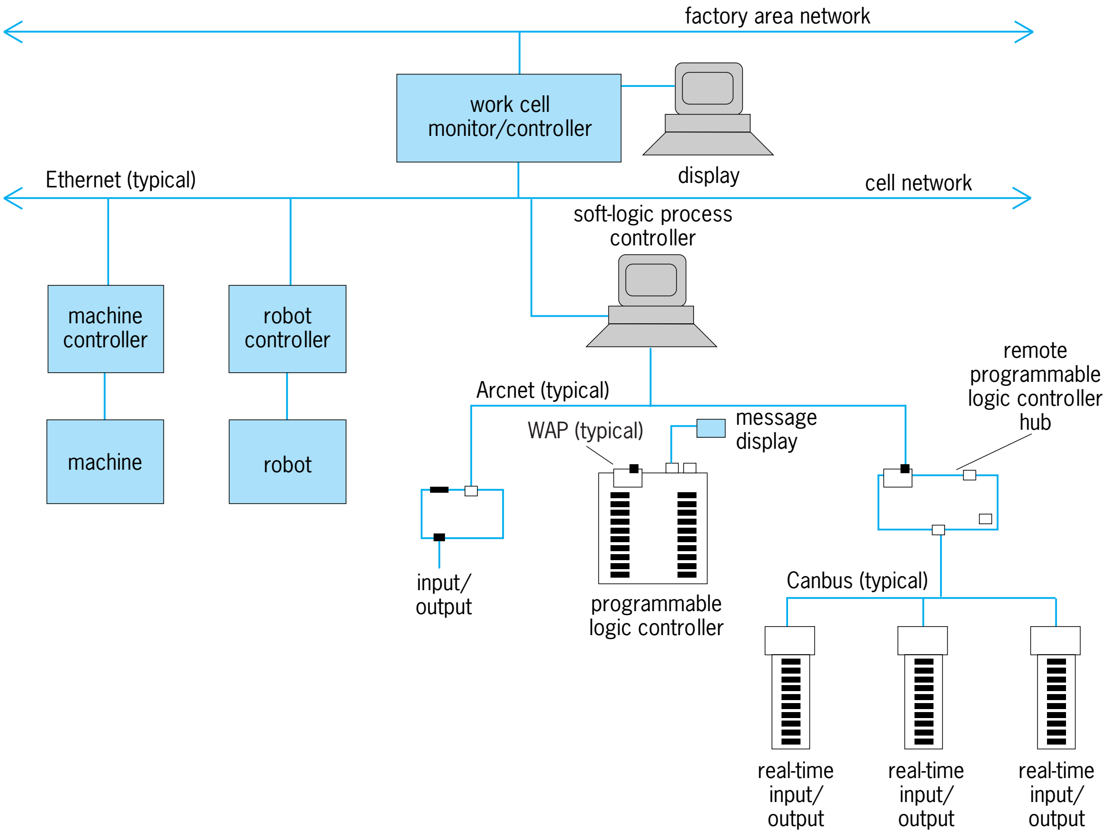

Fig. 3. Organization of a production cell network for computer-integrated manufacturing. Ethernet, Arcnet, Wireless Application Protocol (WAP), and Canbus are international standards for communication.

determine feasibility. Thereby, mistakes are discovered in the computer, not in production in the factory. Simulation and emulation software is used for this purpose. Computer aided software engineering (CASE) software is used to convert the CIM models for decision making into software for operating the CIM factory. Interchangeable and reusable software programs, known as objects, are manipulated by CIM engineers to accomplish this objective. *See* SOFTWARE ENGINEERING. Dennis E. Wisnosky

Computer numerical control

The method of controlling machines by the application of digital electronic computers and circuitry. Machine movements that are controlled by cams, gears, levers, or screws in conventional machines are directed by computers and digital circuitry in computer numerical control (CNC) machines.

Computer numerical control provides very flexible and versatile control over machine tools. Most machining operations require that a cutting tool be fed at some speed against a workpiece. In a conventional machine such as a turret lathe, the turning tool is mounted on a slide with hand-operated infeed and crossfeed slides. The operator manually turns a crank that feeds the cutting tool into the workpiece (infeed) to the desired diameter. Another crank then moves the turning tool along the longitudinal axis of the machine and produces a cylindrical cut along the workpiece. The feed rate of the turning tool is sometimes controlled by selecting feed gears. These gears move the axis slide at the desired feed. A CNC machine replaces the hand cranks and feed gears with servomotor systems. *See* SERVOMECHANISM.

Computer numerical controls allow the desired cut depths and feed rates to be “dialed in” rather than controlled by cranks, cams, and gears. This provides precise, repeatable machine movements that can be programmed for optimal speeds, feeds, and machine cycles. All cutting-tool applications, whether on a lathe, drill press, or machining center, have optimum speeds and feeds, which are determined by carefully weighing the economics of tool life, required production rates, and operator attentiveness. With computer numerical control these parameters are set once, and then they are repeated precisely for each subsequent machine cycle.

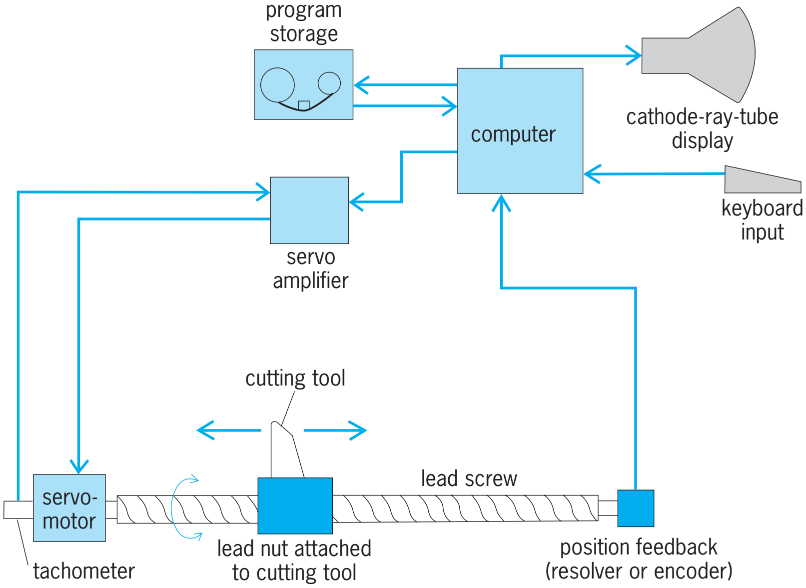

Fig. 1. Schematic diagram of a servo system.

The decision to purchase a CNC machine instead of a conventional machine is a complex one. The CNC machines are usually more complex than conventional machines, which adds to their cost and puts greater burdens on maintenance and support personnel. This added cost is often worthwhile, because of the flexibility and sophistication of the machine. The total cost of purchasing and operating a CNC machine must be weighed against the total cost of purchasing and operating a conventional machine. Complexity of the parts, programming and maintenance costs, and the availability of skilled labor are some of the factors to be considered.

History. Machines with numerical control (NC) became possible in the 1960s, when the development of the transistor made electronic servosystems practical. Earlier NC cutting tools were programmed with punched tape. This technique, while an impressive and productive technology, lacked the sophistication and flexibility that have become available with the development of more advanced systems. Numerical control programs had to be written by hand. Punched tape tended to rip and tear in the hostile environment of the shop floor. Once punched, the programs could not be modified without punching an entirely new tape. Punched tape was also bulky, and if many programs were required, a great deal of space was needed to store the tapes. *See* COMPUTER; TRANSISTOR.

Computer numerical control advanced further with the advent of inexpensive computers in the early 1980s. Instead of being programmed to move to discrete, precalculated locations, the machines can be programmed to perform complex mathematical calculations that determine the locations of the machine's axes. With computer numerical control, milling cutters can be programmed to move in a sinusoidal pattern, for example, by programming a simple sine function into a loop. Previously, each point would have to be explicitly programmed. Programs for computer numerical control can be written parametrically; that is, the same basic motions to be programmed for many different sizes of parts can be controlled with the same program. Programming has become simpler, more powerful, and more user-friendly. It has even become possible to program machine tools graphically at the machine while machining is taking place. *See* PROGRAMMABLE CONTROLLERS.

System components. Machine systems designed for computer numerical control use servosystems to control the position of cutting tools. A typical servosystem (**Fig. 1**) is composed of six parts: a lead screw (ball screw) and lead nut, an electric servomotor, a servoamplifier, a position-feedback device, a velocity-feedback device, and a computer.

Lead screws are precision-ground screws. To prevent any backlash in the screw system, a special lead nut utilizing hundreds of ball bearings tracks the screw. The many ball bearings help equalize and distribute the load forces on the screw. This improves the accuracy, while minimizing friction between the nut and the screw.

Servomotors are specially constructed electric motors. They are designed to operate at very low angular velocities. Although they sometimes drive the lead screw through a gear reduction system, they are usually directly coupled to the lead screw. This direct coupling minimizes any backlash or positioning errors introduced by gears. The motor is required to provide full torque at low, or zero, rpm. Traditionally, servomotors have been direct-current (dc) types. Such motors provide excellent torque at low speeds and have relatively simple electrical requirements, but they have brushes, which are a source of wear and are subject to contamination. The electrical requirements for alternating-current motors are more complex than for dc motors, but the motors themselves are more reliable, especially in hostile environments. *See* ALTERNATING-CURRENT MOTOR; DIRECT-CURRENT MOTOR; GEAR.

The servoamplifier powers the servomotor. Servomotors require precise control of the electrical voltage and current supplied to them. Voltage and current are varied by the servoamplifier. High power is required to accelerate the machine's axes. Moderate power is required to keep them moving. High power (of opposite polarity) is required to decelerate them at the end of a programmed move. Additionally, if the servosystem encounters a physical resistance (such as the load for a heavy cut on a lathe), the servoamplifier must compensate with additional power to keep the lead screw turning at the desired rpm.

The servoamplifier receives a signal voltage from the computer that indicates the desired machine axis direction and speed. A tachometer is mounted on the servomotor and measures the motor's rpm. The output of the tachometer is fed into the servoamplifier, which examines the rpm of the servomotor and varies the voltage and current supplied to the motor to keep it turning at the desired rate. *See* TACHOMETER.

Position feedbacks are provided by resolvers or encoders. These allow the computer to know where the machine's axes are at any time, and to calculate how far the axes must move to reach their programmed positions. Resolvers, and to a lesser extent encoders, are precision devices that must be protected against shock and impact. If not subject to abuse, they generally are very reliable. They are usually directly coupled to the lead screw so that they measure every minute movement of the screw, without the slight backlash that gearing could introduce.

The computer provides overall control of the entire system. It examines the part program, determines the desired positions of the machine axes, then provides special signals to the servoamplifiers to move the servomotors and thereby move the machine's axes. The computer monitors the position feedback provided by the resolvers or encoders. In addition, the computer handles various so-called housekeeping tasks such as displaying the axes' locations on the cathode-ray-tube (CRT). The computer also monitors the program to ensure that dangerous functions, such as opening the chuck in the middle of a cut, have not been programmed.

The speed and computing power of the computer directly affects the quality of the finished workpiece. The computer must examine the axes' locations and velocities, compare their current locations to their programmed locations, and update command signals to the servoamplifiers hundreds or thousands of times each second. Generally, the more often the computer can update in this manner, the smoother and more precise the machine's motions will be. Advances in computing power have led to the construction of CNC machines that can smoothly move six or seven axes simultaneously. This can be accomplished while the computer is still updating the CRT display and checking for errors.

Machine axis layout. Each servo-controlled axis can move either forward or backward in a straight line. The machine tool builder assigns numerical reference (home) locations to each axis. The location of each axis is then determined as a linear measurement from the home position. The home location is usually considered to be 0.0000. A point 2 in. from home would therefore have the coordinate of 2.0000. Programming the machine axis consists of instructing the axis to move to some numerical coordinate.

Most machines require cutting tools to move in at least two directions. On a lathe, this corresponds to the longitudinal and infeed axes (usually labeled Z and X, respectively). Since each axis can move in only one direction, the axes are compounded by being built one on top of the other. In this way, the X axis is mounted on top of the Z axis. A cutting tool mounted to the X axis is therefore also controlled by the Z axis, and has two directions of movement (**Fig. 2**).

Programming. Programming for computer numerical control, at its most basic level, consists of indicating a series of numerical coordinate locations to which the axes will move under program control. Various parameters, such as velocity, are programmed along with the locations of the axes. Ancillary operations, such as turning on both the spindles and the coolant, and specifying the spindle rpm, are also programmed.

Most part programs are broken into lines known as blocks, each of which is a specific program step, executed at one time by the computer. A block may consist of one or more axis locations and a feed rate, a miscellaneous command, or some combination of these. Generally, the execution of each block is completed before the next one is begun.

There are several major classes of part program codes. Although each machine or computer manufacturer is free to define the meaning of each code word, there are several conventions that have been nearly universally adopted.

The block number is coded with an N followed by a number having one to four digits. On older CNC controls, block numbers were necessary, but more modern controls may not require them. Most programmers still use them to assist in reading previously written programs. Block numbers are very useful when part programs must be edited, since they allow specific blocks to be referenced.

The G codes specify how the machine's movements will be made. One of the most common G codes is G01, which activates the linear interpolation mode. In this mode, all the axes move from their current locations to their programmed locations at controlled feed rates, so that they all arrive at the same time. A cutting tool, mounted to both axes, moves in a straight line at the programmed feed rate. If each axis has different distances to traverse in order to reach its programmed location, the one with the longer distance moves faster, so that both axes arrive at the same time. Most part programming consists of moving the axes in coordinated straight lines, and so this function is very common.

A G90 code activates the so-called absolute programming mode. For example, the block N45 G90 X − 2.500 Z − 1.000 will move the X axis to the absolute axis location of −2.500 in., and the Z axis to the absolute axis location of −1.000 in. These

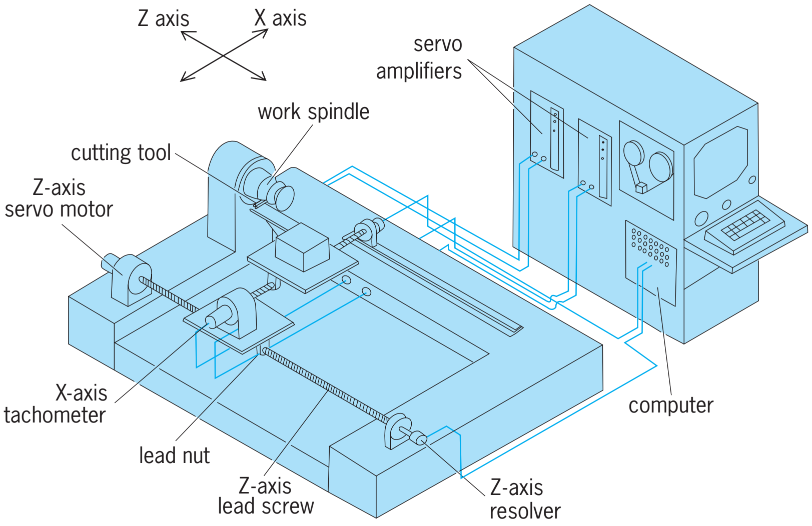

Fig. 2. Diagram of a two-axis computer numerical control lathe.

positions will be reached, regardless of where each axis was before the command was issued.

A G91 code activates the incremental programming mode. In this mode the programmed move is coded as a distance to move from the current location. For example the block N45 G91 X − 2.500 Z − 1.000 will move the X axis 2.500 in. in the negative direction from its current location. The Z axis will move 1.000 in. in the negative direction from its current location. The final locations of the axes will be determined by both their initial locations and the incremental movements programmed.

Just as it is possible to specify the linear interpolation mode, the circular interpolation mode can be specified. This mode causes the axes to move in a controlled circular motion. The programmer merely specifies the radius of the cut and the final location. The computer will automatically calculate the minuscule discrete movements required to move two axes in a coordinated circular fashion.

Parametric programming is the method of programming movements of the axes in terms of computer variables known as parameters. Instead of programming explicit X and Z axes locations in the part program, the programmer indicates that the axes are to move to locations according to specific parameters. Then, by loading the parameter variables with specific values, the computer will move the axes to those locations. This has the advantage of allowing programmers to write programs known as family of parts; these programs have the same basic movements but have differing locations of the axes. The family-of-parts program is logically identical from part to part, but the locations of specific axes may be different.

An example of a parametric program is a program to turn three different truck axle shafts that are identical except for their diameters. A single parametric part program could be written for these three shafts. Instead of specifying the infeed axis locations that correspond to the diameters explicitly, the programmer could have the infeed axis move to the location specified in a parameter variable. By changing the value of the parameter, a shaft with a different diameter can be machined on the lathe with the same program.

In some cases, it is desirable to have all the programs stored in a central computer. The process of direct numerical control can then be used to download the part programs from the central computer to the CNC machine by way of a communication wire. This process eliminates the paper-tape or floppy-disk program storage at the machine. Sophisticated multimachine production lines frequently use this technique to help integrate and automate several machining steps. *See* COMPUTER STORAGE TECHNOLOGY.

In computer-aided manufacturing (CAM), computers are used to assist in programming CNC machines. In sophisticated CNC manufacturing operations, machined parts are first designed on computer-aided-design (CAD) equipment. The same electronic drawing is then used to create the CNC part program automatically. A less advanced version of CAM is the use of high-level part programming languages to write part programs. Special computer programming languages, such as APT and COMPACT II, allow programmers to write complex part programs easily and quickly. For example, indexing a CNC lathe turret may take five or six blocks of a part program. This action can typically be accomplished in just one line of APT or COMPACT II program code. *See* COMPUTER-AIDED DESIGN AND MANUFACTURING.

Typical applications. Computer numerical control machines are used mainly when flexibility is required or variable and complex part geometries must be created. They are used to produce parts in lot sizes of a few pieces to several thousand. Extremely large manufacturing lot sizes frequently call for more product-specific machines, which can be optimized for large production runs.

Complex forms such as pockets, steps, or large radii can be programmed easily on CNC machines. On conventional machines, these features require either special fixturing and tooling or a great deal of operator skill. Often several discrete machining steps can be combined on CNC machines. This saves machine setups and simplifies production processes within a manufacturing plant.

Although CNC machines can help set optimum cutting-tool parameters, the individual cuts made by a CNC machine are usually no faster than those possible on conventional machines of good quality. In fact, sometimes conventional machines can be faster.

Although CNC machines are often simpler to operate than conventional machines, they can sometimes be more difficult. Those CNC machines that allow simultaneous performance of multiple operations require operators who are knowledgable about several production steps. The operator must be able to set up and check more complex parts.

Operators of CNC machines must be able to think numerically. To adjust a machined diameter, the operator usually adds or subtracts a desired amount from the machine's offsets. With conventional machines the operator may only have to turn a crank a few graduations. A CNC machine will require the person to look up an offset on the CRT display, add or subtract the desired diameter change, then type in the new offset. Many people are not adept at such rapid mental arithmetic. In addition, some people find computers intimidating and are not comfortable working with them.

It is often assumed that a machine controlled by a computer is inherently more accurate than an equivalent manual machine, this is not necessarily true. In fact, CNC machines are sometimes less accurate than manual machines. The CNC machines rely on precision-ground slides and screws to position accurately, and normal machine wear can degrade this accuracy. The computer is usually unable to detect or compensate for this wear, while a skilled mechanist can.

Traditionally, CNC machines were mostly lathes and machining centers. Lathes turned axle shafts, drill-bit shanks, or any other multisurfaced cylindrical parts, and machining centers machined engine

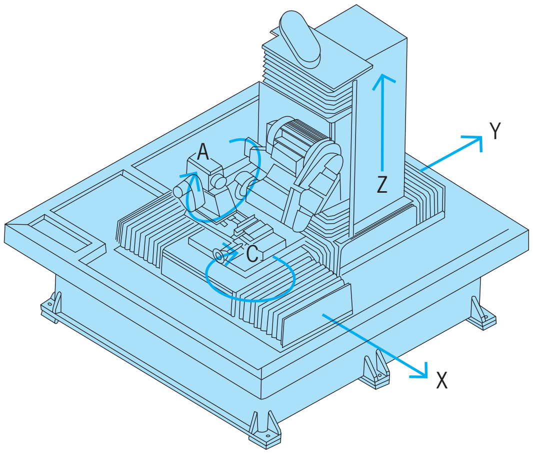

Fig. 3. Five-axis computer numerical control grinder. (*S. E. Huffman Corp.*)

blocks and aircraft rib spars. Now there are complex multiaxis grinders (**Fig. 3**), laser cutters, benders, and many more machines with computer control. Parts such as end mills, airfoils, and universal ball joints can be economically and accurately machined on CNC machines. *See* CONTROL SYSTEMS.

Luggen, *Fundamentals of Computer Numerical Control*, 3d ed., 1994.

Computer peripheral devices

Any device connected internally or externally to a computer and used in the transfer of data to or from a computer. A personal computer (PC) or workstation processes information. Data (unprocessed information) must get into the computer, and the processed information must get out. Information is entered and displayed on a wide variety of accessory devices called peripherals, which are also known as input/output (I/O) devices. Some peripherals (such as keyboards) are only input devices, others (such as most printers) are only output devices, and some are both. Peripherals may be located inside or outside a computer's case (called an internal or external device, respectively). The I/O bus is the collection of circuits where an internal device is attached. An I/O port (such as parallel or serial port) is a connector where an external device is connected (plugged in). *See* DIGITAL COMPUTER; MICROCOMPUTER.

Monitor. The monitor is the device on which images or text produced by the computer operator or generated by the program are displayed on a cathode-ray tube (CRT) or a liquid-crystal display (LCD). Electron guns in a CRT (one in a monochrome monitor, three in a color monitor) irradiate phosphors on the inside of the vacuum tube, causing them to glow. Aside from the presence or absence of color, monitors are mainly distinguished by the size of the screen and the sharpness of resolution. Screens generally range from about 7 in. (18 cm), measured diagonally, for small portable computers to 21 in. (54 cm) for graphic-intensive work. Sharpness is determined by the number of shades of gray, if any, or colors that the monitor, in conjunction with the computer's circuits and memory, can display; the number of pixels (picture elements) per inch; and the dot pitch, the size of the individual phosphorescent dots.

The flat-panel displays on most portable (notebook, laptop, or tablet) computers are known as liquid-crystal displays. LCD flat-panel monitors are superior to CRTs as computer monitors for desktops for a variety of reasons, among them being that CRTs contain hazardous materials (such as phosphors and lead), consume more power, generate more heat, and are more bulky. In place of the vacuum tube coated with phosphors, LCDs use two polarizing filters with liquid crystals between them to produce the image.

A monitor can be connected to an analog or digital video interface. Some flat-panel LCD monitors can be connected as both an analog monitor to one computer and a digital monitor to another and include a "toggle" switch to connect to either. *See* CATHODE-RAY TUBE; ELECTRONIC DISPLAY; LIQUID CRYSTALS.

Keyboard. The computer keyboard, based on the typewriter keyboard, contains keys for entering letters (usually in the familiar QWERTY arrangement), numbers, and punctuation marks, as well as keys to change the meaning of other keys. For example, pressing the "s" key on any keyboard produces a lowercase s, and pressing the "shift" and "s" keys produces an uppercase S. But pressing the "control" and "s" keys on computers running some programs saves a copy of the file being worked on to the disk or diskette, whereas this function is accomplished by pressing the "command" and "s" keys on other systems' keyboards. Other special keys or combinations of keys move the section of the file being viewed, such as "page up," move the cursor (pointer); or perform other tasks, such as "print screen." The function keys, usually a row across the top or along the left side of the keyboard and numbered F1 through F10 or F12, perform tasks that vary from program to program. In some programs, for example, the F1 key brings a "help" file to the screen. Keyboards generally are physically connected to a computer via one of three interfaces: specialized keyboard interface, a serial port, or a universal serial bus (USB). Keyboards also can connect through a wireless IR (infrared) port or Bluetooth (2.4 GHz) port.

Mouse. A mouse is a device that is rolled on the desktop to move the cursor on the screen. The mouse has one to three buttons. In the syntax of computers, the cursor is moved to select the object on which an action is performed, and then one or more buttons are pressed to perform the action. A ball on the bottom of the mouse translates the device's movements to sensors within the mouse and then through the connecting port to the computer. There are also mice that substitute optical devices for mechanical balls, and mice that use wireless infrared or Bluetooth technology. Many mouse actions can be accomplished with a keyboard using substitute keystroke sequences.

Trackball. A trackball is essentially an upside-down mouse, with the ball located on the top rather than on the bottom. Since a trackball is attached and therefore does not require an area in which to be moved, it requires less working space than a mouse (although most trackballs occupy more standing space than a stationary mouse).

Touchpad. A touchpad is a device that senses both a user's finger movement and downward pressure exerted on the device (for example, tapping). The movement of the user's finger on the pad results in a corresponding cursor movement on the monitor in a manner corresponding to the movement of a mouse.

Pointing stick. A pointing stick (for example, the IBM TrackPoint™) is a small eraserlike device that is located in the center (between the "g", "h," and "b" keys) of a keyboard. A user applies pressure on this device to the point in the direction desired for the movement of the cursor.

Joystick. A joystick is a pointing device with a vertical handle that is used principally for games. Moving the handle moves the cursor or other simulated object on the screen; pressing the button or buttons on the base or vertical piece performs an action that depends on the software program.

Touch-enabled device. Touch-enabled devices allow an individual to experience a sense of touch. Such a device typically works with a user's computer screen to create a sense that one is actually touching what appears on the screen.

Light pen. A light pen performs the same functions as a mouse or trackball, but it is held up to the screen, where its sensors detect the presence of pixels and send a signal through a cable to the computer. Light pens seem to be a more natural transition from paper and pencil to computers than mice or trackballs, but they have proven to be tiring to use.

Graphic tablet. A graphics, or digitizing, tablet is a pad with electronics beneath the surface on which one can write or draw using a pointed device, called a stylus. The shapes drawn appear on the device's screen. For any but the simplest projects, it is easier to draw with a stylus and tablet than with a mouse or trackball. Tablets are used on PDAs (personal digital assistant) and tablet PCs (a form of notebook computer).

Microphone. A microphone, sometimes called a mic (pronounced "mike"), is a transducer that converts sound into an electrical signal. Microphones are used as input devices in many applications where speech recognition is involved.

Disk drive. The term disk drive has taken on new meanings in recent years. Originally, disk drives were magnetic media devices. Now, there are many devices that connect via a universal serial bus (USB) port and look like a disk drive to the operating system; however, they are devices with no moving parts that use flash memory.

Magnetic media (hard drives and diskettes). The most common input/output, or storage, device in personal computers or workstations is a hard disk drive, a stack of magnetized platters on which information is stored by heads generating an electrical current to represent either 1 or 0 in the binary number system. The device is called hard because the platters are inflexible, and is called a drive because it spins at 3600 revolutions or more a minute, within a sealed case. The heads are only a few millionths of an inch from the platters. Storage capacity of hard disk drives has grown from a few megabytes of data (1 megabyte $= 10^6$ characters or bytes) to 40 or more gigabytes (10^9 characters). Diskettes, made of flexible plastic (usually polyester) film like that used in recording tape, are stored within a hard shell and are spun by their drives at about 360 revolutions per minute. Their capacity is quite limited, commonly about 1.1 megabytes (3.5-in. diskette), although both smaller and larger ones are available. Since they are removable, they are useful for transporting data.

Bernoulli boxes, zip drives, and jazz drives are similar to a hard drive in storing larger amounts of information and similar to a diskette drive because they can be removed and replaced.

A disk drive as described above is an output device when writing information to the device. When stored programs and data are needed again, it is an input device, reversing the storage procedure to transfer the instructions or information to the computer's working memory for use or further processing. *See* COMPUTER STORAGE TECHNOLOGY.

USB drive. A USB drive, also called a jump drive or flash drive, is a device smaller than a key (it often is placed on a keychain and hence is called a keychain drive) that connects to a computer via the universal serial bus port. USB drives range in size from 16 megabytes to multiple gigabytes of information. They are preferred to floppy disks and zip drives because of their size and capacity. Other devices that connect to a USB through a special adapter and look like a disk drive include compact flash cards and memory sticks. *See* SEMICONDUCTOR MEMORIES.

Optical drives. Most programs and data are stored on magnetic media, including diskettes, hard disks, and tapes. But data can also be stored and retrieved with light, the light of a laser beam reading a pattern of pits on a so-called optical disk.

CD-ROM drive. The most familiar type of optical disk is the CD-ROM (compact disk read-only memory). It is called a compact disk because it is almost identical to audio compact disks; it is read-only because the data can be viewed or heard on the computer but not altered or added to. CD-ROMs have moved from such specialized uses as storing vast amounts of information for businesses and government agencies to consumer products offering software, especially games and reference works, enhanced with video clips, animation, and music and sound effects. CD-R (write) drives are write-only devices, while CD-RW (rewritable) drives can be rewritten numerous times. The capacity of a standard CD-ROM is 650–700 megabytes.

DVD drive. A DVD (digital videodisc) drive is similar to a CD-ROM drive and is backward-compatible in that the can read CD-ROMs. Standard DVDs have a minimum capacity of 4.7 GB of data. There are a number of different formats for DVDs (such as DVD-R, DVD+R, DVD-RW, and DVD+RW). DVD+RW and DVD-RW drives are rewritable. DVDs are excellent backup devices for personal computers. *See* COMPACT DISK; OPTICAL RECORDING; VIDEO DISK.

Tape drives. The early personal computers of the 1970s stored programs and data on tape cassettes in recorders similar or identical to those of audio tape recorders. The drawback with tape storage is that it is sequential; that is, the tape must be gone through from the beginning until the desired data are reached. Disks, whether floppy or hard, are random-access, which means they can go directly to the data. Because of their greater efficiency and speed, disk drives have quickly replaced tape drives as the primary means of data and program storage. Tape drives are still in use for backup storage, copying the contents of a hard disk as insurance against mechanical failure or human error. The relative slowness of tape drives does not matter when they are used for backup because the recording can be scheduled to begin at the end of the workday or work week, and the recovery of the data may never be necessary. Usually, the entire hard disk is backed up in the first session. In later sessions, only files that have changed are recorded (incremental backup). Tape capacity has grown from tens of megabytes of data to more than 100 gigabytes of data, depending on the format and how much data compression is used. *See* MAGNETIC RECORDING.

Camera. A digital camera can be connected to a computer through a USB port. It essentially looks like a USB drive to the computer system. Hence, photos can be moved to and from the camera with simple copy commands or automatically uploaded to the computer via special software supplied with the camera.

A PC or Web camera provides video input to a computer. Such cameras can be used for a variety of applications, including security monitoring. A common use of such cameras is for online "chatting" in which participants can see each other as well hear each other. Such a use requires broadband connections for high-speed transmission and receiving of data.

Scanner. A scanner converts a hard-copy image, such as text, a drawing, or a photograph, into a digital image and sends into the computer for display or further processing. Hand-held scanners are rolled over the image, while flatbed scanners hold the image on a sheet of glass. The image is viewed as a graphics image, not a text image, so it can be altered with a graphics program but not edited with a word-processing program unless the scanner is part of an optical character-recognition (OCR) system. To digitize photographs, a scanner may dither the image (put the dots a varying amount of space apart), or use the tagged image file format (TIFF), storing the image in 16 gray values. Some scanners can use standard video cameras to capture images for the computer. *See* CHARACTER RECOGNITION; IMAGE PROCESSING.

Bar-code reader. Bar-code readers are specialized scanners. A bar-code reader is able to scan and interpret bar codes, the most common of which is a UPC (universal product code) stored as a one-dimensional bar code, where each digit is represented by the ratio of the widths of adjacent stripes and white areas. Such bar-code readers are found on products in grocery stores and other establishments. Two-dimensional bar-code readers are able to read bar-codes that store information along the height as well as the length of the code. Common examples of such bar codes are those printed on income tax forms by tax software.

RFID reader. An RFID (radio-frequency identification) reader is used to poll an RFID tag with radio signals sent via its antenna. The tag in turn responds with identification information sent to the reader. Hence, RFID readers are technically input/output devices.

Printer. This device puts text or other images produced with a computer on paper or other surfaces. In the early days of personal computers, it was widely believed that computers would lead to the paperless office. But because of the convenience of paper copies and the ease of duplicating them, the personal computer and printer have resulted in a great increase in paper documents. Printers are either impact or nonimpact devices.

Impact printers. A daisy-wheel or thimble printer is so called from the shape of the elements bearing raised images of the characters that strike the paper through an inked or carbon ribbon. They produce printouts similar to those from a typewriter. The quality of the printouts is high, but they are limited to the characters contained on the printing element, and their speed, perhaps 30 characters per second, which is considered too slow.

Dot-matrix printers produce their images by striking a series of wire pins, typically 9, 18, or 24, through a ribbon in the pattern necessary to form the letter, number, line, or other character. The quality of the printout varies. A matrix with a small number of pins will produce characters in which the individual dots can be distinguished; one with a large number of pins can produce characters of a crispness that rivals the quality of daisy-wheel or laser printers. Some dot-matrix printers can strike a line a second time, with the dots slightly offset to produce more solid characters but with a penalty of reduced speed.

A thermal printer uses heated pins against heat-sensitive paper. The disadvantage of this type of printer is that it cannot print on standard paper. Many store receipts are printed on small thermal printers.

Line printers generally print a line at a time. There are two types of line printers: drum printers and chain (or "train") printer. Chain printers use a chain with a print "slug" for each character that can be printed. As the chain moves across the printer, a print hammer strikes the slug against a ribbon from the back of the paper resulting in the struck character being printed in that position. A drum printer uses a similar method of hammers behind the paper striking against a rotating drum. Chain and drum printers can operate at speeds of thousands of lines per minute.

Nonimpact printers. Laser printers are similar to photocopying machines. A laser beam is directed by a rotating mirror to draw the image on a drum, where it is changed to an electrostatic charge that attracts a fine powder, called toner. The paper, also charged, rolls on the drum and attracts the toner's image, which is then fused to the paper by heat. The image can be formed, with a sharpness of 300 dpi (dots per inch) or more, at a speed of four pages or more per minute. The quality of laser printer output is the highest generally available. However, laser printers cannot print through multipart forms or, usually, on wider paper, so dot-matrix and even daisy-wheel printers have not been totally abandoned. *See* PHOTOCOPYING PROCESSES.

Ink-jet printers carry their ink in a well, where it is turned into a mist by heat or vibration and sprayed through tiny holes to form the pattern of the character on paper, much as a dot-matrix printer does by direct impact with the ribbon. The quality of the printout rivals that of laser printers, although ink-jet printers can suffer problems with clogging, smearing, and speed.

Color printers. Printers designed to print images in one color or a full range of colors may use similar technologies to black-and-white printers. Most color printers use ink-jet and laser technology. Some color printers are thermal-transfer printers, in which heat melts colored wax onto the paper. Many color printers also provide for photo printing of digital photos. *See* PRINTING.

Modem. A modem (modulator demodulator) connects one computer to another, ordinarily through the telephone lines, to exchange information. A modem sending data modulates the digital information from the computer into tones, the analog signals that can be transmitted over a telephone line. A modem receiving data demodulates the tones coming from a telephone line back into digital information for its computer. The speed of a modem is measured in bits per second (bps), and the speed for most dial-up modems is 28 to 56 kbps (kilobits per second). [The baud is occasionally and incorrectly used as a synonym for bps.] Higher speeds are preferable not only for convenience but also for reducing telephone charges. The communicating modems operate at the highest speed that they have in common, or the highest speed that the quality of the telephone connection permits. Most modems also send and receive facsimile images. A cable modem operates over a coaxial or fiber-optic cable. The speed of cable modems is over 1 Mbps (megabits per second). *See* MODEM.

Multifunction devices. While printers are typically considered output devices, some are multifunction devices that include a scanner, a laser or color ink-jet printer, and a fax modem. Because the multifunction nature of these devices, they can also operate as a standalone fax machine, a copier, or a color copier (if the printer is a color printer). *See* FACSIMILE.

Computer programming

Designing and writing computer programs, or sequences of instructions to be executed by a computer. A computer is able to perform useful tasks only by executing computer programs. A programming language or a computer language is a specialized language for expressing the instructions in a computer program. A person engaged in computer programming is commonly called a programmer. Two major stages can be identified in a typical process to develop a computer program: problem solving and implementation.

Problem solving. In this stage the programmer gains a full understanding of the problem that the computer program under development is supposed to solve, and devises a step-by step procedure (an algorithm) that, when followed, will solve the problem. Such a procedure is then expressed in a fairly precise yet readily understandable notation such as pseudo code, which outlines the essentials of a computer program using English statements and programming language–like key words and structures. *See* ALGORITHM.

A useful example concerns the problem of finding the greatest common divisor (gcd) of two given positive integers. After an analysis of the problem, a programmer may choose to solve the problem by the procedure described by the following pseudo code. (In the pseudo code, the modulus operator produces the remainder that results from the division of one integer by another; for example, 15 modulus 6 yields 3.)

```
1) Let x and y be the two given integers
2) As long an x and y are greater than 0,
   repeat lines 3–5
3)     if x is greater than y
4)         then replace x by the value of x
           modulus y
5)         else replace y by the value of y
           modulus x
6) If x is 0
7)     then y is the gcd
8)     else x is the gcd
```

See NUMBER THEORY.

Lines 3–5 and 6–8 are examples of the selection control structure, which specifies alternative instructions and enables a computer to choose one alternative for execution and ignore the other. Lines 2–5 form a repetitive control structure (commonly called a loop), which causes the computer to execute certain instructions (lines 3–5) repeatedly.

Programmers indent to show the structural relationship among the statements and to enhance the readability of the program. In the example, indentation makes it clear that lines 4 and 5 are part of the selection structure beginning at line 3, that lines 3–5 are part of the loop that begins at line 2, and that lines 7 and 8 are part of the selection structure that begins at line 6.

An algorithm developed to solve a given problem should be verified to ensure that it will function correctly. The following list shows how the above procedure derives the gcd of 48 and 18 by successively modifying the values of x and y.

x	y
48	18 (Let x be equal to 48 and y equal to 18)
48	18 (48 modulus 18 is 12, which replaces 48)
12	18 (18 modulus 12 is 6, which replaces 18)
12	6 (12 modulus 6 is 0, which replaces 12)
0	6 (since x is 0, the loop ends and 6 is the gcd)

Implementation. In this stage the pseudo-code procedure developed in the problem-solving stage will be expressed in a programming language. There are numerous programming languages, in two broad classes: low-level languages, which are difficult for human programmers to understand and use but can be readily recognized by a physical computer; and high-level languages, which are easier for human programmers to use but cannot be directly recognized by a physical computer. Nowadays most computer programs are first written in a high-level language and then translated into an equivalent program in a low-level language so that a physical computer can recognize and obey the instructions in the program. The translator itself is usually a sophisticated computer program called a compiler. *See* PROGRAMMING LANGUAGES.

Shown below is the gcd-finding procedure written in a widely used high-level language called C++.

```
/*********************************************************
 * The function findgcd computes the greatest   *
 * common divisor of two int parameters, and    *
 * returns the result as an int value           *
 *********************************************************/
 int findgcd (int x, int y)
 {  while (x > 0 && y < 0)
          if (x > y)
                  x = x % y;
          else    y = y % x;
    if (x == 0)
                  return y;
          else    return x;
 } .
```

The text beginning with /∗ and ending with ∗/ (the first five lines above) is a program comment. Program comments are not executable instructions and do not affect the functioning of a computer program in any way, but are intended as a way to document a computer program. Appropriate program comments enhance program readability and are considered an important part of a computer program. A more readable program is usually easier to enhance or modify when such needs arise later. The rest of the above text is C++ code (instructions in the language C++) to compute the gcd of two given integers. Indentation in C++ code serves the same purpose as in pseudo code. It is obvious that the above C++ code closely parallels the pseudo code developed previously, as they both express the same abstract procedure.

Syntax errors and logic errors. When a program in a high-level language is being compiled (translated) into machine-executable instructions, the compiler is usually able to detect syntax errors in the program. Syntax errors reflect the incorrect use of a programming language and must be corrected before a program can be successfully compiled. However, error-free compilation of a program does not guarantee that the program will function correctly when it is executed by a computer. Execution of such a program on a computer may not yield the desired result if there is a logic error in the program. Logic errors often require more skill to correct than syntax errors. In order to identify the source of an error in program logic, a programmer may need to revisit both the problem-solving and the implementation stages in the program development process.

Top-down design. Seldom is a large computer program constructed as a single, monolithic entity. The problem that a program is intended to solve can usually be divided into subproblems, each of which can often be further divided into even smaller subproblems. The process can be repeated until all subproblems are sufficiently small and easy to solve. Known as top-down design or stepwise refinement, such repeated decomposition of a large, complex task into smaller, more manageable ones is a widely accepted principle for designing large, complex computer programs.

Object-oriented programming. Object-oriented programming is a way to structure a computer program. The object-oriented paradigm has gained widespread acceptance in recent years and is supported by such widely used languages as C++ and Java. An object includes relevant data and operations on the data as a self-contained entity. Interaction with an object can be made by invoking the object's operations. Each object is an instance of an object class. Object classes may be related by inheritance; one class may be a subclass (specialization) of another class. At the center of an object-oriented program design is a collection of objects that represent entities in the application domain. Identifying the objects and object classes, the relationship among the object classes, and the interactions among the objects is a major issue in designing an object-oriented program. *See* OBJECT-ORIENTED PROGRAMMING.

Language processors. Although many widely used programming languages are processed by compilation into machine-executable instructions, some programming languages (for example, LISP and Prolog) are usually interpreted instead of being compiled. When a computer program is interpreted, it is directly executed by another program called an interpreter without being translated into low-level, machine-executable instructions. Some other languages are processed by a hybrid approach. For example, a program in the language Java is first compiled into an equivalent program in an intermediate-level language, which is executed by an interpreter. *See* COMPUTER; DIGITAL COMPUTER. Computer security

The process of protecting against threats to computing systems. A threat is an event that can cause harm to computers, data or programs, or computations. A failure of computer security occurs because of a vulnerability or weakness in a computing system. A threat agent—person, event, or circumstance—exploits a vulnerability. Computer security involves protecting against failures of availability, integrity or correctness, and confidentiality or privacy.

A failure of availability is also known as denial of service. Partial denial of service is lack of capacity or unacceptable responsiveness. Computer users expect programs and data to be available on demand to meet computing needs. Applications such as power generation, stock trading, and even airplane cockpit navigation and aspects of medical care have become so dependent on computing that loss of availability becomes a serious threat to life or society. Even on a less dramatic level, people have become dependent on computers in aspects of everyday life, and so maintaining expected availability of computers is probably the most important of the three goals of computer security.

Integrity means different things in context: sometimes it means that data or programs should be returned exactly as they were when they were recorded, or that modifications to data or programs should be made only by authorized persons, or by authorized programs, or in certain ways, or that the quality of data should be maintained. Data and programs should meet the demands of the way in which they are to be used.

The third category of failure is loss of confidentiality or privacy or inappropriate disclosure. Privacy of personal information or of data about individuals is a significant concern, as is that of sensitive corporate data (such as trade secrets and proprietary information) and government classified data.

The categories of security failures relate to authorized or acceptable behavior. In order for actions to be authorized or acceptable, a security policy must define who is allowed what access to what resources, what is to be protected, against what threats, to achieve what goals.

Computer users explicitly or implicitly perform a risk analysis by assessing the threats to computing, the likelihoods of these threats, and the harm that could occur from actualization of these threats. Risk must be balanced against the value of computing. Users select controls that prevent exploitation of one or more vulnerabilities as a means of lowering risk. Controls can be physical (such as a lock on a door), procedural (such as a policy that only supervisors can modify critical data items), or technical (such as a program control that blocks access to the password file). Controls can alter the balance among the three categories of failure: a high degree of confidentiality can reduce the availability of a system. *See* RISK ASSESSMENT AND MANAGEMENT.

Technical Controls

Technical controls can be a part of a computing system or application, or they can be added separately. If controls are added to an existing system, they must be integrated properly so that they function as expected.

Security enforcement mechanisms. A computing system must first be able to determine with high assurance the identity of the person who is seeking access (a process called identification and authentication), and the system must then verify that this person's proposed access is consistent with the security policy (a process called access control).

Identification and authentication. Identification is typically performed by logging in or entering a username. But after entering a name, a user may be asked to prove it, so that the system can be certain that one user is not trying to impersonate another. A user can authenticate an identity based on (1) what the user knows, such as a password, (2) who the user is, such as a physical characteristic (for example, a fingerprint), or (3) what the user possesses, such as a token. An authenticator must be something that cannot be easily forged, lost, forgotten, or guessed, while still making it easy for the legitimate owner to use. Techniques can use two or more approaches.

User passwords are commonly employed. Password guessing attacks use computers and actual dictionaries or large word lists to try likely passwords. Brute force attacks generate and try all possible passwords. To block these attacks, users should choose strong passwords.

Physical characteristics can be determined by biometric devices. In addition to fingerprints, voice recognition, retina patterns, and pictures are used. Although biometric authentication devices can be expensive, they are less susceptible to forgery and guessing than other methods, and they tend to be easy for users to adopt. *See* FINGERPRINT.

Tokens are widely used. Identity cards containing magnetic stripes or other elements that can be sensed combine computer access control with physical access control. Some identity cards contain small processors; these cards, called smart cards, can perform computation to guard against forgery. Another form of token resembles a pocket calculator; it is used for challenge-response, in which the user is given a challenge, a problem to solve, to which the calculator provides part of the answer. Each time the user seeks authentication, a different challenge is set, with a different corresponding answer. Challenge-response is especially desirable with computer network authentication because, even if someone intercepts the challenge and response, the interceptor cannot later reuse the response for impersonation because the challenge will be different.

Access control. The system uses a validated user identity to limit the actions the user can perform. An access control policy is a series of acceptable triples (user, object, action), such as (system administrator, password file, modify), meaning that the user "system administrator" is allowed to perform the action "modify" on the object "password file." An access control list (ACL) is a set of these triples. Access control lists can be represented as a two-dimensional matrix, as a set of rules, or in other ways.

Before permission to access an object is allowed, a reference monitor (also known as a reference validation mechanism or access control mechanism) checks that the access is allowable. A reference monitor must be complete (invoked to validate every reference permission), correct (made to implement the intended access control policy exactly), and tamperproof (unable to be disabled).

Reference monitors can simply process a representation of the access control policy in list or table form. Alternatively, they can process capabilities, which are prevalidated access "tickets." The access control system gives a user a capability to perform a certain access on a particular object, and the user later presents the capability to a reference monitor, which will inspect the capability and allow the access. Capabilities are useful in networked and distributed systems, in which access control may be done at one point and actions on objects may be done elsewhere. The Kerberos system is a popular distributed access control system based on capabilities.

Cryptography. A valuable tool in computer security is cryptography or encryption. Encryption is the process of transforming data so that the data are not readily understandable to unauthorized users; consequently unauthorized people cannot modify encrypted data in a knowledgeable way. Encryption is an important tool in computer security because it provides concealment and immunity to modification, so that it can be used to protect integrity and confidentiality. Cryptography alone is not a security control; it is a technology upon which controls can be based.

Encryption is a transformation function. Data to be encrypted are called plaintext, and the encrypted form is called ciphertext. The encryption function E is denoted $C = E(P)$, where P is a body of plaintext and C is its resulting ciphertext. There may also be a decryption function D that reverses the effect of encryption, so that $P = D(C) = D(E(P))$.

Encryption is a means by which two people can share a secret: one encrypts the secret and the other decrypts it. To facilitate sharing secrets using encryption, people use keyed encryption. A key is an additional parameter that tailors the encryption function, in the same way that a key tailors a basic lock so that it can be opened only by someone possessing the key. The key must be supplied to encrypt or decrypt, and so a single algorithm can represent many different encryptions with different keys.

Key management—arranging the distribution, revocation, and replacement of cryptographic keys—is very difficult, especially in a situation with many users who have no common basis for trust, as is true in many computing systems. The implementation of encryption must be secure in order for the encrypted results to protect the data adequately. *See* CRYPTOGRAPHY.

Security of Programs

Computer programs are both part of the protection and part of the things protected in computer security. Programs implement access controls and other technical security controls. But those same programs must be protected against accesses that would modify or disable their ability to protect. And those programs must be implemented correctly.

Correctness, completeness, and exactness. A computer program is correct if it meets the requirements for which it was designed. A program is complete if it meets all requirements. Finally, a program is exact if it performs only those operations specified by requirements. Computer security requires correct, complete, and exact programs, and nothing more. A program has inevitable side effects. For example, a program inevitably assigns values to internal variables, uses computing time, and causes entries to be generated in audit logs. Although side effects seem benign, they can be used maliciously to leak information. The exactness requirement really concerns only those significant operations specified by requirements, but in security almost any side effect can be significant. Determining which additional actions are security-relevant is difficult, if not impossible.

Correctness and completeness can be determined to some degree by careful testing, although with large or complex systems it may be infeasible to test all possible situations. It is difficult to test security systems appropriately, because they can be large and complex, and because it is hard to simulate all the environments and approaches by which systems can be attacked.

Malicious code. Computing is so fast and complex that users cannot know everything a program is doing. Programs can be modified or replaced by hostile forms, with the replacements seeming outwardly the same as the originals. The general term "malicious code" covers Trojan horses, viruses, worms, and trapdoors. Malicious code has been present in computing systems since the 1960s, and it is increasingly prevalent and serious in impact. Unfortunately, there are no known complete forms of protection against malicious code.

A Trojan horse is a program that has an undocumented function in addition to an apparent function.

For example, a program may ostensibly format and display electronic mail messages while also covertly transmitting sensitive data.

A virus is a program that replicates and transfers itself to another computing system. When executed, each copy can also replicate, so that the infection spreads at a geometric rate. A virus typically inserts its replicated copy into another executable program so that when the other program is executed, so is the copy of the virus. Viruses often perform covert malicious actions.

A worm is a program that, like a virus, seeks to replicate and spread. However, the goal of the worm is only to spread and consume resources. The malicious effect of the worm is denial of service by exhaustion of resources.

A trapdoor is an undocumented entry point into a program. The trapdoor is inserted by a programmer to allow discreet access to a program, possibly with exceptional privileges. A user who had legitimate access at one time might have installed the trapdoor as a means of obtaining access in the future.

All these forms of malicious code are serious security threats for several reasons. First, malicious code can be relatively small, so that it is not readily detected. Second, its actions can be concealed: If a program fails to perform as it did, the change is evident, but an attacker can cause the change to be subtle, delayed, or sporadic, making it very difficult to detect, let alone diagnose and correct. The covert effect of malicious code can be almost anything: It can delete files, transmit messages or files, modify documents or data files, and block a user from accessing a computer system. The attack can be transmitted in pieces that activate only when the entire attack has been delivered. Finally, protecting against malicious code is difficult: The only known totally effective countermeasure is not to accept any executable items from anyone else, a solution that is scarcely acceptable for current networking and information-sharing environments.

Security of code. It is infeasible for a user to determine that a program is secure. The user has little evidence on which to base an opinion, an insecure program may intentionally hide its weaknesses, and many users have little control even over the sources from which programs are derived. Even well-intentioned programmers can fail. Beyond principles of good software engineering, the security field uses rigorous independent evaluation and penetration testing to add confidence that a program is secure. *See* COMPUTER PROGRAMMING; SOFTWARE ENGINEERING.

Independent evaluation. Users need an independent quality assessment, both that the programs meet their stated requirements and that they have no obvious security requirements. An international effort has led to the publication of the *Common Criteria for Information Technology Security Evaluation* (CC). The successor to the U.S. *Trusted Computer System Evaluation Criteria* (TCSEC or "Orange Book") and the European *Information Technology Security Evaluation Criteria* (ITSEC), the CC specifies a structure for defining security and functionality requirements (a protection profile) and a description of a product meeting those requirements (a security target) so that the security target can be evaluated objectively against the protection profile. The evaluation then serves as a seal of approval that, with a stated degree of confidence on the part of the evaluators, the product has met the requirements. The CC scheme has been applied to operating systems, firewalls, intrusion detection systems, cryptographic systems, database management systems, and networking products.

Penetration testing. Because programs intended to enforce security must be robust enough to enforce it rigorously, a special form of security testing is sometimes performed. Ordinary testing is directed toward verifying that the program does what it is expected to do; penetration testing is intended to determine if there is a way to make the program not do what it is expected to do. Penetration testers use known flaw types, common actual (and well-known) attacks, and intuition to study the system, hypothesize flaws that would prevent it from enforcing security, and conduct experiments to confirm or refute the flaws hypothesized.

Security of Operating Systems

Operating systems are the basis of security enforcement in a computing system because the operating system has control over the system resources: the file system, printers, shared buffers, memory, time, and shared programs. The original purpose of an operating system was to promote efficient and equitable sharing of computing resources, which led swiftly and naturally to security enforcement.

Operating system security functions. Operating systems are the first contact of a user with a computing system. Thus, the operating system performs user identification and authentication, as a basis for controlling resource usage and providing each user with a unique computing environment. Operating systems control access to primitive resources, such as files, devices, network connections, programs, and computing time. Most operating systems generate an audit log of what security-relevant events have occurred to the resources they control.

Operating system design for security. Operating systems are the point of fundamental security enforcement. Consequently, for strong security enforcement, security cannot be added successfully to an operating system after the design is partially completed. The reference monitor is the gate that controls access to all security-relevant objects. Several examples of secure operating systems have been implemented based on the reference monitor concept. These examples have involved thoughtful design followed by intense analysis of the design and its implementation. *See* OPERATING SYSTEM.

Database Security

A database is a collection of records containing fields, organized in such a way that a single user can be allowed access to none, some, or all of the data.

Typically the data are shared among several users, although not every user will have access to every item of data. A database is accessed by a database management system that performs the user interface to the database.

Integrity is a much more encompassing issue for databases than for general applications programs, because of the shared nature of the data. Integrity has many interpretations, such as assurance that data are not inadvertently overwritten, lost, or scrambled; that data are changed only by authorized individuals; that when authorized individuals change data, they do so correctly; that if several people access data at a time, their uses will not conflict (for example, two people cannot write a single data item at the same time); and that if data are somehow damaged, they can be recovered.

A database management system is an application program that does not necessarily have a reliable interface to the operating system, and the operating system cannot necessarily be highly trusted. Therefore, a database management system typically maintains its own lists of users and their permitted actions, and the database management system may perform its own identification and authentication of users, quite independent from that performed by the operating system.

Inference and aggregation. Database systems are especially prone to inference and aggregation. Through inference, a user may be able to derive a sensitive or prohibited piece of information by deduction from nonsensitive results without accessing the sensitive information itself. For example, knowledge of any individual's salary may be restricted, but statistical measures (such as mean, median, maximum, and minimum) of the general salary pool may be freely released. If a user can formulate a database query that selects exactly one record (for example, "select all employees who are 6′2″ tall and live in Glenwood, Maryland"), the user can then determine a single individual's salary by asking for the mean salary for the select set (of one employee). Various statistical methods make it very difficult to prevent inference.

A related problem is aggregation, the ability of two or more separate data items to be more (or less) sensitive together than separately. For example, neither the longitude nor the latitude of the location of a secret gold mine is sensitive by itself, but these two values together pinpoint the mine. It is infeasible to release one value to some people and the second value to others (even though no single person is told both) because two people could pool their knowledge. Aggregation is extremely difficult to prevent, since users can access great volumes of data from a database over long periods of time and then correlate the data independently.

Database controls. Encryption is sometimes used in database management systems for both confidentiality and integrity. A device called an integrity lock is used to ensure that the contents of a field are not modified. The field may be stored in plaintext, but a cryptographic checksum of the field, the integrity lock, is also stored. Each time an authorized change to the field is made, a new integrity lock is computed and stored; each time the contents of the field are retrieved (in response to a query), a lock is computed on the value of the field and compared with the stored lock. If the two values do not match, the field has been modified without authorization. To guard against swapping data and their locks, the encrypted data may comprise the actual data of the field together with the record identifier and the name of the field. *See* DATABASE MANAGEMENT SYSTEM.

Network Security

Enforcing security across a network has all the problems of local enforcement, coupled with problems brought on by distance and transmission. Identification and authentication, for example, requires not just verifying the identity of a requesting user but also identifying the system to the user. A user does not want to supply a password (or a credit card number or other sensitive information) to the wrong system. Even if the user is assured initially that the remote system is authentic, the user may need assurance continuously throughout a transaction that the remote system has not been commandeered by an attacker or that the communication has not been diverted to a hostile system.

In a network, the same considerations apply as with nonnetworked systems: identification and authentication, access control, and auditing. The two additional areas of concern are the communications link between the local user and the remote system, and the physical and technical security of the remote system. (In fact, the remote system may be multiple systems, with the user's communication passing from one to another without the user's knowledge.)

Communications security. It is necessary to protect the communications lines by which users communicate with remote systems. Lines are subject to interception, redirection, falsification, and interruption, and the attacks range from very crude (simply cutting a wire) to very sophisticated (intercepting a message, modifying portions of it, and retransmitting the modified message).

Strong encryption is very effective in protecting against interception and modification. It is useful to consider a communication from A, through intermediate points X and Y, and ultimately to B. With end-to-end encryption, the message is encrypted at A and travels in encrypted form all the way to B. End-to-end encryption can be applied from an application to a corresponding application, so that the message is protected even as it is stored temporarily on a file system or as it passes through the operating system. This approach requires that part of the message, the routing and destination information, not be encrypted, so that along the way X and Y, which do not share the encryption between A and B, are able to move the message toward its destination.

An alternative is link encryption, in which a message is encrypted just along one path, say from A to X. At X the message is decrypted and reencrypted for the link from X to Y, and so forth. Link encryption can be applied at the physical link from A to X, so that all communications along that path are protected. Key management may be simpler than with end-to-end encryption because the encryptor needs to have keys only for its neighbors, the next points to which it sends communications. The individual user does not have to apply the encryption, manage cryptographic keys, or even understand encryption. However, a message is exposed at X and Y and also within the source and destination computing systems up to the application that handles the message.

Virtual private networks. Organizations can benefit from sharing access to computing systems that are not all located together. To do this, organizations have established virtual private networks (VPNs). These networks approach the security of a private network at costs closer to those of shared public resources. The primary security technique used is encryption. A virtual private network involves a set of known participants since an organization knows which systems will form a part of its network. Thus, cryptographic key management is reasonably straightforward: By some secured means, such as postal mail or a telephone conversation, a seed or master cryptographic key is distributed to all the systems that will participate in the private network. One party of the virtual private network then generates a new key, sometimes called a session key, that will be used for communications with that system or for a specific period of time. The session key is encrypted under the master key to be passed on to the other VPN partners.

Internet security. The Internet, or any similar public network, is subject to threats to its availability, integrity, and confidentiality. A complicating feature is that there is effectively no control on transmissions over the Internet. Consequently, a system connected to the Internet is exposed to any malicious attack that any other Internet user wants to launch.

Availability threats. Availability or denial of service threats range from disabling the connection of a system to flooding or saturating the system. The main cause of this type of threat is natural: loss of power, equipment failure, or a failed communications link. Disabling the physical connection requires access to the target system, but disabling the logical connection does not require physical access, and so it is a more likely choice for a malicious outside attacker. It requires only changing the routing information of the Internet so that the target host's address is no longer recognized. Fortunately, the Internet routing information is very well protected, so that this type of attack seldom succeeds.

A flooding attack is fairly common and difficult to protect against. The attacker either transmits (automatically) a vast amount of data to the target host, overwhelming its ability to handle legitimate communication, or the attacker exploits a flaw in the network communications protocols to cause the target host to generate its own massive volume of traffic to itself. A crafty attacker will falsify the source address of malicious communications, so that it is difficult to trace back to the attacker, making it infeasible to block or disregard communications from the malicious source.

Integrity threats. Threats to integrity include unauthorized changes to the data or programs of the target computing system. Integrity attacks seek to modify the data or programs at a target host. Malicious programs can be introduced by commandeering the target host, delivering the malicious program as if it were from a reliable source, or conveying the malicious program through a Trojan horse attack. Additionally, data can be modified by an attacker at any point on the communications link between the source and destination.

Again, encryption becomes a significant tool to control integrity. However, an advantage of the Internet is that it connects millions of sites, but the disadvantage is that there may be no shared encryption between all pairs of those sites. The difficulty is for two previously unknown entities (representing hosts or users) to authenticate each other. A certificate can be used to establish shared encryption with some degree of trust. A certificate contains an identification, an encryption key, and an encrypted field, called a digital signature, from a third party, attesting to the authenticity of the identity. Certificates can be countersigned by trustworthy third parties to add to their credibility. The encryption key in a certificate provides a basis for two unknown entities to establish a shared encryption.

Confidentiality threats. Confidentiality threats in a distributed environment are closely related to integrity threats. With minor modification, integrity attacks can be made to expose the sensitive data at the remote site or in transit. Several network protocols, such as secure http (shttp) or secure socket layer (ssl), use encryption to protect both confidentiality and integrity of communications on the Internet. *See* INTERNET; WORLD WIDE WEB.

Security perimeter. A security perimeter is a logical boundary surrounding all resources that are controlled and protected. The protected resources are called a domain (or enclave or protected subnetwork). There may be overlapping domains of varying protection, so that the most sensitive resources are in the innermost domain, which is the best protected. Protecting the security perimeter may be physical controls, identification and authentication, encryption, and other forms of access control. Two controls that relate especially to the security perimeter are network vulnerability scanning and firewalls.

Scanning. A network vulnerability scan is the process of determining the connectivity of the subnetwork within a security perimeter, and then testing the strength of protection at all the access points to the subnetwork. With a network domain, if a forgotten access point is not secured, its weakness can undermine the protection of the rest of the domain. A network scanner maps the connectivity of a domain, typically by probing from outside the domain, to determine what resources are visible from the outside. Once all outside connections are identified, each is tested with a range of attacks to determine the vulnerabilities to which it is susceptible and from which it needs to be better protected.

Firewall. It is infeasible to seal off a domain completely against outside access, because a purpose of the domain is to support communication with the outside. For example, a web site may be intended for broad public access. A firewall is a host that functions as a secured gateway between a protected enclave and the outside. The firewall controls all traffic according to a predefined access policy. For example, many firewalls are configured to allow unhindered communication outbound (from the protected domain to a destination outside the domain) but to allow only certain kinds of inbound communication. A firewall can be a separate computer, or firewall functionality can be built into the communications switch connecting the enclave to the external network.

Some firewalls hide internal resources from being visible outside the enclave. An enclave may have registered only the address of the firewall; internal hosts are not registered as part of the Internet or external network, and therefore outsiders have no way to communicate directly with them, only through the firewall. The firewall can be configured to allow only certain types of communications, for example, electronic mail, while blocking communications that could affect the status or integrity or confidentiality of an internal host, such as network management commands. Proxy firewalls simulate the effects of complex interactions across a security perimeter, filtering undesirable information flows.

Unprotected hosts. Hosts that must be accessible to the general public are often situated outside the protected domain, so that they are readily accessible to users without exposing any of the resources inside the domain. An unprotected host is acknowledged to be exposed. Unchanging content of the host can be sealed with integrity checks to detect modification, and if the content is modified, either maliciously or accidentally, the content can be restored readily from a protected copy inside the domain. Data gathered at the open site are moved inside the protected domain for more secure storage.

Intrusion detection. It is most effective to eliminate vulnerabilities, but if that is not possible, it is then desirable to recognize that an attack is occurring or has occurred, and take action to prevent future attacks or limit the damage from the current one. Anti-intrusion technologies are the different ways in which an attack can be detected and countered. Anti-intrusion technologies are prevention, to block an attack; deterrence, to make an attack sufficiently difficult to discourage the attacker; detection, to detect the existence of an attack; deflection, to encourage the attacker to direct the attack elsewhere; and diminution, to limit the negative effect of an attack. Such technologies are often collectively referred to as intrusion detection systems.

Intrusion detection can be either anomaly detection, which seeks to identify an attack by behavior that is out of the norm, or misuse detection, to identify an attack by its attempted effect on sensitive resources. Intrusion detection systems monitor a computing system in order to warn of an attack that is imminent, is under way, or has occurred.

Incident response. When an attack has occurred, the affected organization will generally study the attack in order to learn what has occurred, how to prevent a recurrence, and what is the extent of the damage. The science of computer forensics is the study of evidence from an attack. Computer forensics is much like any other investigative science in that it involves assembling potentially significant pieces of evidence and using insight, experience, and intuition to suggest connections among the pieces.

In order to assemble the knowledge about attacks and their countermeasures, organizations and countries staff computer emergency response teams (CERTs). These teams collect information about significant vulnerabilities and attack patterns and provide warnings and possible countermeasures. *See* LOCAL-AREA NETWORKS; WIDE-AREA NETWORKS.

Computer storage technology

The techniques, equipment, and organization for providing the memory capability required by computers in order to store instructions and data for processing at high electronic speeds. In early computer systems, memory technology was very limited in speed and high in cost. Since the mid-1970s, the advent of high-density, high-speed random-access memory (RAM) chips has reduced the cost of computer main memory by more than two orders of magnitude. Chips are no larger than $^1/_4$ in. (6 mm) square and contain all the essential electronics to store tens to hundreds of thousands of bits of data or instructions. An analogous increase in magnetic recording density has increased the capacity and reduced the cost per bit of secondary memory. Traditionally, computer storage has consisted of a hierarchy of three or more types of memory storage devices (for example, RAM chips, disks, and magnetic tape units). *See* BIT.

Memory Hierarchy

Memory hierarchy refers to the different types of memory devices and equipment configured into an operational computer system to provide the necessary attributes of storage capacity, speed, access time, and cost to make a cost-effective practical system. The fastest-access memory in any hierarchy is

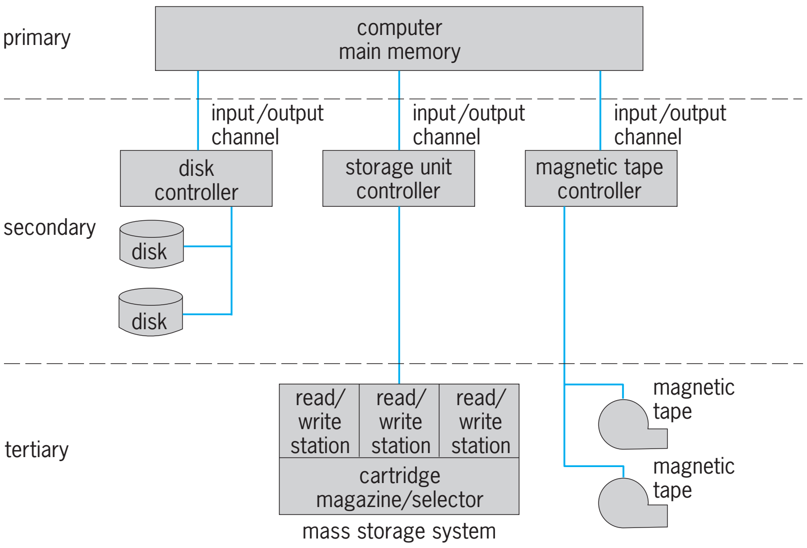

Fig. 1. Memory hierarchy levels and equipment types.

the main memory in the computer. In most computers manufactured after the late 1970s, RAM chips are used because of their high speed and low cost. Magnetic core memories were the predominant main-memory technology in the 1960s and early 1970s prior to the RAM chip. The secondary storage in the hierarchy usually consists of disks. Significant density improvements have been achieved in disk technology, so that disk capacity has doubled every 3 to 4 years. Between main-memory and secondary-memory hierarchy levels, however, there has always been the "memory gap."

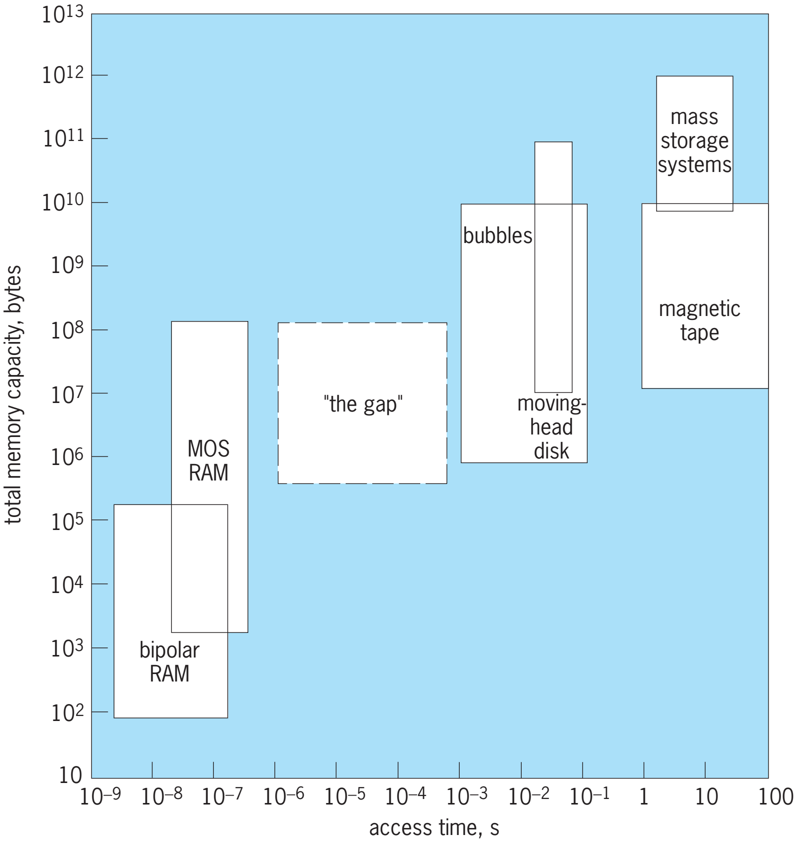

Fig. 2. Memory capacity versus access time for various storage technologies.

The memory gap, noted in the 1940s, still presents a problem for the data-processing system designer. The memory gap for access time is bounded on one side by a 60-nanosecond typical computer main memory cycle time and on the other by the 10-millisecond typical disk-drive access time. Capacity is bounded on the one side by a typical mainframe memory capacity of 256 megabytes and on the other by multiple disks, each with a capacity of from 100 megabytes to over 1 gigabyte.

The last, or bottom, level (sometimes called the tertiary level) of storage hierarchy is made up of magnetic tape transports and mass-storage tape systems (**Fig. 1**). Performance (**Fig. 2**) is usually measured by two parameters: capacity and access time. (Speed or data rate is a third parameter, but it is not so much a function of the device itself as of the overall memory design.) Capacity refers to the maximum on-line user capacity of a single connectable memory unit. Access time is the time required to obtain the first byte of a randomly located set of data.

Memory Organization

The efficient combination of memory devices from the various hierarchy levels must be integrated with the central processor and input/output equipment, making this the real challenge to successful computer design. The resulting system should operate at the speed of the fastest element, provide the bulk of its capacity at the cost of its least expensive element, and provide sufficiently short access time to retain these attributes in its application environment. Another key ingredient of a successful computer system is an operating system (that is, software) that allows the user to execute jobs on the hardware efficiently. Operating systems are available which achieve this objective reasonably well. *See* COMPUTER ARCHITECTURE.

The computer system hardware and the operating system software must work integrally as one resource. In many computer systems, the manufacturer provides a virtual memory system. It gives each programmer automatic access to the total capacity of the memory hierarchy without specifically moving data up and down the hierarchy and to and from the central processing unit (CPU). During the early years of computing, each programmer had to incorporate storage allocation procedures by determining at each moment of time how information would be distributed among the different hierarchic levels of memory, whenever the totality of information was expected to exceed the size of main memory. These procedures involved dividing the program into segments which would overlay one another in main memory. The programmer was intimately familiar with both the details of the machine and the application algorithms of the program. This all changed in the 1970s and improved significantly after 1980, when sophisticated higher-level program languages and database management software became well established, to provide significantly greater problem-solving capability. Thus manufacturer-supported operating systems evolved, with complete built-in virtual memory support capabilities, which made it possible for the user to ignore the details of memory hierarchy internal software and hardware operations. *See* COMPUTER PROGRAMMING; DATABASE MANAGEMENT SYSTEM; OPERATING SYSTEM; PROGRAMMING LANGUAGES.

In the area of memory organization, two types of memory augmentation have been employed in the more widely used computers to enhance the overall computer performance capabilities. These two memory organization techniques are the cache memory, which speeds up the flow of instructions and data into the central processing unit from main memory, and an intelligent disk controller memory that is used as a staging buffer memory to queue up instructions and data for more rapid access into main memory.

Cache memory. A cache memory is a small, fast buffer located between the processor and the main system memory. Data and instructions in current use are moved into cache, producing two benefits. First, the average access time for the processor's memory requests is reduced, increasing the processor's throughput. Second, the processor's utilization of the available memory bandwidth is thereby reduced, allowing other devices on the system bus to use the memory without interfering with the processor. Cache memory is thus used to speed up the flow of instructions and data into the central processing unit from main memory. This cache function is important because the main memory cycle time is typically slower than the central processing unit clocking rates. To achieve this rapid data transfer, cache memories are usually built from the faster bipolar RAM devices rather than the slower metal oxide semiconductor (MOS) RAM devices.

Performance of mainframe systems is very dependent upon achieving a high percentage of accesses from the cache rather than main memory. In typical systems 80–95% of accesses are to cache memory, with a typical cache size of 256K bytes. (1K bytes is equal to 1024 bytes.) Since the cache contents are a duplicate copy of information in main memory, writes (instructions to enter data) to the cache must eventually be made to the same data in main memory. This is done in two ways: write-through cache, in which write is made to the corresponding data in both cache and main memory; and write-back cache, in which main memory is not updated until the cache page is returned to main memory, at which time main memory is overwritten.

Intelligent disk controller memory. This is used as a cache memory between disk and main memories. Typically it consists of MOS RAM chips which overlap the disk operations, with their longer access time, to mask out the disk access delays so that main memory can execute subsequent tasks more rapidly and efficiently. Intelligent disk controllers provide the latest techniques to fill the memory gap with the best practical memory organization techniques for high performance. Microprocessors are also an integral part of intelligent disk controllers, and carry out many central processing unit operating system functions necessary for disk operations. This off-loads the mainframe computer from doing this kind of overhead processing to a large extent. *See* MICROPROCESSOR.

Main Semiconductor Memory

The rapid growth in high-density very large-scale integrated (VLSI) circuits has advanced to a point where only a few applications require the tens to hundreds of thousands of transistors that can now be placed on a chip. One obvious exception is computer main memory, in which there is a continual demand for higher and higher capacity at lower cost. *See* INTEGRATED CIRCUITS.

In the 1960s and early 1970s, magnetic core memories dominated computer main-memory technology, but these have been completely replaced by semiconductor RAM chip devices of ever-increasing density. This transition started with the introduction of the first MOS 1K-bit RAM memory in 1971. This was followed with the 4K-bit RAM chip in 1973, the 16K-bit chip in 1976, the 64K-bit chip in 1979, the 256K-bit chip in 1982, the 1M-bit chip in 1985, and the 4M-bit chip in the 1990s. (A 1M-bit chip has 1024 × 1024 or 1,048,576 bits.) The progression of RAM chips (**Fig. 3**) has followed the "rule of four," according to which the cost of development of a new RAM device generation can be justified only by a factor-of-four increase in capacity. *See* SEMICONDUCTOR MEMORIES.

4M-bit RAM chips. The 4M-bit MOS RAM has continued to push photolithographic fabrication techniques with feature sizes of 1 micrometer or less. For RAM chip densities of 1M bits or more per device, the integrated circuit industry has had to make a twofold improvement to maintain volume production and device reliability: better means, such as x-ray step-and-repeat equipment, to achieve features under 1 μm; and plasma-etching or reactive-ion-etching machines to achieve vertical profiles needed as horizontal dimensions decrease. Considerable progress has been made in the use of both x-ray and electron-beam techniques to achieve the submicrometer-size features needed to make even higher-density RAM chips. Most 4M-bit RAMs are dynamic RAMs. The production techniques for dynamic and static RAM chips are identical. Therefore, the cost per unit quickly becomes the cost for mass-producing one chip. Since building costs per chip are about the same whether they store 4K bits or 4M bits, higher densities lead to lower costs per bit.

RAM chip types and technologies. RAM chips come in a wide variety of organizations and types (**Table 1**). Computer main memories are organized into random addressable words in which the word length is fixed to some power-of-2 bits (for example, 4, 8, 16, 32, or 64 bits). But there are exceptions, such as 12-, 18-, 24-, 48-, and 60-bit word-length machines. Usually RAMs contain NK · 1 (for example, 64K · 1) bits, so the main memory design consists of

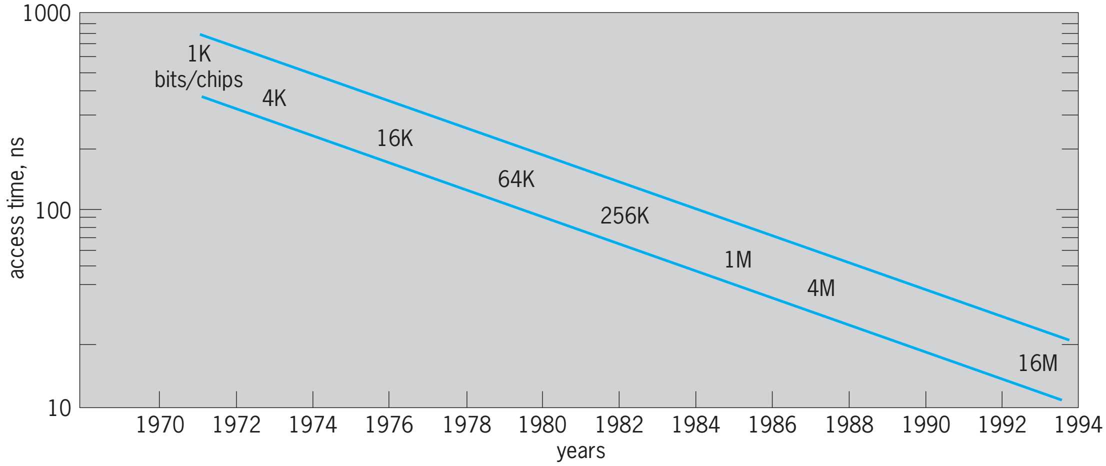

Fig. 3. Trends in performance and density (in bits per chip) of dynamic RAM chips. 1K = 1024 bits; 1M = 1024 × 1024 bits = 1,048,576 bits.

a stack of chips in parallel with the number of chips corresponding to that machine's word length. There are two basic types of RAMs, static and dynamic. The differences are significant. Dynamic RAMs are those which require their contents to be refreshed periodically. They require supplementary circuits on-chip to do the refreshing and to assure that conflicts do not occur between refreshing and normal read-write operations. Even with those extra circuits, dynamic RAMs still require fewer on-chip components per bit than do static RAMs (which do not require refreshing).

Static RAMs are easier to design, and compete well in applications in which less memory is to be provided, since their higher cost then becomes less important. They are often chosen for minicomputer memory, or especially for microcomputers. Because they require more components per chip, making higher bit densities more difficult to achieve, the introduction of static RAMs of any given density occurs behind that of dynamic versions.

There is another trade-off to be made with semiconductor RAMs in addition to the choice between static and dynamic types, namely that between MOS and bipolar chips. Biopolar devices are faster, but have not yet achieved the higher densities (and hence the lower costs) of MOS. Within each basic technology, MOS and bipolar, there are several methods of constructing devices, and these variations achieve a variety of memory speeds and access times, as well as power consumption and price differences. Within the basic MOS technologies there are several types, such as the *n*-channel MOS referred to as NMOS and the complementary MOS solid-state structure referred to as CMOS. For bipolar there are several types such as transistor-to-transistor logic (TTL) and the emitter-coupled logic (ECL). *See* LOGIC CIRCUITS.

Memory cycle and access times. The RAM memory cycle time in a computer is defined as that time interval required to read or write one word of data. Access time is defined as the time interval in which the data are available after the initiation of the read cycle. From the user's point of view, cycle time is also an important characteristic because it has more impact on overall computational speed of the system. A new data read-write cycle does not begin until the previous read cycle is completed. The specified timing, signal overlap, and tolerances allowed vary with each RAM main memory system.

Error checking and correction. Most computer main memories have a memory fault control consisting of a memory controller and a fault control subsystem which automatically corrects all single-bit errors and detects and reports all double-bit or three-bit errors. Each bit in a word is read from a separate RAM

TABLE 1. Summary of characteristics of various memory chip types

Characteristics	Dynamic RAMs	Static RAMs	Static RAMs	ROMs	PROMs	PROMs	EPROMs	EEPROMs (EAROMs)
Chip technology	NMOS CMOS	NMOS CMOS	Bipolar (ECL)	CMOS	Bipolar	CMOS	MOS (UVPROMs)	MOS
Speed (access time)	60–100 ns	50–100 ns	1–5 ns	50–100 ns	5–100 ns	50–200 ns	50–300 ns	50–300 ns
Volatility	Volatile	Volatile	Volatile	Nonvolatile	Nonvolatile	Nonvolatile	Nonvolatile	Nonvolatile
Programmability	Easy	Easy	Easy	During manufacture	Once only	Once only	Many times, long procedure	Many times, easier and faster than EPROMs
Power dissipation	Low	Low	High	Low	High	Low	Medium	Medium
Chip density of currently available devices	4M	1M	4K, 16K, 64K	256K, 1M	16K, 64K	16K, 64K	256K, 1M	64K, 256K, 1M

device. The fault control permits computer operation to continue even if a memory module is malfunctioning, and thus the computer will operate even if a memory chip is removed from the board. Failures are pinpointed to the specific chip by fault-indicating light-emitting diodes built into each array board. *See* LIGHT-EMITTING DIODE.

FIFO and LIFO chips. As memory chips increased in storage density and designers attempted to minimize interconnection circuitry, specialty memory function organizations such as first-in first-out (FIFO) buffers and last-in first-out (LIFO) buffers became available as chips. These kinds of chips are readily used in memory buffering applications to accommodate varying data rates between one element and another. The other complementary feature of FIFO and LIFO chips is the dual data paths (called ports) to allow simultaneous transfer of data into and out of these memory buffer chips. These chip types are commonly used on microcomputer boards and in the computer's peripheral interface and controller electronics.

Gallium arsenide memory chips. All the memory chips discussed above are based on the predominant silicon technology. Reliable gallium arsenide (GaAs) integrated circuits have been produced: 16K-bit and 64K-bit static RAM (SRAM) devices with 1-nanosecond access times. Development of 4M-bit SRAMs has been undertaken for military applications. Considering the need for and emphasis on increasingly rapid computers, there is definite potential for high-speed gallium arsenide logic and memory devices. *See* GALLIUM.

ROMs, PROMs, and EPROMs. Microcomputers have evolved their own special set of semiconductor memory chips (Table 1) to suit their application needs. Whereas large, medium-size, and minicomputers primarily use only RAMs that have read-write capability, microcomputers have found significant use for read-only memory (ROM) chips and programmable read-only memory (PROM) chips. Data and program storage in most microcomputer applications is separately allocated between RAMs and ROMs. ROMs provide protection, since the contents are fixed or hardwired and the chips are completely nonvolatile. During microcomputer program development, PROMs are typically used. A PROM can be written only once and involves the irreversible process of blowing polysilicon fuse links. These PROMs are neither erasable nor reprogrammable. Another kind of device, called an erasable PROM (EPROM), is cleared or rewritten by putting the EPROM chip under an ultraviolet light to zero out its contents and then using a PROM programmer to write in the new bit pattern for the modified program. After the microcomputer application program has completed final tests and acceptance, the final bit pattern in the EPROM can be put into ROMs or PROMs (using a chip mask) to facilitate quantity production. *See* MICROCOMPUTER.

EEPROMs. There are also memory chip devices called electrically erasable programmable read-only memories (EEPROMs). They have an internal switch on the chip to permit a user to electrically rewrite new contents into them. This means EEPROMs do not have to be removed from the circuit in order to clear their contents to put in the new or modified bit pattern representing another program of instructions. Thus EEPROMs have met the need in microcomputer systems for a nonvolatile in-circuit reprogrammable random word access memory device.

EEPROMs use two distinctively different technologies. The more mature technology is metal nitride oxide semiconductor (MNOS), which is a very different gate insulator process technology from that used for MOS. The MNOS technology previously used the generic acronym EAROM (electrically alterable read-only memories) until EEPROMs became common in usage for both technologies. The other technology is floating-gate MOS (also called FAMOS). FAMOS technology was used for ultraviolet erasable EPROMs (UVPROMs) and was subsequently refined to provide an electrically erasable technology. Both technologies rely on Fowler-Nordheim tunneling to move the charge to be stored from the substrate to the gate. FAMOS stores the charge on the gate itself, whereas MNOS devices trap the charge in the nitride layer under the gate.

Secondary Memory

High-capacity, slower-speed memory consists of two major functional types: random-access, which has been provided primarily by disk drives, and sequential-access, which has been provided primarily by tape drives. Since tape drives provide removability of the medium from the computer, tape is used for the majority of off-line, archival storage, although some disks are removable also. The on-line random-access disk devices are classed as secondary, and tape-based systems are classed as tertiary.

Over the history of electronic computers, while the technology for processors and main memory has been evolving from vacuum tubes to transistors to very large-scale integration (VLSI) chips, the predominant technology for secondary memory has continued to be magnetic recording on tape and disk. This has not been due so much to the absence of competing alternatives as to the continuous and rapid progression in magnetic recording capability (**Figs. 4** and **5**).

The current magnetic-disk technology will be discussed, and also the potential of new magnetic recording techniques such as thin-film, vertical recording, and bubble-memory devices; and a nonmagnetic technology, optical recording.

Magnetic disk storage. Conventional magnetic-disk memories consist of units which vary in capacity from the small 360-kilobyte floppy disks (used with microcomputers) to 1-gigabyte disk drives used with large-scale computers. Hard-disk memories are characterized by access times in the 20–80-ms region (versus access times of tens to hundreds of nanoseconds for RAMs). Figure 5 shows the historical progression in several performance factors: capacity, transfer rate, and access time.

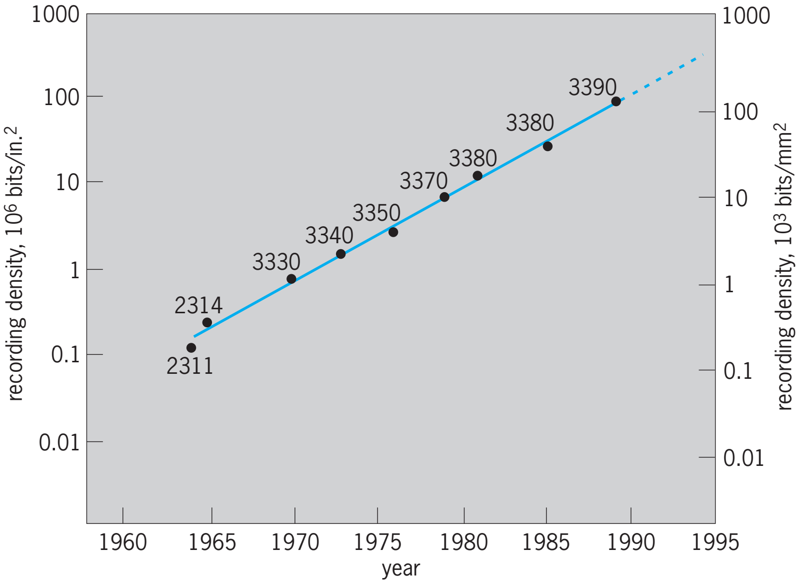

Fig. 4. Increase in recording density on magnetic disk storage. Data points represent IBM models, and model numbers are indicated. Since vertical scale is logarithmic, the straight line represents an exponential increase.

Capacity. The major area of development in disks has been the progressive and even spectacular increases in capacity per drive, particularly in terms of price per byte. There is a substantial economy of scale in storage capacity, in that the cost per byte goes down as the drive capacity goes up. Between small disks and top-end drives, the differences in access time and transfer rate may be only a factor of two to five, while the capacity difference is a factor of as much as 2000, that is, from 20 megabytes to several gigabytes.

Transfer rate. The rotation rate of the disk platter, like the action of the head actuators, is limited by considerations of physical dynamics. Increases in transfer rate will come from greater linear bit density around the track. In an absolute sense, transfer rates are not as often a system performance bottleneck as is access time.

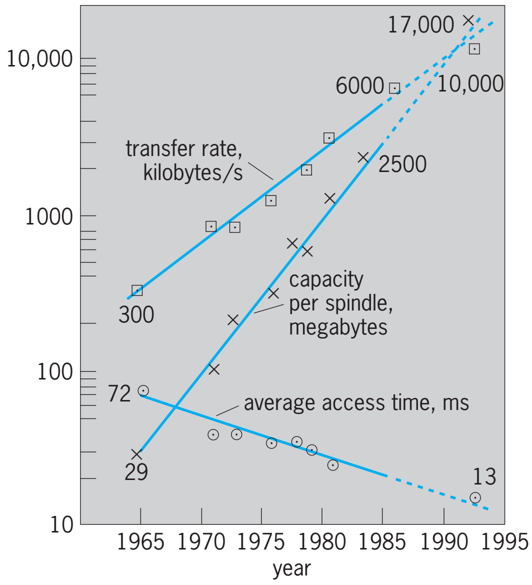

Fig. 5. Development of magnetic disk performance factors.

Average access time. Since the arm supporting the read-write head is one of the few moving mechanical parts in a computer system, it has not shown the multiple-orders-of-magnitude performance improvement over time that the electronic technologies have. Also, average access times for the highest-priced and lowest-prices disks do not vary by an enormous factor, being in the range of 10 to 80 ms for a typical microcomputer hard (as opposed to floppy) disk, and 10 to 30 ms for large disks on mainframe computers. There is nothing which indicates a breakthrough in the technology governing access time, even though greater capacities and transfer rates are still coming. Therefore, for random-access bottlenecks, the solution in the future will be the same as it is now: multiple smaller drives to allow overlapped seeks instead of a single large-capacity drive.

Basic disk technology. Many significant advances in the capabilities of commercially available disk memory technology were made during the late 1970s. One of the major trends was toward larger-capacity disks, progressing from 100 megabytes to several gigabytes per disk drive. The majority of technology improvements to provide higher capacities, lower costs, and better reliabilities resulted from the Winchester technology. Prior to this technology, removable disk packs established themselves as the most advanced technology for large-capacity disks. The Winchester technology is characterized by nonremovable, sealed disk packs, which inherently provide more reliability due to less handling and make more stringent alignment tolerances practical.

The head, or read-write transducer, has undergone substantial refinement. Central to the advance in increasing disk-packing density was the reduction in the flying height of the read-write head. Because flux spreads with distance, reduced separation between the read-write head and the magnetic surface will decrease the area occupied by an information bit. This obviously limits the number of bits that can be defined along an inch of track and increases the minimum spacing between tracks. The ideal would be a direct contact between head and surface, which is the case with magnetic tape. But this is not possible with a rigid aluminum disk whose surface is traveling at rates that can exceed 100 mi/h (45 m/s). By applying a load on the head assembly, proper spacing is maintained. All movable media memories utilize an air-bearing mechanism known as the slider or flying head to space the transducer in proximity to the relatively moving media. The slider, when forced toward the moving surface of the medium, rests on a wedge of air formed between it and the medium by virtue of their relative motion. The thickness of the wedge can be controlled by the applied force, and the wedge in effect is an extremely stiff pneumatic spring. Head-to-medium spacings were well under 10 μin. (0.25 μm) in 1982. *See* TRANSDUCER.

Some standards have been developed for interfaces between the drive and the controller, to permit compatibility among drives of various capacities and manufacturers. Among these are the storage module device (SMD) interface, enhanced small device interface (ESDI), small computer system interface (SCSI), intelligent peripheral interface (IPI), and high performance parallel interface (HPPI).

SMD drives can run at 3 megabytes per second. ESDI drives can also attain that rate. The IPI Level II drives can operate at 10 megabytes per second. The transfer rates of SCSI vary. As an intelligent interface between peripherals and computer systems, SCSI allows system designers to avoid device-level idiosyncrasies that make quick integration of new peripherals difficult. It is suitable for use on small personal computers with standard asynchronous transfer rates of 1.5 megabytes per second. It can also be used with supermicrocomputers and minicomputers with an optional synchronous transfer rate of 4 megabytes per second. Work has been done toward raising the transfer rate to 8 megabytes per second by tightening the timing specifications of the SCSI interface. Although initial versions of SCSI were designed for small computers, SCSI can meet the high-performance and high-capacity requirements of larger computers. For example, a single SCSI bus can support six SCSI-to-ESDI controllers with 24 disks, providing 7.2 gigabytes of storage, in addition to tape drives and other devices.

The HPPI was intended for interprocessor memory communication and as a data path for high-speed display monitors. It is a half-duplex point-to-point channel and can transmit data at 800 or 1600 megabytes per second. By using HPPI, it is possible to set up a high-performance high-capacity storage system of 256 gigabytes (or more) for supercomputer applications.

In addition to fixed Winchester-type disk units of various capacities, disk storage is used in several removable forms.

Cartridge disks. Removable storage cartridges containing single-disk packs are used extensively with minicomputer systems. The cartridge disk-drive unit has capacities ranging from 1 to 10 megabytes, depending on the recording density. Average access times range from 35 to 75 ms, and data transfer rates from 200 to 300 kilobytes per second. Physically, these plastic-encased cartridges are either top-loaded or front-loaded units. These units, besides having a removable disk, also have a fixed disk. The performance features of cartridge disks compete favorably with the larger-capacity disk pack storage equipment. A disadvantage of removable disk cartridges or disk packs is reduced reliability compared to fixed units.

Floppy disks. Floppy disks have become the widely used random-access secondary memory for microcomputer systems. The floppy disk was originally developed by IBM in 1965 for internal use on its large 370 computers. The disk was designed to be a permanent nonvolatile memory storage device, written at the factory. However, large numbers of new and varied applications evolved for these relatively small, compact disk systems. Floppy disks derive their name from the recording medium, an oxide-coated flexible disk (similar to, but more flexible than, plastic 45-rpm music records) enclosed within a protective plastic envelope. The Mylar flexible disk is $7^3/_4$ in. (195 mm) in diameter, 0.003 in. (0.075 mm) thick, and records 3200 bits per inch (125 bits per millimeter) and 48 tracks per inch (1.9 tracks per millimeter). The disk is permanently enclosed in a protective envelope. The common reference to the size of this disk is 8-in. (200-mm). The protective envelope contains alignment holes for spindle loading, head contact, sector-index detection, and write-protect detection. The capacity of this easily transportable medium is 8 megabits, commonly laid out on 77 tracks, each divided into 26 sectors.

The flexible-disk drive subassembly consists of the metal base frame, the disk-drive motor that rotates the spindle (360 rpm for 8-in. or 200-mm, 300 rpm for $5^1/_4$-in. or 133-mm) through a belt drive, and a stepping motor with an integral lead screw to form the head-positioning actuator. The read-write head is mounted on a carriage that the lead screw moves. Head load is achieved by moving a load pad against the disk and restraining the disk between the head and the load pad to accomplish the head-to-disk compliance.

The removable floppy disk, called a diskette, was originally 8 in. (200 mm), in both single and double densities, and single- and double-sided. A variety of incompatible formats exist, particularly in double density, as the majority of suppliers use a common (IBM) format in single density. The most conspicuous format difference is in sector boundaries, hard-sector referring to boundaries of physical holes in the diskette, and soft-sector to boundaries that are software-formatted. As recording density increased and packaging considerations for microcomputers became important, a smaller, $5^1/_4$-in. (133-mm) diskette was introduced in 1976 with a similar proliferation of formats as in 8-in. (200-mm). Many systems use yet smaller sizes such as 3, $3^1/_4$, and $3^1/_3$ in. (75, 83, and 90 mm). Standard storage capacities range from 720 kilobytes to 1.44 megabytes. The dominant format is the $3^1/_2$-in. (90-mm) high-density (1.44-megabyte) floppy diskette. Floppy diskettes (and drives) with density higher than 1.44 megabytes are available. However, floppy diskettes are often replaced with CD-ROM disks.

Thin-film and vertical recording. Several technologies are in development for disk storage.

The recording technology for conventional magnetic disk recording has been based upon ferrite heads and a recording surface consisting of a coating embedded with ferrous oxide particles. One of the limiting factors is the thickness of the recording layer, which is 20–50 μin. (0.5–1.25 μm). With current products pushing the limits of recording density achievable with that approach, a successor technology has been developed, called thin-film.

The thin-film technique uses a continuous magnetic film of cobalt or nickel, applied by electroplating to a controlled thickness of as little as 1 μin.

(25 nanometers). Either the head or the recording surface or both can use thin-film technology. Most of the major conventional large disks use thin-film heads and an oxide recording surface. Advanced models are designed to use a thin-film recording surface. Thin-film technology is the source for current progress in disk capacity and transfer rate. It was first introduced in small disks, partly due to greater ability to withstand the more portable environment of the small computer. The hardness of the medium which provides this resiliency also reduces both the likelihood and consequences of head crashes.

Another magnetic recording technique is vertical, or perpendicular, recording. In this approach the miniature magnets which are formed in the recording media are oriented downward into the surface rather than longitudinally along the surface. This allows closer packing of the magnetized spots, not just because of spatial compression, but also because of improved magnetic interaction between adjacent spots. The adjacent spots repel each other in the longitudinal case but attract in the vertical case. This technique offers the potential for significantly extending recording density and the accompanying performance parameters.

Recording density is the product of the bit density along the recording track, in bits per inch (or bits per millimeter), and the number of tracks per inch (or tracks per millimeter) across the recording surface (**Table 2**). For a given rotation rate of the disk, the bit density along the track determines the transfer rate.

The point at which vertical recording becomes attractive to develop into commercial products depends in part upon the level of capability which can ultimately be achieved with thin-film technology. The density level achieved by vertical recording technology may represent a limit for magnetic recording. If so, one possible answer to the question of how further levels of performance can be obtained is optical recording.

Optical recording. Optical recording is a nonmagnetic disk technology that uses a laser beam to burn pits in the recording medium to represent the bits of information, and a lower-power laser to sense the presence or absence of pits for reading. This technology has the potential for higher ultimate recording density than magnetic recording. The medium is removable and relatively inexpensive. The removability is significant in light of the nonremovability of most current and projected high-capacity magnetic disks. The recording density increase is apparent when it is noted that 4-gigabyte capacity is achieved on a single disk, whereas current-model large-capacity (2.5-gigabyte) magnetic drives typically consist of a cabinet containing two disk assemblies, each assembly having 16 platters.

One of the first optical disk mass-storage devices has 4 gigabytes on a removable, nonerasable, 14-in. (350-mm) disk. The transfer rate of 1.5 megabytes per second buffered or 3.0 megabytes streaming is similar to that of conventional magnetic disks (3.0 for the IBM 3380). The average access time is slower than that of high-performance magnetic disks at 84.7 ms, versus the 3380's 24 ms, but track-to-track access is a comparatively fast 1.0 millisecond. The corrected bit error rate is 1 in 10^{13}, which is compatible with magnetic disk standards.

In addition to the 14-in. (356-mm) disk for large-capacity systems, 12-in. (300-mm) optical disk systems in the 1-gigabyte capacity range have been produced for use with 16- or 32-bit microcomputer and minicomputer systems.

Disadvantages. Optical technology has several disadvantages. First, the medium is not inherently erasable, although systems which can erase and rewrite are also in development. The primary problem in producing a commercial optical disk system has been getting the bit error rate down to an acceptable level, with sufficient recording density to be competitive with magnetic recording. To be competitive with magnetic tape, a bit error rate, after error detect and correct, of 1 in 10^{10} to 10^{11} is needed, and to compete with magnetic disk, 1 in 10^{13} to 10^{14}. Through error detect and correct techniques, the 1 in 10^{13} level has been attained.

The bit error rate problem is far less critical for storage of documents and images, since bit dropout is seldom noticeable, in contrast with financial information, where it could be disastrous. This is the reason that optical disk recording was first used successfully in consumer and industrial systems for videotape image information, and for document storage and retrieval systems. *See* VIDEO DISK.

Applications. The nonerasability of the technology can be an advantage for some applications. Examples are data which must be kept for historical or audit-trail purposes, and applications where large amounts of data must be shipped among different locations.

When this technology matures, it will be an event of major significance, being a removable, large-capacity, random-access device using a recording technology with large potential for further growth. The potential for development of yet higher

TABLE 2. Storage densities for various recording technologies

	Bit density per track		Track density	
Technology	Bits/in.	Bits/mm	Tracks/in.	Tracks/mm
(Magneto) optical	20,500	800	15,000	600
Magnetic (floppy)	17,500	700	135	5
Magnetic (hard disk)	24,000	960	1,000	40
Floptical (optical floppy)	24,000	960	1,250	50

recording densities is perhaps the most significant factor, but in addition, having large capacity on a removable platter would allow some other kinds of system development. One possible system, referred to as a jukebox, would store on the order of 100 disks in an automatic retrieval and mounting device, so that a given disk could be fetched and accessed in around 5 seconds giving an on-line storage in the range of 500 gigabytes. Previous systems for very large online storage which have been delivered in significant quantity are the cartridge tape systems from IBM and CDC and automated tape libraries discussed below. The cartridge tape systems have capacities to 50 megabytes (IBM) and 8 megabytes (CDC) per cartridge; hence the optical system would provide a great improvement in the capacity available on the basic storage unit, and the automated tape libraries of course have the limitation of sequential data access.

CD-ROM and WORM. CD-ROM (compact disk–read-only memory) and WORM (write once, read many) are special types of optical disks. CD-ROM resembles the related audio compact disk technology in that users of CD-ROM can read only prerecorded data on the disk. A 5-in. (125-mm) CD-ROM can hold 500 to 600 megabytes, which is equivalent to 1400 to 1700 (360-kilobyte) diskettes. For example, the text of a 20-volume encyclopedia could be easily stored on a CD-ROM disk. CD-ROM has become an add-on peripheral device for some personal computers and workstations.

The CD-ROM disk and its drive are physically similar to the audio compact disk and its player, but there are several key differences: (1) A CD-ROM drive does not have a digital-to-analog converter. (2) It does have more powerful error correction than the audio system, because computer data requires a lower error rate, typically one error every 10^{15} bits, while the ratio of one error in 10^8 is acceptable in an audio compact-disk system. (3) The CD-ROM drives employ data scrambling to protect the servo control circuits from harmful dc components.

In CD-ROM, data are stored digitally on the surface of the substrate as a series of pits and lands of variable lengths. A land is the surface of the substrate between pits. Instead of using pits and lands to represent ones and zeros, the data in CD-ROM are represented in terms of the transitions from a pit to a land and vice versa (ones) and by the lack of such transitions (zeros). This arrangement, together with a modulation scheme, enhances the resolution with which data are read off the disk from about 1 μm—the diameter of the laser beam—to about 0.6 μm. The result is a 60% increase in the density of the data on the disk.

The pits on the disk surface can be arranged in either concentric circles, like tracks on magnetic disks, or in a spiral track, as on vinyl phonograph records. One common data format uses concentric tracks with the disk rotating at a constant angular speed. This simplifies the servomechanism but wastes space on the outer part of the disk because the bits in the outer tracks are separated from each other by more space than that necessary for adequate resolution. With the spiral track, the disk can be rotated so that the track passes the read head at a constant linear speed. This means that the disk must rotate more slowly when the laser beam is focused on the outer tracks and more quickly when the beam is on the inner tracks. Whether the tracks are concentric or spiral, the intertrack distance is about 1.6 μm, and the width of the pits is about 0.6 μm.

The average access time for CD-ROM drives ranges from 320 ms (for double-speed drives) to 160 ms (for quadruple-speed drives). The average data transfer rates vary from 300 kilobytes per second for double-speed drives to 450 kilobytes per second for triple-speed drives and 600 kilobytes per second for quadruple-speed drives.

While CD-ROM technology is fairly well established, the lack of established standards for WORM technology could delay its acceptance. WORM drives come in different sizes: $3^1/_2$, $5^1/_4$, 8, 12, and 14 (90, 133, 200, 300, and 350 mm). Capacities of $5^1/_4$-in. (133-mm) WORM drives range from 200 megabytes to over 1 gigabyte, while 12-in. (300-mm) WORM drives are in the 2–10-gigabyte range. *See* COMPACT DISK.

Bubble memory devices. Bubble memories are chips rather than disks, but are different from semiconductor memories in that they are magnetic devices, in which the absence or presence of a magnetic domain is the basis for a binary 1 to 0. The performance characteristics of these devices makes them competitive as small-capacity secondary storage. A magnetic bubble is in reality a cylindrical magnetic domain with a polarization opposite to that of the magnetic film in which it is contained. These cylinders appear under a microscope as small circles (which give them their name) with diameters from 80 to 800 μin. (2 to 20 μm). The size of a bubble is determined by the material characteristics and thickness of the magnetic film.

Bubbles are moved or circulated by establishing a magnetic field through a separate conductor mounted adjacent to the bubble chip. A large portion of the bubble chip must be given over to circuitry for generating, detecting, and annihilating the bubbles. Magnetic-domain bubble devices typically operate in an endless serial loop fashion or in an organization with serial minor loops feeding major loop registers. Bubble memories are particularly well suited to applications such as portable recorders because of their physical advantages (low power requirements and light weight) and speed advantage over electromechanical devices such as cassettes and floppy disks. Like their electromechanical counterparts, bubble devices are nonvolatile; that is, they retain their contents when the power goes off.

The controller is central to any bubble memory system, which it serves as the interface between the bubble chip and the system bus. It generates all of the system timing and control functions and supervises the handshaking operations required to access and transfer data between the system bus and the bubble memory module. Usually a controller can operate more than one bubble chip module, in most cases up to eight modules. The function-driver integrated circuit produces the control currents required to generate and input or ouput tracks on the chip. The sense-amplifier integrated circuit converts the analog out-put signals produced by the bubble detector into a transmittable data stream that passes to the controller. The coil-driver integrated circuits excite the x and y coils of the bubble chip package with out-of-phase signals to produce the rotating field that moves the bubbles.

Several companies are producing 1-megabit and 4-megabit bubble memory chips, and 16-megabit bubble memory chips are in the development stages. Under a cross-license and alternate source agreement, these companies have agreed to jointly adopt a low-height leaded package for complete component level interchangeability. Each company developed its peripheral chip set for the 4-megabit magnetic bubble module that will be compatible with the 1-megabit units.

For portable and other special applications, bubbles have definite advantages such as nonvolatility, low power, and high compactness. Performance capabilities relative to floppy disks are 100 kilobits per second for bubbles versus 200–250 kilobits per second for floppies, and 40 milliseconds average access time for bubbles versus 200–250 milliseconds for floppies.

Magnetic Tape Units

In magnetic tape units, the tape maintains physical contact with the fixed head while in motion, allowing high-density recording. The long access times to find user data on the tape are strictly due to the fact that all intervening data have to be searched until the desired data are found. This is not true of rotating disk memories or RAM word-addressable main memories. The primary use of tape storage is for seldom-used data files and as back-up storage for disk data files.

Half-inch tapes. Half-inch (12.5-mm) tape has been the industry standard since it was first used commercially in 1953. Half-inch magnetic tape drive transports are reel-to-reel recorders with extremely high tape speeds (up to 200 in. or 5 m per second), and fast start, stop (on the order of 1 millisecond), reverse, and rewind times.

Performance and data capacity of magnetic tape have improved by orders of magnitude (**Table 3**). Just prior to the 1970s came the single-capstan tape drive, which improved access times to a few milliseconds. These vacuum-column tape drives have such features as automatic hub engagement and disengagement, cartridge loading, and automatic thread operation. There are two primary recording techniques, namely, nonreturn-to-zero-inverted (NRZI) and phase-encoded (PE), used with packing densities of 800 and 1600 bytes per inch (31 and 63 bytes per millimeter). These typically use a 0.6-in. (15-mm) interrecord gap. In phase encoding, a logical “one” is defined as the transition from one magnetic polarity to another positioned at the center of the bit cell. “Zero” is defined as the transition in the opposite direction also at the center of the bit cell, whereas NRZI would involve only one polarity. The advantage of the phase-encoding scheme over NRZI is that there is always one or more transitions per bit cell, which gives phase encoding a self-clocking capability, alleviating the need for an external clock. The disadvantage of phase encoding over NRZI is that at certain bit patterns the system must be able to record at twice the transition density of NRZI.

Computer-compatible magnetic tape units are available with tape drives of 6250 bytes per inch (246 bytes per millimeter). They have nine tracks, where eight bits are data and one bit is parity. Each track is recorded by a technique called group-coded record (GCR), which uses a 0.3-in. (7.5-mm) record gap. Every eighth byte in conjunction with the parity track is used for detection and correction of all single-bit errors. Thus, GCR offers inherently greater reliability because of its coding scheme and error-correction capability. It does, however, involve much more complex circuitry.

The on-line capacity is strictly a function of the number of tape drives that one controller can handle (eight is typical). A 2400-ft (730-m) nine-track magnetic tape at 6250 bytes per inch (246 bytes per millimeter) provides a capacity of approximately 10^9 bits, depending on record and block sizes.

Quarter-inch tapes. The installation of $^1/_4$-in. (6-mm) streaming tape drives has increased very rapidly. There are several recording-format standards for $^1/_4$-in. (6-mm) tape drives; the most common one is called QIC (quarter-inch compatibility)-24, which connotes a full-size cartridge class with formatted storage capacity of 60 megabytes on nine tracks, using 600 ft (183 m) of tape. The device interface for a QIC-24 drive is either an intelligent interface

TABLE 3. Standard recording densities for magnetic tape

		Bit density along track		Area density	
Year	Number of tracks	bits/in.	bits/mm	bits/in.^{2}	bits/mm^2
1953	7	100	4	1,400	2
1955	7	200	8	2,800	4
1959	7	556	22	7,784	12
1962	7	800	32	11,200	17
1963	9	800	32	14,400	22
1965	9	1600	63	28,800	45
1973	9	6250	246	112,500	174
1990	9	43,200	1,864	35,280,000	50,400

such as QIC-02; the SCSI; or a basic drive interface, QIC-36. Another recording format, QIC-120, provides 125 megabytes on 15 tracks. The recording format QIC-1350 provides 1.35 gigabytes.

Cassettes and cartridges. The most frequently used magnetic tape memory devices for microcomputer systems are cassette and cartridge tape units. Both provide very low-cost storage, although their access times are long and their overall throughput performance is not as great as that of floppy disks. Cassette and cartridge units both use $^1/_4$-in. (6-mm) magnetic tape.

The digital cassette transport was orginally an outgrowth of an audio cassette unit. Unfortunately, the very low-cost audio-designed transport did not meet the endurance needs of true digital computer applications. There are two basic design approaches to digital cassette transports: capstan drive and reel-to-reel drive. Capstan tape drives are better for maintaining long-term and short-term tape-speed accuracy, while reel-to-reel transports have better mechanical reliability.

During the 1960s the first true digital tape cartridge was developed. With the cassette, a capstan must penetrate the plastic case containing the tape in order to make contact. There is no such penetration system with the cartridge because the transport capstan simply drives an elastomer belt by pressing against the rim of the belt's drive wheel. This simplicity eliminates a major source of tape damage and oxide flaking.

Cassettes have undergone evolution as a digital medium, and capacity has increased to 1 gigabyte, at a density of 61,000 bits per inch (2400 bits per millimeter). Transfer rates are 30 kilobytes per second at 30 in. (0.76 m) per second, or 100 kilobytes per second at 90 in. (2.29 m) per second. Some cassettes can transfer data at 400 kilobytes per second. The $^1/_4$-in. (6-mm) streaming tape cartridge has a typical capacity range of 100 to 300 megabytes, with some available with over 1 gigabyte. Transfer rates are 30 to 90 kilobytes per second, at densities of from 6400 to 10,000 bits per inch (252 to 394 bits per millimeter).

A typical mainframe tape cartridge can store data at 38,000 bits per inch (1496 bits per millimeter). At typical blocking factors, a 550-ft (168-m) tape cartridge contains about the same amount of data as a 2400-ft (730-m) reel of tape at 6250 bits per inch (246 bits per millimeter), but it requires less storage space. The data transfer rate between the tape cartridge drive and the process is 4.5 megabytes per second.

Half-inch (12.5-mm) tape is also used for back-up for microcomputer hard disk systems. Configured to standard microcomputer packaging sizes, these give 50-megabyte capacity in $5^1/_4$-in. (133-mm) form, and 300 megabytes in 8-in. (200-mm) form.

Mass Storage Tape Systems

With the gradual acceptance of virtual memory and sophisticated operating systems, a significant operational problem arose with computer systems, particularly the large-scale installations. The expense and attendant delays and errors of humans storing, mounting, and demounting tape reels at the command of the operating system began to become a problem. Cartridge storage facilities are designed to alleviate this problem.

Their common attributes are: capacity large enough to accommodate a very large database on-line; access times between those of movable-head disks and tapes; and operability, without human intervention, under the strict control of the operating system. The cartridge storage facility is included within the virtual address range. All such configurations mechanically extract from a bin, mount on some sort of tape transport, and replace in a bin, following reading or writing, a reel or cartridge of magnetic tape.

Cartridge storage systems are hardware devices that need operating system and database software in order to produce a truly integrated, practical hardware-software system. Users require fast access to their files, and thus there is a definite need to queue up (stage) files from the cartridge storage device onto the disks. The database software must function efficiently to make this happen. In general, users base their storage device selection on the file sizes involved and the number of accesses per month. Magnetic tape units are used for very large files accessed seldom or infrequently. Mass-storage devices are for intermediate file sizes and access frequencies. Disk units are used for small files or those which are accessed often.

In practice, most users have been satisfied with tapes and disks, and have not chosen to install mass storage systems. During the 1970s, two basic kinds were delivered, although some others were built and installed in the earlier years. In different ways, these units combine the low cost of tape as a storage medium with the operating advantages of on-line access. One is a mechanical selection and mounting unit to load and unload tape reels onto and off standard magnetic tape units; another is a mechanical selection and accessing unit to operate with special honeycomb short-tape units. The first type (sometimes called automated tape libraries) eliminated manual tape-mounting operations. The main objective of the short-tape honeycomb cartridge system is to improve access time. The shorter tape (770 in. or 20 m, versus 2400 ft or 730 m) results in better access time. Operationally, the honeycomb cartridge tape system and the mechanical standard tape-mounting units are capable of handling 100 to 300 cartridge or tape loads per hour.

The first type of fully automated tape library uses standard magnetic tape $^1/_2$ in. or 12.5 mm wide). Under computer control, this equipment automatically brings the tapes from storage, mounts them on tape drives, dismounts the tapes when the job is completed, and returns them to storage. Accessing up to 150 reels per hour, this unit can store up to 7000 standard tapes or 8000 thin-line reels in a lockable self-contained library that can service up to 32 tape drives and that can interface with up to four computers.

The honeycomb cartridge storage system uses a storage component called a data cartridge. Housed in honeycomb storage compartments, these 2 × 4 in. (24 × 50 mm) plastic cartridges can each hold up to 50,000,000 bytes of information on 770 in. (20 m) of magnetic tape approximately 3 in. (75 mm) wide. Whenever information from a cartridge is needed by the computer, a mechanism selects the desired cartridge and transports it to one of up to eight reading stations. There the data are read out and transferred to the staging disk drives. *See* COMPUTER; DIGITAL COMPUTER.

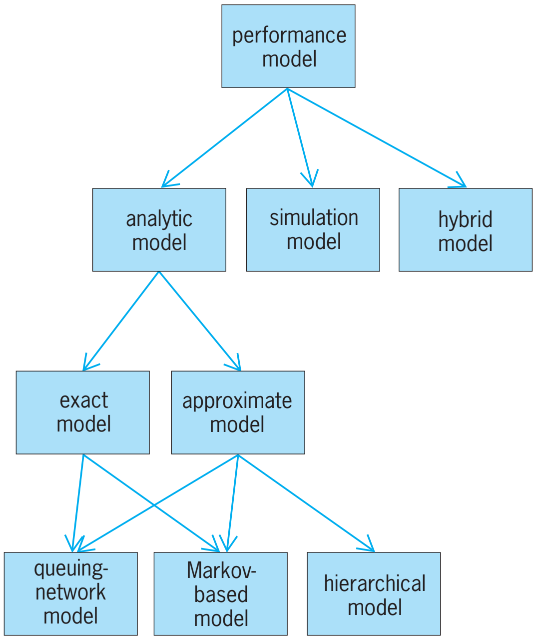
Computer-system evaluation

The evaluation of performance, from the perspectives of both developers and users, of complex systems of hardware and software. Modern computer-based information systems have become increasingly complex because of networking, distributed computing, distributed and heterogeneous databases, and the need to store large quantities of data. People are relying increasingly on computer systems to support daily activities. When these systems fail, significant breakdowns may ensue. *See* DISTRIBUTED SYSTEMS (COMPUTERS); LOCAL-AREA NETWORKS.

A computer system can fail in two major ways. First, functional failure occurs when the system fails to generate the correct results for a set of inputs. For example, if an information system fails to retrieve records that match a set of keywords, or if an air-missile tracking system fails to distinguish between a friendly and enemy missile, a functional failure has occurred. Second, performance failure occurs when the system operates correctly but fails to deliver the results in a timely fashion. For example, if an information system takes a longer time than users are willing to wait for the records they requested, the system is said to fail performancewise even though it may eventually retrieve the correct set of records. Also, if the air-missile tracking system fails to detect an enemy missile in sufficient time to launch a counterattack, the system manifests performance failure.

Therefore, in designing a computer system it is necessary to guarantee that the end product will display neither functional nor performance failure. It is then necessary to predict the performance of computer systems when they are under design and development, as well as to predict the impact of changes in configurations of existing systems. This requires the use of predictive performance models.

Performance models. The input parameters of performance models include workload intensity parameters, hardware and system parameters, and resource demand parameters. The outputs generated by performance models include response times, throughputs, utilization of devices, and queue lengths. There are analytic, simulation, and hybrid performance models (see **illus.**). Analytic models are composed of a set of equations, or computational algorithms, used to compute the outputs from the input parameters. Simulation models are based on computer programs that emulate the behavior of a system by generating arrivals of so-called customers through a probabilistic process and by simulating their flow through the system. As these simulated entities visit the various system elements, they accumulate individual and system statistics. Hybrid models combine both analytic and simulation approaches by, for example, replacing an entire subsystem in an analytic model by an equivalent device whose input–output behavior is obtained by simulating the subsystem. Analytic models can be exact or approximate. *See* SIMULATION.



Taxonomy of performance models.

Approximations are needed either when there is no known mathematically tractable exact solution or when the computation of an exact solution is very complex. Modern computer systems are very complex because of ubiquitous networking, distributed processing using client–server architectures, multiprocessing, and sophisticated input–output subsystems using network-attached storage devices. For this reason, most computer system performance models are approximate models. *See* CLIENT-SERVER SYSTEM; MULTIPROCESSING.

Exact performance models. Exact models may be further classified into queuing-network and Markov-chain-based models. Queuing-network models represent a computer system by a network of devices (also called queues) through which customers (for example, transactions, processes, and server requests) flow. Queues may form at each device because of the finite service rate of the device. Solving a queuing network amounts to finding the probability that the network is found in each of the possible states, or at least finding the performance metrics (for example, response times, throughputs, and queue lengths) associated with the queuing network. The solution to a class of queuing networks, called product-form queuing networks, can be obtained through very efficient computational algorithms such as convolution and mean-value analysis.

In Markov-based models, the system is modeled by a Markov chain, which represents the set of all possible states of the system with the possible transitions between these states. Each state gives rise to a linear flow-equilibrium equation. Solving the Markov chain amounts to solving the resulting system of linear equations, called the global balance equations. The unknowns in the global equations are the probabilities of finding the system at each of the possible states. In some cases, the Markov chain is not explicitly generated from an analysis of the system, but is derived from a higher-level model used to represent the dynamic and temporal behavior of the system. Examples of these higher-level models include generalized stochastic Petri nets (GSPNs), which are timed stochastic extensions to Petri nets. Algorithms exist that generate the Markov chain automatically from the generalized stochastic Petri net. *See* PROBABILITY; STOCHASTIC PROCESS.

Approximate performance models. Product-form queuing networks (PFQNs) cannot model many features of modern computer systems because the conditions for a queuing network to have a product-form (efficient) solution are violated in most cases of interest. For instance, priority-based scheduling disciplines for the devices in the computer system, such as those implemented by many operating systems for scheduling of central processing units, cannot be modeled directly by product-form queuing networks.

Product-form conditions are also violated in a queuing network that exhibits simultaneous resource possession, that is, a situation where a customer is allowed to hold more than one resource at the same time. This occurs when a file is being transferred from a network-attached tape drive to a disk through a HIPPI (High Performance Parallel Interface) switch. In this case, the tape drive is held by the customer simultaneously with the HIPPI switch or the disk during the transfer. Another example of simultaneous resource possession occurs in shared-memory multiprocessors. In this case, a request to access shared memory needs to hold the processor, the bus, and the shared memory bank during the memory access at the same time.

Queuing networks also do not satisfy product-form conditions when fork-and-join synchronization is present. This situation is characterized by a customer being split into more than one customer at the fork point. These customers follow independent paths within the system and are reassembled into a single customer at the join point when all of them arrive. An example of fork-and-join synchronization occurs in the modeling of a RAID-5 disk (a Redundant Array of Inexpensive Disks, with five disks in the array). Here, a read or write request to a RAID-5 disk is split into five requests to the physical disks that compose the RAID-5 disk. *See* COMPUTER STORAGE TECHNOLOGY.

Another case of violation of the product-form conditions occurs when the routing of customers in a queuing network is a function of the number of customers at other parts of the network. This may occur in the modeling of computer network routing algorithms which decide on the next link to which a packet should be sent based on the level of congestion at the set of possible links in the path to the destination.

Finally, another case where product-form conditions do not hold is when there is a constraint on the maximum number of customers in a part of the queuing network. An example occurs in the modeling of multiprogrammed computer systems where there is a maximum degree of multiprogramming.

Many approximate models have been developed to deal with queuing networks with non-product-form solutions. Some of these approximations are based on modifying the equations of the mean value analysis algorithm. Other approximations are based on formulating the problem as a fixed-point equation and solving it iteratively.

Even queuing networks with product-form solutions may be more efficiently solved with the use of approximate algorithms. The reason is that the computational complexity of solving a queuing network is proportional to the product of the number of devices in the computer system times the number of different classes of customers multiplied by the number of customers in each class. This may render models of moderately large computer systems unmanageable. Several approximations have been developed that drastically cut down the number of operations and memory requirements of the algorithms to solve product-form queuing networks. The most widely used approximation technique in this category is the Schweitzer approximation that can be used to derive an efficient iterative algorithm to solve product-form queuing networks.

Approximation techniques are also used when solving large Markov chains with an extremely large number of states. These techniques are aimed at cutting down the number of states without significant loss of accuracy. Finally, an important category of approximate models comprises hierarchical models. In this case, the complete model is decomposed into a hierarchy of models, $M_1, \ldots, M_n$. The output of the model at level i is used as input to the model at level $i + 1$. In some cases, a dependency between models M_n and M_1 is established requiring an iterative fixed-point procedure to solve the series of models. The modeling techniques used at each level may vary. It is possible to use queuing networks at one level and Markov-based models at another level of the hierarchy. Hierarchical models are very useful when dealing with client–server systems.

Performance of software systems. The design and development of complex software systems is a time-consuming and expensive task. Performance modeling techniques must be integrated into the software development methodology. This integrated approach is called software performance engineering. One goal is to estimate the resource consumption of software under development so that performance models can be used to influence the architecture of the software under development. Better estimates on the resource consumption are obtained as the software development process evolves. *See* INFORMATION SYSTEMS ENGINEERING; SOFTWARE ENGINEERING. Daniel A. Menascé

Computer vision

The technology concerned with computational understanding and use of the information present in visual images. In part, computer vision is analogous to the transformation of visual sensation into visual perception in biological vision. For this reason the motivation, objectives, formulation, and methodology of computer vision frequently intersect with knowledge about their counterparts in biological vision. However, the goal of computer vision is primarily to enable engineering systems to model and manipulate the environment by using visual sensing. *See* VISION.

Sensing and image formation. Computer vision begins with the acquisition of images. A camera produces a grid of samples of the light received from different directions in the scene. The position within the grid where a scene point is imaged is determined by the perspective transformation. The amount of light recorded by the sensor from a certain scene point depends upon the type of lighting, the reflection characteristics and orientation of the surface being imaged, and the location and spectral sensitivity of the sensor.

Image segmentation. The objective of this early stage is to compress the huge amount of image detail by identifying and representing those aspects of image structure which are salient for later stages of interpretation. Typically, this is accomplished by detecting homogeneous regions in the image or, equivalently, their edges. It must be done for all degrees of regional homogeneity and sizes, yielding a multiscale segmentation. Further, small regions may group together to form a larger structure seen as a homogeneous texture, which may define another basis for characterizing the homogeneity of a segment. The result of segmentation is a partitioning of the image such that each part is homogeneous in some salient property relative to its surroundings.

Three-dimensional interpretation. One central objective of image interpretation is to infer the three-dimensional (3D) structure of the scene from images that are only two-dimensional (2D). The missing third dimension necessitates that assumptions be made about the scene so that the image information can be extrapolated into a three-dimensional description. The presence in the image of a variety of three-dimensional cues is exploited. These cues may occur in a single image taken by a camera at a single time instant, a sequence of images acquired by one camera over a time interval, a set of images taken by multiple cameras from different positions or angles at a single time instant, or a time sequence of images taken by multiple cameras. In each case, the main task is to devise algorithms that can estimate three-dimensional structural parameters from image-based measurements. Some examples of such cues will now be discussed.

Image curves. The boundaries of image regions, or the curves composing a line-drawing image, reveal scene characteristics such as the extent and shape of an object and the occlusion between objects.

Shading. The nature of gradual spatial variation of image values within a region is related to surface shape characteristics such as convex or concave, and planar or curved.

Texture gradient. Variation in the coarseness of image texture is indicative of how the corresponding texture surface is oriented in the scene. For example, the distant flowers in an image of a large field of flowers are packed more densely together than the closer ones.

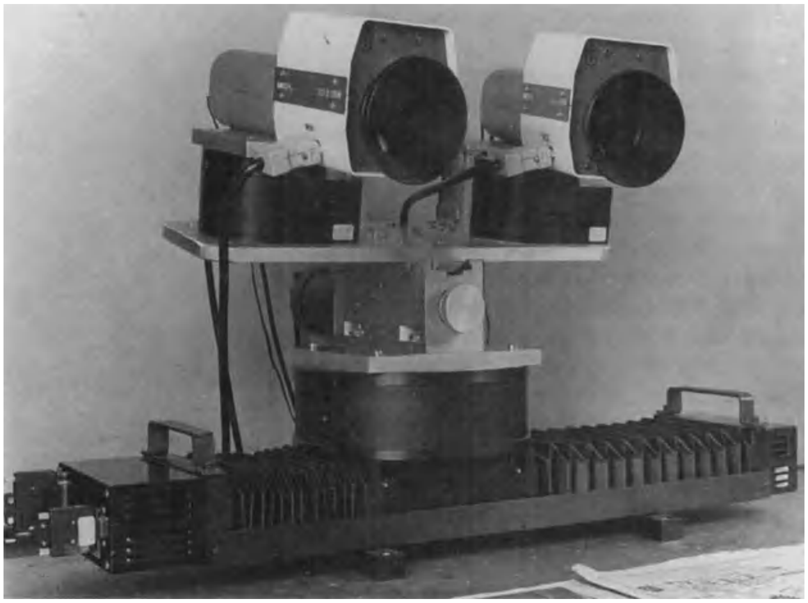
Stereo. If two cameras are placed at different locations and orientations (like the human eyes), then the coordinates at which a given scene projects within the two images are different, and their disparity is trigonometrically related to the three-dimensional position of the scene point. The disparity variation within an image can be used to estimate the three-dimensional configuration of surfaces in the scene. Three or more cameras can also be used.

Dynamic cues. If there is relative motion between the scene and the camera, the image data consists of a dynamic image sequence. Each of the above-mentioned cues then provides added information since observations about the temporal behavior of the cue are available, in addition to its spatial properties. For example, the temporal variation in image values, called optical flow, can be used to estimate the relative motion, surface shape, and layout of the objects. A moving object gives rise to a decreasing amount of flow as its distance from the camera increases. Similarly, moving image curves, such as those corresponding to orientation discontinuities on an object surface or the silhouette of a rotating object, yield a wealth of information about the shape of an object as well as about its motion. Sequences may be taken by multiple cameras simultaneously, making surface estimation easier because a larger amount of data is available, that is, the spatial disparity as well its variation over time.

Active image acquisition. If the cameras maintain a single, fixed geometry or optical configuration, the amount of additional information extracted from successive images depends on the changes occurring in the scene, due, for example, to relative motion. It is possible to maximize the increment in scene information obtained from successive images by dynamically reconfiguring the cameras so that the cues in the new images are most informative. Thus, a partial interpretation of the scene is used to dynamically control the sensing parameters so that each stage of image acquisition adds the most to the interpretation. For example, if a scene is too bright, the aperture size may be reduced; if the object is not in sharp focus, the focus setting may be changed; and if the object is not well placed with respect to both cameras in stereo analysis, the cameras may be verged to fixate on the object, all of these actions happening simultaneously (see **illus.**). As a certain part of the scene is satisfactorily interpreted, the results of the interpretation may be used to determine where to point the cameras next, and even to suggest how to analyze these new parts so as to obtain the best final interpretation in the minimum time.

Representation. The two-dimensional structure of an image or the three-dimensional structure of a scene must be represented so that the structural properties required for various tasks are easily accessible. For example, the hierarchical two-dimensional structure of an image may be represented through a pyramid data structure which records the recursive embedding of the image regions at different scales. Each region's shape and homogeneity characteristics may themselves be suitably coded. Alternatively, the image may be recursively split into parts in some fixed way (for example, into quadrants) until each part is homogeneous. This approach leads to a tree data structure. Analogous to two dimensions, the three-dimensional structures estimated from the imaged-based cues may be used to define three-dimensional representations. The shape of a three-dimensional volume or object may be represented by its three-dimensional axis and the manner in which the cross section about the axis changes along the axis. Analogous to the two-dimensional case, the three-dimensional space may also be recursively divided into octants to obtain a tree description of the occupancy of space by objects.

Recognition. A second central objective of image interpretation is to recognize the scene contents. Recognition involves identifying an object based on a variety of criteria. It may involve identifying a certain object in the image as one seen before. A simple example is where the object appearance, such as its color and shape, is compared with that of the known, previously seen objects. A more complex example is where the identity of the object depends on whether it can serve a certain function, for example, drinking (to be recognized as a cup) or sitting (to be recognized as a chair). This requires reasoning from the various image attributes and the derivative three-dimensional characteristics to assess if a given object meets the criteria of being a cup or a chair. Recognition, therefore, may require extensive amounts of knowledge representation, reasoning, and information retrieval.



Active camera system that can dynamically vary the part of the scene it has under view, focus on it, adjust the zoom, and open the aperture as necessary. Performing such changes under computer control and on the basis of the contents of the scene allows autonomous visual exploration.

Visual learning. Visual learning is aimed at identifying relationships between the image characteristics and a result based thereupon, such as recognition or a motor action. For example, the essentials of the visual appearance of a person may be learned so that whenever the person reappears in the scene his or her identity will be recognized despite changes such as in lighting and observer's viewpoint. Alternatively, continuous use of visual feedback to perform a task may be learned. For example, a person trying to pick up a suitcase moves his or her hands toward it while continuously using vision to control and correct the hand configuration and motion to reach the desired location and grip.

Applications. Vision is the predominant sense in humans, and it can play a correspondingly central role in computer-aided systems. In manufacturing, vision-based sensing and interpretation systems help in automatic inspection, such as identification of cracks, holes, and surface roughness; counting of objects; and alignment of parts. Computer vision helps in proper manipulation of an object, for example, in automatic assembly, automatic painting of a car, and automatic welding. Autonomous navigation, used, for example, in delivering material on a cluttered factory floor, has much to gain from vision to improve on the fixed, rigid paths taken by vehicles which follow magnetic tracks prelaid on the floor. Recognition of symptoms, for example, in a chest x-ray, is important for medical diagnosis. Classification of satellite pictures of the Earth's surface to identify vegetation, water, and crop types, is an important function. Automatic visual detection of storm formations and movements of weather patterns is crucial for analyzing the huge amounts of global weather data that constantly pour in from sensors. *See* ARTIFICIAL INTELLIGENCE; CHARACTER RECOGNITION; COMPUTER GRAPHICS; INTELLIGENT MACHINE; ROBOTICS. Computerized tomography

An imaging technique which uses an array of detectors to collect information from a beam that has passed through an object (for example, a portion of the human body). The information collected is then used by a computer to reconstruct the internal structures, and the resulting image can be displayed—for example, on a television screen.

Technique. Wave phenomena can penetrate into regions where it is impossible or undesirable to introduce ordinary probes—regions as diverse as the ocean, the human body, and the deep interior of the Earth. Since wave attenuation and velocity are affected by material properties, such as temperature and density, information concerning these properties is accumulated by a wave packet as it travels along its path. Thus, the intensities and travel times of such pulses measured at a receiver represent such accumulations. Although a single such datum does not allow point-to-point variation to be inferred, when many rays crisscross a region the corresponding interrelated data contain constraints that allow an inversion to determine interior structures. Considerable computational power and mathematical sophistication are needed in dealing with indirect, incomplete, and imperfect measurements. The relevant branch of mathematics is called inverse theory. The term computerized tomography for this type of remote sensing arose in medicine, where x-ray attenuation data along many straight paths confined to a plane were used to obtain a map of density structure in a body section. The term tomography refers to methods that display only thin slices or sections through an object or a human body. *See* INVERSE SCATTERING THEORY.

Examining a person or object in the laboratory requires the use of a gantry, composed of an x-ray tube, an array of detectors opposite the tube, and a central aperture in which the person or object is placed. The rigid gantry maintains the proper alignment between the x-ray tube and the detectors.

Earlier computerized tomography scanners had a conventional x-ray tube with a rotating anode and small focal spot. X-rays generated in short bursts, usually lasting 2–3 ms, were picked up by detectors after passing through a section of the body (for example, the abdomen). Invisible images picked up by the detectors were fed to the computer, which reconstructed the image. The thickness of the section to be examined varied from 1 to 10 mm and was determined by collimating the x-ray beam.

Less sophisticated scanners used linear and rotational motions of both x-ray tube and detector. One employs a pencil-shaped x-ray beam and a single detector. The time needed for a single slice or scan was 4.5–5 min. A fan-shaped beam with an array of detectors (as many as 30) and a greater rotation increment (30○ instead of 1○) made possible a time interval of 10–90 s.

Sophisticated electronic technology eliminates the need for mechanical movement. An electron beam is used, which is focused on stationary anode rings located in the gantry surrounding the patient, making it possible to generate considerable x-ray output within a very short time and to acquire images while the patient is advancing through the gantry. Up to 34 scans or slices can be obtained within 1 s; a single slice can be obtained in only 50 ms. Some computerized tomography scanners use as many as 1536 measuring channels constituted by xenon detectors with extremely high efficiency. *See* IONIZATION CHAMBER; SCINTILLATION COUNTER.

The computer reconstructs the image from the information collected by the detectors in the following way. The cross section of the object to be reconstructed is divided into tiny blocks, called voxels, giving a square matrix. Matrices can be constructed having voxels of different sizes; for example, 80 × 80, 160 × 160, 320 × 320, 512 × 512, and 1024 × 1024 voxels. In the 320 × 320 matrix, the voxels are simply one-fourth of the volume of those of an 80 × 80 matrix, and therefore the resolution is greater. The computer assigns each voxel a number proportional to the degree that the voxel has attenuated the beam passing through it. Once the voxel has received a computer number, it is called a pixel (picture element). The linear attenuation coefficient (a measure of the quantity of radiation attenuated by each centimeter of absorber) is used to quantify the attenuation of the beam. Each voxel is "examined" by the beam incident from several positions, generating many "positional" equations. The computer must solve many thousands of equations to determine the linear attenuation coefficient for a single voxel. In order to obtain enough information to calculate one image, at least 90,000 readings (300 pulses and 300 detectors) are needed.

Applications. The ability of computerized tomography to explore the internal structure of objects has made it a valuable tool in medicine and geophysics.

Medical tomography. In medicine, computerized tomography represents a noninvasive way of seeing internal structures. In the brain, for example, computerized tomography can readily locate tumors and hemorrhages, thereby providing immediate information for evaluating neurological emergencies. Equally important is the fact that, in a great majority of cases, computerized tomography offers an alternative approach to the more problematic invasive procedures.

Reductions in scanning time have made it possible to do whole-body scans, and many abdominal tumors, hemorrhages, and infections can now be detected without the need for exploratory surgery. Tumors deep in the body can be biopsied easily with fine needles by using computerized tomography guidance, thereby alleviating the need for surgery. Another advantage of computerized tomography is three-dimensional reconstruction. It is most useful in cases of fracture of the hip or facial bones, helping the surgeon to do reconstructive surgery. Other medical imaging techniques that make use of computerized tomographic methods include magnetic resonance imaging, positron emission tomography, and single-photon emission tomography. *See* MEDICAL IMAGING; RADIOGRAPHY. Nicole-Fr. Bolender

Geophysical tomography. After the success of computerized tomography in medicine, its possibilities in other fields were quickly realized. In the earth, atmospheric, and ocean sciences it has supplemented, but by no means replaced, older methods of remote sensing. Seismic tomography is now an important tool for investigating the deep structure of the Earth, testing theories such as plate tectonics, and exploring for oil. Ocean acoustic tomography is applied to physical oceanography, climatology, and antisubmarine warfare. Atmospheric tomography finds applications to weather, climate, and the environment.

1. *Seismic tomography.* The data for tomographic analysis are the earthquake signal arrival times monitored by the global network of seismic stations. These signals are propagated as elastodynamic waves that can be classified as compressional or shear and as body or surface waves. Compressional waves such as acoustic waves consist of alternating compressions and rarefactions caused by the oscillations of material particles in the direction of wave propagation. Shear waves are of a different (slower) type in which the motion of material particles is at right angles to the wave motion. Surface waves are guided by the Earth's surface; they travel along great circle paths and penetrate the upper mantle, but not deeper. However, body waves are not confined to the surface and can penetrate deeply, even reaching the Earth's core. They can be of the compressional or shear type. There are also two kinds of surface waves: Rayleigh waves, composed of a vertical shear component and a compressional component, and Love waves, which are pure horizontal shear waves. *See* SEISMOLOGY.

The diversity of wave phenomena allows various physical variables to be computed from wave velocities. Temperature, density, and crystalline structure of rock are the most important of these. Body-wave ray paths are not straight as in medical tomography but are curved by refraction in the vertical due to variation in the Earth's mechanical properties. Body and surface ray paths and travel times are calculated from arrival time data at many stations by means of a standard spherically symmetric reference model of the Earth. The travel time associated with thousands of crossing paths are treated as tomographic data and used to draw maps of wave velocity anomalies (deviations from the reference model). These maps reveal much about internal structure and dynamics of the Earth. Since velocity decreases as temperature increases, an anomalously slow velocity may point, for example, to upwelling hot material from the mantle toward the surface. An opposite anomaly may represent subduction of cool surface matter as one tectonic plate is thrust beneath another. Large anomalies near the core have revealed a previously unknown aspherical (bumpy) structure. *See* PLATE TECTONICS.

Smaller-scale seismic tomography serves as a tool for oil exploration. In cross-borehole tomography a seismic source such as a small explosive or impact device creates a mechanical disturbance at a number of different depths in a shaft. A linear array of receivers in a second borehole measures signal arrival times. The propagation paths connecting each source position with each receiver form a tomographic network. Maps of propagation velocity in the region between boreholes are used to detect changes in rock strata. *See* SEISMIC EXPLORATION FOR OIL AND GAS.

2. *Ocean acoustic tomography.* A tomographic array in the ocean consists of a number of acoustic sources and receivers that span an ocean region of interest. Each source transmits a pulse that is detected at each receiver. Because of refraction due to temperature variations and other (smaller) effects, the pulses follow curved paths, which usually reverse direction in the vertical at a number of upper and lower turning points. These paths are determined mainly by the temperature stratification of the ocean and tend to be restricted to a vertical plane because of strong vertical stratification. The elements of each source-receiver pair are connected by many acoustic paths (called multipaths). Since a system typically contains many source-receiver pairs, the ocean volume within the tomographic array is penetrated by hundreds of acoustic paths. Pulse travel times along these paths are the measured data. They are determined by the variation of sound speed and currents along the respective paths. To the first order, sound speed in the ocean is determined by temperature, and the effect of currents is negligible. Thus, the information contained in the data is related mainly to the temperature variation in the ocean, and the monitoring of this distribution has been the primary objective in the development of this technology. However, monitoring of currents is also possible by the use of reciprocal (two-way) transmissions. By subtracting reciprocal travel times, temperature effects are canceled out and the effect of currents becomes dominant.

The operation of a system begins with initialization of the array, referring to the fact that a knowledge of the distribution of ocean variables (mainly temperature) is required at the initial moment of operation in order to identify the acoustic paths that connect sources and receivers. Thereafter, as these paths change position, they can be tracked by the system. In early experiments the necessary initial information was supplied by ship surveys of vertical temperature profiles.

It is not possible in the ocean environment to achieve the extremely fine spatial resolution obtained in medical scanning; a prohibitively large number of sources and receivers would be required.

However, future ocean monitoring systems will include satellite observations, providing global coverage of the ocean surface with excellent horizontal resolution but no significant vertical penetration. Acoustic tomography provides vertical penetration but poorer resolution. These two techniques can play complementary roles in ocean monitoring. *See* OCEANOGRAPHY; UNDERWATER SOUND.

3. *Atmospheric tomography.* Electromagnetic waves interact with the atmosphere in two ways useful for remote sensing. Parts of the atmosphere can reflect incident radiation directly to a detector or can absorb energy and reradiate it. Lidar, a form of radar that uses laser beams, is a suitable source for active tomographic systems because it confines incident energy to narrow beams and because optical frequencies interact strongly with the atmosphere. Alternatively, a system can be based on passive detection of emitted energy from the atmosphere by means of the radiometer, an instrument that measures the intensity of waves arriving from a particular direction. For active systems, measured data are the attenuation of lidar pulses along straight path segments from source to point of reflection to receiving telescope. For passive systems, a measured datum is the total intensity of radiation emitted toward the radiometer by all sources on its line of sight. *See* LIDAR.

A simple example of a configuration that provides the network of crossing paths required for tomography consists of two radiometers in fan beam mode: Each instrument moves its line of sight up and down, forming a fan of receiving beams. The intersection of the two fans forms a network of paths for tomography; this configuration has been used to map the liquid water content of clouds. Other tomographic configurations have been obtained from instruments mounted on satellites, aircraft, surface vehicles, and the ground. *See* AIRGLOW.

As a characteristic tomography, the data represent not the value of physical variables at a point but the integration of variables along a line. Point-to-point mapping is accomplished by inversion algorithms similar to those used in other fields. Although attenuation and emissivity are often of interest in themselves, they can also be related to other physical variables of interest. Thus, atmospheric applications also include mapping of visible airglow, temperature, and properties of aerosols. **Thomas J. Eisler; Ronald New**

Concentration scales

Numerical systems defining the quantitative relations of the components of mixtures. In solutions the concentration is expressed as the mass, volume, or number of moles of solute present in proportion to the amount of solvent or of total solution. Each scale of concentration has significant features of experimental simplicity or of theoretically significant relationship.

Percentage. The simplest scale to measure is percentage; hence it is often used for medicinal or household solutions. Weight percent is the number of parts of weight of solute per hundred parts of weight of solution (total). For example, a 10% saline solution contains 10 g of salt in 90 g of water, that is, 100 g total weight. Gaseous mixtures, being difficult to weigh, are often expressed as volume percent. Thus, air is said to contain 78% nitrogen by volume. Solutions of liquids in liquids (say, alcohol in water) may also be expressed in volume percent.

Molarity. To the chemist, the number of moles of solute is of more significance than the number of grams. In SI units the concentration would be given in moles per cubic meter (mol m^{-3}). The molarity (abbreviated M) is the number of moles of solute per liter of total solution. Thus, 12 M HCl means that the solution contains 12 formula weights (12×36.5), or 438 g, of hydrochloric acid per liter (or, in SI units, mol dm^{-3}). Concentration is an intensive, rather than an extensive, property of solutions. Thus, 0.5 liter of the acid just mentioned is still 12 M, although it contains only 6 moles of solute. As used here, the mole is an amount of substance whose weight in grams is numerically the same as the molecular weight. Chemical engineers sometimes use a mole which is a pound-molecular weight.

Molality. Certain solution properties, for example, the lowering of the freezing point of water by addition of salt, require the use of a concentration scale which relates the number of moles of solute to the weight of solvent rather than to the volume of solution. This scale, called molality (abbreviated m), indicates the number of moles of solute per 1000 g of solvent. Thus 34.2 g of sucrose ($C_{12}H_{22}O_{11}$, mol wt 342), if dissolved in 200 g of water, has the concentration of 0.5 mole of sucrose per 1000 g of water, and hence is 0.5 m. For dilute aqueous solutions, the molality is essentially identical with the molarity. In solutions with densities other than unity, the two scales differ. Molality may be computed from molarity, as shown in the equation below, by first subtracting from the weight of 1 liter ($1000 \times$ density d)

$$m = M\left(\frac{1000}{1000d - M \times \text{mol wt}}\right)$$

the weight of solute, and then scaling the result by proportion to the number of moles per 1000 g, where the molecular weight is that of the solute.

Normality. Molarity does not represent reactive capacity for solutes which possess more than one active unit per molecule. Since sulfuric acid (H_2SO_4) molecules yield twice as many hydrogen ions (H^+) as do those of hydrochloric acid, a liter of 0.1 *M* sulfuric acid will neutralize twice as much base as will a liter of 0.1 *M* hydrochloric acid. When it is important to know the reactive capacities of reagents, as in volumetric analysis, the normality scale is used. Normality (abbreviated *N*) is found by multiplying molarity by the number of active units in the formula.

In methathesis (double decomposition) reactions, normality may be an ambiguous concept unless referred to a specific reaction. Phosphoric acid (H_3PO_4) may be reacted with sodium hydroxide (NaOH) to yield NaH_2PO_4, Na_2HPO_4, or Na_3PO_4; thus, phosphoric acid may have three normalities, depending on whether the reaction involves replacing one, two, or three hydrogen atoms. In oxidation-reduction reactions, there is a change in oxidation number, and normality must be calculated on the basis of this change. *See* OXIDATION-REDUCTION.

For reaction in a solution, the product of normality times the volume is the same for both reactants; for a solution of normality N_1, determined by titrating a volume V_1, with volume V_2 of a known solution of normality N_2, this equivalence can be expressed as $V_2N_2 = N_1V_1$. If the volume is expressed in milliliters, the products are in milliequivalents; if in liters, in equivalents.

Formality. The molarity scale is ambiguous when applied to ionic reactions. For example, 1 mole of Na_2HPO_4 in a liter of solution can yield 2 moles of sodium ion (Na^+), 1 mole of H^+, and 1 mole of phosphate ion (PO_4^{3-}), leaving zero mole of undissociated Na_2HPO_4. What the proper molarity is may not be clear. To obviate the confusion, it is possible to disregard moles and to use instead the number of formula weights of solute per liter of solution. This scale is designated the formality scale. In the example given, the solution would be 1 *F* Na_2HPO_4. This identifies the amount of total solute per liter and removes ambiguity in making up a solution; the reactive capability of the solution under various conditions is not considered.

Other scales. For very dilute solutions, for example, hard water, it is useful to express concentration in parts per million (ppm). Parts per billion are given in nanograms (10^{-9} g) per liter. With modern analytical techniques, quantities can be expressed in picogram (10^{-12} g) and femtogram (10^{-15} g) ranges. Particular applications often require special scales; for example, radon concentration in the atmosphere is given in units of picocuries per liter.

Mole percent (mole fraction). Many properties of solutions (for example, vapor pressure of one component) are dependent on the ratio of the number of moles of solute to the number of moles of solvent, rather than on the ratios of respective volumes or masses. The mole fraction (abbreviated N_A or X_A for component *A*) is the ratio of the number of moles of solute to the total number of moles of all components. Thus for 16 g of methanol (0.5 mole) dissolved in 18 g of water (1 mole), the mole fraction of methanol is 0.5/1.5, or 1/3; the mole percent is 33.3. For gases the mole percent is identical with the volume percent. *See* GRAM-MOLECULAR WEIGHT; SOLUTION; STOICHIOMETRY; TITRATION. Allen L. Hanson

Concrete

A composite material that consists essentially of a binding medium, such as a mixture of portland cement and water, within which are embedded particles or fragments of aggregate, usually a combination of fine and coarse aggregate.

Concrete is by far the most versatile and most widely used construction material worldwide. It can be engineered to satisfy a wide range of performance specifications, unlike other building materials, such as natural stone or steel, which generally have to be used as they are. Because the tensile strength of concrete is much lower than its compressive strength, it is typically reinforced with steel bars, in which case it is known as reinforced concrete. *See* REINFORCED CONCRETE.

Materials. A composite material is made up of various constituents. The properties and characteristics of the composite are functions of the constituent materials' properties as well as the various mix proportions. Before discussing the properties of the composite, it is necessary to discuss those of the individual constituents as well as the effects of the mix proportions and methods of production. *See* COMPOSITE MATERIAL.

Cement. There are many different kinds of cements. In concrete, the most commonly used is portland cement, a hydraulic cement which sets and hardens by chemical reaction with water and is capable of doing so under water. Cement is the "glue" that binds the concrete ingredients together and is instrumental for the strength of the composite. Although cements and concrete have been around for thousands of years, modern portland cement was invented in 1824 by Joseph Aspdin of Leeds, England. The name derives from its resemblance of the natural building stone quarried in Portland, England. *See* CEMENT.

Portland cement is made up primarily of four mineral components (tricalcium silicate, dicalcium silicate, tricalcium aluminate, and tetracalcium aluminoferrite), each of which has its own hydration characteristics. By changing the relative proportions of these components, cement manufacturers can control the properties of the product.

The primary product of cement hydration is a complex and poorly crystalline calcium-silicate-hydroxide gel (or CSH). A secondary product of hydration is calcium hydroxide, a highly crystalline material. A category of siliceous materials known as pozzolans have little or no cementitious value, but in finely divided form and in the presence of moisture will react chemically with calcium hydroxide to form additional CSH. This secondary hydration process has a generally beneficial effect on the final concrete properties. Examples of pozzolans are fly ash, ground granulated blast-furnace slag, and microsilica or silica fume.

The American Society for Testing and Materials (ASTM) defines five types of cement, specifying for each the mineral composition and chemical and physical characteristics such as fineness. The most common cement is Type I. Type III cement is used if more rapid strength development is required. The other types are characterized by either lower heat of hydration or better sulfate resistance than that of Type I cement.

Aggregate. The aggregate is a granular material, such as sand, gravel, crushed stone, or iron-blast furnace slag. It is graded by passing it through a set of sieves with progressively smaller mesh sizes. All material that passes through sieve #4 [0.187 in. (4.75 mm) openings] is conventionally referred to as fine aggregate or sand, while all material that is retained on the #4 sieve is referred to as coarse aggregate, gravel, or stone. By carefully grading the material and selecting an optimal particle size distribution, a maximum packing density can be achieved, where the smaller particles fill the void spaces between the larger particles. Such dense packing minimizes the amount of cement paste needed and generally leads to improved mechanical and durability properties of the concrete.

The aggregate constitutes typically 75% of the concrete volume, or more, and therefore its properties largely determine the properties of the concrete. For the concrete to be of good quality, the aggregate has to be strong and durable and free of silts, organic matter, oils, and sugars. Otherwise, it should be washed prior to use, because any of these impurities may slow or prevent the cement from hydrating or reduce the bond between the cement paste and the aggregate particles.

Fig. 1. Workers placing and vibrating concrete on a bridge deck including epoxy-coated reinforcing steel. (*Portland Cement Association*)

Admixtures. While aggregate, cement, and water are the main ingredients of concrete, there are a large number of mineral and chemical admixtures that may be added to the concrete. The four most common admixtures will be discussed.

1. Air-entraining agents are chemicals that are added to concrete to improve its freeze–thaw resistance. Concrete typically contains a large number of pores of different sizes, which may be partially filled with water. If the concrete is subjected to freezing temperatures, this water expands when forming ice crystals and can easily fracture the cement matrix, causing damage that increases with each freeze–thaw cycle. If the air voids created by the air-entraining agent are of the right size and average spacing, they give the freezing water enough space to expand, thereby avoiding the damaging internal stresses.

2. Water-reducing admixtures, also known as superplasticizers, are chemicals that lower the viscosity of concrete in its liquid state, typically by creating electrostatic surface charges on the cement and very fine aggregate particles. This causes the particles to repel each other, thereby increasing the mix flowability, which allows the use of less water in the mix design and results in increased strength and durability of the concrete. *See* FLOW OF SOLIDS.

3. Retarding admixtures delay the setting time, which may be necessary in situations where delays in the placement of concrete can be expected. Accelerators shorten the period needed to initiate cement hydration—for example, in emergency repair situations that call for the very rapid development of strength or rigidity.

4. Color pigments in powder or liquid form may be added to the concrete mix to produce colored concrete. These are usually used with white portland cement to attain their full coloring potential. *See* PIGMENT (MATERIAL).

Reinforcing steels. Because of concrete's relatively low tensile strength, it is typically reinforced with steel bars (**Fig. 1**). These bars are produced in standard sizes. In the United States, the identification number of a reinforcing bar refers to the nominal diameter expressed in eighths of an inch. For example, a number 6 bar has a diameter of $^6/_8 = 0.75$ inch. The available bar sizes range in general from 2 to 18. Reinforcing steel usually has a nominal yield strength of 60,000 lb/in.^{2} (414 MPa). To improve the bond strength between the bars and the concrete, the bars are fabricated with surface deformations or ribs. The relatively high cost of steel mandates its sparing use. This means that the concrete is usually assigned the task of resisting compressive forces, while the steel carries primarily the tensile forces. The alkalinity of the cement paste generally provides sufficient protection of the steel against corrosion. However, corrosion protection is often breached, for example, in highway bridge decks with continuous pore structure or traffic-induced cracks that permit the deicing chemicals used in winter to penetrate the protective concrete cover. Additional protective measures may be necessary, such as using epoxy coatings on the bars, noncorrosive steels, or nonmetallic reinforcement (for example, fiber-reinforced polymers). *See* CORROSION.

Other important concrete terminology can be defined. A mixture of cement and water is called cement paste. Cement paste plus fine aggregate is called mortar or concrete matrix. Mortar plus coarse aggregate constitutes concrete. Concrete reinforced with steel or other high-strength material is known as reinforced concrete. *See* MORTAR.

Production of concrete. The properties of the end product depend not only on the various constituent materials listed above but also on the way they are proportioned and mixed, as well as on the methods of placing and curing the composite.

Mix design. It is not possible to predict the strength and other concrete properties solely based on the properties and proportions of the mix components. Therefore, mixes are designed on an empirical basis, often with the help of trial mixes. The objective of the mix design is to assure that the product has specified properties in both the fresh and hardened state. The most important mix design variable is the weight ratio between water and cement, referred to as the w/c ratio. There is a theoretical minimum amount of water needed for the cement to completely hydrate, which can be determined using the equations of hydration chemistry. Any excess water creates pores which, together with any air-filled pores, do not contribute to the material strength. The result is a drastic decrease in strength as a function of increasing the w/c ratio. On the other hand, too low w/c ratios cause poor workability of the concrete. For practical reasons, the w/c ratio typically varies between 0.4 and 0.6. The other important mix design variables are the cement-to-aggregate ratio and the fine-to-coarse aggregate ratio. Also, the maximum aggregate size is of importance. And since cement is the most expensive bulk ingredient, the mix design will generally aim at the least amount of cement necessary to achieve the design objectives.

Construction practice. The material obtained immediately upon mixing of the various concrete ingredients is called fresh concrete, while hardened concrete results when the cement hydration process has advanced sufficiently to give the material mechanical strength. Concrete that is batched and mixed in a plant and then transported by truck in its fresh, or plastic, state to the construction site for final placement is called ready-mixed concrete. If the resulting structure or highway pavement, for example, remains in place after placement, the concrete is referred to as cast-in-place concrete, whether mixed on-site or off-site. Precast concrete refers to any structure or component that is produced at one site, typically in a precasting plant, and then transported in its hardened state to its final destination. The controlled environment of a precasting plant generally permits higher quality control of the product than is possible with cast-in-place concrete produced at a construction site. *See* CONSTRUCTION METHODS; PAVEMENT.

Code-writing organizations, such as the American Society for Testing and Materials, the American Concrete Institute (ACI), and the American Association of State Highway and Transportation Officials (AASHTO), have published detailed specifications and recommendations for measuring, mixing, transporting, placing, curing, and testing concrete. A proper mix design assures that the concrete mix is well proportioned. The mixing time should be sufficient to assure a uniform mixture. When placing the concrete, care should be taken to avoid segregation. For example, if dropped too far, the heavy or big aggregate particles can settle and lighter mix components, such as water, tend to rise. The concrete is conveyed from the mixing truck to its final destination in dump buckets by cableways or cranes or by pumping through pipelines. In modern high-rise building construction, concrete has been pumped as high as a thousand feet (330 m).

During placement, large amounts of air are entrapped in the mix, which lowers the strength of the hardened concrete. Much of the air is removed by compaction, which is achieved by either immersing high-frequency vibrators into the fresh concrete or attaching them to the outside faces of the formwork (Fig. 1). Care must be taken to avoid excessive vibration; otherwise the heavy aggregate particles settle down and the light mixing water rises to the surface.

For underwater construction, the concrete is placed in a large metal tube, called a tremie, with a hopper at the top and a valve arrangement at the submerged end. For so-called shotcrete applications such as tunnel linings and swimming pools, the concrete mixture is blown under high pressure through a nozzle directly into place to form the desired surface.

Before the concrete sets and hardens, it is relatively easy to give its exposed surfaces the desired finish. Surfaces cast against forms can be given various textures by using form liners or treating the surfaces after forms are removed. Hardened surfaces can be textured by grinding, chipping, bush-hammering, or sandblasting.

Curing. Once the concrete has been placed and compacted, it is critical that none of the mixing water needed for cement hydration is lost. This is the objective of curing. For example, in hot or dry weather large exposed surfaces will lose water by evaporation. This can be avoided by covering such surfaces with sheets of plastic or canvas or by periodically spraying them with water. In precast concrete plants, concrete elements are often steam-cured, because the simultaneous application of hot steam and pressure accelerates the hydration process, which permits high turnover rates for the formwork installations.

Quality control. To assure that the finished material has the specified properties, quality assurance and quality control procedures need to be implemented. From a public safety viewpoint, strength is the most important property. To assure adequate strength,

Fig. 2. Concrete slump test with a slump of 1.5 in., typical for pavement work. (*Portland Cement Association*)

such as determining the time of safe formwork removal, concrete batches are sampled by casting test cylinders at the same time and place as the structure being built. These cylinders are then tested by accredited laboratories to determine their strength. If the in-situ strength of existing structures needs to be evaluated, concrete cores may be drilled from selected parts of the structure and tested in the laboratory. There are also nondestructive test methods available to determine various properties of hardened concrete.

Properties of fresh concrete. The most important property of fresh concrete is its workability or flowability, because this determines the ease with which it can be placed. It is determined using a slump test, in which a standard truncated metal cone form is filled with fresh concrete (**Fig. 2**). The mold is then lifted vertically, and the resulting loss in height of the concrete cone, or the slump value, is indicative of the concrete's workability. For very liquid mixes, the flow test is performed, which is similar to the slump test, except that the mean diameter of the cake formed by the fresh concrete (or mortar) is measured.

A short while after casting, the concrete stiffens and loses its plasticity. The time of setting can be determined by repeatedly dropping a calibrated needle into the fresh concrete and measuring the time when the needle no longer sinks in.

Properties of hardened concrete. By far, the most important property of hardened concrete is its compressive strength. Since this strength continues to increase with continuing cement hydration, it is a function of age which is the time after casting. In the United States, the strength is determined 28 days after casting by loading standardized test cylinders up to failure. In Europe, test cubes are often used. Most commercially produced concrete has compressive strengths between 3000 and 6000 lb/in.^{2} (20 and 40 MPa). If loaded in tension, the material fails at a stress much lower than that, typically of the order of 10% of the compressive strength. Because of this low (and unreliable) tensile strength, concrete is usually reinforced with steel bars. *See* STRESS AND STRAIN.

During hydration and especially if allowed to dry after hardening, the concrete volume decreases by a small amount because of shrinkage. If this shrinkage is restrained somehow, it can lead to cracking. Shrinkage deformations caused by drying can be reversed only partially upon wetting. A concrete member or structure subjected to external load will undergo deformations which, up to a point, are proportional to the amount of applied load. If these loads remain in place for an appreciable time (months or years), these deformations will increase due to a material property called creep. Even for regular concrete mixes, creep deformations can be two or three times as high as the initial elastic deformations, especially if the concrete is loaded at a very young age. When designing concrete structures, such creep and shrinkage deformations must be accounted for. *See* CREEP (MATERIALS); ELASTICITY.

Durability. Durability is the ability of a material (or structure) to maintain its various properties throughout its design or service life. Some concrete structures built by the Romans served for over 2000 years. A material that loses its strength in time, for whatever reason, cannot be considered durable.

There can be numerous causes for loss of durability or deterioration of concrete structures. The most common one is an excessive amount of cracking or pore structure. Most concrete structures contain numerous cracks. But as long as these remain small (of the order of 0.25 mm or less), they are generally invisible to the naked eye, and the concrete remains basically impermeable to salts and other aggressive agents, so that it can continue to protect the reinforcing steel against corrosion. Larger cracks provide easy access for such agents to the steel, thereby promoting corrosion. Since the steel corrosion products occupy a larger volume than sound steel, they produce internal pressure during expansion and can spall off the protective concrete cover, the loss of which may render the structure unsafe to resist loads.

The concrete itself may deteriorate or weather, especially if subjected to many cycles of freezing and thawing, during which the pressure created by the freezing water progressively increases the extent of internal cracking. In addition, carbon in the atmosphere can react chemically with the cement hydration products. This process is known as carbonation. It lowers the pH of the concrete matrix to the point where it can no longer protect the steel against corrosion.

Most types of aggregate used for concrete production are inert; that is, they do not react chemically with the cement or hydration products. However, there are various aggregate types, including those containing amorphous silica such as common glass, which react chemically with the alkali in the cement. In the presence of moisture, the alkali–aggregate reaction products can swell and cause considerable damage. The deterioration of numerous major structures and highway pavements has been attributed to such reactions, especially alkali–silica reaction, often after years of seemingly satisfactory service. Other common causes of chemical attack are sulfates found in soils, chlorides in seawater, acid rain, and other industrial pollutants. Generally, structures built with well-designed concrete mixes, having low porosity or high density and minimal cracking, are likely to resist most causes of chemical attack, although for service in particularly aggressive environments special countermeasures may have to be taken.

Under repeated load applications, structures can experience fatigue failure, as each successive load cycle increases the degree of cracking and material deterioration to the point where the material itself may gradually lose its strength or the increased extent of cracking is the source of loss of durability.

Thermal and other properties. The heavy weight of concrete [its specific gravity is typically 2.4 g/cm^3 (145 lb/ft^3)] is the source of large thermal mass. For this reason, massive concrete walls and roof and floor slabs are well suited for storing thermal energy. Because of this heat capacity of concrete, together with its reasonably low thermal conductivity, concrete structures can moderate extreme temperature cycles and increase the comfort of occupants. Well-designed concrete mixes are impermeable to liquids and therefore suitable for storage tanks without the need for impermeable membranes or liners. Although steel reinforcing bars conduct electricity and influence magnetic fields, the concrete itself does neither. *See* CONCRETE SLAB; FLOOR CONSTRUCTION; ROOF CONSTRUCTION.

Special concretes and recent developments. Concrete is an engineered material, with a variety of specialty products designed for specific applications. Some important ones are described below.

Lightweight concrete. Although the heavy weight or large mass of typical concrete members is often an advantage, there are situations where this is not the case. For example, because of the large stresses caused by their own heavy weight, floor slabs are often made lighter by using special lightweight aggregate. To further reduce weight, special chemical admixtures are added, which produce large porosity. Such high porosity (in either the matrix or the aggregate particles themselves) improves the thermal resistance of the concrete as well as sound insulation, especially for higher frequencies. However, because weight density correlates strongly with strength, ultralightweight concretes [1.1 g/cm^3 (70 lb/ft^3) and less] are used only for thermal or sound insulation purposes and are unsuitable for structural applications.

Heavyweight concrete. When particularly high weight densities are needed, such as for shielding in nuclear reactor facilities, special heavyweight aggregate is used, including barite, limonite, magnetite, scrap metal, and steel shot for fine aggregate. Weight densities can be achieved that are twice that of normal-weight concrete.

Architectural concrete. Concrete surfaces that remain exposed may call for special finishes or textures according to the architect's desires. Textures are most readily obtained by inserting special form liners before casting the concrete. Sometimes the negative imprint of roughly sawn timber is considered attractive and left without further treatment. Other surface textures are obtained by sandblasting, bush-hammering, and similar treatments. Ordinary portland cement gives concrete the typical gray color. By adding color pigments to the mix, a large variety of colors can be produced, especially in combination with white portland cement. Concrete mixed with specialty aggregate, such as marble, and ground smooth is known as terrazzo concrete, which is very popular for decorative surfaces on floors and walls. Recently, crushed postconsumer glass has been used as aggregate for decorative applications because of the esthetic possibilities, provided suitable countermeasures against alkali–silica reaction are taken (**Fig. 3**).

Fiber-reinforced concrete. The concrete matrix can be reinforced with short, randomly distributed fibers. Fibers may be metallic (primarily steel), synthetic (such as polypropylene, nylon, polyethylene, polyvinyl alcohol, and alkali-resistant glass), or natural (such as sisal, coconut, and rice husk). Such fibers are typically used in addition to conventional steel reinforcement, but in some applications as its replacement. For example, precast glass-fiber-reinforced building façade elements are widely used in the United States. By being uniformly distributed and randomly oriented, the fibers give the concrete matrix tensile strength, ductility, and energy absorption capacities that it otherwise would not have. In particular, when these fibers are engineered to optimize the fracture energy, so-called high-performance fiber-reinforced concrete is obtained, which has remarkable deformational characteristics and extraordinary resistance to blast and impact loads. In the

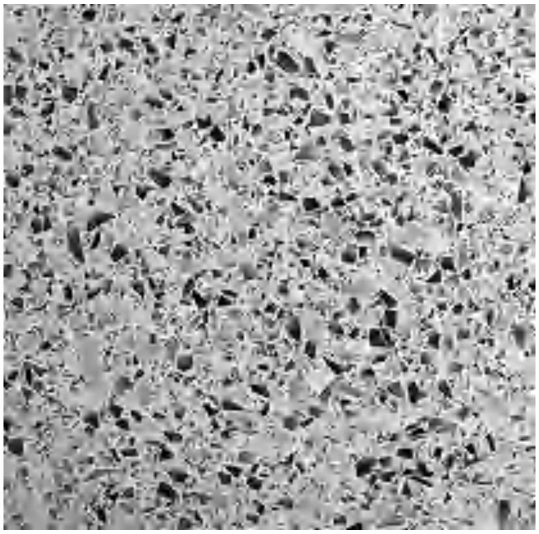

Fig. 3. Glass concrete tile. (*C. Meyer*)

concrete industry, it is very common to add small amounts of polypropylene fibers to reduce the extent of shrinkage cracking.

Textile-reinforced concrete. Whereas in fiber-reinforced concrete the fibers are short [usually no longer than 2 in. (5 cm)] and discontinuous, textile-reinforced concrete contains continuous woven or knitted mesh or textiles. Conceptually, such reinforcement acts similarly to conventional steel reinforcing bars or welded steel wire fabrics. But these fabric materials are noncorrosive and can have mechanical properties that are superior to those of steel. The fabrics can be premanufactured in a wide variety of ways, thereby lending themselves to new applications, especially for repairing or strengthening existing concrete structures. *See* TEXTILE.

Polymer-modified concrete. In polymer-modified concrete, also known as latex-modified concrete, a polymer is added to improve the material's strength, imperviousness, or both. In applications such as highway bridge decks, often a layer of latex-modified concrete is placed on top of a regular reinforced concrete deck for additional protection of the steel reinforcement. In polymer concrete, the hydraulic cement is replaced by an organic polymer as the binder. *See* POLYMER; POLYMERIC COMPOSITE.

Roller-compacted concrete. This type of concrete is formulated with very low contents of portland cement and water and therefore is of relatively low-cost. It is often used for pavements and dams. It can be transported by dump trucks or loaders, spread with bulldozers or graders, and compacted with vibratory rollers. Because the cement content is so low, the heat of hydration does not cause the kind of problems encountered in dams built with conventional concrete.

Ultra-high-strength concrete. Whereas concretes with compressive strengths of 6000 to 12,000 lb/in.^{2} (40 to 85 MPa) can now be categorized as high-strength, a new technology has been developed that results in strengths of 30,000 lb/in.^{2} (200 MPa) and higher. The key ingredient of this ultra-high-strength concrete is a reactive powder; therefore, it is also known as reactive-powder concrete. Other characteristics of this material are low water–cement ratios, carefully selected high-strength aggregates, and small steel fibers.

Self-leveling concrete. The need for good workability has been mentioned. The need for highly skilled workers who can properly compact concrete at the construction site prompted researchers in Japan to optimize the mix design such that the fresh concrete can flow into place without the need for further vibration. The main challenge was to obtain a low-viscosity mix without the threat of desegregation. This innovation is particularly important in applications with dense steel reinforcement, which traditionally have caused severe difficulties of producing high-quality concrete.

"Green" concrete. Concrete is by far the most widely used building material. Well over 10 billion tons are produced worldwide each year, requiring enormous natural resources. Also, it has been estimated that the production of 1 ton of portland cement causes the release of 1 ton of carbon dioxide (CO_2) into the atmosphere, a gas that is known to contribute to global warming. Together with the large amounts of energy required to produce portland cement, the cement and concrete industry has a major impact on the environment worldwide. Efforts are underway to reduce this impact and transform the industry to conform to the principles of sustainable development. The most significant step is the replacement of portland cement by other cementitious or pozzolanic materials, preferably materials that are by-products of industrial processes, such as fly ash (the by-product of coal-burning power plants) and granulated blast furnace slag (a by-product of the steel industry). To reduce the need for virgin aggregate, recycled concrete is the most promising approach, because construction debris, in particular demolished concrete, constitutes a major component of solid waste that fills up sparse landfill capacity. These recent developments are much more advanced in Europe and Japan than in the United States. But the "green" building movement is gaining momentum there as well, and for the concrete industry to maintain its dominant position within the construction industry, it is undertaking major efforts to make concrete a more "green" material.

Concrete beam

A structural member of reinforced concrete placed horizontally to carry loads over openings.

Because both bending and shear in such beams induce tensile stresses, steel reinforcing tremendously increases beam strength. Usually, beams are designed under the assumption that tensile stresses have cracked the concrete and the steel reinforcing is carrying all the tension. *See* STRESS AND STRAIN.

Two design theories are used, elastic design and ultimate-load design.

Elastic design. The following assumptions are made for elastic design:

1. Plane sections remain plane after bending and are perpendicular to the longitudinal fibers.
2. The stress-strain curve is a straight line.
3. The ratio n of the modulus of elasticity of steel E_s to that of concrete E_c is a constant $n = E_s/E_c$
4. The concrete does not carry tensile stress.

Transformed section. One approach to elastic design of reinforced concrete beams is to convert the steel to concrete. Because the steel and concrete are assumed to be firmly bonded and thus strained the same amount, the stress in the steel is n times the concrete stress. Hence the steel area may be replaced by an equivalent concrete area which is n times as large (**Fig. 1**).

If the equivalent area is placed at the same level as the steel and the moment of inertia I computed for the transformed section, the bending stresses can be computed from the simple flexural formula $f = Mc/I$ where M is the bending moment and c the distance from the neutral axis to the level at which stresses are to be computed.

Rectangular beams. The following formulas can be derived from the basic assumptions of elastic theory. Equation (1) locates the neutral axis, given steel and

$$\frac{nf_c}{f_s} = \frac{k}{1-k} \tag{1}$$

concrete extreme stresses, where n is the ratio of the modulus of elasticity of steel to that of concrete, f_c is the stress in the extreme fiber of the concrete, f_s is the stress in the steel, and k is the ratio of the distance between the top of the beam and the neutral axis to the distance between the top of the beam and the steel (**Fig. 2**).

The design equation for equal moment resistance of concrete and steel (balanced design) is Eq. (2).

$$k = \frac{1}{1 + f_s/nf_c} \tag{2}$$

Equations (3)–(6) are review equations.

$$k = \sqrt{2np - (np)^2} - np \tag{3}$$

$$j = \frac{1-k}{3} \tag{4}$$

$$M_c = {}^1/_2 f_c kjbd^2 \tag{5}$$

$$M_s = f_s A_s jd \tag{6}$$

Here p is the ratio of effective area of tension reinforcement to effective area of concrete in beams, j is the ratio of lever arm of resisting couple to depth d, M_c is the moment resistance of the concrete, b is the width of the rectangular beam or width of flange of the T beam, d is the depth from the compressive surface of beam or slab to center of longitudinal tension reinforcement, M_s is the moment resistance of the steel, and A_s is the steel area.

When M_s is less than M_c, the capacity of the steel determines the maximum moment that the beam will carry. The beam is called underreinforced. If the beam is loaded to failure, the steel rather than the concrete determines the maximum load that is sustained.

When M_c is less than M_s, the concrete determines the maximum moment the beam will carry. The beam is said to be overreinforced. Usually, overreinforced beams are avoided because they are not considered economical and failure may occur without warning.

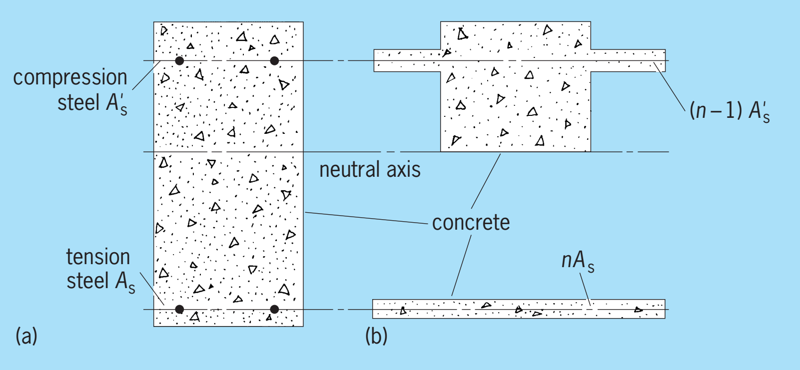

Fig. 1. Sketch of concrete beam. (*a*) Actual beam section. (*b*) Same section transformed. The use of the term $(n-1)A'_s$ prevents compression steel area from being included twice when computing moment of inertia of section; $(n-1)A'_s = nA'_s - A'_s$, because computations require the equivalent steel area to be added to the original concrete area above the neutral axis.

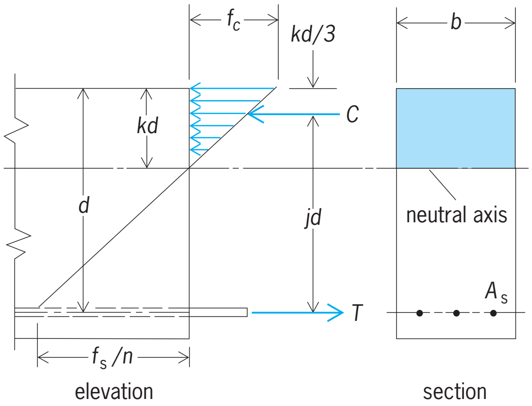

Fig. 2. Stress distribution in a rectangular beam designed according to elastic theory. *C* is total compressive force in concrete and *T* is total tensile stress in longitudinal reinforcement.

To design a rectangular beam by the elastic theory: (1) Select allowable unit stresses and determine k from the formula for balanced design; (2) compute j; (3) assuming the resisting moment of the concrete equal to the bending moment on the section, calculate bd^2 and select values for b and d; and (4) determine the steel area by equating the resisting moment of the steel to the bending moment on the section. This equation indicates that the amount of steel required can be reduced by increasing the depth. If the depth is fixed and an overreinforced beam results, it may be economical to use compression steel.

Compression-reinforced rectangular beams. Reinforcement may be added in the compression zone of concrete beams when the resisting moment of the concrete is less than the bending moment on the section or to avoid an overreinforced design. The compression steel is assumed to act as in plastic design; the Building Code Requirements of the American Concrete Institute allow the steel to take twice the stress given by elastic-theory formulas, provided the allowable tensile stress of the steel is not exceeded. Formulas for design of beams with both tension and compression reinforcement can be derived from the elastic theory in the same manner as for beams with tension reinforcement only, but they are too complicated for ordinary use. Equations (7)–(12) are either exact or a close approximation.

$$k = \frac{1}{1 + f_s/nf_c} \tag{7}$$

$$f_s' = nf_c\frac{kd - d'}{d - kd} \tag{8}$$

$$A_s = \frac{M}{f_s jd} \tag{9}$$

$$M_c = {}^1/_2 f_c bkd\left(d - \frac{kd}{3}\right) \tag{10}$$

$$M_s' = M - Mc \tag{11}$$

$$A_s' = \frac{M_s'}{2f_s'(d - d')} \tag{12}$$

k = ratio of distance between top of beam and neutral axis to the distance between top of beam andtension steel
f_s = allowable steel stress
f_c = allowable concrete stress
n = ratio of modulus of elasticity of steel to that of concrete
f_s' = stress in compression steel computed from elastic theory formula
d' = distance from top of beam to compression steel
A_s = area of tension steel
M = bending moment on the section
jd = moment arm of the tensile
jd = reinforcement (assumed)
M_c = resisting moment of the concrete
b = width of beam
d = distance from top of beam to tension steel
M_s' = resisting moment of the compression steel
A_s' = area of compression steel

Concrete T beams. A slab cast integrally with a rectangular concrete beam usually is assumed to assist the beam in carrying loads. In regions of positive bending moment, the two act together as a T beam. In regions of negative moment, the beam is designed as a rectangular section because the slab is in tension and is assumed not to be able to resist such stresses, which must be taken by the reinforcing. *See* CONCRETE; CONCRETE SLAB.

If the neutral axis of a T beam is within the slab, it is designed as a rectangular beam, with width b the same as that of the flange, to resist bending moments. For shear, however, only the width of stem b' can be assumed to be effective.

If the neutral axis falls within the stem, the section can be designed as a T beam. However, the compression in the stem is negligible and can be ignored to simplify computations.

The American Concrete Institute's code recommends the following limits for the part of the slab that can be considered effective as the flange: (1) b shall be less than one-fourth the span length, (2) the overhanging width of flange shall not exceed eight times the slab thickness, and (3) the overhanging width shall not exceed one-half the clear distance between beams.

If t is the flange thickness and the remaining symbols are the same as for elastic-theory design of rectangular beams, Eqs. (13) through (20) can be used

$$k = \frac{1}{1 + f_s/nf_c} \tag{13}$$

$$\frac{f_s}{f_c} = \frac{bt(2kd - t)}{2A_s kd} \tag{14}$$

$$kd = \frac{2ndA_s + bt^2}{2nA_s + 2bt} \tag{15}$$

$$z = \frac{t(3kd - 2t)}{3(2kd - t)} \tag{16}$$

$$jd = d - z \tag{17}$$

$$M_s = A_s f_s jd \tag{18}$$

$$M_c = \frac{f_c btjd}{2kd}(2kd - t) \tag{19}$$

$$f_c = \frac{f_s}{n}\left(\frac{kd}{d - kd}\right) \tag{20}$$

for T beams when stem compression is neglected.

The shear unit stress in T beams is computed from Eq. (21), where V is the shear on the section. *See*

$$v = \frac{V}{b'd} \tag{21}$$

ELASTICITY; HOOKE'S LAW; YOUNG'S MODULUS.

Ultimate-load design. Other names for ultimate-load design are ultimate-strength design, limit-load design, and the plastic design. Design assumptions differ from those of the elastic theory principally in that the stress-strain curve is not a straight line. Instead of being designed to carry allowable unit stresses, as in the elastic theory, beams are proportioned to carry at ultimate capacity the design load multiplied by a safety factor.

Among the reasons for using ultimate-load design are the following:

1. The elastic theory is not corroborated with sufficiently great accuracy by beam tests.
2. It is logical to use different safety factors for live and dead loads. Different factors can easily be used with ultimate-load design but not with elastic design.
3. Column design is based on a modified ultimate load theory. To avoid inconsistency, structural members subjected to both bending and compressive stress should also be designed by ultimate-load theory.

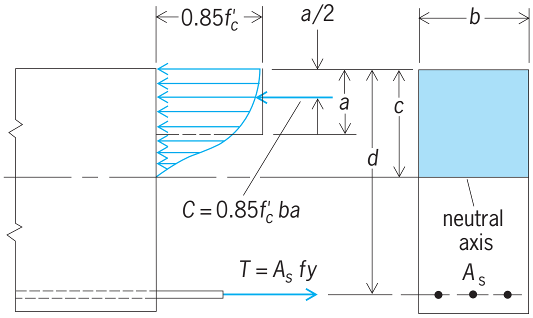

Fig. 3. Stress distribution in a rectangular beam under ultimate load; *T* and *C* are as in Fig. 2.

4. The ultimate strength of beams carrying both bending and axial compression, as determined in tests, conforms closely with ultimate-load theory.

Rectangular beams. The comprehenssive stress distribution may be assumed to be a rectangle, parabola, trapezoid, or any other shape that conforms to test data. Maximum concrete stress is assumed to be $0.85f'_c$, where f'_c is the compressive strength of a standard-test concrete cylinder at 28 days (**Fig. 3**).

When the moment resistance of the steel is less than that of the concrete, the bending moment that a rectangular beam with only tension reinforcement can sustain under ultimate load is Eq. (22).

$$\begin{aligned} M_u &= \phi\left[A_s f_y (d - a/2)\right] \\ &= \phi\left[bd^2 f'_c q(1 - 0.59q)\right] \end{aligned} \qquad (22)$$

A_s = area of tension reinforcement
f_y = yield point stress of steel
f'_c = comprehensive strength of standard-test concrete cylinder at 28 days
ϕ = reduction factor = 0.90 for this type of beam in flexure
b = width of beam
d = distance from top of beam to centroid of the steel
a = depth of rectangular stress block
$q = A_s f_y / bdf'_c$

Reinforcement ratio $p = A_s/bd$ should not exceed $0.75p_b$, where p_b is given by Eq. (23), and k_1 =

$$p_b = \frac{0.85k_1 f'_c}{f_y}\left(\frac{87,000}{87,000 + f_y}\right) \qquad (23)$$

0.85 for values of f'_c up to 4000 lb/in.^{2}, 0.80 for 5000 lb/in.^{2}, and 0.75 for 6000 lb/in.^{2}.

Compression-reinforced rectangular beams. Based on a nonlinear stress-strain relation, the bending moment that a rectangular beam with both compression and tension reinforcement can sustain under ultimate loads is shown in Eq. (24).

$$M_u = \phi[(A_s - A'_s)f_y(d - a/2) + A'_s f_y(d - d')] \qquad (24)$$

A_s = area of tension steel
A'_s = area of compression steel
f_y = yield point stress of the steel
d = distance from top of beam to centroid of tension steel
d' = distance from top of beam to centroid compression steel
$a = (A_s - A'_s)f_y/0.085f'_c b$
b = width of beam
f'_c = compressive strength of standard-test concrete cylinder at 28 days

Equation (24) holds only if Eq. (25) is true, where

$$\begin{aligned} (p - p') &\geq 0.85k_1 \frac{f'_c d'}{f_y d}\left(\frac{87,000}{87,000 - f_y}\right) \\ &\leq 0.75p_b \end{aligned} \qquad (25)$$

$p = A_s/bd$; $p' = A'_s/bd$; and p_b and k_1 are the same as for beams with tension steel only.

Concrete T beams. Two cases should be considered, one with a relatively thick slab and one with a thin slab. If the flange thickness exceeds $1.18qd/k_1$, where $q = pf_y/f'_c$, the bending moment under ultimate load may be taken to be the same as that for a rectangular beam with tension reinforcement only. The value of p used in computing q should be A_s/bd, with b the width of the flange. For thinner flanges, use Eq. (26) to compute bending moment.

$$\begin{aligned} M_u = \phi[(A_s - A_{sf})f_y(d - a/2) \\ + A_{sf} f_y(d - 0.5t)] \end{aligned} \qquad (26)$$

$A_{sf} = 0.85f'_c(b - b)t/f_y$
f_y = yield point stress of the steel
t = flange thickness
b = width of flange
b' = width of stem
d = distance from top of beam to centroid of tension steel
$a = (A_s - A_{sf})f_y/0.85f'_c b'$

Equation (26) holds only if $p_w - p_f$ does not exceed $0.75p_b$, where $p_w = A_s/bd$, $p_f = A_{sf}/bd$, and p_b is the same as for beams with tension reinforcement only, as in Eq. (23).

Shear and bond. Maximum unit shear stress v acting on a section of a beam subjected to total shear V is given by Eq. (27), where b is the beam width, and

$$v = \frac{V}{bd} \qquad (27)$$

d is depth from top of beam to the tensile steel. The bond stress can be computed from Eq. (28), where

$$u = \frac{V}{\sum_o jd} \qquad (28)$$

Σ_o is the sum of the bar perimeters. This formula applies only to tension steel. Bond stresses will be at a maximum where shear is a maximum and the steel is in the tension side of the concrete.

To develop a given bar stress through bond, a bar should be embedded a length L at least equal to Eq. (29), where a is the side of a square bar or the

$$L = \frac{f_s a}{4u} \qquad (29)$$

diameter of a round bar. This length of embedment is called anchorage. Usually, bars are extended 10 diameters past the section where they are no longer required for bending stress.

Shear in itself is not as important in the design of a concrete beam as the tensile stresses that accompany it on a diagonal plane. To resist these stresses, concrete beams should be reinforced with bent-up bars or with stirrups. The latter are bars placed vertically or on an incline in a beam. They may be the legs of a single U-shaped bar or the sides of a rectangle.

The shear V' taken by stirrups is assumed to be the total shear on the section at which the stirrups are to be placed, less the shear taken by the concrete, vbd. The cross-sectional area of the stirrups needed at a section is given by Eq. (30), where f_v is the allowable

$$A_v = \frac{V's}{f_v d} \qquad (30)$$

tensile stress of the steel, and s is the stirrup spacing.

If the stirrups, instead of being vertical, are laid at an angle α with the horizontal, greater steel area is required, as in Eq. (31). Every potential 45° crack

$$A_v = \frac{V's}{d(\sin\alpha + \cos\alpha)f_v} \qquad (31)$$

should be crossed by at least one line of reinforcement.

If the area of the stirrups is given, the spacing can be computed from the two formulas above. The first stirrup is usually placed as close to the support as practical, generally 2 in. (5 cm). Stirrups should be placed throughout a beam, even if theoretically they are not needed. They serve also as supports for the longitudinal steel. When not required for diagonal tension, stirrups should be placed at most 18 in. (45 cm) apart.

It is common practice to cut off bars or bend them up where they are no longer needed to resist tension at the bottom of the beam. The bent bars serve as diagonal-tension reinforcement and tensile reinforcement at the top of the beam over the support.

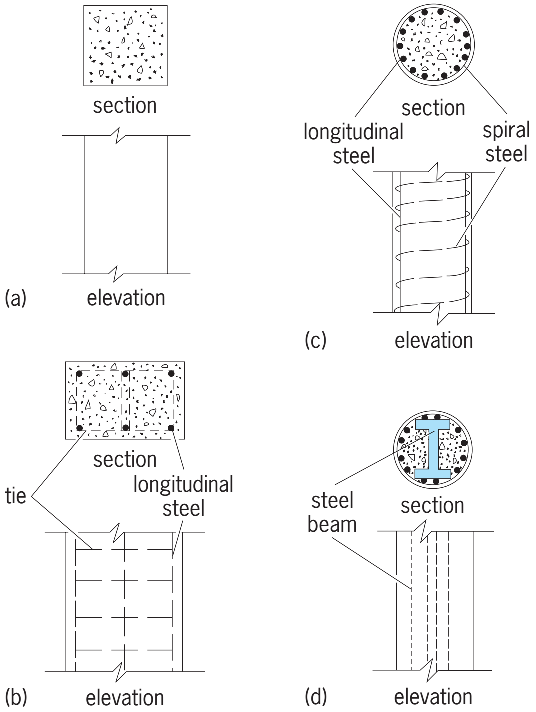
Concrete column

A structural member subjected principally to compressive stresses. Concrete columns may be unreinforced, or they may be reinforced with longitudinal bars and ties (tied columns) or with longitudinal bars and spiral steel (spiral-reinforced columns). Sometimes the columns may be a composite of structural steel of cast iron and concrete (see **illus.**).



Column types. (*a*) Plain concrete. (*b*) Tied column. (*c*) Spiral-reinforced column. (*d*) Composite column.

Plain concrete columns. Unreinforced concrete columns are seldom used because of transverse tensile stresses and the possibility of longitudinal tensile stresses being induced by buckling or unanticipated bending. Because concrete is weak in tension, such stresses are generally avoided.

When plain concrete columns are used, they usually are limited in height to five or six times the least thickness. Under axial loading, the load divided by the cross-sectional area of the concrete should not exceed the allowable unit compressive stress for the concrete.

Axially loaded reinforced columns. Reinforced concrete columns are designed by ultimate-load theory. Two types of column are considered: short and long. Those whose length is three to ten times their least lateral dimension are called short columns.

For spiral-reinforced short columns, the American Concrete Institute code gives the formula for the allowable load in pounds shown in Eq. (1), where

$$P = 0.25 f'_c A_g + f_s A_s \qquad (1)$$

f'_c is the 28-day compressive strength of a standard concrete test cylinder in pounds per square inch (lb/in.^{2}), A_g the gross area of section in square inches, f_s the allowable unit stress for steel in pounds per square inch, and A_s the area of reinforcing steel in square inches.

For a tied column, the allowable load is 85% of that for a spiral-reinforced column. Spiral-reinforced columns are stronger because columns tend to fail by a lateral bursting of the concrete as the longitudinal bars bend outward, and spiral reinforcing is more effective than ties in restraining the concrete. If spirals are used, the longitudinal bars should be arranged in a circle.

For long columns, the allowable load is reduced from that permitted for short columns because of the possibility of buckling. When *h*/*d*, the ratio of unsupported length of column to least lateral dimension, is equal to or greater than 10, one should use the appropriate reduction factor given in Sec. 916 of the Building Code Requirements for Reinforced Concrete (ACI 318–63).

Spiral reinforcement is determined from Eq. (2),

$$p' \geq \frac{0.45(R-1)f'_c}{f'_s} \qquad (2)$$

where p' is the ratio of the volume of spiral reinforcement to the volume of the spiral core (out-to-out of the spiral), R is the ratio of gross area to core area, and f'_s is the yield-point stress of spiral steel, with a maximum of 60,000 lb/in.^{2}

Composite columns. A concrete compression member having a structural steel or cast iron core with a cross-sectional area not exceeding 20% of the gross area of the column is called a composite column. Spiral and longitudinal reinforcing also may be incorporated in the concrete.

The allowable load in pounds on a composite column is given by Eq. (3), where A_c is the net area of

$$P = 0.225A_c f'_c + f_r A_r + f_s A_s \qquad (3)$$

the concrete section (A_g-A_r-A_s), A_s is the area of longitudinal reinforcement other than the metal core, A_r is the cross-sectional area of the structural steel or cast iron core, f_r is the allowable unit stress for the core, and f_s is the allowable unit stress for the longitudinal reinforcement.

If the core area is 20% or more of the gross area and the concrete is at least 2 in. (5 cm) thick over all metal except rivet heads, the members is called a combination column. If the concrete is to be allowed to share the load with the core, the concrete must be reinforced; usually wire fabric is wrapped completely around the core.

Combined bending and axial load. Because columns are designed by ultimate-load theory and this theory has also been developed for beams, it is logical to design columns subjected to both bending and axial loads by ultimate-load theory. The ultimate load is given by Eqs. (4) and (5), where f'_c is the compressive

$$P_u = \phi(0.85f'_c ba + A'_s f_y - A_s f_s) \qquad (4)$$

$$P_u e = \phi[0.85f'_c ba(d - a/2) + A'_s f_y(d - d')] \qquad (5)$$

strength of concrete at 28 days; f_y is the yield strength reinforcement; f_s is the calculated stress in reinforcement when less than yield strength; A'_s is the area of compression reinforcement; A_s is the area of tension reinforcement; e is the eccentricity of axial load at the end of the member measured from centroid of tension reinforcement; a is the depth of equivalent rectangular compression-stress block; b is the width of compression flange; d is the distance from extreme compression fiber to centroid of tension steel; d' is the distance from extreme compression fiber to centroid of compression steel; and ϕ is a capacity reduction factor. It equals 0.75 for spiral-reinforced members and 0.70 for tied members.

For strength reduction factors when length-thickness ratio exceeds 10, one should consult Sec. 916 of the Building Code Requirements for Reinforced Concrete (ACI 318–63). *See* CONCRETE SLAB; REINFORCED CONCRETE.

Frederick S. Merritt

Concrete slab

A shallow, reinforced-concrete structural member that is very wide compared with depth. Spanning between beams, girders, or columns, slabs are used for floors, roofs, and bridge decks. If they are cast integrally with beams or girders, they may be considered the top flange of those members and act with them as a T beam. *See* CONCRETE; CONCRETE BEAM.

One-way slab. A slab supported on four sides but with a much larger span in one direction than in the other may be assumed to be supported only along its long sides. It may be designed as a beam spanning in the short direction. For this purpose a 1-ft width can be chosen and the depth of slab and reinforcing determined for this unit.

Some steel is also placed in the long direction to resist temperature stresses and distribute concentrated loads. The area of the steel generally is at least 0.20% of the concrete area.

Two-way slab. A slab supported on four sides and with reinforcing steel perpendicular to all sides is called a two-way slab. Such slabs generally are designed by empirical methods. A two-way slab is divided into strips for design purposes.

The American Concrete Institute (ACI) code recommends the following design method: Divide the slab in both directions into a column strip and middle strip (**Fig. 1**). If the ratio *S*/*L* of the short span to the long span is equal to or greater than 0.5, the width

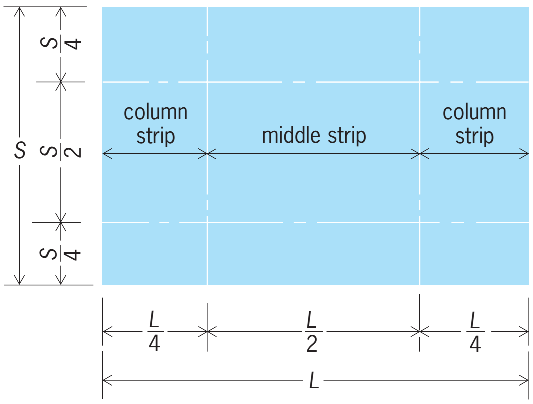


Fig. 1. A two-way slab in strips for design purposes.

of the middle strip extending in the short direction equals $L/2$, as shown. If S/L is less than 0.5, the width of the middle strip in the short direction is $L - S$; the remaining width is divided equally between the two column strips. However, when S/L is less than 0.5, most of the load would be carried in the short direction, and it would be desirable to design the slab as a one-way slab.

A table in the ACI code gives coefficients for calculation of the bending moments in the middle strip for different values of S/L and different types of panels. The moment in the column strip is assumed to be two-thirds that in the middle strip. The reinforcing steel area is determined from $A_s = M/f_s jd$, where M is the bending moment, f_s the tensile unit stress in longitudinal reinforcement, and j the ratio of lever arm of resisting couple to d, the depth from compressive surface of beam or slab to center of longitudinal tension reinforcement.

In the design of the beams that support a two-way slab along its sides, the load is assumed to be uniform over the slab and distributed to the beams as shown in **Fig. 2**. If w is the slab load in lb/ft^2, moments in the beams may be approximated by assuming the beams loaded with the following equivalent uniform loads: for the short span, $wS/3$; for the long span, $wS(3 - S^2/L^2)/6$.

Flat slabs. When a slab is supported directly on columns, without beams and girders, it is called a flat plate or flat slab (**Fig. 3**).

A flat plate generally is of uniform thickness throughout. Usually, the columns also have constant dimensions throughout the story height below the slab (excluding the portion forming capitals, which are discussed later). In designing such construction, it is necessary to investigate shear and diagonal tension in the vicinity of the columns; frequently, reinforcements which are known as shear heads are embedded at the column tops.

In flat-slab construction it is customary to flare out the columns at the top to form capitals so as to give the slab-column junction greater rigidity. The capital is usually sloped at 45°. For exterior columns the capital is sometimes only a bracket that projects inward.

Flat slabs generally are thickened in the region around the columns. The thickened portion, called a drop panel, may be extended until it reaches from column to column, forming shallow beams and giving the effect of a paneled ceiling.

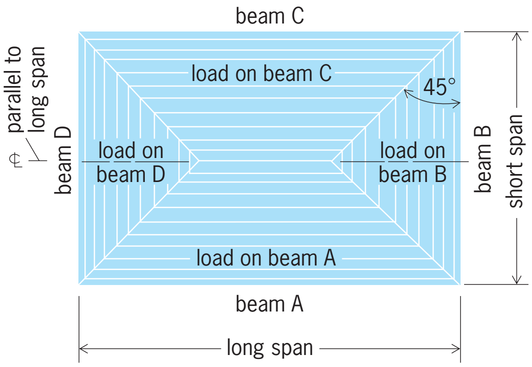

Fig. 2. Load distribution assumed for beams supporting a uniformly loaded two-way slab.

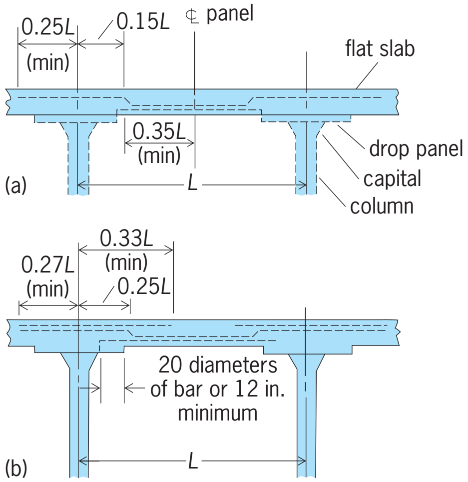

Fig. 3. Details of a flat slab drawn in cross section at two points. (*a*) Middle strip. (*b*) Column strip. *L* is the center-to-center distance between columns.

Although thicker and more heavily reinforced than slabs in beam-and-girder construction, flat slabs are advantageous because they offer no obstruction to passage of light (as beam construction does); savings in story height and in the simpler formwork involved; less danger of collapse due to overload; and better fire protection with a sprinkler system because the spray is not obstructed by beams.

Flat slabs may be reinforced in several ways:

1. *Two-way system.* When the columns are arranged to form rectangular bays, the reinforcing steel may be placed in two directions, perpendicular to the column lines. Design is based on column strips and middle strips, similar to that for a two-way slab.

2. *Four-way system.* Column strip steel is similar to that for a two-way slab. But middle-strip reinforcing consists of diagonal bands of steel extending over the columns.

3. *Circumferential system.* Bars are placed in the top of the slab in concentric rings around the columns, also radially. Similar radial and circular bars are placed in the bottom of the slab in the central portion.

4. *Three-way system.* When columns are arranged so that lines joining them would form triangles, the reinforcing steel may be laid parallel to the column lines.

Design of flat slabs and flat plates is based on empirical formulas. The ACI code presents design rules that are widely used. *See* CONCRETE COLUMN; REINFORCED CONCRETE.

Frederick S. Merritt

Concretion

A loosely defined term used for a sedimentary mineral segregation that may range in size from inches to many feet. Concretions are usually distinguished from the sedimentary matrix enclosing them by a difference in mineralogy, color, hardness, and weathering characteristics. Some concretions show definite sharp boundaries with the matrix, while others have gradational boundaries. Most concretions are composed dominantly of calcium carbonate, with or without an admixture of various amounts of silt, clay, or organic material. Less common are the clay-ironstone concretions characteristic of the Carboniferous coal measures in many parts of the world. The latter are mixtures of iron carbonate minerals and iron silicate minerals. Coal balls are calcareous concretions, found in or immediately above coal beds, in which there may be a high percentage of original plant organic matter, showing wonderfully preserved plant fossils in a noncompressed condition. Concretions are normally spherical or ellipsoidal; some are flattened to disklike shapes. Frequently a concretion is dumbbell-shaped, indicating that two separate concretionary centers have grown together. *See* COAL BALLS; SEDIMENTARY ROCKS.

Raymond Siever

Concurrent processing

The simultaneous execution of several interrelated computer programs. A sequential computer program consists of a series of instructions to be executed one after another. A concurrent program consists of several sequential programs to be executed in parallel. Each of the concurrently executing sequential programs is called a process. Process execution, although concurrent, is usually not independent. Processes may affect each other's behavior through shared data, shared resources, communication, and synchronization.

Concurrent programs can be executed in several ways. Multiprogramming systems have one processing unit and one memory bank. Concurrent process execution is simulated by randomly interleaving instructions of the sequential programs. All processes have access to a common pool of data. In contrast, multiprocessing systems have several processing units and one memory bank. Processes are executed in parallel on the separate processing units while sharing common data. In distributed systems, or computer networks, each process is executed on its own processor with its own memory bank. Interaction between processes occurs by transmission of data from one process to another along a communication channel. *See* DISTRIBUTED SYSTEMS (COMPUTERS); MULTIPROCESSING.

Uses and examples. Concurrent programs are inherently more complex to create and to execute than sequential programs. However, concurrent programs are often more appropriate than sequential programs for a particular computing environment. Additionally, concurrent programs often perform the same tasks much more efficiently than sequential programs.

Historically, one of the first uses of concurrent processing was in operating systems. The operating system of a computer is the software that provides an interface between the user, the computer, and input/output devices such as terminals, printers, and disk drives. If the computer is to support a multiuser environment, the operating system must employ concurrent programming techniques to allow several users to access the computer simultaneously. The operating system should also permit several input/output devices to be used simultaneously, again utilizing concurrent processing. *See* MULTIACCESS COMPUTER; OPERATING SYSTEM.

Concurrent programming is also used when several computers are joined in a network. An airline reservation system is one example of concurrent processing on a distributed network of computers. Agents at many different locations on different computers simultaneously book passenger reservations. The concurrent program controlling the system allows this simultaneity while ensuring that the parallel processes do not conflict, for example, that two agents do not book the same seat on the same flight for two different passengers. *See* LOCAL-AREA NETWORKS; WIDE-AREA NETWORKS.

A simple example of a task that can be performed more efficiently by concurrent processing is a program to calculate the sum of a large list of numbers. A sequential program must iterate through each element of the list, accumulating the sum. In a concurrent program, several processes can simultaneously compute the sum of a subset of the list, after which these sums are added to produce the final total. Depending on the size of the list and the number of processes, the concurrent program may perform the computation in only a small fraction of the time required by the sequential program.

Process interaction. The processes of a concurrent program are usually required to interact and cooperate. An operating system must ensure that processes coordinate the use of shared resources such as printers, memory, and processors. An airline reservation system must ensure that conflicting reservations are not made at different sites. The processes of a concurrent program to sum a list of numbers must cooperate to combine their subtotals into a final total. Many tasks also require concurrent processes to synchronize certain actions. For example, a process controlling a sensor that produces data at a varying rate must be synchronized with a process that reads and analyzes these data.

In multiprogramming and multiprocessing systems, communication and synchronization are achieved through shared variables. Certain memory locations contain data to be read and modified by several processes, such as the number of disk drives available, the next process to send a file to the printer, the number of elements in a buffer, or the total of a sublist of numbers. Reading and writing of shared variable values must be synchronized to avoid undesirable situations. For example, one process may read a shared value in order to update it, and a second process may change the value before the first process is completed. The change in the second process is lost when the first process finally performs its update. This is known as the lost update problem, and it is prevented by ensuring that processes have the ability to gain exclusive access to shared variables for the duration of an operation.

Distributed systems have no shared memory; communication and synchronization are achieved by transmitting messages along shared communication links. Communication can be either synchronous or asynchronous. With synchronous communication, both the sending and receiving processes must be ready to communicate before a message is actually transmitted. With asynchronous communication, the sending process may transmit messages whether or not the receiving process is prepared to receive them. The sent messages are held in a queue until requested by the receiving process. Synchronous communication is used when coordination between processes may be required, as in a series of computers controlling an automated assembly line. Asynchronous communication is used when coordination between processes is not required, as in the transmission of electronic mail messages from one computer to another. *See* DATA COMMUNICATIONS; ELECTRONIC MAIL.

Creating concurrent programs. Concurrent programs can be created explicitly or implicitly. Explicit concurrent programs are written in a programming language designed for specifying processes to be executed concurrently. Implicit concurrent programs are created by a compiler that automatically translates programs written in a sequential programming language into programs with several components to be executed in parallel.

Many programming languages provide facilities for creating concurrent programs. These languages typically include a component for specifying sequential programs and a component for combining and coordinating several sequential programs into one concurrent program. Examples of such languages are Ada, Communicating Sequential Processes (CSP), Concurrent Pascal, Mesa, Modula, and Synchronizing Resources (SR).

Compilers that translate sequential programs into concurrent programs are called parallelizing compilers. They employ a technique called dependency analysis to identify regions of a sequential program that are independent and may therefore be executed in parallel. The regions may be as large as several hundred lines of code or as small as a single arithmetic operation. The object of a parallelizing compiler is to introduce as much parallelism as possible in order to increase the speed of the program. *See* PROGRAMMING LANGUAGES. Jennifer Widom

Concussion

Mild traumatic brain injury, due to externally inflicted trauma. While such injury has many symptoms, there is often no physical evidence of damage to the brain. It is clinically manifested by at least one of the following:

Loss of consciousness for 30 minutes or less.

Posttraumatic amnesia for less than 24 hours.

An initial score of 13–15 on the Glasgow Coma Scale, which measures eye, verbal, and motor responses. [Scores can range from 3 (deep coma) to 15 (fully awake).]

Alteration in mental state at time of injury (for example, feeling dazed, disoriented, or confused).

Individuals with concussion do not experience focal neurological deficits (that is, they have no paralysis or sensory loss) and imaging studies (such as computerized tomography and magnetic resonance imaging usually do not show evidence of brain damage. However, after concussion the afflicted persons may experience:

Cognitive deficits (for example, difficulties with concentration and attention, a decrease in information processing speed, and deficits in executive functioning and memory).

Affective disorders (for example, irritability, anxiety, and depression).

Somatic complaints (such as headaches, dizziness, nausea, insomnia, fatigue, and sensory disturbances).

Most of these symptoms disappear within weeks or months, but approximately 15% of individuals continue to experience such symptoms, a condition often referred to as postconcussion syndrome. Actual causes and influencing factors of postconcussion syndrome are much debated but may involve premorbid (preexisting) conditions, psychological reactions, age, mechanism of injury, as well as unidentified organic (physical) disorders.

Since most symptoms of concussion resolve spontaneously and no specific treatment has been validated scientifically, management initially is “wait and see.” It is prudent for the individual to promptly undergo a brief neuropsychological assessment and receive appropriate rest. If difficulties persist beyond 6 months, a comprehensive neuropsychological evaluation is indicated. Individuals with persistent complaints months after the injury may benefit from psychotherapy, pain management, cognitive rehabilitation, physical therapy, judicious use of medications, professional counseling, and group support. *See* BRAIN; COGNITION. Condensation

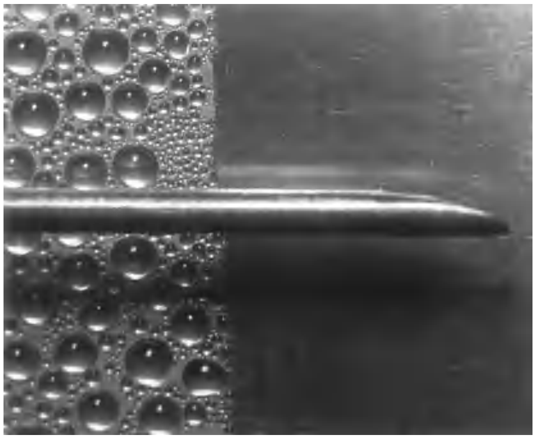
A phase-change process in which vapor converts into liquid when the temperature of the vapor is reduced below the saturation temperature corresponding to the pressure in the vapor. For a pure vapor this pressure is the total pressure, whereas in a mixture of a vapor and a noncondensable gas it is the partial pressure of the vapor. Sustaining the process of condensation on a cold surface in a steady state requires cooling of the surface by external means. Condensation is an efficient heat transfer process and is utilized in various industrial applications. Condensation of vapor on a cold surface can be classified as film-wise or drop-wise. Direct-contact condensation refers to condensation of vapor (bubbles or a vapor stream) in a liquid or condensation on liquid droplets entrained in the vapor. If vapor temperature falls below its saturation temperature, condensation can occur in the bulk vapor. This phenomenon is called homogeneous condensation (formation of fog) and is facilitated by foreign particles such as dust. *See* GAS; HEAT TRANSFER.

Film condensation. A thin film of liquid forms upon condensation of vapor on a cold surface that is well wetted by the condensate (see **illus.**). The liquid film flows downward as a result of gravity. The temperature drop between the vapor-liquid interface of the film and the surface of the solid on which vapor condenses is representative of the condensation resistance, which is inversely proportional to the condensation heat transfer coefficient. The film is initially laminar in the direction of flow. As the mass flow rate through the film and, in turn, the thickness of the film increase due to addition of condensate, ripples start to form on the free surface of the film. The ripples form as a result of capillary and inertia forces, and generally begin at a Reynolds number of about 30, where the Reynolds number is based on the average velocity of the condensate in the film, four times the thickness of the film, and the kinematic viscosity of the condensate. The film becomes turbulent when the Reynolds number attains a value of about 1800. *See* REYNOLDS NUMBER; SURFACE TENSION; TURBULENT FLOW.



Steam at atmospheric pressure condensing on a vertical copper surface. Film condensation is visible on the right side, and dropwise condensation in the presence of a promoter is visible on the left side. The horizontal tube is a thermocouple. (*J. F. Welch and J. W. Westwater, Department of Chemical Engineering, University of Illinois, Urbana*)

The earliest work on laminar film condensation was performed by W. Nusselt in 1916. He assumed that the vapor was pure, stagnant, and at its saturation temperature; that inertia and convective contributions in the film were small; and that thermophysical properties of the condensate film could be evaluated at the mean temperature of the film. He then obtained the equation below for the dimensionless average heat transfer coefficient, or Nusselt number.

$$\mathrm{Nu} = \frac{\bar{h}L}{k_\ell} = C\left[\frac{\rho_\ell g(\rho_\ell - \rho_v)h_{fg}L^3}{\mu_\ell k_\ell (T_{\mathrm{sat}} - T_W)}\right]^{1/4}$$

Here, $\bar{h}$ is the average heat transfer coefficient for film condensation, L is the plate height over which laminar film condensation occurs, k_ℓ is the thermal conductivity of the liquid, ρ_ℓ is the density of liquid, ρ_v is the density of vapor, h_{fg} is the latent heat of vaporization, μ_ℓ is the molecular viscosity, T_{sat} is the saturation temperature, and T_W is the surface temperature. The latent heat of vaporization and vapor density correspond to the saturation condition in the vapor. From the form of the equation, it follows that average heat transfer coefficients are higher for small bodies (small L). For condensation of steam, typical values of the heat transfer coefficient $\bar{h}$ are of the order of 5000 W/($\mathrm{m}^2 \cdot \mathrm{K}$). *See* CONDUCTION (HEAT); EVAPORATION; VISCOSITY.

The dimensionless constant C in the equation above is of order unity and varies with geometry. For a vertical plate, $C = 0.943$. Other geometries, such as tubes and spheres, can be analyzed. The latent heat term h_{fg} is also modified by convection and subcooling in the film. If ripples form or turbulence ensues in the film, new formulas and correlations are needed.

Bulk motion of vapor in the direction of the flow of the condensate film tends to increase the heat transfer coefficient from that given by the equation above. If the vapor is at a temperature higher than the saturation temperature, the vapor must be cooled to saturation temperature before it is condensed. As such, the vapor superheat tends to increase the condensation heat transfer rate; however, the condensate mass flow rate decreases. The presence of noncondensable gases in the vapor can substantially reduce the condensation heat transfer rate because of the additional resistance imposed by the diffusion of the vapor to the interface. In the presence of noncondensables, the mass flow rate of the condensate also decreases. In refrigeration and air-conditioning systems, film condensation occurs inside tubes. Since vapor and condensate flow simultaneously through the tube and the fractional cross-sectional area occupied by each phase changes in the direction of the flow, different flow configurations or regimes are encountered which in turn influence the condensation heat transfer coefficients.

Dropwise condensation. On surfaces that are not well wetted, vapor may condense in the form of droplets (see illus.). The droplets form on imperfections such as cavities, dents, and cracks on the surface. The droplets of 10–100 μm diameter contribute most to the heat transfer rate. As a droplet grows to a size that can roll down the surface because of gravity, it wipes the surface of the droplets in its path. In the wake behind the large droplet, numerous smaller droplets form and the process repeats. The heat transfer coefficients with dropwise condensation can be one to two orders of magnitude greater than that for film condensation. Thus, dropwise condensation is preferable to film condensation. Attempts have been made to deposit an ultrathin coating of a nonwetting material such as Teflon on the condensing surface to promote dropwise condensation. However, in heat exchange equipment, because of the buildup of foreign material on the surface or degradation of the promoter layer, dropwise condensation shifts with time to film condensation. Therefore, equipment is designed on the basis of film condensation.

Direct contact condensation. Condensation of vapor bubbles in a host liquid and condensation on droplets entrained in vapor are also very efficient heat transfer processes, especially when the vapor-liquid interface oscillates. The magnitude of the heat transfer coefficient depends on several variables such as the size of the bubble or droplet, liquid subcooling, the relative velocity between the continuous and the discontinuous phase, and the appropriate thermophysical properties of the two phases. Conditioned reflex

A learned response performed by a trained animal to a signal that was previously associated with an event of consequence for that animal. Conditioned reflex (CR) was first used by the Russian physiologist I. P. Pavlov to denote the criterion measure of a behavioral element of learning, that is, a new association between the signal and the consequential event, referred to as the conditioned stimulus (CS) and unconditioned stimulus (US), respectively. In Pavlov's classic experiment, the conditioned stimulus was a bell and the unconditioned stimulus was sour fluid delivered into the mouth of a dog restrained by harness; the conditioned stimulus was followed by the unconditioned stimulus regardless of the dog's response. After training, the conditioned reflex was manifested when the dog salivated to the sound of the bell.

Classical conditioning. Ideally, certain conditions must be met to demonstrate the establishment of a conditioned reflex according to Pavlov's classical conditioning method. Before conditioning, the bell conditioned stimulus should attract the dog's attention or elicit the orienting reflex (OR), but it should not elicit salivation, the response to be conditioned. That response should be specifically and reflexively elicited by the sour unconditioned stimulus, thus establishing its unlearned or unconditioned status. After conditioned pairings of the conditioned stimulus and the unconditioned stimulus, salivation is manifested prior to the delivery of the sour unconditioned stimulus. Salivation in response to the auditory conditional stimulus is now a "psychic secretion" or the conditioned reflex.

This simple conditioned reflex was important to Pavlov because it presumably demonstrated concretely a new temporary connection in the brain, a neural connection established by training between the auditory apparatus and salivary mechanisms. It provided him with an opportunity to study the psyche objectively. "Here we have exact and constant facts," Pavlov said, "facts that seem to imply intelligence." He had already won the Nobel Prize in Physiology or Medicine for his studies of digestion and its associated secretory reflexes. He knew that the food stimuli contracted oral receptors, and how the impulses were transmitted via centripetal nerves to a specific area of the brainstem. He knew that this reflexive mechanism controlled salivation by centrifugal nerves, so as to match the quality and quantity of saliva precisely with the nature of oral stimulation in accordance with the "wisdom of the body." He understood how the auditory conditioned stimulus might control the head-turning orienting reflex in the dog. But the final mystery was how the auditory conditioned stimulus gained control over the salivary reflex through conditioning or, in other words, how the bell became a stimulus substitute for food. Pavlov's goal was to elucidate these new pathways of control in the brain, and that task was not completed. But to this day, Pavlov's methods provide important guidelines for basic research upon brain mechanisms in learning and memory.

By 1909, other Russian workers had extended the study of the conditioned reflex to other stimulus-reflex combinations in dogs and humans, and since that time scientists all over the world have paired a vast array of stimuli with an enormous repertoire of reflexes to test conditioned reflexes in representative species of almost all phyla, classes, and orders of animals. As a result, classical conditioning is now considered a general biological or psychobiological phenomenon which promotes adaptive functioning in a wide variety of physiological systems in various phylogenetic settings.

Selective learning and homeostatic feedback. The unconditioned stimulus is usually contact with a object or event that is significant for survival, evoking pleasure or pain. This is only a rough guide because some "pleasures" (for example, drugs and alcohol) can be ultimately detrimental. Food, the most popular unconditioned stimulus, is vital for survival. Consumption is followed by digestion which provides feedback (FB) to adjust the palatability of food commensurate with its homeostatic effect. If food is nutritious, it tastes "good" next time. If food is followed by nausea induced by injection, conditioned food aversion is acquired and the food tastes "bad." Therefore the entire conditioning sequence is composed of two different associative processes denoted as CS-US-FB. The first CS-US link and the second US-FB link differ in many ways. For rapid one-trial learning: (1) The CU-US interval must be a matter of seconds, but the US-FB interval can be a matter of hours. (2) The unconditioned stimulus must be presented to an alert subject, but the feedback is completely effective when delivered to a subject asleep under anesthesia. (3) After CS-US training, the subject gains a precise appreciation of both stimuli and their association in time and space and modifies its behavior accordingly. But after conditioned food aversion training the hedonic value of the unconditional stimulus is modified even in the absence of any memory of its association with the nauseous feedback. The subject often approaches the unconditioned stimulus again and rejects it in surprise and disgust.

Furthermore, while many different conditioned stimuli can easily be linked with food unconditioned stimulus, there is a strong selective affinity of the food feedback for taste. In the complete absence of taste, even an aversion to odor paired with poison is absent or weak. With repeated trials, the aversion spreads to other cues associated with feeding. In descending order of effectiveness, these cues are oral stimuli other than taste or odor, visual and tactual aspects of the food, visual and tactual aspects of the food locus, and auditory stimulation paired with food. All these cues are potentiated when accompanied by taste. Natural selection resulted in this specialized US-FB learning system to protect the gut from natural toxins. Charles Darwin was concerned with the mechanisms by which natural toxins protected poisonous insect larvae from predators. Subsequent research revealed that the predators acquired a conditional food aversion for such insects and their mimics; thus the US-FB association has been called Darwinian conditioning.

A brief electric shock impinging on the skin, also a well-known unconditioned stimulus, engages another specialized CS-US-FB system designed by natural selection to protect the skin from predatory attacks. Since the attack is usually swift and preceded by vibrations in the substrate, an immediate noise-shock combination is about as effective for conditioned fear as a delayed taste-toxin combination is for conditioned food aversion. Conversely, taste-shock and noise-toxin are relatively ineffective combinations for rapid conditioning because these stimuli impinge upon two different integrative systems. The shock unconditioned stimulus is followed by an endogenous analgesic feedback that raises the pain threshold. This feedback action is of long duration and is also effective in subjects sleeping under anesthesia. US-FB relationships have not been elucidated for other unconditoned stimulus events, but there is evidence that they exist. Core temperature of the body is apparently feedback for thermal skin receptors. When core temperature is low, a warm unconditioned stimulus is pleasant to the skin. When the core is warmed, the same unconditioned stimulus is unpleasant. In mating behavior of mammals, reproductive success seems to make odors associated with mates more attractive.

Instrumental conditioning. In this procedure the experimenter selects a response (R) emitted by the animal and reinforces it with an unconditioned stimulus. R-US methodology is favored by B. F. Skinner. For example, consider an operant conditioning situation in which a pigeon is placed in the Skinner box with a key or target connected to a food delivery mechanism. Whenever the key illuminates, the pigeon can obtain food by depressing it. Skinner's procedure differs from Pavlov's situation in that the subject is unrestrained, and food is contingent upon depression of the key whenever the light is on. No key press, no food; thus the birds appeared to be working for the pay of food in economic fashion. Skinner, avoiding physiological mechanisms, defined his conditioned reflex as a depression of the key and called it an operant; his pigeon was operating the key to get food. However, high-speed photographs indicated that the pigeon pecked at the target in the same way it pecked at grain. When depressing the lighted key to get water, the pigeon worked the key with the same action it used to drink water. For other birds, the key was disconnected from the food delivery mechanism and seeds were delivered regardless of the pigeon's response, a procedure called autoshaping. These pigeons also learned to peck at the lighted key as if it were a substitute for food. The pigeon's peck, like the dog's salivation, is a Pavlovian conditioned reflex that is characteristic of the consummatory phase of learning.

True instrumental learning is displayed by subjects long before they gain their consummatory objective. For example, E. L. Thorndike confined hungry cats in a puzzle box and placed the food (unconditioned stimulus) outside. Manipulation of a trigger (the response) released the cat, giving access to food. Another procedure is to place a hungry rat in the starting box and to provide food at the end of a maze with cul-de-sacs along the way. With repeated trials in such apparatus, animals will reduce extraneous responses and decrease time from start to finish. With prolonged training under controlled conditions, subjects can combine CS-US and R-US units into long instrumental sequences. However, behavioral units and sequences do not provide a complete answer to the question "What is learned?" Laboratory studies and detailed observations under natural conditions indicate that animals often forego satisfaction of needs to spontaneously explore their surroundings, acquiring memorial representation or a cognitive map of the spatial and temporal relationships among many stimuli. With this cognitive map well in hand, they will exhibit novel shortcuts, detours, strategies, and expectations, modifying instrumental means to achieve desired ends. After consumption, these incentives to action are automatically reevaluted in accordance with their homeostatic utility. *See* COGNITION; MEMORY. John Garcia

Conductance

The real part of the admittance of an alternating-current circuit. The admittance Y of an alternating-current circuit is a complex number given by Eq. (1). The real part G is the conductance. The units

$$Y = G + jB \tag{1}$$

of conductance, like those of admittance, are called siemens or mhos. Conductance is a positive quantity. The conductance of a resistor R is given by Eq. (2).

$$G = \frac{1}{R} \tag{2}$$

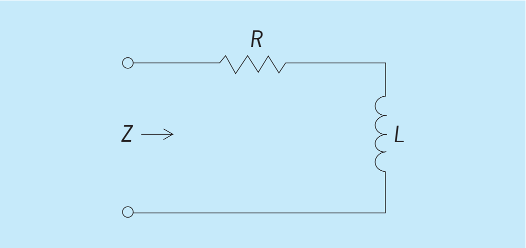
In general the conductance of a circuit may depend on the capacitors and inductors in the circuit as well as on the resistors. For example, the circuit in the **illustration** has impedance at frequency ω given by Eq. (3) and admittance given by Eq. (4), so that the conductance, given by Eq. (5), depends on the inductance L as well as the resistance R. *See* ADMITTANCE; ALTERNATING-CURRENT CIRCUIT THEORY; ELECTRICAL IMPEDANCE.

$$Z = R + jL\omega \tag{3}$$

$$Y = \frac{1}{R + jL\omega} \tag{4}$$

$$G = \frac{R}{R^2 + L^2\omega^2} \tag{5}$$

J. O. Scanlan



Circuit with a resistor and inductor in series.

Conduction (electricity)

The passage of electric charges due to a force exerted on them by an electric field. Conductivity is the measure of the ability of a conductor to carry electric current; it is defined as the ratio of the amount of charge passing through unit area of the conductor (perpendicular to the current direction) per second divided by the electric field intensity (the force on a unit charge). Conductivity is the reciprocal of resistivity and is therefore commonly expressed in units of siemens per meter, abbreviated S/m. *See* ELECTRICAL RESISTIVITY.

The magnitude of the conductivity of a material or system is determined by two properties: the number n of its charges in unit volume that are free to move in the field, and how effectively the field can move them. Acted on by the field, which accelerates them, and by the resistance of the material to their motion, the free charges achieve a drift velocity that is proportional to the electric field intensity. The mobility μ of the charges is defined as the ratio of this drift velocity to the field. From the above definition of the conductivity σ, it follows directly that $\sigma = ne\mu$, where e is the charge of a free carrier and n is the number of free carriers per unit volume.

Electron and hole conduction. In metals and semiconductors (such as silicon, of which transistors are made) the charges that are responsible for current are free electrons and holes (which, as missing electrons, act like positive charges). These are electrons or holes not bound to any particular atom and therefore able to move freely in the field. Conductivity due to electrons is known as n-type conductivity; that due to holes is known as p-type. *See* HOLE STATES IN SOLIDS; SEMICONDUCTOR.

The conductivity of metals is much higher than that of semiconductors because they have many more free electrons or holes. The free electrons or holes come from the metal atoms. Silver is the highest-conductivity metal, with a room-temperature conductivity of 7×10^7 S/m. Copper has almost as high a room-temperature conductivity, 5.9×10^7 S/m. Semiconductors differ from metals in two important respects. First, the semiconductor atoms do not contribute free electrons or holes unless thermally excited, and second, free electrons or holes can also arise from impurities or defects. The latter process may also require thermal excitation, but the temperature rise needed is smaller than that for exciting electrons and holes from the semiconductor atoms. These two differences cause the conductivity of semiconductors, in contrast to that of metals, to be quite dependent on temperature and on their purity. Pure silicon, for example, has a room-temperature conductivity of 3×10^{-4} S/m. If impurities such as aluminum or arsenic are added, a process called doping, the conductivity of silicon can be raised to 10^5 S/m and even higher. Gallium arsenide, of which laser diodes are made, when pure has a room-temperature conductivity of 2×10^{-7} S/m, but it can also be doped, for example, with silicon, to 10^5 S/m.

An exception to some of the rules stated above has been found in conjugated polymers. Polyacetylene, for example, although a semiconductor with extremely high resistance when undoped, can be doped so heavily with certain nonmetallic impurities (iodine, for example) that it attains a conductivity comparable to that of copper. *See* ORGANIC CONDUCTOR.

In metals, although the number of free carriers does not vary with temperature, an increase in temperature decreases conductivity. The reason is that increasing temperature causes the lattice atoms to vibrate more strongly, impeding the motion of the free carriers in the field. This effect also occurs in semiconductors, but the increase in number of free carriers with temperature is usually a stronger effect. At low temperatures the thermal vibrations are weak, and the impediment to the motion of free carriers in the field comes from imperfections and impurities, which in metals usually does not vary with temperature. At the lowest temperatures, close to absolute zero, certain metals become superconductors, possessing infinite conductivity. *See* ELECTRICAL CONDUCTIVITY OF METALS; SUPERCONDUCTIVITY.

Although there is no material that does not conduct electricity at all, that is, behaves as a perfect insulator, there are materials that are very poor conductors. Examples are ceramics, with conductivities of 10^{-12} to 10^{-14} S/m; amorphous selenium, with a conductivity of 10^{-14} S/m; and paraffin, with 3×10^{-17} S/m. *See* ELECTRIC INSULATOR.

Ionic conduction. Electrolytes conduct electricity by means of the positive and negative ions in solution. In ionic crystals, conduction may also take place by the motion of ions. This motion is much affected by the presence of lattice defects such as interstitial ions, vacancies, and foreign ions. *See* ELECTROLYTIC CONDUCTANCE; IONIC CRYSTALS.

Ionic conduction can also take place in a gas by using a strong electric field to ionize the gas molecules. If enough ions are formed, there may be a spark. *See* ELECTRIC SPARK; ELECTRICAL CONDUCTION IN GASES.

Vacuum conductivity. Electric current can flow through an evacuated region if electrons or ions are supplied. In a vacuum tube the current carriers are electrons emitted by a heated filament. The conductivity is low because only a small number of electrons can be "boiled off" at the normal temperatures of electron-emitting filaments. *See* ELECTRON EMISSION; ELECTRON MOTION IN VACUUM; VACUUM TUBE.

Conduction (heat)

The flow of thermal energy through a substance from a higher- to a lower-temperature region. Heat conduction occurs by atomic or molecular interactions. Conduction is one of the three basic methods of heat transfer, the other two being convection and radiation. *See* CONVECTION (HEAT); HEAT RADIATION; HEAT TRANSFER.

Steady-state conduction is said to exist when the temperature at all locations in a substance is constant with time, as in the case of heat flow through a uniform wall. Examples of essentially pure transient or periodic heat conduction and simple or complex combinations of the two are encountered in the heat-treating of metals, air conditioning, food processing, and the pouring and curing of large concrete structures. Also, the daily and yearly temperature variations near the surface of the Earth can be predicted reasonably well by assuming a simple sinusoidal temperature variation at the surface and treating the Earth as a semi-infinite solid. The widespread importance of transient heat flow in particular has stimulated the development of a large variety of analytical solutions to many problems. The use of many of these has been facilitated by presentation in graphical form.

For an example of the conduction process, consider a gas such as nitrogen which normally consists of diatomic molecules. The temperature at any location can be interpreted as a quantitative specification of the mean kinetic and potential energy stored in the molecules or atoms at this location. This stored energy will be partly kinetic because of the random translational and rotational velocities of the molecules, partly potential because of internal vibrations, and partly ionic if the temperature (energy) level is high enough to cause dissociation. The flow of energy results from the random travel of high-temperature molecules into low-temperature regions and vice versa. In colliding with molecules in the low-temperature region, the high-temperature molecules give up some of their energy. The reverse occurs in the high-temperature region. These processes take place almost instantaneously in infinitesimal distances, the result being a quasi-equilibrium state with energy transfer. The mechanism for energy flow in liquids and solids is similar to that in gases in principle, but different in detail.

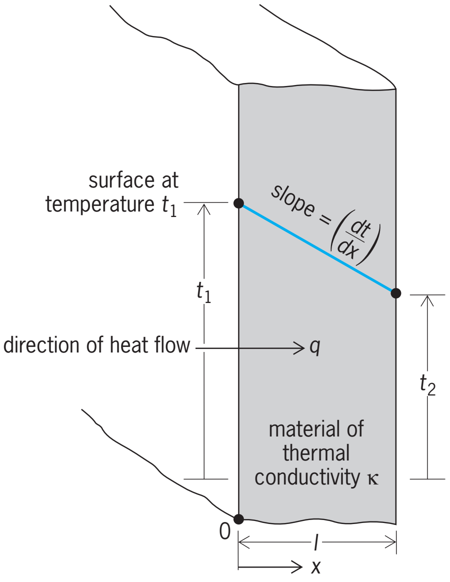

Fig. 1. Heat flow by conduction.

Fourier equation. The mathematical theory as well as the practical calculation of heat conduction is based on a macroscopic interpretation, as contrasted to the basic microscopic mechanism just described. From a physical point of view, it is reasoned that the steady heat flow from a surface (**Fig. 1**) at temperature t_1 to a parallel surface at t_2 is directly proportional to $(t_1 - t_2)$, the area A normal to the direction of flow, and the time of flow τ, and inversely proportional to the distance l between the two planes. These factors are modified by a coefficient κ accounting for the heat-conducting nature of the particular substance between the two planes. Thus, the heat flow Q (in British thermal units, for example) is given by Eq. (1). In terms of the time rate of flow $q = Q/\tau$

$$Q = \kappa A \frac{t_1 - t_2}{l} \tau \tag{1}$$

through an infinitesimally thin layer *dx,* in which the temperature change is *dt,* this becomes Eq. (2). The

$$q = -\kappa A \frac{dt}{dx} \tag{2}$$

minus sign is conventionally included to make q positive when heat flows in the increasing direction of x, since dt/dx is then negative. Although this equation was first proposed by J. Biot, it is named after J. Fourier in honor of Fourier's extensive contributions to the theory of heat conduction.

Thermal conductivity. The coefficient κ in Eqs. (1) and (2), called the thermal conductivity, is an important property of matter. It accounts for the heat–conducting ability of a substance, and depends not only on the particular substance involved, but also on the state of that substance. The Fourier equation is essentially a definition of κ which (Fig. 1) can be interpreted as the rate of heat flow per unit of area normal to the direction of flow when a unit temperature difference exists in unit length. Thus from Eq. (2) is derived Eq. (3), where κ is seen to have

$$\kappa = \frac{-q/A}{dt/dx} = \frac{q/A}{(t_1 - t_2)/l} \tag{3}$$

the dimensions of a heat rate per unit area and per unit of temperature gradient. In the cgs system, it can be expressed in cal/(s) · (cm^2)(°C/cm), which is equivalent to cal/(s)(cm)(°C). In engineering, the units most frequently used are Btu/(h)(ft)(°F).

Considerable progress has been made in the interpretation of thermal properties from theories of matter. This is particularly true for gases, where theory involving intermolecular forces has yielded very accurate results. The process of heat conduction in liquids is believed to be similar to that of sound transmission. In dielectric solids, energy is transmitted primarily by means of waves traveling through the atomic lattice; in metals, the electrons behave like an electron gas and provide for energy transfer as well as electrical conduction. This is the basis of the Widemann-Franz law, which states that $\kappa/\sigma T =$ constant (σ is the electrical conductivity and T the absolute temperature). *See* INTERMOLECULAR FORCES; KINETIC THEORY OF MATTER; THERMAL CONDUCTION IN SOLIDS.

For materials occurring as crystalline or amorphous solids, the general trend of κ at atmospheric pressure throughout the three physical states is as shown in **Fig. 2**. The numerical value at the maximum, which occurs near absolute zero in crystalline substances, is comparatively high. For example, the κ of a copper crystal at 20 K has been found to be 7050 Btu/(h)(ft)(°F)—more than 30 times its value at room temperature. Thermal conductivity of solids is discussed in a later section.

Because of the complexity and incomplete understanding of the mechanisms responsible for heat conduction, values of κ are usually determined experimentally. Results for typical gases, liquids, and solids in appropriate temperature ranges are shown in **Fig. 3**. The effect of pressure is significant primarily in gases.

Differential equation of conduction. The evidence of heat flow by conduction through a substance is the variation of the temperature with location and time.

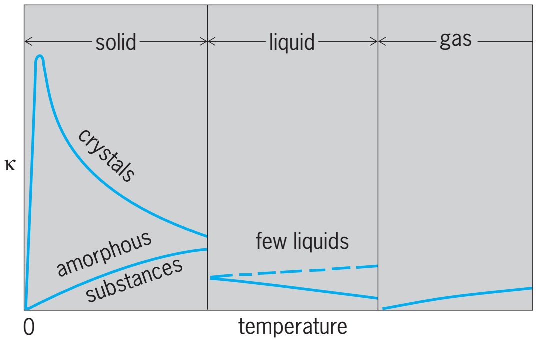

Fig. 2. General variation of thermal conductivity with temperature throughout the three physical states. (*After L. S. Kowalczyk, Trans. ASME, 77:1021–1035, 1955*)

If the temperature as a function of the space coordinates and time is known or can be determined, the heat flow at any location and in any direction can be specified by appropriate differentiation. A given problem is normally attacked by solving the differential equation governing the temperature distribution in a homogeneous substance and making this solution fit the prescribed initial or boundary conditions. This differential equation, essentially an expression of the first law of thermodynamics applied to the heat flow, is derived by making a heat balance on an elemental volume in a medium (**Fig. 4**).

Considering first the x direction, the net heat flow into the element in time $\Delta\tau$ is the difference between the flowing in on the left minus that flowing out on the right; or, applying Eq. (1), Eq. (4) is obtained.

$$\Delta Q_x = -\kappa\ \Delta y\ \Delta z \left(\frac{\partial t}{\partial x}\right)_x \Delta\tau - \left[-\kappa\ \Delta y\ \Delta z \left(\frac{\partial t}{\partial x}\right)_{x+\Delta x} \Delta\tau\right] \qquad (4)$$

Accounting for the variation of κ with temperature is extremely difficult and may make the analytical solution of a problem impossible. Because of this, it is customary to use an appropriate average value which is regarded as constant. Equation (4) can then be rearranged to read as Eq. (5*a*), which, as $\Delta x \to 0$, becomes Eq. (5*b*). Similar expressions apply for the y and z directions. Heat generated within the

$$\Delta Q_x = \kappa\ \Delta y\ \Delta z\ \Delta x \frac{\left(\dfrac{\partial t}{\partial x}\right)_{x+\Delta x} - \left(\dfrac{\partial t}{\partial x}\right)_x}{\Delta x} \Delta\tau \qquad (5a)$$

$$\Delta Q_x = \kappa\ \Delta x\ \Delta y\ \Delta z\ \Delta\tau \frac{\partial^2 t}{\partial x^2} \qquad (5b)$$

element at a uniform rate G per unit volume and time would add an amount $G\ \Delta x\ \Delta y\ \Delta z\ \Delta\tau$.

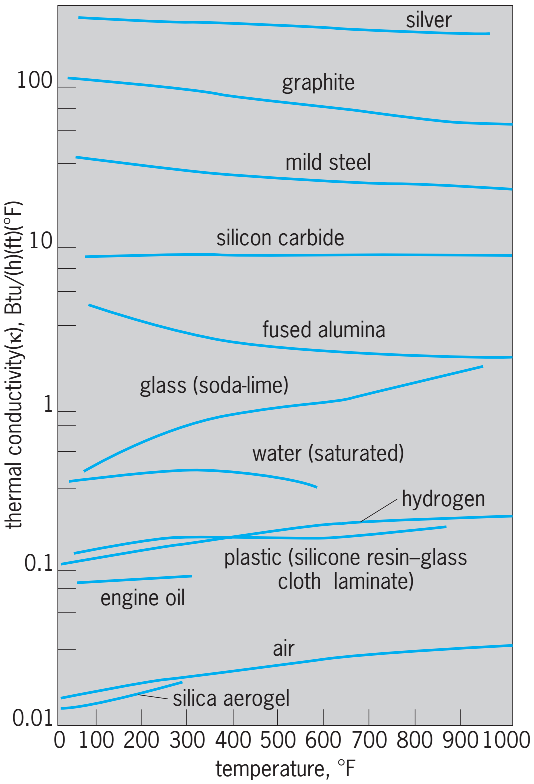

Fig. 3. Thermal conductivities of some typical examples of gases, liquids, and solids. °C = (°F − 32)/1.8.

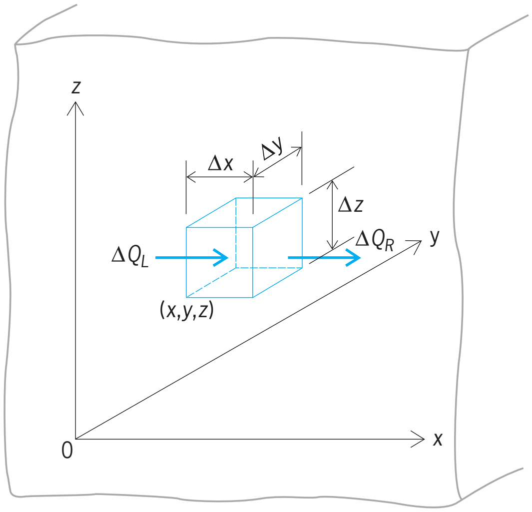

Fig. 4. Diagram of the heat flow through an elemental volume in a homogeneous medium.

The net heat flow into the element would be manifest as stored energy and would be equal to notation (6), where w is the specific weight (weight per

$$\Delta x\ \Delta y\ \Delta z\ wc\ \Delta t \qquad (6)$$

unit volume) of the medium, c its specific heat, and Δt the temperature rise in the time increment $\Delta\tau$. Equating the net flow into the element to that stored and letting Δx, Δy, Δz, and $\Delta\tau \to 0$ leads to Eq. (7).

$$\kappa\left(\frac{\partial^2 t}{\partial x^2} + \frac{\partial^2 t}{\partial y^2} + \frac{\partial^2 t}{\partial z^2}\right) + G = wc\,\frac{\partial t}{\partial \tau} \qquad (7)$$

When no heat source is present, Eq. (7) becomes Eq. (8). The ratio $\kappa/wc = \alpha$ is defined as the ther-

$$\left(\frac{\partial^2 t}{\partial x^2} + \frac{\partial^2 t}{\partial y^2} + \frac{\partial^2 t}{\partial z^2}\right) = \frac{1}{\kappa/wc}\frac{\partial t}{\partial \tau} = \frac{1}{\alpha}\frac{\partial t}{\partial \tau} \qquad (8)$$

mal diffusivity, and is the significant thermal property of a material for transient heat flow (**Fig. 5**). Equation (8) will be recognized as the equation governing a potential field written in terms of temperature. Similar equations are satisfied by other potential field phenomena, such as electricity, magnetism, diffusion, and ideal fluid flow. Because of this, solutions to problems in one field are applicable to analogous systems in the others. Also, an experimental solution of a problem in one field may be obtained from an analogous system in another. *See* POTENTIALS.

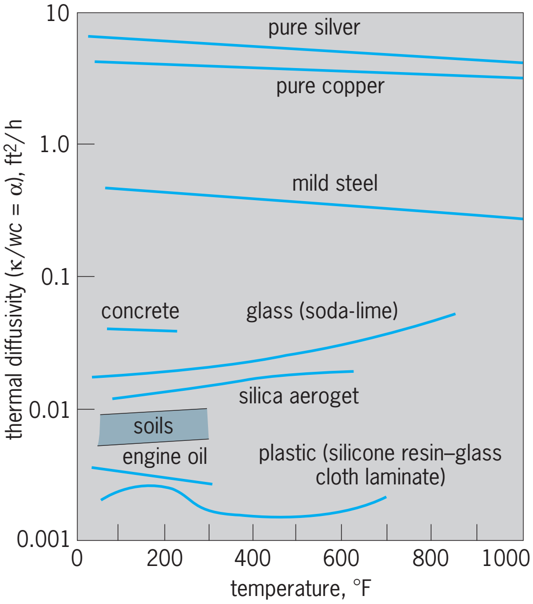

Fig. 5. Thermal diffusivities of some materials. °C = (°F − 32)/1.8.

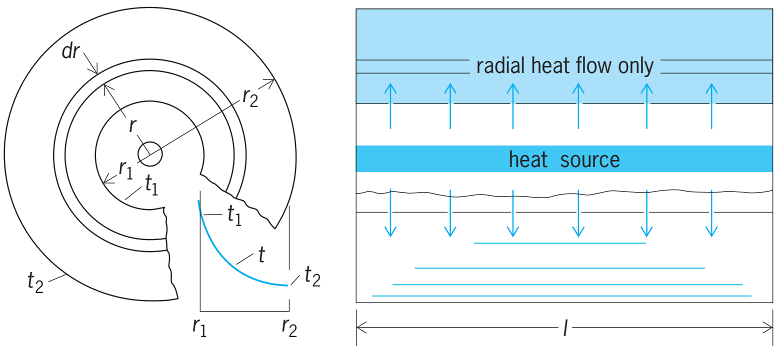

Fig. 6. Steady-state conduction. Diagrams show the temperature distribution for steady radial heat flow through a circular cylinder wall.

Steady-state conduction. When the temperature at all locations is constant with time or, mathematically, when $\partial t/\partial \tau = 0$, steady-state conduction exists. Many important practical problems fall in this category, the most familiar being heat flow through a wall and a hollow cylinder. Referring to Fig. 1 and assuming no heat generation within the wall, Eq. (8) reduces to Eq. (9). The terms $\partial^2 t/\partial y^2$ and $\partial^2 t/\partial z^2$ are

$$\frac{\partial^2 t}{\partial x^2} = 0 \tag{9}$$

eliminated, since t is considered to vary only with x. The desired temperature distribution is obtained by integrating Eq. (9) twice and evaluating the two constants from the known temperatures at $x = 0$ and $x = l$. This leads to Eq. (10). Application of Eq. (2) to obtain q yields Eq. (11).

$$t = t_1 - (t_1 - t_2)\,\frac{x}{l} \tag{10}$$

$$q = \kappa A \frac{(t_1 - t_2)}{l} \tag{11}$$

In the case of steady radial heat flow through a cylindrical wall (**Fig. 6**), Eq. (2) is applicable to any imaginary thin annular ring in the wall; thus Eq. (12)

$$q = -\kappa A \frac{dt}{dr} = -\kappa 2\pi r l \frac{dt}{dr} \tag{12}$$

is obtained. Integration from $t = t_1$ to t, and r_1 to r leads to Eq. (13), which indicates that the effect

$$t = t_1 - q \frac{\ln (r/r_1)}{2\pi \kappa l} \tag{13}$$

of the increasing area for heat flow is to produce a logarithmic variation in the temperature, as shown by the curve in the left part of Fig. 6.

Heat flow through a cylindrical wall is usually expressed in the same form as Eq. (11), written as Eq. (14). Solving Eq. (13) for q and substituting in

$$q = \kappa A_m \frac{t_1 - t_2}{r_2 - r_1} \tag{14}$$

Eq. (14) shows that the appropriate value for A_m must be as given in Eq. (15), which is called the logarithmic-mean area.

$$A_m = \frac{A_2 - A_1}{\ln (A_2/A_1)} \tag{15}$$

If the rate of heat flow and the inner and outer temperatures of a plane wall or hollow cylinder are measured during steady heat conduction, values of κ can be determined from Eq. (11) or Eq. (14). Because of the simplicity of the equations and the physical systems, most devices for measuring thermal conductivity are based on these types of heat flow.

Interface resistance. Now consider steady-state heat flow through a wall composed of two or more layers of material, each with different uniform thermal properties. If the surfaces of the various layers are very smooth and in very good contact with each other, the temperature distribution will be continuous. At any interface (**Fig. 7***a*), since q is constant, Eq. (16) holds. This shows that there is a disconti-

$$\kappa_1 \left(\frac{dt}{dx}\right)_1 = \kappa_2 \left(\frac{dt}{dx}\right)_2 \tag{16}$$

nuity in the temperature gradient due to the change in κ.

Actual surfaces, even polished ones, are not smooth but have small projections and depressions.

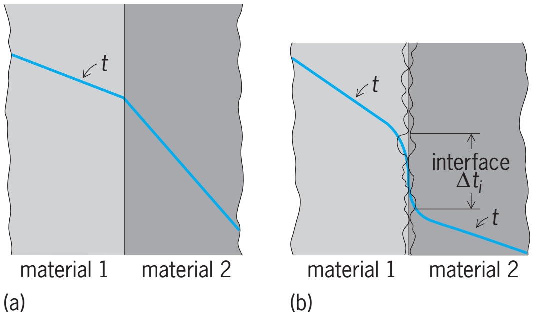

Fig. 7. Temperature distribution through composite wall. (*a*) With perfect interface contact. (*b*) For typical actual surfaces.

Consequently, when two surfaces are brought together, contact occurs primarily at projecting spots, as illustrated in Fig. 7*b*. The resulting contact area is only a small fraction of the nominal contact area. Plastic deformation at the points of contact of one or both materials usually occurs with the application of force to hold them together. Heat flows through both the small contact areas and the substance (usually a gas or liquid) filling the voids between the contacting protuberances.

The impairment to the heat-flow path caused by this imperfect contact is referred to as contact resistance. This is determined by extrapolating the measured temperature distribution in each material to the apparent interface location (Fig. 7*b*). The quotient of the resulting temperature difference Δt_i thus determined and the heat flux defines an interface resistance $R_i = \Delta t_i/q$. R_i depends on the roughnesses of the surfaces, the gas or liquid filling the voids, and the contact pressure. In general, the effect of contact resistance is significant only at low (for example, below 100 lb/in.^{2} or 700 kPa) interface pressures.

Internally generated heat. Conduction of heat generated internally occurs, for example, in the fuel elements used in nuclear reactors. Many of these elements are essentially long, flat plates over which a coolant flows. It is usually necessary to clad the fissionable material to prevent corrosion and keep radioactive particles from entering the coolant (**Fig. 8**). This cladding is undesirable from a heat-transfer standpoint, and is made as thin as possible and of the best adaptable heat-conducting material. Consequently, the temperature drop through it is usually small. *See* NUCLEAR REACTOR.

To illustrate the effect of the heat generation, assume that it is uniform with space and time in the radioactive material of Fig. 8 [that is, G in Eq. (7) is constant]. Heat flow from the ends of the elements and parallel to the flow direction of the coolant is negligible.

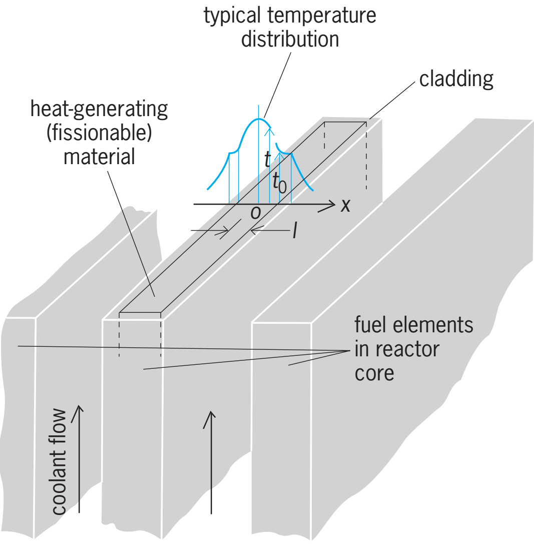

Fig. 8. Temperature distribution in reactor fuel plate.

Therefore, Eq. (7) reduces to Eq. (17). A solution

$$\frac{d^2t}{dx^2} + \frac{G}{\kappa} = 0 \tag{17}$$

for t is obtained by integrating twice and applying the boundary conditions (considering cooling to be the same on each side) $dt/dx = 0$ at $x = 0$ and $t = t_0$ at $x = l$. The result shows the temperature distribution to be parabolic, as in Eq. (18). The rate of heat transfer to the coolant is obtained by differentiating Eq. (18) with respect to x, evaluating at $x = l$, and substituting in Eq. (2).

$$t = t_0 + \frac{G}{2\kappa}(l^2 - x^2) \tag{18}$$

Since the heat generation rate is frequently dependent on the temperature, G will be more complex, possibly making an analytical solution impossible. Numerical methods of solution are then employed.

Periodic and transient conduction. These are the two kinds of non-steady-state heat flow. Periodic means a quasi-steady-state condition in which the temperature and heat flow at any location in a body vary continuosly with time, but pass through the same series of values in a definite period of time, τ_0. A transient state results when the heat flow at any location is momentarily or permanently changed. The duration of the transient period is the time required for the system to return to its original or a new steady-state condition. A transient change may be superimposed on a periodic variation.

Restricting consideration to examples in which no heat generation is present, the fundamental differential equation to be satisfied for either periodic or transient heat flow is Eq. (8). An interesting application is the temperature variation in the Earth due to the diurnal temperature variation, or to a sudden change in surface temperature. Equation (8) reduces in this case to Eq. (19). Assume the existence of a mean temperature of the Earth which is invariable with depth and that its surface temperature has been varying in a steady periodic manner long enough so that the original transient state due to starting the cyclic surface temperature has reached a steady periodic condition. If the surface temperature variation is given by Eq. (20), the appropriate solution to Eq. (19) is given by Eq. (21). This result shows that the temperature distribution looks like a wave traveling into the medium with the amplitude decreasing as the factor $e^{\sqrt{\pi/2\gamma x}}$. Computation of the heat flow by determining $(\partial t/\partial t)_{x\,=\,0}$ from Eq. (21) indicates that heat flows in during one-half of the period τ_0 and out during the other half.

$$\alpha\frac{\partial^2 t}{\partial x^2} = \frac{\partial t}{\partial \tau} \tag{19}$$

$$t = t_0 \cos 2\pi\frac{\tau}{\tau_0} \tag{20}$$

$$t = t_0 e^{-\sqrt{\pi/2\alpha x}} \cos\left(2\pi\frac{\tau}{\tau_0} = \sqrt{\pi/2\alpha}\,x\right) \tag{21}$$

Calculations of the temperature distribution in the Earth over an 8-h interval, using Eq. (21), are shown

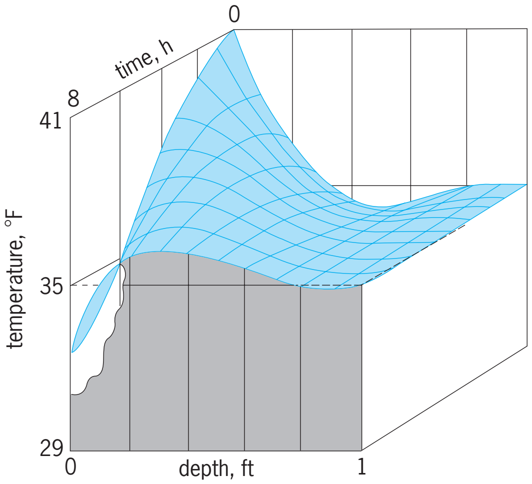

Fig. 9. Temperature distribution in the ground for a daily periodic surface variation. °C = (°F − 32)/1.8.

in **Fig. 9**. In this case the surface temperature varied from 29 to 41°F (−1.6 to 5.0°C) over a 24-h period; the diffusivity of the soil was 0.0065 ft^2/h (6.0×10^{-4} m^2/h).

An illustration of a transient state is the temperature variation resulting from a sudden change of magnitude t_0 in the temperature at the surface of the Earth. When the initial temperature throughout is uniform and taken as the datum, the applicable solution to Eq. (19) is given by Eq. (22). If a body of soil

$$t = \frac{2t_0}{\sqrt{\pi}} \int_0^{x/2\sqrt{\alpha\tau}} e^{-\beta^2}\, d\beta \qquad (22)$$

in the Earth's surface is at a uniform temperature of 40°F (4.4°C) and the surface temperature suddenly drops to 20°F (−6.7°C), Eq. (22) can be applied to determine the depth at which the temperature will have dropped to freezing (32°F or 0°C) in 12 h. Taking $\alpha = 0.0065$ ft^2/h, $t = 32$°F after 12 h is found to occur at $x = 0.27$ ft $= 3.2$ in. $= 8.2$ cm.

Variable thermal conductivity. Most materials are sufficiently homogeneous so that their thermal properties are independent of position. Assuming that they vary only with temperature, the heat balance on the element of Fig. 4 leads to Eq. (23). Upon carrying out the indicated differentiation, Eq. (23) becomes Eq. (24). By introducing a new variable θ called the conductivity potential, notation (25), Eq. (24) can be simplified to Eq. (26).

$$\frac{\partial}{\partial x}\left(\kappa \frac{\partial t}{\partial x}\right) + \frac{\partial}{\partial y}\left(\kappa \frac{\partial t}{\partial y}\right) + \frac{\partial}{\partial z}\left(\kappa \frac{\partial t}{\partial z}\right) + G = wc\,\frac{\partial t}{\partial \tau} \qquad (23)$$

$$\kappa\left(\frac{\partial^2 t}{\partial x^2} + \frac{\partial^2 t}{\partial y^2} + \frac{\partial^2 t}{\partial z^2}\right) + \frac{\partial k}{\partial t}\left[\left(\frac{\partial t}{\partial x}\right)^2 + \left(\frac{\partial t}{\partial y}\right)^2 + \left(\frac{\partial t}{\partial z}\right)^2\right] + G = wc\,\frac{\partial t}{\partial \tau} \qquad (24)$$

$$\theta = \int_0^t \kappa\, dt \qquad (25)$$

$$\frac{\partial^2 \theta}{\partial x^2} + \frac{\partial^2 \theta}{\partial y^2} + \frac{\partial^2 \theta}{\partial z^2} + G = \frac{1}{\alpha}\frac{\partial \theta}{\partial \tau} \qquad (26)$$

Equation (26) has exactly the same form as Eq. (7). In many cases the variation of α with temperature (Fig. 5) is less than that of κ so that a mean constant value may be selected. This is true, for example, of metals at temperatures near absolute zero. In such cases, if G is not a function of t (or no heat source is present), solutions for constant α will apply with θ replacing t, provided that the boundary conditions are specified in terms of t or $\kappa(\partial t/\partial n)$ where n represents the variables x, y, z.

The utility of the conductivity potential is demonstrated in the calculation of the heat leak to a liquid-nitrogen tank through a support rod. Consider steady-state conditions with the exposed end of the rod at 300 K and the other at 77.3 K. Also assume there are no losses from the side of the rod which is 1 cm^2 in cross section, is 15 cm long, and is made of stainless steel (for which κ decreases from 0.15 at 300 K to 0.08 W/cm K at 77.3 K). At any location q is given by Eq. (27). Since q is constant, Eq. (28) holds. Then Eqs. (29) follows.

$$q = -A\,\kappa\,\frac{dt}{dx} \qquad (27)$$

$$\frac{q}{A}\int_0^L dx = -\int_{t_1}^{t_2} \kappa\, dt = \int_0^{t_1} \kappa\, dt - \int_0^{t_2} \kappa\, dt \qquad (28)$$

$$\frac{qL}{A} = \theta_1 - \theta_2 \quad q = A\,\frac{\theta_1 - \theta_2}{L} = 1\,\frac{30 - 3.3}{15} = 1.78 \text{ W} \qquad (29)$$

Conduction band

The electronic energy band of a crystalline solid which is partially occupied by electrons. The electrons in this energy band can increase their energies by going to higher energy levels within the band when an electric field is applied to accelerate them or when the temperature of the crystal is raised. These electrons are called conduction electrons, as distinct from the electrons in filled energy bands which, as a whole, do not contribute to electrical and thermal conduction. In metallic conductors the conduction electrons correspond to the valence electrons (or a portion of the valence electrons) of the constituent atoms. In semiconductors and insulators at sufficiently low temperatures, the conduction band is empty of electrons. Conduction electrons come from thermal excitation of electrons from a lower energy band or from impurity atoms in the crystal. *See* BAND THEORY OF SOLIDS; ELECTRIC INSULATOR; ELECTRICAL CONDUCTIVITY OF METALS; SEMICONDUCTOR; VALENCE BAND. H. Y. Fan

Conductor (electricity)

Metal wires, cables, rods, tubes, bus-bars, and any other conducting media used for the purpose of carrying electric current. Although any metal assembly or structure can conduct electricity, the term conductor usually refers to the component parts of the current-carrying circuit or system.

Types of conductor. The most common forms of conductors are wires, cables, and bus-bars.

Wires. Wires employed as electrical conductors are slender rods or filaments of metal, usually soft and flexible. They may be bare or covered by some form of flexible insulating material. They are usually circular in cross section; for special purposes they may be drawn in square, rectangular, ribbon, or other shapes. Conductors may be solid or stranded, that is, built up by a helical lay or assembly of smaller solid conductors (**Fig. 1**).

Cables. Insulated stranded conductors in the larger sizes are called cables. Small, flexible, insulated cables are called cords. Assemblies of two or more insulated wires or cables within a common jacket or sheath are called multiconductor cables.

Bus-bars. Bus-bars are rigid, solid conductors and are made in various shapes, including rectangular, rods, tubes, and hollow squares. Bus-bars may be applied as single conductors, one bus-bar per phase, or as multiple conductors, two or more bus-bars per phase. The individual conductors of a multiple-conductor installation are identical. *See* BUS-BAR.

Sizes. Most round conductors less than $^1/_2$ in. (1.3 cm) in diameter are sized according to the American wire gage (AWG)—also known as the Brown & Sharpe gage. AWG sizes are based on a simple mathematical law in which intermediate wire sizes between no. 36 (0.0050-in. or 0.127-mm diameter) and no. 0000 (0.4600-in. or 11.684-mm diameter) are formed in geometrical progression. There are 38 sizes between these two diameters. An increase of three gage sizes (for example, from no. 10 to no. 7) doubles the cross-sectional area, and an increase of six gage sizes doubles the diameter of the wire.

Sizes of conductors greater than no. 0000 are usually measured in terms of cross-sectional area. Circular mil (cmil) is usually used to define cross-sectional area and is a unit of area equal to the area of a circle 1 mil (0.001 in. or 25.4 micrometers) in diameter.

Fig. 1. End views of stranded round conductor.

Wire lengths are usually expressed in units of feet or miles in the United States. Bus-bar sizes are usually defined by their physical dimensions—height and width in inches or fractions of an inch, and length in feet.

Materials. Most conductors are metals, but there is a wide range of conductivities (as much as a 70-to-1 ratio between different metals). Conductors are usually classified as good conductors, such as copper, aluminum, and silver, and poor conductors, such as iron; alloys of nickel, iron, copper, and chromium; and carbon products. In 1914, the U.S. Bureau of Standards made measurements of a large number of representative samples of copper and established standard values of resistivity and temperature coefficients, which have been adopted by the International Electrotechnical Commission. *See* ELECTRICAL CONDUCTIVITY OF METALS; ELECTRICAL RESISTIVITY; METAL.

Most wires, cables, and bus-bars are made from either copper or aluminum. Copper, of all the metals except silver, offers the least resistance to the flow of electric current. Both copper and aluminum may be bent and formed readily and have good flexibility in small sizes and in stranded constructions. Typical conductors are shown in Fig. 1.

Aluminum, because of its higher resistance, has less current-carrying capacity than copper for a given cross-sectional area. However, its low cost and light weight (only 30% that of the same volume of copper) permit wide use of aluminum for bus-bars, transmission lines, and large insulated-cable installations. *See* ALUMINUM; COPPER.

Metallic sodium conductors were used in 1965 on a trial basis for underground distribution insulated for both primary and secondary voltages. Sodium cable offered light weight and low cost for equivalent current-carrying rating compared with other conductor metals. Because of marketing problems and a few safety problems—the metal is reactive with water—the use of this cable was abandoned. *See* SODIUM.

For overhead transmission lines where superior strength is required, special conductor constructions are used. Typical of these are aluminum conductors, steel reinforced (ACSR), a composite construction of electrical-grade aluminum strands surrounding a stranded steel core (**Fig. 2**). Other constructions include stranded, high-strength aluminum alloy and a composite construction of aluminum strands around a stranded high-strength aluminum alloy core (ACAR). *See* TRANSMISSION LINES.

For extrahigh-voltage (EHV) transmission lines, conductor size is often established by corona performance rather than current-carrying capacity. Thus special "expanded" constructions are used to provide a large circumference without excessive weight. Typical constructions use helical lays of widely spaced aluminum strands around a stranded steel core. The space between the expanding strands is

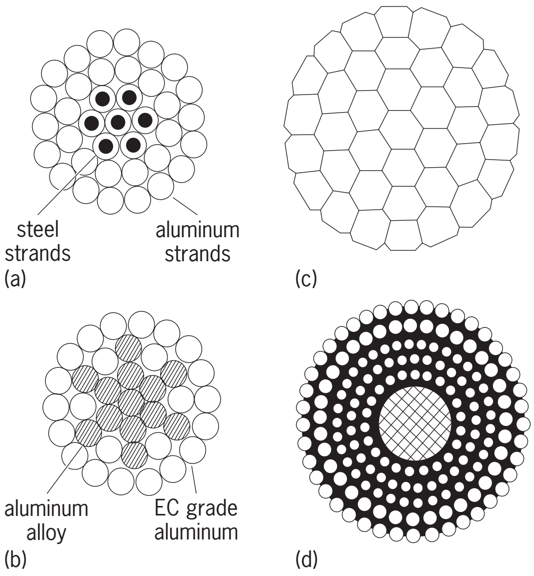

Fig. 2. Aluminum conductors. (*a*) ACSR. (*b*) ACAR. (*c*) Compact concentric stranded conductor. (*d*) Expanded-core concentric stranded conductor.

filled with paper twine, and outer layers of conventional aluminum strands are applied. In another construction the outer conductor stranding is applied directly over lays of widely separated helical expanding strands, without filler, leaving substantial voids between the stranded steel core and the closely spaced outer conductor layers. Diameters of 1.6 to 2.5 in. (41 to 63 mm) are typical. For lower reactance, conductors are "bundled," spaced 6–18 in. (15–45 cm) apart, and paralleled in groups of two, four, or more per phase. Figure 2 shows views of typical aluminum-conductor–steel-reinforced and expanded constructions.

Materials research has focused on amorphous or glassy materials, which include amorphous silicon-based semiconductors and metal alloys that totally lack crystalline structure. *See* AMORPHOUS SOLID.

Bare conductors. Bare wires and cables are used almost exclusively in outdoor power transmission and distribution lines. Conductors are supported on or from insulators, usually porcelain, of various designs and constructions, depending upon the voltage of the line and the mechanical considerations involved. Voltages as high as 765 kV are in use, and research has been undertaken into the use of EHV transmission lines, with voltages as high as 1500 kV.

Bare bus-bars are used extensively in outdoor substation construction, in switchboards, and for feeders and connections to electrolytic and electroplating processes. Where dangerously high voltages are carried, the use of bare bus-bars is usually restricted to areas accessible only to authorized personnel. Bare bus-bars are supported on insulators which have a design suitable for the voltage being carried.

Insulated conductors. Insulated electric conductors are provided with a continuous covering of flexible insulating material. A great variety of insulating materials and constructions has been developed to serve particular needs and applications. The selection of an appropriate insulation depends upon the voltage of the circuit, the operating temperature, the handling and abrasion likely to be encountered in installation and operation, environmental considerations such as exposure to moisture, oils, or chemicals, and applicable codes and standards. *See* ELECTRICAL INSULATION.

Magnet wires, used in the windings of motors, solenoids, transformers, and other electromagnetic devices, have relatively thin insulations, usually of enamel or cotton or both. Magnet wire is manufactured for use at temperatures ranging from 220 to 390°F (105 to 200°C). *See* MAGNET WIRE.

Conductors in buildings. Building wires and cables are used in electrical systems in buildings to transmit electric power from the point of electric service (where the system is connected to the utility lines) to the various outlets, fixtures, and utilization devices. Building wires are designed for 600-V operation but are commonly used at utilization voltages substantially below that value, typically 120, 240, or 480 V. Insulations commonly used include thermoplastic, natural rubber, synthetic rubber, and rubber-like compounds. Rubber insulations are usually covered with an additional jacket, such as fibrous braid or poly(vinyl chloride), to resist abrasion. Building wires are grouped by type in several application classifications in the National Electrical Code. *See* ELECTRICAL CODES.

Classification is by a letter which usually designates the kind of insulation and, often, its application characteristics. For example, type R indicates rubber or rubberlike insulation. TW indicates a thermoplastic, moisture-resistant insulation suitable for use in dry or wet locations; THW indicates a thermoplastic insulation with moisture and heat resistance. Other insulations in commercial use include silicone, fluorinated ethylene, propylene, varnished cambric, asbestos, polyethylene, and combinations of these.

Building wires and cables are also available in duplex and multiple-conductor assemblies; the individual insulated conductors are covered by a common jacket. For installation in wet locations, wires and cables are often provided with a lead sheath (**Fig. 3**).

For residential wiring, the common constructions used are nonmetallic-sheath cables, twin- and multiconductor assemblies in a tough abrasion-resistant jacket; and armored cable with twin- and multiconductor assemblies encased in a helical, flexible steel armor as in **Fig. 4**.

Power cables. Power cables are a class of electrical conductors used by utility systems for the

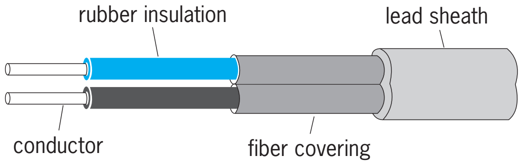

Fig. 3. Rubber-insulated, fiber-covered, lead-sheathed cable, useful for installation in wet places.

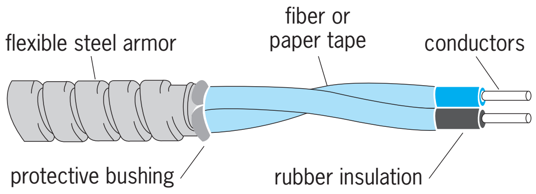

Fig. 4. Two-conductor armored cable.

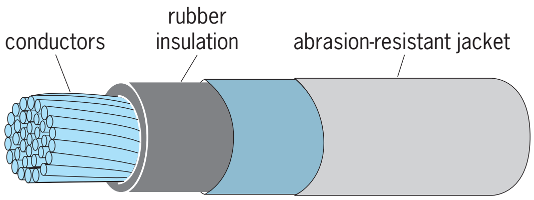

Fig. 5. Rubber-insulated power cable.

distribution of electricity. They are usually installed in underground ducts and conduits. Power cables are also used in the electric power systems of industrial plants and large buildings.

Power-cable insulations in common use include rubber, paper, varnished cambric, asbestos, and thermoplastic. Cables insulated with rubber (**Fig. 5**), polyethylene, and varnished cambric (**Fig. 6**) are used up through 69 kV, and impregnated paper to 138 kV. The type and thickness of the insulation for various voltages and applications are specified by the Insulated Power Cable Engineer Association (IPCEA).

Spaced aerial cable. These cable systems are used for pole-line distribution at, typically, 5–15 kV, three-phase. Insulated conductors are suspended from a messenger, which may also serve as a neutral conductor, with ceramic or plastic insulating spacers, usually of diamond configuration. For 15 kV, a typical system may have conductors with $^{19}/_{64}$-in. (4-mm) polyethylene insulation, 9-in. (23-cm) spacing between conductors, and 20 ft (6 m) between spacers.

High-voltage cable. High-voltage cable constructions and standards for installation and application are described by IPCEA. Insulations include (1) paper, solid type; (2) paper, low-pressure, gas-filled; (3) paper, low-pressure, oil-filled; (4) pipe cable, fully impregnated, oil-pressure; (5) pipe cable, gas-filled, gas-pressure; (6) rubber or plastic with neoprene or plastic jacket; (7) varnished cloth; (8) AVA and AVL (asbestos-varnished cloth).

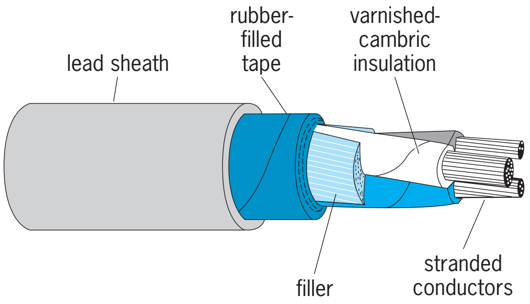

Fig. 6. Varnished cambric-insulated, lead-sheathed power cable, for voltages up to 28 kV.

Underground transmission cables are in service at voltages through 345 kV, and trial installations have been tested at 500 kV. Research has also been undertaken to develop cryoresistive and superconducting cables for transmitting power at high density.

Superconducting cables. It may be possible to apply the phenomenon of superconductivity to help provide more efficient and more compact electrical systems. In the area of electric power transmission, generation, and storage, superconductivity could have a major impact by increasing energy conservation. With the advent, in 1986, of superconducting materials with transition temperatures as high as 125 K (−235°F), there is a possibility of designing superconducting transmission lines that would carry as much as 1 GVA (10^9 W) of power. *See* SUPERCONDUCTING DEVICES; SUPERCONDUCTIVITY.

Busways. Enclosed bus-bar assemblies, or busways, are extensively used for service conductors and feeders in the electrical distribution systems of industrial plants and commercial buildings. They consist of prefabricated assemblies in standard lengths of bus-bars rigidly supported by solid insulation and enclosed in a sheet-metal housing.

Busways are made in two general types, feeder and plug-in. Feeder busways have no provision for taps or connections between the ends of the assembly. Low-reactance feeder busways are so constructed that conductors of different phases are in close proximity to minimize inductive reactance. Plug-in busways have provisions at intervals along the length of the assembly for the insertion of bus plugs.

Voltage drop in conductors. In electric circuits the resistance and (in ac circuits) the reactance of the circuit conductors result in a reduction in the voltage available at the load (except for capacitive loads). Since the line and load resistances are in series, the source voltage is divided proportionally. The difference between the source voltage and the voltage at the load is called voltage drop.

Electrical utilization devices (such as motors, household appliances, and electronic equipment) are designed to operate at a particular voltage or within a narrow range of voltages around a design value. The performance and efficiency of these devices are adversely affected if they are operated at a significantly lower voltage. Incandescent-lamp light output is lowered; fluorescent-lamp light output is lowered and starting becomes slow and erratic; the starting and pull-out torque of motors is seriously reduced.

Voltage drop in electric circuits caused by line resistance also represents a loss in power which appears as heat in the conductors. In excessive cases, the heat may rapidly age or destroy the insulation. Power loss also appears as a component of total energy use and cost. *See* COPPER LOSS.

Thus, conductors of electric power systems must be large enough to keep voltage drop at an acceptable value, or power-factor corrective devices—such as capacitors or synchronous condensers—must be installed. A typical maximum for a building wiring system for light and power is 3% voltage drop from the utility connection to any outlet under full-load condition. *See* WIRING. H. Wayne Beaty

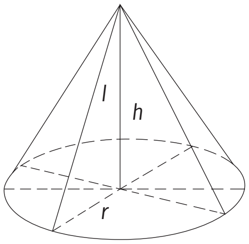
Cone

The solid of revolution obtained by revolving a right triangle about one of its shorter sides is called a cone, or more precisely a right circular cone (see **illus.**).



Right circular cone.

More generally, the term cone is used in solid geometry to describe a solid bounded by a plane and a portion of one nappe of a conical surface. In analytic geometry, however, the term cone refers not to a solid but to a conical surface. This is a surface generated by a straight line which moves so that it always intersects a given plane curve, called the directrix, and passes through a point, called the vertex, not in the plane of the directrix. The generating line in each of its positions is called an element of the cone. The vertex divides the surface into two parts, called nappes, that are congruent to each other in the extended sense (under rotation and reflection combined) but may not be superposable by a rigid motion in three-dimensional space.

If the elements of a cone make equal angles with a line through the vertex, the cone is called a cone of revolution, the line is called the axis of revolution, and the angle is called the semivertical angle ϵ. Plane sections of a cone of revolution are called conic sections.

If the plane makes an angle θ with the axis and does not contain the vertex, the resulting conic section is called nondegenerate and is a circle if $\theta = 90^\circ$, an ellipse if $\epsilon < \theta < 90^\circ$, a parabola if $\theta = \epsilon$, or a hyperbola if $\theta < \epsilon$. In the latter case the plane cuts both nappes of the cone, and the conic section consists of two separate congruent arcs called the branches of the hyperbola.

If the cutting plane contains the vertex of the cone, the conic section is degenerate and consists of a point, a line, or a pair of intersecting lines. Cones whose directrices are conic sections are called quadric cones.

The volume of a solid cone is $V = Bh/3$, where B is the base area included within the directrix, and h is the altitude (or height) measured from the vertex to the plane of the base. The volume V and surface area S of a right circular cone are $V = \pi r^2 h/3$ and $S = \pi rl + \pi r^2$, where r denotes the radius of the base and $l = \sqrt{r^2 + h^2}$ denotes the slant height, measured from vertex to base along an element of the cone.

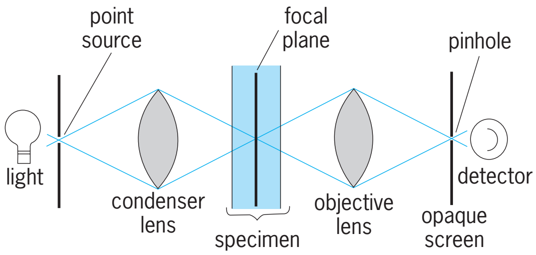
A frustum of a cone is a solid bounded by two parallel planes and a portion of a conical surface. The plane boundaries are called bases. If the bases are circles of radii r and R, the volume of the frustum is $V = (\pi h/3)(r^2 + rR + R^2)$. *See* CONIC SECTION; EUCLIDEAN GEOMETRY. J. Sutherland Frame

Confocal microscopy

A technique that creates high-resolution images of very small objects but differs from conventional optical microscopy in that it uses a condenser lens to focus the illuminating light from a point source into a very small, diffraction-limited spot within the specimen, and an objective lens to focus the light emitted from that spot onto a small pinhole in an opaque screen (see **illus.**). Located behind the screen is a detector capable of quantifying how much light passes through the hole at any instant. Because only light from within the illuminated spot is properly focused to pass through the pinhole and reach the detector, any stray light from structures above, below, or to the side of the spot is filtered out. The image quality is therefore greatly enhanced.

Only the smallest possible spot is illuminated at any one time, and so a coherent image must be built up by scanning point by point over the desired field of view and recording the intensity of the light emitted from each spot. The size of the spot is equal to the ultimate resolution of the instrument and is typically about 0.25 micrometer in diameter and about 0.5 μm deep, although the dimensions vary with the wavelength of the light and the lens system used.

Scanning can be accomplished in several ways, but the most common system is laser scanning. This system uses a pair of mirrors, vibrating at precisely



Schematic diagram of a confocal microscope. Light passes through a point source and a condenser lens to a point on the specimen. Only light coming from that spot is focused again by the objective lens onto a pinhole, through which it passes to reach the detector. Light from structures above or below the focal plane is too diffuse to pass through, and light from structures beside the spot is directed to the side of the pinhole. (*After R. J. Taylor, Confocal microscopy sheds new light on the dynamics of living cells, J. NIH Res., 1(1):113–115, 1989*)

controlled frequencies, which are placed in the path of a laser beam and direct it in a sweeping pattern over the specimen. The intensity of light emitted from each spot is digitally recorded, and the complete set of intensities from each point is displayed on a video screen, allowing the total image to be seen at one time. Because the information is already in a digital form, it can easily be passed to a computer for storage or further analysis.

Although confocal microscopy was first described in 1961, instruments were not available commercially until the late 1980s. They have found applications in several fields, including materials science and the semiconductor industry, but they have a number of advantages that make them particularly useful in the biological sciences. Many dyes used in biological studies are fluorescent and emit light at a wavelength different from the illuminating light. The amount of fluorescence from different parts of a cell, which is often directly proportional to the concentration of a specific intracellular constituent, can be measured far more precisely with a confocal microscope, because of the rejection of interference from other parts of a specimen. Haze from out-of-focus structures above the focal plane is eliminated, and so it is possible to see very clear images from fairly deep within a relatively thick slice of tissue without having to disrupt its three-dimensional organization. A stack of images from successive focal planes can be obtained simply by moving the narrow focal plane through the specimen. That technique makes it relatively easy to build up complex, three-dimensional views of cellular interconnections or subcellular structures. *See* FLUORESCENCE MICROSCOPE.

Conformal mapping

A special operation in mathematics in which a set of points in one coordinate system is mapped or transformed into a corresponding set in another coordinate system, preserving the angle of intersection between pairs of curves.

A mapping or transformation of a set E of points in the xy plane onto a set F in the uv plane is a correspondence, Eqs. (1), that is defined for each

$$u = \varphi(x, y) \qquad v = \psi(x, y) \qquad (1)$$

point (x,y) in E and sends it to a point (u,v) in F, so that each point in F is the image of some point in E. A mapping is one to one if distinct points in E are transformed to distinct points in F. A mapping is conformal if it is one to one and it preserves the magnitudes and orientations of the angles between curves (**Fig. 1**). Conformal mappings preserve the shape but not the size of small figures.

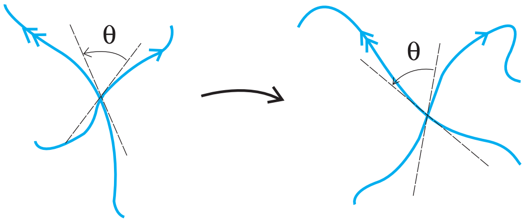

Fig. 1. Angle-preserving property of a conformal mapping.

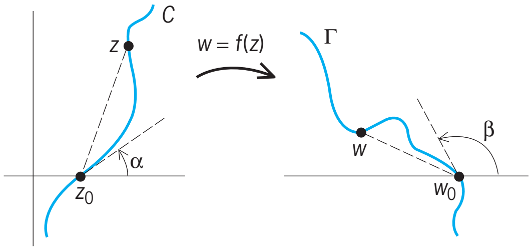

Fig. 2. Illustration for proof that analytic functions preserve angles.

Relation to analytic functions. If the points (x,y) and (u,v) are viewed as the complex numbers $z = x + iy$ and $w = u + iv$, the mapping becomes a function of a complex variable: $w = f(z)$. It is an important fact that a one-to-one mapping is conformal if and only if the function f is analytic and its derivative $f'(z)$ is never equal to zero. This can be seen by considering a function f that is analytic near $z_0 = x_0 + iy_0$, with $f'(z_0) \neq 0$, and mapping a curve C passing through z_0 to a curve Γ passing through $w_0 = f(z_0)$. Then, as a point z tends to z_0 along C, the angle arg $\{z - z_0\}$ tends to the angle α between C and the line $y = y_0$ (**Fig. 2**). But by assumption, expression (2) is valid. In particular,

$$\frac{f(z) - w_o}{z - z_o} \to f'(z_o) \qquad (2)$$

$\arg\{f(z) - w_0\} - \arg\{z - z_0\}$ tends to a limit $\gamma = \arg\{f'(z_0)\}$. In other words, $\arg\{w - w_0\} \to \beta$ as $w \to w_0$ along Γ, where $\beta = \alpha + \gamma$. But any other curve through z_0 is rotated by the same angle γ, so that the mapping preserves the angle between the two curves. In a similar manner, it can be shown that a conformal mapping is necessarily given by an analytic function. *See* COMPLEX NUMBERS AND COMPLEX VARIABLES.

Examples. Some examples of functions that provide conformal mappings (and one that is not conformal) will now be given.

1. The function $w = (z - 1)/(z + 1)$ maps the right half-plane, defined by $\text{Re}\{z\} > 0$, conformally onto the unit disk, defined by $|w| < 1$.

2. The function $w = \log z$ maps the right half-plane conformally onto the horizontal strip defined by $-\pi/2 < \text{Im}\{w\} < \pi/2$.

3. The function $w = z^2$ maps the upper semidisk, defined by $\mathrm{Im}\{z\} > 0$ and $|z| < 1$, conformally onto the unit disk $|w| < 1$ with the segment $0 \leq u < 1$ removed. It doubles angles at the origin, but this is a boundary point which does not lie in the semidisk.

4. The function $w = \bar{z}$ of complex conjugation preserves the magnitudes but not the orientations of angles between curves. It is nowhere conformal.

5. The function $w = z + 1/z$ maps the unit disk $|z| < 1$ conformally onto the extended complex plane (including the point at infinity) with the line segment $-2 \leq u \leq 2$ removed.

6. The Koebe function $k(z) = z(1 - z)^{-2}$ maps the unit disk conformally onto the complex plane with the half-line $-\infty < u \leq -1/4$ removed.

Linear fractional transformations. A linear fractional transformation is a function of the form given by Eq. (3), where *a, b, c*, and *d* are complex constants.

$$w = \frac{az + b}{cz + d} \qquad ad - bc \neq 0 \tag{3}$$

It is also known as a Möbius function. One example is the function $w = (z - 1)/(z + 1)$, discussed above. Simpler examples are magnifications, given by Eq. (4), rotations, given by Eq. (5), and inversion, given by Eq. (6). Every linear fractional transformation is a composition of linear fractional transformations of these three special types. Thus each linear fractional transformation provides a conformal mapping of the extended complex plane onto itself, and in fact the linear fractional transformations are the only such mappings. There is a unique linear fractional transformation which carries three prescribed (distinct) points z_1, z_2, z_3 to prescribed images w_1, w_2, w_3. The most general conformal mapping of the unit disk onto itself is a linear fractional transformation of the form given by Eq. (7).

$$w = az \qquad a > 0 \tag{4}$$

$$w = az \qquad |a| = 1 \tag{5}$$

$$w = 1/z \tag{6}$$

$$w = \frac{z - z_0}{1 - \bar{z}_0 z} \qquad |z_0| < 1 \tag{7}$$

Each linear fractional transformation carries circles to circles and symmetric points to symmetric points. Here a circle means a circle or a line. Two points are said to be symmetric with respect to a circle if they lie on the same ray from the center and the product of their distances from the center is equal to the square of the radius. Two points are symmetric with respect to a line if the line is the perpendicular bisector of the segment joining the two points. As an instance of this general property of linear fractional transformations, the mapping $w = (z - 1)/(z + 1)$ sends the family of circles of Apollonius with symmetric points 1 and -1 (defined by requiring that on each circle the quotient of the distances from 1 and -1 be constant) onto the family of all circles centered at the origin. It carries the orthogonal family of curves, consisting of all circles through the points 1 and -1, onto the family of all lines through the origin (**Fig. 3**).

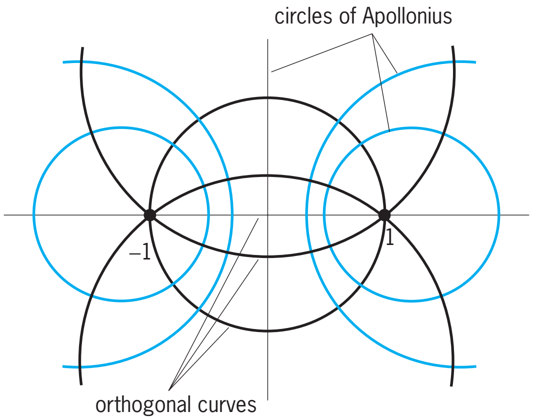

Fig. 3. Circles of Apollonius and members of the orthogonal family of curves.

Applications. Conformal mappings are important in two-dimensional problems of fluid flow, heat conduction, and potential theory. They provide suitable changes of coordinates for the analysis of difficult problems. For example, the problem of finding the steady-state distribution of temperature in a conducting plate requires the calculation of a harmonic function with prescribed boundary values. If the region can be mapped conformally onto the unit disk, the transformed problem is readily solved by the Poisson integral formula, and the required solution is the composition of the resulting harmonic function with the conformal mapping. The method works because a harmonic function of an analytic function is always harmonic. *See* CONDUCTION (HEAT); FLUID-FLOW PRINCIPLES; LAPLACE'S DIFFERENTIAL EQUATION; POTENTIALS.

The term conformal applies in a more general context to the mapping of any surface onto another. A problem of great importance for navigation is to produce conformal mappings of a portion of the Earth's surface onto a portion of the plane. The Mercator and stereographic projections are conformal in this sense. *See* MAP PROJECTIONS.

Riemann mapping theorem. In 1851, G. F. B. Riemann enunciated the theorem that every open simply connected region in the complex plane except for the whole plane can be mapped conformally onto the unit disk. Riemann's proof was incomplete; the first valid proof was given by W. F. Osgood in 1900. Most proofs exhibit the required mapping as the solution of an extremal problem over an appropriate family of analytic univalent functions. (A univalent function is simply a one-to-one mapping.) For instance, the Riemann mapping maximizes $|f'(z_0)|$ among all analytic univalent functions which map the given region into the unit disk: $|f(z)| < 1$. Here z_0 is chosen arbitrarily in the region, and the Riemann mapping has $f(z_0) = 0$.

Multiply connected regions. There is no exact analog of the Riemann mapping theorem for multiply connected regions. For instance, two annuli, $r_1 < |z| < r_2$ and $R_1 < |w| < R_2$, are conformally equivalent if and only if $r_2/r_1 = R_2/R_1$. Any doubly connected region can be mapped conformally onto a (possibly degenerate) annulus. Any finitely connected region (other than a punctured plane) can be mapped conformally onto the unit disk minus a system of concentric circular arcs, or onto the whole plane minus a system of parallel segments, or radial segments, or concentric circular arcs. Other canonical regions are bounded by arcs of lemniscates or logarithmic spirals, or by full circles.

Distortion theorems. Conformal mappings are often studied by considering the class S of functions $f(z)$ which are analytic and univalent in the unit disk and have the normalizing properties $f(0) = 0$ and $f'(0) = 1$. Alternatively, the class S may be defined as the class of all univalent power series of the form $f(z) = z + a_2z^2 + a_3z^3 + \cdots$ that are convergent for $|z| < 1$. The Koebe distortion theorem gives the sharp bounds, Eqs. (8), for all functions f in S and all points

$$\begin{aligned} r(1+r)^{-2} \le |f(z)| \le r(1-r)^{-2} \quad r = |z| \\ (1-r)(1+r)^{-3} \le |f'(z)| \le (1+r)(1-r)^{-3} \end{aligned} \tag{8}$$

z in the disk. The Koebe $^1/_4$-theorem asserts that each function f in S includes the full disk $|w| < {}^1/_4$ in its range. Suitable rotations of the Koebe function (discussed above) show that each of these bounds is the best possible. All of these statements can be deduced from a theorem of L. Bieberbach (1916) that $|a_2| \le 2$ for all functions f in S, with equality occurring only for the Koebe function, given by Eq. (9), or one of

$$k(z) = z(1-z)^{-2} = z + 2z^2 + 3z^3 + \cdots \tag{9}$$

its rotations, given by $e^{-i\theta}k(e^{i\theta}z)$ for some value of θ. Bieberbach conjectured that in general $|a_n| \le n$ for all n. For many years, the Bieberbach conjecture stood as a challenge and inspired the development of powerful methods in geometric function theory. After a long series of advances by many mathematicians, the final step in the proof of the Bieberbach conjecture was taken by L. de Branges in 1984.

Boundary correspondence. The open region inside a simple closed curve is called a Jordan region. Riemann's theorem ensures the existence of a conformal mapping of one Jordan region onto another. C. Carathéodory proved in 1913 that such a mapping can always be extended to the boundary and the extended mapping is a homeomorphism, or a bicontinuous one-to-one mapping, between the closures of the two regions. In fact, Carathéodory proved a much more general theorem which admits inaccessible boundary points and establishes a homeomorphic correspondence between "clusters" of boundary points, known as prime ends. For a conformal mapping of the unit disk onto a Jordan region with a rectifiable boundary, the Carathéodory extension preserves sets of measure zero (or zero "length") on the boundary. It is also angle-preserving at almost every boundary point, that is, except for a set of points of measure zero. If the boundary of the Jordan region has a smoothly turning tangent direction, the derivative of the mapping function can also be extended continuously to the boundary. *See* MEASURE THEORY.

Quasiconformal mappings. A theory of generalized conformal mappings, known as quasiconformal mappings, has evolved. Roughly speaking, a univalent function $w = f(z)$ is said to be K-quasiconformal in a certain region if it maps infinitesimal circles to infinitesimal ellipses in which the ratios of major to minor axes are bounded above by a constant $K \ge 1$. Equivalently, a mapping is quasiconformal if it distorts angles by no more than a fixed ratio. The simplest examples are linear mappings of the form $u = ax + by$, $v = cx + dy$, $ad - bc \ne 0$, where a, b, c, and d are real constants. The 1-quasiconformal mappings are simply the conformal mappings. The notion of a quasiconformal mapping is readily extended to higher dimensions. **Peter L. Duren**

Conformal optics

Conformal optical systems have outer surfaces whose shape is chosen to optimize the interaction with the environment in which the optical system is being used. The imaging through such conformal optical windows is likely to suffer from extreme aberration, requiring special techniques for correction. *See* ABERRATION (OPTICS).

For example, a conformal optical window might relate to the nose of an infrared-seeking missile. These conformal surfaces permit a beneficial interface with the environment and allow substantial improvements in the overall performance of the vehicle. Recently there has been considerable research into methods of compensating for the aberrations produced by such windows. Computer-intensive methods of design, fabrication, and testing of optics have reached a level where the development of cost-effective methods for insertion of these conformal optics concepts into operational systems appears to be practical.

Applications. Important applications of conformal optics are found in missile and aircraft systems. Missiles and aircraft carry optical sensors for imaging, detection, and ranging that must look at the world through the outer skin of the vehicle. Traditionally, the windows for viewing through the skin of missiles and aircraft have had simple optical forms, such as flats or spheres, that enable the optical tracking systems to operate by using well-known technology. But these optically advantageous windows degrade the performance of the vehicle through increased drag, aerodynamic heating, or other undesirable effects. One example is the use of an optical tracker or seeker on the front end of a missile. These optical systems, usually used with infrared sensors, need to have a wide and unobstructed field of view. The classical solution for the window for these optics is a hemispherical dome mounted at the front of the missile. An optical tracker located within the dome is scanned around the field of view to keep track of a target. The spherical-surfaced-dome approach is easy to accommodate in the design, fabrication, and testing of the system, but the blunt spherical form adds considerable aerodynamic drag to the missile. The use of a conformal window, whose shape conforms more closely to the optimal, pointed ogival shape, reduces the drag of the missile and provides significant gains in the missile's performance. Such ogival shapes produce considerable optical aberration, however.

Similar considerations apply to aircraft. The optical sensors of most combat aircraft are mounted in pods that attach to the wings or other outer surfaces. These pods increase drag and reduce maneuverability and stealth properties of the aircraft. Location of the sensors within the body of the aircraft using traditional flat windows limits their field of view. The use of windows that have surfaces conforming to the desirable aerodynamic shapes of the aircraft is necessary to permit internal, drag-free location of these sensors.

One example of the benefits to be obtained through the appropriate use of conformal optics is a typical missile. Replacement of a hemispherical front-end window by an optimal-shaped ogival window can reduce the drag coefficient by as much as 25%. This reduction of the drag will lead to an increase in range for the same fuel consumption. There are additional advantages such as improved maneuverability of the missile.

The **illustration** shows one possible implementation of a conformal window to replace a conventional optical spherical window. It is a diagram of a conformal window, shaped to provide an improved drag profile for the missile. The optical tracker behind the conformal window can be seen looking toward the side of the missile. The optical tracker no longer sees a simple and constant spherical form for the window at any angle of view. The aspheric shape of the window produces a significant amount of aberration that must be compensated at some location in the optical system. The variation of the aberration with direction of view requires that this correction be dynamic.

There are other applications in which general aspheric optical surfaces are needed. Compact illumination systems require many unique forms of conformal surfaces, sometimes for utilitarian reasons and frequently for design or styling reasons. One growing area of interest comprises unique compact headlight systems for automobiles. Unobscured reflecting imaging systems used in spacecraft or microlithographic optics require nonconventional aspheric shapes for packaging or aberration correction purposes.

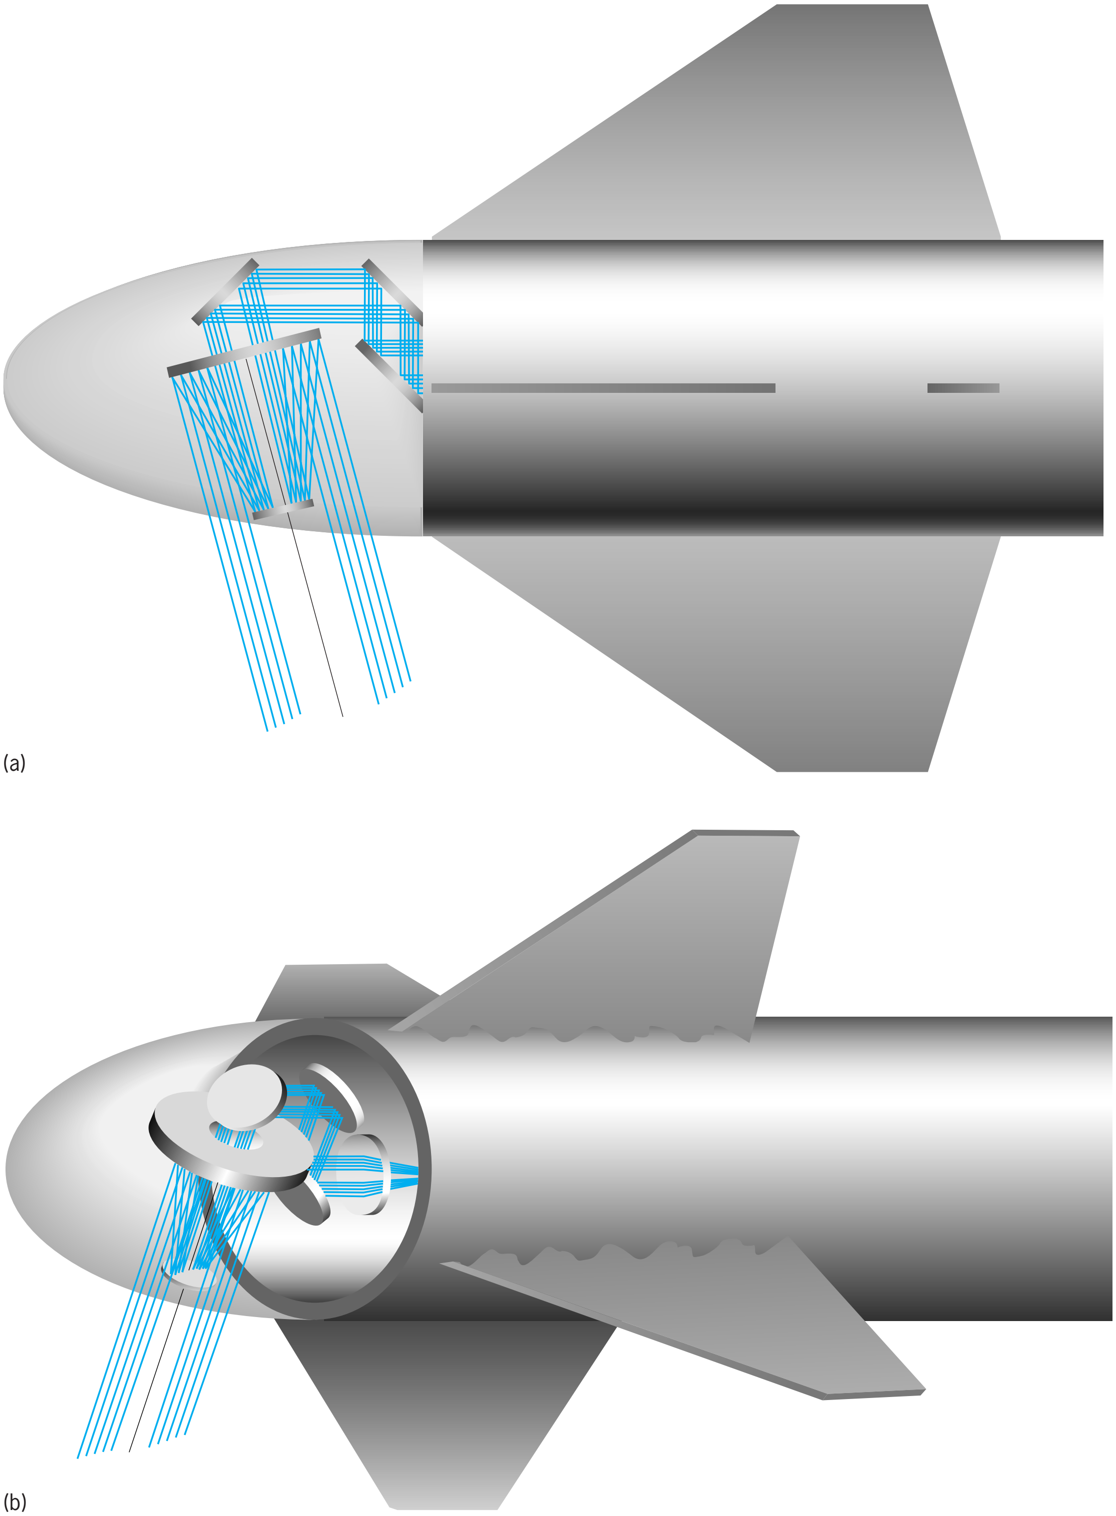
Challenges. The most desirable form for the front end of a missile is a pointed shape called an ogive. This ogival shape reduces the aerodynamic drag on the missile but produces a greatly distorted view of the scene that is viewed through the ogival dome. An optical tracker looking through the dome will see large amounts of aberration. A conformal optical surface is extremely aspheric and cannot be described by traditional surface prescriptions. Traditional optical design and fabrication methods cannot cope with the large amount of aberration that is generated by such conformal shapes. There are no established guidelines for the incorporation of these extreme aspheric conformal surfaces in the design of optical systems.

Fabrication of these conformal surfaces provides a new set of challenges. Traditional optical fabrication is based on the generation and polishing of spherical or flat surfaces by a lapping process. The surface eventually converges to the final required shape as a natural result of the process. Most aspherics used in lenses are minor deviations from these base spherical surfaces. Conformal surfaces require significant departures from traditional optical surfaces. New techniques for shape generation and polishing need to be developed so that conformal surfaces can be successfully fabricated. *See* OPTICAL SURFACES.

Test and measurement of these surfaces provide a new set of challenges. There are no natural nulling tests, which provide an absolute reference for the surface shape. Testing requires new methods of numerically constructing reference surfaces for defining, aligning, and calibrating the conformal surface. The use of these new surfaces as windows for optical systems also provides some new challenges in operation. The alignment between the window and the tracking optics is very critical. Therefore, alignment during installation and field operation must frequently be carried out by new adaptive optical techniques.

All of these new approaches require novel technical solutions within the framework of economic reality. None of these conformal techniques can be inserted into operational practice unless they are cost effective. Thus the cost of introducing conformal surfaces into missiles and aircraft must not exceed a small fraction of the cost benefit.

Design approach. The approach to design with conformal optics does not call for complete abandonment of current understanding of the image-formation process. Optical design methods are based on the description of the wavefront passing through surfaces by use of numerical ray tracing. The understanding of the aberrations arising at surfaces is obtained from an analytic method for describing the surface and the wavefront to stated levels of accuracy. The aberrations produced by general aspheric surfaces defy simple analytic descriptions but can be obtained by fitting of the numerical ray-tracing results. It is found that for most conformal surfaces the local aberration for a wavefront passing through a conformal window can be well described in terms of combinations of simple aberration shapes such as focus, astigmatism, and coma. The variation of these aberrations with location on the window becomes very difficult to describe analytically, leading to a



Geometric optics of an optical tracker behind a conformal window that is shaped to provide an improved drag profile for a missile. Paths of rays through the optical system are shown. (*a*) Side view. (*b*) Oblique view. *(Optical Research Associates)*

design process in which the numerical ray tracing is used to establish the aberration level.

An intuitive grasp of the aberration content of conformal windows can be obtained by graphical presentations of the behavior of the aberrations with respect to the angle of view through the window. New design approaches permit expressing the targets of the design programs in terms of combinations of the sets of aberrations that naturally describe the effect of the conformal windows. New types of nonsymmetric aspheric components are required to compensate these sets of aberrations and are incorporated into the tracker optics. New approaches to tolerancing and assembling of these unusual optical systems are being investigated. *See* GEOMETRICAL OPTICS.

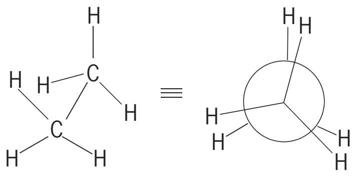
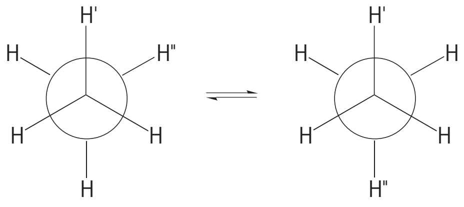
Conformational analysis

The study of the energies and structures of conformations of organic molecules and their chemical and physical properties. Organic molecules are not static entities. The constituent atoms vibrate and groups rotate about the bond axes. *See* STEREOCHEMISTRY.

Linear structures. Rotation about the C-C bond in ethane, for example, results in an infinite number of slightly different structures called conformations, two of these are indicated below.



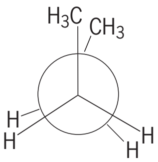
(**1**)



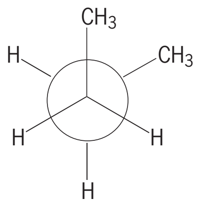
(**2**) (**3**)

In conformation (**1**) of ethane, the pairs of C-H bonds on the two carbon atoms reside in a plane, and are termed eclipsed. (The circle represents the front-most carbon atom, and the long bonds those from that carbon atom to the hydrogen atoms. The bonds from the circle represent those bonds from the rearward carbon to its hydrogen atoms.) Conformation (**1**) is called the eclipsed conformation. In conformation (**2**), the C-H bonds on one carbon reside between the C—H bonds on the other carbon. Conformation (**2**) is called the staggered conformation. An infinite number of conformations between (**1**) and (**2**) are possible; however, conformations (**1**) and (**2**) are of greatest interest because they are the maximum and minimum energy structures. In conformation (**1**), the electrons in the C-H bonds and the nuclear charges of the hydrogen atoms repel each other, resulting in a higher energy state. In conformation (**2**), the electrons and hydrogen atoms are at their greatest possible separation and the repulsion is at a minimum. The conversion of (**2**) to (**3**) by rotation of one of the methyl groups by 120° requires the input of energy, approximately 3.0 kcal (13 kilojoules) per mole, in order to pass through the eclipsed conformation. This amount is small compared to the thermal energy at room temperature, and the rotation about the C-C bond in ethane occurs at about 10^9–10^{10} times per second.

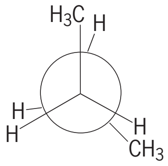
Butane provides a more complicated case. There are two different eclipsed (**4** and **6**) and two staggered (**5** and **7**) conformations which are designated by the names below the structures. As the methyl group is larger than a hydrogen atom, (**4**) is higher in energy than (**6**), and (**5**) is higher in energy than (**7**) [see **illus.**]. As the molecular weight of an alkane increases, the number of molecular conformations (combinations of all possible individual bond conformations) increases dramatically, although the antiperiplanar conformations are always favored.



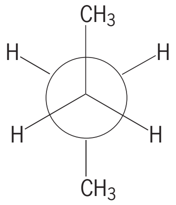
(**4**)
synperiplanar



(**5**)
synclinal

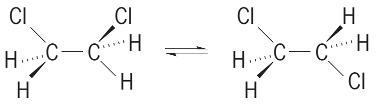


(**6**)
anticlinal

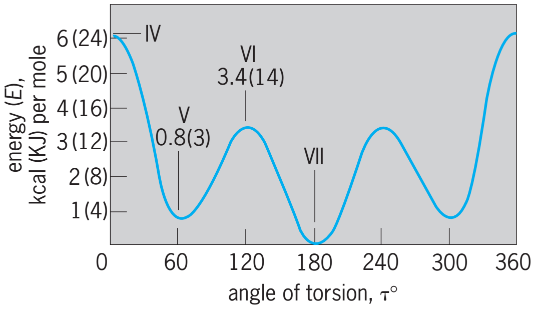


(**7**)
antiperiplanar

1,2-Dichloroethane also exists in conformations similar to those of butane (see interconverting conformations below). In the gas phase, the antiperiplanar conformation predominates. This is not due to a steric repulsion in the synclinal conformation, but to C-Cl bond dipole repulsion. (The bond dipole moment arises from the fact that chlorine is more electronegative than carbon.) In a polar solvent, the energy difference between the antiperiplanar and synclinal conformations is decreased due to



synclinal antiperiplanar

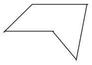


Potential energy diagram for butane. (*After E. L. Eliel et al., Conformational Analysis, Interscience Publishers, 1965*)

stabilization of the synclinal form. In pure liquid 1,2-dichloroethane, the enthalpy difference is zero. Such solvent effects are not observed with nonpolar molecules such as the alkanes.

Cyclic structures. These also exist in various conformations. Cyclopropane, a planar structure, can exist in only one conformation. In cyclobutane, slight twisting about the C-C bonds can occur which relieves some of the C-H eclipsing strain energy. Cyclobutane exists in rapidly interconverting so-called butterfly conformations (**8**). Cyclopentane exists in two types of nonplanar conformations: the envelope conformation (**9**) and the half-chair (or twist) conformation (**10**). The flap atom of (**9**), the atom out of the plane of the other four, can migrate around the ring, as can also the twist in (**10**). These motions, called pseudorotation, require very little energy, and cyclopentane presents a very complex conformational system.

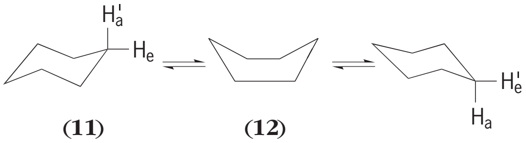
(8)



(9)

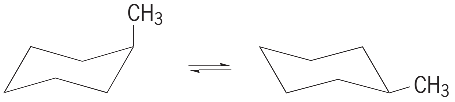
(10)

Cyclohexane exists predominantly in the chair conformation (**11**), in which all C-C bond conformations are of the staggered type. Interconversion between chair conformations occurs rapidly at room temperature, passing through the high-energy, boat conformation (**12**). In the chair conformation, there are two distinctly different types of hydrogen atoms; one set oriented perpendicular to the general plane of the ring, called axial (a) hydrogens, and one set oriented parallel to the plane of the ring, called equatorial (e) hydrogens. These hydrogens interchange orientation on chair interconversion. Axial and equatorial hydrogens possess different chemical and physical properties, although at room temperature the interconversion occurs very rapidly (~10^5 per second), and it is in general not possible to detect the differences. It is easy to design molecules in which the interconversion is not possible and the differences in properties become readily apparent.



(11) **(12)**

A substituted cyclohexane, for example methylcyclohexane, exists in two different chair conformations which are in equilibrium. In the axial conformation (**13**), the methyl group is in proximity with the other two axial hydrogens on the same side of the ring. This steric repulsion disfavors the axial conformation and favors equatorial conformation (**14**). The measurement of conformational equilibrium constants has allowed the construction of a relative size scale for organic functional groups.



(13) **(14)**

Rotation about C-C bond. Rotation about the C-C double bond requires a very large amount of energy, and is rarely observed except under very forcing conditions. Thus, although *cis*- and *trans*-2-butene can be considered to be conformational isomers, practically this does not occur.

An illustration of how the conformation of a molecule affects a chemical reaction is provided by the elimination of hydrogen bromide from 2-bromobutane, which can exist in either of the two staggered conformations (**15**) and (**16**). The elimination of hydrogen bromide requires that the hydrogen and bromine be antiperiplanar. Thus, the elimination from (**15**) produces *trans*-2-butene [reaction (1)], and from **16**, *cis*-2-butene [reaction (2)].

Conformational analysis represents a very large area of study and has provided important information on the structures and reactivities of complex natural products such as steroids and alkaloids. *See* MOLECULAR ISOMERISM; STEREOCHEMISTRY. Daniel J. Pasto

Bibliography. E. L. Eliel et al., *Conformational Analysis*, 1965; E. L. Eliel and S. H. Wilen, *Stereochemistry of Organic Compounds*, 1994; E. Juaristi, *Introduction to Stereochemistry and Conformational Analysis*, 1991.

Confuciusornithidae

An extinct family of flying birds that represents one of the most primitive avian groups. It comprises three genera (*Confuciusornis*, *Changchengornis*, and *Jinzhouornis*) and is known exclusively from western Liaoning Province and neighboring areas in northeastern China. Fossils of this group have been collected from the Yixian and Jiufotang formations, which represent freshwater lake deposits that were formed in the Early Cretaceous period 125–120 million years ago.

Confuciusornithids are generally similar in size to *Archaeopteryx* and retain three wing claws and an unreduced phalangeal formula, that is, the phalangeal formula of the hand is 2-3-4 (two phalanges in the first digit, three phalanges in the second digit, and four phalanges in the third digit). The latter may indicate that the hand was used as an aid in climbing or grasping tree trunks and branches, as has also been suggested in the case of *Archaeopteryx* and some of their closely related dinosaurian ancestors. In addition to these primitive features, confuciusornithids share a number of features with modern birds, including a short skeletal tail in which the final few vertebrae are fused together into a pygostyle (or plowshare bone). Tail feathers would have been attached to the pygosyle, suggesting that confuciusornithids were probably better fliers than *Archaeopteryx*. The large and curved toe claws, as well as the toe proportions, suggest that confuciusornithids were arboreal.

The holotype specimen of *Confuciusornis*, the first named confuciusornithid, was discovered in 1993 by an amateur fossil collector and described in 1995 as the earliest known bird to have possessed a horny beak. Unlike living birds, most Mesozoic birds possessed teeth in the jaws; however, all known members of Confuciusornithidae completely lost their teeth. In addition, confuciusornithids have some very specialized skeletal features, such as a hole near the upper end of the humerus (upper arm bone). Although there is as yet no direct evidence concerning the diet of these birds, they probably fed mainly on insects.

Confuciusornis is the only Mesozoic bird that is abundantly represented in the fossil record; at least several hundred specimens are known, due to the exceptional preservation of the fossil assemblages in which they occur. (These deposits, of alternating volcanic ash layers and lake sediments, also yield many other important fossils such as feathered dinosaurs, pterosaur embryos, early mammals, and flowering plants.) In most *Confuciusornis* specimens, the feathers are preserved, including asymmetric flight feathers that indicate powerful flight capability. *Confuciusornis* also displays evidence of sexual dimorphism in the tail feathers; it is generally believed that those with short tail feathers are females, whereas those with a pair of long central tail feathers are males (see **illustration**). In some rare cases, male and female individuals are preserved together on a single slab. The discovery of hundreds of *Confuciusornis* specimens from a relatively small area may also indicate that they were gregarious. Geological evidence, and the abundance of specimens in the same strata, suggests that flocks of these birds may have died in mass mortality events, possibly caused by eruptions of nearby volcanoes. *See* ARCHAEOPTERYX; AVES; FEATHER; FOSSIL.

Zhonghe Zhou

Male *Confuciusornis* with a pair of long central tail feathers from the Early Cretaceous of Liaoning, northeastern China.

Congenital anomalies

Structural abnormalities of the body that develop during embryogenesis and the fetal period; also called birth defects. Children with significant birth defects need more medical care than other children do, require more frequent hospitalizations, need community support services, and often require special education programs. Among children, over half of all visits to subspecialty medical clinics and admissions to hospitals are for treatment of disorders resulting from errors in embryonic development, chromosomal abnormalities, and genetic and familial disorders. Two-thirds of the deaths of infants and children in pediatric hospitals in developed countries are caused by underlying congenital anomalies.

Incidence. Although any particular birth defect may be rare, birth defects as a group are common. They are identified in 2–3% of newborns and in about an equal percentage later, in the first year of life, as structural defects and development delays become evident.

The overall incidence of congenital anomalies is about the same throughout the world, but certain geographic and racial groups have higher rates of certain disorders. For example, those developmental defects of the brain and spinal cord known as neural tube disorders are much more common in the British Isles than in North America, occurring in 10 per 1000 live births in Ireland as compared with 1–2 per 1000 in Canada and the United States.

Screening. Screening programs are available to identify fetuses and newborns likely to have disorders such as congenital malformations and genetic diseases. Examples of screening include amniocentesis to detect fetal chromosomal abnormalities in mothers over 35 years of age; measurement of maternal serum alpha-fetoprotein levels at 15–16 weeks' gestation to help identify fetuses with certain malformations; and screening of newborns for phenylketonuria, sickle cell disease, thalassemia, galactosemia, and congenital hypothyroidism. *See* ALPHA FETOPROTEIN; PHENYLKETONURIA; SICKLE CELL DISEASE.

Causes. Birth defects can be caused by genetic factors, exposure to malformation-causing agents (teratogens), or a combination of both. It is estimated that single-gene disorders cause 7.5% of birth defects identified in newborns and structural abnormalities of chromosomes cause 6%. Maternal infections that have been transmitted to the embryo or fetus are responsible for 2–3% of congenital anomalies. Maternal diabetes is associated with 1.5% and other maternal diseases with less than 1.5%. Maternal use of drugs and alcohol is responsible in about 1–2% of cases. In more than 50% of newborns with congenital anomalies, however, the specific etiology is not known. *See* DIABETES; FETAL ALCOHOL SYNDROME; HUMAN GENETICS.

Dysmorphology is the area of medicine and science concerned with the cause of congenital anomalies resulting from errors in embryonic development (dysmorphogenesis). The study of normal and abnormal embryonic development allows identification of the latest time in embryogenesis when a malformation could occur. Examples of such times include 28 days of gestation for neural tube defects, 36 days for cleft lip, and 10 weeks for cleft palate. Because the heart is an embryologically complicated organ, different congenital heart defects develop at different times in embryogenesis. Abnormalities of digestive tract formation can occur as early as 30 days of gestation and as late as 10 weeks.

Classification. To facilitate the study, birth defects are divided into malformations, disruptions, deformations, and dysplasias.

Malformations. Malformations are structural defects that are caused by primary errors in morphogenesis. They are classified as major and minor. Major malformations require medical or surgical intervention or are of substantial cosmetic importance. Various defects that were mentioned above are among such malformations. Minor malformations do not require such treatment or do not greatly affect appearance; examples include protruding ears, wide-set eyes, curvature of the fifth finger, webbing of the toes, and many others. Most individuals have two or three minor malformations, and the same minor malformations are frequently found in various family members. An excess of minor malformations is often associated with major malformations.

Disruptions. These are structural defects resulting from interruption of normal morphogenesis, with consequent destruction of previously existing structures and incomplete development of tissues. For example, if the fetus becomes entangled in the amnion (the inner lining of the placental sac), ring constrictions of the limbs can occur.

Deformations. These are congenital anomalies resulting from external compression of a normally formed part of the fetus. The most common deformations are bowing of the lower legs and in-toeing of the feet. In otherwise normal infants, minor deformations usually improve without treatment. If deformations are major, splints and special shoes may be required for correction.

Dysplasias. These are disorders that result from an abnormal organization of cells into tissues; the morphological result is called dyshistogenesis. Examples of such disorders include hemangiomas and lymphangiomas, which result from overgrowth of blood vessels and lymphatic vessels, respectively. Neurofibromatosis is an autosomal dominant genetic disorder that results in overgrowth of neural tissue.

Syndromes. Some individuals have various major and minor congenital anomalies that together form a recognizable pattern, called a syndrome. The medical diagnosis of a specific congenital syndrome in a child aids in determining etiology, identifying associated anomalies that previously were unrecognized, and establishing prognosis. Often, further diagnostic studies are required to confirm the diagnosis of a syndrome. Syndromes can have both genetic and environmental causes.

Teratology. Tetratology is the study of the effect of environmental agents on the developing embryo and fetus. Teratogens are agents that interfere with normal embryonic development. They can cause miscarriages, retard prenatal growth, and produce congenital anomalies or mental retardation.

There are five general groups of teratogens: (1) infectious diseases and agents, including rubella, toxoplasmosis, syphilis, cytomegalovirus, chickenpox, Venezuelan equine encephalitis, and human immunodeficiency virus; (2) physical agents, such as radiation, maternal hyperthermia, and abnormalities of the intrauterine environment; (3) drugs and chemical agents; (4) maternal metabolic and genetic factors, such as diabetes, epilepsy, smoking, and nutritional deficiencies; and (5) paternal factors, although rare. (Paternal exposures contribute mainly to decreased fertility rather than birth defects.)

Treatment, detection, and prevention. Treatment of congenital anomalies is specific for each individual. Individuals with severe or numerous abnormalities usually require multidisciplinary treatment, including such measures as medical management, surgical correction, nursing care, special diets, rehabilitation, prosthetic devices, special education, and community support.

If a couple has had a child with a congenital anomaly, tests may be done in subsequent pregnancies to help detect recurrence. Prenatal tests that are sometimes performed include chorionic villus sampling and amniocentesis to detect chromosomal and some metabolic defects, detailed ultrasound imaging of the fetus to identify significant structural malformations, and fetal echocardiograms to detect congenital heart disease.

Measures that help reduce the risk of having a child with congenital anomalies include avoidance of teratogenic exposures, medical treatment of maternal illnesses, good nutrition, and routine obstetrical care. However, much remains to be learned about the cause, detection, and prevention of congenital anomalies. *See* PREGNANCY. **Margot I. Van Allen**

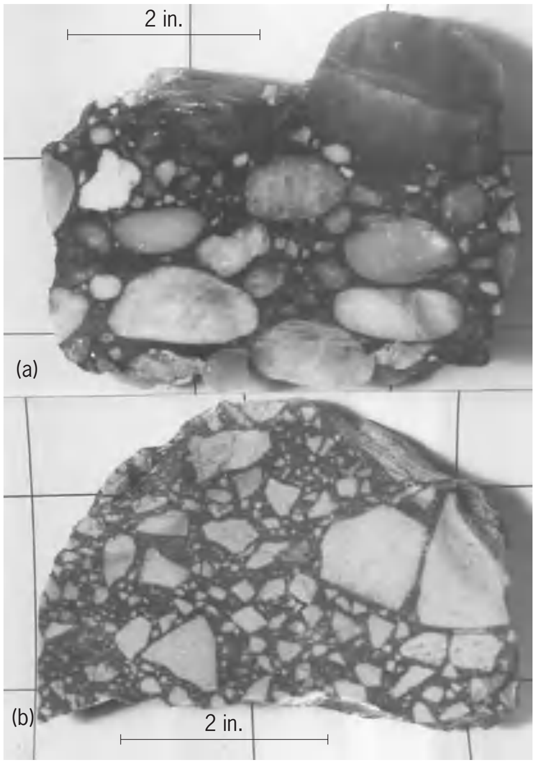
Conglomerate

The consolidated equivalent of gravel. Conglomerates are aggregates of more or less rounded particles greater than 0.08 in. (2 mm) in diameter. Frequently they are divided on the basis of size of particles into pebble (fine), cobble (medium), and boulder (coarse) conglomerates. The common admixture of sand-sized and gravel-sized particles in the same deposit leads to further subdivisions, into conglomerates (50% or more pebbles), sandy conglomerates (25–50% pebbles), and pebbly or conglomeratic sandstones (less than 25% pebbles). The pebbles of conglomerates are always somewhat rounded, giving evidence of abrasion during transportation; this distinguishes them from some tillites and from breccias, whose particles are sharp and angular (see **illus.**).

Conglomerates fall into two general classes, based on the range of lithologic types represented by the pebbles, and on the degree of sorting and amount of matrix present. The well-sorted, matrix-poor conglomerates with homogeneous pebble lithology are one type, and the poorly sorted, matrix-rich conglomerates with heterogeneous pebble lithology are the other. The well-sorted class includes quartz-pebbles, chert-pebble, and limestone-pebble conglomerates. The quartz pebbles were derived from long, continued erosion of the source-rock terrain that resulted in the disappearance of all unstable minerals, such as feldspars and ferromagnesian minerals, that make up most igneous and metamorphic rocks. Typically the quartz-pebble conglomerates are thin sheets that overlie an unconformity and are basal to a series of overlapping marine beds. Chert pebble conglomerates are derived from weathered limestone terrains. Limestone pebble conglomerates seemingly are the result of special conditions involving rapid mechanical erosion and short transport distances; otherwise the limestone would quickly become degraded to finer sizes and dissolve. The well-sorted conglomerates tend to be distributed in thin, widespread sheets, normally interbedded with well-sorted, quartzose sandstones. *See* UNCONFORMITY.

The poorly sorted, lithologically heterogeneous conglomerates include many different types, all related in having very large amounts of sandy or clayey matrix and pebbles of many different rock classes. The graywacke conglomerates are the outstanding representatives. They are composed of pebbles, many times only slightly rounded, or many different kinds of igneous and metamorphic rock as well as sedimentary rocks, bound together by a matrix that is a mixture of sand, silt, and clay. They seem to have been formed from the products of rigorous mechanical erosion of highlands and transported in large part by turbidity or density currents.



Lithified gravels. (*a*) Conglomerate, composed of rounded pebbles. (*b*) Breccia, containing many angular fragments. 2 in. = 5 cm. (*Specimens from Princeton University Museum of Natural History; photo by Willard Starks*)

Another representative of the poorly sorted class is fanglomerate, a conglomerate formed on an alluvial fan. Fanglomerates in many cases are much better sorted than the graywacke conglomerates but have heterogeneous pebble composition. A tillite is another representative of this class of conglomerate. All of these poorly sorted conglomerates tend to occur in fairly thick sequences, and some of them, typically the fanglomerates, are wedge-shaped accumulations. *See* SEDIMENTARY ROCKS; TURBIDITY CURRENT.

Special types of conglomerates, such as volcanic conglomerates and agglomerates and some intraformational conglomerates composed of shale pebbles or deformed limestone pebbles, do not seem to fall easily into either class. Some of the shale and limestone intraformational conglomerates have formed from the tearing up of previously deposited beds at the sea bottom while they were still relatively soft and only partially consolidated. Because of the angularity of some of these pebbles, they have often been called breccias. *See* BRECCIA; GRAVEL; GRAYWACKE; TILL.

Raymond Siever

Conglutination

A term used in serology to describe the completion or enhancement of an incomplete agglutinating system by the addition of certain substances. Some bacteria or erythrocyte suspensions do not exhibit the visible agglutination ordinarily expected after they have been coated with their specific antibodies and complement. Further addition of a conglutinating agent—normal bovine serum—however, initiates visible agglutination. Complement is an essential component of the system. The conglutination reagent is itself without effect in the absence of antibody and complement. Similar overall actions, such as agglutination of Rh^+ cells, occur when human serum, gelatin, or bovine serum albumin are added to the incomplete Rh antibodies found in some sera, but since this enhancing effect occurs also in the absence of complement, these reactions probably are to be distinguished in mechanism from that of the traditional conglutination. *See* BLOOD GROUPS.

Like the related complement-fixation reaction, the conglutination reaction can be used for a variety of serological diagnostic reactions in bacterial and viral infections. *See* AGGLUTINATION REACTION; COMPLEMENT-FIXATION TEST; SEROLOGY.

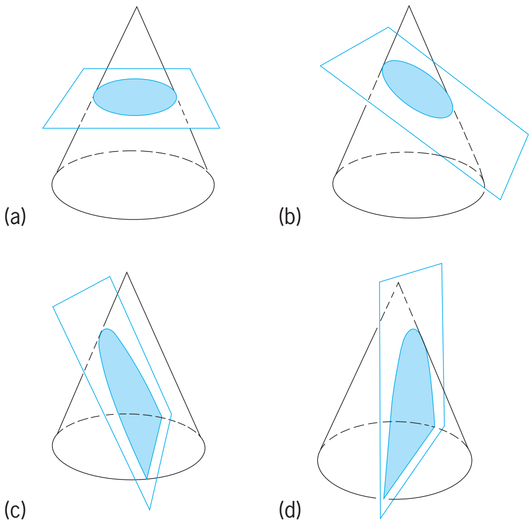
Conic section

One of the class of curves in which a plane may cut a cone (surface) of revolution. They were extensively studied by the ancient Greeks. The section is a parabola if the plane is parallel to an element of the cone, an ellipse or circle if the plane cuts all elements of one nappe (but does not go through the apex), and a hyperbola if the plane cuts elements of both nappes (for example, the plane parallel to the cone's axis of revolution) and does not go through the apex (see **illus.**) If a line g intersects the cone's axis perpendicularly at a point distinct from the apex, a plane that revolves about g will cut all three kinds of conics from the cone. If a plane contains the cone's axis, it intersects the cone in a pair of lines (a degenerate hyperbola); if it goes through the apex but does not contain the axis, it has in common with the cone either the apex alone (degenerate ellipse) or an element of the cone (degenerate parabola).



Four conic sections. (*a*) Circle. (*b*) Ellipse. (*c*) Parabola. (*d*) Hyperbola.

Algebraic definitions. After the advent of analytic geometry, the synthetic method used by the Greeks to develop the properties of conics gave way to algebraic procedures which, using other definitions, divorced these curves from their original relationship to cones and regarded them as graphs of second-degree equations in cartesian coordinates x, y. Let plane π cut all the elements of one nappe of a cone C (π not perpendicular to the cone's axis and not passing through the apex), and let E denote the curve of intersection of π and C. To show that E is an ellipse, consider the spheres S_1 and S_2 inside C that are tangent to π and to all the elements of C and that lie on the opposite sides of π. The contact points of S_1 and S_2 with C form circles whose planes π_1 and π_2 are perpendicular to the axis of C. Let F_1 and F_2 denote the contact points of S_1 and S_2, respectively,with π. If P is any point of E, then Eqs. (1) holds, where Q_1, Q_2

$$\text{dist}\,(P, F_1) = \text{dist}\,(P, Q_1) \tag{1a}$$

$$\text{dist}\,(P, F_2) = \text{dist}\,(P, Q_2) \tag{1b}$$

are those contact points of S_1, S_2, respectively, that lie on the element of C through P. Since dist (P,Q_1) + dist (P,Q_2) is the (constant) distance between the parallel planes π_1, π_2, then Eq. (2) holds, and so E is

$$\text{dist}\,(P, F_1) + \text{dist}\,(P, F_2) = \text{constant} \tag{2}$$

an ellipse. The directrices of E are the lines in which π_1, π_2 intersect π. *See* ANALYTIC GEOMETRY.

Conics are basic in astronomy, where it is shown that the newtonian inverse-square law of gravitation implies that the orbits of the planets are ellipses, with the Sun at one focus. Other heavenly bodies, certain comets, for example, have parabolic and hyperbolic paths.

Projective geometry. The third phase in the study of conic sections began with the development of projective geometry. In that subject it is shown that the locus of the points of intersection of two projective (nonperspective), coplanar (nonconcentric) pencils of lines is a nondegenerate (point) conic. All nondegenerate conics are projectively equivalent; that is to say, if C_1, C_2 are any two such conics, there is a projective transformation of their plane into itself that transforms C_1 into C_2. Conics may be classified into types by their behavior with respect to an arbitrarily selected line g, say the ideal line of the plane. In the geometry (affine) obtained by considering only those projective transformations that transform g into itself, a conic is a hyperbola, a parabola, or an ellipse accordingly as the number of points that the conic has in common with g is two, one, or none, respectively. Dual to point conics are line conics, the locus of all lines joining corresponding points of two projective (not perspective), coplanar (not collinear) point ranges. The tangents to a point conic form a line conic, and the contact points of a line conic form a point conic. One of the most famous theorems concerning conics was proved by the French philosopher-mathematician Blaise Pascal in 1640, when only 16 years old. The theorem asserts that if six points A_i, with $i = 1, 2, \ldots, 6$, are on a conic, then the intersections P,Q,R of the lines (A_1, A_2) and (A_4, A_5), (A_2, A_3) and (A_5, A_6), (A_3, A_4) and (A_6, A_1), respectively, lie on a line. This theorem, together with its converse (which is also valid) had numerous interesting consequences. The Brianchon theorem, proved 166 years later, is its dual. It states that if a hexagon circumscribes a conic, the three lines joining the three pairs of opposite vertices are concurrent. *See* CONE; ELLIPSE; HYPERBOLA; PARABOLA; PROJECTIVE GEOMETRY.

Bibliography. G. Fuller and D. J. Tarwater, *Analytic Geometry*, 7th ed., 1993; L. E. Garner, *Outline of Projective Geometry*, 1981; D. F. Riddle, *Analytic Geometry*, 6th ed., 1996; P. Samuel, *Projective Geometry*, 1988.

Conjugation and hyperconjugation

A higher-order bonding interaction between electron orbitals on three or more contiguous atoms in a molecule, which leads to characteristic changes in physical properties and chemical reactivity. One participant in this interaction can be the electron pair in the π-orbital of a multiple (that is, double or triple) bond between two atoms, or a single electron or electron pair or electron vacancy on a single atom. The second component will be the pair of π-electrons in an adjacent multiple bond in the case of conjugation, and in the case of hyperconjugation it will be the pair of electrons in an adjacent polarized σ-bond (that is, a bond where the electrons are held closer to one atom than the other due to electronegativity differences between the two atoms). *See* CHEMICAL BONDING.

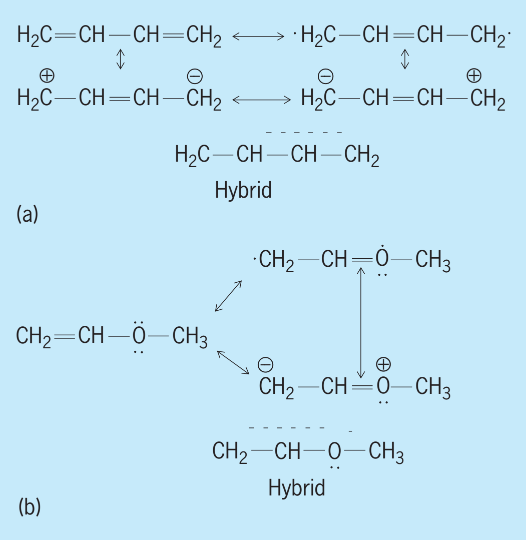

Fig. 1. Conjugated molecules. Broken overbars indicate the effects of conjugation. (*a*) 1,3-Butadiene. (*b*) Methyl vinyl ether.

Conjugation. The conjugated orbitals reside on atoms that are separated by a single bond in the classical valence-bond molecular model, and the conjugation effect is at a maximum when the axes of the component orbitals are aligned in a parallel fashion because this allows maximum orbital overlap. Conjugation thus has a stereoelectronic requirement, or a restriction on how the participating orbitals must be oriented with respect to each other. Two simple examples are shown in **Fig. 1**; in 1,3-butadiene ($H_2C{=}H\underline{C{-}C}H{=}CH_2$) conjugation occurs between the p orbitals (π-bonds) of the two double bonds, and in methyl vinyl ether ($H_2C{=}H\underline{C{-}O}{-}CH_3$) the nonbonding sp^3 orbital on oxygen is conjugated with the p orbitals of the double bond. This interaction is manifest in an effective bond order between single and double for the underlined single bond.

If the component orbitals are orthogonal (at right angles) to each other, or if the atoms bearing these orbitals are separated by more than one single bond or by no bond, the molecule is not conjugated. Two examples of molecules which do not exhibit conjugation are 1,4-pentadiene ($H_2C{=}CH{-}CH_2{-}CH{=}CH_2$) and allene ($H_2C{=}C{=}CH_2$), the former because there is more than one single bond between the component orbitals and the latter because the component orbitals are orthogonal to each other and are not separated by a single bond.

Chemists have used the conjugation rationale since the midnineteenth century, and it has become well accepted. The valence-bond model of conjugation invokes delocalization: the participating electrons are no longer localized or fixed on a particular atom or between a pair of atoms, but are shared throughout the conjugated orbitals. This increases their entropy, which contributes to a lower overall energy and generally results in greater stabilization for the molecule. From the valence-bond point of view, conjugated molecules are viewed as a weighted average hybrid of two or more valence-bond structures as shown in Fig. 1 for the two examples. Thus butadiene has a major contribution from the standard valence-bond structure, $H_2C{=}CH{-}CH{=}CH_2$, but the diradicals or the structures with separation of charge are valid alternative representations, and the same is true for methyl vinyl ether. The effects of conjugation are suggested by the broken lines on the hybrid structures in Fig. 1. When more orbital units are linked together or conjugated, more resonance structures can be drawn, and the molecule will be more stable and behave less according to the expectation based on the simple structure drawn from the classical valence-bond model. *See* DELOCALIZATION; ENTROPY; RESONANCE (MOLECULAR STRUCTURE); STRUCTURAL CHEMISTRY.

Three of the four resonance contributors for butadiene are drawn with only one multiple bond compared to the two multiple bonds in the standard valence-bond structure (Fig. 1*a*); this is known as sacrificial conjugation, in that some bonds in the standard depiction are sacrificed. In methyl vinyl ether (Fig. 1*b*) and in molecules or chemical intermediates, the different pictures drawn for the resonance contributors have the same number of multiple bonds; this is known as isovalent conjugation and results in a greater resonance energy stabilization than in the case of sacrificial conjugation. Other examples of isovalent conjugation include the allyl cation ($CH_2{=}CH{-}CH_2^+$ and $C^+H_2{-}CH{=}CH_2$) and benzene.

Conjugation is better understood by considering the molecular orbitals which can be approximated by the mathematical combination of the wave functions for the constituent atomic *s* and *p* orbitals (and *d* orbitals for elements beneath the first row of the periodic table). **Figure 2** shows simple pictorial results of complex molecular orbital (MO) calculations for the π-electrons in butadiene; here the σ bonds are neglected for clarity. The combination of four atomic *p* orbitals (two each for each of the double bonds) leads to four molecular orbitals. Each of the molecular orbitals is a quartet of "*p*-like" orbitals of different size (determined by calculation) situated on the four carbon atoms of butadiene (C^1–C^4). The four π-electrons are placed in these orbitals from the bottom up, so that the two lowest-energy orbitals, MO #1 and MO #2, both contain paired electrons. These two molecular orbitals thus account for the π-bonding in butadiene. In MO #1 the continuous bonding across all four lobes can be seen, with the highest orbital density between C^2 and C^3. In MO #2 there is a phase change between C^2 and C^3, with consequent repulsion between the adjacent lobes, but this repulsion is relatively less important because the electron orbital density (depicted as orbital size) is much lower here. In both of these molecular orbitals, the bonding interactions between $C^1{-}C^2$ and $C^3{-}C^4$ are in phase and add up to strong π-bonds. Thus, the π-delocalization interaction across $C^2{-}C^3$ that characterizes conjugation appears very naturally from the molecular orbital description. *See* MOLECULAR ORBITAL THEORY.

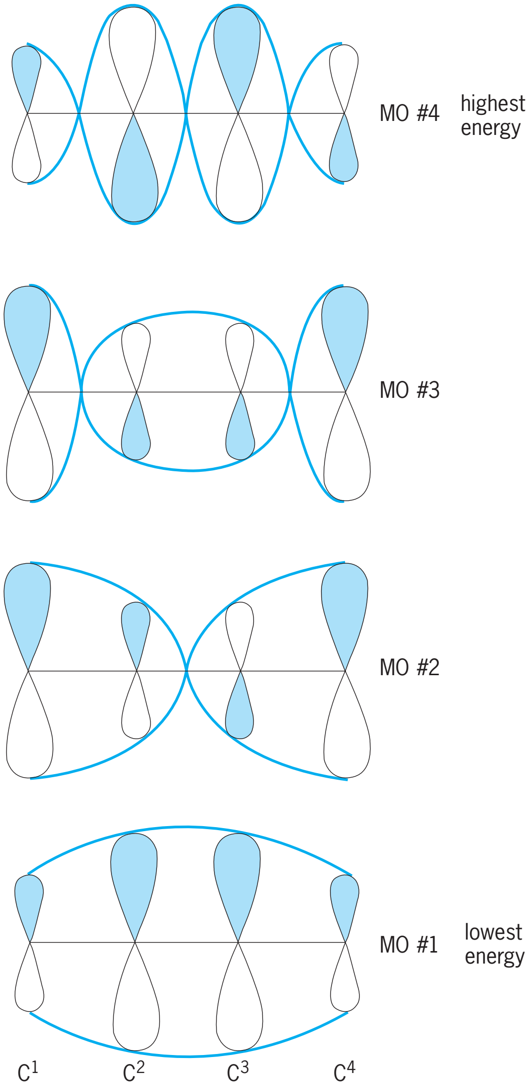

Fig. 2. Molecular orbital (MU) diagram for butadiene as determined by calculation. Algebraic phase is indicated by the presence or absence of tint. Orbital density is depicted as orbital size.

Hyperconjugation. This concept posits the conjugation of polarized σ-bonds with adjacent π-orbitals, and was introduced in the late 1930s by R. S. Mulliken. This rationale was used to explain successfully a wide variety of chemical phenomena; however, the confusing adaptation of the valence-bond model necessary to depict it and its inappropriate extension to some phenomena led to difficulties. The advent of the molecular orbital treatment has eliminated many of these difficulties.

Early on, hyperconjugation was used to explain the stabilization by alkyl groups of carbocations, or positively charged trivalent carbon. **Figure 3** shows how the orbitals of the σ-bonds of a methyl group (H_3C) exert a hyperconjugative stabilizing

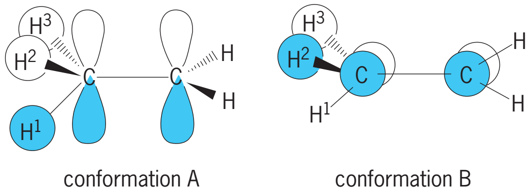

Fig. 3. Diagram showing hyperconjugative effect of orbitals of the σ-bonds of a methyl group (H_3C) on a neighboring *p* orbital of a methylene group (CH_2). Algebraic phrase is indicated by the presence or absence of tint.

effect upon a neighboring *p* orbital on a methylene group (CH_2). The bonding molecular orbitals of the methyl group utilize aspects of its carbon *p* orbitals; in both of the conformations or rotations the methyl group has such an orbital which overlaps in phase with the neighboring *p* orbital on CH_2. As hydrogen is an electropositive atom, the methyl group acts as an electron donor to stabilize an empty *p* orbital and to destabilize a filled *p* orbital on the right-hand carbon. This is in accord with empirical observations. If H^1 is replaced with some other atom X, the hyperconjugative effect of X will be at a maximum in conformation A, where there is orbital density on X, and it will be at a minimum in conformation B, where X is in the nodal or null plane. If X is a more electropositive atom such as silicon, the C-X bond is a donor bond and will stabilize an adjacent empty *p* orbital, such as in a cation. If X is a more electronegative element such as fluorine, the C-X bond is an acceptor bond and will stabilize an adjacent filled *p* orbital such as in an anion; this result accords with experiment as well. The donor and acceptor effects are also important where the single *p* orbital is replaced by a multiple bond. *See* REACTIVE INTERMEDIATES.

Physical properties and chemical reactivity. The most notable differences in physical properties attributed to conjugation are as follows: (1) The single bonds lying between the two orbital components are shortened. For example, the length of the C^2-C^3 bond in butadiene is 0.148 nanometer, as compared to 0.154 nm for the carbon-carbon single bond in ethane. This shortening can also be explained by the changes in orbital hybridization at these carbons. (2) Electronic absorption spectra begin at significantly longer wavelengths for conjugated than for related unconjugated molecules. (3) Ionization potentials are lower than for isomeric unconjugated molecules. (4) Related to points 2 and 3 is the fact that polarizabilities are larger for conjugated than for the corresponding unconjugated dienes. Polarizability is the ease with which the electron orbitals (electron clouds) of the molecule can be distorted through dipole-dipole interactions with other molecules, ions, atoms, or electrons; it is generally a measure of how loosely the electrons are held by the nuclei. (5) As compared with predictions from formulas for unconjugated molecules, conjugated molecules show lower energies, for example, about 6 kcal/mol (25 kilopascals/mol) lower for 1,3-butadiene than for unconjugated dienes; the excess is describable theoretically as resonance energy (valence-bond picture) or delocalization (molecular orbital theory picture). (6) The magnitude and orientation of dipole moments can be derived from hyperconjugation arguments, although the aforementioned differences in hybridization can also explain this. *See* BOND ANGLE AND DISTANCE; DIPOLE MOMENT.

In terms of changes in chemical reactivity, the following are exemplary: (1) The acidity of carboxylic acids stems from the conjugation stabilization of their ionized forms. (2) The addition of many chemical reactants takes place across the conjugated system (conjugate addition) rather than at the isolated double bonds, for example, the addition of bromine to butadiene to give a mixture of 1,4-dibromo-2-butene and 1,2-dibromo-3-butene. (3) The well-recognized orientation rules for the addition of chemical reagents to substituted benzenes and other aromatic systems can be rationalized through conjugated intermediates. (4) The facile formation of an anion from cyclopentadiene and of a cation from cycloheptatriene derives from the conjugation stabilization for those ions. (5) The chemistry of unsaturated organosilicon compounds can be explained only by hyperconjugation effects. (6) Certain changes in chemical reaction rates that occur when hydrogen atoms are substituted by deuterium atoms are clearly hyperconjugative effects.

A number of scientific phenomena depend on the properties of conjugated systems; these include vision (the highly tuned photoreceptors are triggered by molecules with extended conjugation), electrical conduction (organic semiconductors such as polyacetylenes are extended conjugated systems), color (most dyes are conjugated molecules designed to absorb particular wavelengths of light), and medicine (a number of antibiotics and cancer chemotherapy agents contain conjugated systems which trap enzyme sulfhydryl groups by conjugate addition). *See* VALENCE.

Connecting rod

A link in several kinds of mechanisms. Usually one end of a connecting rod is intended to follow a circular path, while the other end follows a path along a straight line or a curve of large radius. The term is sometimes applied, however, to any straight link that transmits motion or power from one linkage to another within a mechanism. **Figure 1** shows conventional arrangements of connecting rods in typical mechanisms. In some applications (for example, the connecting rod between the crank and an overhead oscillating member or walking beam in a well-drilling

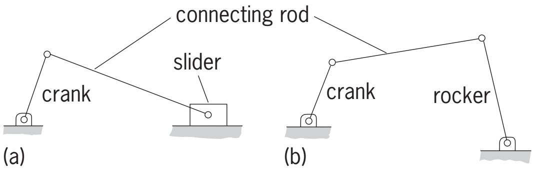

Fig. 1. Connecting rod in (*a*) slider-crank mechanism and (*b*) crank-and-rocker mechanism.

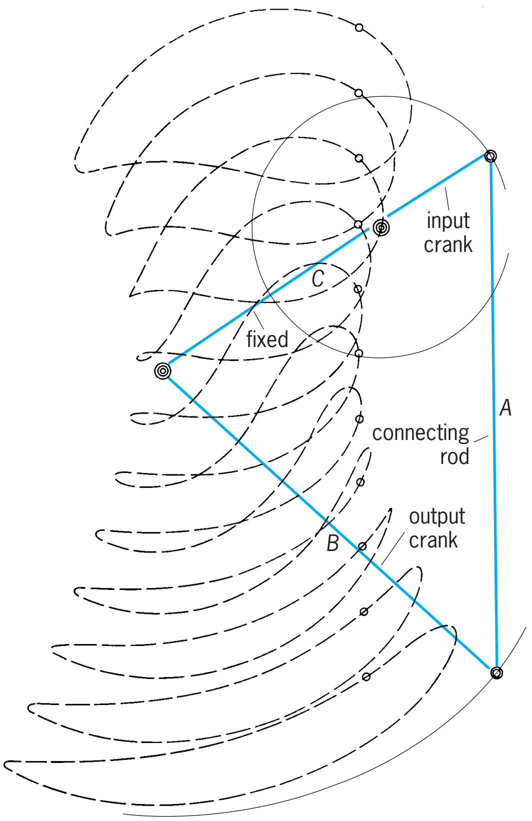

Fig. 2. Paths of points on connecting-rod plane traced by four-bar crank-and-rocker mechanisms for $A = 4.0$, $B = 3.5$, $C = 2.0$. (*After J. A. Hrones and G. L. Nelson, Analysis of Four-Bar Linkage*, John Wiley and Sons, *1951*)

rig, or between the steering column and cross-links in an automobile) the connecting rod is called a pitman. *See* AUTOMOTIVE STEERING.

The connecting rod of the four-bar linkage, often called the coupler, has special significance. The motion of its plane can now be synthesized to furnish desired paths for points not necessarily on the straight line *AB* (coupler-point paths), or desired positions of the entire connecting-rod plane. The connecting rod is then not primarily used for transmission of force or motion from input to output crank, but the entire mechanism is employed to impart to the connecting-rod plane certain displacements, and sometimes velocities and accelerations. **Figure 2** illustrates paths traced by various points in the plane of the rod, also revealing some velocities and accelerations there. *See* FOUR-BAR LINKAGE; MECHANISM.

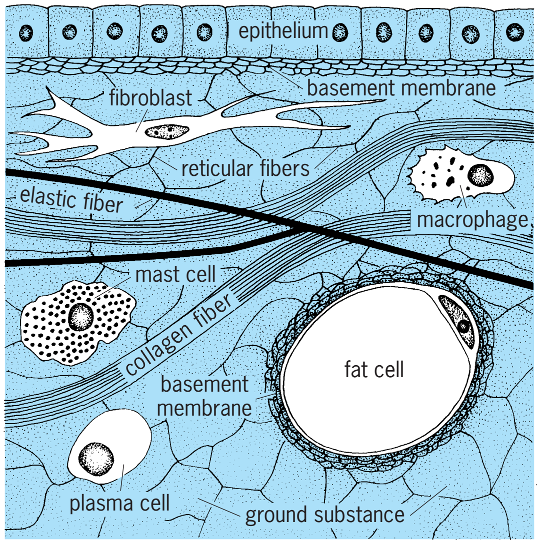
Connective tissue

One of the four primary tissues of the body. It differs from the other three tissues in that the extracellular components (fibers and intercellular substances) are abundant. It cannot be sharply delimited from the blood, whose cells may give rise to connective tissue cells, and whose plasma components continually interchange with and augment the ground substance of connective tissue. Bone and cartilage are special kinds of connective tissue. *See* BLOOD.

Functions. The functions of connective tissues are varied. They are largely responsible for the cohesion of the body as an organism, of organs as functioning units, and of tissues as structural systems. This cohesive function is achieved through their permeation of other tissues of the body. The connective tissues are essential for the protection of the body both in the elaborate defense mechanisms against infection and in repair from chemical or physical injuries. Nutrition of nearly all cells of the body and the removal of their waste products are both mediated through the connective tissues.

Connective tissues are important in the development and growth of many structures. Constituting the major environment of most cells, they are probably the major contributor to the homeostatic mechanisms of the body so far as salts and water are concerned. They act as the great storehouse for the body of salts and minerals, as well as of fat. The connective tissues determine in most cases the pigmentation of the body. Finally, the skeletal system (cartilage and bones) plus other kinds of connective tissue (tendons, ligaments, fasciae, and others) make motion possible.

Cellular components. The connective tissues consist of cells and extracellular or intercellular substance (see **illus.**). The cells include many



Components of connective tissue.

varieties, of which the following are the most important: (1) fibroblasts—variable in shape, frequently outstretched to form many fine processes, some as small as 20–30 nanometers; (2) macrophages (histiocytes)—variable in shape, strongly motile or outstretched, frequently with numerous minute cell processes, highly phagocytic (the ability to take particulate material into the cytoplasm); (3) mast cells—frequently large, ameboid, nucleus centrally located, cytoplasm very often packed with granules about 0.4 micrometer in diameter; (4) plasma cells—generally ovoid, weakly ameboid, nucleus eccentric, granular cytoplasm staining strongly with basic dyes (toluidine blue, methylene blue, hematoxylin); (5) melanocytes—cytoplasm of highly branched cells filled with minute granules which appear yellow or brown because of the melanin they contain; and (6) fat cells of two kinds: (a) yellow fat cells—very large (80 μm or more), generally spherical, with a thin shell of protoplasm (3.0–0.1 μm or less) enclosing a single enlarged fat droplet which appears yellowish; and (b) brown fat cells—moderately large, generally spherical, with small droplets of variable size (about 2 μm or less), scattered in the cytoplasm. In addition, connective tissues may contain, especially in the vicinity of small blood vessels, undifferentiated mesenchymal cells which may be considered as potentially embryonic, and blood cells which have wandered through the walls of blood vessels, including lymphocytes and polymorphonuclear granular leukocytes. It is especially important to realize that most of the cells of the connective tissue are developmentally related even in the adult; for example, fibroblasts may be developed from histiocytes or from undifferentiated mesenchymal cells.

Extracellular components. The extracellular components of connective tissues may be fibrillar or nonfibrillar. The fibrillar components are (1) reticular fibers which may be stained differentially with certain silver stains; (2) collagenous fibers which have a longitudinally striated appearance with the light microscope and are readily stainable with the acid dyes cosin and aniline blue; and (3) elastic fibers which are highly refractile, appear slightly yellowish, and may be stained differentially by certain dyes like orcein. With the higher resolution achieved with the electron microscope, both reticular and collagenous fibers are seen to be made up of smaller fibrils of about 20–100 nm in diameter, each with an internal cross-banded structure which is repeated on an average of every 64 nm. The unit of structure is tropocollagen. This is an elongated protein molecule about 300 nm long and about 1.3 nm in diameter, and is made up of three subunits. These are wound spirally around each other in very specific manners. The elastic fibers are also resolvable into finer fibrils which may be 8 nm or larger in diameter. All fibers visible with the light microscope are thus composed of bundles of submicroscopic fibrils visible only with the electron microscope. In addition, there are many collagenous and elastic fibers composed of the same fibrillar constituents which are too fine to be visible with the light microscope (fibers that are less than 0.2 μm in diameter). *See* COLLAGEN.

The nonfibrillar component of connective tissues appears amorphous with the light microscope and is the matrix in which cells and fibers are embedded. It consists of two groups of substances: (1) those probably derived from secretory activity of connective tissue cells including mucoproteins, protein-polysaccharide complexes, tropocollagen, and antibodies; and (2) those probably derived from the blood plasma, including albumin, globulins, inorganic and organic anions and cations, and water. In addition, the ground substance contains metabolites derived from, or destined for, the blood.

The ground substance of local origin and the tissue fluid of hematogenous origin are not only coextensive but are dynamically related in a two-phase system. The two phases of this thermodynamic system are probably recognizable in the electron microscope as a series of small, watery vacuoles (about 60 nm in diameter) embedded in a denser matrix. The basement membrane is a specially differentiated sheetlike part of the ground substance (10–50 nm thick) which underlies directly many epithelia, and encloses muscle fibers and fat cells. It is denser than the adjacent ground substance, with which it is continuous, and may contain fibrils. There is some evidence that epithelial cells may contribute some constituents to the basement membrane.

Classification. All the manifold varieties of connective tissue may contain all the cells and fibers discussed above in addition to ground substance. They differ from each other in the relative occurrence of one or another cell type, in the relative proportions of cells and fibers, in the preponderance and arrangement of one or another fiber, and in the relative amount and chemical composition of ground substance. In the classification which follows, some of these differences are pointed out.

1. Irregularly arranged connective tissue—which may be loose (subcutaneous connective tissue) or dense (dermis). The dominant fiber type is collagen, though others may be present. The fibers are irregularly interwoven and the cells irregularly distributed. The looser type has more ground substance than the denser type.

2. Regularly arranged connective tissue—primarily collagenous—with the fibers arranged in certain patterns depending on whether they occur in tendons or as membranes (dura matter, capsules, fasciae, aponeuroses, or ligaments). *See* TENDON.

3. Mucous connective tissue—ground substance especially prominent (umbilical cord).

4. Elastic connective tissue—predominance of elastic fibers or bands (ligamentum nuchae) or lamellae (aorta). *See* LIGAMENT.

5. Reticular connective tissue—fibers mostly reticular, moderately rich in ground substance, frequently numerous undifferentiated mesenchymal cells. In contrast with collagenous fibers which are unbranched, reticular fibers are branched and may be selectively stained by silver methods. These branched fibers, however, consist of submicroscopic

fibrils which have the same submicrostructure as unbranched collagen fibrils.

6. Adipose connective tissue—yellow or brown fat cells constituting chief cell type, reticular fibers most numerous. *See* ADIPOSE TISSUE.

7. Pigment tissue—melanocytes numerous.

8. Cartilage—cells exclusively of one type, derived from mesenchymal cells. The latter persist even in the adult in the perichondrium which encloses cartilage. The extracellular matrix is of three types: (1) hyaline (joint cartilage), containing no bundles of fibers; (2) fibrocartilage (patella), containing numerous coarse bundles of collagen fibers; and (3) elastic cartilage (external ear), containing elastic fibers. Hyaline cartilage does, however, contain collagen fibrils of submicroscopic dimensions. In all three types of cartilage, the fibrils and fibers are embedded in a homogeneous matrix, which is almost entirely composed of protein-polysaccharide complex, whose predominant polysaccharide is chondroitin sulfate. *See* CARTILAGE.

9. Bone—cells predominantly osteocytes, but also include fibroblasts, mesenchymal cells, endothelial cells, and osteoclasts. The fibers are almost entirely collagenous in nature, and may be highly organized into osteones. The fibers are embedded in a ground substance matrix. The outstanding property of bone is its hardness, due to deposition in the extracellular regions of many minute crystals of a calcium mineral, apatite. *See* BONE.

In some forms of connective tissue (fat), blood capillaries are extremely numerous. In others (cartilage and dentine), blood capillaries are lacking. Tendon is nearly avascular, and bone is also poorly supplied with blood capillaries. But all these different kinds of connective tissue must be supplied with nutrients and oxygen and must be drained of metabolic waste products in order to maintain the cells, however sparse, in a functional condition, and to effect turnover of extracellular components. How an adequate nutritive state is maintained is a great puzzle, and is attracting the attention of research workers. *See* HISTOLOGY.

Connective tissue disease

Any of a group of diseases involving connective tissue; formerly termed collagen vascular disease. These diseases are clinically and pathologically discrete but have overlapping features. The group includes lupus erythematosus, systemic vasculitis, scleroderma (and systemic sclerosis), polymyositis, and Sjögren's syndrome. Each of the diseases can involve multiple organ systems and is often coupled with various immunologic abnormalities. *See* CONNECTIVE TISSUE.

Lupus erythematosus. This set of diseases includes limited, primarily cutaneous disorders (discoid lupus and subacute cutaneous lupus) and a diffuse systemic illness (systemic lupus erythematosus), all of which are of unknown cause. Also, a lupuslike reaction known as drug-induced lupus can be caused by certain therapeutic agents.

Systemic lupus erythematosus. This is an inflammatory, multisystem disorder in which tissue injury is mediated by immune complexes. In this incompletely understood disorder, lymphocytes known as T cells lose some of their control over the antibody production by lymphocytes known as B cells. Thus, in most individuals with systemic lupus, antibodies are found in the blood serum that are not normally present.

The immunologic events of systemic lupus are influenced by multiple factors. In some families, a genetic predisposition seems to be present. That the disease sometimes flares up after excessive exposure to ultraviolet light emphasizes the importance of environmental factors. Finally, hormonal factors also seem to play a contributing role; eight to nine times as many young women compared with men have systemic lupus; and in some animal models of lupus, femaleness is associated with more severe disease. *See* CELLULAR IMMUNOLOGY.

Although systemic lupus can be an acute and fulminating illness, it is far more often a chronic disorder with long periods (years, sometimes even decades) of remission and good health and with infrequent flareups. With the recognition of the immune markers (that is, autoantibodies) in serum, milder forms of the disorder can now be identified.

The manifestations and course of systemic lupus vary greatly from one individual to another and even in one person over time. Fever and other constitutional symptoms (for example, fatiguability, lack of appetite, and weight loss) are prominent. Skin rashes are common, and the so-called butterfly rash over the nose and cheeks is most characteristic. Joint pain and inflammation (arthritis) are among the common features and often are the first manifestations of the disease. Many other parts of the body—such as the lungs, heart, skeletal muscles, kidneys, and nervous system—can be involved. Small blood vessels at any site may be inflamed. Hematologic abnormalities also can occur when antibodies reactive with cell membrane antigens are present. Anemia and low levels of white blood cells and platelets are common. Certain autoantibodies affect blood clotting and can be associated with clots in blood vessels anywhere in the body. *See* ARTHRITIS; HEMATOLOGIC DISORDERS.

The diagnosis of systemic lupus is based on a combination of clinical and laboratory findings; no single clinical feature or laboratory test makes the diagnosis. Even the characteristic immune markers in serum (that is, the autoreactive antibodies) are not specific. For example, the routine screening test for antinuclear antibodies (ANA), which is positive in 95% of patients with systemic lupus erythematosus, can also be positive in those with the other connective tissue disorders and certain other diseases, as well as some healthy family members of patients with systemic lupus. Discoid lupus and subacute cutaneous lupus are variants, primarily with skin involvement.

Photosensitivity is prominent. Systemic features are infrequent and milder than in systemic lupus erythematosus, and kidney and nervous systems are usually spared. ANA positivity is often present.

Drug-induced lupus. This form subsides when the offending agent is discontinued. Many drugs that are chemically unrelated to each other can produce the disorder. Genetic factors play a role in susceptibility to induction of lupus by at least some drugs.

Cause. Except for drug-related lupus, the cause of systemic lupus and its variants is not known; thus, a rational basis for specific curative therapy does not exist. However, the clinical manifestations of systemic lupus can generally be managed effectively for long years or even decades. Prognosis is steadily improving. Drugs that are used to control the disease by suppressing inflammation and altering the immune system include nonsteroidal anti-inflammatory drugs, an antimalarial agent (hydroxychloroquine), corticosteroids, and immunosuppressive agents. Sound general medical management and vigorous treatment of associated illnesses (especially infections) are essential.

Systemic vasculitis. This is a series of different clinical illnesses that are characterized by intense inflammation in the walls of blood vessels, especially arteries (that is, arteritis). These illnesses differ clinically, pathologically, and with respect to therapeutic responsiveness and outcome. Even the age and sex of the typically affected person varies from one to another.

The clinical pattern of illness varies with the sites of blood vessel involvement and the character of vascular injury. Tissue death in the vessel wall can lead to narrowing, or even blockage, of the vessel or weakening of the wall with formation of an aneurysm. Impaired circulation and altered blood flow result. Symptoms, therefore, can arise not only from the tissue inflammation itself but also from the lack of adequate blood supply in the organ supplied by that vessel. Vasculitis can be a systemic condition or can be confined to a single organ or to the skin. *See* ANEURYSM; CIRCULATION DISORDERS.

Polyarteritis. Formerly called polyarteritis nodosa, polyarteritis most commonly occurs in young adult men. In most instances, the cause of the inflammatory reaction, which affects medium-sized and small arteries, is not known. Sometimes, however, the condition appears to be associated with a viral infection (such as hepatitis B) or to be induced by a drug.

The clinical features of polyarteritis include both nonspecific manifestations of diffuse inflammation and reflections of arterial involvement at specific sites. Fever, fatiguability, and loss of appetite and weight are prominent. Arteritis may occur in the kidney (often associated with high blood pressure), the heart, the liver, and the circulation to the bowel. A peripheral nervous system disease is more frequent than involvement of the central nervous system. Joint pain and arthritis, muscle pain, and vasculitic skin lesions are also common. Polyarteritis varies greatly from one person to another; any one of these features, or any combination, can be present and cause clinical problems.

The laboratory manifestations are mostly nonspecific reflections of tissue inflammation, with elevations of the white blood cell count and platelets. The blood sedimentation rate is a standard test for the presence of an inflammatory process of some type but is nonspecific; it is elevated well above the normal in most individuals with polyarteritis. There is no diagnostic blood test specifically for polyarteritis; the diagnosis is established by either a biopsy of an involved site (for example, muscle or peripheral nerve) or demonstration of structural changes in the arteries by x-ray visualization after injection of dye (an angiogram).

Optimal therapy is yet to be defined, but disease control and prognosis have progressively improved, first with the administration of corticosteroids and in combination with a cytotoxic drug.

Granulomatous arteritis. This category encompasses several rare disorders, including Churg-Strauss syndrome, Wegener's granulomatosis, aortic arch arteritis, and giant cell arteritis. These disorders cause very different clinical problems, but all are generally characterized by the presence of granulomas and giant cells in the affected sites. The causes and mechanisms are unknown. These disorders differ from each other in age group and sex predominantly affected, and prognosis. Early recognition and prompt treatment are key to an optimal outcome. Indeed, without treatment these disorders tend to have a poor prognosis.

Churg-Strauss syndrome is rare. It involves small and medium-sized arteries as well as the smallest arterioles and venules. It is usually associated with pulmonary disease, with an allergic asthmatic component often present. A characteristic feature of this syndrome is a marked increase in the number of white blood cells known as eosinophils, both in peripheral blood and in the affected tissue.

Wegener's granulomatosis is characterized by inflammation of small vessels in the respiratory tract, in the kidneys, and elsewhere. Both the upper respiratory tract (nasopharynx and sinuses) and lungs can be involved; biopsy of lung tissue or upper airways best establishes the diagnosis. Addition of a cytotoxic drug, especially cyclophosphamide, to corticosteroid therapy can reverse the pulmonary process and prevent kidney failure.

Aortic arch arteritis, also called Takayasu's arteritis, occurs almost exclusively in young women. Large and medium-sized arteries that branch off the aorta are involved, with consequent narrowing or even occlusion. Impaired blood flow results, with diminished or absent pulses in the upper extremities and neck; thus this condition is sometimes called the pulseless syndrome. Decreased circulation to the head can impair brain function, with recurrent lightheadedness and fainting or even a stroke. Similarly, impaired coronary artery flow may result in heart failure and the pain of angina. These major complications occur late and can be prevented if the process is recognized and treated early. Diagnosis is established by intra-arterial dye studies that demonstrate characteristic structural changes in the large vessels.

Temporal arteritis occurs mainly in women over 50 years of age and especially in those who are elderly. Aching pain and severe stiffness in the proximal limb-girdle regions (that is, shoulder/arm, pelvis/thigh) are common early manifestations. Later, with temporal artery involvement (in the head), symptoms such as headaches, scalp tenderness, and visual abnormalities can occur. A tender, dilated temporal artery may be found. Visual loss is the most feared complication, and is preventable by prompt corticosteroid therapy. The musculoskeletal pain syndrome, which can be progressive and incapacitating, also promptly responds to steroids.

Primary central nervous system arteritis is rare. Headaches, altered mentation and confusion, decreased level of consciousness, and even coma can occur; infrequently, unexplained seizures can occur.

Hypersensitivity angitis. In this disease there is an intense inflammation of the smaller vessels, especially venules, that represents an adverse immunologic reaction to an offending agent. The agent could be a drug, a foreign protein, or an infectious agent. Skin lesions occur in all cases; they vary in type but typically include localized areas of bleeding into the skin from injured vessels over the feet and ankles. Systemic features also can be present. Henoch-Schönlein purpura is a designation applied to one subset of this disorder.

In all types of hypersensitivity vasculitis, the diagnosis is clinical since there are no specific blood tests. A skin biopsy may support the diagnosis if inflammation of small vessels is found. Treatment focuses on withdrawal of the offending antigen, if known, or treatment of any causal infection, if present. Occasionally, use of corticosteroids may be necessary.

Vasculitis associated with specific diseases. Vasculitis can also be a secondary process occurring along with other connective tissue diseases (for example, systemic lupus, polymyositis, and Sjögren's syndrome) and with rheumatoid arthritis, infections, and malignant neoplasms. The existence of this wide array of underlying disorders suggests that various immunologic pathways can lead to vascular injury. Although the appropriate therapy is generally determined by the associated disease process, emergence of vasculitis may indicate the need to administer, or increase the dosage of, corticosteroids. *See* VASCULAR DISORDERS.

Polymyositis. Polymyositis involves intense inflammation in skeletal muscle that, if untreated, can lead to destruction of muscle fibers. When typical skin lesions are present, the term dermatomyositis is applied. The pathology of these two entities differs and suggests different mechanisms of inflammation.

The cause of polymyositis or dermatomyositis is not known in most cases. These conditions can occur alone or in association with other connective tissue disorders (that is, systemic lupus, scleroderma, and Sjögren's syndrome). Dermatomyositis may sometimes accompany malignant tumors.

Polymyositis may be abrupt or insidious in onset. The dominant manifestation is progressive weakness of the proximal limb-girdle muscle groups. Difficulty rising from a chair, in climbing stairs, lifting modest weights, and keeping the arms elevated are common symptoms. Despite intense inflammation in the skeletal musculature, pain and tenderness of the involved muscles are infrequent. Most serious are the potential involvement of pharyngeal musculature which may impair swallowing, or of the chest muscles, which may impair breathing.

Destruction of muscle fibers causes release into the circulation of various enzymes normally contained in muscle; measuring levels of these enzymes in blood thus aids in diagnosis. Also, inflamed muscle is abnormal in its electrical activity; therefore the test known as an electromyogram yields abnormal results. Finally, muscle biopsy firmly establishes the diagnosis; it can be important in distinguishing polymyositis from noninflammatory disorders affecting muscle. Although polymyositis is presumed to be an immune-mediated process, the mechanisms are obscure. Antinuclear antibodies may be found in the serum. Other less frequent but more myositis-specific autoantibodies may also be present.

The inflammatory process is generally responsive to corticosteroid therapy, but in some cases the addition of a cytotoxic drug, especially methotrexate, is required. In the few individuals with tumor-related polymyositis, appropriate treatment of the malignancy is essential; and when polymyositis occurs together with other connective tissue disorders, such as lupus, the additional features of these illnesses must also be controlled.

If diagnosed early, before loss of muscle fibers and replacement by fibrous scarring is extensive, myositis is reversible; recovery with minimal residual loss of strength is to be expected in almost all patients.

Scleroderma. The term scleroderma means "hard skin," designating a disorder in which increased deposition of collagen fibers in the deeper dermis leads to thickened, leathery, bound-down skin. This deposition is variable in extent and degree. When organ involvement is associated with such skin changes, the term systemic sclerosis is used.

Raynaud's phenomenon, a hyperreactivity to cold exposure with blanching and discoloration of the fingers and toes, is the common initial manifestation and may precede sclerodermatous skin changes by decades. Only a small fraction of those with Raynaud's eventually develop scleroderma or systemic illness; but of those who do have scleroderma, at least 80% will have Raynaud's. Skin changes may be confined to the distal digits or become generalized.

Systemically, the gastrointestinal tract is commonly involved. Difficulty in swallowing and midchest discomfort result from loss of peristalsis in the esophagus. Diarrhea, inability to absorb nutrients, abdominal pain, and distention can occur with bowel involvement and lead to weight loss and wasting. Scarring of the lungs and decreased pulmonary function occur frequently. The most serious lesions are those of the heart and kidney, and may result from vascular abnormalities. Joint inflammation is mild and uncommon; but advanced skin changes, especially in the hands, may restrict joint mobility.

Polymyositis is occasionally present and is the major indication for corticosteroid therapy in this disorder.

A variant called the CREST syndrome (calcinosis, Raynaud's, esophageal dysmotility, sclerodactyl- or scleroderma-like finger, and telangiectasia) is notable because of its mildness and slow progression. It is also referred to as limited scleroderma.

Multiple autoantibodies (including ANA) may be found in serum. The diagnosis is usually a clinical one, based on characteristic skin tightening. A skin biopsy, if peformed, will demonstrate increased collagen fibers in the deeper dermis without any inflammatory reaction.

Management involves treatment of high blood pressure that can arise because of kidney involvement, use of agents to improve circulation by reducing small-vessel spasm, and reducing gastrointestinal complications with special diets and sometimes antibiotics. The drug D-penicillamine may produce improvement in the skin and possibly systemic features. In a few cases, skin changes may subside spontaneously.

Sjögren's syndrome. This condition is characterized primarily by dryness of the membranes due to excretory gland failure, especially dryness of the eyes (xerophthalmia) and mouth (xerostomia) from loss of tears and saliva, respectively. This sicca (dryness) syndrome reflects the infiltration of lacrimal and salivary glands by immunologically competent cells (lymphocytes).

Sjögren's syndrome may be primary or secondary, the latter occurring in the context of another disorder, such as rheumatoid arthritis or systemic lupus. The typical individual with primary Sjögren's syndrome is a woman later in life. In most cases, the sicca complex dominates, but there can be loss of secretions in the skin, bronchial tree, esophagus and stomach, and vaginal vault. In some people with primary Sjögren's, systemic features may evolve. Diagnosis is primarily clinical, but ocular dryness can be quantitated. Lip biopsy of the minor salivary glands can confirm the infiltration by immune cells. Noninvasive scanning of the parotids can confirm the loss of functional glandular structure. Autoantibodies in the blood are common and can aid in differentiating Sjögren's syndrome from other causes of dry eyes and dry mouth, but in no instance is a blood test diagnostic of either Sjögren's or any companion disorder.

Management involves artificially keeping membranes moist (for example, with artificial tears). Extraglandular inflammatory lesions and associated disorders are treated with anti-inflammatory agents and occasionally cytotoxic agents. *See* IMMUNOLOGY; INFLAMMATION; STEROID.

Conodont

A group of extinct marine animals that are often abundant in strata of Late Cambrian to Late Triassic age, a time span of about 300 million years. Only the mineralized elements, which are usually 0.2 to 2 mm (0.008 to 0.08 in.) in dimension (the largest known reach 14 mm or 0.6 in.), are normally preserved. They are routinely extracted as isolated discrete specimens by chemical degradation of the rock in which they occur. The apatite (calcium phosphate) of which conodont elements are composed is laid down as lamellae. In the earliest euconodonts ("true" conodonts, as opposed to the more primitive, and possibly unrelated, protoconodonts and paraconodonts), the elements comprise an upper crown and a basal body. The basal body occupies a cavity in the base of the crown, but is not present in the majority of post-Devonian species. In advanced conodonts the crown incorporates regular patches of opaque, finely crystalline, white matter.

For many years, conodont taxonomists treated individual element types as separate species. There are three major shape categories, coniform, ramiform, and pectiniform (**Fig. 1**). Coniform elements were dominant in the Cambrian to Early Ordovician and common until the Devonian. They vary in curvature and in cross section, including the development of costae. Ramiform (comblike) elements extend into elongate processes with various arrangements of denticles. Pentiniform elements include straight and arched blades, and may be expanded laterally to form a platform.

Skeletal apparatus. In the 1930s the discovery of "natural assemblages" on bedding surfaces provided direct evidence that each animal possessed a skeletal apparatus consisting of several different kinds of elements. Several hundred such associations have now been found, each representing the skeletal remains of an individual animal. Most are from shales, as their preservation requires that the soft parts of the animal decay undisturbed by currents, so that the skeleton remains intact. Some elements may also become fused into clusters during the diagenesis of the sediments in which they occur, and these, too, give an indication of the configuration of the conodont apparatus. Although most conodont species are still known only from elements scattered in the sediment, it is now conventional practice in conodont taxonomy to reconstruct their skeletal apparatus by using morphological and statistical criteria.

The evidence of bedding-plane assemblages shows that most of the elements in an apparatus were symmetrically paired across the midline. A common type of apparatus in the Upper Paleozoic (Fig. 1*i*) consisted of a set of 7 to 11 ramiform elements (one of which was an unpaired median, bilaterally symmetrical form), followed by a pair of arched blades and, posterior of these, a pair of platform pectiniform elements. Variations in this arrangement occur; early Paleozoic apparatus often consisted of a series of coniform elements alone.

Soft parts. In the absence of preserved soft parts, the nature of the affinities of conodonts was the subject of considerable speculation and debate. Since the discovery of isolated elements in 1856, conodonts have been variously aligned with algae, higher plants, several wormlike phyla, mollusks, arthropods, lophophorates, chaetognaths, and chordates, or have been assigned to a separate phylum, Conodonta. It was not until 1983 that evidence of the soft parts was described by D. E. G. Briggs, E. N. K. Clarkson, and R. J. Aldridge, on the basis of the first of several specimens discovered in lower Carboniferous rocks near Edinburgh, Scotland.

Features of the soft parts are preserved as a calcium phosphate film (**Fig. 2**). They show that conodonts were elongate animals (40–60 mm or 1.6–2.4 in.). The apparatus lies in the head region, behind a bilobed structure which is preserved as a film darker than the rest of the body (**Fig. 3**). All of the Carboniferous examples discovered to date are compacted in lateral view, and the apparatus lies to one side, in some cases beyond the apparent outline of the body. This suggests that the soft tissue which supported the elements is not preserved. The trunk shows clear evidence of V-shaped structures, the apex of the V's pointing anteriorly. These structures are interpreted as muscle blocks, but the nature of two parallel lines which run the length of the

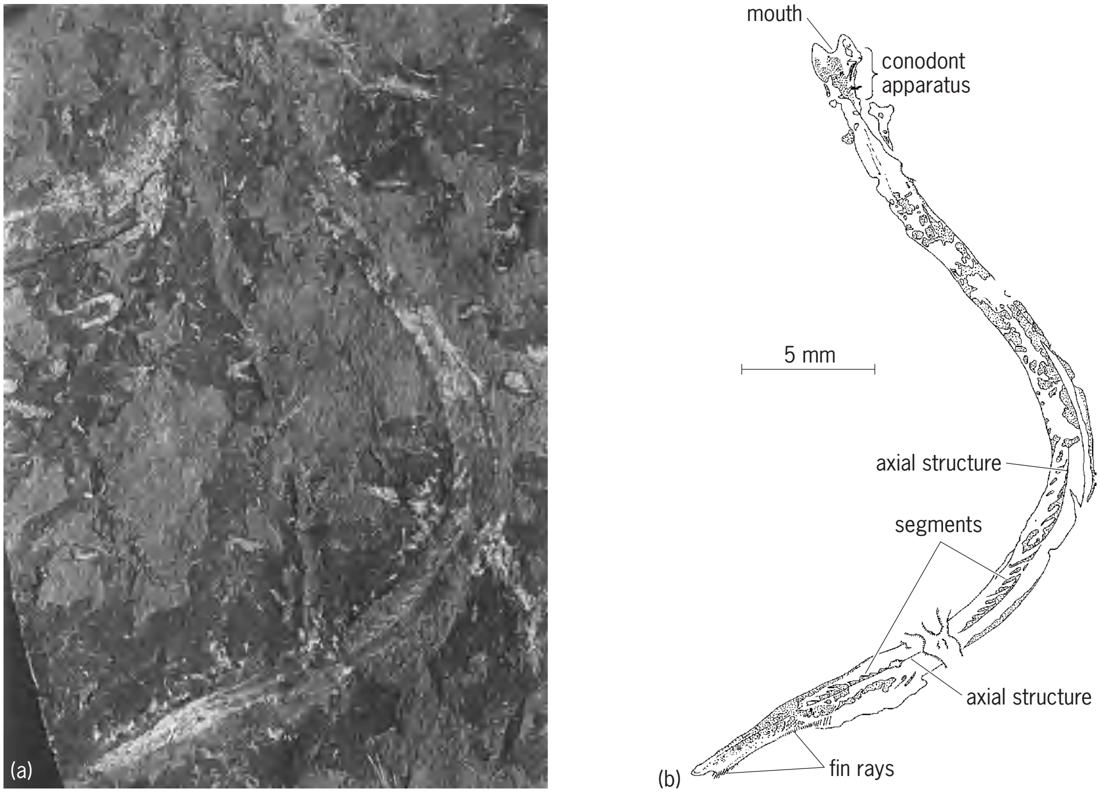

Fig. 2. The first specimen of the conodont animal discovered in Lower Carboniferous rocks in Edinburgh. (*a*) Photograph of specimen. (*b*) Outline of the specimen for comparison. (*From D. E. G. Briggs, E. N. K. Clarkson, and R. J. Aldridge, The conodont animal, Lethaia, 16:1–14, 1983*)

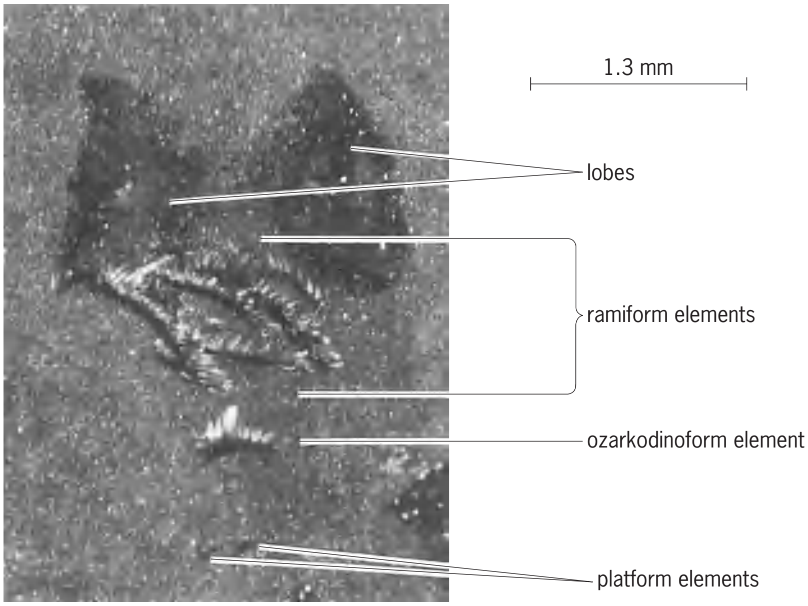

Fig. 3. Head region of the conodont animal, showing the conodont elements on the side of the slab opposing that illustrated in Fig. 2. (*From D. E. G Briggs, E. N. K Clarkson, and R. J. Aldridge, The conodont animal, Lethaia, 16:1–14, 1983*)

trunk is less certain. Fin rays indicate the presence of an asymmetrical fin around the margin of the tail. A single poorly preserved specimen from the Silurian of Wisconsin, the only other example known which shows traces of the soft parts, suggests that the body of some conodonts may have been broader than that in the Scottish specimens.

Biological affinities. The evidence of the soft-part morphology indicates that the conodonts belong within the chordates; it is no longer possible to justify their separation as a phylum, Conodonta. The lack of jaws and of a bony skeleton suggests that they represent a primitive group of jawless craniates, perhaps close to the Myxinoidea (hagfishes). The apparatus is thought to have functioned in food capture. The ramiform elements (or coniform elements in earlier conodonts) appear to be adapted for grasping prey. In later conodonts this would have been processed by the shearing and grinding action of the paired pectiniform elements *See* CHORDATA.

Geological applications. Although the biological affinities of conodonts and the function of the elements were essentially unknown until recently, they have nonetheless been extensively studied because of their important geological applications. Most significant of these is the use of conodont elements in biostratigraphy. Biozonal schemes have been erected for all the systems through which conodonts range, Cambrian to Triassic; the most detailed subdivision is in Upper Devonian strata (conodont subbiozones representing, on average, 0.5 million years). Some conodonts are restricted in their distribution to certain sedimentary environments and can be used to define biofacies. Most conodont biofacies are, at least indirectly, related to depth, as reflected in the contrasts between nearshore and offshore assemblages.

Conodont elements can also be used to determine the thermal history of strata. The color of elements alters from pale yellow through brown to black as their carbon content is fixed during organic metamorphism. This is the basis for a conodont Color Alteration Index (CAI, from 1 to 5) which can be applied in assessing oil and gas potential, and in wider studies of the thermal history of sedimentary basins.

The apatite of which conodont elements are formed is stable and resistant to diagenetic alteration. The trace-element and isotopic-ratio characteristics of the seawater in which the organism lived were retained in the apatite, which can be analyzed to yield significant information about the temperature and chemistry of ancient oceans. Thus an assemblage of conodont elements extracted from a rock sample not only may allow biostratigraphic correlation, but also may give an indication of the paleoenvironment of the locality; the temperature, geochemistry, and oxygen content of the seawater; and the subsequent thermal history of the sedimentary basin. *See* STRATIGRAPHY. Consciousness

Accounting for the sensations or "raw feels" which constitute conscious experience has been a persistent problem for scientific approaches to psychology. In addressing this problem, each new scientific approach has put forth a new account of the relationship between those conscious sensations, as they are privately experienced by individuals, and the nervous system, as it is experienced by scientists.

Fechner on consciousness. In 1860 Gustav Fechner published his *Elemente der Psychophysik*, wherein he developed scientific techniques to measure the magnitudes of conscious sensations such as brightness and loudness, and then derived a mathematical equation to describe the relationship between each sensory magnitude and the physical magnitude which stimulated it. Fechner derived this psychophysical equation as a scientific solution to the mind-body problem. He interpreted it as support for panpsychism, the metaphysical position that all matter is conscious of other matter. His interpretation was based on the equation's implication that a very small physical magnitude stimulates a negative sensation: the consciousness of a magnitude beneath the threshold at which neural substances produce awareness of each other's magnitudes, a conscious sensation such as that experienced by flowers and other nonneural substances.

Inasmuch as the mathematical relationship between psychological sensations and physical stimuli must be derivable from psychoneural and neurophysical equations, Fechner's panpsychist interpretation of his psychophysical equation assumed that the underlying psychoneural equation was a logarithmic equation yielding the negative sensations and that the neurophysical equation was linear. However, critics argued that the logarithmic relationship reflected the neurophysical relationship between the magnitude of the brain state evoked by the stimulus and the magnitude of the physical stimulus itself, both of which are physically and scientifically measurable magnitudes. *See* PSYCHOPHYSICAL METHODS.

Wundt on consciousness. Historically, Wilhelm Wundt convinced the scientific establishment that the methods of science are sufficient to study the sensory data of consciousness. He argued that the inner aspects of conscious experience, the data of psychology, are the only immediately known data of science: that the outer world of physical reality has to be inferred from the data of scientific psychology and, thus, is known only mediately. His scientific studies of perceptual consciousness confirmed that perceptual experience provides no immediate knowledge of external reality.

In logically and experimentally supporting his thesis that the data of scientific psychology constitute the foundation for all sciences, Wundt sought to reduce physical reality to a subset of consciousness itself. Three founders of subsequent approaches to psychology were not satisfied with this effort to rewrite psychophysical and psychoneural equations in purely mental terms. One of them—John Watson, who founded behaviorism around 1913—sought, instead, to reduce mental terms to physical terms. The other two—Sigmund Freud, who founded psychoanalysis around 1900, and Max Wertheimer, who founded Gestalt psychology around 1912—sought to put mental terms on the psychological sides of the psychoneural and psychophysical equations and to put physical terms on the opposite sides.

Freudian reaction to Wundt. By arguing for the existence of unconscious mental events, Freud took issue with both the metaphysical and the methodological underpinnings of Wundt's approach to the psychology of consciousness. If unconscious mental events existed, then much of the mind itself—much of the data of scientific psychology—was no more immediately knowable than the inferred data of physical sciences. Moreover, to the extent that the unconscious mind was actually part of physical reality, Wundt was not justified in treating physical reality as a subset of the mind. In the light of Freud's analysis of the unconscious mind, the psychophysical and psychoneural relationships reemerged as unsolved and problematical relationships.

Behaviorist reaction to Wundt and Freud. In creating and developing behaviorism, Watson introduced both a new methodological approach to psychology and a new metaphysical approach to consciousness. Watson's scientific methods and metaphysical positions were addressed to the psychology of the other. The starting point for behaviorism was the scientist's immediate experience of another organism's behavioral response to a stimulus; metaphysical inferences about conscious events within that other organism were deemed to be unnecessary and unwarranted.

From the standpoint of behaviorism, all scientific conclusions regarding the psychophysical and psychoneural relationships—including Fechner's panpsychist interpretation of his psychophysical equation and Freud's distinction between conscious and unconscious mental events—were meaningless. This did not necessarily imply that mental terms such as consciousness were meaningless. It did imply that the behavioral scientist's physical descriptions of other entities like brains (including the physical description of his or her own brain) could not meaningfully be related to mental descriptions of his or her own consciousness.

From behaviorism to computer models. At the beginning of the twentieth century, Ivan Pavlov and Edward Thorndike initiated psychological research on animals, and Watson's psychology of the other organism provided the rationale for viewing other animals and other people as scientifically equivalent subjects of psychological study. Since the late 1960s, animal-behavior models of psychological processes have been replaced by computer models, and Watson's animal behaviorism has been transformed into a computer behaviorism or a psychology of the other machine. The goal of computer behaviorism is to program computers to produce output responses which observers experience as indistinguishable from human beings' responses. If and when this goal is achieved, computer models of psychological processes will provide logically sufficient explanations of the psychological processes of other human beings. The critical question is whether such computer models of psychological processes would also provide sufficient explanations of the psychological processes of the scientist who consciously experiences the other machine.

Some computer behaviorists argue that neither the scientist's conscious experience nor the computer's lack thereof has any causal effect on behavior. However, a subset of these computer behaviorists believe that any conscious psychological process in the scientist's computerlike brain can actually occur with or without consciousness of that process, implying that the scientist's psychological processes are, in principle, not different from the computer's. Another implication is that the scientist's brain contains a metaphysical subject which can consciously inspect or not inspect the same neural process. Other computer behaviorists adopt the functionalist argument that sensations like blueness and other privately experienced phenomena will "emerge" from any functionally equivalent psychological processes present either in the scientist's computerlike brain or in the other computer studied by the scientist. Metaphysically, computer behaviorism presupposes that the conscious mind is a machine; methodologically, it starts with the scientist's conscious experience of other machines. Another metaphysical and methodological approach, the approach of Gestalt psychology, presupposed also that the mind is a machine, but started instead with the scientist's phenomenal experience of his or her own machine.

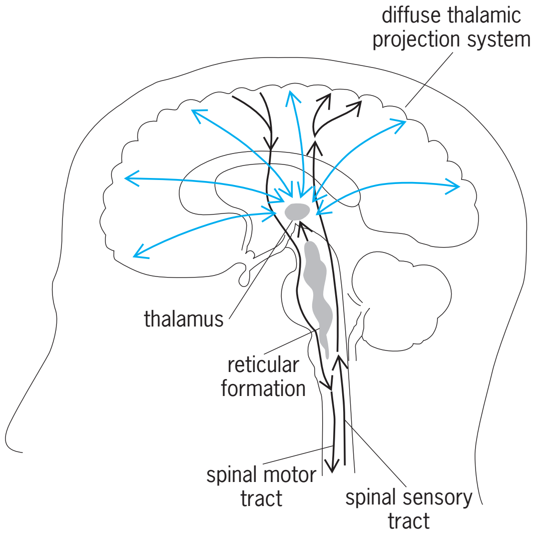
Gestalt reaction to Wundt and behaviorism. While the Gestalt psychologist Max Wertheimer rejected Watson's scientific psychology of the other organism, he also rejected Wundt's contention that nothing in the scientist's immediately known experience corresponds directly with the mediately known physical world. Gestalt psychologists objected that Wundt had restricted his observations to elementary sensations and had not observed the Gestalt, the holistic relationship among the immediately known sensations. According to Gestalt psychology, there was a direct psychophysical correspondence between perceptual experience and physical stimulation.

From Gestalt to mind-brain identity theory. In his effort to rebut Wundt's contention that any psychophysical correspondence is a necessarily indirect, arbitrarily learned, and basically illusory correspondence, Wertheimer adopted the scientist's conscious experience as his starting point and looked for phenomenal evidence to support a direct psychophysical relationship. In so making his case for a direct psychophysical correspondence, he set the stage for the Gestalt psychologist Wolfgang Köhler and other mind-brain identity theorists to argue for a direct psychoneural relationship.

According to mind-brain identity theorists, the scientist's sensations are qualities of particular brain structures in their excited state. Thus, the scientist is "conscious of" neither sensations nor the brain; the scientist is the sensory qualities of his or her brain states. The scientist immediately experiences nothing besides the qualities of the brain states which he or she is; and the scientist's experiential qualities change over time, simply because the patterning of excited structures in his or her brain changes.

According to mind-brain identity theory, a scientist could simultaneously experience his or her own brain both immediately and mediately, by visually experiencing the exposed brain on a television screen. In spite of the fact that such a mediately experienced brain would be a subset of the immediately experienced brain, the scientist could look for mediately experienced brain states which correlate perfectly with immediately experienced sensory qualities. Gestalt psychologists argue that mind-brain identity theory predicts that psychoneural correspondences can be discovered. Scientists adopting a mind-brain identity position have not yet discovered any structural differences in various parts of the brain, much less discovered any correspondences between conscious qualities and brain structures. Robert G. Kunzendorf

Lines of evidence. Psychologists and neuroscientists have developed many productive lines of evidence. Psychological investigations have compared conscious and unconscious processes in selective attention, visual perception, implicit versus explicit learning, conscious availability in problem solving and memory, automatic versus controlled task components, working memory, and so on. Theoretical approaches have emerged, couched in the vocabulary of information processing, cognitive architectures, and adaptive systems. Brain researchers have developed promising lines of evidence, including studies of brain damage (as in amnesia, neglect syndromes, split brain cases, hemispherectomies, and blindsight), as well as normal neurosensory processes, anesthesia, sleep, dreaming, and coma.



Brain structures most closely associated with the conscious experience. (*After B. J. Baars, A Cognitive Theory of Consciousness, Cambridge University Press, 1988*)

The effects of the presence and absence of consciousness reveal enormous neurobehavioral differences between the brain in deep sleep, stupor, or coma compared to when it is wakeful. The anatomical structures required for waking consciousness are well known. They include the brainstem reticular formation, the reticular nuclei of the thalamus (its outer shell), and the fountain of neuronal fibers projecting from the intralaminar nuclei of the thalamus to all parts of the cortex (see **illus.**). Damage to any of these structures will induce coma, whereas massive lesions elsewhere in the brain generally produce no loss of conscious wakefulness; actually, an entire hemisphere can be removed without producing coma.

In many cases, exact experimental comparisons can be made between mental events that are clearly conscious and very similar events that are not. Everyone has experienced repetitive stimuli fading from consciousness (for example, the repeated sound of a noisy refrigerator pump). Sometimes, when such a highly predictable train of events suddenly stops, the stimulus becomes conscious, so that an individual then perceives that something has changed, even though the person was not aware of it while it was taking place. Scientific observations of such habituation phenomena suggest that the nervous system must maintain a rather accurate, unconscious representation of the repetitive stimulus, since a change in any parameter of the stimulus (for example, an increase or decrease in intensity or a change in the temporal pattern) may bring it to consciousness.

Similarly, if someone is spoken to while reading a book, the person's first impulse may be to ask, "What did you say?", but suddenly the memory of what was said comes to mind. The words must have been stored unconsciously, or they would not be remembered a few seconds later.

A useful distinction can be made between conscious experience, that is, what people can report and act upon, and selective attention, which is the ability to choose between alternative streams of conscious contents. Once an individual attends to one dense stream of speech or visual flow, competing trains of stimulation appear to be processed unconsciously. In a classic dichotic listening task, subjects closely monitored sentences presented to one ear. Information presented to the other ear is not reportable under these conditions; it cannot be acted upon voluntarily, and it can be repeated many times without creating recallable memories. This result is consistent with the subjects' reports that the unattended stream was not conscious. However, the meaning of unattended words is in fact processed, since the listeners' understanding of the attended sentences can be influenced by those words.

In subliminal priming, subjects may be exposed to a printed word via one eye, while a visual mask is presented to the other eye in such a way that the target word cannot be reported. The masked word will nevertheless influence the time needed to recognize a related word presented immediately afterward, again suggesting that the unconscious stimulus must be processed and represented unconsciously.

The question is what is the difference between the mental representation of a stimulus when it is conscious versus unconscious. It has been suggested that novel combinations of stimuli require consciousness; unconscious processing may be rigid and automatic. But the unconscious is not simple. Complex tasks such as linguistic analysis, memory search, motor control, executive planning, and emotional response, which often involve abstract representations and symbolic processes, are performed unconsciously. Unconscious processes can be quite formidable in speed, accuracy, and complexity. The functional capacities of conscious and unconscious processes can be compared as follows.

Conscious processes:

1. They are computationally inefficient. Many errors, relatively low speed, and mutual interference occur between processes.
2. The range of contents is great. There is great ability to relate different conscious contents to each other, and conscious events to their unconscious contexts.
3. In regard to access, largely unconscious executive functions can gain control over unconscious specialists via consciousness. Conscious contents can refer to and sometimes trigger other conscious contents. Conscious contents can trigger unconscious automatisms.
4. There is high internal consistency at any single moment, seriality over time, and limited processing capacity.

Unconscious processes:

1. They are very efficient in routine tasks. Few errors, high speed, and little mutual interference occur between processes.
2. Each routine process has a limited range of contents. It is relatively isolated and autonomous, and is relatively context free.
3. Entirely unconscious processes probably have only routine (highly practiced, hard-wired, or both) access to each other.
4. The set of routine, unconscious processes are diverse, can sometimes operate in parallel, and together have great processing capacity.

Methodology. An individual's understanding of consciousness, while no doubt influenced by personal experience, needs to be based on publicly observable events that can be tested and verified by multiple observers. Conscious processes can be operationally defined as the set of events that are claimed by a subject to be conscious and can be reported and acted upon with verifiable accuracy, under optimal reporting conditions. Optimal reporting conditions imply a minimum delay between the conscious event and the report (for example, freedom from distraction). This definition fits existing practice in the study of perception, short-term memory, explicit problem solving, and imagery. *See* MEMORY; PERCEPTION; PROBLEM SOLVING (PSYCHOLOGY).

By contrast, unconscious processes can be operationally defined as those which are not claimed to be conscious, and cannot be reported or acted on, even under optimal reporting conditions, but whose presence can nevertheless be verified. By this definition, automatic processes are unconscious, as are visually masked stimuli, visual objects in blindsight, implicit memory, unattended information, subliminal effects, the details of language processing, and the effects of priming. Again, there is a good fit between this definition and existing scientific practice.

There is a curious asymmetry in the assessment of conscious and unconscious processes. Obtaining verifiable reports is a viable method for specifying conscious events, but unconscious ones are much more difficult to define. William James suggested that because the evidence for unconscious processes could always be challenged there were no unconscious psychological processes at all. This is known as the zero point problem. For example, if a word shown for a few milliseconds cannot be reported, it does not necessarily mean that the person is truly unconscious of the stimulus. There could have been a fleeting awareness that is soon masked or replaced by succeeding events. It is extraordinarily difficult to be sure of the zero point of consciousness.

Alternatively, a criterion for unconscious events can be applied which does not solve the problem exactly but which gives a reasonable basis for consensus. Suppose that a subject is asked to avoid recently primed processes. If the subject cannot do so, those processes are plausibly unconscious. James could argue that by this criterion unconscious events could still be fleetingly conscious, however briefly. The criterion only guarantees that the unconscious event cannot be used in working consciousness—the ability to report and act upon the fleeting stimulus.

Limited capacity system. Most cognitive models formerly did not refer to consciousness explicitly but used terms and mechanisms that were very closely associated with it. For example, one of the first models was short-term memory, which is roughly the domain in which one rehearses telephone numbers while walking from the phone book to the telephone. More broadly, it may include the domain in which individuals mentally talk to themselves. It is true, of course, that not all items in short-term memory are conscious at any single instant. Of the seven digits of a new telephone number that can be mentally rehearsed, only one or two are conscious at any time. Thus, short-term memory is not identical to consciousness but seems to be very closely related.

All phenomena associated with conscious experience are characteristically limited in capacity. A person watching a baseball game on television cannot simultaneously experience a football game overlaid on the same screen, nor can a person follow a normal conversation while performing any other unpredictable, skilled task. Short-term memory is characterized by a limit of seven plus or minus two chunks of information. Voluntary control, which is also intimately involved with conscious experience, seems similarly limited. Finally, the flow of conscious information is relatively serial.

There is a curious dichotomy between limited-capacity models and evidence suggesting that the unconscious parts of the nervous system have enormous capacity. The vast capacity of long-term memory, the great size of the linguistic lexicon, and the large set of available automatic skills are known in a psychological sense. The most obvious illustration of enormous unconscious capacity is the sheer size and complexity of the brain. The cerebral cortex alone has some 50 billion neurons, with similar numbers for the large subcortical mass, the spinal cord, and the great network of peripheral neurons. Each neuron sends an electrochemical signal to its neighbors an average of 40 times per second, up to perhaps 1000 Hz. The system is thoroughly interconnected: Neurons have up to 10,000 connections, and a path can be traced from any single neuron in the brain to any other neuron in seven steps or less. This enormous organ, the most complex in the body, operates concurrently rather than serially and performs highly complex and intelligent tasks with minimal conscious involvement. *See* BRAIN.

Society models. The society model of the nervous system suggests that the great bulk of information processing is performed by local networks that are unconscious, though they are complex, specialized, and intelligent, and operate in parallel and normally very efficiently. Such expert societies have great flexibility in problem solving and control. Repetitive events and routine actions can be handled by specialized processors with minimal conscious involvement. It is possible that conscious experience corresponds to a domain of interaction between the multitude of unconscious experts, one that may act as a global "publicity organ'' or meeting place in the society of intelligent processors. Consciousness in this view serves as an indispensable adaptive function. *See* COGNITION; INFORMATION PROCESSING (PSYCHOLOGY); PSYCHOLOGY.

Conservation laws (physics)

Principles which state that the total values of specified quantities remain constant in time for an isolated system. Conservation laws occupy enormously important positions both at the foundations of physics and in its applications.

Realization in classical mechanics. There are three great conservation laws of mechanics: the conservation of linear momentum, often referred to simply as the conservation of momentum; the conservation of angular momentum; and the conservation of energy. It is almost impossible to understand the modern form of the conservation laws without understanding their original and simplest realization in the classical mechanics of particles. Therefore, the conservation laws as they appear within that framework will first be discussed, and then their generalization and modification to cover larger domains.

Conservation of momentum. The linear momentum, or simply momentum, of a particle is equal to the product of its mass and velocity. It is a vector quantity. The total momentum of a system of particles is simply the sum of the momenta of each particle considered separately. The law of conservation of momentum states that this total momentum does not change in time.

An important application of this principle is to collisions. For example, in a collision between two bodies of equal mass, starting with opposite velocities, the total momentum is zero. The conservation of momentum states that it will still be zero after the collision. Thus, if the bodies remain intact they must move off again with opposite velocities—though not necessarily the original ones, for both bodies may have been deflected through a common angle. If the collision causes part of one of the original bodies to adhere to the other, the two bodies will again move off in opposite directions, but the heavier one will move slower and the lighter one faster, by factors inversely proportional to their new masses. Even if the bodies shatter into several bits, there are three constraints on the motion of the debris that emerges: each component of the total momentum must vanish. *See* COLLISION (PHYSICS).

This application is typical in showing both the power and the limitations of general conservation laws as they are applied to complex processes. They cannot tell what happens in detail, but they constrain the possibilities in ways that are nontrivial and unequivocal. *See* CONSERVATION OF MOMENTUM; MOMENTUM.

Conservation of angular momentum. The angular momentum of a particle is more complicated. It is also a vector quantity. It is defined with respect to some origin of coordinates O. Let the position P of the particle be specified by the position vector $\overline{r} = \overline{OP}$ pointing from the origin to it; and let its mass and velocity be m and $\overline{v}$ respectively. Then the angular momentum of the particle is defined by the vector product of the position and momentum vectors, Eq. (1). The total

$$\vec{L} = \vec{r} \times (m\vec{v}) \qquad (1)$$

angular momentum of a system of particles is equal to the sum of the angular momenta of each particle separately. The law of conservation of angular momentum states that the total angular momentum of an isolated system is constant in time.

An extremely important instance of the conservation of angular momentum is Kepler's second law of planetary motion, which states that a line drawn from the Sun to a planet sweeps out equal areas in equal times. This would be a geometrical statement entirely equivalent to the conservation of angular momentum if the planet and Sun formed an isolated system. In reality they do not: A planet is subject to gravitational forces from other planets as well as the Sun, so that Kepler's law is only approximately correct. There are many other important applications of the law of conservation of angular momentum to mechanical problems involving rotation, particularly the motion of tops and gyroscopes. *See* ANGULAR MOMENTUM; KEPLER'S LAWS; RIGID-BODY DYNAMICS.

Conservation of energy. The third great conservation law of classical mechanics, conservation of energy, is perhaps the most important of all (although it was the last to be properly appreciated, for reasons discussed below). Energy is a scalar quantity, and it takes two forms: kinetic and potential. The kinetic energy of a particle is defined to be one-half the product of its mass with the square of its velocity, $T = {}^1/_2 mv^2$, and the total kinetic energy of a system of particles is simply the sum of their separate kinetic energies. The potential energy is loosely defined as the ability to do work; more precisely, it is a function V of the particles' positions, such that the force felt by a particle is minus the derivative of the potential energy with respect to that particle's position. The total energy is the sum of the kinetic and potential energies, $E = T + V$, and according to the conservation law it remains constant in time for an isolated system.

The essential difficulty in applying the conservation of energy can be appreciated by considering once again the problem of two colliding bodies. In general, even if they retain their integrity, the bodies emerge from the collision moving more slowly than when they entered. When this happens, the collision is said to be inelastic. An inelastic collision seems to violate the conservation of energy, until it is recognized that the bodies involved may consist of smaller particles. If these particles are shaken up and rattle around within the larger bodies after the collision, their random small-scale motions will require kinetic energy, which robs kinetic energy from the overall coherent large-scale motion of the bodies that are observed directly.

Such difficulties make it more challenging to extract concrete quantitative consequences from the conservation of energy than from the other conservation laws. One of the greatest achievements of nineteenth-century physics was the recognition that small-scale motion within macroscopic bodies could be identified with the perceived property of heat. By measuring the heat created by a given amount of mechanical work, J. P. Joule was able to define a precise mechanical equivalent of heat—for example, how much work it takes to heat a gram of water by one degree. *See* THERMODYNAMIC PRINCIPLES.

The first law of thermodynamics is simply an expression of the conservation of energy, using this concept that energy can take the form of heat (that is, microscopic, random motion) as well as perceived macroscopic motion or potential energy. The idea of heat as microscopic motion is used to explain some of the properties of gases. Finally, careful observations on the microscopic motions of small bodies have experimentally verified the theoretical predictions for this so-called brownian motion in great detail. *See* BROWNIAN MOVEMENT; CONSERVATION OF ENERGY; ENERGY; KINETIC THEORY OF MATTER; STATISTICAL MECHANICS.

Methodology. In Newton's original scheme of mechanics, the notion of force was primary. Later workers obtained simpler and more powerful mathematical formulations of the laws, without changing their physical content, by regarding energy as the primary notion. In modern physics this change in emphasis has become more pronounced, so that, for example, in quantum mechanics the concept of force is hardly ever encountered, but always energy. *See* HAMILTON'S EQUATIONS OF MOTION; LAGRANGE'S EQUATIONS.

Position in modern physics. As physics has evolved, the great conservation laws have likewise evolved in both form and content, but have never ceased to be important guiding principles, and never more so than now. Only a few highlights will be discussed.

Electromagnetism. In order to account for the phenomena of electromagnetism, it was necessary to go beyond the notion of point particles, to postulate the existence of continuous electric and magnetic fields filling all space. An assembly of charged particles can excite propagating waves in the fields. These are interpreted as electromagnetic radiation, of which, for example, light and radio waves are special cases. When such radiation occurs, the total energy of the particles is diminished in a definite way, depending on the amount and type of radiation emitted. Thus, to obtain valid conservation laws, energy (and, for similar reasons, momentum and angular momentum) must be ascribed to the electromagnetic fields. *See* ELECTROMAGNETIC RADIATION; MAXWELL'S EQUATIONS; POYNTING'S VECTOR.

Special relativity. In the special theory of relativity, energy and momentum are not independent concepts. A leading idea of this theory is that the laws of physics take the same form when viewed by two observers who move with respect to one another at a constant velocity. In particular, each observer will associate both a conserved energy and a conserved momentum with a given isolated system. However, the energy reported by one observer is equal to a certain combination of the energy and momentum reported by the other.

Einstein discovered perhaps the most important consequence of special relativity, that is, the equivalence of mass and energy, as a consequence of the conservation laws. He considered a thought-experiment wherein an atom emits equal packets of radiation in opposite directions. He showed that the law of conservation of energy could be valid for this process, as viewed by a moving observer, only if, as a result of the radiation, the atom's mass is diminished, according to Eq. (2), where E is the energy

$$\Delta m = \frac{E}{c^2} \qquad (2)$$

of the radiation emitted and c is the speed of light. In the nineteenth century, the law of conservation of mass was a major item in any discussion of conservation laws. Now this "law" is understood as an approximate consequence of the conservation of energy (valid in the limit $c \to \infty$). *See* CONSERVATION OF MASS; RELATIVITY.

Connection with symmetries. A remarkable, beautiful, and very fruitful connection has been established between symmetries and conservation laws. Thus the law of conservation of linear momentum is understood as a consequence of the homogeneity of space, the conservation of angular momentum as a consequence of the isotropy of space, and the conservation of energy as a consequence of the homogeneity of time. *See* SYMMETRY LAWS (PHYSICS).

General relativity. The development of general relativity, the modern theory of gravitation, necessitates attention to a fundamental question for the conservation laws: The laws refer to an "isolated system," but it is not clear that any system is truly isolated. This is a particularly acute problem for gravitational forces, which are long range and add up over cosmological distances.

Indeed, according to general relativity, a small region of space-time cannot be regarded as isolated, and the conservation laws are not valid. However, special solutions of the equations of general relativity, including model universes which closely model that of the Earth, support the conservation laws as a good approximation, valid over distances and times that are not too large. The relevant feature of these model universes is that they are approximately homogeneous and evolve slowly.

Fortunately, the scales are such that practical applications of the conservation laws are completely unaffected by this limitation. However, there is an important philosophical consequence: The symmetry of physical laws, which, as mentioned above, is closely tied up with the conservation laws, is actually a more fundamental property than the conservation laws themselves, for the symmetries remain valid while the conservation laws, strictly speaking, fail.

Quantum theory. In quantum theory, the great conservation laws remain valid in a very strong sense. Generally, the formalism of quantum mechanics does not allow prediction of the outcome of individual experiments, but only the relative probability of different possible outcomes. One might therefore entertain the possibility that the conservation laws were valid only on the average. However, the power of the conservation laws is much stronger: Momentum, angular momentum, and energy are conserved in every experiment, not just on the average.

How this can be so is one of the strangest yet simplest and most profound aspects of quantum theory. It is helpful to consider the decay of an excited state of an atom, wherein it radiates a single photon. If an apparatus is set up to detect the photon, then for every possible direction there is a probability that the photon will be detected moving in that direction. Now, if after detecting the photon the observer goes back and examines the atom, it will be found to be moving in the opposite direction in such a way that the total momentum is zero, as it was initially. This raises the question of how the atom could "find out" the result of the measurement of the photon. This is one form of what Einstein called the "spooky action-at-a-distance" in quantum mechanics. To interpret this situation, it must be acknowledged that the atom, like the photon, has a range of potential motions, but that these two potentialities, though they can be measured in either order and quite separately, are rigorously correlated. *See* NONRELATIVISTIC QUANTUM THEORY; QUANTUM MECHANICS; QUANTUM THEORY OF MEASUREMENT.

Conservation laws of particle type. There is another important class of conservation laws, associated not with the motion of particles but with their type. Perhaps the most practically important of these laws is the conservation of chemical elements, that is, the principle that, in a chemical reaction, for each chemical element the total number of atoms of that element in the products is equal to the total number of atoms of that element in the original reactants. From a modern viewpoint, this principle results from the fact that the small amount of energy involved in chemical transformations is inadequate to disrupt the nuclei deep within atoms. It is not an absolute law, because some nuclei decay spontaneously, changing the elemental nature of the atoms in which they reside. At sufficiently high energies the "law" of conservation of elements is grossly violated; indeed, a well-developed theory traces the origin of chemical elements to processes occurring within minutes after the big bang, and in stars and supernova explosions. *See* BIG BANG THEORY; NUCLEOSYNTHESIS; RADIOACTIVITY.

Several conservation laws in particle physics are of the same character: They are useful even though they are not exact because, while known processes violate them, such processes are either unusually slow or require extremely high energy. Examples of such approximate conservation laws are the conservation of strangeness, of charm, and of isospin. *See* CHARM; ELEMENTARY PARTICLE; I-SPIN; STRANGE PARTICLES.

Two laws of conservation of particle type deserve special mention: the conservation of electric charge and the conservation of baryon number.

Conservation of electric charge. This law is believed to be exact. In principle, it is very simple to state, involving only counting. Every kind of elementary particle has a definite electric charge, which is an integer times the charge of the electron. The conservation law simply specifies that in any reaction the total electric charge of the reactants is equal to the total electric charge of the products.

Conservation of electric charge is deeply connected to the principle of electromagnetic gauge invariance and to the foundations of electromagnetic theory. One aspect is that the total charge inside a volume can be inferred by measurements of the electric field at a distant bounding surface, according to Gauss's law. Thus, if the charge suddenly changed it would require an instantaneous change in the electric field far away, contrary to the principle that the speed of light limits the transfer of information. *See* ELECTRIC CHARGE; ELECTRODYNAMICS; GAUGE THEORY.

Conservation of baryon number. This law is also very easy to state, as a counting rule. Among the common so-called elementary particles, protons and neutrons are assigned baryon number one—and their antiparticles baryon number minus one—while electrons, positrons, photons, and pions are assigned baryon number zero. A more modern and fundamental perspective is that quarks are assigned baryon number one-third, antiquarks baryon number minus one-third, and all other fundamental particles zero. In either formulation, the law of conservation of baryon number is simply the statement that, in any reaction, the total baryon number of the reactants is equal to the total baryon number of the products. *See* BARYON; QUARKS.

The most important evidence for the law of conservation of baryon number is the stability of the proton. There is no principle, other than this (or some similar conservation law, such as the conservation of lepton number), that forbids, for example, the decay [reaction (3)] of a proton into a neutral pion and a

$$p \rightarrow \pi^0 + e^+ \qquad (3)$$

positron. Yet, whereas otherwise similar decays take place within a small fraction of a second, the lifetime of the proton is greater than 10^{30} years. Despite its accuracy, the law of conservation of baryon number, unlike the law of conservation of electric charge, is not tied up with any known profound dynamical principles. Indeed, important ideas in modern particle physics definitely suggest that the conservation of baryon number is not exactly valid, and difficult but important experiments are planned to search for small violations of it. *See* PROTON.

Conservation of energy

The principle of conservation of energy states that energy cannot be created or destroyed, although it can be changed from one form to another. Thus in any isolated or closed system, the sum of all forms of energy remains constant. The energy of the system may be interconverted among many different forms—mechanical, electrical, magnetic, thermal, chemical, nuclear, and so on—and as time progresses, it tends to become less and less available; but within the limits of small experimental uncertainty, no change in total amount of energy has been observed in any situation in which it has been possible to ensure that energy has not entered or left the system in the form of work or heat. For a system that is both gaining and losing energy in the form of work and heat, as is true of any machine in operation, the energy principle asserts that the net gain of energy is equal to the total change of the system's internal energy. *See* THERMODYNAMIC PRINCIPLES.

Application to life processes. The energy principle as applied to life processes has also been studied. For instance, the quantity of heat obtained by burning food equivalent to the daily food intake of an animal is found to be equal to the daily amount of energy released by the animal in the forms of heat, work done, and energy in the waste products. (It is assumed that the animal is not gaining or losing weight.) Studies with similar results have also been made of photosynthesis, the process upon which the existence of practically all plant and animal life ultimately depends. *See* METABOLISM; PHOTOSYNTHESIS.

Conservation of mechanical energy. There are many other ways in which the principle of conservation of energy may be stated, depending on the intended application. Examples are the various methods of stating the first law of thermodynamics, the work-kinetic energy theorem, and the assertion that perpetual motion of the first kind is impossible. Of particular interest is the special form of the principle known as the principle of conservation of mechanical energy (kinetic E_k plus potential E_p) of any system of bodies connected together in any way is conserved, provided that the system is free of all frictional forces, including internal friction that could arise during collisions of the bodies of the system. Although frictional or other nonconservative forces are always present in any actual situation, their effects in many cases are so small that the principle of conservation of mechanical energy is a very useful approximation. Thus for a missile or satellite traveling high in space, the dissipative effects arising from such sources as the residual air and meteoric dust are so exceedingly small that the loss of mechanical energy $E_k + E_p$ of the body as it proceeds along its trajectory may, for many purposes, be disregarded. *See* ENERGY; PERPETUAL MOTION.

Mechanical equivalent of heat. The mechanical energy principle is very old, being directly derivable as a theorem from Newton's law of motion. Also very old are the notions that the disappearance of mechanical energy in actual situations is always accompanied by the production of heat and that heat itself is to be ascribed to the random motions of the particles of which matter is composed. But a really clear conception of heat as a form of energy came only near the middle of the nineteenth century, when J. P. Joule and others demonstrated the equivalence of heat and work by showing experimentally that for every definite amount of work done against friction there always appears a definite quantity of heat. The experiments usually were so arranged that the heat generated was absorbed by a given quantity of water, and it was observed that a given expenditure of mechanical energy always produced the same rise of temperature in the water. The resulting numerical relation between quantities of mechanical energy and heat is called the Joule equivalent, or mechanical equivalent of heat. The present accepted value of the 15-degree calorie is $1\ \mathrm{cal}_{15^\circ} = 4.1855 \pm 0.0004$ J; in thermochemical work it is now more common to use the thermochemical calorie, which is defined as $1\ \mathrm{cal} = 4.184$ J exactly.

Conservation of mass-energy. In view of the principle of equivalence of mass and energy in the restricted theory of relativity, the classical principle of conservation of energy must be regarded as a special case of the principle of conservation of mass-energy. However, this more general principle need be invoked only when dealing with certain nuclear phenomena or when speeds comparable with the speed of light (1.86×10^5 mi/s or 3.00×10^5 km/s) are involved. *See* RELATIVITY.

If the mass-energy relation, $E = mc^2$, where c is the speed of light, is considered as providing an equivalence between energy E and mass m in the same sense as the Joule equivalent provides an equivalence between mechanical energy and heat, there results the relation, $1\ \mathrm{kg} = 9 \times 10^{16}$ joules.

Laws of motion. The law of conservation of energy has been established by thousands of meticulous measurements of gains and losses of all known forms of energy. It is now known that the total energy of a properly isolated system remains constant. Some parts or particles of the system may gain energy but others must lose just as much. The actual behavior of all the particles, and thus of the whole system, obeys certain laws of motion. These laws of motion must therefore be such that the energy of the total system is not changed by collisions or other interactions of its parts. It is a remarkable fact that one can test for this property of the laws of motion by a simple mathematical manipulation that is the same for all known laws: classical, relativistic, and quantum mechanical.

The mathematical test is as follows. Replace the variable t, which stands for time, by $t + a$, where a is a constant. If the equations of motion are not changed by such a substitution, it can be proved that the energy of any system governed by these equations is conserved. For example, if the only expression containing time is $t_2 - t_1$, changing t_2 to $t_2 + a$ and t_1 to $t_1 + a$ leaves the expression unchanged. Such expressions are said to be invariant under time displacement. When daylight-saving time goes into effect, every t is changed to $t + 1$ h. It is unnecessary to make this substitution in any known laws of nature, which are all invariant under time displacement. Without such invariance laws of nature would change with the passage of time, and repeating an experiment would have no clear-cut meaning. In fact, science, as it is known today, would not exist.

Conservation of mass

The notion that mass, or matter, can be neither created nor destroyed. According to conservation of mass, reactions and interactions which change the properties of substances leave unchanged their total mass; for instance, when charcoal burns, the mass of all of the products of combustion, such as ashes, soot, and gases, equals the original mass of charcoal and the oxygen with which it reacted.

The special theory of relativity of Albert Einstein, which has been verified by experiment, has shown, however, that the mass of a body changes as the energy possessed by the body changes. Such changes in mass are too small to be detected except in subatomic phenomena. Futhermore, matter may be created, for instance, by the materialization of a photon (quantum of electromagnetic energy) into an electron-positron pair; or it may be destroyed, by the annihilation of this pair of elementary particles to produce a pair of photons. *See* ELECTRON-POSITRON PAIR PRODUCTION; LIGHT; MASS; RELATIVITY.

Leo Nedelsky

Conservation of momentum

The principle that, when a system of masses is subject only to forces that masses of the system exert on one another, the total vector momentum of the system is constant. Since vector momentum is conserved, in problems involving more than one dimension the component of momentum in any direction will remain constant. The principle of conservation of momentum holds generally and is applicable in all fields of physics. In particular, momentum is conserved even if the particles of a system exert forces on one another or if the total mechanical energy is not conserved.

Use of the principle of conservation of momentum is fundamental in the solution of collision problems. *See* COLLISION (PHYSICS).

If a person standing on a well-lubricated cart steps forward, the cart moves backward. One can explain this result by momentum conservation, considering the system to consist of cart and human. If both person and cart are originally at rest, the momentum of the system is zero. If the person then acquires forward momentum by stepping forward, the cart must receive a backward momentum of equal magnitude in order for the system to retain a total momentum of zero.

When the principle of conservation of momentum is applied, care must be taken that the system under consideration is really isolated. For example, when a rough rock rolls down a hill, the isolated system would have to consist of the rock plus the earth, and not the rock alone, since momentum exchanges between the rock and the earth cannot be neglected.

Rocket propulsion. The propulsion of a rocket through space can be explained in terms of momentum conservation. Hot gases produced by the combustion of the fuel are expelled at high speed from the rear of the rocket. Although the total mass of these hot gases may not be large, the gases move with such a high velocity that the total momentum associated with them is appreciable. The momentum of the gases is directed backward. For momentum to be conserved, the rocket must acquire an equal momentum in the forward direction. If the rocket carries all the materials needed for the combustion of its fuel, its propulsion does not require air, and it can move through empty space. *See* PROPULSION; ROCKET.

Exploding bomb. An exploding bomb gives another application of the conservation of momentum. The total resultant vector momentum of all the pieces of the bomb immediately after explosion must equal the momentum of the unexploded bomb just before the explosion. *See* EXPLOSIVE.

Proof of principle. The principle of conservation of momentum follows directly from Newton's second and third laws. While the principle will be proved here only for the straight-line motion of a two-particle system, it can be generalized to systems containing any number of particles. A particle is a mass with dimensions so small that rotational effects are negligible. Momentum will also be conserved for rigid bodies large enough that rotation must be considered, since rigid bodies can be treated as assemblies of many particles.

For the one-dimensional motion of an isolated two-particle system, Newton's third law states that the force F_{12} that particle 1 exerts on particle 2 is equal in magnitude and opposite in direction to the force F_{21} that particle 2 exerts on particle 1. Thus Eq. (1) holds.

$$F_{21} = -F_{12} \tag{1}$$

By use of Newton's second law this equation can be expressed in terms of the momenta m_1v_1 and m_2v_2 of particles 1 and 2, respectively, where m_1, m_2, v_1, and v_2 are the masses and velocities of particles 1 and 2, respectively. Then Eq. (2) holds. Integration

$$m_1\frac{dv_1}{dt} = -m_2\frac{dv_2}{dt} \tag{2}$$

gives Eq. (3), where c is a constant. This equation

$$m_1v_1 + m_2v_2 = c \tag{3}$$

expresses the conservation of momentum for two particles moving in the same straight line.

Finally it should be mentioned that angular and linear momentum are independent quantities. A complete description of a system must include both quantities. The angular momentum of a system is conserved under quite general conditions. *See* ANGULAR MOMENTUM; CONSERVATION OF ENERGY; MOMENTUM.

Paul W. Schmidt

Conservation of resources

Management of the human use of natural resources to provide the maximum benefit to current generations while maintaining capacity to meet the needs of future generations. Conservation includes both the protection and rational use of natural resources.

Natural resources. Earth's natural resources are either nonrenewable, such as minerals, oil, gas, and coal, or renewable, such as water, timber, fisheries, and agricultural crops. Natural resources are the basic goods and services that sustain human societies. Renewable resources play central roles in providing air, water, and food. Nonrenewable resources provide the energy essential for industrial economies and are the source of important products ranging from iron tools to silicon chips.

Although humans are entirely dependent upon Earth's natural resources, the combination of growing populations and increasing levels of resource consumption is now degrading and depleting the natural resource base. The world's population stood at 850 million at the onset of the industrial age, sharing the Earth with life forms nearly as diverse as the planet has ever possessed. The global population has grown to nearly seven times as large (6 billion), and the level of consumption of resources is far greater. This human pressure now exceeds the carrying capacity of many natural resources.

Nonrenewable. Nonrenewable resources, such as fossil fuels, are replaced over geologic time scales of tens of millions of years. Human societies will eventually use up all of the economically available stock of many nonrenewable resources, such as oil. Peak oil production in the United States, for example, occurred in 1984 and has since declined significantly as the most easily accessible oil fields have been drained. Clearly, because the stock of nonrenewable resources is fixed, future generations will inherit a world depleted of those important resources. Conservation thus entails actions to use these resources most efficiently and thereby extend their life as long as possible. By recycling aluminum, for example, the same piece of material is reused in a series of products, reducing the amount of aluminum ore that must be mined. Similarly, energy-efficient products help to conserve fossil fuels since the same energy services, such as lighting or transportation, can be attained with smaller amounts of fuel. *See* HUMAN ECOLOGY.

It may be expected that the biggest challenge of resource conservation would involve nonrenewable resources, since renewable resources can replenish themselves after harvesting. In fact, the opposite is the case. Historically, when nonrenewable resources have been depleted, new technologies have been developed that effectively substitute for the depleted resources. Indeed, new technologies have often reduced pressure on these resources even before they are fully depleted. Fiber optics, for example, has substituted for copper in many electrical applications, and it is anticipated that renewable sources of energy, such as photovoltaic cells, wind power, and hydropower, will ultimately take the place of fossil fuels when stocks are depleted. Renewable resources, in contrast, can be seriously depleted if they are subjected to excessive harvest or otherwise degraded, and no substitutes are available for, say, clean water or food products such as fish or agricultural crops. Moreover, when the misuse of biological resources causes the complete extinction of a species or the loss of a particular habitat, there can be no substitute for the esthetic and moral values that many people associate with that diversity of life.

Renewable. The urgent need to conserve renewable resources, particularly biological resources, can be seen in trends associated with major ecosystems. For example, 60% of the world's most important fish stocks are now overfished. Well over one-half of the world's coral reefs are at risk of degradation from human activities. The world has lost nearly half of its original forest cover, and each year an additional 12 million hectares (29.7 million acres) are deforested. These pressures of overharvesting and habitat loss, combined with other pressures such as pollution and the introduction of exotic species (which often outcompete or otherwise threaten native species), are now depleting the very building blocks of living natural resources—the diversity of genes, species, and ecosystems that constitute living systems. *See* ECOSYSTEM; REEF.

The diversity of life is threatened with a massive extinction that could rival the loss of diversity that took place some 65 million years ago around the time that dinosaurs became extinct. Since the 1600s, nearly 500 animal and 650 plant species (mostly vertebrates and flowering plants) are known to have become extinct, and many more species undoubtedly became extinct before they were even identified. The rate of extinctions in groups such as birds and mammals has increased dramatically during this period. Not all species extinctions are necessarily caused by humans. Species went extinct long before humans appeared on the planet, but the background rate of natural extinction is estimated to be nearly 100 times slower than current rates. If the current rate of loss of closed tropical forest (about 1% globally per year) continues until 2030, the number of species these habitats will support will be reduced by 5–10%. This could amount to an additional tens of thousands of extinctions in groups of organisms such as plants.

Current overuse and misuse of renewable living resources cannot be sustained and poses significant economic costs to societies. A critical element of ensuring a sustainable biosphere—one that continues to provide the goods and services from living systems upon which society depends—is thus the conservation of natural resources. "Conservation" is sometimes used synonymously with "protection." More appropriately, however, it refers to the protection and sustainable use of resources. Critical elements of the effective conservation of natural resources include sustainable resource management, establishment of protected areas, and ex situ (off-site) conservation.

Resource management. Some of the most pressing resource conservation problems stem directly from the mismanagement of important biological resources. Many marine fisheries are being depleted, for example, because of significant overcapacity of fishing vessels and a failure of resource managers to closely regulate the harvest. In theory, a renewable resource stock could be harvested at its maximum sustainable yield and maintain constant average annual productivity in perpetuity. In practice, however, fishery harvest levels are often set too high and, in many regions, enforcement is weak, with the result that fish stocks are driven to low levels. A similar problem occurs in relation to the management of timber resources. Short-term economic incentives encourage cutting as many trees as quickly as possible. Without effective resource management policies and enforcement, sound stewardship of forest resources is difficult. *See* FISHERIES ECOLOGY; FOREST MANAGEMENT.

Early conservation efforts primarily involved regulation of wildlife harvests. Historically, hunters often depleted game or commercial species until they were effectively extinct (or completely extinct in the case of such species as passenger pigeons in the United States or the great auk in the north Atlantic). However, in the last half century the development and application of principles of wildlife management has led to more effective regulation of harvests. It is now rare that commercial harvest of individual species threatens a species with extinction, although, as in the case of fisheries, it is still common for some species to be harvested at levels that substantially deplete the population. *See* FOOD WEB.

A number of steps are being taken to improve resource conservation in managed ecosystems. (1) Considerable scientific research has been undertaken to better understand the natural variability and productivity of economically important resources. (2) Many national and local governments have enacted regulations for resource management practices on public and private lands. These include laws regulating management practices (for example, laws that require timber companies to leave buffers of trees standing near rivers and creeks), as well as laws protecting specific resources, such as endangered species. (3) Problems of resource mismanagement often have stemmed from the fact that local residents, who would have a greater incentive to manage for long-term production, had little rights to local resources, whereas the companies or individuals with rights to harvest resources found it economically beneficial to deplete the resource and move on to new regions. In some of these regions, programs recently have been established either to involve local communities more directly in resource management decisions or to return to them resource ownership rights. (4) Efforts are under way to manage resources on a regional or ecosystem scale using methods that have come to be known as ecosystem management or bioregional management. Since the actions taken in one location often influence species and processes in other locations, traditional resource conservation strategies were often focused too narrowly to succeed.

Protected areas. Regardless of the success in better managing resources, the fact remains that human activities now have reshaped much of the land surface to meet human needs. Human changes in land use and land cover, for example, have transformed one-third to one-half of Earth's icefree surface. This is an area equal to North America, South America, and Africa combined. Clearly, without significant management interventions, many species that once lived in these transformed regions are likely to become extinct. One of the most effective strategies to protect species from extinction is the establishment of protected areas designed to maintain populations of a significant fraction of the native species in a region. Worldwide, 9832 protected areas, totaling more than 9.25 million square kilometers (24 million square miles), cover about 8% of land on Earth. Although these sites are not all managed exclusively for the conservation of species, they play an essential role in protecting species from extinction.

Many problems remain, however, in ensuring effective protected-area conservation networks. For example, several regions with important biodiversity still lack effective protected-area networks. In addition, where protected areas have been designated, human and financial resources are not always available to effectively manage the areas, creating "paper parks." Particularly in developing countries, the establishment of protected areas has resulted in conflicts with local communities that had been dependent upon the areas for their livelihood. These challenges are now being addressed through international efforts, such as the International Convention on Biological Diversity, which aims to increase the financing available for protected areas and to integrate conservation and development needs.

Ex situ conservation. The most effective and efficient means for conserving biological resources is to prevent the loss of important habitats and to manage resources for their long-term productivity of goods and services. In many cases, effective conservation in the field is no longer possible. For example, some species have been so depleted that only a few individuals remain in their natural habitat. In these cases, there is no alternative to the ex situ conservation of species and genetic resources in zoos, botanical gardens, and seed banks. Ex situ collections play important conservation roles as well as serving in public education and research. Worldwide, zoos contain more than 3000 species of birds, 1000 species of mammals, and 1200 species of reptiles, and botanic gardens are believed to hold nearly 80,000 species of plants. These collections hold many endangered species, some of which have breeding populations and thus could potentially be returned to the wild. Genebanks hold an important collection of the genetic diversity of crops and livestock.

Much can be done to better conserve the world's natural resources, but in the face of growing pressure on these resources the challenge is growing. One of the most important steps to bolster any conservation activity is to learn more about the target resource. Scientists have identified only about 1.7 million of an estimated 13 million species of plants, animals, fungi, and microbes on Earth. Many more species are described each year. Unless basic scientific information on this biodiversity is obtained, it is unlikely that conservation will be effective. *See* LAND-USE PLANNING; MINERAL RESOURCES; SOIL CONSERVATION; WATER CONSERVATION.

Constellation

One of the 88 areas into which the sky is divided. Each constellation has a name that reflects its earliest recognition. Though pictures are associated with the constellations, they have no official status, and constellations have been depicted differently by different artists.

The identifications of the constellations are lost in antiquity. No doubt ancient peoples associated myths with the heavens and imagined pictures connecting or surrounding the bright stars. The names of some constellations have been handed down by the Chaldeans or Egyptians, but most of those that can be seen from midnorthern latitudes have Greek or Roman origins. Star maps are found in various cultures, and constellation figures and myths usually differ from those found in Greek and Roman sources.

Star catalogs and atlases. The catalog of Ptolemy, in Hellenic Alexandria in the second century of the Christian Era, included over 1000 stars grouped into 48 constellations. Many of today's images of constellations are derived from the beautiful engravings by Alexander Mair in Johann Bayer's *Uranometria* (1603) [**Fig. 1**]. Bayer included the constellations listed by Ptolemy and also named 12 new ones containing stars observed on expeditions to the Southern Hemisphere. Bayer originated the scheme of labeling individual stars in constellations with Greek and other letters, roughly in order of brightness, and the genitive form of the constellation name. For example, the bright star Betelgeuse (the second brightest in the constellation Orion) is alpha Orionis (alpha of Orion), and Sirius, the brightest star in the sky, is alpha Canis Majoris (alpha of the Big Dog). In some cases, Bayer labeled stars in order around figures in the sky, as for the Big Dipper. Bayer also used some uppercase (as in the star P Cygni) and lowercase Latin letters. In 1624, Jakob Bartsch placed three new constellations in gaps in Bayer's atlas and separated the southern constellation Crux from Centaurus. Coma Berenices (Berenice's Hair) was also added at about this time, reportedly by Tycho Brahe.

Johannes Hevelius added nine more southern constellations in his 1690 star atlas, *Firmamentum Sobiescianum sive Uranographia*. His figures represent the view of a celestial globe from the outside and thus are reversed from Bayer's. Nicolas Louis de Lacaille added 14 constellations in 1763 from his expedition to the Cape of Good Hope, using names reflecting the mechanical age, such as air pump, microscope, and telescope.

John Flamsteed (1729) and Johan Elert Bode (1801) produced other elegant star atlases, with engravings of constellations. Since the mid-1800s, Ptolemy's largest constellation, Argo Navis, has been divided into Carina, the keel; Puppis, the stern; and Vela, the sails.

Modern star atlases, from the *Millennium Star Atlas* to the *Guide Star Catalogue* compiled in the late 1980s for the use of observers with the Hubble Space Telescope, do not usually show the figures of tradition. *See* ASTRONOMICAL ATLASES; ASTRONOMICAL CATALOGS.

International agreement. In 1928, the International Astronomical Union formally accepted the division

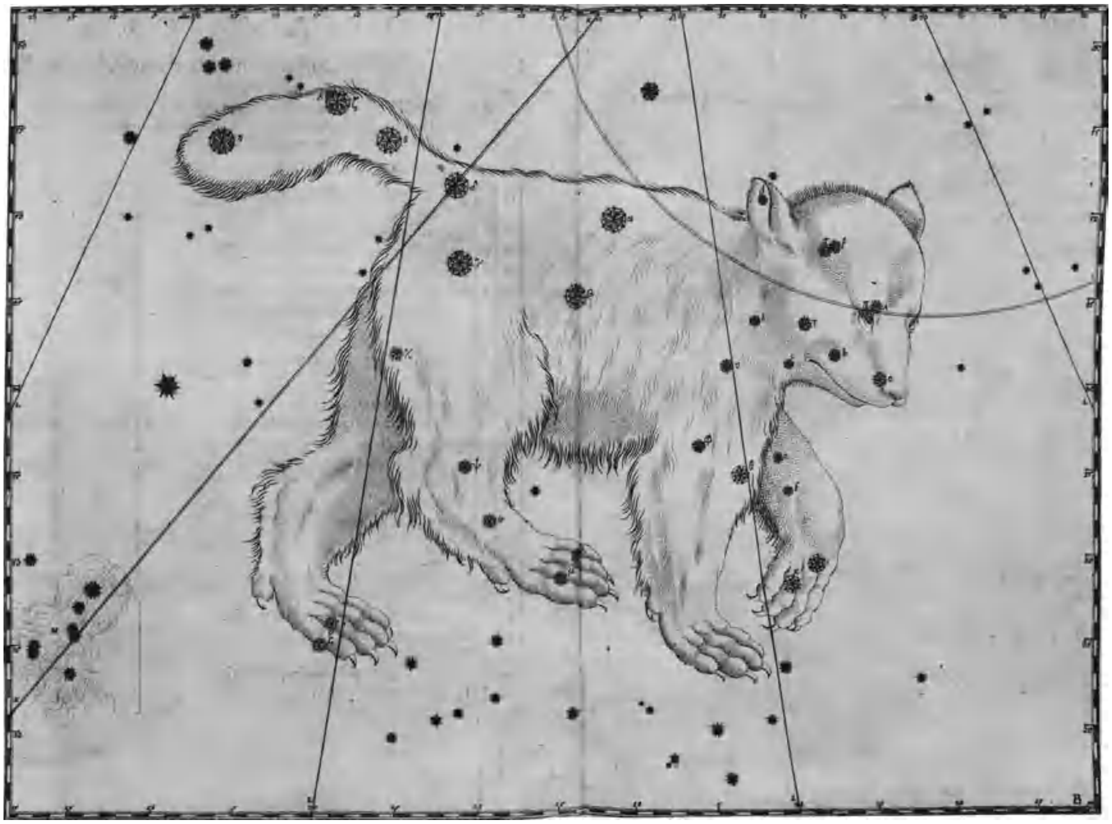

Fig. 1. The constellation Ursa Major from Bayer's star atlas (1603). (*Jay M. Pasachoff collection*)

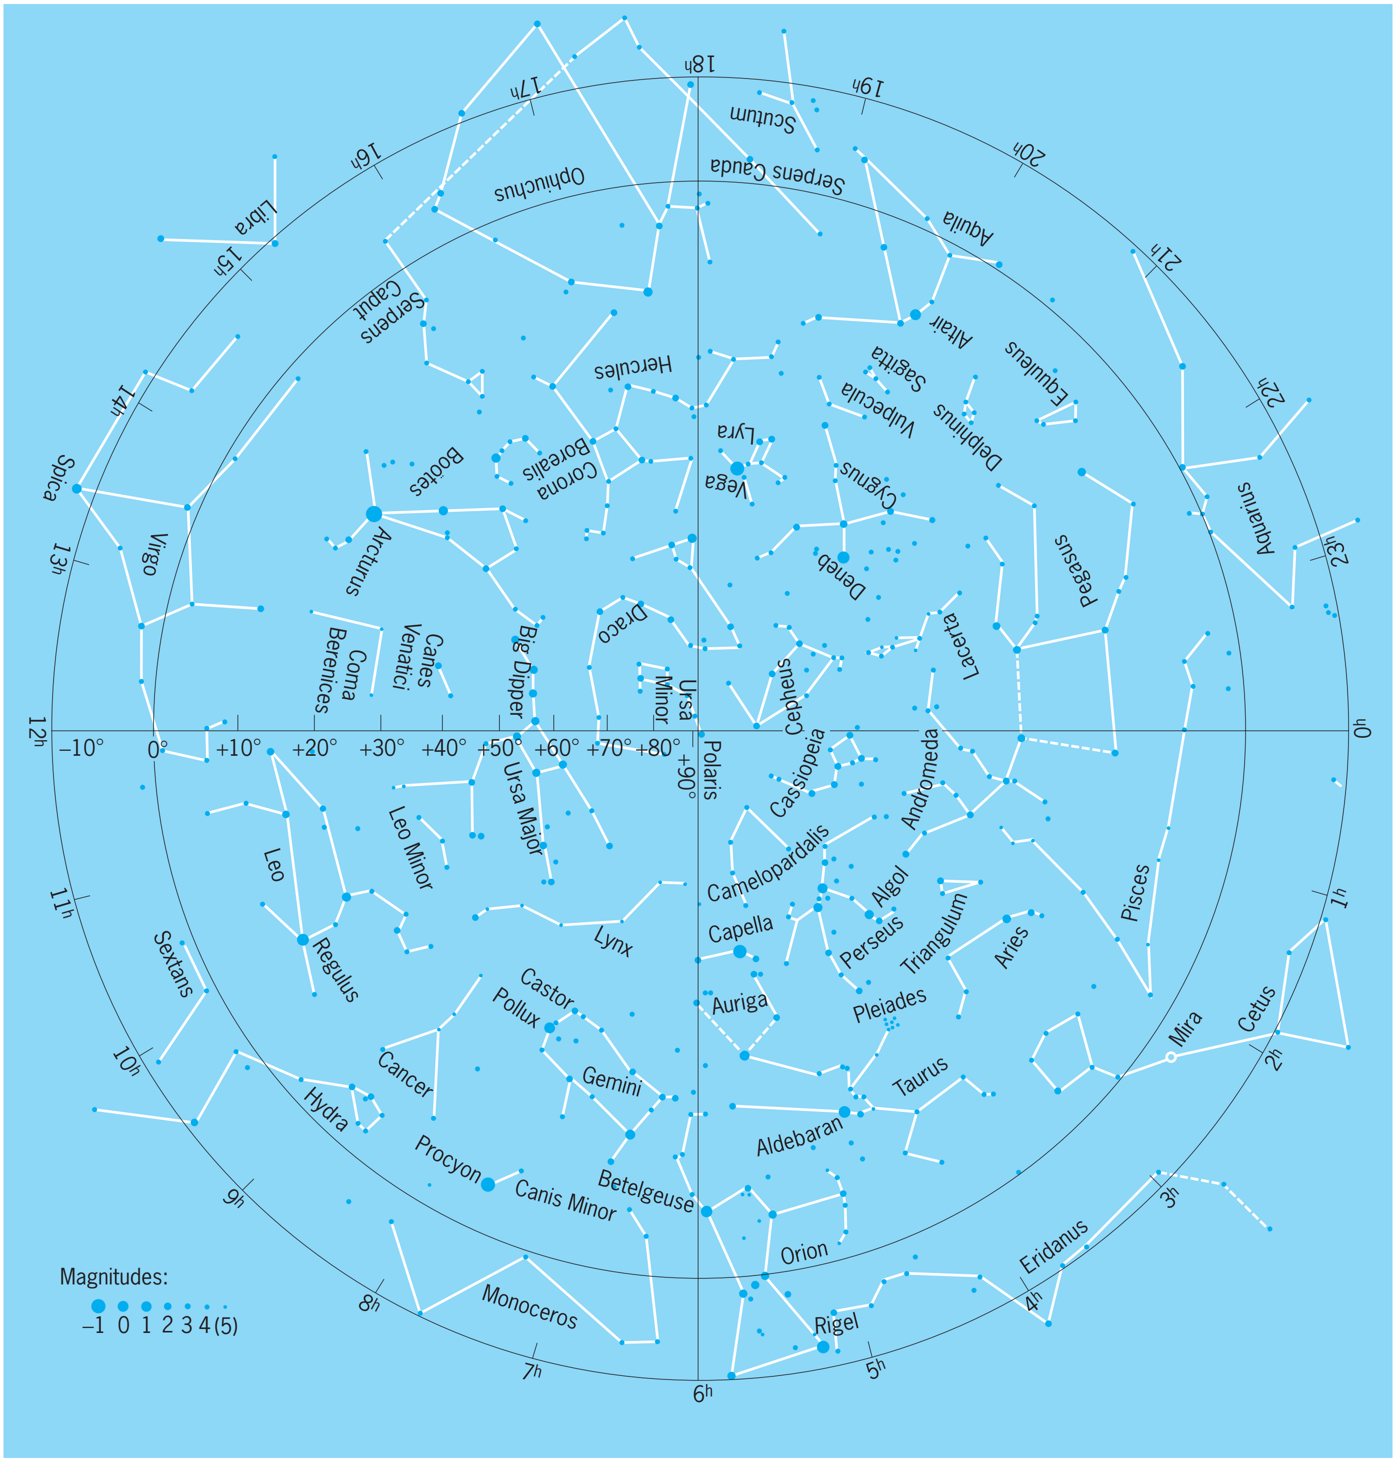

Fig. 2. Constellations of the northern hemisphere; brighter stars are shown by larger dots. (*After J. M. Pasachoff, A Field Guide to the Stars and Planets, Houghton Mifflin, 4th ed., 2000*)

of the sky into 88 constellations (see **table**), with the final list provided 2 years later; each star now falls in only one constellation (**Figs. 2** and **3**). The boundaries follow north-south or east-west celestial coordinates (right ascension and declination lines) from the year 1875; because of precession, the current boundaries do not match rounded values of celestial coordinates. *See* ASTRONOMICAL COORDINATE SYSTEMS; PRECESSION OF EQUINOXES.

Asterisms. Some of the most familiar patterns in the sky are asterisms rather than constellations. For example, the asterism known as the Big Dipper is part of the constellation Ursa Major. The asterism known as the Great Square of Pegasus has three of its corners in Pegasus but the fourth in Andromeda. The Northern Cross is made of stars in Cygnus.

Zodiac. The Sun, the Moon, and the planets move through a band in the sky known as the ecliptic. The

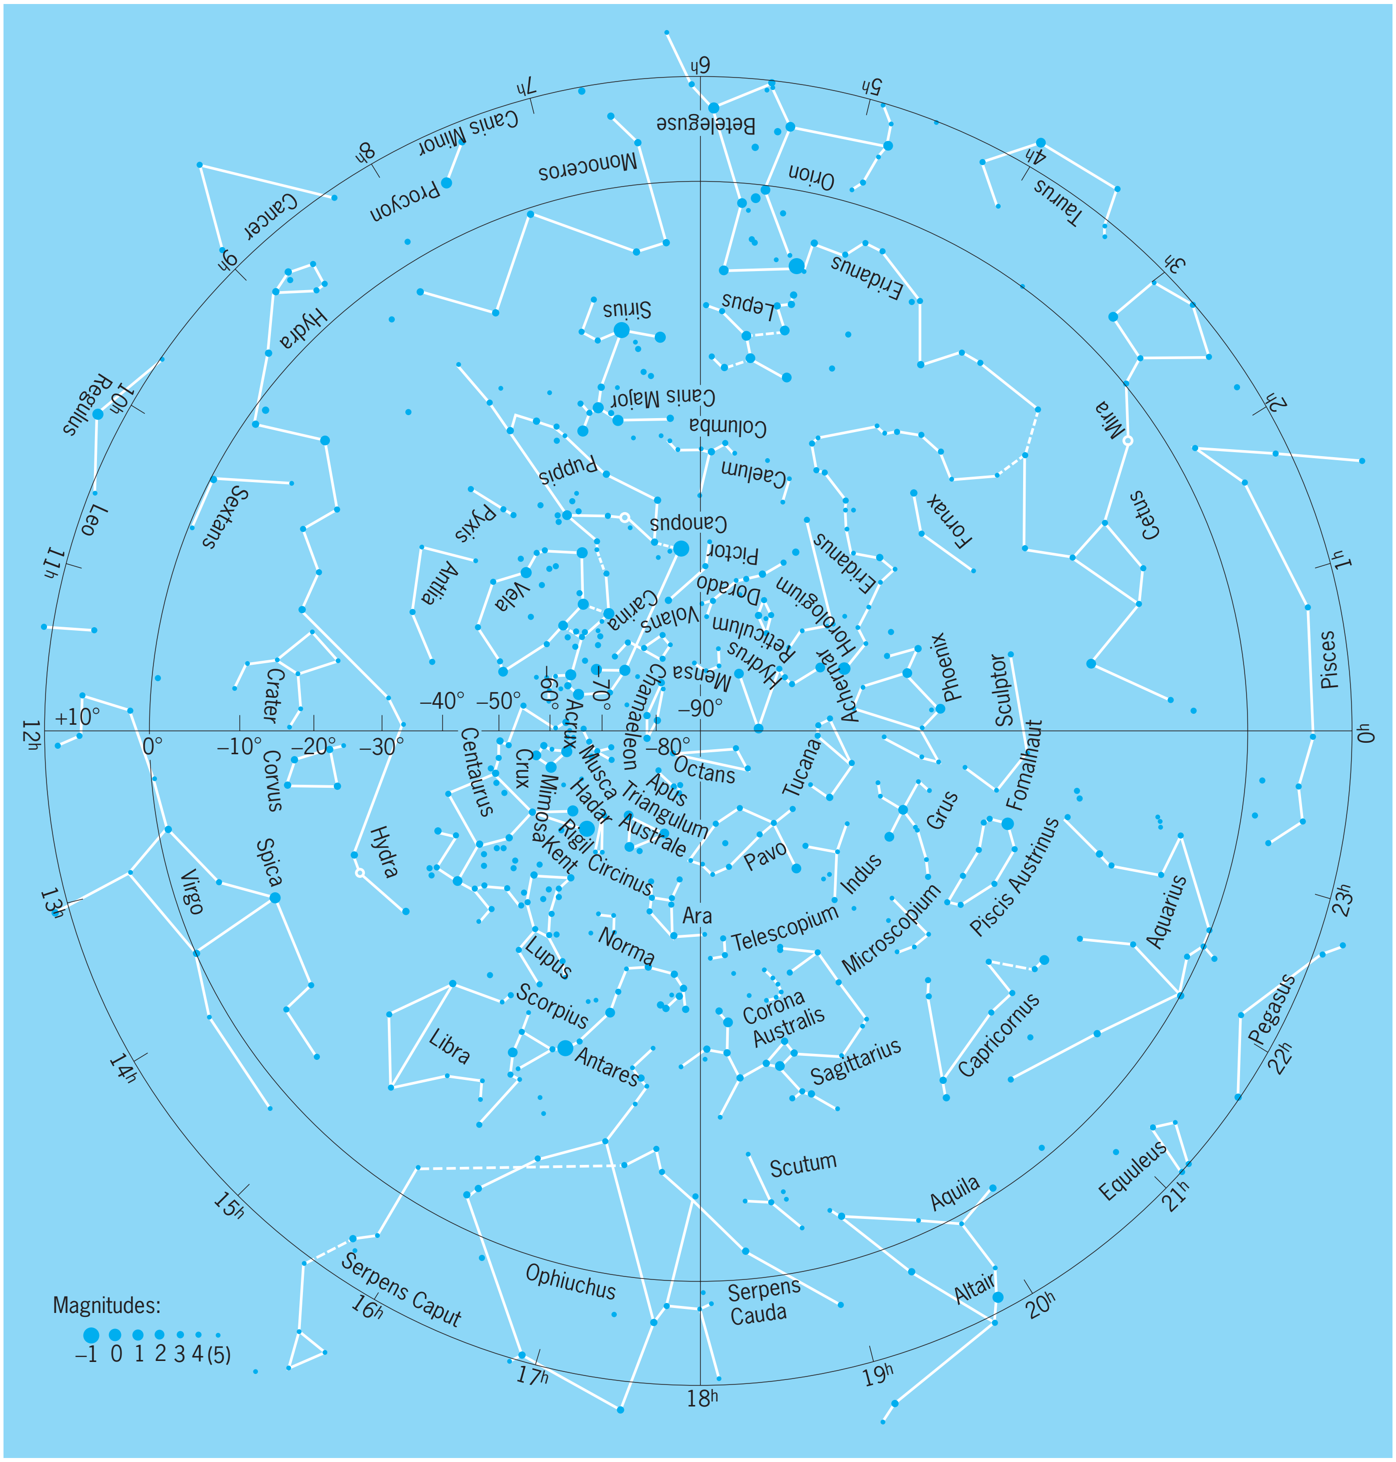

Fig. 3. Constellations of the southern hemisphere; brighter stars are shown by larger dots. (*After J. M. Pasachoff, A Field Guide to the Stars and Planets, Houghton Mifflin, 4th ed., 2000*)

constellations that fall close to the ecliptic through which the Sun traditionally moves are known as the zodiac. Actually, the Sun moves through 13 constellations, and precession has changed the dates at which the Sun passes through the zodiacal constellations. The intersection of the ecliptic and the celestial equator (the extension of the Earth's Equator into the sky) is known as the vernal equinox, or the first point of Aries. It has been used to mark the zero point of the celestial coordinate system. Westward from Aries, the zodiacal constellations are Taurus, the Bull; Gemini, the Twins; Cancer, the Crab; Leo, the Lion; Virgo, the Virgin; Libra, the Scales; Scorpius, the Scorpion; Sagittarius, the Archer; Capricornus, the Seat Goat; Aquarius, the Water Bearer; and Pisces, the Fish. *See* ECLIPTIC; EQUINOX; ZODIAC.

With the advent of equatorial drives on telescopes, astronomers no longer use the constellations to

The constellations[*]

Latin name	Genitive	Abbreviation	English translation
Andromeda	Andromedae	And	Andromeda[†]
Antlia	Antliae	Ant	Pump
Apus	Apodis	Aps	Bird of Paradise
Aquarius	Aquarii	Aqr	Water Bearer
Aquila	Aquilae	Aql	Eagle
Ara	Arae	Ara	Altar
Aries	Arietis	Ari	Ram
Auriga	Aurigae	Aur	Charioteer
Boötes	Boötes	Boo	Herdsman
Caelum	Caeli	Cae	Chisel
Camelopardalis	Camelopardalis	Cam	Giraffe
Cancer	Cancri	Cnc	Crab
Canes Venatici	Canum Venaticorum	CVn	Hunting Dogs
Canis Major	Canis Majoris	CMa	Big Dog
Canis Minor	Canis Minoris	CMi	Little Dog
Capricornus	Capricorni	Cap	Goat
Carina	Carinae	Car	Ship's Keel[‡]

Constraint

A restriction on the natural degrees of freedom of a system. If n and m are the numbers of the natural and actual degrees of freedom, the difference $n - m$ is the number of constraints. In principle $n = 3N$, where N is the number of particles, for example, atoms. In practice n is determined by the number of effectively rigid components. *See* DEGREE OF FREEDOM (MECHANICS).

A holonomic system is one in which the n original coordinates can be expressed in terms of m independent coordinates and possibly also the time. It is characterized by frictionless contacts and inextensible linkages. The new coordinates, $q_1, q_2, \ldots, q_m$, are called generalized coordinates. The equations of equilibrium and of motion may be expressed in terms of these coordinates. *See* LAGRANGE'S EQUATIONS.

Nonholonomic systems cannot be reduced to independent coordinates because the constraints are not on the n coordinate values themselves but on their possible changes. For example, an ice skate may point in all directions but at each position it must point along its path. This is a condition between changes (dx,dy) in the two position coordinates (x,y) and the direction angle θ, as in Eq. (1). This cannot

$$dy = \tan\theta \, dx \tag{1}$$

be put in an integrated form, as in Eq. (2), since a

$$f(x, y, \theta) = 0 \tag{2}$$

skater can pass in different directions repeatedly over a point.

The static equilibrium conditions of a constrained system under impressed forces F_1, F_2, and so on are contained in a general statement, the principle of virtual work or virtual displacement. *See* STATICS; VIRTUAL WORK PRINCIPLE.

A moving constraint is one which changes with time, as in the case of a system on a moving platform. Moving constraints differ from the stationary constraints of static equilibrium in being able to do work. For example, a mass constrained to move on the floor of a rising elevator is carried also in the direction of the (vertical) force of constraint which does work on it. Bernard Goodman

Construction engineering

A specialized branch of civil engineering concerned with the planning, execution, and control of construction operations for such projects as highways, buildings, dams, airports, and utility lines.

Planning consists of scheduling the work to be done and selecting the most suitable construction methods and equipment for the project. Execution requires the timely mobilization of all drawings, layouts, and materials on the job to prevent delays to the work. Control consists of analyzing progress and cost to ensure that the project will be done on schedule and within the estimated cost.

Planning. The planning phase starts with a detailed study of construction plans and specifications. From this study a list of all items of work is prepared, and related items are then grouped together for listing on a master schedule. A sequence of construction and the time to be allotted for each item is then indicated. The method of operation and the equipment to be used for the individual work items are selected to satisfy the schedule and the character of the project at the lowest possible cost. *See* CONSTRUCTION EQUIPMENT; CONSTRUCTION METHODS.

The amount of time allotted for a certain operation and the selection of methods of operation and equipment are generally determined by the equipment that is readily available to the contractor. After the master or general construction schedule has been drawn up, subsidiary detailed schedules or forecasts are prepared from the master schedule. These include individual schedules for procurement of material, equipment, and labor, as well as forecasts of cost and income.

Execution. The speedy execution of the project requires the ready supply of all materials, equipment, and labor when needed. The construction engineer is generally responsible for initiating the purchase of most construction materials and expediting their delivery to the project. Some materials, such as structural steel and mechanical equipment, require partial or complete fabrication by a supplier. For these fabricated materials the engineer must prepare or check all fabrication drawings for accuracy and case of assembly and often inspect the supplier's fabrication.

Other construction engineering duties are the layout of the work by surveying methods, the preparation of detail drawings to clarify the design engineer's drawings for the construction crews, and the inspection of the work to ensure that it complies with plans and specifications.

On most large projects it is necessary to design and prepare construction drawings for temporary construction facilities, such as drainage structures, access roads, office and storage buildings, formwork, and cofferdams. Other problems are the selection of electrical and mechanical equipment and the design of structural features for concrete material processing and mixing plants and for compressed air, water, and electrical distribution systems.

Control. Progress control is obtained by comparing actual performance on the work against the desired performance set up on the master or detailed schedules. Since delay on one feature of the project could easily affect the entire job, it is often necessary to add equipment or crews to speed up the work. *See* PERT.

Cost control is obtained by comparing actual unit costs for individual work items against estimated or budgeted unit costs, which are set up at the beginning of the work. A unit cost is obtained by dividing the total cost of an operation by the number of units in that operation.

Typical units are cubic yards for excavation or concrete work and tons for structural steel. The actual unit cost for any item at any time is obtained by dividing the accumulated costs charged to that item by the accumulated units of work performed.

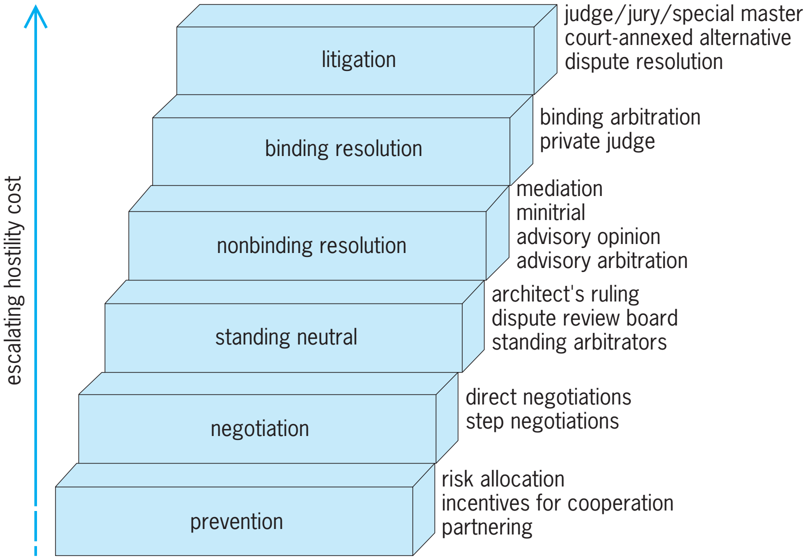
Individual work item costs are obtained by periodically distributing job costs, such as payroll and invoices to the various work item accounts. Payroll and equipment rental charges are distributed with the aid of time cards prepared by crew forepersons. The cards indicate the time spent by the job crews and equipment on the different elements of the work. The allocation of material costs is based on the quantity of each type of material used for each specific item.

When the comparison of actual and estimated unit costs indicates an overrun, an analysis is made to pinpoint the cause. If the overrun is in equipment costs, it may be that the equipment has insufficient capacity or that it is not working properly. If the overrun is in labor costs, it may be that the crews have too many workers, lack of proper supervision, or are being delayed for lack of materials or layout. In such cases time studies are invaluable in analyzing productivity. William Hershleder

Legal aspects. The construction industry is structured by contracts and other legal obligations. Construction company managers are in daily contact with legal requirements that relate to the contractual provisions of the projects that they are designing or constructing. Other legal considerations relate to subcontractor and materials procurement, the law applied to labor relations, and the legal form of a given company's organization. A firm knowledge of the law is absolutely necessary.

The relationship between owner, designer, and constructor has become so complex and open to misunderstandings that a formal legal framework for performing a given project is essential. Projects are governed by a number of legally binding documents. The construction contract typically consists of an agreement, a description of the general conditions for the project, special or supplementary conditions directly related to the project, and a listing of technical requirements or specifications. These documents, together with the project drawings, provide a legally binding description of the project and establish the relationships between the parties to the contract. On large projects this set of documents can be very large and must be understood in detail by the construction management.

It is not uncommon for disputes to arise regarding the legal interpretation of the contract provisions. In many cases, this has led to an adversarial relationship between the owner, designer, and constructor. The contract itself contains mechanisms for the resolution of disputes. Usually, it is beneficial for all parties to negotiate and to come to a mutual agreement. In extreme cases, the parties become so confrontational that a third party is required to resolve the



Steps in resolving a construction dispute.

conflict. In the past, this has resulted in the dispute being presented to a civil court in the form of a claim, with a judge or jury deciding the outcome. In some cases, the contract provides that arbitration will be utilized by the parties to settle disputes. In the United States, the American Arbitration Association (AAA) has developed comprehensive procedures for the reconciliation of contract disputes. Other methods of dispute resolution are shown in the **illustration**.

A large body of law regulates the interactions between workers and management as well as working conditions at the construction site. In the United States, labor laws pertain to the operation of labor unions and specific issues such as minimum pay rates on federally funded projects (Davis Bacon Act). The National Labor Relations Act and other laws established the National Labor Relations Board (NLRB), which acts to resolve disputes between labor and management. The construction worksite is regulated by the Occupational Safety and Health Act (OSHA), originally enacted in 1970. This law requires all employers to provide a safe workplace free of hazards that could cause serious harm to employees. Daniel W. Halpin

Construction equipment

A wide variety of relatively heavy machines which perform specific construction (or demolition) functions under power. The power plant (which is treated in later paragraphs) is commonly an integral part of an individual machine, although in some cases it is contained in a separate prime mover, for example, a towed wagon or roller. It is customary to classify construction machines in accordance with their functions such as hoisting, excavating, hauling, grading, paving, drilling, or pile driving. There have been few changes for many years in the basic types of machines available for specific jobs, and few in the basic configurations of those that have long been available. Design emphasis for new machines is on modifications that increase speed, efficiency, and accuracy (particularly through more sophisticated controls); that improve operator comfort and safety; and that protect the public through sound attenuation and emission control. The selection of a machine for a specific job is mainly a question of economics and depends primarily on the ability of the machine to complete the job efficiently, and secondarily on its availability.

Hoisting equipment. This class of equipment is used to raise or lower materials from one elevation to another or to move them from one point to another over an obstruction. The main types of hoisting equipment are derricks, cableways, cranes, elevators, and conveyors. *See* BULK-HANDLING MACHINES; HOISTING MACHINES.

Derricks. The two main types of derricks are the guy and the stiff-leg. The former has a mast that is held in a vertical position by guy wires and a boom that can rotate with the mast 360°. In the stiff-leg the mast is tied to two or more rigid structural members, and the rotation of the boom is limited by the position of these members. The derrick is practical only where little mobility is required as in some types of steel erection, excavation of a shaft, or hoisting of materials through a shaft. *See* DERRICK.

Cableway. This is a combination hoist and tram system comprising a trolley that runs on main load cables stretched between two or more towers which may be stationary or tiltable. Since even with towers that can be tilted slightly from side to side the cableway is limited almost entirely to linear movement of materials, its use in construction is restricted to dams, to some dredging and drag-line operations, and in special cases to bridges.

Elevator. The construction elevator, like the passenger elevator, consists of a car or platform that operates within a structural framework and is raised and lowered by cables. Because the elevator can move materials only in a vertical linear direction and because the materials so moved must subsequently be moved horizontally by other means, the elevator is limited to moving relatively light materials on jobs of small areas. *See* ELEVATING MACHINES.

Crane. A crane is basically a fast-moving boom mounted on a frame containing the power supply and mechanisms for moving the boom and for raising and lowering the load-bearing cables that run through sheaves at the top of the boom. Once all cranes in the United States were mobile; that is, they were attached to a chassis mounted on pneumatic tires, crawler treads, or flanged (railroad) wheels. This type of machine is still predominant in all

Fig. 1. Hydraulic truck crane.

operations where mobility is a must. **Figure 1** shows a hydraulic truck crane. However, European and Australian tower cranes and climbing cranes have become popular throughout the United States and the world for high-rise building construction where mobility requirements are negligible. These machines, which carry horizontal or diagonal masts or booms, can “grow” with the construction by climbing with it or by adding sections to their own towers. They have the fast boom and line action of the mobile crane but are not restricted in boom reach.

Conveyor. Occasionally a conveyor is used to raise materials needed for construction of low buildings. This machine, which has a movable endless belt mounted on a frame, can carry only light loads such as bricks and cement sacks and is not practical for buildings of more than one or two floors. A conveyor carrying rock over a railroad yard is shown in **Fig. 2**.

Excavating equipment. This type of equipment is divided into two main classes: standard land excavators and marine dredges; each has many variations.

Standard land excavator. This comprises machines that merely dig earth and rock and place it in separate hauling units, as well as those that pick up and transport the materials. Among the former are power shovels, draglines, backhoes, cranes with a variety of buckets, front-end loaders, excavating belt loaders, trenchers, and the continuous bucket excavator. The second group includes such machines as bulldozers, scrapers of various types, and sometimes the front-end loader.

Power shovel. This has for years been regarded as the most efficient machine for digging into vertical banks and for handling heavy rock. Generally mounted on crawler treads, the power shovel carries a short boom on which rides a movable dipper stick carrying an open-topped bucket. The bucket digs in an upward direction away from the machine and dumps its load by lowering the front of its hinged bottom. **Figure 3** shows power shovels in the process of loading dump trucks.

Front-end loader. This has made heavy inroads into the domain of the power shovel and in time may well replace it in all but the biggest operations. Loaders are built that can handle buckets having 12, 14, and 24 yd^3 (9, 11, and 18 m^3) capacities. The loader, basically an articulated bucket mounted on a series of movable arms at the front of a crawler or rubber-tired tractor, has the advantage of mobility, speed, economy of cost and operation, and light weight. A loader of any given capacity can cost as little as one-half or even one-third as much as a power shovel of the same capacity and requires only one person to run it as opposed to the two or more normally required for the power shovel. **Figure 4** shows a loader operating in a swamp.

Backhoe. This is fundamentally an upside-down power shovel. Its bucket, mounted on a hinged boom, digs upward toward the machine and unloads by being inverted over the dumping point. Backhoes are manufactured as individual machines but more often are attachments mounted on a crawler crane, a rubber-tired truck crane, or a tractor (which usually has a front-end loader bucket at the other end). It is particularly well adapted to the digging of deep trenches.

Dragline. This is a four-sided bucket that is used mainly on soil too wet to support an excavating machine. It is usually carried on a mobile machine mounting a crane boom, but it can also be worked from a cableway where excavating distances are great. The bucket is carried or cast to a point ahead of its support and dropped to the ground. The dragline is designed to excavate and to fill itself as it is drawn across the ground. It empties when its front end is lowered.

Fig. 2. Conveyor carrying rock over a railroad yard.

Fig. 3. Power shovels loading over-the-road rear-dump trucks.

Clamshell. A clamshell is a two-sided bucket that can dig only in a vertical direction. The bucket is dropped while its leaves are open and digs as they close. Formerly, clamshells were suspended from cables on cranes or gantries and worked only under their own weight. Therefore they were imprecise in digging and were practical only in relatively soft soil or loose rock. Presently many clamshell buckets are attached directly to powered booms, are closed hydraulically, and can work with greater precision in dense soils.

Orange peel. This is a multileaved bucket, generally round in configuration. It is normally cable-supported and, like the clamshell, works under its own weight. Like the clamshell, however, it too is being mounted on powered booms and closed hydraulically. One of the commonest uses of the orange peel is the cleaning of small shafts, sewers, and storm drains. Larger sizes are often used for handling broken rock.

Grapple. This group includes a wide variety of special-purpose tined grabs that work on the principle of the clamshell and orange peel. The grapple is used mainly for handling rock, pipe, and logs.

Excavating belt loader. This type of machine is used mainly for loading granular materials from a stockpile, or as a vertical or inclined belt, or as a pair of chains on which are mounted small buckets. Some belt loaders are mobile and can move into a bank under their own power as the material is moved. Others are fixed and are fed by bulldozers which push material onto the belt from above. Their advantage over most excavators lies in their continuous operation.

Trenching machine. This equipment for digging trenches ranges in size from small hand-pushed units

Fig. 4. A loader operating in a swamp.

Fig. 5. A scraper in operation, as it is pulled by a tractor.

used for getting small pipes from streets to private homes to monsters of many tons capable of cutting a 4-ft-wide (1.2-m) swath for 2000 mi (3200 km) of transcontinental pipelines. All, however, work on basically the same principle: A series of buckets, mounted on a chair or a wheel, lift dirt from the ground and deposit it alongside the trench being dug.

Continuous bucket excavator. This excavator works like a trenching machine but is designed to remove earth and loose rock from a wider area and at shallower depths. These machines are self-propelled; they can load trucks in a continuous operation and can switch from a filled to an empty truck in less than 2 s. The continuity of loading and the absence of intermittent activities, such as those necessary in shovel or loader operations, make the continuous bucket excavator a fast, economical machine for large excavating jobs.

Combination excavators and haulers. This classification of construction equipment includes bulldozers, carrying scrapers, self-loading or elevating scrapers, and sometimes front-end loaders.

Bulldozer. This is a curved blade mounted on the front of a crawler or rubber-tired tractor for the purpose of digging and pushing earth and broken rock from one place to another. It is often used in conjunction with a ripper, a heavy tooth or series of teeth mounted on the rear of a tractor to break up rock so that it can be handled by the dozer. Because the amount of dirt the dozer can move at one time is limited by the size of its blade, it is not economical to use the dozer for moving dirt more than a few hundred feet.

Front-end loader. This is sometimes used for moving dirt in the same manner as the dozer, but with the same limitations.

Scraper. This is the most economical of the combination excavating-hauling units for hauls of over a few hundred feet. A wheel-mounted, open-top box or “bowl,” the scraper has a hinged bottom that is lowered to scoop up dirt as the machine moves forward. When the bowl is full, the bottom is closed and the unit is moved to the dumping area, where the bottom is lowered and a hydraulic pushing unit in the back of the bowl moves the dirt out through the opening in the bottom, to spread the dirt as needed. Scrapers are pulled by tractors, most of which are an integral part of the unit. A scraper is shown in **Fig. 5**.

Self-loading or elevating scraper. This group of machines does the same work as the conventional scraper, but in front of the bowl is a series of horizontal plates mounted on moving chains. As the chains move, the plates lift the dirt into the bucket in the same manner as a bucket loader. The advantage of the elevating scraper is that it needs less tractor power during the loading operation.

Marine excavator. Usually called a dredge, the marine excavator is an excavating machine mounted on a barge or boat. Two common types are similar to land excavators, the clamshell and the bucket excavator. The suction dredge is different; it comprises a movable suction pipe which can be lowered to the bottom, usually with a fast-moving cutter head at the bottom end. The cutter churns up the bottom so that the pumps on the barge or boat suck up water and the earth suspended in it. When practical, the pumped material is then piped to land, where the solids settle out, allowing the liquids to run back to the body of water being dredged. When distance to land is too great or where there is no empty land on which to discharge the material, the effluent is pumped into barges in which the settled-out solids are towed to a dump area at a distant point.

Hauling equipment. Excavated materials are moved great distances by a wide variety of conveyances. The most common of these are the self-propelled rubber-tired rear-dump trucks, which are classed as

Fig. 6. A 100-ton (90-metric-ton) rear-dump truck.

over-the-road or off-the-road trucks. The main difference between these two is weight and carrying capacity. Many states restrict the total weight of highway-using trucks (truck and load) to as little as 30 tons (27 metric tons). For jobs where trucks remain on site, such as at dams and some highway construction areas, trucks with a carrying capacity of 50 tons (45 metric tons) are common and some capable of carrying loads in excess of 100 tons (90 metric tons) are in use. A 100-ton (90-metric-ton) rear-dump truck is shown in **Fig. 6**. Wagons towed by a rubber-tired prime mover are also used for hauling dirt. These commonly have bottom dumps which permit spreading dirt as the vehicle moves. In special cases side-dump trucks are also used.

Conveyors, while not commonly used on construction jobs for hauling earth and rock great distances, have been used to good advantage on large jobs where obstructions make impractical the passage of trucks. One such conveyor which was utilized on a New Jersey highway job exceeded 2 mi (3.2 km) in length.

Graders. Graders are high-bodied, wheeled vehicles that mount a leveling blade between the front and rear wheels. The principal use is for fine-grading relatively loose and level earth. Commonly considered a maintenance unit, the grader is still an important machine in highway construction. While the configuration of graders has not changed in many years, some models have been built with articulated main frames that permit faster turns of shorter radii and safer operation at the edges of steep slopes.

Pavers. These place, smooth, and compact paving materials. They may be mounted on rubber tires, endless tracks, or flanged wheels. Asphalt pavers embody tamping pads that consolidate the material; concrete pavers use vibrators for the same purpose. Concrete pavers had been required to use forms to contain the material until the advent of the slip-form pavers. These drag their own short forms behind them and consolidate the concrete sufficiently to stand without slumping after removal of the forms. Many high-speed conventional pavers have been produced with highly sophisticated automated control devices that provide extremely accurate and consistent surface elevations.

Drilling equipment. Holes are drilled in rock for wells and for blasting, grouting, and exploring. Drills are classified according to the way in which they penetrate rock, namely, percussion, rotary percussion, and rotary. The first two types are the most common for holes up to 6 in. (15 cm) in diameter and under 40 ft (12 m) in depth. In smaller sizes these drills may be hand-held, but for production work they are mounted on masts which are supported by trucks or, as shown in **Fig. 7**, special tracks mounted on drill rigs. In tunnel work the drills are commonly mounted on platform-supported movable arms or posts that are hydraulically or pneumatically controlled to permit drilling in horizontal or angled positions, with a minimum of effort by the drill operator. The rotary drill is most common in larger sizes, but drills as small as 3 in. (7.5 cm) in diameter are used for coring rock to obtain samples.

Specialized equipment. Among the most common specialized construction equipment are augers, compactors, and pile hammers.

Augers. These are used for drilling wells, dewatering purposes, and cutting holes that can be filled with concrete for foundations. Augers up to 6 ft (1.8 m) in diameter are common.

Compactors. These machines are designed solely to consolidate earth and paving materials to sustain loads greater than those sustained in the uncompacted state. They range in size from small pneumatic hand-held tampers to multiwheeled machines weighing more than 60 tons (50 metric tons). Actual compaction may be achieved by heavily loaded rubber tires or steel rollers. The steel rollers may be solid

Fig. 7. Crawler-mounted drill. (*Gardner-Denver*)

cylinders, or have separate pads or grids, or contain protrusions (sheep-foot roller). Many machines induce a vibratory action into the compacting units so that compaction is achieved by impact force rather than sheer weight.

Pile hammers. These machines are used to install bearing piles for foundations, or sheet piles for cofferdams and retaining walls. The prehistoric pile hammer consisted of a heavy weight lifted by a rope and allowed to drop on top of a pile. This drop hammer is still in use, basically unchanged. More efficient modern hammers are true machines activated by steam, air, oil, hydraulic fluid, or electricty. Conventional hammers contain pistons that are raised by one of these means and then either allowed to fall freely because of gravity (single-acting) or to be driven downward by the same means (double-acting) to impart an impact to the pile. Vibratory hammers have been developed which use electrically activated eccentric cams to vibrate piles into place. Relatively rare are machines that use hydraulic action to install piles.

Road planer. This machine looks like a conventional motor grader, but instead of a blade it carries near its center a horizontal drum that has on its periphery many rows of replaceable hardened steel teeth. As the drum revolves, the teeth pulverize cracked asphalt or decayed concrete pavement to depths of up to 4 in. (10 cm). This permits the placement of a smooth new riding surface on a sound base without raising the road surface elevation, having to raise manhole covers, and reducing the clearances under bridges.

Bore tunneling machine. This is a machine capable of placing water, sewer, or utility pipes accurately for great distances underground. Key to the operation is a series of intermediate hydraulic jacking rings that expand or contract as controlled to permit the movement of any section of pipe independent of the sections before or behind. This independent movement of short sections reduces the friction on the line and therefore the amount of pressure that would be required if the entire pipe were moved from a single push point.

Power plants. Steam is seldom used as a source of power today except in some marine applications and rarely for pile driving. Gasoline and diesel engines of the piston type are the most common source of power for construction machines, with the diesel attaining an increasingly greater prominence for at least two major reasons. First, the size of many construction machines has increased to proportions formerly thought impractical. With this increase in size, the economy of operation and maintenance of the diesel has come to far outweigh its greater initial cost. Second, the increased popularity of the diesel lies in the fact that manufacturers have been able to build lightweight economical diesel engines in very small sizes, thus making practical their application in small compressors, pumps, portable electric power plants, and so on. *See* DIESEL ENGINE.

Electricity is sometimes, though not often, used as a primary source of power for some construction machines, but usually only at the site of large dams and strip-mining operations where mobility is not a primary requirement. Electricity is making its appearance as a secondary source of power on several types of mobile construction machinery, such as trucks and scrapers, which use diesel or gas engines to turn generators that provide power for electric wheels.

A more common type of secondary power, however, is the hydraulic motor which, activated by a gasoline or diesel-powered hydraulic pump, is being used to provide direct power for virtually every movement, including travel, of construction machines.

Some manufacturers have experimented with turbine engines for construction applications. While they are being used with success as primary power sources for large stationary electric power plants on job sites, their practical use in mobile equipment is not evident. *See* CONSTRUCTION ENGINEERING.

Bibliography. F. Harris, *Modern Construction and Ground Engineering Equipment*, 2d ed., 1994; J. Russel, *Construction Equipment,* 1985; J. Singh, *Heavy Construction*: *Planning, Equipment, and Methods*, 1994; M. J. Tomlinson, *Pile Design and Construction Practice*, 3d ed., 1987.

Construction methods

The procedures and techniques utilized during construction. Construction operations are generally classified according to specialized fields. These include preparation of the project site, earthmoving, foundation treatment, steel erection, concrete placement, asphalt paving, and electrical and mechanical installations. Procedures for each of these fields are generally the same, even when applied to different projects, such as buildings, dams, or airports. However, the relative importance of each field is not the same in all cases. For a description of tunnel construction, which involves different procedures, *see* TUNNEL

Preparation of site. This consists of the removal and clearing of all surface structures and growth from the site of the proposed structure. A bulldozer is used for small structures and trees. Larger structures must be dismantled.

Earthmoving. This includes excavation and the placement of earth fill. Excavation follows preparation of the site, and is performed when the existing grade must be brought down to a new elevation. Excavation generally starts with the separate stripping of the organic topsoil, which is later reused for landscaping around the new structure. This also prevents contamination of the nonorganic material which is below the topsoil and which may be required for fill. Excavation may be done by any of several excavators, such as shovels, draglines, clamshells, cranes, and scrapers. For a discussion of their application *see* CONSTRUCTION EQUIPMENT.

Efficient excavation on land requires a dry excavation area, because many soils are unstable when wet

Fig. 1. Steel erection with guy derricks on a high structure. (*Bethlehem Steel Co.*)

and cannot support excavating and hauling equipment. Dewatering becomes a major operation when the excavation lies below the natural water table and intercepts the ground-water flow. When this occurs, dewatering and stabilizing of the soil may be accomplished by trenches, which conduct seepage to a sump from which the water is pumped out. Dewatering and stabilizing of the soil may in other cases be accomplished by wellpoints and electroosmosis. *See* WELLPOINT SYSTEMS.

Some materials, such as rock, cemented gravels, and hard clays, require blasting to loosen or fragment the material. Blast holes are drilled in the material; explosives are then placed in the blast holes and detonated. The quantity of explosives and the blast-hole spacing are dependent upon the type and structure of the rock and the diameter and depth of the blast holes.

After placement of the earth fill, it is almost always compacted to prevent subsequent settlement. Compaction is generally done with sheep's-foot, grid, pneumatic-tired, and vibratory-type rollers, which are towed by tractors over the fill as it is being placed. Hand-held, gasoline-driven rammers are used for compaction close to structures where there is no room for rollers to operate.

Foundation treatment. When subsurface investigation reveals structural defects in the foundation area to be used for a structure, the foundation must be strengthened. Water passages, cavities, fissures, faults, and other defects are filled and strengthened by grouting. Grouting consists of injection of fluid mixtures under pressure. The fluids subsequently solidify in the voids of the strata. Most grouting is done with cement and water mixtures, but other mixture ingredients are asphalt, cement and clay, and precipitating chemicals. *See* FOUNDATIONS.

Steel erection. The construction of a steel structure consists of the assembly at the site of mill-rolled or shop-fabricated steel sections. The steel sections may consist of beams, columns, or small trusses which are joined together by riveting, bolting, or welding. It is more economical to assemble sections of the structure at a fabricating shop rather than in the field, but the size of preassembled units is limited by the capacity of transportation and erection equipment. The crane is the most common type of erection equipment, but when a structure is too high or extensive in area to be erected by a crane, it is necessary to place one or more derricks on the structure to handle the steel (**Fig. 1**). In high structures the derrick must be constantly dismantled and reerected to successively higher levels to raise the structure. For river bridges the steel may be handled by cranes on barges, or, if the bridge is too high, by traveling derricks which ride on the bridge being erected. Cables for long suspension bridges are assembled in place by special equipment that pulls the wire from a reel, set up at one anchorage, across to the opposite anchorage, repeating the operation until the bundle of wires is of the required size.

Concrete construction. Concrete construction consists of several operations: forming, concrete production, placement, and curing. Forming is required to contain and support the fluid concrete within its desired final outline until it solidifies and can support itself. The form is made of timber or steel sections or a combination of both and is held together during the concrete placing by external bracing or internal ties (**Fig. 2**). The forms and ties are designed to withstand the temporary fluid pressure of the concrete.

The usual practice for vertical walls is to leave the forms in position for at least a day after the concrete is placed. They are removed when the concrete has solidified or set. Slip-forming is a method where the form is constantly in motion, just ahead of the level of fresh concrete. The form is lifted upward by means of jacks which are mounted on vertical rods embedded in the concrete and are spaced along the perimeter of the structure. Slip forms are used for high structures such as silos, tanks, or chimneys.

Concrete may be obtained from commercial batch plants which deliver it in mix trucks if the job is close to such a plant, or it may be produced at the job site. Concrete production at the job site requires the erection of a mixing plant, and of cement and aggregate receiving and handling plants. Aggregates are sometimes produced at or near the job site. This requires opening a quarry and erecting processing equipment such as crushers and screens.

Fig. 2. Concrete form. (*Superior Concrete Accesories*)

Concrete is placed by chuting directly from the mix truck, where possible, or from buckets handled by means of cranes or cableways, or it can be pumped into place by special concrete pumps.

Curing of exposed surfaces is required to prevent evaporation of mix water or to replace moisture that does evaporate. The proper balance of water and cement is required to develop full design strength. *See* CONCRETE.

Concrete paving for airports and highways is a fully mechanized operation. Batches of concrete are placed between the road forms from a mix truck or a movable paver, which is a combination mixer and placer. A series of specialized pieces of equipment, which ride on the forms, follow to spread and vibrate the concrete, smooth its surface, cut contraction joints, and apply a curing compound. *See* HIGHWAY ENGINEERING; PAVEMENT.

Asphalt paving. This is an amalgam of crushed aggregate and a bituminous binder. It may be placed on the roadbed in separate operations or mixed in a mix plant and spread at one time on the roadbed. Then the pavement is compacted by rollers.

William Hershleder

Contact aureole

The zone of alteration surrounding a body of igneous rock caused by heat and volatiles given off as the magma crystallized. Changes can be in mineralogy, texture, or elemental and isotopic composition

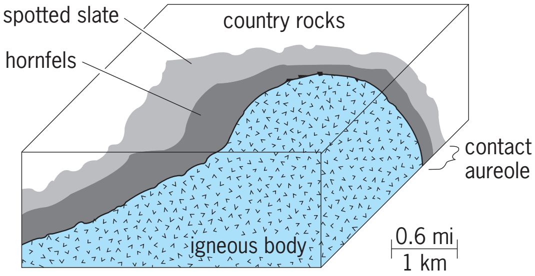

Fig. 1. Zoned contact aureole developed around an igneous body.

of the original enclosing (country or wall) rocks, and progressively increase closer to the igneous contact. The contact aureole is the shell of metamorphosed or metasomatized rock enveloping the igneous body (**Fig. 1**). The ideal contact aureole forms locally around a single magma after it is emplaced.

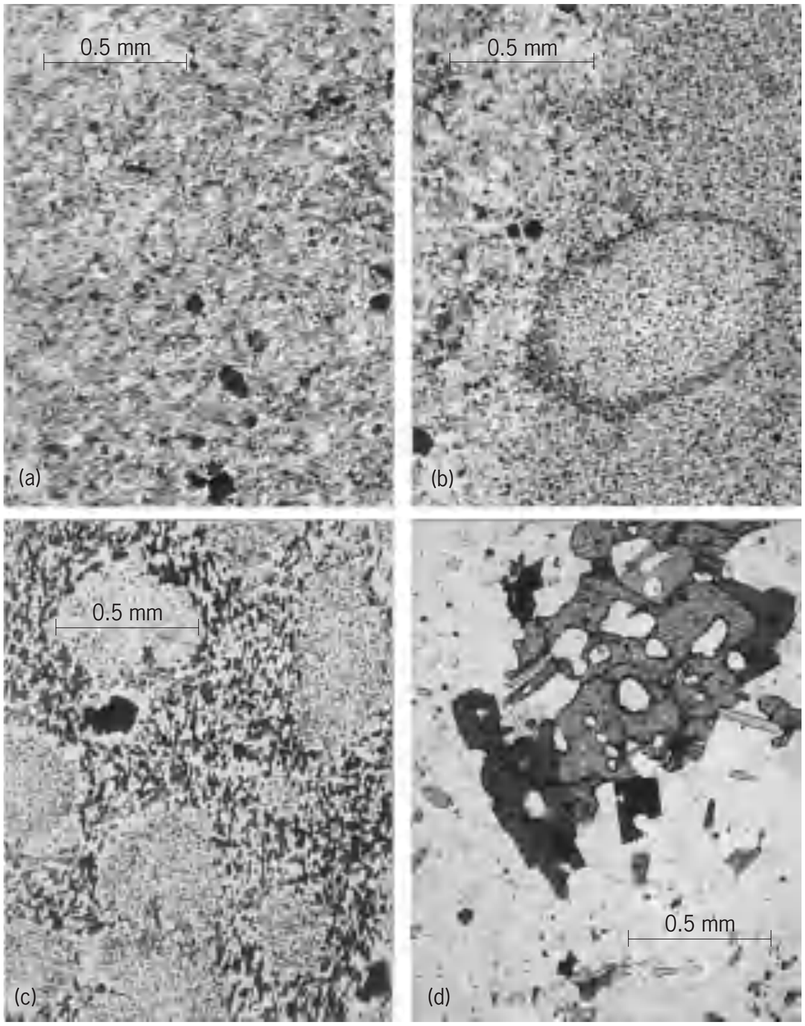

Fig. 2. Microscopic appearance of progressive metamorphism in a contact aureole. (*a*) Original slate country rock comprising chlorite, muscovite, albite, and quartz. (*b*) Spotted slate with the same mineralogy and texture as country rock but with the addition of cordierite plus biotite spots. (*c*) Hornfels with poikiloblastic porphyroblasts of cordierite in a matrix of biotite, muscovite, quartz, and plagioclase. (*d*) Granoblastic hornfels with garnet, biotite, cordierite, alkali feldspar, plagioclase, and quartz.

Metamorphism over a much larger area can result from coalescing of several contact aureoles. This is termed a contact-regional metamorphic aureole and is thought responsible for the regional metamorphism of several mountain areas. Other contact aureoles develop at greater depths and may be physically emplaced to shallower levels along with the igneous body. These are termed dynamothermal aureoles. *See* IGNEOUS ROCKS; MAGMA; METAMORPHIC ROCKS; METAMORPHISM; METASOMATISM; PLUTON.

Extent. The aureole extends from the igneous contact, where the metamorphic effects are the greatest, out into the country rocks to where the temperature or heat energy is insufficient to effect any changes. This temperature lies between 400 and 750°F (200 and 400°C), and actual widths of contact aureoles range from several inches to miles.

Most important in determining the metamorphic intensity and the extent of the aureole are the heat content of the magma and the temperature contrast between the magma and country rock. Initial temperature of the magma depends on its type; metamorphic effects around gabbro magma (∼2200°F or 1200°C) are generally more extensive and intensive than those around granite (∼1400°F or 750°C). Better developed aureoles are found around larger igneous bodies, magmas which were not extensively crystallized before emplacement, and convecting magmas. Under the right circumstances, the highest temperature in the aureole can approach that of the magma. At deeper crustal levels, country rock temperatures increasingly coincide with those of common magmas, and the contact effects are correspondingly reduced until they are indistinguishable from metamorphic changes brought about by normal burial. Thus contact aureoles are most commonly found around shallow igneous bodies where magma temperatures exceed those of the country rock. They are considered to have low-pressure metamorphism, occurring at pressures less than 5 kilobars (500 megapascals), but usually much less. This corresponds to depths of less than 12 mi (20 km).

Factors of heat transfer also affect the extent and intensity of the metamorphism in the contact aureole. Geometry and orientation of the igneous body are important; intense metamorphism occurs at acute corners of the body and wider aureoles occur at the roof of an igneous body, where most heat is escaping, as opposed to the floor. Wider aureoles and less intense metamorphism occur in country rocks with good thermal conductivity. Heat transfer by conduction produces narrower, more regular, aureoles in contrast to heat transfer by fluid convection. Convective heat transport can produce wide or very narrow aureoles depending on the fluid content of the magma, fluid content of the wall rock, permeability of the system, and direction of fluid flow. Dry magmas and impermeable systems tend to have narrow aureoles. Cool fluid from the wall rocks can flow into the magma, cooling it and preventing development of the aureole. Conversely, hot fluid from the magma or wall rock fluid heated by the magma flowing outward can produce an extensive aureole.

Aureoles are most pronounced where wall rocks are easily affected by metamorphism because of their composition, texture, or previous metamorphism. Shale and limestone generally show a more conspicuous metamorphism than does sandstone. Aureoles are best developed in fine-grained and previously unmetamorphosed or weakly metamorphosed rocks; they may not be detected in intensely metamorphosed rocks because minerals of the wall rocks are stable at the conditions imposed upon them by the magma. Heat absorption by energy-consuming reactions will lessen the intensity of metamorphism elsewhere in the aureole. If the rate of heating and subsequent cooling exceeds the rate of recrystallization or reaction in the aureole, metamorphic effects will be reduced.

Rocks. Weakly contact-metamorphosed wall rocks may be only discolored or indurated. Contact aureoles with more intense metamorphism are progressively zoned, with appearance of new textures and minerals toward the igneous body (**Fig. 2**). At the outer edge of the aureole, textural changes include development of scattered aggregates of existing or new minerals, which are larger than the matrix minerals. If the host rock is shale, these recrystallized rocks become spotted slates. Further inward there is sequential appearance of new minerals, more extensive recrystallization, and color changes. Average grain size may increase but is still small, usually less than 0.08 in. (2 mm). Fine grain size in contact metamorphism results from short-duration heating and lack of deformation. Well within the aureole, where new mineral growth and recrystallization is complete, older structures (bedding or schistosity) may be eliminated. Mineral grains tend to become equidimensional with little or no preferred orientation and lack their crystal form in an interlocking mosaic (granoblastic texture); the rock is called a hornfels. The term hornfels is applied in a wide sense to any contact-metamorphosed rock and made specific by mineral or rock compositional modifiers. The massive texture of hornfelses results from the lithostatic or hydrostatic nature of the pressure; directed pressure as in regional metamorphism is absent. However, some hornfelses develop a preferred alignment because of intrusion of the adjacent magma. Hornfelses typically have a few larger mineral grains (porphyroblasts) which can contain abundant inclusions of the smaller matrix minerals (poikiloblastic texture). Adjacent to the igneous contact, melting of the wall rocks can occur. *See* HORNFELS; PORPHYROBLAST; ROCK.

Mineral facies. Contact metamorphism can occur over a wide range of temperatures, pressures, or chemical gradients in rocks of any composition. Thus any mineral assemblage or facies of metamorphic rocks can be found. However, the nature of contact aureoles results in minerals characteristic of low to moderate pressures and moderate to high temperatures usually in common rock types: shales, basalt, limestone, and sandstone. Characteristic minerals developed in shales are andalusite, sillimanite, cordierite, biotite, orthopyroxene, and garnet. At the highest temperatures, tridymite, sanidine, mullite, and pigeonite form; whereas in limestone unusual calcium silicates form, including tilleyite, spurrite, rankinite, larnite, merwinite, akermanite, monticellite, and melilite. *See* FACIES (GEOLOGY).

Chemical alterations. Compositional changes in a contact aureole range from none to great, but as a rule, contact metamorphism entails relatively little change in bulk rock composition. Because metamorphic changes are largely brought about by heat, contact aureoles are often termed thermal aureoles. However, there is a tendency for volatiles (water, carbon dioxide, oxygen) and alkalies (sodium, potassium) to be lost from rocks in the aureole. Stable isotope compositions (oxygen, sulfur) change in response to the thermal gradient and flow of fluids through the rocks. In some cases, volatiles (boron, fluorine, and chlorine) and other elements from the crystallizing magma are gained.

Some wall rock compositions, such as limestone, can be greatly changed and form rocks termed skarn. These contact aureoles are economically important because they often contain ore deposits of iron, copper, tungsten, graphite, zinc, lead, molybdenum, and tin. Conversely, the magma can incorporate material from the wall rocks by assimilation or mixing with any partial melts formed. Mixing results in elemental and isotopic contamination of the magma, crystallization of different minerals from the melt, and hybrid rock types at the margin of the igneous body. *See* ORE AND MINERAL DEPOSITS; PNEUMATOLYSIS; SKARN.

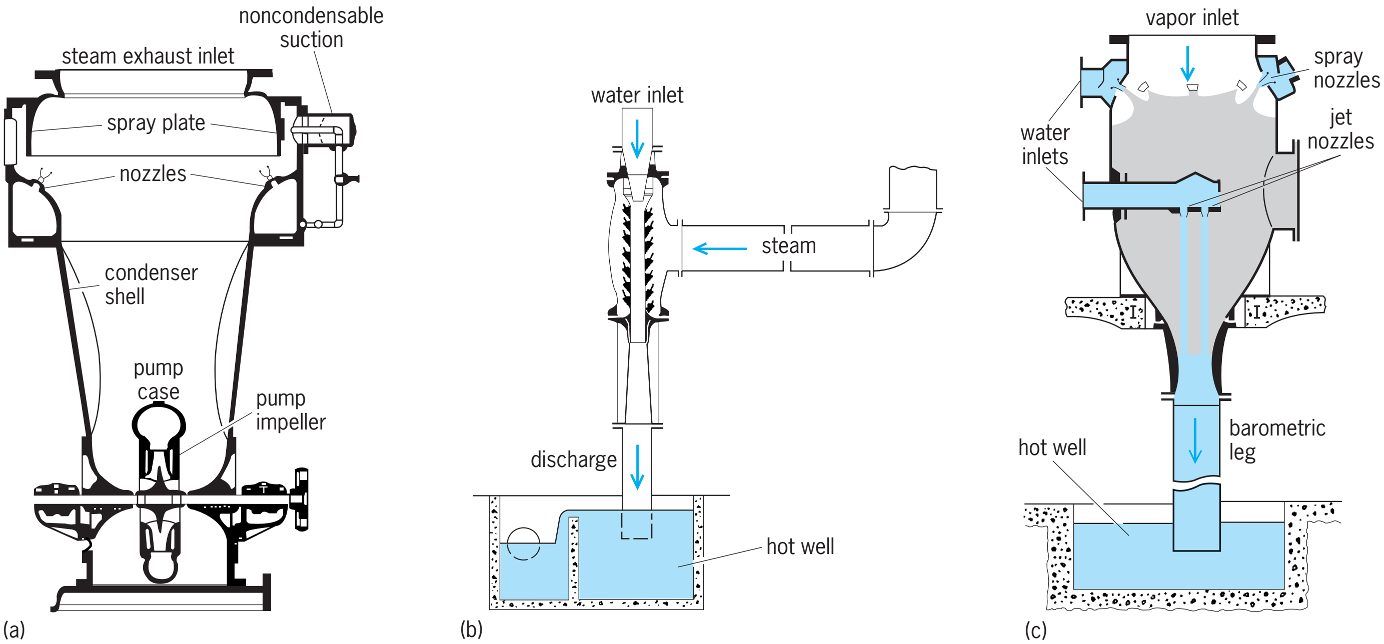
Contact condenser

A device in which a vapor is brought into direct contact with a cooling liquid and condensed by giving up its latent heat to the liquid. In almost all cases the cooling liquid is water, and the condensing vapor is steam. Contact condensers are classified as jet, barometric, and ejector condensers (see **illus.**). In all three types the steam and cooling water are mixed in a condensing chamber and withdrawn together. Noncondensable gases are removed separately from the jet condenser, entrained in the cooling water of the ejector condenser, and removed either separately or entrained in the barometric condenser. The jet condenser requires a pump to remove the mixture of condensate and cooling water and a vacuum breaker to avoid accidental flooding. The barometric condenser is self-draining. The ejector condenser converts the energy of high-velocity injection water



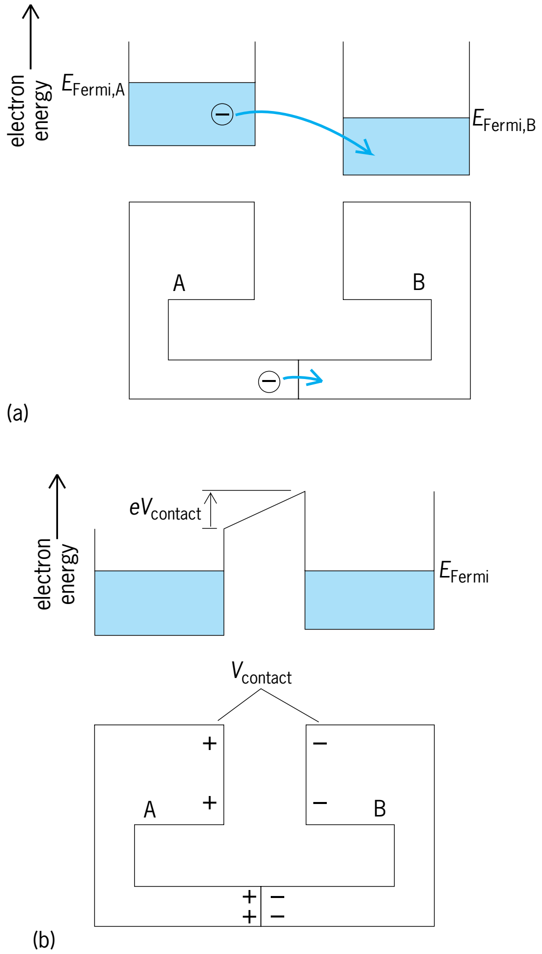
Three basic types of contact condenser: (*a*) low-level jet condenser (*C. H. Wheeler Manufacturing Co.*); (*b*) single-jet ejector condenser; (c) multijet barometric condenser (*Schutte and Koerting Co.*).

to pressure in order to discharge the water, condensate, and noncondensables at atmospheric pressure. *See* VAPOR CONDENSER. Joseph F. Sebald

Contact potential difference

An electrostatic potential that exists between samples of two dissimilar electrically conductive materials (metals or semiconductors with different electron work functions) that have been brought into thermal equilibrium with each other, usually through a physical contact. Although normally measured between two surfaces which are not in contact, this potential is called the contact potential difference. Its origin can be described in terms of the process necessary to bring the samples into equilibrium. Initially it is expected that mobile charge carriers (electrons or holes) will migrate from one sample to the other. If there is a net flow of electrons from material A to material B (see **illus.**), material B will become negatively charged and material A will become positively charged, assuming that they were originally neutral. This process is self limiting because a potential difference between the two samples will develop due to the charge separation and will grow to a value sufficient to stop further motion of the electrons from A to B.

In a metal or a semiconductor, the electrons are distributed in energy such that virtually all of them exist at or below a "sea level" called the Fermi level. When any combination of metals and semiconductors are put into equilibrium with one another, the Fermi levels in all will coincide. The contact potential difference between materials is that value necessary to raise or lower the potential energies of the electrons to produce a common Fermi sea level.



Development of a contact potential as two conductive materials are brought into thermal equilibrium. (*a*) Initial charge transfer. (*b*) Thermal equilibrium. Diagrams show corresponding electron energy distributions. E_{Fermi} = Fermi level; V_{contact} = contact potential difference; e = electron charge.

Since they are then at the same energy, electrons at the Fermi level in either material will have no net force on them, that is, no reason to travel to the other material. Because it causes no net force on the equilibrium distribution of electrons, contact potential difference cannot be directly measured with an ordinary voltmeter. Nevertheless, it profoundly affects the behavior of a number of electronic devices. *See* FREE-ELECTRON THEORY OF METALS; SCHOTTKY BARRIER DIODE; SEMICONDUCTOR; WORK FUNCTION (ELECTRONICS). James E. Nordman

Continent

A protuberance of the Earth's crustal shell with an area of several million square miles and with sufficient elevation above neighboring depressions (the ocean basins) so that much of it is above sea level.

The term was originally applied to the most extensive continuous land areas of the globe. The great majority of maps now in use imply that the boundaries of continents are their shorelines. From the geological point of view, however, the line of demarcation between a continent and an adjacent ocean basin lies offshore, at distances ranging from a few to several hundred miles, where the gentle slope of the continental shelf changes somewhat abruptly to a steeper declivity. This change occurs at depths ranging from a few to several hundred fathoms (1 fathom = 6 feet) at different places around the periphery of various continents. *See* CONTINENTAL MARGIN.

On such a basis, numerous offshore islands, including the British Isles, Greenland, Borneo, Sumatra, Java, New Guinea, Tasmania, Taiwan (formerly Formosa), Japan, and Sri Lanka (formerly Ceylon), are parts of the nearby continent. Thus, there are six continents: Eurasia (Europe, China, and India are parts of this largest continent), Africa, North America, South America, Australasia (including Australia, Tasmania, and New Guinea), and Antarctica.

All continents have similar structural features but display great variety in detail. Each includes a basement complex (shield) of metamorphosed sedimentary and volcanic rocks of Precambrian age, with associated igneous rocks, mainly granite. Originally formed at considerable depths below the surface, this shield was later exposed by extensive erosion, then largely covered by sediments of Paleozoic, Mesozoic, and Cenozoic age, chiefly marine limestones, shales, and sandstones. In at least one area on each continent, these basement rocks are now at the surface (an example is the Canadian Shield of North America). In some places they have disappeared beneath a sedimentary platform occupying a large fraction of the area of each continent, such as the area in the broad lowland drained by the Mississippi River in the United States. In each continent there are long belts of mountains in which thick masses of sedimentary rocks have been compressed into folds and broken by faults. *See* CONTINENTS, EVOLUTION OF.

Presumably because of the large volume of acidic aluminum-rich granitic rocks beneath the surface of each continent, the velocity of transmission of earthquake vibrations in continental segments of the Earth's crust is slower than in oceanic segments, in which alkaline, iron-rich basaltic rather than granitic rocks are the dominant type. For the same reason the average density of the rocks composing continents is less than that of the rocks beneath the deep-sea floors. *See* EARTHQUAKE.

Continents are the less dense, subaerially exposed portion of the large and not-so-large plates that make up the Earth's lithosphere, or outer shell of rigid rock material. As such, continents together with part of the ocean's floor are intimately joined portions of the lithospheric plates. As plates rip apart and migrate horizontally over the Earth's surface, so too do continents rip apart and migrate, sometimes colliding with other continental segments scores of millions of years later. Mountain systems, such as the Appalachian-Ouachita, the Arbuckle-Wichita, and the Urals systems, are now believed to represent the sutures of former continents attached to their respective plates which collided long ago. The Red Sea and the linear rift-volcano-lakes district of Africa are also believed by many to manifest continental ripping and early continental drifting. Such continental collision and accretion are believed to have occurred throughout most of the Earth's history. *See* AFRICA; ANTARCTICA; ASIA; AUSTRALIA; EARTH, GRAVITY FIELD OF; EUROPE; ISOSTASY; LITHOSPHERE; NORTH AMERICA; PLATE TECTONICS; SEISMOLOGY; SOUTH AMERICA. Continental drift

The concept that the world's continents once formed part of a single mass and have since drifted into their present positions. Although it was outlined by Alfred Wegener in 1912, the idea was not particularly new. Paleontological studies had already demonstrated such strong similarities between the flora and fauna of the southern continents between 300,000,000 and 150,000,000 years ago that a huge supercontinent, Gondwana, containing South America, Africa, India, Australia, and Antarctica, had been proposed. However, Gondwana was thought to be the southern continents linked by land bridges, rather than contiguous units.

Wegener's ideas were almost universally rejected at a meeting of the American Association of Petroleum Geologists in 1928. His evidence and timing were undoubtedly wrong in many instances, and only a few scientists accepted his general concepts and remained sympathetic to the ideas. The fundamental objection was the lack of a suitable mechanism. Studies of the passage of earthquake waves through the Earth had shown that, whereas the core is liquid, the Earth's mantle and crust are solid. It was therefore difficult to find sufficient force to move the continents through the mantle and oceanic crust, and even more difficult to picture them moving without leaving obvious evidence of their passage.

Almost simultaneously with the temporary eclipse of Wegener's theory, Arthur Holmes was considering a mechanism that is still widely accepted. With the knowledge that radioactive minerals occurring within the Earth could result in an internal zone of slippage, Holmes conceived the idea of convective currents within the Earth's mantle which were driven by the radiogenic heat produced by radioactive minerals within the mantle. Since the rates of motion were slow, but vast and inexorable, the Earth appeared solid to the rapid passage of seismic waves, but behaved plastically to such slow motions. This accounted for the apparent discrepancy between the seismic observations and the drift of continents. At that time, Holmes's ideas, like those of Wegener, were largely ignored, as it was no longer thought that continental drift was worthy of further consideration. Nonetheless, several geologists, particularly those living in the Southern Hemisphere, continued to believe the theory and accumulate more data in its support, particularly from the study of the similarities in fossils and rock types on now separated continents.

By the 1950s, convincing evidence had accumulated, with studies of the magnetization of rocks, paleomagnetism, beginning to provide numerical parameters on the past latitude and orientation of the continental blocks. Early work in North America and Europe clearly indicated how these continents had once been contiguous and had since separated. The discovery of the mid-oceanic ridge system also provided more evidence for the geometric matching of continental edges, but the discovery of magnetic anomalies parallel to these ridges and their interpretation in terms of sea-floor spreading finally led to almost universal acceptance of continental drift as a reality. In the 1970s and 1980s, the interest changed from proving the reality of the concept to applying it to the geologic record, leading to a greater understanding of how the Earth has evolved through time. The fundamental change in concept was that not only have the continents drifted, but the continents are merely parts of thicker tectonic plates, comprising both oceanic and continental crust, with 50–300 km (31–186 mi) of the Earth's mantle moving along with them. *See* CONTINENTS, EVOLUTION OF; EARTH, CONVECTION IN; PALEOMAGNETISM; PLATE TECTONICS; GEODYNAMICS.

Siever, *Understanding the Earth*,1993; D. H. Tarling and M. P. Tarling, *Continental Drift*, 2d ed., 1975; T. H. Van Andel, *New Views on an Old Planet*: *A History of Global Change*, 1994.

Continental margin

The submerged portions of the continental masses on crustal plates, including the continental shelf, the continental slope, and the continental rise. All continental masses have some continental margin, but there is great variety in the size, shape, and geology depending upon the tectonic setting.

The most common settings are the trailing-edge margin and the leading-edge margin. The former is associated with tectonic stability, as exemplified by the Atlantic side of the North American landmass (**Fig. 1**). Here the margin is wide and geologically relatively uncomplicated, with thick sequences of coastal plain to shallow marine strata dipping slightly toward the ocean basin. By contrast, the leading-edge margin (for example, the Pacific side of the United States) is narrow, rugged, and geologically complicated. The global distribution of these widespread continental margin types is controlled by the plate tectonic setting in which the landmass resides. Some major landmasses, such as Australia, are surrounded by wide margins, but most, such as North and South America, have some of both types. *See* PLATE TECTONICS.

Any consideration of the continental margin must include a general understanding of global seal-level history over the past few million years. As glaciers expanded greatly just over 2 million years ago, sea level was lowered more than 300 ft (100 m). The cyclic growth and decay of glaciers during this period caused the shoreline to move from near its present position to near the edge of the present continental shelf on multiple occasions. These sea-level changes had a profound effect on the entire continental margin, particularly the shelf and the rise. During times of glacial advance, the coast was near the shelf edge, causing large volumes of river-borne sediment to flow down the continental slope and pile up on the rise; deltas were poorly developed for lack of place for sediment to accumulate. During times of high sea-level stand similar to the present time, little sediment crossed the shelf and large volumes of riverine sediment accumulated in large fluvial deltas. *See* DELTA.

Continental shelf. This part of the margin is simply an extension of the adjacent landmass. It is characterized by a gentle slope and little relief except for shelf valleys (Fig. 1), which are old rivers that were active during times of low sea level. Because of the great variability in the depth, width, and gradient, it is misleading to give average values for these characteristics. The width ranges from a few kilometers to hundreds of kilometers, with the Florida peninsula being a good example of both. The Atlantic shelf is very narrow, and the Gulf side is very wide. The gradient also ranges, generally between 6 and 22 ft/mi (1 and 4 m/km); it is so gentle that it would not be possible for a person walking over it to detect a change. The outer limit of the shelf shows a distinct change in gradient to the much steeper slope. This change may occur at depths of less than 300 ft (100 m) or up to nearly 1000 ft (300 m).

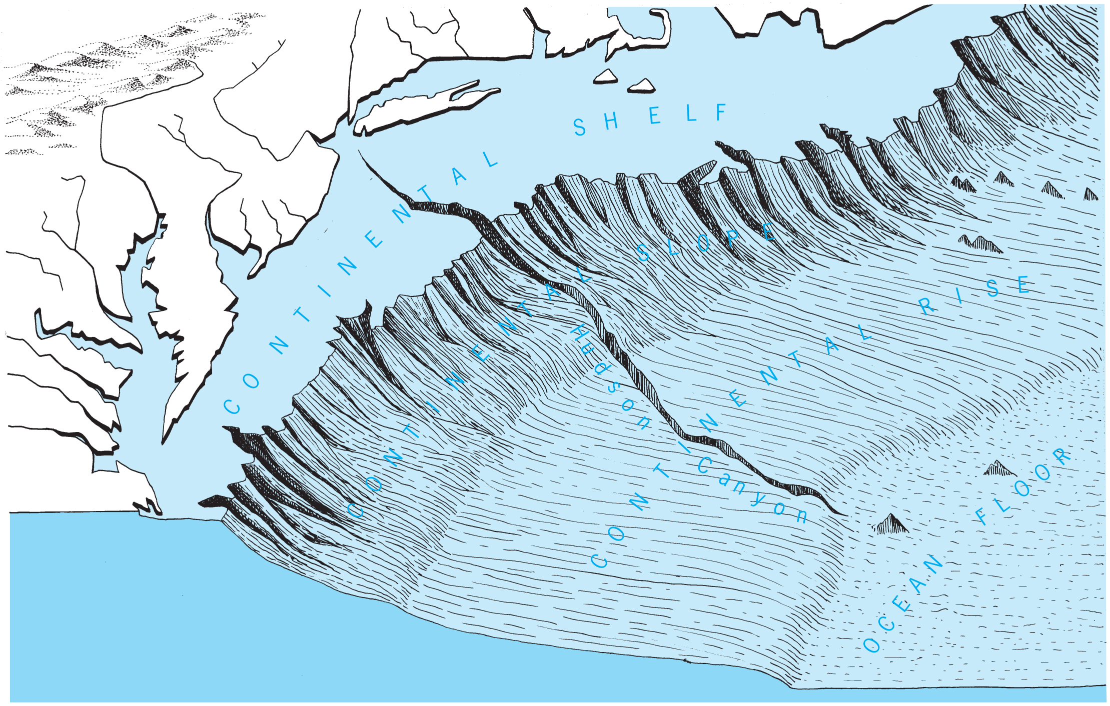

Fig. 1. Continental margin off the northeastern United States.

Unfortunately, legal definitions typically use depth limits to define the shelf for economic purposes without paying attention to the geologic or geomorphic boundaries. The shelf environment may include complete seas, such as the North Sea between Great Britain and Europe.

The modern continental shelf is covered with a combination of Holocene sediments that were deposited as sea level rose over the last 18,000 years, when the last extensive glaciers melted, and older sediments that have yet to be covered. The outer one-half to two-thirds of the shelf has relict sediments that were deposited in coastal environments when sea level was lower, and that were drowned without being buried when sea level rose rapidly in the early Holocene. Intense storms and burrowing organisms can rework these outer shelf sediments into palimpsest sediments. The inner shelf is covered with Holocene sand and mud in thicknesses that vary depending upon sediment flux from the adjacent continent. The shelf also supports an abundant and diverse benthic community that includes both epifauna and infauna. The numerous grazers, burrowers, and filter feeders rework sediment and extract it from suspension. Fecal pellets are a significant part of continental sediments. *See* HOLOCENE; MARINE SEDIMENTS.

Continental slope and rise. The outer continental margin includes the relatively steep slope and the rise that accumulates at the base of the slope (Fig. 1). This continental material has the same general composition as the landmass. Although the slope is steep relative to the shelf and rise, it has an average gradient of only about 4.5° but the range is from less than 2° to more that 40°. The very gentle gradients are areas of large deltas or fans, and the steep ones are associated with faulted margins. The gradient of the continental rise is generally less than 1°. The slope is dissected by numerous deep and steep-sided submarine canyons. These canyons are conduits for sediment transported in various sediment gravity modes to the continental rise. Some have continuations across the shelf where former rivers were located during low stands of sea level. These canyons may also extend across at least part of the rise. During low stands of sea level the rise received great quantities of sediment in rapid rates of accumulation as rivers dumped their loads near the shelf-slope break, whereas sediment supply is now relatively slow. *See* FAULT AND FAULT STRUCTURES; SUBMARINE CANYON.

The sediments carried by sediment gravity processes have a wide range in grain size, from mud to gravel. They accumulated in strata with a wide range of thickness, partly related to their grain size and partly to the volume of sediment introduced. Most of these units display graded bedding, a decreasing-upward grain-size trend.

In addition to sediment gravity processes supplying sediment to the slope and particularly to the continental rise, there are two other sources of sediments for these areas. Contour currents that flow parallel to bathymetric contours carry and deposit sediment along the outer continental margin. These contourites may be hundreds of meters thick. The other sediment supplied to this region is in the form of the tests of planktonic organisms that fall through the water column and accumulate slowly. They include both calcium carbonate (calcite and aragonite) from foraminifera and coccolithophores, and silicon dioxide (opal) from diatoms and radiolaria.

Continental borderland. The leading-edge continental margin that is commonly associated with a crustal plate boundary displays a very different geology, geomorphology, and bathymetry than the outer continental margin. In this type there is no distinct shelf, slope, and rise. Like the trailing-edge margin, the leading-edge margin exhibits the same characteristics as the adjacent landmass, in this case a structurally complex geology with numerous fault basins and high relief. The borderland is narrow and overall steep. Its geomorphology consists of numerous local basins that receive sediment through numerous submarine canyons. The canyons commonly extend nearly to the beach; there is no shelf as such. Because much of the sediment is trapped in these basins, there is only a modest rise accumulation adjacent to the ocean floor. The best example of this type of continental margin is adjacent to southern California (**Fig. 2**), where dozens of fault-bounded basins exist. These basins range from being essentially filled with sediment to having considerable accommodation space.

Resources. The continental margin contains a vast amount and array of natural resources, most of which are being harvested. The primary fishing grounds around the globe are in shelf waters. The Grand Banks off northeastern North America and the North Sea adjacent to Europe are among the most heavily fished. There are also many mineral resources that are taken from shelf sediments, including heavy minerals that are sources of titanium, phosphate, and even placer gold. Important commodities such as sand, gravel, and shell are also taken in large quantities from the inner shelf. Salt domes that underlie the shelf, especially in the northern Gulf of Mexico, provide salt and sulfur.

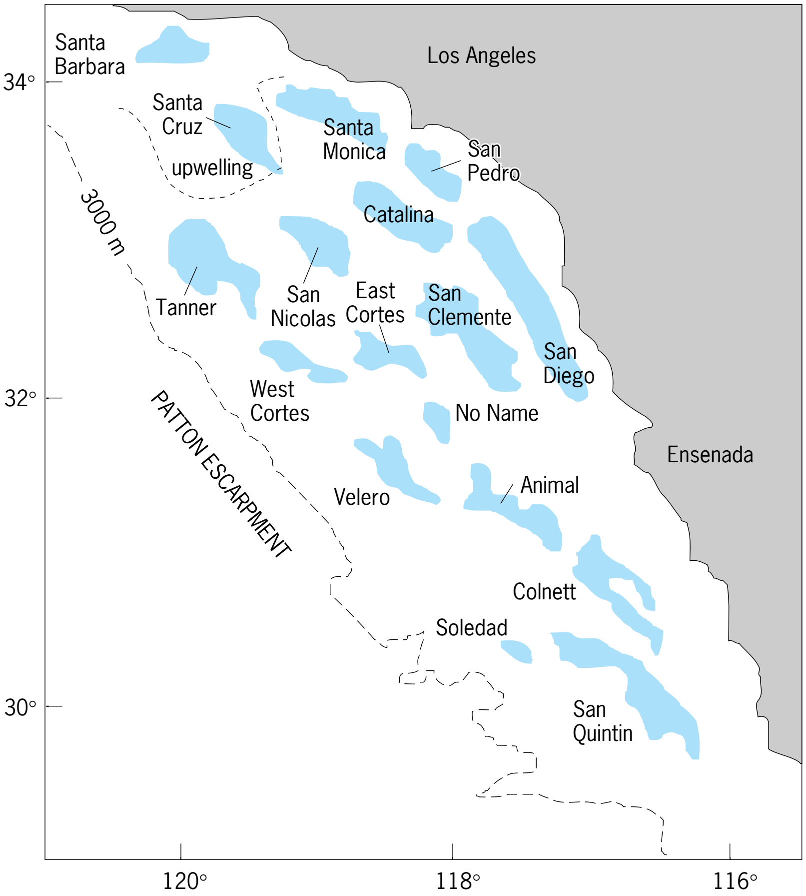

Fig. 2. California continental borderland, showing the outlines of the major basins. Upwelling is centered in the area south of the northern Channel Islands and extends south to 33°N latitude. (*After D. S. Gorsline, J. Sediment. Petrol., 48:1056, 1978*)

Probably the most important resource obtained from the continental margin is petroleum, in the form of both oil and gas. Production is extremely high in some places, ranging from the deltas at the coast across the entire shelf and onto the outer margin, and reserves are high. *See* MARINE GEOLOGY; OIL AND GAS, OFFSHORE.

Richard A. Davis, Jr.

Shelf circulation. Shelf circulation is the pattern of flow over continental shelves. An important part of this pattern is any exchange of water with the deep ocean across the shelf-break and with estuaries or marginal seas at the coast. The circulation transports and distributes materials dissolved or suspended in the water, such as nutrients for marine life, freshwater and fine sediments originating in rivers, and domestic and industrial waste.

Water movements over continental shelves include tidal motions, wind-driven currents, and long-term mean circulation. Tidal currents reverse every half tidal cycle (about 6 h for the usually dominant semidiurnal tide), and water particles undergo back-and-forth excursions due to tides amounting to a few miles. Storms generate currents which persist typically for several days and lead to particle excursions of tens of kilometers. A pattern of long-term mean circulation is characteristic of each major subdivision of the continental shelves. Off the North American east coast, for example, the region of the shelf between the Grand Banks of Newfoundland and Cape Hatteras is characterized by a persistent southwestward drift, always present over the outer portions of the shelf (in water at least 150 ft or 50 m deep). The mean shelf circulation in this area is one leg of a larger oceanic gyre lying offshore (**Fig. 3**). Water particles are eventually swept off the shelf and into a deepwater current adjacent to the Gulf Stream. The coupling of shelf circulation to a more massive deep-ocean boundary current is tighter in some other locations, for example in the South Atlantic Bight, where the Gulf Stream controls outer shelf flow. Along the west coast of North America, the seasonally changing upwelling-downwelling regime is coupled to the weaker boundary currents along the eastern margin of the Pacific Ocean. *See* GULF STREAM.

Important for the exchange of water between a shelf region and the deep ocean are differences in motion between surface and bottom layers. At the ocean surface, the wind is a dominant influence, while at depths greater than about 30 ft (10 m) internal forces determine the intensity and direction of motion. In the east coast example discussed above, the surface layers move significantly offshore over the long term, a consequence of westerly winds, in addition to their general southwestward drift. Over shorter periods they move in whatever direction the wind carries them. The bottom layers move shoreward, to replace the water driven offshore by the wind, transporting saltier, nutrient-rich water from the deep ocean onto the shelf.

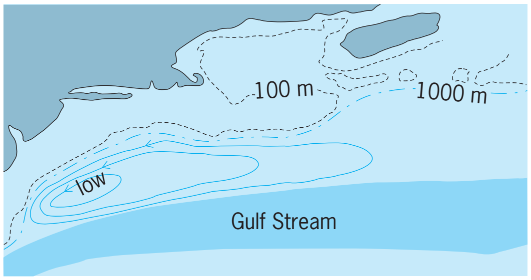

Fig. 3. Deepwater gyre between the Gulf Stream and the North American continent, influencing continental shelf circulation. Georges Bank is at the center of the illustration, separating the Gulf of Maine from deep water, and is subject to intense tidal flow. 1 m = 3.3 ft.

Tidal currents are mainly important for shelf circulation on account of the mixing they cause. While tidal currents are typically 0.6 ft/s (0.2 m/s) in amplitude, they are much stronger in some locations where shallow depth constricts the flow, for example, over Georges Bank where tidal currents are up to 3 ft/s (1 m/s). Currents of this intensity cause strong bottom friction, turbulence, and mixing. Tides on continental shelves are not caused directly by the pull of the Moon and Sun, but propagate in from the deep ocean, where the gravitational attraction of the heavenly bodies acts over a much larger water mass.

The inflow of fresh water from land also contributes to shelf circulation, because such water would tend to spread out on the surface on account of its low density. Rapid nearshore mixing reduces the density contrast, and the Earth's rotation deflects the offshore flow into a shore-parallel direction, leaving the coast to the right. A compensating shoreward flow at depth is deflected in the opposite direction, adding to the complexity of shelf circulation. *See* NEARSHORE PROCESSES; OCEAN CIRCULATION.

Continents, evolution of

The process that led to the formation of the continents. The Earth's crust is distinctively bimodal in thickness. Oceanic crust is normally about 4 mi (7 km) thick, varying mainly with the temperature of the mantle beneath the sea-floor spreading ridges when the crust was formed. In contrast, the typical 22–25-mi (35–40-km) thickness of continental crust is controlled ultimately—through the agents of erosion, sedimentation, and isostatic adjustment—by sea level. Oceanic crust is formed at spreading ridges, continental crust at subduction zones. Both are recycled to the mantle, but oceanic crust, being less buoyant, is recycled about 30 times faster than continental crust. Consequently, continents, having a mean age of almost 2 billion years and a maximum age of 4 billion years, provide the only directly accessible record spanning most of Earth history. They are, however, structurally more complex than ocean basins because of their great antiquity and weak rheology. *See* EARTH CRUST; MID-OCEANIC RIDGE.

Constructive processes. Subduction zones are the main factories for making continental crust (**Fig. 1**). The primary constructive processes are trench accretion, arc magmatism, and arc-continent collision. Mantle plumes and lithospheric stretching cause secondary magmatic additions to continental crust. *See* LITHOSPHERE; MAGMA; SUBDUCTION ZONES.

Trench accretion. Where an oceanic plate sinks beneath a continental plate or another oceanic plate, sediment scraped off the top of the descending plate accumulates as an accretionary prism at the leading edge of the overriding plate (Fig. 1). Accretionary prisms are bounded by trenches on one side and fore-arc basins on the other. They are best developed at trenches containing thick accumulations of terrigenous sediment, where the off-scraping process is facilitated by high fluid pore pressures in the sediment. Accretionary prisms may also contain slices of pelagic ooze and underlying oceanic crust, volcanic seamounts and their capping atoll reefs, or far-traveled deep-sea fans. They are typically dismembered: accretion does not proceed smoothly because the top of the descending plate is subject to block faulting related to the bending of the plate. The accreted material is dewatered, deformed, and metamorphosed as the accretionary prism grows. Accretionary prisms are rarely active magmatically. Where they intersect spreading ridges, the descending oceanic crust may be hot enough to partially melt at relatively shallow depths. A distinctive suite of sodic granitoid intrusive rocks record such events. Trench accretion is dominantly a process of crustal reworking, not crustal growth, because the bulk of the sediment is derived from the erosion of preexisting crust. *See* ATOLL; REEF.

Arc magmatism. A volcanic arc is a surface manifestation of partial melting near the tip of the mantle wedge above the subducting slab (Fig. 1). Melting in the wedge is induced by the infiltration of aqueous fluids, which lower the temperature required for melting to begin (hydration melting). The fluids are derived from the breakdown of hydrous minerals associated with the subducting oceanic crust. Depth-dependent release of water controls the location of the volcanic front facing the trench, typically 60–70 mi (100–120 km) vertically above the slab. A fertile source of melting in the mantle wedge is maintained by convective flow driven by the viscous drag of the cold descending slab. Although the main source of arc magmas is the mantle wedge, sediment and ablated crust entrained in the slab make subordinate contributions to arc magmas. The

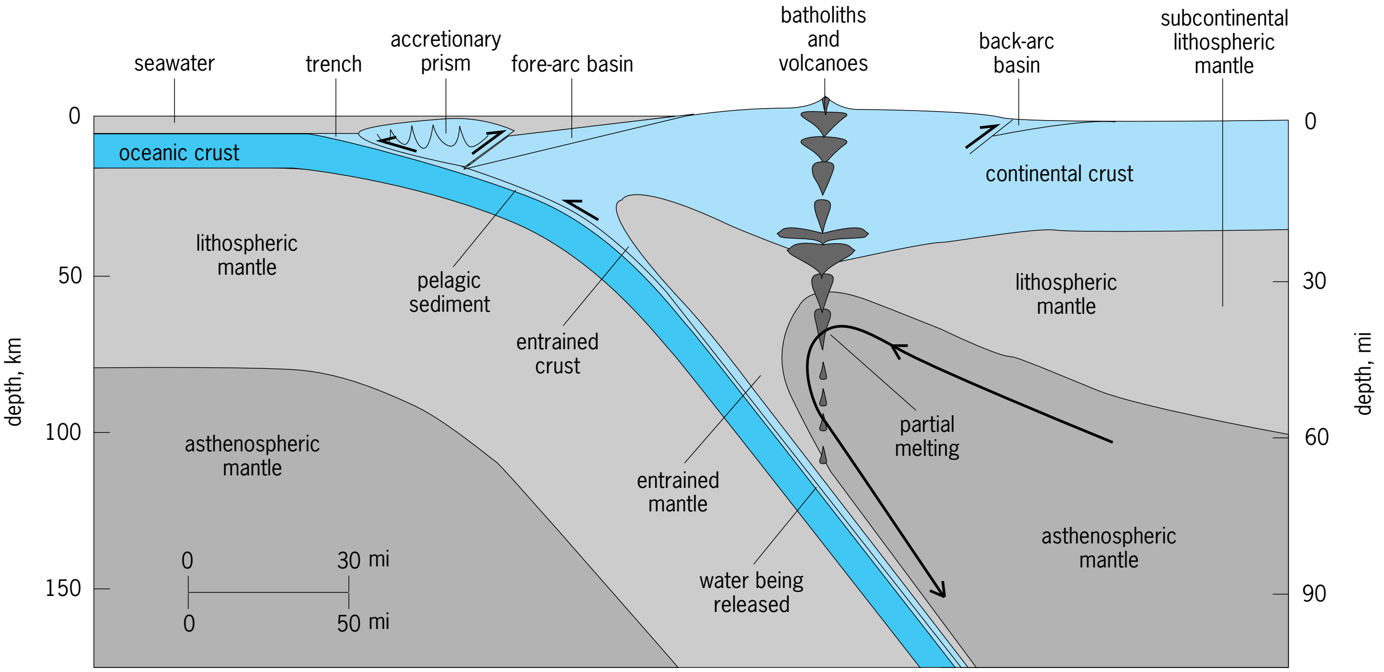

Fig. 1. Recycling of continental crust at a subduction zone. Arrows show direction of movement.

mantle-derived fraction represents new crustal addition. The slab-derived melts serve to speed up (fast-track) the mantle recycling process.

Unlike mid-ocean ridges, magmatic arcs evolve with time because the supply of magma is not balanced by crustal spreading. The crust of volcanic arcs thickens through the addition of new magma. Consequently, the compositions of the magmas evolve as the height of the mantle melting column decreases and the filtering effect of the overlying crust increases. The filtering effect causes crustal differentiation with more buoyantly mobile components concentrating upward. Denser and more refractory components collect in the lower crust. The magmas ingest and assimilate wall rocks and interact with meteoric ground waters, producing hybrid, compositionally diverse, igneous rock suites. Moreover, magmatic arcs are usually the rheologically weakest part of the lithosphere in subduction zones because of their high heat flow. Consequently, they localize tectonic deformation, which generally combines wrenching parallel to the trench (driven by oblique subduction) and extension or compression across the arc (governed by changes in buoyancy of the subducting slab or motion of the upper plate). *See* IGNEOUS ROCKS.

Collisions. Where subduction occurs beneath continental lithosphere, trench accretion and arc magmatism add crust to the continent directly. Continental-type protocrust is also formed at subduction zones (often having complex developmental histories) situated entirely within oceanic lithosphere. Incorporation of such protocrust in a continent is accomplished by arc-continent collision (**Fig. 2**). The reversal of subduction polarity that typically follows arc-continent collision (best exemplified in the modern world by the diachronous collision—a collision progressing from north to south with time—at Taiwan between the Luzon arc of the Philippines and southeast China) is the principal means by which subduction beneath a continent is initiated.

Final closure of an ocean basin results in continent-continent collision, a mainly destructive event. Tectonic crustal thickening produces mountains and greatly accelerated rates of erosion. Much of the resulting sediment is washed off the continent onto deep-sea fans or trenches, and some fraction of that sediment will be subducted. Small crustal gains may be made if the tectonically thickened lithospheric mantle becomes unstable and sinks away. The hotter replacement mantle may partially melt as it rises to take its place (decompression melting), causing small magmatic additions to the already thickened continental crust. *See* BASIN; OROGENY.

Plumes and rifts. Plumes are jets of anomalously hot mantle that partially melts as it reaches the lithosphere, causing the volcanism of Hawaiian-type islands and related seamount chains. Plumes also cause volcanism on continents, for example, Yellowstone in North America. Starting plumes have large heads and relatively small tails through which the plume is maintained. The arrival of starting plume heads at the lithosphere is signaled by continental flood basalt or oceanic plateau volcanism. The largest volumes of melt are generated where lithospheric stretching (upper crustal rifting) occurs in conjunction with a plume. The combination maximizes the potential for decompression melting. In addition to surface volcanism, the melts may pond at or near the base of the crust, causing magmatic underplating. Seamounts and oceanic plateaus are fragmentarily accreted to continents at trenches. *See* BASALT; OCEANIC ISLANDS; SEAMOUNT AND GUYOT; VOLCANOLOGY.

Destructive processes. Subduction zones are sites of continental accretion, but they may also cause

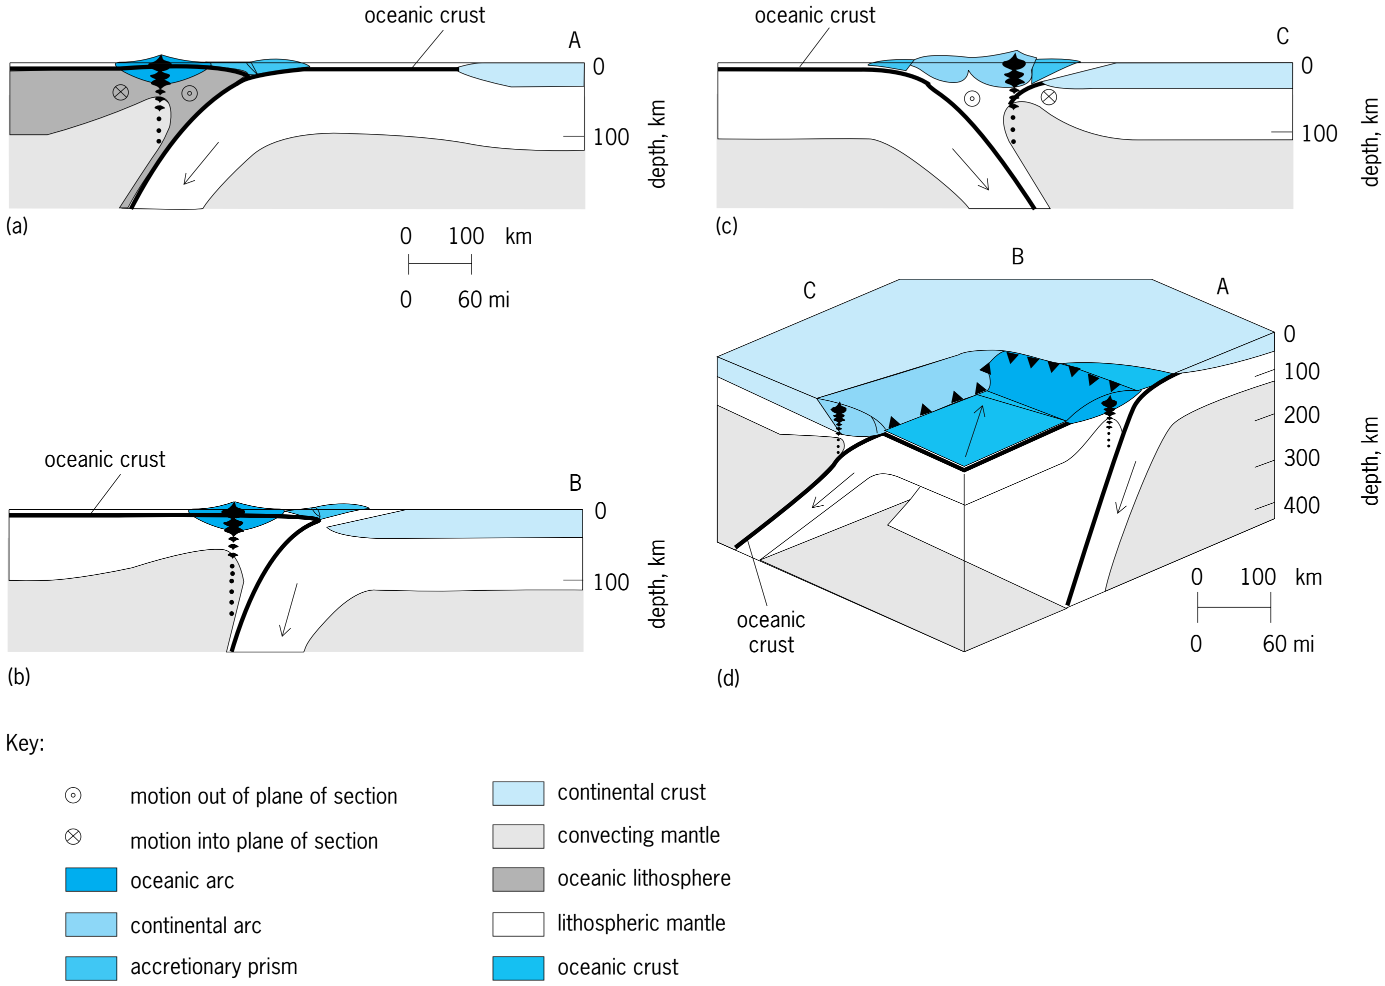

Fig. 2. **Stages of an arc-continent collision; arrows give direction of lithospheric movement. (*a*) Passive continental margin converging with an oceanic arc. (*b*) Arc colliding with continent. (*c*) Subduction polarity reversed and continental arc established. (*d*) General diachrony of the collision.**

destruction of continental crust (Fig. 1). The destructive processes are sediment subduction and subduction ablation. Constructive and destructive processes may be at work simultaneously, and the net balance may swing one way or the other with time. Selective destruction of lower crust may occur in continent-continent collision zones as a result of convective dripping of tectonically thickened lithosphere.

Sediment subduction. Accretionary prisms are poorly developed or lacking where trenches receive only very sparse amounts of terrigenous sediment. In such cases, pelagic oozes are subducted along with the oceanic crust. Even at subduction zones with well-developed accretionary prisms, some of the pelagic and terrigenous sediments disappears beneath the deformation front of the prism. Some is accreted structurally to the base of the prism, and some is transferred to the magmatic arc by melting. Some escapes melting and sinks deeply into the mantle, where it constitutes an isotopically recognizable component in the source of plume basalts. Sediment subduction, being fed by surface erosion, preferentially destroys the upper crust.

Subduction ablation. It is postulated that crust and lithospheric mantle from the overriding plate may become entrained in the subducting slab, causing tectonic ablation. Like subducted sediment, ablated crust is potentially capable of melting as it passes beneath the convecting mantle wedge. Unlike subducted sediment, ablated material may include lower crust and lithospheric mantle as well as upper crust. The ablation flux is quantitatively unknown.

Continental drip. Where continental lithosphere is tectonically thickened, cold lithospheric mantle is forced downward into hotter convecting mantle. Lithospheric thickening generates lateral thermal gradients, which drive mantle convection. The thickened lithospheric mantle is therefore unstable and may drip away. The missing lithospheric mantle is replaced by hotter asthenospheric mantle, causing melting and surface uplift. Lower crust may be entrained in the drip if it has been transformed to eclogite (a high-density rock chemically equivalent to basalt but composed of garnet and pyroxene) under the load of the tectonically thickened crust. Unlike sediment subduction, upper crust is not lost by dripping; and unlike subduction ablation, continental drips are not susceptible to hydration melting. Drips may sink deeply into the mantle; this view is based on the recognition of distinctive chemical and isotopic signatures of subcontinental lithospheric mantle in plume basalts. *See* ASTHENOSPHERE; ECLOGITE.

Continents and Earth history. The oldest surviving crust on Earth was formed 4 billion years ago. The absence of crust older than 4 billion years is attributed to recycling associated with the early high-impact flux inferred from the dated cratered surface of the Moon. Since the impact flux waned, processes that construct and destroy continental crust have adjusted to slow cooling and convective slowing of the mantle. The estimated magnitude of the secular change in mean upper-mantle temperature since 4 billion years ago is on the order of 360°F (200°C). This is comparable in magnitude to regional temperature variations in the upper mantle at the present time. In effect, mantle plumes in the present simulate more general conditions that prevailed in the early Earth. Furthermore, processes limited to the earlier or later parts of Earth history should be only those that operate in anomalous situations. This reasoning is consistent with empirical comparisons of continental crust of different ages. The basic forms and scales of continental accretion as well as those of continental fragmentation and collision appear to have changed remarkably little over geologic time. *See* MOON.

Oldest crustal relics. Areas of crust between 3.5 and 4 billion years old are small (less than 390 mi^2 or 1000 km^2), and there is nothing extraordinary about the rock suites they contain. Their isotopic characteristics and variability are striking. They show that the contemporaneous mantle was very heterogeneous, containing different sectors strongly depleted in some crustal components and strongly enriched in others. The crust was also heterogeneous and included sectors having long crustal residence times (greater than 200 million years) as well as newly formed sectors. These observations suggest that abundant continental-type crust already existed and that it was subject to vigorous recycling. However, these inferences are widely disputed. *See* ROCK AGE DETERMINATION.

Early juvenile crust. Juvenile crust, in a strict temporal sense, is continental crust recently separated from the mantle. In the broader nontemporal sense used here, it is continental crust not strongly modified by postaccretionary tectonism. Coherent areas up to 1550 mi (2500 km) in diameter of juvenile crust older than 2 billion years are exposed in Precambrian shields. Although rocks and structures typical of accretionary prisms, magmatic arcs, and fore-arc and back-arc basins abound, some systematic differences in comparison with geological younger juvenile crust are evident. The relative abundance of certain sodic granitoid suites in old shields implies a secular decline in the importance of slab (crustal) melting relative to wedge (mantle) melting in subduction zones. Komatiites (extremely hot, magnesium-rich, lava flows) are essentially confined to old shields and are interpreted as representing mantle-plume volcanism in the early Earth. Conversely, blueschists (rocks metamorphosed at high pressure and low temperature) are unknown in old shields. They are products of extremely rapid burial and exhumation in subduction zones having severely depressed geothermal gradients. Blueschists could not have survived even slightly increased geothermal gradients. These and other observations are consistent with the estimated cooling of the Earth and consequent adjustments in the tectonic regime. *See* BLUESCHIST; PRECAMBRIAN.

Cratons and mantle roots. Areas of juvenile crust older than about 2 billion years tend to be rheologically stiffer than younger areas. Such strong blocks are called cratons. Most have survived several rounds of continental fragmentation and collision, their margins battered by repeated openings and closing of ocean basins. Mantle tomography (three-dimensional mantle thermal structure inferred from velocity variations of earthquake-generated seismic waves) shows that cratons are underlain by anomalously cold mantle corresponding to lithosphere more than twice the approximately 60-mi (100-km) thickness of mature oceanic or noncratonic continental lithosphere. The mantle roots must be chemically distinct because, given that cratons tend to have neutral or even positive buoyancy, a low intrinsic density is required to offset the density increase due to thermal contraction. *See* COMPUTERIZED TOMOGRAPHY; CONTINENTAL MARGIN.

Conveniently, rock samples of mantle roots (peridotites) have been delivered to the surface as inclusions in diamond-bearing subvolcanic pipes. The inclusions have appropriate densities and are composed of residual mantle material from which high degrees of partial melt were driven. A class of associated inclusions, called eclogites, consists of rocks corresponding compositionally to oceanic crust but metamorphosed under mantle depth conditions. Isotopic studies reveal that the eclogite inclusions are samples of ancient oceanic crust subducted billions of years ago to depths exceeding 90 mi [150 km (into the diamond stability field)]. There they remained, fixed within drifting lithospheric plates, until fired volcanically to the surface in relatively recent times. If the peridotite and eclogite inclusions are cogenetic, the former should also have originated at seafloor spreading ridges billions of years ago. *See* DIAMOND; PERIDOTITE.

When the Earth was hotter, greater degrees of melting at oceanic spreading ridges (comparable to modern spreading ridges situated above mantle plumes, for example, Iceland) would have generated oceanic lithosphere characterized by thick (greater than 12 mi or 20 km) crust and highly depleted mantle. Such lithosphere might not sink deeply upon subduction because of the buoyancy of the thick crust and because the removal of melt actually lowers the density of the residual mantle. Accordingly, it is postulated that cratonic mantle roots are composed of buoyantly subducted slabs of highly depleted oceanic lithosphere. The presence of mantle roots would have increased the survivability of cratons: they would have been less susceptible to tectonic thickening and destruction by sediment subduction. Therefore, noncratonic continents may have existed on the young Earth but were selectively destroyed.

Continental growth. The mean age of extant continental crust is about 2 billion years. The primary mode in crustal abundance by geologic age is at 2.7 billion years, and perhaps half of all extant crust formed between 1.5 and 3 billion years ago. The conventional interpretation is that there was little continental crust following the period of high impact flux and that continental growth was slow at first, then rose to a peak 2–3 billion years ago, after which it slowly tapered off. An alternative interpretation, however, holds that the volume of continental crust has been in a near steady state since the impact flux waned. The present age distribution is explained by assuming a secular decline in the rate of crustal recycling, presumably modulated by the decreasing vigor of mantle convection as the Earth cooled. The difference in interpretation hinges on the importance assigned to recycling of continental crust. In crustal growth models, there is little crust older than 3 billion years, because little was formed. In steady-state models, much crust was formed early on but little of it survives. The steady-state interpretation is consistent with isotopic data showing that the oldest crustal relics contain highly evolved as well as juvenile components, and that the contemporaneous mantle was also heterogeneous and included strongly depleted regions. Furthermore, the near steady-state alternative is supported by comparative planetology, which indicates that for the hot young mantle not to be thoroughly differentiated by near-surface melting is physically implausible. *See* CONTINENTAL DRIFT; EARTH; EARTH, AGE OF; EARTH, CONVECTION IN; FAULT AND FAULT STRUCTURES; GEOPHYSICS; MARINE GEOLOGY; PLATE TECTONICS; SEISMOLOGY. Continuous-wave radar

A radar in which the transmitter output is uninterrupted, in contrast to pulse radar, where the output consists of short pulses. Among the advantages of continuous-wave (CW) radar is its ability to measure velocity with extreme accuracy by means of the Doppler shift in the frequency of the echo. The detected, reflected wave is shifted in frequency by an amount which is a function of the relative velocity between the target and the transmitter-receiver. Range data are extracted from the change in Doppler frequency with time. *See* DOPPLER RADAR.

In order to measure the range of targets, some form of frequency modulation (FM) of the continuous-wave output must be used. In one very effective form of modulation, the carrier frequency of the transmitted signal is varied at a uniform rate. Range is determined by comparing the frequency of the echo with that of the transmitter, the difference being proportional to the range of the target that produced the echo. Systems in which this is done are known as FM-CW radars. *See* FREQUENCY MODULATION.

A modified form of FM-CW radar employs long, but not continuous, transmission. This might be regarded as the same as transmitting extremely long pulses on an FM carrier. Systems of this type are referred to as pulse compression radars.

An FM-CW radar used in the radio-proximity fuses of missiles generates functions of the Doppler signal envelope that have identifiable characteristics at certain ranges. The amplitude of the received FM-CW signal is used to determine when the missile has attained the proper altitude. Then the generated functions tell when the missile has arrived at the desired point of burst. Three triangular-wave modulators can be used to enhance the accuracy of an FM-CW radar fusing system.

In advanced short-range air defense radar (ASHORAD) a coded continuous-wave signal reflected from the target is fed to a tapped delay line, where a predetermined delay between adjacent taps is used to establish the range.

Design objectives. Design objectives for continuous-wave radar include protecting the receiver from the transmitter output and close-by return echoes when a single antenna is used; resolving side-lobe ambiguity; resolving range ambiguity; distinguishing between approaching and receding targets; eliminating noise and clutter; simultaneously measuring both target range and velocity; determining the shapes of targets; handling multiple targets; measuring target acceleration; communicating with targets; and increasing the received signal-to-noise ratio.

Receiver protection. One disadvantage of continuous—wave radar is that when a single antenna is used for both reception and transmission it is difficult to protect the receiver against the transmitter because, in contrast to pulse radar, both are on all the time. Use of isolation circuitry gives the receiver protection from a transmitter output up to 200 W. Use of magnetically biased yttrium-iron-garnet (YIG) provides three tuned, tandem-connected power-limiter stages in one X-band FM-CW radar. *See* FERRIMAGNETIC GARNETS.

In continuous-wave surveillance radars where wide bandwidth is required to meet range and range-rate measurement requirements despite clutter and other interfering environments, the transmitter output can be coded by pseudorandom binary signals that vary with range. This is an ideal waveform for permitting range measurements, retaining a capability for range-rate measurements, and rejecting the transmitter output and other nearby echoes.

Side-lobe ambiguity. The problem of distinguishing between echoes from the main lobe and those from the side lobes has been addressed by providing a demodulated range response that has one polarity for the main-lobe echoes and the opposite polarity for side-lobe echoes.

Side-lobe ambiguity is removed in an FM-CW radar fusing system in which the reflected signal is compared with a sample of the continuous-wave output in a pair of FM discriminators displaced from each other in the frequency domain. Thresholding circuits determine in which half of which discriminator the difference frequency signal is concentrated.

Side-lobe ambiguity in the range response of an FM-CW radar can be resolved when a periodic modulation frequency is reflected from a target and combined with a sample of the transmitted signal. Selected harmonics of the combination signal are processed to develop a main-lobe response of one polarity with all side lobes of the opposite polarity.

Range ambiguity. This ambiguity results from reception of echoes from targets beyond the range of interest and of second-time-around echoes. It can be resolved by range gates that make the radar insensitive to targets beyond the range of interest or by filters that put limits on range. Resolution of range ambiguity is very important in radars for personnel surveillance.

Directional ambiguity. To distinguish between approaching and receding targets, a continuous wave beamed by a radar is sampled continuously but delivers an output voltage only when the distance to the target is changing significantly. The voltage is positive if the target is closing, and negative if it is receding.

Noise and clutter. Suppression of noise, clutter, chaff, and jamming has received a great deal of attention. In one approach, a fixed pair of amplitude-modulation (AM) sidebands is added and used to null out the noise.

Echo signal analyzers can be selectively adjusted for a certain moving-target size so that small targets are not detected. A series of digital range cells can be defined such that each cell represents the minimum allowable distance between two reflective points on a target. The radar also can be adaptively adjusted to attend to a desired average signal level.

Use of digitally controlled voltage-tunable radio-frequency generators permits frequency jumping to avoid jamming or spoofing. Pseudorandom-noise-modulated continuous-wave radar can be used to establish perimeter surveillance in a heavily foliaged environment. Pseudorandomly coded continuous-wave radar can also be used to detect targets in the presence of clutter. *See* ELECTRICAL NOISE; ELECTRONIC WARFARE.

Range and velocity sensing. Several techniques are used to obtain simultaneous measurements of range and velocity. One involves transmitting sidebands of linearly increasing and decreasing frequency or using triangular modulation, and comparing the difference between transmitted and received frequencies with the difference between the received frequency and the transmitted frequency delayed by a period of time proportional to the range of the target. Phase-shift keying by a pseudorandom code also permits simultaneous measurement of range and velocity. *See* MODULATION.

A double-sideband linear FM radar obtains simultaneous range and Doppler measurements. Waveforms of both increasing and decreasing frequency are transmitted simultaneously and combined coherently to give an output that is a measure of the target's radial velocity. The received signals are processed separately to obtain range information.

Target shape. Millimeter-wave FM-CW radar can be used to determine the shape of a target. These radars operate at frequencies in excess of 90 GHz. They often use Gunn oscillators as the source. *See* MICROWAVE SOLID-STATE DEVICES.

French and Russian research suggests that in some applications it may be necessary to use space diversity in which two beams illuminate the target in order to compensate for nonlinearities in frequency scanning.

The dependence of radar cross section on transmitted frequency over a wide bandwidth can be used to make the signal amplitude scintillate so that target characteristics can be determined.

Rapid discontinuous fluctuations in the scattering from a moving multielement target is known as the intermittent-contact RADAM (radar detection of agitated metals) effect. This effect is observed in the contact between the drive sprocket and the tread of a tank and can be used to define signatures of various kinds of fighting vehicles.

Multiple targets. Discrete Fourier analysis of the video heterodyne (beat) signals using a digital computer permits multiple-target handling and achieves good resolution between approaching and receding targets. *See* SPECTRUM ANALYZER.

Target acceleration. An indication of the acceleration of a target can be obtained by double subtraction and delay of the returned signal.

Communicating with the target. In radar missile guidance, homing beacons, and identification–friend-or-foe, it is necessary to communicate with the target. This can be done by interrupting the range beat frequency at short intervals near its peak excursion and transmitting AM signals to the illuminated target.

Signal-to-noise ratio. The signal-to-noise ratio can be improved by digitizing the beat frequency signals. Moreover, compressing the received signals to a sine-squared shape can increase the signal level more than 20 decibels. *See* SIGNAL-TO-NOISE RATIO.

Applications. Applications of continuous-wave radar include missile guidance; detection of hostile targets; terrain clearance indication and ground surveillance; laser radar systems; atmospheric studies; automobile safety; surveillance of personnel; ice studies; remote sensing; and reproduction of the shape of a patient's pulse.

Missile guidance. The principal use of continuous-wave radar is in short-range missile guidance. Typically the missile's course is tracked from the ground while the missile is simultaneously illuminated. Continuous-wave radar, in some cases the same radar, can be used for both tracking and illumination, although it is more common for pulse Doppler radar to be used for tracking.

Advances in the design of phased-array antennas have led to pulse Doppler radar becoming more attractive than continuous-wave radar even for illumination. However, at least one system allows the operator to select either continuous-wave or pulse Doppler radar for illumination.

Illumination radar is for target acquisition. Two signals are of interest. One, the directly received illumination of the missile, is called the rear signal. The other, the signal reflected from the target, is called the front signal. The front signal is shifted in frequency as the missile closes with the target. This shift occurs because of the Doppler effect. The shift, and therefore the range to the target, is obtained by coherently detecting the front signal against the rear signal. In an active guidance system, detection is performed on board the missile. Semiactive missile guidance is more frequently used, and in this system the signals are relayed over a data link for processing at the ground station.

A late version of the MPQ-34 tracking and acquisition radar for the Hawk ground-to-air missile incorporates the choice of either continuous-wave or pulse Doppler radar illumination. The ability of continuous-wave radar to discriminate against clutter made it attractive in this system, which was intended to be used against low-flying aircraft.

Pulsed tracking radar with continuous-wave acquisition radar is used with the Sparrow air-to-air missile system and with the Tartar shipborne missile system.

A miss-distance indicator (MDI) is a special application of continuous-wave radar. It uses radio-frequency signals to determine the relative velocity between two objects, the time of intercept when the distance will be a minimum, and the actual value of that minimum distance. With the availability of real-time intercept information, a prior determination of guidance parameters that will produce a direct hit can be made. *See* GUIDANCE SYSTEMS; GUIDED MISSILE.

Detection of hostile targets. Modulated continuous-wave radar has been used to detect hostile military vehicles and personnel.

The Navy MK-92 fire-control system uses a linear FM-CW radar with multiple resonant filters.

An FM-CW naval radar operating at 95.6 GHz uses pseudorandom-coded phase-shift keying, digital signal processing, and microprocessor-controlled azimuth and elevation scanning. It can display the shape, range, velocity, and direction of vessels. *See* NAVAL ARMAMENT.

In the United States, Canada, and the United Kingdom, there has been interest in continuous-wave radar for detecting nonmetallic mines. One radar operates between 2 and 4 GHz and can detect plastic objects buried in 10 in. (25 cm) of wet sand.

Terrain surveillance. One of the first uses of FM continuous-wave radar was in terrain clearance indicators or radar altimeters. Today intruder aircraft and air-breathing missiles obtain continuous guidance from that kind of equipment. *See* ALTIMETER.

The ability of side-looking radar on reconnaissance aircraft and Earth-observation satellites to resolve targets has been enhanced by the use of synthetic-aperture radar. Although this technique usually requires a huge data rate and great processing complexity, special-purpose processors have been used to extract useful data economically. Such a processor on the *Seasat 1* was able to determine the direction of ocean wave from 800 mi (1300 km) up. *See* REMOTE SENSING.

Earth surveillance has been hampered by some radar reflection phenomena, notably foreshadowing, which distorts distance; layover, which tends to fill in depressions; and shadow, which obscures features. These problems place limiting requirements on the size and contrast of images needed for successful interpretation. These limitations can be partially overcome by training radargrammetrists with simulators.

Laser radar systems. An experimental modulated continuous-wave laser radar was built to track low-flying airborne targets from the ground. The system can determine both range and the rate at which the range is changing. An advantage of this system is its extreme precision. The divergence of the beam is less than 1 milliradian. The transmitter is a carbon dioxide laser operating at a wavelength of 10.6 micrometers. The infrared carrier is frequency-modulated with 10-MHz excursions occurring at a frequency of 1 kHz. *See* LASER.

Atmospheric studies. The ability of FM-CW radar to measure distance and velocity despite smoke, dust, and thermal gradients makes it attractive for many industrial automatic control applications. The Naval Ocean Systems Center uses S-band continuous-wave radar to update refractive index profiles of the troposphere. This work forms the basis for radio interception and over-the-horizon targeting. In France, continuous-wave radar has been used to measure the electron temperatures in the ionosphere. The National Oceanic and Atmospheric Administration (NOAA) has used continuous-wave radar to measure wind in clear air.

Automobile safety. An experimental continuous-wave radar which exploits the Doppler principle has been developed for use in automobiles. The radar can anticipate a crash when an obstacle is 30 ft (10 m) away in order to deploy air-cushion-type passive restraints. It can sense obstacles 500 ft (150 m) away to govern automatic braking and headway control. The source of carrier power is an X-band Gunn-type solid-state oscillator.

Surveillance of personnel. A variant of continuous-wave radar is used to illuminate persons under surveillance by techniques employing semiconductor tracer diodes. These devices are secreted on or implanted in the subject's body without his or her knowledge, or else concealed in objects that are to be protected against theft. Despite the fact that pulsed X-band sources could provide the needed power levels more conveniently, the requirement to reduce clutter makes it desirable to use continuous-wave power.

These techniques are also used to sweep premises to discover clandestine listening devices and to guard protected locations against the introduction of concealed tape recorders.

Implementation of tracer-diode surveillance utilizes a single carrier frequency and looks for reflections of the third harmonic as evidence that the person sought has been acquired by the beam. The surveillance operations have been carried out from fixed posts, vans, and low-flying aircraft.

An improved version makes use of two carrier frequencies for illumination and depends upon coherent detection of the third and fourth harmonics of the sum and difference frequencies to signify acquisition of the target. *See* ELECTRONIC LISTENING DEVICES.

Other applications. In Finland, a continuous-wave radar operating between 1 and 1.8 GHz has been used to measure ice and frost thickness in lakes and bogs. Continuous-wave radars operating at 1.5 and from 8 to 18 GHz have been used to discriminate among different types of Arctic Sea ice.

Continuous-wave radar has been used in the Netherlands to discriminate among different types of vegetation, crops, and bare soils.

With its antenna placed over a patient's wrist artery, continuous-wave radar has been shown to be able to reproduce the shape of the arterial pulse. *See* RADAR.

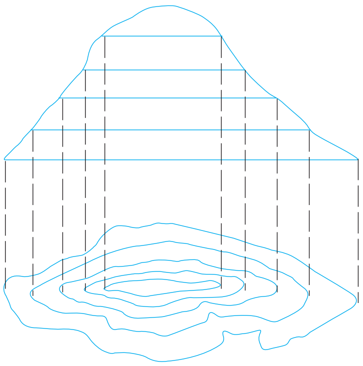
Contour

The locus of points of equal elevation used in topographic mapping. Contour lines represent a uniform series of elevations, the difference in elevation between adjacent lines being the contour interval of the given map. Thus, contours represent the shape of terrain on the flat map surface (see **illus.**). Closely spaced contours indicate steep ground; sparseness or absence of contours indicates gentle slope or flat ground. Contours do not cross each other unless there is an overhang. *See* TOPOGRAPHIC SURVEYING AND MAPPING.

In ground-survey procedures the horizontal positions and elevation of numerous points are observed. Points on the elevations chosen for contouring are then located by interpolation, and each contour is sketched by connecting the points found for its elevation. *See* SURVEYING.

In photogrammetric mapping with a stereoplotting instrument, the operator sets the plotting table at the chosen contour elevation; the elevation is "hunted" by shifting the table until a floating dot appears to touch the stereoscopic image; the operator then lowers the plotting pencil and traces the contour by keeping the floating dot in apparent touch with the image. *See* CARTOGRAPHY; PHOTOGRAMMETRY.



Contour representation; vertical projection indicates the profile of the elevation as it relates to the spacing of the contours.

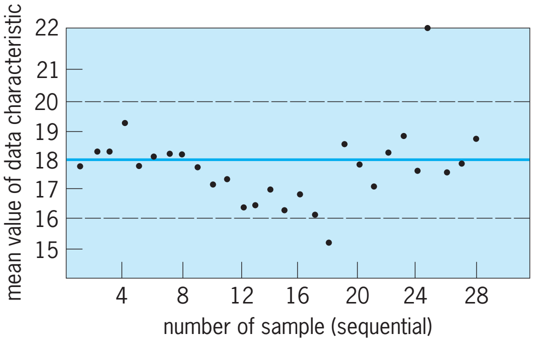
Control chart

A graphical technique for determining whether a process is or is not in a state of statistical control. Being in statistical control means that the extent of variation of the output of the process does not exceed that which is expected on the basis of the natural statistical variability of the process. Several main types of control charts are used, based on the nature of the process and on the intended use of the data.

Every process has some inherent variability due to random factors over which there is no control and which cannot be eliminated economically. For instance, in a metal fabrication process random factors may include the distribution of impurities and structural faults among the metal molecules, vibrations of the fabrication equipment, fluctuations in the power supply that affect the speed and torque of the equipment, and variations in the operator performance from one cycle to the next. The inherent variability of the process is the aggregate result of many individual causes, each having a small impact.

The control chart technique is applicable to processes that produce a stream of discrete output units. Control charts are designed to detect excessive variability due to specific assignable causes that can be corrected. Assignable causes result in relatively large variations, and they usually can be identified and economically removed. Examples of assignable causes of variations that may occur in the example of metal fabrication include a substandard batch of raw material, a machine malfunction, and an untrained or poorly motivated operator.

A control chart is a two-dimensional plot of the evolution of the process over time. The horizontal dimension represents time, with samples displayed in chronological order, such that the earliest sample taken appears on the left and each newly acquired sample is plotted to the right. The vertical dimension represents the value of the sample statistic, which might be the sample mean, range, or standard deviation in the case of measurement by variables, or in the case of measurement by attributes, the number of nonconforming units, the fraction nonconforming,



Control chart, showing changes in average of process.

the number of nonconformities, or the average number of nonconformities per unit.

Typically a control chart includes three parallel horizontal lines (see **illustration**): a center line and two control limits. The centerline (CL) intersects the vertical dimension at a value that represents the level of the process under stable conditions (natural variability only). The process level might be based on a given standard or, if no standard is available, on the current level of the process calculated as the average of an initial set of samples. The two lines above and below the centerline are called the upper control limit (UCL) and lower control limit (LCL) respectively, and they both denote the normal range of variation for the sample statistic. The control limits intersect the vertical axis such that if only the natural variability of the process is present, then the probability of a sample point falling outside the control limits and causing a false alarm is very small. Typically, control limits are located at three standard deviations from the centerline on both sides. This results in a probability of a false alarm being equal to 0.0027.

The principle of operation of control charts is rather simple and consists of five general steps:

1. Samples are drawn from the process output at regular intervals.

2. A statistic is calculated from the observed values of the units in the sample; a statistic is a mathematical function computed on the basis of the values of the observations in the sample.

3. The value of the statistic is charted over time; any points falling outside the control limits or any other nonrandom pattern of points indicate that there has been a change in the process, either its setting or its variability.

4. If such change is detected, the process is stopped and an investigation is conducted to determine the causes for the change.

5. Once the causes of the change have been ascertained and any required corrective action has been taken, the process is resumed.

The main benefit of control charts is to provide a visual means to identify conditions where the process level or variation has changed due to an assignable cause and consequently is no longer in a state of statistical control. The visual patterns that indicate either the out-of-control state or some other condition that requires attention are known as outliers, runs of points, low variability, trends, cycles, and mixtures. *See* CONTROL SYSTEMS; QUALITY CONTROL; STATISTICAL PROCESS CONTROL.

Control system stability

The well-behavedness of the output of a control system in response to either external inputs or internal excitations. Several definitions of stability are in use, each being appropriate to a different application. The objective of stability theory is to obtain information concerning the behavior of a control system without actually solving the equations that describe the system.

Stability theory can be applied in a wide variety of disciplines, such as engineering, mathematics, physics, biology, and economics.

A few examples illustrate such stability theory: (1) The classical problem studied by the Soviet mathematician A. M. Lyapunov was the stability of the solar system. The objective was to determine the ultimate behavior of the trajectories of the various planets, in particular whether they would all spiral into the Sun, fly off into space, or do something else. (2) In digital filters, it is sometimes possible to encounter limit cycles, that is, round off errors that do not decay, perhaps due to the finite word length of the operations. It has been experimentally observed that certain configurations and certain coefficient values never exhibit limit cycles, and a mathematical explanation of this phenomenon would be useful. (3) A voltage source is connected to an electronic circuit containing resistors, capacitors, and operational amplifiers. For a broad but prespecified class of voltage excitations, it would be useful to know whether the resulting current will eventually decay to zero. (4) In a plasma laboratory, a scheme is proposed for confining the plasma to a specified cylindrical region; it would be useful to know whether the proposed scheme will work. (5) A model is developed for the spread of an infectious disease within a population, and it would be useful to be able to determine how the number of survivors is affected by various parameters of the model. *See* ELECTRIC FILTER; NUCLEAR FUSION.

As shown by the discussion below, stability theory encompasses systems described by a wide variety of models. Thus the equations governing the system may be linear or nonlinear; they may be difference equations or differential equations; they may be ordinary, partial, or functional differential equations; finally, they may be difference equations in more than one parameter. This article deals chiefly with differential equations; the theory for other types of equations is similar in concept, though not in detail.

Routh, Hurwitz, and related tests. Consider a system whose transfer function is of the form given by Eq. (1), where $\hat{n}$ and $\hat{d}$ are polynomials and s denotes

$$\hat{h}(s) = \frac{\hat{n}(s)}{\hat{d}(s)} \tag{1}$$

the variable of Laplace transformation. Such a system exhibits a bounded response to every bounded excitation if and only if the following two conditions hold: (1) $\hat{h}$ is proper, that is, the degree of the polynomial $\hat{n}$ is less than or equal to that of $\hat{d}$; (2) all poles of $\hat{h}$, that is, all zeros of the polynomial $\hat{d}$, must have negative real parts. (A polynomial satisfying these conditions is called a strictly Hurwitz polynomial.) Given a transfer function $\hat{h}$, inspection will verify whether or not the first condition is satisfied, but the second condition is harder to verify. In particular, it would be useful to determine whether or not all zeros of $\hat{d}$ have negative real parts (that is, whether or not $\hat{d}$ is strictly Hurwitz) without actually computing these zeros. The various tests described below are addressed to this problem. *See* LAPLACE TRANSFORM.

Routh test. Suppose the polynomial $\hat{d}$ is of the form given by Eq. (2), where it may be supposed, with-

$$\hat{d}(s) = d_m s^m + d_{m-1} s^{m-1} + \cdots + d_1 s + d_0 \tag{2}$$

out loss of generality, that $d_m > 0$. The Routh test is based on forming the ratio of the even part of $\hat{d}$ over the odd part of $\hat{d}$ (or vice versa), and then carrying out a continued fraction expansion. To illustrate, suppose $m = 2k$ is an even number; then $\hat{d}_{\text{even}}(s)$ and $\hat{d}_{\text{odd}}(s)$ are defined by Eqs. (3) and (4). Then the ratio $\hat{d}_{\text{even}}(s)/\hat{d}_{\text{odd}}(s)$ is expressed in the form given by Eq. (5). [If m is odd, $\hat{d}_{\text{odd}}(s)/\hat{d}_{\text{even}}(s)$ this form.] The

$$\hat{d}_{\text{even}}(s) = \sum_{i=0}^{k} d_{2i} s^{2i} \tag{3}$$

$$\hat{d}_{\text{odd}}(s) = \sum_{i=0}^{k-1} d_{2i} +{}_1 s^{2i+1} \tag{4}$$

$$\frac{\hat{d}_{\text{even}}(s)}{\hat{d}_{\text{odd}}(s)} = b_m s + \cfrac{1}{b_{m-1} s + \cfrac{1}{\cdots + \cfrac{1}{b_1 s}}} \tag{5}$$

basis of the Routh test is in the following fact: $\hat{d}$ is a strictly Hurwitz polynomial if and only if (1) it is possible to completely carry out the continued fraction expansion in Eq. (5), and (2) all the constants $b_m, \ldots, b_1$ are positive. The test also furnishes one additional piece of information. Suppose that the expansion in Eq. (5) is completed, but not all the b_i's are positive. (Then of course $\hat{d}$ is not strictly Hurwitz.) Under these conditions, if none of the b_i's is zero, then the number of zeros of $\hat{d}$ with positive real part is equal to the number of negative b_i's.

Though the above is the theoretical basis of the Routh test, this is not the manner in which the test is actually carried out. To perform the test in an efficient manner, an array is set up, called the Routh array, as shown in Eq. (6), for the case that m is even,

$$\begin{array}{l|lllll}
s^m & d_m & d_{m-2} & \cdots & d_2 & d_0 \\
s^{m-1} & d_{m-1} & d_{m-3} & \cdots & d_1 & \\
s^{m-2} & a_{m-2,1} & a_{m-2,2} & \cdots & a_{m-2,k} & \\
\cdot & & & & & \\
\cdot & & & & & \\
\cdot & & & & & \\
s^1 & a_{1,1} & & & & \\
s^0 & a_{0,1} & & & &
\end{array} \tag{6}$$

and the entries in the array are recursively defined by Eq. (7). With reference to Eq. (5), it can be shown

$$a_{i,j} = a_{i+2,j+1} - \frac{a_{i+2,1} \cdot a_{i+1,j+1}}{a_{i+1,1}} \tag{7}$$

that the b_i's are given by Eq. (8). Hence the Routh

$$b_i = a_{i,1}/a_{i-1,1} \qquad i = m, \ldots, 1 \tag{8}$$

test can be concisely stated as follows: The polynomial $\hat{d}$ is strictly Hurwitz if and only if all the entries in the first column of the Routh array are positive. Now suppose d is not strictly Hurwitz, but none of the entries in the first column of the Routh array is zero. Then the number of zeros of $\hat{d}$ with positive real part is equal to the number of sign changes in the first column of the Routh array.

Hurwitz test. The Routh test is frequently misnamed the Routh-Hurwitz test. Actually the Hurwitz test is different from the Routh test, though they are equivalent in the sense that they both give the same information. The Hurwitz test is as follows: Given a polynomial $\hat{d}$ of the form in Eq. (2), construct the $m \times m$ matrix **H** given by Eq. (9), and let $\Delta_1, \ldots, \Delta_m$ denote

$$\mathbf{H} = \begin{bmatrix}
d_{m-1} & d_{m-3} & \cdots & 0 & 0 & \cdots & 0 \\
d_m & d_{m-2} & \cdots & & & & \\
0 & d_{m-1} & d_{m-3} & \cdots & & & \\
0 & d_m & d_{m-2} & \cdots & & & \\
\cdot & & & & & & \\
\cdot & & & & & & \\
\cdot & & & & & & \\
0 & 0 & \cdots & & & d_3 & d_1 \\
0 & 0 & \cdots & & & d_2 & d_0
\end{bmatrix} \tag{9}$$

the leading principal minors of **H**. (That is, Δ_i is the determinant of the matrix consisting of the entries in **H** that belong to both the first i rows and the first i columns.) Then $\hat{d}$ is a strictly Hurwitz polynomial if and only if $\Delta_i > 0$ for all i. If $\hat{d}$ is not strictly Hurwitz but none of the Δ_i's is zero, then the number of zeros of $\hat{d}$ with positive real part is equal to the number of negative Δ_i's. *See* DETERMINANT.

The relationship between the Hurwitz determinants and the first column of the Routh array is given by Eq. (10), where $\Delta_0 = 1$.

$$a_{i,1} = \Delta_{m-i}/\Delta_{m-i-1} \qquad i = 1, \ldots, m-1 \tag{10}$$

Liénard-Chipart test. Given a polynomial $\hat{d}$ of the form in Eq. (5), a necessary but by no means sufficient condition for $\hat{d}$ to be strictly Hurwitz is that all the coefficients d_i be positive. In this case, it is possible to somewhat simplify the Hurwitz test. In particular, if $d_i > 0$ for all i, then $\hat{d}$ is strictly Hurwitz if and only if either of the equivalent conditions (11) and (12) is satisfied. This simplification is known as the Liénard-Chipart test.

$$\Delta_1 > 0, \Delta_3 > 0, \Delta_5 > 0, \ldots \tag{11}$$

$$\Delta_2 > 0, \Delta_4 > 0, \Delta_6 > 0, \ldots \tag{12}$$

Tests for zeros all of magnitude less than 1. In analyzing the stability of sampled-data control systems, digital filters, and so forth, it is desirable to determine not whether all zeros of $\hat{d}$ have negative real parts, buy whether all zeros of $\hat{d}$ have magnitude less than 1. One means of doing so is by using the bilinear transformation defined by Eq. (13), which maps the inte-

$$s = \frac{v+1}{v-1} \tag{13}$$

rior of the unit circle in the s plane into the left half of the v plane. Thus, all zeros of $\hat{d}$ in the form (2) have magnitude less than 1 if and only if the associated polynomial given by Eq. (14) is strictly Hurwitz. This

$$p(v) = \sum_{i=0}^{m} d_i (v+1)^i (v-1)^{m-i} \tag{14}$$

can be determined using the tests described above.

However, there are many tests that can be applied directly to the polynomial $\hat{d}$ without requiring any transformation. One of these is the Schur-Cohn test: Let $\hat{d}(s)$ be a polynomial of the form in Eq. and define the determinants Δ_i by Eq. (15) Δ_i is the determinant of a $2i \times 2i$ matrix. The Schur-Cohn test states that all zeros of $\hat{d}$ have magnitude less than 1 if and only if $(-1)^i\Delta_i > 0$ for all i, that is Δ_i positive for even i and negative for odd i.

$$\Delta_i = \left|\begin{array}{ccccc|cccc}
d_0 & 0 & 0 & \cdots & 0 & d_m & d_{m-1} & \cdots & d_{m-i+1} \\
d_1 & d_0 & 0 & \cdots & 0 & 0 & d_m & \cdots & d_{m-i+2} \\
d_2 & d_1 & d_0 & \cdots & 0 & 0 & 0 & \cdots & d_{m-i+3} \\
\cdot & & & & & \cdot & & & \\
\cdot & & & & & \cdot & & & \\
\cdot & & & & & \cdot & & & \\
d_{i-1} & d_{i-2} & d_{i-3} & \cdots & d_0 & 0 & 0 & \cdots & d_m \\
\hline
d_m & 0 & 0 & \cdots & 0 & d_0 & d_1 & \cdots & d_{i-1} \\
d_{m-1} & d_m & 0 & \cdots & 0 & 0 & d_0 & \cdots & d_{i-2} \\
\cdot & & & & & \cdot & & & \\
\cdot & & & & & \cdot & & & \\
\cdot & & & & & \cdot & & & \\
d_{m-i+1} & d_{m-i+2} & & \cdots & d_m & 0 & 0 & \cdots & d_0
\end{array}\right| \tag{15}$$

The theoretical advantage of the Schur-Cohn test is that it can be used (with slight modifications) even if the coefficients d_i are complex. However, in practical situations, the coefficients d_i are all real, in which case it is possible to simplify the Schur-Cohn test. The Jury-Blanchard test is as follows: Given a polynomial $\hat{d}$ in the form of Eq. (2), define an array of elements $a_{i,j,}$ $i = 0$ to $m = 2, j = 0$ to $(m - i)$, by the rules of Eqs. (16) and (17). With these definitions, all zeros of

$$a_{0,j} = d_j \qquad j = 0, \ \ldots, m \tag{16}$$

$$a_{i,j} = \begin{vmatrix} a_{i-1,0} & a_{i-1,m-i-j} \\ a_{i-1,m-i} & a_{i-1,j} \end{vmatrix} \tag{17}$$

$\hat{d}$ have magnitude less than 1 if and only if conditions (18) and (19) are satisfied.

$$\hat{d}(1) > 0 \quad (-1)^m \hat{d}(-1) > 0 \quad |d_0| > |d_m| \tag{18}$$

$$|a_{i,0}| > |a_{i,m-i}| \ \text{ for } i = 1 \text{ to } m-2 \tag{19}$$

Nyquist, circle, and Popov criteria. The Nyquist criterion provides a necessary and sufficient condition for the stability of a broad class of linear, time-invariant systems. The criterion can be stated at various levels of generality, and what is given below is one of the simplest versions.

Nyquist plot. Consider a feedback system of the form shown in **Fig. 1**, where the forward element has a transfer function $\hat{g}(s)$ and the feedback contains a constant gain k. It is assumed that the transfer function consists of the sum of three terms, in the form of Eq. (20), where g_0 is a constant; $\hat{g}_a(s)$ is the Laplace

$$\hat{g}(s) = g_0 + \hat{g}_a(s) + \hat{g}_b(s) \tag{20}$$

transform of an absolutely integrable function, that is, Eq. (21) is valid, and $\hat{g}_b(s)$ is a proper rational

$$\hat{g}_a(s) = \mathcal{L}[g_a(t)] \qquad \text{where} \int_0^\infty |g_a(t)|\, dt \text{ is finite} \tag{21}$$

function. Under these conditions, it is possible to determine whether or not the closed-loop system

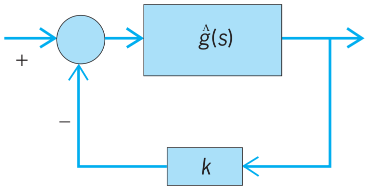

Fig. 1. Feedback system with feedback containing a constant gain *k*.

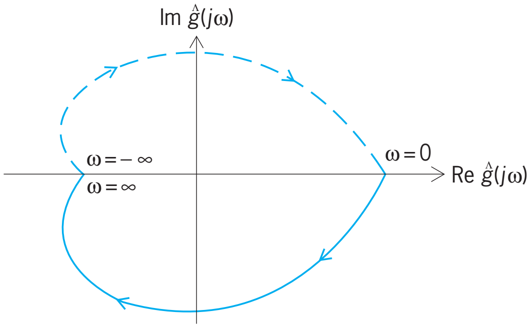

Fig. 2. Nyquist plot of a transfer function $\hat{g}$.

is stable by examining only the behavior of $\hat{g}(j\omega)$, where $j = \sqrt{-1}$ and the frequency parameter ω is allowed to vary along the real axis from $-\infty$ to ∞.

The plot of the real part of $\hat{g}(j\omega)$ versus the imaginary part of $\hat{g}(j\omega)$, as the frequency parameter ω varies from $-\infty$ to ∞, is called the Nyquist plot of $\hat{g}$ (**Fig. 2**). Since $\hat{g}(-j\omega)$ is the complex conjugate of $\hat{g}(j\omega)$, the plot as ω varies from 0 to $-\infty$ is the mirror image, about the real axis, of the plot as ω varies from 0 to ∞.

It sometimes happens that $\hat{g}$ has some poles on the imaginary axis, in which case $\hat{g}(j\omega)$ may be undefined for certain values of ω. In such cases, it is necessary to indent the $j\omega$ axis around the poles of $\hat{g}(j\omega)$, as shown in **Fig. 3**.

Nyquist criterion. With these conventions, the Nyquist criterion can be stated as follows: The system of Fig. 1 is stable if and only if (1) the Nyquist plot of $\hat{g}(j\omega)$ does not intersect the critical point $-(1/k) + j0$, and (2) as ω increases from $-\infty$ to ∞, the Nyquist plot encircles the critical point exactly μ times in the counterclockwise direction, where μ is the number of poles of $\hat{g}$ with positive real parts.

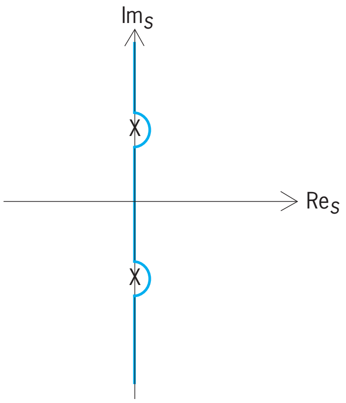

Fig. 3. Modification of Laplace transformation variable to avoid poles of the transfer function $\hat{g}$.

Several advantages of the Nyquist criterion are immediately apparent. (1) It is based on the behavior of $\hat{g}(j\omega)$, which can be readily obtained by frequency response measurements. (2) Since $\hat{g}$ is not required to be a rational function of s (only $\hat{g}_b$ is required to be rational), the criterion is applicable to systems containing transmission lines, time delays, and so forth. (3) For a given transfer function $\hat{g}$, one can readily calculate the range of values of k that result in a stable closed-loop system. (4) Even if the system of Fig. 1 is unstable, it can easily be determined what sort of "compensation" is needed to make the system stable.

Circle criterion. Now consider the system of **Fig. 4**, which is similar to that of Fig. 1, except that the constant gain k has been replaced by a time-varying gain $k(t)$. The assumptions on $\hat{g}(s)$ are the same as before.

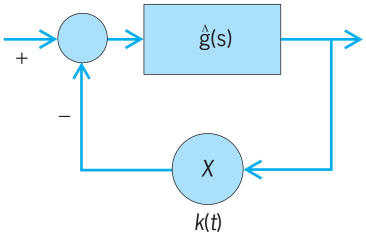

Fig. 4. Feedback system with feedback containing a time-varying gain *k*(*t*).

The circle criterion gives sufficient conditions for the stability of such a system, and can be stated as follows: Suppose the gain $k(t)$ varies in the range $[\alpha,\beta]$, that is, $\alpha \le k(t) \le \beta$ for all t. Let $D(\alpha,\beta)$ denote the critical disk, which passes through $-1/\alpha + j0$ and $-1/\beta + j0$, and is centered on the real axis. Under these conditions, the system of Fig. 4 is stable if one of the following conditions, as appropriate, holds:

Case 1: $0 < \alpha < \beta$. The Nyquist plot of $\hat{g}(j\omega)$ does not intersect the critical disk $D(\alpha,\beta)$ and encircles it in the counterclockwise direction exactly μ times (**Fig. 5**).

Case 2: $0 = \alpha < \beta$. The Nyquist plot of $\hat{g}(j\omega)$ lies in the half-plane Re $\hat{g}(j\omega) < 1/\beta$.

Case 3: $\alpha < 0 < \beta$. The Nyquist plot of $\hat{g}(j\omega)$ is contained within the critical disk $D(\alpha,\beta)$.

Case 4: $\alpha < \beta < 0$. Replace $\hat{g}$ by $-\hat{g}$, α by $-\beta$, β by $-\alpha$, and apply case 1 (since $0 < -\beta < -\alpha$).

The circle criterion shares the same advantages as the Nyquist criterion. In addition, if $\alpha \to \beta$, so that the time-varying gain $k(t)$ approaches a constant gain β, then the critical disk in the circle criterion shrinks to the critical point of the Nyquist criterion.

Popov criterion. Finally, consider the system shown in **Fig. 6**, wherein the feedback contains a memoryless nonlinear element N. Suppose the graph of the nonlinearity lies in the sector $[0,k]$, that is, between the horizontal axis and a line of slope k through the origin (**Fig. 7**). Finally, suppose $\hat{g}(s)$ is strictly proper and that all poles of $\hat{g}$ have negative real parts. The Popov criterion gives a sufficient condition for the stability of such a system.

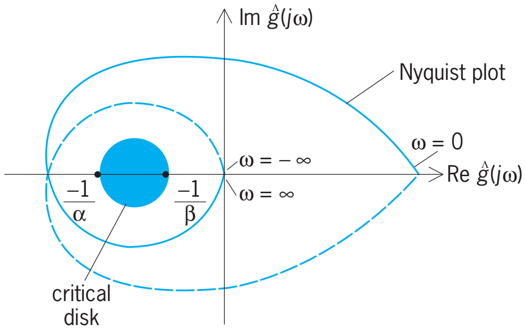

Fig. 5. Circle criterion for $0 < \alpha < \beta$. The Nyquist plot does not intersect the critical disk and encircles it in the counterclockwise direction exactly μ times, where μ is the number of poles of $\hat{g}$ with positive real parts.

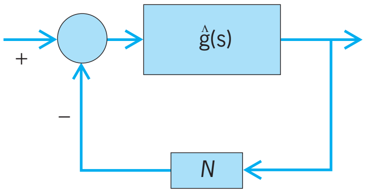

Fig. 6. Feedback system with feedback containing a memoryless nonlinear element *N*.

It states that the system of Fig. 6 is stable, provided one can find a number $q \geq 0$ and a number $\delta > 0$ such that inequality (22) is satisfied.

$$\text{Re}\,[(1 + j\omega q)\hat{g}(j\omega)] + 1/k \geq \delta > 0 \quad \text{for all } \omega \tag{22}$$

The criterion (22) can also be given a graphical interpretation by means of a plot of Re $\hat{g}(j\omega)$ versus ω a Im $\hat{g}(j\omega)$, called a Popov plot (**Fig. 8**). It is only necessary to do the plot for $\omega \geq 0$, since both Re $\hat{g}(j\omega)$ and ω Im $\hat{g}(j\omega)$ are even functions of ω. The inequality (22) states that it is possible to draw a line of slope $1/q$ through the point $1/k + j0$ in such a way that the Popov plot of $\hat{g}(j\omega)$ lies strictly to the right of this line (Fig. 8).

Lyapunov theory. This can be used to analyze the behavior of the solutions of the vector differential equation (23), corresponding to various initial conditions $\mathbf{x}(t_0) = \mathbf{x}_0$ without actually solving the differential equation (23).

$$\dot{\mathbf{x}}(t) = \mathbf{f}(t, \mathbf{x}(t)) \tag{23}$$

The form of Eq. (23) is quite general, and is referred to as the set of state equations for a system; it is distinguished by the fact that the system under study is described by a set of first-order differential equations. The form of Eq. (23) is sufficiently general that any set of coupled ordinary differential equations, of any order, can be equivalently expressed in this form. To simplify the exposition, only the case where the time *t* does not explicitly appear in the state equations will be discussed, that is, where the state equations are of the form of Eq. (24).

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t)) \tag{24}$$

See DIFFERENTIAL EQUATION; LINEAR SYSTEM ANALYSIS.

Equilibrium. An important concept for the system of Eq. (23) is that of an equilibrium. A vector $\mathbf{x}_0$ is called an equilibrium of the system of Eq. (24) if Eq. (25)

$$\mathbf{f}(\mathbf{x}_0) = \mathbf{0} \tag{25}$$

is satisfied. Equivalently, if $\mathbf{x}_0$ is an equilibrium of Eq. (24), then the solution of Eq. (24) corresponding to the initial condition $\mathbf{x}(0) = \mathbf{x}_0$ is $\mathbf{x}(t) = \mathbf{x}_0$ for all $t \geq 0$.

Asymptotic stability. There are many distinct concepts of "stability" in Lyapunov theory, each of them suitable for a different application, and only one of them will be discussed here. Suppose $\mathbf{x} = \mathbf{0}$ is an equilibrium of Eq. (24) [that is, $\mathbf{f}(\mathbf{0}) = \mathbf{0}$], and let $\mathbf{x}(t,\mathbf{x}_0)$ denote the solution of Eq. (24), corresponding to the initial condition $\mathbf{x}(0) = \mathbf{x}_0$. Finally, let the norm of the vector $\mathbf{x}$ be defined by Eq. (26). Then $\mathbf{0}$ is called

$$|\mathbf{x}| = \left(\sum_i x_i^2\right)^{1/2} \tag{26}$$

an asymptotically stable equilibrium of Eq. (24) if the following two conditions are satisfied: (1) There is a number $\delta_0 > 0$ such that $|\mathbf{x}(t,\mathbf{x}_0)|$ is bounded as a function of *t* whenever $|x_0| < \delta_0$. Moreover, the function ϕ defined by Eq. (27) is continuous at $r = 0$.

$$\phi(r) = \sup_{|\mathbf{x}_0| \leq r} \sup_{t \geq 0} |\mathbf{x}(t, \mathbf{x}_0)| \tag{27}$$

(2) There is a number $\delta_1 > 0$ $|\mathbf{x}(t,\mathbf{x}_0)| \to 0$ as $t \to \infty$, whenever $|\mathbf{x}_0| < \phi_1$.

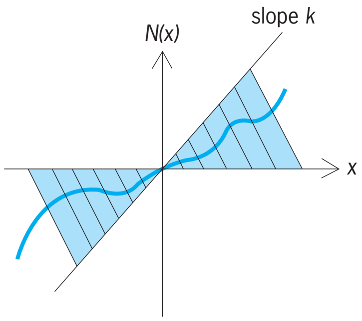

Fig. 7. Graph of nonlinear element *N*.

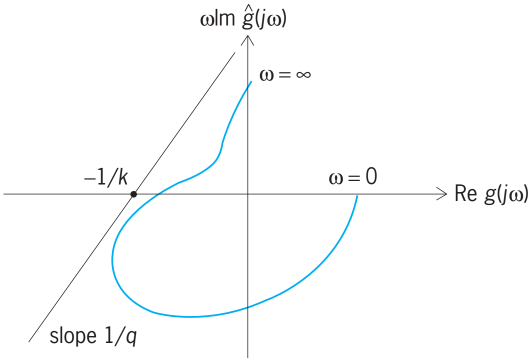

Fig. 8. Popov plot of a transfer function $\hat{g}$.

Basically, condition (1) states that, whenever the magnitude of the initial condition is sufficiently small ($|\mathbf{x}_0| < \delta_0$), small perturbations in the initial condition produce small perturbations in the corresponding solution. Condition (2) states that there is a domain of attraction (the sphere of radius δ_1) such that, whenever the initial condition belongs to this domain, the corresponding solution approaches **0** as $t \to \infty$.

Linear systems. In the case of a linear system, Eq. (28), where $\mathbf{x}(t)$ is an $m \times 1$ vector and **a** is

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) \tag{28}$$

an $m \times m$ matrix, the equilibrium $\mathbf{x} = \mathbf{0}$ stable if and only if all eigenvalues of **A** have negative real parts, that is, the characteristic polynomial $\phi(s) = \det(s\mathbf{I} - \mathbf{A})$ is strictly Hurwitz. Moreover, if $\mathbf{x} = \mathbf{0}$ is asymptotically stable, then the domain of attraction is the entire state space, that is, $|\mathbf{x}(t,\mathbf{x}_0)| \to 0$ as $t \to \infty$ for every $\mathbf{x}_0$.

A test that can be used to determine whether or not all eigenvalues of **A** have negative real parts (that is, whether **A** is a Hurwitz matrix), without actually computing them, is summarized in the following theorem:

Given an $m \times m$ matrix **A**, the following three conditions are equivalent: (1) All eigenvalues of **A** have negative real parts. (2) For some symmetric positive definite matrix **Q**, Eq. (29) has a unique solution **P**;

$$\mathbf{A}^{\mathrm{T}}\mathbf{P} + \mathbf{P}\mathbf{A} = -\mathbf{Q} \tag{29}$$

moreover, this solution is symmetric and positive definite. (3) For every symmetric positive definite matrix **Q**, Eq. (29) has a unique solution for **P**, and this solution is positive definite.

Thus the testing procedure is as follows: Given a matrix **A**, select a symmetric positive definite matrix **Q** arbitrarily, and solve Eq. (29) [known as the Lyapunov matrix equation] for **P**. If a unique **P** cannot be found, or if the unique **P** is not positive definite, then **A** is not a Hurwitz matrix; if there is a unique **P** satisfying Eq. (29) and this **P** is positive definite, the **A** is a Hurwitz matrix. The test also provides additional information: If Eq. (29) has a unique solution for **P**, then the number of negative eigenvalues of **P** equals the number of eigenvalues of **A** having positive real part. *See* EIGENFUNCTION; MATRIX THEORY.

Nonlinear systems. To analyze the nonlinear system of Eq. (24), two general methods are available, namely the direct and indirect methods of Lyapunov. The indirect method is based on expanding $\mathbf{f}(\mathbf{x})$ in a Taylor series around the point $\mathbf{x} = \mathbf{0}$. Specifically, let **A** be defined by Eq. (30). Since $\mathbf{f}(\mathbf{0}) = \mathbf{0}$ by assumptions, Eq. (31) follows. Lyapunov's indirect method is

$$\mathbf{A} = \frac{\partial \mathbf{f}}{\partial \mathbf{x}} \bigg|_{\mathrm{x}=0} \tag{30}$$

$$\mathbf{f}(\mathbf{x}) = \mathbf{A}\mathbf{x} + \text{higher} - \text{order terms in } \mathbf{x} \tag{31}$$

based on the following fact: If **A** is strictly Hurwitz, then $\mathbf{x} = \mathbf{0}$ is an asymptotically stable equilibrium of the nonlinear system of Eq. (24); if **A** has some eigenvalues with positive real parts, then $\mathbf{x} = \mathbf{0}$ is an unstable equilibrium of Eq. (24).

The direct method of Lyapunov is based on constructing an energylike function $v(\mathbf{x})$, known as a Lyapunov function, whose value decreases along the solution trajectories of Eq. (24). The actual details are somewhat complex, but the direct method provides a very powerful tool for analyzing nonlinear systems. *See* NONLINEAR CONTROL THEORY.

Advanced methods. The techniques described here have been extended to systems governed by partial or even functional differential equations, as well as to multidimensional systems (for example, two-dimensional digital filters). In addition, advanced mathematical techniques such as functional analysis and differential geometry have been applied to stability problems. *See* CONTROL SYSTEMS. M. Vidyasagar

Control systems

Interconnections of components forming system configurations which will provide a desired system response as time progresses. The steering of an automobile is a familiar example. The driver observes the position of the car relative to the desired location and makes corrections by turning the steering wheel. The car responds by changing direction, and the driver attempts to decrease the error between the desired and actual course of travel. In this case, the controlled output is the automobile's direction of travel, and the control system includes the driver, the automobile, and the road surface. The control engineer attempts to design a steering control mechanism which will provide a desired response for the automobile's direction control. Different steering designs and automobile designs result in rapid responses, as in the case of sports cars, or relatively slow and comfortable responses, as in the case of large autos with power steering.

Open- and closed-loop control. The basis for analysis of a control system is the foundation provided by linear system theory, which assumes a cause-effect relationship for the components of a system. A component or process to be controlled can be represented by a block. Each block possesses an input (cause) and output (effect). The input-output relation represents the cause-and-effect relationship of the process, which in turn represents a processing of the input signal to provide an output signal variable, often with power amplification. An open-loop control system utilizes a controller or control actuator in order to obtain the desired response (**Fig. 1**). *See* BLOCK DIAGRAM.

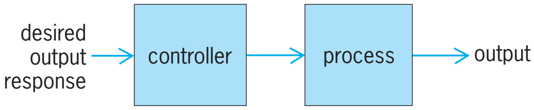

Fig. 1. Open-loop control system.

A closed-loop control system utilizes an additional measure of the actual output in order to compare the actual output with the desired output response (**Fig. 2**). A standard definition of a feedback control system is a control system which tends to maintain a prescribed relationship of one system variable to another by comparing functions of these variables and using the difference as a means of control. In the case of the driver steering an automobile, the driver visually measures and compares the actual location of the car with the desired location. The driver then serves as the controller, turning the steering wheel. The process represents the dynamics of the steering mechanism and the automobile response.

A feedback control system often uses a function of a prescribed relationship between the output and reference input to control the process. Often, the difference between the output of the process under control and the reference input is amplified and used to control the process so that the difference is continually reduced. The feedback concept has been the foundation for control system analysis and design.

Because of the increasing complexity of the system under control and the interest in achieving optimum performance, the importance of control system engineering has grown over the years. Furthermore, as the systems become more complex, the interrelationship of many controlled variables must be considered in the control scheme.

History of automatic control. The first automatic feedback controller used in an industrial process was James Watt's flyball governor (1769) for controlling the speed of a steam engine. Prior to World War II, one main impetus for the use of feedback control in the United States was the development of the telephone system and electronic feedback amplifiers. The frequency domain was used primarily to describe the operation of the feedback amplifiers in terms of bandwidth and other frequency variables. In contrast, the Russian theory, which was dominated by mathematicians, tended to utilize a time-domain formulation using differential equations.

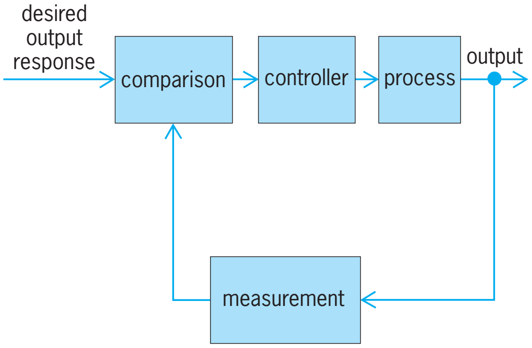

Fig. 2. Closed-loop control system.

A large impetus to the theory and practice of automatic control occurred during World War II, when it became necessary to design and construct automatic airplane pilots, gun-positioning systems, radar antenna control systems, and other military systems based on the feedback control approach. The complexity and expected performance of these military systems necessitated an extension of the available control techniques and fostered interest in control systems and the development of new insights and methods.

Frequency-domain techniques continued to dominate the field of control following World War II, with the increased use of the Laplace transform and the complex frequency plane. During the 1950s, the utilization of both analog and digital computers for control components became possible. These new controlling elements possessed an ability to calculate rapidly and accurately, which was formerly not available to the control engineer. Digital process control computers are employed especially for process control systems in which many variables are measured and controlled simultaneously by the computer. *See* ANALOG COMPUTER; DIGITAL COMPUTER; PROCESS CONTROL.

With the advent of the space age, it became necessary to design complex, highly accurate control systems for missiles and space probes. Furthermore, the necessity to minimize the weight of satellites and to control them very accurately spawned the important field of optimal control. It appears that control engineering must consider both the time-domain and the frequency-domain approaches simultaneously in the analysis and design of control systems. *See* GUIDANCE SYSTEMS; OPTIMAL CONTROL THEORY; SPACE NAVIGATION AND GUIDANCE.

Applications. Familiar control systems have the basic closed-loop configuration as shown earlier. For example, a refrigerator has a temperature setting for desired temperature, a thermostat to measure the actual temperature and the error, and a compressor motor for power amplification. Other examples in the home are the oven, furnace, and water heater. In industry, there are controls for speed, process temperature and pressure, position, thickness, composition, and quality, among many others.

In order to provide a mass transportation system for modern urban areas, a large, complex, high-speed system is necessary. Automatic control is necessary in order to maintain a constant flow of trains and to ensure comfortable deceleration and braking conditions at stations (**Fig. 3**). A measurement of the distance from the station and the speed of the train is used to determine the error signal and therefore the braking signal. *See* RAILROAD CONTROL SYSTEMS.

The electric power industry is primarily interested in energy conversion, control, and distribution. It is critical that computer control be increasingly applied to the power industry in order to improve

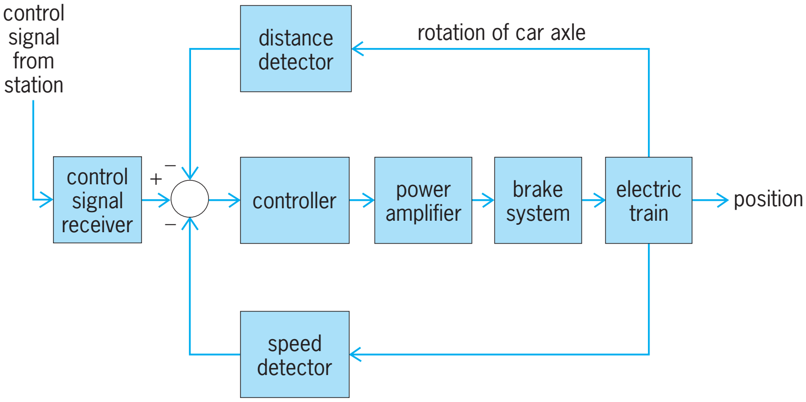

Fig. 3. Train-brake control system.

the efficiency of use of energy resources. Also, the control of power plants for minimum waste emission has become increasingly important. The modern large-capacity plants which exceed several hundred megawatts require automatic control systems which account for the interrelationship of the process variables and the optimum power production. It is common to have as many as 90 or more manipulated variables under coordinated control. Computer controls are also used to control energy use in industry and stabilize and connect loads evenly to gain fuel economy.

Feedback control concepts have been applied to automatic warehousing and inventory control and to the automatic control of agriculture systems (farms). Automatic control of wind turbine generators, solar heating and cooling, and automobile engine performance are other important examples.

Also, there have been many applications of control system theory to biomedical experimentation, diagnosis, prosthetics, and biological control systems. The control systems under consideration range from the cellular level to the central nervous system and include temperature regulation and neurological, respiratory, and cardiovascular control. Most physiological control systems are closed-loop systems. However, they involve not one controller but rather control loop within control loop, forming a hierarchy of systems. The modeling of the structure of biological processes confronts the analyst with a high-order model and a complex structure. Prosthetic devices are designed to provide automatically controlled aids to the disabled. An artificial hand that uses force feedback signals and is controlled by the amputee's bioelectric control signals is an example. *See* MATHEMATICAL BIOLOGY; PROSTHESIS.

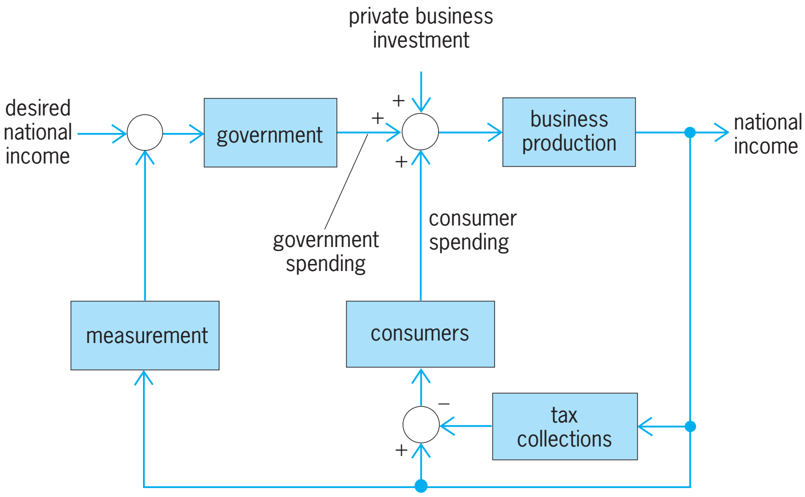

Fig. 4. Feedback control system model of the United States economy.

Finally, it has become of interest to attempt to model the feedback processes prevalent in the social, economic, and political spheres. This approach is undeveloped but appears to have a reasonable future. A simple lumped model of the national-income feedback control system is shown in **Fig. 4**. This type of model helps the analyst to understand the effects of government control—granted its existence—and the dynamic effects of government spending. Of course, many other loops not shown also exist. This type of political or social feedback model, while usually nonrigorous, does impart information and understanding. *See* SYSTEMS ANALYSIS; SYSTEMS ENGINEERING.

Analysis using the Laplace transform. In order to understand a complex control system, it is necessary to analyze the relationships between the system variables and to obtain a quantitative mathematical model of the system. Since the systems under consideration are dynamic in nature, the descriptive equations are usually differential equations. Furthermore, if these equations can be linearized, then the Laplace transform can be utilized in order to simplify the method of solution. In practice, the complexity of systems and incomplete knowledge of the relevant factors necessitate the introduction of assumptions concerning the system operation. Therefore, it is often useful to consider the physical system, delineate some necessary assumptions, and linearize the system. Then, by using the physical laws describing the linear equivalent system, one can obtain a set of linear differential equations. Finally, utilizing mathematical tools, such as the Laplace transform, a solution describing the operation of the system is obtained. In summary, the approach to dynamic system problems can be listed as follows: (1) define the system and its components; (2) formulate the mathematical model and list the necessary assumptions; (3) write the differential equations describing the model; (4) solve the equations for the desired output variables; (5) examine the solutions and the assumptions; and then (6) reanalyze or design. *See* DIFFERENTIAL EQUATION.

The Laplace transform of a function f of time t is given by Eq. (1), where s is a complex variable

$$F(s) = \mathcal{L}\{f(t)\} = \int_0^\infty f(t)e^{-st}dt \qquad (1)$$

related to the frequency ω by the equations $s = \sigma + j\omega$ (where $j = \sqrt{-1}$). The analysis thus takes place in the frequency domain. The inverse Laplace

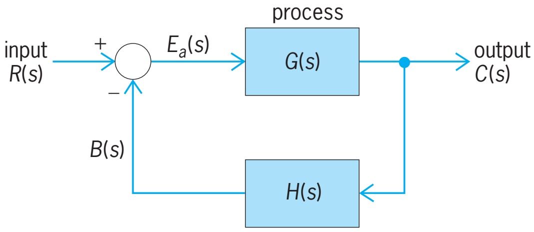

Fig. 5. Negative-feedback control system.

transformation is usually obtained by a partial fraction expansion. *See* LAPLACE TRANSFORM.

The transfer function of a linear system is the ratio of the Laplace transform of the output variable to the Laplace transform of the input variable with all initial conditions assumed to be zero. The block diagram of a negative-feedback control system is shown in **Fig. 5**. The transfer function $G(s)$ of the process is given by Eq. (2).

$$\frac{C(s)}{E_a(s)} = G(s) \tag{2}$$

The transfer function of the closed-loop system can be obtained by the algebraic manipulation of the system equations. The error, $E_a(s)$, is given by Eq. (3), and the output is given by Eq. (4).

$$E_a(s) = R(s) - B(s) = R(s) - H(s)C(s) \tag{3}$$

$$C(s) = G(s)E_a(s) = G(s)[R(s) - H(s)C(s)] \tag{4}$$

Solving for $C(s)$, Eq. (5) is obtained, and therefore $C(s)$ is given by Eq. (6).

$$C(s)[1 + G(s)H(s)] = G(s)R(s) \tag{5}$$

$$C(s) = \frac{G(s)}{1 + G(s)H(s)}R(s) \tag{6}$$

The closed-loop transfer function $T(s) = C(s)/R(s)$ is given by Eq. (7), and the error is then given by Eq. (8).

$$\frac{C(s)}{R(s)} = T(s) = \frac{G(s)}{1 + G(s)H(s)} \tag{7}$$

$$E_a(s) = \frac{1}{1 + G(s)H(s)}R(s) \tag{8}$$

It is clear that in order to reduce the error, the magnitude of $[1 + G(s)H(s)]$ must be greater than 1 over the range of s under consideration.

Advantages of feedback control. The addition of feedback to a control system results in several important advantages.

Reduction in sensitivity. A process, represented by the transfer function $G(s)$, whatever its nature, is subject to a changing environment, aging, ignorance of the exact values of the process parameters, and other natural factors which affect a control process. In the open-loop system, all these errors and changes result in a changing and inaccurate output. However, a closed-loop system senses the change in the output due to the process changes and attempts to correct the output. The sensitivity of a control system to parameter variations is of prime importance. A primary advantage of a closed-loop feedback control system is its ability to reduce the system's sensitivity.

For the closed-loop case, if $G(s)H(s)$ is much greater than 1 for all complex frequencies of interest, then from Eq. (6) one obtains Eq. (9). That is,

$$C(s) = \frac{1}{H(s)}R(s) \tag{9}$$

the output is affected only by $H(s)$, which may be constant. If $H(s) = 1$, the desired result is obtained; that is, the output is equal to the input. However, this approach cannot be used for all control systems because the requirement that $G(s)H(s)$ be much greater than 1 may cause the system response to be highly oscillatory and even unstable. But the fact that an increase in the magnitude of the loop transfer function $G(s)H(s)$ results in a reduction of the effect of $G(s)$ on the output is an exceedingly useful concept. Therefore, the first advantage of a feedback system is that the effect of the variation of the parameters of the process, $G(s)$, is reduced.

Control of transient response. One of the most important characteristics of control systems is their transient response, which often must be adjusted until it is satisfactory. If an open-loop control system does not provide a satisfactory response, then the process, $G(s)$, must be replaced with a suitable process. By contrast, a closed-loop system can often be adjusted to yield the desired response by adjusting the feedback loop parameters. It is often possible to alter the response of an open-loop system by inserting a suitable cascade filter, $G_1(s)$, preceding the process, $G(s)$. Then it is necessary to design the cascade transfer function $G_1(s)G(s)$ so that the resulting transfer function provides the desired transient response. Therefore, the second advantage of feedback control is control of the transient response of the system.

Reduction of effects of disturbance. The third most important effect of feedback in a control system is the control and partial elimination of the effect of disturbance signals. Many control systems are subject to extraneous disturbance signals which cause the system to provide an inaccurate output. Electronic amplifiers have inherent noise generated within the integrated circuits or transistors, radar antennas are subjected to wind gusts, and many systems generate unwanted distortion signals due to nonlinear elements. Feedback systems have the beneficial aspect that the effect of distortion, noise, and unwanted disturbances can be effectively reduced.

As a specific example of a system with an unwanted disturbance, consider the speed control system for a steel rolling mill. Rolls passing steel through are subject to large load changes or disturbances. As a steel bar approaches the rolls, the rolls turn unloaded. However, when the bar engages in the rolls, the load on the rolls increases immediately to a large value. This loading effect can be approximated by a step change of disturbance torque.

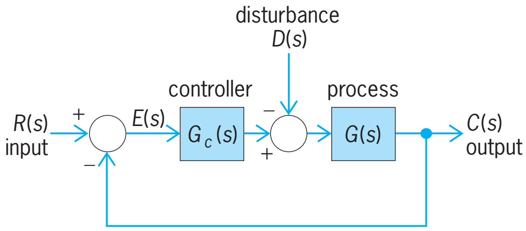

Fig. 6. Feedback control system with a disturbance.

The block diagram of a feedback control system with a disturbance, $D(s)$, is shown in **Fig. 6**, where $H(s) = 1$. Then the output, $C(s)$, may be shown to be given by Eq. (10) when the input, $R(s)$, is set to zero.

$$C(s) = \frac{-G(s)D(s)}{1 + G_c(s)G(s)} \qquad (10)$$

Then if $G_c(s)G(s)$ is much greater than one over the range of s, the approximate result given by Eq. (11)

$$C(s) \simeq -\frac{1}{G_c(s)}D(s) \qquad (11)$$

is obtained. Therefore, if $G_c(s)$ is made sufficiently large, the effect of the disturbance can be decreased by closed-loop feedback.

Reduction of steady-state error. The reduction of the steady-state error of a control system is another advantage of feedback control.

The error of the closed-loop system when $H(s) = 1$ is given by Eq. (12). The steady-state error can be

$$E(s) = \frac{1}{1 + G(s)}R(s) \qquad (12)$$

calculated by using the final-value theorem which is given by Eq. (13), where $e(t)$ is the error variable in

$$\lim_{t\to\infty} e(t) = \lim_{s\to 0} sE(s) \qquad (13)$$

the time domain. Therefore, using a unit step input as comparable input, Eq. (14) is obtained for the closed-

$$e(\infty) = \lim_{s\to 0} s\left(\frac{1}{1 + G(s)}\right)\left(\frac{1}{s}\right) = \frac{1}{1 + G(0)} \qquad (14)$$

loop system. The value of $G(s)$ when $s = 0$ is often called the dc gain and is normally greater than 1. Therefore, the open-loop system will usually have a steady-state error of significant magnitude. By contrast, the closed-loop system with a reasonably large dc-loop gain $G(0)H(0)$ will have a small steady-state error.

Costs of feedback control. While the addition of feedback to a control system results in the advantages outlined above, it is natural that these advantages have an attendant cost.

Increased complexity. The cost of feedback is first manifested in the increased number of components and the complexity of the system. In order to add the feedback, it is necessary to consider several feedback components, of which the measurement component (sensor) is the key component. The sensor is often the most expensive component in a control system. Furthermore, the sensor introduces noise and inaccuracies into the system.

Loss of gain. The second cost of feedback is the loss of gain. For example, in a single-loop system, the open-loop gain is $G(s)$ and is reduced to $G(s)/[1 + G(s)]$ in a unity negative-feedback system. The reduction in closed-loop gain is $1/[1 + G(s)]$ which is exactly the factor that reduces the sensitivity of the system to parameter variations and disturbances. Usually, there is open-loop gain to spare, and one is more than willing to trade it for increased control of the system response.

However, it is the gain of the input-output transmittance that is reduced. The control system does possess a substantial power gain which is fully utilized in the closed-loop system.

Possibility of instability. Finally, a cost of feedback is the introduction of the possibility of instability. While the open-loop system is stable, the closed-loop system may not be always stable.

Necessity of considering problems. The addition of feedback to dynamic systems results in several additional problems for the designer. However, for most cases, the advantages far outweigh the disadvantages, and a feedback system is utilized. Therefore, it is necessary to consider the additional complexity and the problem of stability when designing a control system.

It is desired that the output of the system $C(s)$ equal the input $R(s)$. However, one might ask, "Why not simply set the transfer function $G(s) = C(s)/R(s)$ equal to 1?" The answer to this question is that the process (or plant) $G(s)$ was necessary in order to provide the desired output; that is, the transfer function $G(s)$ represents a real process and possesses dynamics which cannot be neglected. To set $G(s)$ equal to 1 implies that the output is directly connected to the input. However, it must be recalled that a specific output, such as temperature, shaft rotation, or engine speed, is desired, while the input might be a potentiometer setting or a voltage. The process $G(s)$ is necessary in order to provide the physical process between $R(s)$ and $C(s)$. Therefore, a transfer function $G(s) = 1$ is unrealizable, and a practical transfer function must be adopted.

State variables and the time-domain. A useful approach to the analysis and design of feedback systems was outlined above. The Laplace transform was utilized to transform the differential equations representing the system into an algebraic equation expressed in terms of the complex variable, s. Utilizing this algebraic equation, a transfer function representation of the input-output relationship was obtained. The Laplace transform approach, carried out in terms of the complex variable s and accomplished in the frequency domain, is extremely useful; it is and will remain one of the primary tools of the control engineer. However, the limitations of the frequency-domain techniques and the attractiveness of the time-domain approach require a reconsideration of the time-domain formulation of the equations representing control systems.

The frequency-domain techniques are limited in applicability to linear, time-invariant systems.

Furthermore, they are particularly limited in their usefulness for multivariable control systems because of the emphasis on the input-output relationship of transfer functions. By contrast, the time-domain techniques may be readily utilized for nonlinear, time-varying, and multivariable systems. A time-varying control system is a system for which one or more of the parameters of the system may vary as a function of time. For example, the mass of a missile varies as a function of time as the fuel is expended during flight. A multivariable system is a system with several input and output signals. Furthermore, the solution of a time-domain formulation of a control system problem is facilitated by the availability and ease of use of digital and analog computers.

Definition of state variables. The time-domain analysis and design of control systems utilizes the concept of the state of a system. The state of a system is a set of numbers such that the knowledge of these numbers and the input functions will, with the equations describing the dynamics, provide the future state and output of the system. For a dynamic system, the state of a system is described in terms of a set of state variables $[x_1(t), x_2(t), \ldots, x_n(t)]$. The state variables determine the future behavior of a system when the present state of the system and the excitation signals are known. A set of state variables $(x_1, x_2, \ldots, x_n)$ is a set such that knowledge of the initial values of the state variables $[x_1(t_0), x_2(t_0), \ldots, x_n(t_0)]$ at the initial time t_0, and of the input signals $u_1(t)$ and $u_2(t)$ for times t greater than t_0, suffices to determine the future values of the output and state variables. *See* LINEAR SYSTEM ANALYSIS.

A simple example of a state variable is the state of an on-off light switch. The switch can be in either the on or off position, and thus the state of the switch can assume one of two possible values. Thus if the present state (position) of the switch is known at t_0 and if an input is applied, the future value of the state of the element can be determined.

Example of dynamic system. The concept of a set of state variables which represent a dynamic system can be illustrated in terms of the spring-mass-damper system shown in **Fig. 7**. The number of state variables chosen to represent this system should be as few as possible in order to avoid redundant state variables.

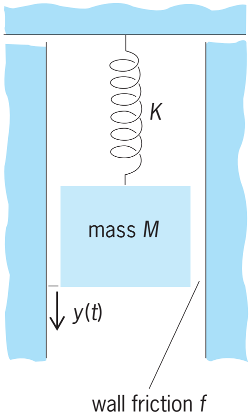

Fig. 7. **Spring-and-mass system with wall friction.**

A set of state variables sufficient to describe this system is the position $y(t)$ and the velocity of the mass. Therefore, a set of state variables is defined as (x_1,x_2), given by Eqs. (15).

$$x_1(t) = y(t) \qquad x_2(t) = \frac{dy(t)}{dt} \tag{15}$$

The differential equation describing the behavior of the system is usually written as Eq. (16), where M

$$M\frac{d^2y}{dt^2} + f\frac{dy}{dt} + Ky = u(t) \tag{16}$$

is the mass, K is the force constant of the spring, and the coefficient f determines the frictional force exerted by the wall. In order to write Eq. (16) in terms of the state variables, one substitutes the definition of the state variables and obtains Eq. (17). Therefore,

$$M\frac{dx_2}{dt} + fx_2 + Kx_1 = u(t) \tag{17}$$

the differential equations which describe the behavior of the spring-mass-damper system may be written as a set of two first-order differential equations, Eqs. (18) and (19). This set of differential equations

$$\frac{dx_1}{dt} = x_2 \tag{18}$$

$$\frac{dx_2}{dt} = \frac{-f}{M}x_2 - \frac{K}{M}x_1 + \frac{1}{M}u \tag{19}$$

describes the behavior of the state of the system in terms of the rate of change of each state variable.

Matrix differential equation. The state of a system is described by the set of first-order differential equations written in terms of the state variables $(x_1, x_2, \ldots, x_n)$. These first-order differential equations may be written in general form as Eqs. (20), where $\dot{x} = dx/dt$.

$$\begin{aligned}
\dot{x}_1 &= a_{11}x_1 + a_{12}x_2 + \cdots \\
&\qquad + a_{1n}x_n + b_{11}u_1 + \cdots + b_{1m}u_m \\
\dot{x}_2 &= a_{21}x_1 + a_{22}x_2 + \cdots \\
&\qquad + a_{2n}x_n + b_{21}u_1 + \cdots + b_{2m}u_m \\
&\ \cdot \\
&\ \cdot \\
&\ \cdot \\
\dot{x}_n &= a_{n1}x_1 + a_{n2}x_2 + \cdots \\
&\qquad + a_{nn}x_n + b_{n1}u_1 + \cdots + b_{nn}u_m
\end{aligned} \tag{20}$$

Thus this set of simultaneous differential equations may be written in matrix form. The column matrix consisting of the state variables is called the state vector and is written as Eq. (21), where the boldface indicates a matrix. The matrix of input signals

$$\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ \cdot \\ \cdot \\ \cdot \\ x_n \end{bmatrix} \tag{21}$$

is defined as **u**. Then the system may be represented by the compact notation of the system vector differential equation as Eq. (22). The matrix **A** is an

$$\dot{\mathbf{x}} = \mathbf{Ax} + \mathbf{Bu} \tag{22}$$

$n \times n$ square matrix, and **B** is an $n \times m$ matrix. The vector matrix differential equation relates the rate of change of the state of the system to the state of the system and the input signals. In general, the outputs of a linear system may be related to the state variables and the input signals by the vector matrix equation (23), where **c** is the set of output signals expressed in

$$\mathbf{c} = \mathbf{Dx} + \mathbf{Hu} \tag{23}$$

column vector form. *See* MATRIX CALCULUS; MATRIX THEORY.

The solution of the matrix differential equation uses the matrix exponential given by Eq. (24). The

$$\phi(t) = e^{\mathbf{A}t} \tag{24}$$

matrix exponential function describes the unforced response of the system and is called the fundamental or transition matrix $\phi(t)$. Therefore, the solution may be written as Eq. (25).

$$\mathbf{x}(t) = \phi(t)\mathbf{x}(0) + \int_0^t \phi(t-\tau)\mathbf{Bu}(\tau)\,d\tau \tag{25}$$

The solution to the unforced system (that is, when $u = 0$) is given simply by Eq. (26). Hence, in order to

$$\begin{bmatrix} x_1(t) \\ x_2(t) \\ \cdot \\ \cdot \\ \cdot \\ x_n(t) \end{bmatrix} = \begin{bmatrix} \phi_{11}(t) & \cdots & \phi_{1n}(t) \\ \phi_{21}(t) & \cdots & \phi_{2n}(t) \\ \cdot & & \cdot \\ \cdot & & \cdot \\ \cdot & & \cdot \\ \phi_{n1}(t) & \cdots & \phi_{nn}(t) \end{bmatrix} \begin{bmatrix} x_1(0) \\ x_2(0) \\ \cdot \\ \cdot \\ \cdot \\ x_n(0) \end{bmatrix} \tag{26}$$

determine the transition matrix, all initial conditions are set to zero except for one state variable, and the output of each state variable is evaluated. That is, the term $\phi_{ij}(t)$ is the response of the ith state variable due to an initial condition on the jth state variable when there are zero initial conditions on all the other states. The time-domain approach may be used to investigate the performance of a control system as well as to design improved systems.

Time response. The time response of a second-order feedback control system (**Fig. 8**) is illustrative of the normal range of response of a control system. The transfer function of the process of such a system has the general form $G(s) = K/s(s+p)$, where K is the gain of the process, and the transfer function contains a pole at the origin of the s-plane and one pole at $s = -p$. The response to a unit step input will be determined. The closed-loop output is given by Eq. (27). Utilizing a generalized notation, Eq. (27) may be rewritten as Eq. (28),

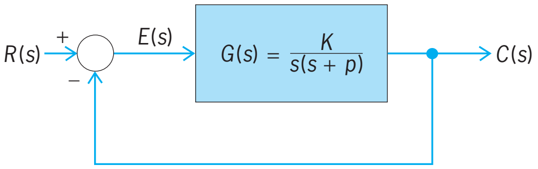

Fig. 8. Closed-loop second-order control system.

$$C(s) = \frac{G(s)}{1+G(s)}R(s) = \frac{K}{s^2+ps+K}R(s) \tag{27}$$

$$C(s) = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n^2 + \omega_n^2}R(s) \tag{28}$$

where ω_n is the natural frequency and ζ is called the damping ratio. With a unit step input, this becomes Eq. (29), for which the transient output is given by Eq. (30), where $\beta = \sqrt[2]{1-\zeta^2}$ and $\phi = \tan^{-1}\beta/\zeta$.

$$C(s) = \frac{\omega_n^2}{s(s^2 + 2\zeta\omega_n s + \omega_n^2)} \tag{29}$$

$$c(t) = 1 - \frac{1}{\beta}e^{-\zeta\omega}n^t \sin(\omega_n t + \theta) \tag{30}$$

The transient response of this second-order system for various values of the damping ratio ζ is shown in **Fig. 9**. As ζ decreases, the overshoot of the response increases. It is usually desired to have a rapid response to a step input while minimizing the overshoot.

Standard performance measures are usually defined in terms of the step response of a system (**Fig. 10**). The swiftness of the response is measured by the rise time T_r and the peak time T_p. For underdamped systems with an overshoot, the 0–100% rise time is a useful index.

The similarity with which the actual response matches the step input is measured by the percent overshoot and settling time T_s. The percent overshoot, P.O., is defined by Eq. (31) for a unit step input,

$$\text{P.O.} = \frac{M_{p_t} - 1}{1} \times 100\% \tag{31}$$

where M_{pt} is the peak value of the time response. The settling time T_s is defined as the time required for the system to settle within a certain percentage δ of the input amplitude. This band of $\pm\delta$ is shown in Fig. 10. For the second-order system with a closed-loop damping constant ω_n, the response remains within 2% after four time constants τ, Eq. (32). There-

$$T_s = 4\tau = \frac{4}{\zeta\omega_n} \tag{32}$$

fore, the settling time is defined as four time constants of the dominant response. Finally, the steady-state error of the system may be measured on the step response of the system as shown in Fig. 10. *See* TIME CONSTANT.

Stability of closed-loop systems. The transient response of a feedback control system is of primary interest and must be investigated. A very important characteristic of the transient performance of a system is the stability of the system. A stable system is defined as a system with a bounded system response. That is, if the system is subjected to a bounded input

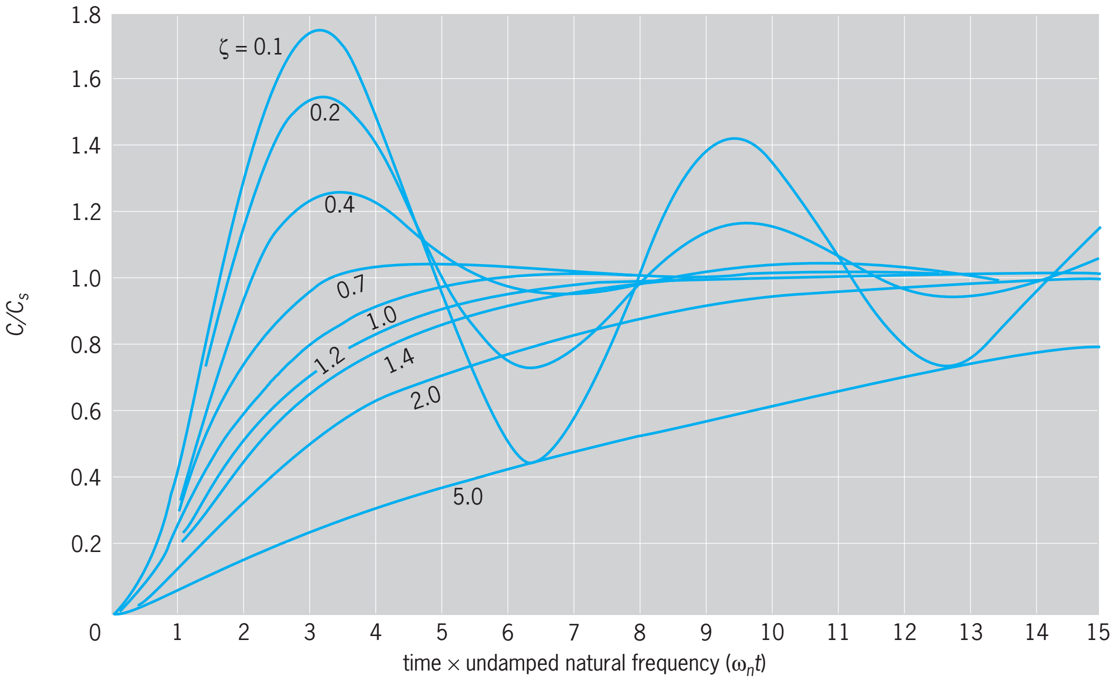

Fig. 9. Response of a second-order system to a step input. C = output at time t; C_s = output when time t is ∞.

or disturbance and the response is bounded in magnitude, the system is said to be stable.

The concept of stability can be illustrated by considering a right circular cone placed on a plane horizontal surface. If the cone is resting on its base and is tipped slightly, it returns to its original equilibrium position. This position and response is said to be stable. If the cone rests on its side and is displaced slightly, it rolls with no tendency to leave the position on its side. This position is designated as neutral stability. On the other hand, if the cone is placed on its tip and released, it falls onto its side. This position is said to be unstable.

The stability of a dynamic system is defined in a similar manner. The response to a displacement, or initial condition, will result in either a decreasing, neutral, or increasing response. Specifically, it follows from the definition of stability that a linear system is stable if and only if the absolute value of its response to an impulse input $g(t)$, integrated over an infinite range, is finite.

There are three general approaches to determining the stability of a system: (1) the s-plane approach, (2) the frequency-plane ($j\omega$) approach, and (3) the time-domain approach. Only the first will be considered here.

The stability requirement of a linear system may be defined in terms of the location of the poles in the closed-loop system transfer function, which may be written as Eq. (33), where $q(s) = \Delta(s)$ is the characteristic polynomial whose roots are the poles of the closed-loop system. The output response for an impulse function input is then given by Eq. (34),

$$T(s) = \frac{p(s)}{q(s)} = \frac{K\prod_{i=1}^{M}(s+z_i)}{S^N\prod_{k=1}^{Q}(s+\sigma_k)\prod_{m=1}^{R}[s^2+2\alpha_m s+(\alpha_m^2+\omega_m^2)]} \tag{33}$$

$$c(t) = \sum_{k=1}^{Q} A_k e^{-\sigma} k^t + \sum_{m=1}^{R} B_m \left(\frac{1}{\omega_m}\right) e^{-\alpha} m^t \sin \omega_m^t \tag{34}$$

when $N = 0$. It follows from Eq. (34) that the poles in the left-hand portion of the s plane result in a decreasing response for disturbance inputs. Similarly, poles on the imaginary axis (the $j\omega$ axis) and in the

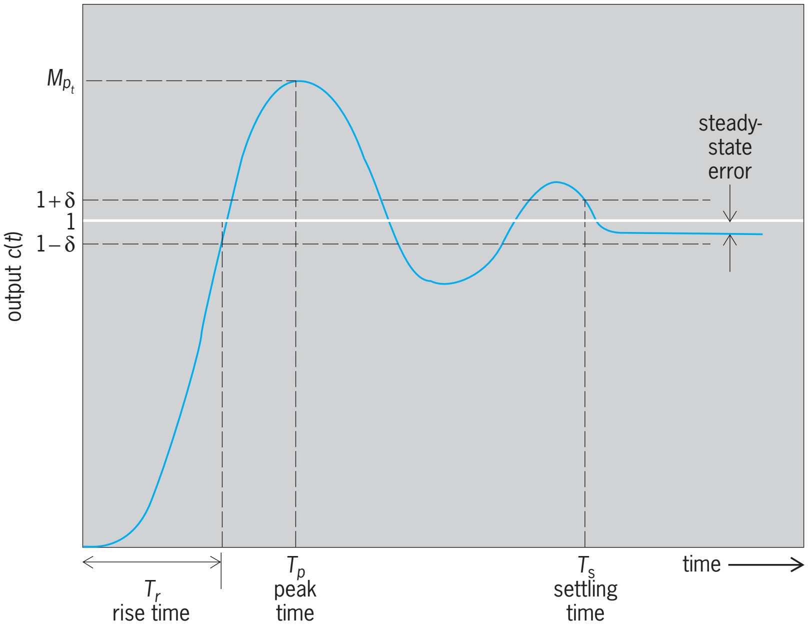

Fig. 10. Step response of a control system.

right-hand plane result in a neutral and an increasing response, respectively, for a disturbance input. Clearly, in order to obtain a bounded response, the poles of the closed-loop system must be in the left-hand portion of the *s* plane. Thus, a necessary and sufficient condition that a feedback system be stable is that all the poles of the system transfer function have negative real parts.

Therefore, one can ascertain the stability of a feedback control system by determining the roots of the characteristic polynomial $q(s)$. A method for determining whether any of the roots of $q(s)$ lie in the right half of the *s* plane, and thereby ascertaining the stability of the system, was developed independently by A. Hurwitz and E. J. Routh, in the late 1800s. *See* CONTROL SYSTEM STABILITY.

Design and compensation. The performance of a feedback control system is of primary importance. A suitable control system is stable and results in an acceptable response to input commands, is less sensitive to the system parameter changes, results in a minimum steady-state error for input commands, and finally, is able to eliminate the effect of undesirable disturbances. A feedback control system that provides an optimum performance without any necessary adjustments is rare indeed. Usually one finds it necessary to compromise among the many conflicting and demanding specifications and to adjust the system parameters to provide a suitable and acceptable performance when it is not possible to obtain all the desired optimum specifications.

As discussed above, it is often possible to adjust the system parameters in order to provide the desired system response. However, it is often not possible to simply adjust a system parameter and thus obtain the desired performance. Rather, the scheme or plan of the system must be reexamined, and a new design or plan must be obtained which results in a suitable system. Thus, the design of a control system is concerned with the arrangement, or the plan, of the system structure and the selection of suitable components and parameters. For example, if one desires a set of performance measures to be less than some specified values, one often encounters a conflicting set of requirements. If these two performance requirements cannot be relaxed, the system must be altered in some way. The alteration or adjustment of a control system, in order to make up for deficiencies and inadequacies and provide a suitable performance, is called compensation.

In redesigning a control system in order to alter the system response, an additional component or device is inserted within the structure of the feedback system to equalize or compensate for the performance deficiency. The compensating device may be an electric, mechanical, hydraulic, pneumatic, or other type of device or network, and is often called a compensator. An electric circuit serves as a compensator in many control systems. The transfer function of the compensator is designated as $G_c(s) = E_{out}(s)/E_{in}(s)$, and the compensator may be placed in a suitable location within the structure of the system. The system when the compensator is placed in the forward path is illustrated in **Fig. 11**.

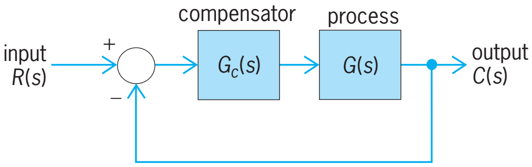

Fig. 11. Cascade compensator in a feedback system.

The performance of a system may be specified by requiring a certain peak time T_p, maximum overshoot, and settling time for a step input. Furthermore, it is usually necessary to specify the maximum allowable steady-state error for several test signal inputs and disturbance inputs. These performance specifications may be defined in terms of the desirable location of the poles and zeros of the closed-loop system transfer function, $T(s)$. Thus, the performance of a control system may be described in terms of frequency-domain performance measures.

The time-domain method, expressed in terms of state variables, may also be utilized to design a suitable compensation scheme for a control system. Typically, one is interested in controlling the system with a control signal $u(t)$, which is a function of several measurable state variables. Then one develops a state-variable controller which operates on the information available in measured form. This type of system compensation is quite useful for system optimization.

Quite often, in practice, the best and simplest way to improve the performance of a control system is to alter, if possible, the process itself. That is, if the system designer is able to specify and alter the design of the process which is represented by the transfer function $G(s)$, then the performance of the system may be readily improved. For example, in order to improve the transient behavior of a servomechanism position controller, one can often choose a better motor for the system. In the case of an airplane control system, one might be able to alter the aerodynamic design of the airplane and thus improve the flight transient characteristics. However, often the process is fixed and unalterable or has been altered as much as is possible and is still found to result in an unsatisfactory performance. Then the addition of compensation networks becomes useful for improving the performance of the system. In the following discussion, it will be assumed that the process has been improved as much as possible and that the $G(s)$ representing the process is unalterable.

Digital computer control systems. The use of a digital computer as a compensator device grew after 1970 as the price and reliability of digital computers improved dramatically. A block diagram of a single-loop digital control system is shown in **Fig. 12**. The digital computer in this system configuration receives the input and output and performs calculations in order to provide an output $u^*(t)$. It may

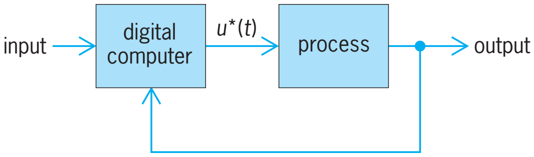

Fig. 12. Digital computer control system.

be programmed to provide an output $u^*(t)$, so that the performance of the process is near or equal to that desired. Many computers are able to receive and manipulate several inputs, so a digital computer control system can often be a multivariable system. *See* DIGITAL COMPUTER; DIGITAL CONTROL.

Within a computer control system, the digital computer receives and operates on signals in digital (numerical) form, as contrasted to continuous signals. The measurement data are converted from analog form to digital form by means of a converter. After the digital computer has processed the inputs, it provides an output in digital form. This output is then converted to analog form through the use of a digital-to-analog converter. *See* ANALOG-TO-DIGITAL CONVERTER; DIGITAL-TO-ANALOG CONVERTER.

Automatic handling equipment for home, school, and industry is particularly useful for hazardous, repetitious, dull, or simple tasks. Machines that automatically load and unload, cut, weld, or cast are used by industry in order to obtain accuracy, safety, economy, and productivity.

Robots are programmable computers integrated with machines. They often substitute for human labor in specific repeated tasks. Some devices even have anthropomorphic mechanisms, including what might be recognized as mechanical arms, wrists, and hands. Robots may be used extensively in space exploration and assembly as well as for various industrial applications. *See* ROBOTICS. Richard C. Dorf

Modeling and simulation. The design of feedback control systems generally assumes that a mathematical model of the system to be controlled is available. The model may have been obtained experimentally by applying test input signals and measuring the response, or analytically by utilizing the laws of physics to derive the equations representing the system. The model would generally be expressed either as a differential equation relating the system's input and output signals or as a transfer function in the complex Laplace variable $s = \sigma + j\omega$ for the special case where the system is linear. The values of the coefficients in the differential equation or transfer function would be functions of the physical quantities in the system. The form of the compensator used in the feedback control system to make it respond satisfactorily to inputs, as well as to possess sufficient stability, would depend on the model for the system being controlled.

At several stages in the control system design process, it is desirable to use a simulation of the control system. Simulation refers in general to the process of numerically representing the equations that describe the system on a digital computer. This allows the designer to analyze the performance of the control system relative to the specifications, and indicates how the design should be modified in order to make its performance more acceptable. Analog computers, although still available for simulation, are now less used than digital computers. Simulation on a computer (analog or digital) permits the system to be analyzed without expending the time and the cost of constructing a physical model, or of testing the system itself. The risk of damage to the equipment by an incorrectly designed compensator is also reduced considerably.

System modeling. When models for physical systems are derived analytically, the equations are developed by applying the appropriate conservation laws. For an electrical system, Kirchhoff's current and voltage laws may be used to model the relationships between variables. For mechanical systems, Newton's second law of motion or Lagrange's equations may be used. An example is the spring-mass damper system of Fig. 7, and the variables and parameters of this simple example. The sum of the applied and reactive forces from the spring, mass, and damper is equal to zero. The reactive forces are given in Eqs. (35)–(37), where

$$F_k = K(y) \quad \text{for spring} \qquad (35)$$

$$F_m = M(\ddot{y}) \quad \text{for mass} \qquad (36)$$

$$F_f = f(\dot{y}) \quad \text{for damper (wall friction)} \qquad (37)$$

the dots over the variables represent differentiation with respect to time. The model for this mechanical system, expressed as a second-order differential equation, becomes, through use of Newton's law, Eq. (16), where $u(t)$ is the total applied force.

Equation (16) is often not convenient in form for control system design. The model of this linear system may be expressed either in state-variable form or as a transfer function. In state-variable form, an nth-order differential equation is expressed as n first-order differential equations. For the model of Equation (16), the state variables $x_1 = y$ and $x_2 = \dot{y}$ and input variable u can be defined. The system model's state equations then become Eq. (38). The output equation for this model is Eq. (39).

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -(K/M) & -(f/M) \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 0 \\ (1/M) \end{bmatrix} u \qquad (38)$$

$$y = [1 \quad 0] \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + [0]\, u \qquad (39)$$

In order to develop the transfer-function model for this system, the Laplace transform is taken of Eq. (16) under the assumption that all initial conditions are zero. This yields Eq. (40). The transfer function is

$$(Ms^2 + fs + K)Y(s) = U(s) \qquad (40)$$

defined as the ratio of the Laplace transform of the output to the Laplace transform of the input with zero initial conditions. Equation (37) thus provides the transfer function, Eq. (41).

$$\frac{Y(s)}{U(s)} = \frac{(1/M)}{s^2 + (f/M)s + (K/M)} \tag{41}$$

Comparison of Eqs. (16), (38), and (41) shows that the coefficients in the various model forms are related to the component parameters in the physical system. For simple systems, such as that in Fig. 7, the state equation or transfer-function models can be developed by inspecting the original differential equation.

In order to model a system experimentally, certain input test signals are chosen and applied to the system, and the output is measured. Perhaps the most common set of input signals for this purpose is composed of sinusoids of various frequencies. Each input signal is of the form given in Eq. (42) for some value

$$u(t) = \sin(\omega t) \tag{42}$$

of angular frequency ω. The input signals are applied singly to the system until a steady-state condition is reached at the output, which will be of the form given in Eq. (43). Therefore, the ratio of the mag-

$$y(t) = A(\omega)\sin[\omega t + \theta(\omega)] \tag{43}$$

nitudes of output to input signal is $A(\omega)$, and the phase shift of the output relative to the input is $\theta(\omega)$. The plots of $A(\omega)$ and $\theta(\omega)$ versus ω are called Bode plots. Generally, $20\log_{10}[A(\omega)]$ is plotted rather than $A(\omega)$, thereby expressing the magnitude ratio in decibels (dB). From known rules of constructing Bode plots, the transfer function for the system can be obtained from the experimental results. To obtain the best plots for developing the transfer function, the frequencies chosen for the input signals should be evenly spaced on a logarithmic scale. **Figure 13** shows the magnitude plot for a particular system. The circles are the values of magnitude ratio that would be determined experimentally if the corresponding sinusoidal frequencies were input to the system. The curve represents the actual magnitude.

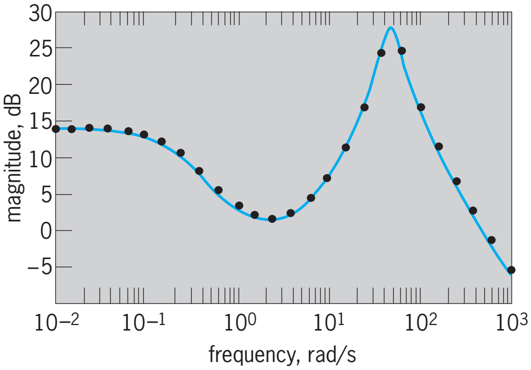

Fig. 13. Frequency domain magnitude for an experimentally determined model.

Equation (44) gives the transfer function for this system.

$$\begin{aligned} G(s) &= \frac{500(s+1)(s+5)}{(s+0.2)(s^2+20s+2500)} \\ &= \frac{5(1+s)(1+s/5)}{(1+s/0.2)[1+s/125+(s/50)^2]} \end{aligned} \tag{44}$$

The second form of $G(s)$ shows how the transfer function can be obtained from the plot. The dc (zero-frequency) gain in the plot is 14 dB $= 20\log_{10}(5)$. The plot starts to curve down near a pole of the transfer function and curves up near a zero. Underdamped complex poles cause an overshoot in the curve, with a sharper peak for less damping. The quadratic factor in the denominator of Eq. (44) corresponds to an undamped natural frequency $\omega_n = 50$ rad/s and a damping ratio $\zeta = 0.2$. The slopes of the Bode magnitude curve change by integral multiples of ±20 dB per decade as poles or zeros are encountered.

Care must be taken in determining a system model experimentally. The amplitude of the input signal must be so chosen that the system response remains linear throughout the experiment. Feedback loops must not be broken if the open-loop system has unstable poles.

System simulation. Simulation is used to evaluate the performance of both open- and closed-loop systems. With simulation on a digital computer, either the continuous-time equations forming the mathematical model may be converted into a discrete-time state equation or difference equation, or they may be solved directly by numerical integration. In any case, a sampling period T must be chosen small enough for the important dynamics of the continuous-time system to be reproduced. In converting to a discrete-time system, a rule of thumb is to choose T so that the highest-frequency components of the original system are sampled five to ten times per period. In using numerical integration, T must be so chosen that the products of T with each of the poles of the system all lie inside the region of absolute stability for the particular integration operator used.

If the system model is given in the state-variable form shown in Eqs. (45), then the discrete-time

$$\begin{aligned} \dot{x}(t) &= Ax(t) + Bu(t) \\ y(t) &= Cx(t) + Du(t) \end{aligned} \tag{45}$$

model which can be used for simulation is given by Eqs. (46) and (47). Here k takes on values

$$x[(k+1)T] = \Phi x(kT) + \Psi u(kT) \tag{46}$$

$$y(kT) = Cx(kT) + Du(kT) \tag{47}$$

[0, 1, 2, ...] and the matrices in Eq. (46) are defined by Eqs. (48) assuming that $u(t)$ is constant in

$$\Phi = e^{AT} \qquad \psi = \int_0^T e^{A\tau} B\, d\tau \tag{48}$$

the interval from kT to $(k+1)T$. Equations (46) and (47) can be solved for the output at each discrete point in time kT.

If the simulation is to be performed as an nth-order difference equation, the system model is expressed in the form of a discrete-time transfer function through the use of the Z transform, as shown in Eq. (49). In this form, the sample period T is implicit

$$\frac{Y(z)}{U(z)} = \frac{b_m z^m + b_{m-1} z^{m-1} + \cdots + b_1 z + b_0}{z^n + a_{n-1} z^{n-1} + \cdots + a_1 z + a_0} \tag{49}$$

in the values of the a_i and b_i coefficients. The solution for the output $y(kT)$ is given by Eq. (50). The

$$\begin{aligned} y(kT) = {} & -a_{n-1} y[(k-1)T] - \cdots \\ & - a_1 y[(k-n+1)T] - a_0 y[(k-n)T] \\ & + b_m u[(k+m-n)T] + \cdots \\ & + b_1 u[(k-n+1)T] + b_0 u[(k-n)T] \end{aligned} \tag{50}$$

output is generated recursively as a sum of previous values of the output and present (if $n = m$) and past values of the input.

If the simulation is to be performed by numerical integration, the continuous-time state model of Eq. (45) is used, along with the selected integration operator. Many computer installations have software which can provide highly accurate solutions to linear or nonlinear differential equations. *See* NUMERICAL ANALYSIS; SIMULATION. Guy O. Beale

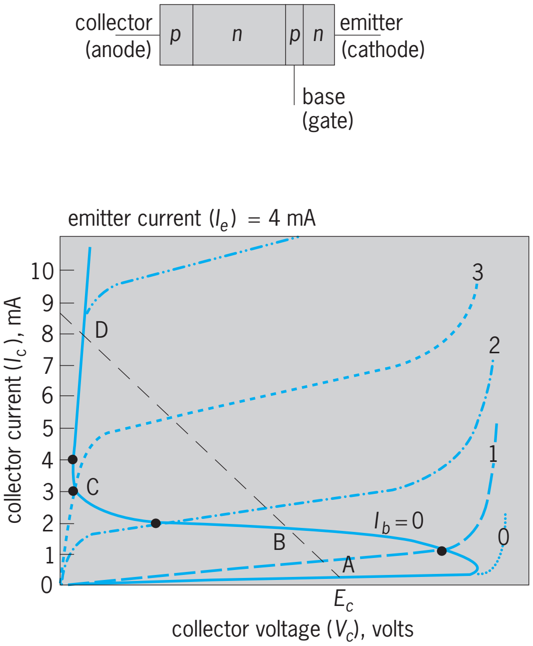
Controlled rectifier

A three-terminal semiconductor junction device with four regions of alternating conductivity type (*pnpn*), also called a thyristor. This switching device has a characteristic such that, once it conducts, the voltage in the circuit in which it conducts must drop below a threshold before the controlled rectifier regains control. Such devices are useful as high-current switches and may be used to drive electromagnets and relays.

The principle of operation can be understood by referring to the **illustration**. The central junction is reverse-biased (positive collector, grounded emitter). The wide n region between collector and base regions prevents holes injected at the collector junction from reaching the collector-to-base barrier by diffusion. The junction between emitter and base is the emitter. When operated as a normal transistor, this device shows a rapid increase of current gain of α (equal to I_c/I_e) with collector current. This effect may be due to a field-induced increase of transport efficiency across the floating n region, or to increased avalanching in the high-field barrier region, or to increased injection efficiency at the two forward-biased junctions, or to a combination of these phenomena.



Controlled rectifier diagram and characteristics.

With a floating-base region ($I_b = 0$), the device is a two-terminal device and collector current I_c must equal emitter current I_e.

By selecting the points on the illustrated characteristics where $I_c = I_e$, the characteristic for the base current $I_b = 0$ is shown as the heavy curve with the negative-resistance characteristic. This characteristic will be found in any transistor which shows an integrated α increasing from below unity at low collector currents to above unity at high collector currents.

If this device is operated as a three-terminal device, the switching between the nonconducting and conducting states can be controlled by the base. If in the grounded-emitter case the collector is biased to $+E_c$ as shown, the device will remain at point A until the base is pulsed positive by at least enough current to carry the emitter current to point B. At this point α exceeds unity and the device will spontaneously switch to point D in the conducting state. To reset the unit, either the emitter must be cut off or the collector voltage must be reduced so that the load line falls below the valley point C. The current of point C is called the holding current. Either of these results can be achieved by appropriate pulses on the base. Modern terminology usually refers to the rectifier terminals as anode and cathode and to the control terminal as the gate. *See* SEMICONDUCTOR RECTIFIER.

Overall current gain α may be maintained below unity for low anode-cathode currents by designing the junction between the anode and the floating *n* region and the junction between the gate and the cathode so each has a low-current injection efficiency below 0.5. For further discussion of four-layer devices *see* TRANSISTOR Lloyd P. Hunter

Controlled/living radical polymerization

A synthetic method which avoids the premature termination of growing radicals and produces polymers with precise compositions, architectures, and functionalities.

Free-radical polymerization is used extensively in industry for the synthesis of a variety of polymeric materials. Its widespread use is due to its compatibility with many functional groups, its tolerance toward water and acidic media, and its simplicity. Free-radical polymerization routinely is done under various conditions and processes, including bulk, solution, or aqueous environments, and is now the leading industrial method for producing vinyl polymers and copolymers. *See* COPOLYMER; FREE RADICAL; POLYMER; POLYMERIZATION; POLYVINYL RESINS.

In spite of its utility, free-radical polymerization is considered unsuitable for the synthesis of polymers with precise compositions, architectures, and functionalities. This is because of the very limited lifetime of the propagating free-radical species (typically 0.1 to 10 s), which suffer from the propensity to undergo diffusion-controlled termination by recombination or disproportionation (**Fig. 1**), unlike growing ionic species which inherently repel each other. The polymers obtained by free-radical means are therefore generally ill defined and polydisperse (wide molecular-weight distribution), with only limited control over molecular weight or architecture.

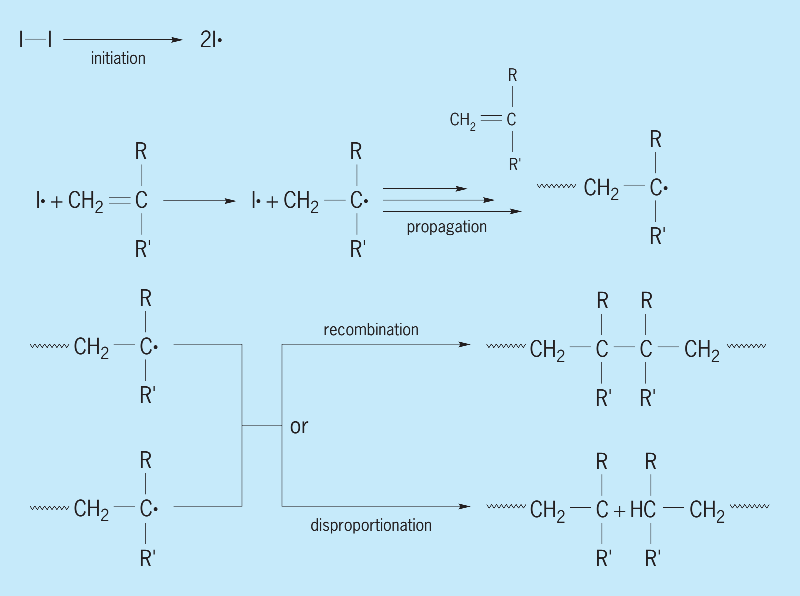

Fig. 1. Free-radical polymerization.

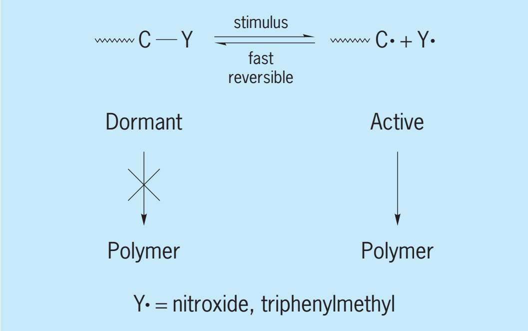

Fig. 2. Active and dormant radical equilibrium.

Until recently, the only option for efficiently controlling the structure and architecture of vinyl polymers was ionic or coordination polymerizations, which do not suffer from irreversible chain-terminating (deactivating) reactions and are known as "living" polymerizations. Unfortunately, living ionic polymerizations are of limited scope since they require stringent purity conditions as well as the total absence of water and oxygen, and are generally incompatible with monomers with functional groups. The necessity to overcome these limitations fueled the development of a new polymerization procedure that would exhibit all characteristic features of regular free-radical polymerization, as well as "living" character, similar to ionic polymerizations.

When addressing this challenge, the primary difficulty was to find a way to avoid the premature termination of the growing radicals. The idea that eventually predominated was to lower the instantaneous concentration of growing radicals by trapping them in a large reservoir of covalent, dormant species and establish a fast equilibrium between the latter and a minute concentration of active, growing radical species. If such a dynamic equilibrium could be established, the probability for spontaneous bimolecular radical termination would be minimized, and all chains would be given an equal opportunity to grow through constant interconversion between their active and dormant forms (**Fig. 2**). Another interesting outcome would be a nearly uniform molecular weight, as determined by the ratio of the concentrations of converted monomer to that of the dormant species (or the initiator). First conceptualized by T. Otsu in 1982, this seminal idea has given birth to the field of controlled/living radical polymerization, which has grown explosively.

Characterized by different mechanisms and chemicals involved, three main methods (by far the most studied) of control of radical polymerization are (1) nitroxide-mediated radical polymerization (NMP), (2) atom transfer radical polymerization (ATRP), and (3) reversible addition-fragmentation chain transfer (RAFT) polymerization.

Nitroxide-mediated radical polymerization. Nitroxides are stable free radicals that are generally used in organic chemistry to trap transient radicals. They react at diffusion-controlled rates with carbon-centered radicals and are known not to initiate polymerization. Taking advantage of these features, M. K. Georges and coworkers used the commercially available nitroxide, 2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO), to trap growing polymer chains and demonstrated that the trapping process is reversible when the temperature range is appropriately chosen. The mechanism of control involves the reversible termination of growing radicals by TEMPO, which functions as a counter radical. Samples of polystyrene exhibiting narrow molecular-weight distributions could be obtained by heating styrene at 123°C (253°F) in the presence of TEMPO and a free-radical initiator. However, the reversible radical capping by TEMPO could not be used for most monomers other than styrene, since most other vinyl monomers showed a total incompatibility with this kind of nitroxide. Anticipating that the structure of the stable radical used to trap the growing radicals must play a crucial role in the success or failure of such living radical polymerization, Y. Gnanou and P. Tordo designed a more effective nitroxide to extend the scope of NMP. They developed a α-hydrogen-bearing nitroxide, namely *N-tert*-butyl-*N*-[1-diethylphosphono-(2,2-dimethylpropyl)]nitroxide [DEPN], which is of slightly lower stability than TEMPO and whose main characteristics is to give alkoxyamines with much weaker C—O bonds than TEMPO. Not only could styrene be polymerized at faster rates and under living conditions in the presence of DEPN and a radical initiator, but also the polymerization of acrylates, acrylamides, and more recently methacrylates were found to be living in the presence of DEPN (**Fig. 3**). *See* POLYACRYLATE RESIN; POLYSTYRENE.

In a similar approach, C. Hawker and coworkers developed unimolecular alkoxyamines based on 2,2,5-trimethyl-4-phenyl-3-azahexane-3-nitroxide (TIPNO), another α-hydrogen-bearing nitroxide, and used these as initiators and controlling agents for the living polymerization of the above monomers, as well as for acrylonitrile, butadiene, and so others. The beauty of nitroxide-mediated radical polymerization lies in the fact that the amount of terminated chains eventually formed is exactly equal to the excess nitroxide produced by the system to minimize termination reactions. H. Fischer conceptualized this remarkable phenomenon and called it the persistent radical effect. To minimize the amount of terminated chains to a level lower than that determined by the system, the nitroxide can be used in excess with respect to the initiator.

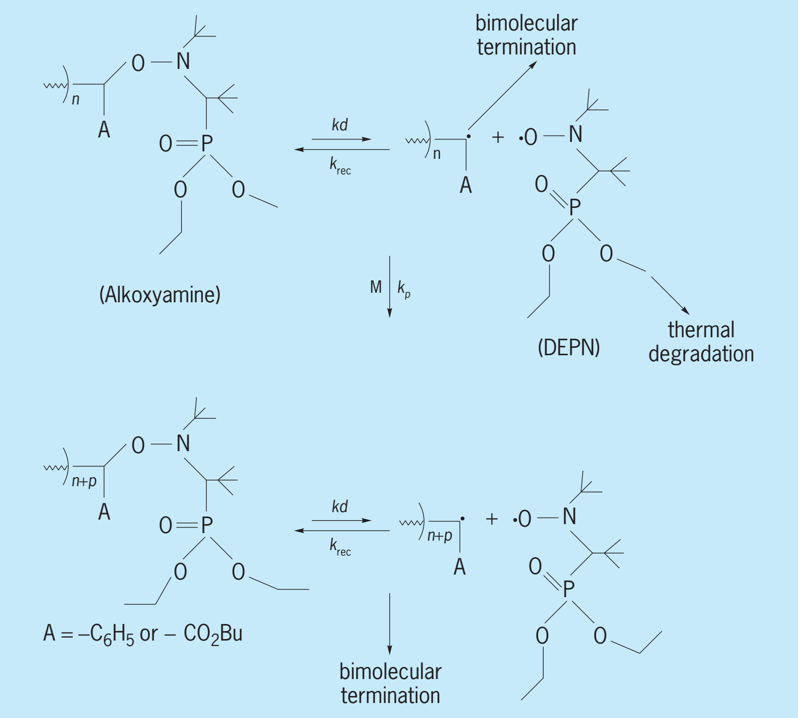

Fig. 3. Nitroxide-mediated radical polymerization of styrene or butylacrylate.

Atom transfer radical polymerization (ATRP). Discovered by K. Matyjaszewski in 1995, atom transfer radical polymerization entails a reversible one-electron oxidation of a transition metal, abstracting a halogen from an organic halide (RX), thus generating a radical species ($R^{\bullet}$) that can attack an unsaturated compound ($CH_2{=}CHR'$) and further propagate ($R{-}[CH_2{-}CHR']_n{-}CH_2{-}C^{\circ}HR'$), followed by a one-electron reduction of the now oxidized metal, transferring its halogen to the growing chain ($R{-}[CH_2{-}CHR']_n{-}CH_2{-}C^{\circ}HR'$), and thus producing ($R{-}[CH_2{-}CHR']_n{-}CH_2{-}CHR'{-}X$) as a dormant species. Such halide abstraction (k_{act}) and subsequent transfer (k_{deact}) occur repeatedly, and polymer chains grow between each activation/deactivation cycle (**Fig. 4**).

Provided the latter process is rapid, all the chains can grow uniformly. The oxidized metal complexes $X\text{-}M_t^{n+1}$ generated by activation of the dormant alkyl halides behave like persistent radicals and therefore reduce the stationary concentration of growing radicals, minimizing the extent of termination. Like nitroxide-mediated radical polymerization, atom transfer radical polymerization is under the control of the persistent radical effect, which means that a successful atom transfer radical polymerization contains a small amount of terminated chains. Also in 1995, M. Sawamoto independently described metal-catalyzed living radical polymerization (MCRP), which appeared to exhibit the same

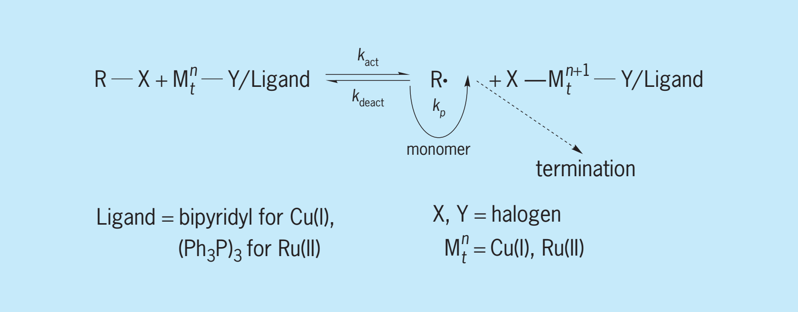

Fig. 4. Atom transfer radical polymerization.

mechanism as that of atom transfer radical polymerization. The initiating systems for both methodologies consist of a transition-metal/ligand complex and an initiator (typically an activated alkyl halide), the role of the former being to generate radical species from the latter by the above mechanism. In choosing the appropriate metal/ligand catalyst for controlling the polymerization, four criteria are critical: (1) the metal center must have at least two accessible oxidation states separated by one electron, (2) it must exhibit affinity toward halogen, (3) the coordination sphere around the metal must be able to accommodate the halogen upon oxidation, and (4) the ligand must form a strong complex with the metal. On these grounds, Matyjaszewski proposed copper(I)bromide associated with a variety of nitrogen-based ligands as the atom transfer radical polymerization catalysts, and Sawamoto associated Ru(II) with phosphine and other ligands as metal-catalyzed living radical polymerization catalysts. As demonstrated by its extensive use in the synthesis of polymers with precise composition and architecture, atom transfer radical polymerization is superior to metal-catalyzed living radical polymerization by its versatility and cost. *See* LIGAND.

Reversible addition-fragmentation chain transfer (RAFT) polymerization. In 1998, E. Rizzardo described a new method for controlling free-radical polymerization that involved the use of thiocarbonylthio compounds reacting by reversible addition-fragmentation transfer (RAFT) with the growing radicals. The effectiveness of these RAFT reagents, mirrored in chain-transfer constants Ctr larger than 1, depends on the nature of their (Z) and (R) groups, Z determining their reactivity toward entering radicals and R its aptitude for fragmentation. The key step in a successful RAFT process is the chain transfer of growing radicals to the RAFT reagent and the subsequent formation of the intermediate radical. The latter then undergoes fragmentation, releasing a radical ($R^\bullet$) which can initiate polymerization. The entering polymer chain now carries a terminal [S═C(Z)S—] moiety and is transformed into a dormant species. After total consumption of the thiocarbonylthio compound, an equilibrium is established between the dormant thiocarbonylthio-carrying chains and active ones, producing a polymer with narrow polydispersity (**Fig. 5**), for large C_{tr} values of the thiocarbonylthio compound.

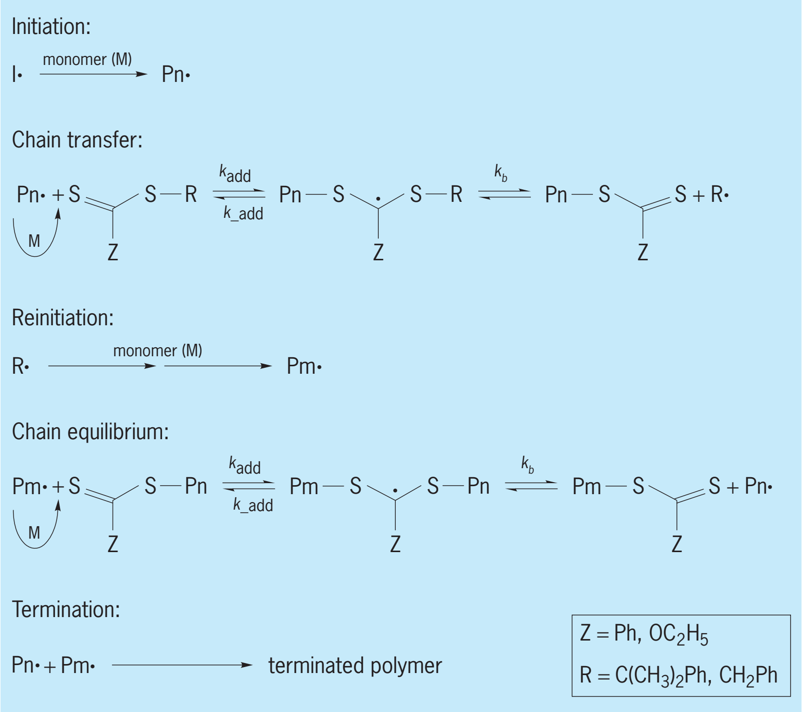

Fig. 5. RAFT polymerization.

The molecular weight is given by the ratio of monomer to thiocarbonylthio compound, and the amount of terminated chains correspond to that of the radical initiator used to trigger the polymerization. The main advantage of RAFT over nitroxide-mediated radical polymerization and atom transfer radical polymerization is its applicability to a wider range of monomers, including functional ones such as acrylic acid or those carrying an electron-donating substituent such as vinyl acetate. D. Charmot of Rhodia Recherches, France, showed that xanthates, which are also thiocarbonylthio compounds, are excellent RAFT reagents for vinyl acetate and analogues, and termed its invention MADIX for macromolecular design via interchange of xanthates.

Application. The three methodologies of controlling free-radical polymerization have their merits and limitations. ATRP is easy to carry out but it cannot be used with certain functional monomers and requires a tedious metal-removal step, whereas RAFT or NMP can be applied to functional and nonfunctional monomers but their controlling agents may necessitate complex synthesis.

With the advent of NMP, ATRP, and RAFT, novel polymeric materials—many of which are totally original and exhibit precise composition such as block and gradient copolymers and complex topology such as star-, comb-, and dendrimer-like polymers—can be obtained under the conditions of regular free-radical polymerization. This paves the way for tremendous opportunities in bio- and nanotechnologies and other high-tech areas. **Yves Gnanou; Daniel Taton**

Conulariida

A group of extinct invertebrate organisms normally having an elongate, four-sided pyramidal exoskeleton of calcium phosphate composition. Due to poor preservation of key biological structures, the evolutionary affinities and classification of conulariids are uncertain; however, they are often regarded as an unusual group of cnidarians.

Morphology. The conulariid exoskeleton has an aperture at the widest end, and tapers to a closed, slightly rounded apex. The apex is rarely observed in fossils (**Fig. 1***a*). Usually the apical end of the exoskeleton is broken, revealing an internal, slightly bowed partition called the apical wall. Specimens typically range in size from 1 to 30 cm (0.4 to 12 in.). Externally, each of the four sides or faces is crossed by numerous pairs of transverse, curved ridges that meet at a distinct longitudinal midline. On the inside of the exoskeleton, the midline may be represented by a carina, or ridge. Ridges are formed through thickenings of phosphatic skeletal layers (sometimes called rods), and they probably conferred structural strength to an otherwise rather flexible integument. The external surface commonly shows other features such as nodes and small crests. Adjacent sides meet at a longitudinal groove called a corner groove.

Conulariids were evidently attached epibenthic (ocean-bottom-dwelling) organisms. In rare circumstances, the attachment structure, an elongate organic (probably proteinaceous) stalk (Fig. 1*b*), is preserved. The stalk sheaths the apical end of the exoskeleton.

The conulariid exoskeleton was pliable. In shales, they are often found compacted, and in storm bed deposits, they are sometimes oddly bent. Often the faces are bent inward at the aperture (**Fig. 2***b*), and this is interpreted as a taphonomic (postmortem) phenomenon.

Classification. Conulariids are problematic fossils and comprise more than 400 species that are assigned to about 50 genera. Not all these species and genera are undisputed members of the group, however. Because of the rather simple pyramidal or conical morphology of conulariids, it is possible that some fossils have been erroneously categorized. In general, the evolutionary affinities of conulariids and their position within the Linnaean classification system are uncertain because key biological structures were not preserved as fossils. Because of their skeletal shape or composition, at various times they have been classified as worms, mollusks, cnidarians, chordate relatives, and representatives of an extinct phylum. The majority opinion is that these fossils represent an unusual group of cnidarians. The main characters supporting this view include a four-sided symmetry and the presence of a carina along the inside of each side's midline that resembles one of the four interradial septa formed by the ectoderm that divides the enteron (alimentary canal) of a scyphozoan (jellyfish). The pattern of ridge distribution and the phosphatic composition of the conulariid exoskeleton tend to argue against a cnidarian affinity, but not unequivocally. Preserved soft parts of conulariids include an elongate gut tract and various internal ovoid-shaped organs but do not include tentacles. *See* CNIDARIA.

Fig. 1. Conulariid morphology. (*a*) *Paraconularia byblis*, a well-preserved specimen in siderite (iron carbonate) from the Carboniferous (Mississippian) of Ohio showing two adjacent sides meeting at a deep corner groove (arrow). Ridges along each side meet at a subtle longitudinal midline. Length of specimen: 13 cm (5.1 in.). (*b*) Specimen of *Paraconularia chesterensis* from the Carboniferous (Mississippian) of British Columbia showing attachment stalk (black) extending from the apical end. Length of specimen: 26 mm (1 in.).

Geologic occurrence, paleoecology, and taphonomy. Conulariid fossils are known from marine strata of all continents except Antarctica. In most shale, limestone, and sandstone deposits, articulated conulariids are uncommon to rare. There are notable exceptions, however. Dark, organic-rich shales representing low-oxygen (dysaerobic or exaerobic) environments in the Carboniferous of Kansas and Missouri yield hundreds of specimens per square meter along some bedding planes. Concretions composed of siderite (iron carbonate) in the Carboniferous of Ohio and Kentucky, as well as concretions composed of phosphate in the Carboniferous of Kansas and silica in the Devonian of Bolivia, also yield large numbers of specimens. Normally, deposits rich in conulariid remains have biotas of low overall diversity. Clusters of conulariids (Fig. 2*a*) are a common occurrence. In such circumstances, individuals are usually of approximately the same size. This suggests that the clusters originated from either a spat-fall of larvae or perhaps from asexual budding of a single progenitor.

Following death, conulariid exoskeletons disarticulated into small pieces of integument or even

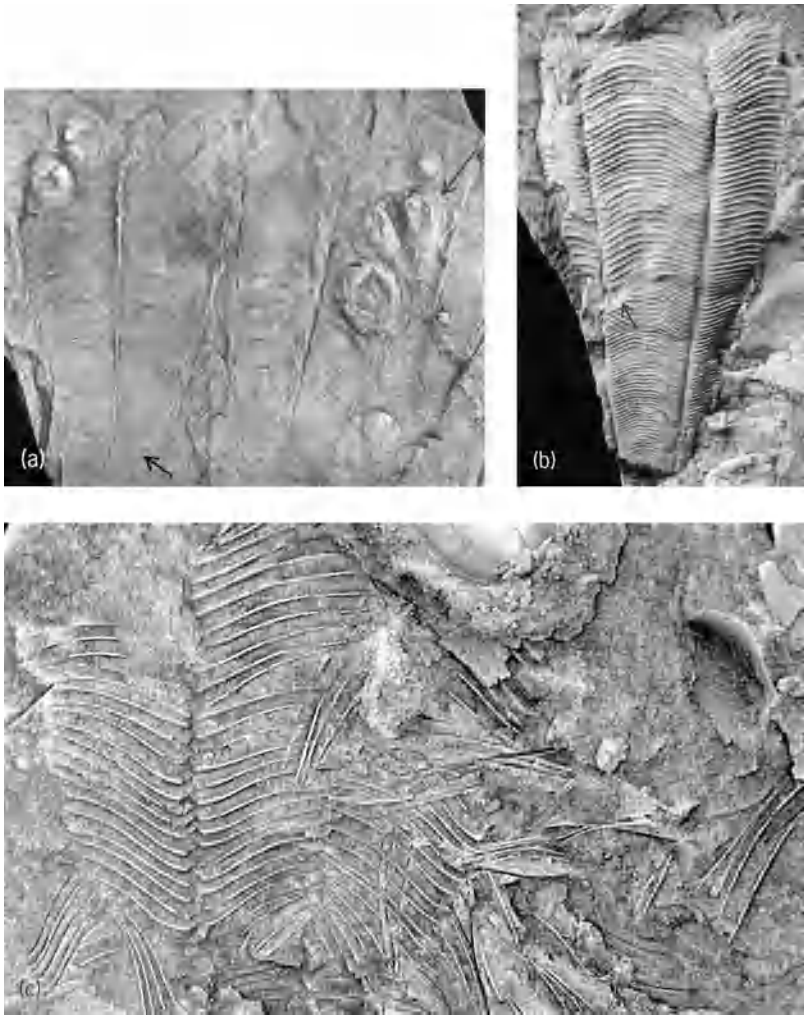

Fig. 2. Conulariid paleoecology and taphonomy. (*a*) Cluster of *Conularia congregata* compacted in shale from the Devonian of New York. The specimens show apical walls (lower arrow), indicating detachment from, or nonpreservation of, their attachment stalks. The conulariids are encrusted by round shells of inarticulate brachiopods (upper arrow). Length of large specimen at left: 6 cm (2.4 in.). (*b*) *Paraconularia chesterensis*, a specimen compacted in shale from the Carboniferous (Mississippian) of Indiana showing one complete, exposed face flanked by two partly exposed sides. Pairs of ridges meeting at the longitudinal midline are exposed on the complete face. At the aperture, the faces have been folded inwardly. A healed bite mark, marked by broken ridges and scar tissue, is present about midway down the left side of the specimen (arrow). Length of specimen: 8 cm (3.1 in.). (*c*) *Paraconularia subulata* from the Carboniferous (Mississippian) of Ohio in mostly disarticulated condition showing fragments of integument (especially at left) and thin, scattered rods. Average length of rods: 3.6 mm (0.14 in.).

into individual rods (Fig. 2*c*). Injuries, both sublethal (Fig. 2*b*) and lethal, inflicted by carnivores such as cephalopods and sharks, have been recorded in conulariids, sometimes in large numbers of specimens from an individual locality. Predation must have led to the breakage of conulariid exoskeletons and may account, in part, for the low numbers of articulated specimens in numerous deposits.

Conulariid skeletons, both in life and afterward, often served as attachment sites for other marine organisms. Inarticulate brachiopods (Fig. 2*a*), edrioasteroid echinoderms, sponges, and other animals have been observed attached to conulariid exoskeletons. *See* FOSSIL; PALEOECOLOGY; TAPHONOMY.

Evolutionary history. Conulariids are a relatively small group that have a stratigraphic range through much of the Paleozoic and the lowermost Mesozoic. Small phosphatic fossils that are usually classified as conulariids occur in the lower part of the Cambrian. These fossils, which include hexaconulariids and hexangulaconulariids, if they are phylogenetically related to Ordovician and younger conulariids, differ from these later examples in having small size (typically less than 1 cm in length) and in having a variable number of faces, instead of just four sides. Some fossils from the Neoproterozoic (Ediacaran Period) have been questionably interpreted as close relatives of conulariids, and even as possible ancestral taxa.

Undisputed conulariids occur in the upper part of the Cambrian but do not become a significant part of fossil assemblages until the Middle Ordovician. Peak diversity was apparently reached in the Devonian through Carboniferous. Conulariids became nearly extinct at the end of the Permian, and barely recovered in the Early Mesozoic. They are represented in the Triassic by only one known genus. *See* ANIMAL EVOLUTION; GEOLOGIC TIME SCALE.

Convection (heat)

The transfer of thermal energy by actual physical movement from one location to another of a substance in which thermal energy is stored. A familiar example is the free or forced movement of warm air throughout a room to provide heating. Technically, convection denotes the nonradiant heat exchange between a surface and a fluid flowing over it. Although heat flow by conduction also occurs in this process, the controlling feature is the energy transfer by flow of the fluid—hence the name convection. Convection is one of the three basic methods of heat transfer, the other two being conduction and radiation. *See* CONDUCTION (HEAT); HEAT RADIATION; HEAT TRANSFER.

Natural convection. This mode of energy transfer is exemplified by the cooling of a vertical surface in a large quiescent body of air at temperature t_∞. The lower-density air next to a hot vertical surface moves upward because of the buoyant force of the higher-density cool air farther away from the surface

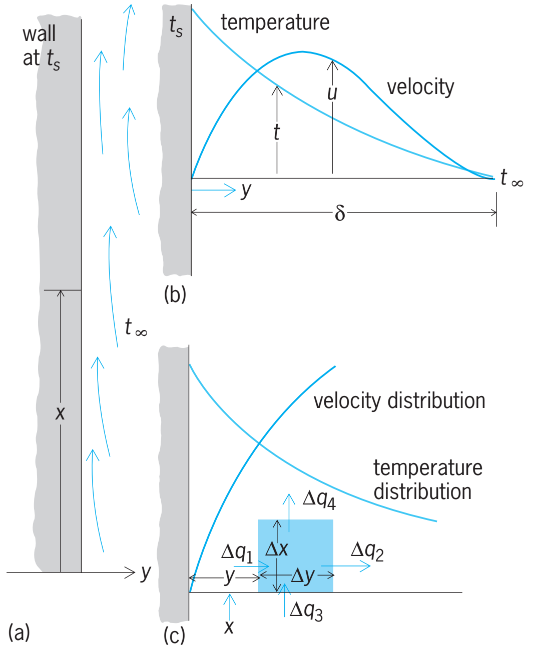

Fig. 1. Temperature and velocity distributions in air near a heated vertical surface. (*a*) Upward movement of hot air. (*b*) Distributions at arbitrary vertical location. The distance δ is that distance at which the velocity and the temperature reach ambient surrounding conditions. (*c*) Distributions in boundary layer.

(**Fig. 1*a***). At any arbitrary vertical location x, the velocity parallel to the surface will increase from zero at the surface to a maximum, and then decrease to zero as ambient surrounding conditions are reached (Fig. 1*b*). In contrast, the temperature of the air decreases from the heated wall value to the surrounding air temperature. These temperature and velocity distributions are clearly interrelated, and the distances from the wall through which they exist are coincident because, when the temperature approaches that of the surrounding air, the density difference causing the upward flow approaches zero.

The region in which these velocity and temperature changes occur is called the boundary layer. Because velocity and temperature gradients both approach zero at the outer edge, there will be no heat flow out of the boundary layer by conduction or convection. *See* BOUNDARY-LAYER FLOW.

An accounting of all of the energy streams entering and leaving a small volume in the boundary layer (Fig. 1*c*) during steady-state conditions yields Eq. (1),

$$\kappa\left(\frac{\partial^2 t}{\partial x^2}+\frac{\partial^2 t}{\partial y^2}\right)=\rho c_p\left(u\frac{\partial t}{\partial x}+v\frac{\partial t}{\partial y}\right) \qquad (1)$$

where κ, ρ, and c_p are the thermal conductivity, the mass density, and specific heat at constant pressure of the air, and u and v are the velocity components in the x and y directions, respectively. Equation (1) states that the net energy conducted into the element equals the increase in energy of the fluid leaving (convected) over what it had entering.

Very close to the surface, the velocity components u and v both approach 0, and the partial derivatives $\partial^2 t/\partial x^2$ and $\partial t/\partial x$ also approach 0. Therefore, the heat transfer from the wall must be by conduction through a thin layer of air which is effectively stationary relative to the surface. Thus, Eq. (2) is obtained,

$$q=-\kappa\left.\frac{\partial t}{\partial y}\right|_{y\to 0} \qquad (2)$$

where q is the time rate of heat flow per unit of surface area through an infinitesimally thin layer of air. At a very small distance from the surface, the velocity becomes finite and some of the energy conducted normal to the surface is convected parallel to it. This process causes the temperature gradient to decrease, eventually to zero. The solution of a problem requires simultaneous determination of the velocity and temperature distributions throughout the boundary layer. From this, the temperature gradient at the wall and the rate of heat flow can be computed.

The effect of energy leaving a surface and remaining in the boundary layer is (1) a gradual increase in temperature of the air in this layer as it moves upward, and (2) diffusion of energy farther from the surface, entraining more air in (thickening) the boundary layer. This effect can be visualized with interference photographs (**Figs. 2** and **3*a***), where the interference fringes indicate lines of constant temperature (isotherms).

Forced convection. If air is blown across a cylinder (Fig. 3*b*), the boundary layer on the forward half of the cylinder will become so thin that it is not possible to resolve the isotherms within it. Although the natural convection forces are still present in this latter case, they are clearly negligible compared with the imposed forces. The process of energy transfer from the heated surface to the air is not, however, different from that described for natural convection. The major distinguishing feature is that the maximum fluid velocity is at the outer edge of the boundary layer. This difference in velocity profile and the higher velocities provide more fluid near the surface to carry along the heat conducted normal to the surface. Consequently, boundary layers are very thin.

The properties of a fluid which influence its heat-convecting ability are the dynamic viscosity μ, heat capacity at constant pressure c_p, and thermal conductivity κ. These combine in a single significant property in the form $\mu c_p/\kappa = \mu/(\kappa/c_p)$, which is the ratio of the fluid viscosity to the quotient of its heat-conducting and heat-storage capacities. With proper units, this ratio is dimensionless and is called the Prandtl number, N_{Pr}. For air N_{Pr} is approximately 1. Fluids such as oils have values greater than 100. Liquid metals, for which $N_{\mathrm{Pr}} \sim 0.01$, are particularly effective for convective heat-transfer applications. *See* FLUIDS.

Heat-transfer coefficient. The convective heat-transfer coefficient h is a unit conductance used for

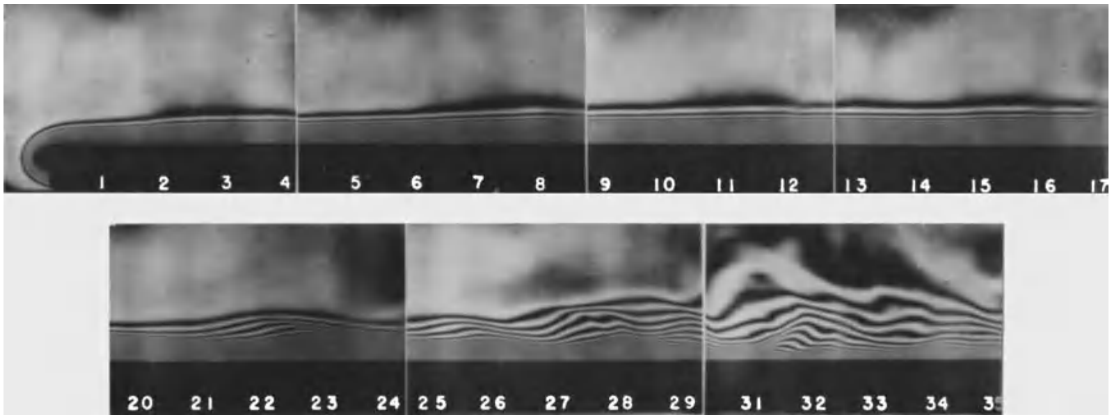

Fig. 2. **Laminar and turbulent convection along a vertical plate, as revealed by interference photographs. Interference fringes indicate lines of constant temperature (isotherms). (*Courtesy of E. R. G. Eckert and E. Soehngen*)**

calculation of convection heat transfer. It was introduced by Isaac Newton and, until the mechanism of convection was properly interpreted, was thought to be a characteristic of the fluid flowing. To describe quantitatively the cooling of objects in air, Newton suggested Eq. (3). This equation, known

$$q = hA(t_{\text{surface}} - t_{\text{fluid}}) \qquad (3)$$

as Newton's law of cooling, is really a definition of h. By comparison with Eq. (2), this coefficient can be seen to be proportional to the slope of the fluid temperature distribution right at the surface, and the thermal conductivity κ of the fluid. Metric units are W/(m^2)(°C); common engineering units are Btu/(h)(ft^2)(°F).

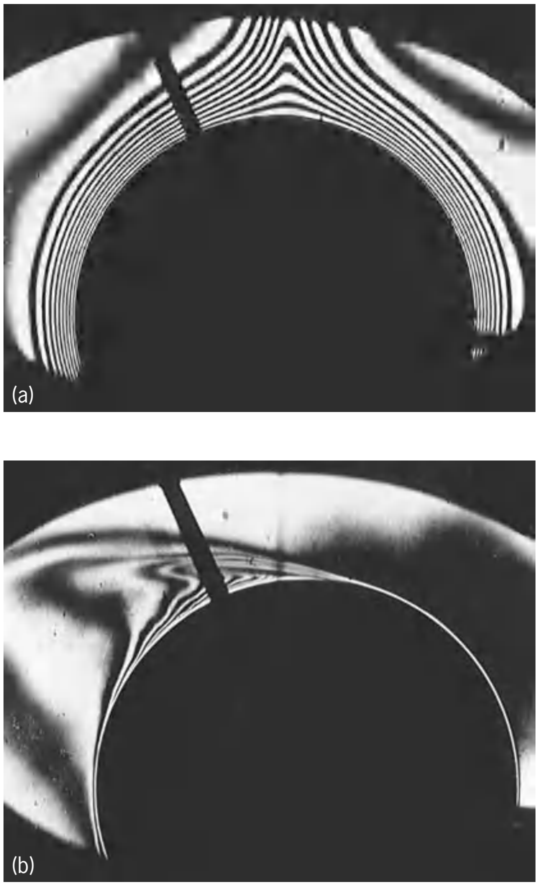

Fig. 3. **Interference photographs of isotherms around a heated horizontal cylinder 4 in. (10 cm) in diameter. (*a*) Cylinder in still air. The outer broad fringe indicates the approximate edge of the boundary layer, which is about $^3/_4$ in. (2 cm). (*b*) Cylinder normal to a 33-ft/s (10-m/s) airstream. The boundary layer on the forward half of the cylinder is so thin that the isotherms cannot be resolved. (*Courtesy of D. L. Doughty and W. H. Giedt*)**

Local and average coefficients. As the fluid in the heated or cooled boundary layer moves along an isothermal surface, it gradually approaches the temperature of the surface. This causes the temperature gradient in the fluid at the surface (and the rate of heat transfer) to decrease in the direction of flow. Taking, for example, an airstream at 104°F (40°C) moving at 50 ft/s (15 m/s) over a flat plate at 68°F (20°C), the local heat-transfer coefficient h_x decreases in 1 ft (0.3 m) to about one-fifth of its leading-edge value. For practical calculations, an average heat-transfer coefficient h is more useful. It is obtained by integrating h_x over the heat-transfer surface and dividing by the surface area. For this system, h is a function of the plate length l, κ, μ, ρ, and u_∞ of the fluid. For comparing geometrically similar systems involving different fluids, dimensional analysis shows that the specific properties can be combined into dimensionless parameters, conveniently reducing the number of independent variables. For the flat plate, these are the Nusselt number, $N_{\text{Nu}} = hl/\kappa$, the Reynolds number, $N_{\text{Re}} = lu_\infty\rho/\mu$, and the Prandtl number, N_{Pr}. For example, it can be shown that in this case Eq. (4) holds. In the case of free convection, the

$$N_{\text{Nu}} = 0.664 N_{\text{Pr}}^{1/3} \sqrt{N_{\text{Re}}} \qquad (4)$$

Grashof number, $N_{\text{Gr}} = \beta g l^3\,\Delta t/\nu^2$ (where β is the coefficient of thermal expansion, and $\nu = \mu/\rho$), replaces the Reynolds number. The product of N_{Gr} and N_{Pr} is known as the Rayleigh number (N_{Ra}), and is used in correlating free convection transfer. Other dimensionless numbers pertinent to convection include the Stanton number, $N_{\mathrm{St}} = h/\rho u c_p = N_{\mathrm{Nu}}/N_{\mathrm{Re}}N_{\mathrm{Pr}}$, which is related to the skin-friction coefficient. *See* DIMENSIONAL ANALYSIS; REYNOLDS NUMBER.

Turbulent flow. Heat convection in turbulent flow is interpreted similarly to that in laminar flow, which has been implied in the above discussion. Rates of heat transfer are higher for comparable velocities, however, because the fluctuating velocity components of the fluid in a turbulent flow stream provide a macroscopic exchange mechanism which greatly increases the transport of energy normal to the main flow direction. For example, if free-stream turbulence caused the boundary-layer flow in the example above to be turbulent, the heat-transfer rate would be about 2.5 times higher. Because of the complexity of this type of flow, most of the information regarding heat transfer has been obtained experimentally. Such results, combined with dimensional analysis, have yielded useful design equations, typical of which is Eq. (5), for predicting the heat transfer in a pipe,

$$\frac{hd}{\kappa} = 0.023\left(\frac{du}{\nu}\right)^{0.8}\left(\frac{\mu c_p}{\kappa}\right)^{0.4} \qquad (5)$$

where d is the pipe diameter.

An illustration of the controlling effect of fluid flow on convective heat transfer is provided by measurements of the local variation around a bluff body such as a cylinder normal to an airstream of velocity u_∞. Major changes occur in the streamline pattern as u_∞ is increased from very low to high values (**Fig. 4**). At very low velocities the flow at the edge of the boundary layer is slowed to zero as it approaches the forward stagnation point. It accelarates as it flows around the cylinder to a maximum at an angle from the stagnation point $\theta = 90^\circ$, and then decelerates to zero at the rear. As the free-stream velocity is increased, the flow separates from the surface before reaching $\theta = 180^\circ$ (Fig. 4*a*). With further increase the separation point moves farther forward (Fig. 4*b*). When the Reynolds number, $N_{\mathrm{Re}} = Du_\infty\rho/\mu$ (where D is the cyclinder diameter), reaches about 1×10^5 (Fig. 4*c*), the flow in the boundary layer around $\theta = 90^\circ$ becomes turbulent. Thus, the boundary can remain attached to the surface longer and the separation point moves toward the rear (Fig. 4*d*). This change may be delayed until N_{Re} reaches as high as 5×10^5 in a low-turbulence-level airstream.

Dramatic changes in the local rate of heat transfer are produced by these changes in the flow. For $N_{\mathrm{Re}} \geq 140{,}000$, the local heat transfer rises rapidly from a minimum around $\theta = 90^\circ$ to a maximum and then decreases to a second minimum around 140°. This variation is due to the change to turbulent flow before separation on the rear of the cyclinder occurs. *See* LAMINAR FLOW; TURBULENT FLOW.

Condensation and boiling. Condensation and boiling are important phase-change processes involving heat release or absorption. Because vapor and liquid movement are present, the energy transfer is basically by convection. Local and average heat-transfer coefficients are determined and used in the Newton cooling-law equation for calculating heat rates which include the effects of the latent heat of vaporization.

Condensation. Consider a saturated or superheated vapor of a single substance in some region. When it comes in contact with a surface maintained at a temperature lower than the saturation temperature, heat flow results from the vapor, releasing its latent heat and condensing on the surface. The condensation process may proceed in two more or less

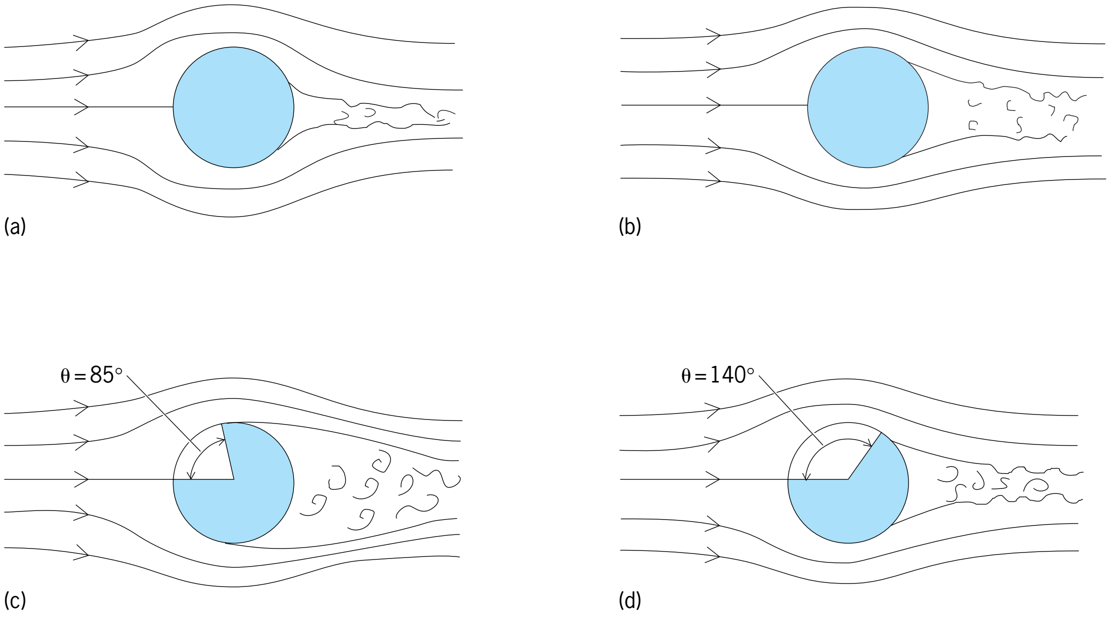

Fig. 4. Streamlines in flow past a cylinder normal to flow at increasing values of the flow velocity (expressed in terms of the Reynolds number, N_{Re}). (*a*) $N_{\mathrm{Re}} \approx 10$. (*b*) $N_{\mathrm{Re}} \approx 10^4$. (*c*) $N_{\mathrm{Re}} \leq 1 \times 10^5$. (*d*) $N_{\mathrm{Re}} \geq 1.5 \times 10^5$.

distinct ways. If there are no impurities in the vapor or on the surface (which need not be smooth), the condensate will form a continuous liquid film. If, however, such contaminants as fatty acids or mercaptans are present, the vapor will condense in small droplets. These droplets increase in size until their weight causes them to run down the surface. In doing so, they sweep the surface free for formation of new droplets. For the same temperature difference between the vapor and surface, heat transfer with dropwise condensation may be 15–20 times greater than filmwise condensation. The dropwise type is therefore very desirable, but conditions under which it will occur are not predictable, and designs are limited to systems for which experimental results are available.

Boiling. In boiling, results indicate the existence of several regimes. The important independent variable is the temperature difference Δt between the hot surface and the fluid relatively far from the surface. For values of Δt up to approximately 10°F (6°C), the liquid is being superheated by natural convection, and q/A is proportional to $\Delta t^{5/4}$. With further increase in Δt, bubbles form at active nuclei on the heated surface. These bubbles break away and rise through the pool, their stirring action causing the heat transfer to be much above that due to natural convection. This phenomenon is called nucleate boiling, and q/A varies as Δt^3 to Δt^4. When the rate of bubble formation becomes so rapid that the bubbles cannot get away before they tend to merge, a vapor film begins to form, through which heat must flow by conduction. The rate of heating then decreases with Δt until complete film boiling is reached and heat flows by radiation and conduction through the film.

The high heat rates which occur during boiling make it a very effective means of absorbing the energy capable of being released in furnaces and nuclear reactors. The high heat rates are also one reason why the vapor power-generating cycles have been successful.

Convective instability

A state of fluid flow in which the distribution of body forces along the direction of the net body force is unstable and will thus break down. Fluid flows are subject to a variety of instabilities, which may be broadly viewed as the means by which relatively simple flows become more complex. Instabilities are an important step in the transition between smooth and turbulent flow, and in the atmosphere they are responsible for phenomena ranging from thunderstorms to low- and high-pressure systems. Meteorologists and oceanographers divide instabilities into two broad classes: convective and dynamic. *See* DYNAMIC INSTABILITY.

In the broadest terms, convective instabilities arise when the displacement of a small parcel of fluid causes a force on that parcel which is in the same direction as the displacement. The parcel of fluid will then continue to accelerate away from its initial position, and the fluid is said to be unstable. In most geophysical flows, the convective motions that result from convective instabilities operate very quickly compared with the processes acting to destabilize the fluid; the result is that such fluids seem to be nearly neutrally stable to convection.

Types. The simplest type of convective instability arises when a fluid is heated from below or cooled from above. This heating and cooling result in a temperature distribution as shown in **Fig. 1**; here a small chunk of fluid at temperature T_3 is shown displaced upward. If it conserves its original temperature, it will be warmer than its environment at the same altitude and will accelerate upward, since warm air is less dense than cold air. The parcel is said to be positively buoyant. Warm air rises and cold air sinks; thus a fluid whose temperature decreases with altitude is convectively unstable, while one in which the temperature increases with height is convectively stable. A fluid at constant temperature is said to be convectively neutral. *See* ARCHIMEDES' PRINCIPLE.

The above description assumes that density depends on temperature alone and that density is conserved in parcels of fluid, so that when the parcels are displaced their density does not change. However, in the Earth's atmosphere, neither of these assumptions is true. In the first place, the density of air depends on pressure and on the amount of water vapor in the air, in addition to temperature. Second, the density will change when the parcel is displaced because both its pressure and its temperature will change. Because of these conditions it is convenient to define a quantity known as virtual potential temperature (θ_v) that is conserved and reflects the actual density of

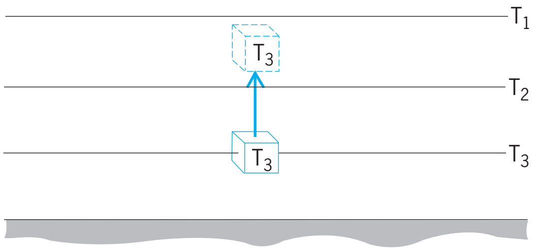

Fig. 1. Diagram showing temperature decreasing upward in a fluid and convective instability. When a small parcel of fluid is displaced upward from its initial position (solid-line box) to a new position (dashed-line box), it will be warmer than its environment and will continue to accelerate upward. T denotes temperature, with T_3 the highest and T_1 the lowest.

air. This quantity is given by Eq. (1), where T is the

$$\theta_v \equiv T\left(\frac{1+(r/0.622)}{1+r}\right)\left(\frac{1000}{p}\right)^{0.287} \qquad (1)$$

temperature in kelvins, p is the pressure in millibars, and r is the number of grams of water vapor in each gram of dry air. When θ_v decreases with height in the atmosphere, it is convectively unstable, while θ_v increasing with height denotes stability.

Over the tropical oceans, the θ_v of air adjacent to the sea surface is continually increased by addition of both heat and water vapor from the ocean, while at higher levels θ_v is decreased by cooling due to radiation to space. The result is that a layer roughly 1600 ft (500 m) deep is continually convecting. The convection is so efficient that this layer of the atmosphere is kept very close to a state of convective neutrality. Measurements show that θ_v is constant with height in this layer to within measurement error. A similar situation prevails over land during the day, when the land is heated by the Sun, but at night the land cools and the air becomes convectively stable (θ_v increases with height).

In the oceans, density is a function of pressure, temperature, and salinity; convection there is driven by cooling of the ocean surface by evaporation of water into the atmosphere and by direct loss of heat when the air is colder than the water. It is also driven by salinity changes resulting from precipitation and evaporation. In many regions of the ocean, a convectively driven layer exists near the surface in analogy with the atmospheric convective layer. This oceanic mixed layer is also nearly neutral to convection.

Convective instabilities are also responsible for convection in the Earth's mantle, which among other things drives the motion of the plates, and for many of the motions of gases within other planets and in stars.

Convective motions. Experiments have been performed to determine what kind of motions result from convective instability. Typically these experiments use a fluid contained between two parallel, horizontal plates maintained at constant temperature, with the lower plate warmer than the upper plate. If the temperature difference is small, the viscosity of the fluid prevents convection from occurring. As the temperature difference is increased beyond a critical value, convection begins as steady overturning cells whose width is roughly equal to the distance between the plates. When the temperature difference is increased further, the cells begin to oscillate and eventually the flow becomes chaotic. Variations on this experiment include one in which the flux of heat, rather than the temperature, is fixed at the parallel plates. In this case, the cells tend to be much broader than they are deep.

Virtually all convection in nature is well into the chaotic regime determined by experiments, and yet natural convection is often organized in distinctive patterns. In the atmosphere, these include long rows of clouds known as cloud streets and regular hexagonal arrays of clouds whose width can be more than 50 times their depth. The reason for this is as yet unknown. Little is known about the organization of convecting fluid in the Earth's mantle, which determines the motion of the plates that make up the Earth's crust. Convection on the Sun is also known to be organized in clumps called granules; these are in turn organized in larger clumps, or supergranules.

Moist convection. In the atmosphere, convection is complicated by the phase changes of water substance. When water vapor condenses into the liquid waterdroplets that make up clouds, for example, the heat that was used to evaporate the water in the first place is released, making the air warmer than it would otherwise be. Conversely, when rain evaporates it takes up heat and makes the air cooler. In addition to these effects, suspended condensate (that is, cloud, rain, snow, hail, and so forth) adds directly to the effective density of the air. All of these effects make moist convection, which produces cumulus clouds and thunderstorms and is considerably more exotic than dry convection.

The criterion for convective instability of moist atmospheres has been the subject of much research. A basic tool for examining the stability of moist atmospheres is the thermodynamic diagram, an example of which is presented in **Fig. 2**. This diagram has pressure on the vertical coordinate, and temperature increases downward and to the right. (Since pressure

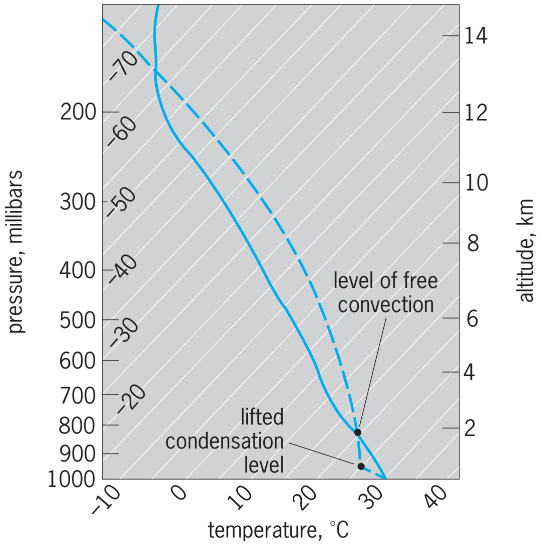

Fig. 2. Thermodynamic diagram with height on the vertical coordinate (with pressure decreasing upward), while temperature increases downward and to the right. The solid line shows an example of temperature measured at various levels in the atmosphere, typically by an ascending instrumented balloon. The broken line shows the temperature that a parcel would have if lifted from near the surface. At the lifted condensation level, water vapor begins to condense, and the parcel cools less rapidly above this point. At the level of free convection, it becomes warmer than its environment and would ascend freely above this point. 1 millibar = 10^2 pascals. 1 km = 0.6 mi. °F = (°C × 1.8) + 32.

decreases with height in the atmosphere, the vertical coordinate also represents height.) The temperature of air measured from an ascending balloon has been plotted as the solid line on this diagram. The thermodynamic diagram may contain various sets of background curves that permit a determination of the temperature of a parcel of air lifted from any point on the sounding. For example, the broken line shows the temperature a parcel of air would have if it were lifted from near the surface. At first, its temperature decreases rapidly with height, since the first law of thermodynamics states that temperature must fall with pressure. Then, when it reaches the lifted condensation level, water vapor begins to condense into cloud, releasing heat, and the temperature does not fall as fast with height.

In the example shown in Fig. 2, the lifted parcel has about the same temperature as the surrounding atmosphere up to its lifted condensation level, reflecting the neutral stability of the layer of air next to the surface. But if the parcel is displaced beyond its level of free convection, it will be warmer than its environment and will accelerate upward. This type of atmosphere is said to be conditionally unstable; that is, it is stable unless near-surface parcels are forcibly displaced beyond their level of free convection. Such an atmosphere will not spontaneously convect, and thus the amount of conditional instability can build up to large values until something triggers convection. The result is severe thunderstorms and sometimes tornadoes. This situation is common in the plains of North America in spring. *See* THUNDERSTORM; TORNADO.

It was formerly believed that the tropical atmosphere is conditionally unstable, but convective stability that is assessed by using thermodynamic diagrams like the one in Fig. 2 omits an important contribution to density: the weight of suspended condensate such as rain, snow, and cloud. When this is included, the tropical atmosphere is nearly neutrally stable to parcels of air displaced upward from near the surface. It is maintained in such a state by the nearly continuous activity of moist convection, which takes the form of cumulus clouds and thunderstorms. In this sense, the whole depth of the tropical troposphere (a layer of air extending up to about 7 mi or 12 km altitude in the tropics) exists in a convectively adjusted state in analogy with the layer near the surface, which has constant θ_v. *See* TROPICAL METEOROLOGY.

Convective instability may be driven by centrifugal as well as by gravitational forces. This is illustrated in **Fig. 3**, which shows the distribution of angular momentum per unit mass (M) in a rotating cylinder of fluid. This angular momentum is defined by expression (2), where r is the radius from the center

$$M \equiv rV \tag{2}$$

and V is the velocity of the fluid rotating about the center. If a ring of fluid centered about the axis of the cylinder is displaced radially inward or outward, it conserves its angular momentum. For example, as the ring of fluid in Fig. 3 is displaced outward, its angular momentum is less than that of the surrounding fluid, and the laws of physics can be used to demonstrate that since the centrifugal force on that fluid is less than on the surrounding fluid, it will accelerate inward. The fluid is then said to be centrifugally stable. A corollary to Archimedes' law states that a fluid with low M tends to sink toward the axis of rotation, while fluid with high M rises away from the axis. A fluid whose angular momentum increases outward is centrifugally stable, while a fluid with M decreasing outward is unstable. The nature of this instability is much like that of thermal convection, and this, too, is a type of convective instability. *See* ANGULAR MOMENTUM.

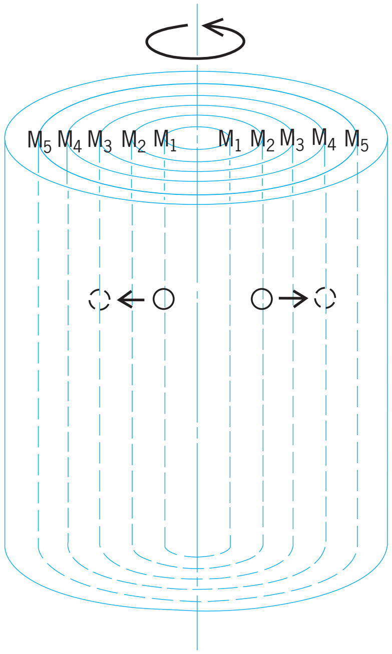

Fig. 3. Diagram of a cylinder of rotating fluid with an angular momentum per unit mass, *M*, which in this case increases outward from the axis (M_1, M_2, M_3, and so forth denote increasing values of *M*). This arrangement is centrifugally stable, since a ring of fluid (solid-line circle) displaced outward to a new position (broken-line circle) will have less centrifugal force acting on it than on its environment; it will therefore accelerate inward toward its initial position.

In the atmosphere, it is possible to have a combination of centrifugal and buoyant convection. It turns out that the criterion for this to happen is that parcels displaced upward along angular momentum surfaces must become positively buoyant. These surfaces are usually sloped in the atmosphere because of the increase with height of atmospheric winds. Convection that results from this combined instability (which is also known as symmetric instability) is also generally sloped and is thus called slantwise convection. This form of convection results in bands of rain and snow embedded in winter storms; these bands may be hundreds of miles wide and as much as 600 mi (1000 km) long. The concept of convective neutrality applies here as well, as measurements made by flying instrumented aircraft along angular momentum surfaces show that parcels displaced along them are almost neutrally buoyant. *See* ATMOSPHERE; ATMOSPHERIC GENERAL CIRCULATION; FLUID FLOW; PRECIPITATION (METEOROLOGY); STORM.

Converter

A device for processing alternating-current (ac) or direct-current (dc) power to provide a different electrical waveform. The term converter denotes a mechanism for either processing ac power into dc power (rectifier) or deriving power with an ac waveform from dc (inverter). Some converters serve both functions, others only one. *See* RECTIFIER.

Historically, converters were needed to accommodate various needs to match characteristics of the supply voltage. For example, dc motors, which in principle could be connected directly to early dc distribution systems, required a rectifier for operation with ac supplies. *See* DIRECT-CURRENT MOTOR.

While ac has been universally adopted for power distribution and consequently is the standard power supply for industrial, commercial, and domestic purposes, the range of demands for conversion far exceeds the occasional rectifier load. Converters are used for such applications as (1) rectification from ac to supply electrochemical processes with large controlled levels of direct current; (2) rectification of ac to dc followed by inversion to a controlled frequency of ac to supply variable-speed ac motors; (3) interfacing dc power sources (such as fuel cells and photoelectric devices) to ac distribution systems; (4) production of dc from ac power for subway and streetcar systems, and for controlled dc voltage for speed-control of dc motors in numerous industrial applications; and (5) transmission of dc electric power between rectifier stations and inverter stations within ac generation and transmission networks. *See* DIRECT-CURRENT TRANSMISSION.

These are a few examples of the need for converters to be versatile, controllable, and able to handle a wide range of power levels. Furthermore, emphasis on long-term cost of power losses has drawn attention to the efficiency of converters and the ability to contribute to the overall efficiency of their loads. For example, it can be economically advantageous to recapture the kinetic energy of some mechanical loads, which are subject to frequent stops and starts, through a converter power reversal back to the supply (regeneration) rather than losing it as heat in friction braking. This increases operating efficiency in such applications as electric vehicles and steel rolling mills.

Converter development has been furthered by advances in power semiconductors and microprocessors for their control. Beyond the basic converter action, there may be control of voltage, current, power, reactive power, and frequency at the converter output terminals. *See* MICROPROCESSOR.

Types. Until the advent of power semiconductors, converter action was achieved either by rotary converters or mercury-arc valves. In a rotary converter, an electric motor drives a generator. For example, a dc motor drives an ac generator to provide ac voltage at a chosen frequency. The mercury-arc valve is a unidirectional switching device which relies on ionization between a pool of mercury and an anode. Later developments permitted the timing of the start of conduction to be controlled by a grid between the mercury and the anode. Some of the modern semiconductor circuits have evolved from mercury-arc technology.

The introduction of the thyristor (silicon-controlled rectifier) in the 1960s had an immediate effect on converter applications because of its ruggedness, reliability, and compactness. As a controlled, unidirectional, solid-state switch, it replaced mercury-arc devices with ratings in the kilowatt range and, through series–parallel combinations, at high power levels. Power semiconductor devices for converter circuits include (1) thyristors, controlled unidirectional switches that, once conducting, have no capability to suppress current; (2) triacs, thyristor devices with bidirectional control of conduction; (3) gate turn-off devices with the properties of thyristors and the further capability of suppressing current; and (4) power transistors, high-power transistors operating in the switching mode, somewhat similar in properties to gate turn-off devices.

Thyristors are available with ratings from a few watts up to the capability of withstanding several kilovolts and conducting several kiloamperes. All the devices incorporate one or more gates, that is,

low-power input connections to permit point-on-wave control of turn-on relative to the waveform of applied voltage. *See* SEMICONDUCTOR RECTIFIER.

Circuits. Of the many different converter circuits, three types are described.

Half-wave rectifier. The thyristor in the controlled half-wave rectifier (**Fig. 1***a*) conducts on parts of the positive half-cycles of the ac supply to provide a mean dc voltage across the load. Conduction is delayed by the variable control angle α resulting in the nonsmooth dc waveform shown (Fig. 1*b*). In practice, the dc component in the supply current tends to cause saturation problems in supply transformers.

Full-wave circuit. A full-wave circuit (**Fig. 2***a*) has a bidirectional current in the ac supply transformer. Thyristors 1 and 2 are gated together and then, in turn, dc-side current is transferred to thyristors 3 and 4 to provide the negative half-cycle of ac current. The inductor provides some smoothing of the dc waveform. By delaying gating by more than 90 electrical degrees while providing a dc power source (Fig. 2*b*), the sign of the mean dc voltage is reversed so that the circuit now inverts dc power into the ac supply. The ac system must provide an existing ac voltage waveform sufficient to naturally allow the thyristors to turn on and off in the conducting sequence. The ac current waveform is not sinusoidal (Fig. 2*c*); ac filters may be added to reduce the harmonic content. *See* COMMUTATION; ELECTRIC FILTER.

The above examples are called bridge circuits. Inversion into an ac system that does not contain an ac voltage source requires a circuit that either develops internal reverse voltages to turn off thyristors or uses gate turn-off devices. Other types include the cycloconverter which synthesizes a lower frequency from an ac waveform, and the pulse-width-modulated converter which processes a waveform into a series of segments that are recombined into the desired waveform. *See* PULSE MODULATION.

Three-phase bridge. Three-phase ac/dc converters are often used in industrial applications. Very high-power versions are used in power transmission systems.

Converters at the terminal stations of the dc transmission system either rectify three-phase ac voltages to dc or invert the dc voltage to feed power into the adjacent ac system. A three-phase converter bridge is made up of six thyristor valves conducting in sequence as numbered 1, 2, . . . , 6 in **Fig. 3***a*. Bridges are usually connected in series pairs, as shown. The 30° ac phase difference between the converter-side voltages of the wye/wye and the wye/delta converter transformers permits a conduction sequence 1, 1′, 2, 2′, . . . , 6, 6′. This is called 12-pulse operation and gives a smoother dc waveform and less ac harmonic currents.

Each valve is made up of many thyristors in series together with additional components to aid in the voltage sharing between individual thyristors (Fig. 3 *b*). Valves are often combined into single units, such as the quadrivalve in Fig. 3*a*.

Converters range from low-power applications, such as the power supply in a television, up to thousands of megawatts in dc power transmission. *See* ALTERNATING CURRENT; DIRECT CURRENT. John Reeve

Conveyor

A horizontal, inclined, declined, or vertical machine for moving or transporting bulk materials, packages, or objects in a path predetermined by the design of the device and having points of loading and discharge fixed or selective. Included in this category are skip hoist and vertical reciprocating and inclined reciprocating conveyors; but in the strictest sense this category does not include those devices known as industrial trucks, tractors and trailers, cranes, hoists, monorail cranes, power and hand shovels or scoops, bucket drag lines, platform elevators, or highway or rail vehicles. The more usual basic types of conveyors and their normal, rather than exceptional, operating characteristics

[*] Some bucket conveyors may use endless rubber belts.
[†] Most products or bulk materials can be conveyed by selection of attachments to the trolleys.
[‡] Cableways or serial tramways are used primarily for cross-country conveying of coal, ashes, lumber, and similar products used in construction.

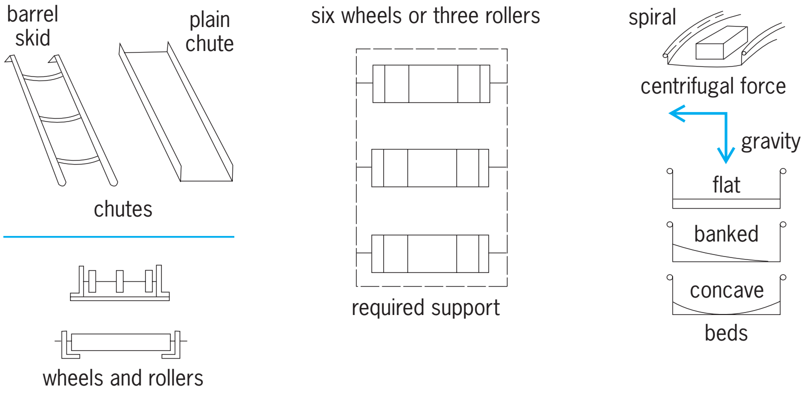

Fig. 1. Elements used in gravity conveyors.

are shown in the **table**. *See* BULK-HANDLING MACHINES.

Gravity conveyors. The economical means for lowering articles and materials is by gravity conveyors. Chutes depend upon sliding friction to control the rate of descent; wheel and roller conveyors use rolling friction for this purpose (**Fig. 1**).

With a body resting on a declined plane, friction *F* opposes component *P* parallel to the surface of the plane of weight *W* of the body. When the angle of elevation equals the angle of repose, the body is just about to start sliding, or to express it another way, when the inclination of the plane equals the angle of repose, *F* equals *P*. In this position the tangent of the angle of repose equals the coefficient of friction. For metal on metal the coefficient of friction is 0.15 to 0.25, and for wood on metal it is 0.2 to 0.6, which is why steel tote boxes slide more readily on metal chutes than do wooden cases.

When the body is a smooth-surfaced container and the inclined plane is replaced by rollers, the rollers are spaced so that at least three rollers support the smallest container to be conveyed; then each roller supports one-third the weight of the load. Component *P* of the weight *W* which acts downward and parallel to the inclination of the plane produces a turning moment *Pr* about the roller's axle, where *r* is the radius of the roller. As the inclination of the conveyor is increased, *P* increases until, at the point where rolling is about to start, *Pr* equals *Fr*. In this case, however, the force of friction is made up of the friction between the contacting surfaces and the friction in the bearings of the rollers. The mass of a tubular roller is concentrated near its circumference; hence rollers have greater starting inertia than wheels, but after they have started rolling, they have a flywheel effect that tends to keep products in motion, especially when packages follow each other in close succession. Inclination (or declination) is expressed as the number of inches of rise or fall per foot of conveyor or per 5-ft (1.5-m) or 10-ft (3-m) length.

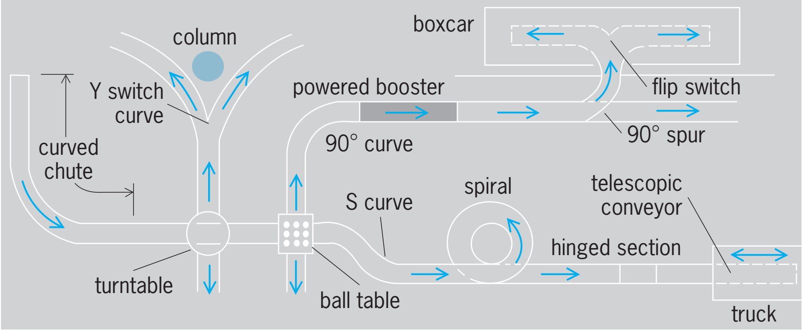

Fig. 2. Gravity components for conveyor lines.

Gravity chutes. Gravity chutes may be made straight or curved and are fabricated from sheet metal or wood, the latter being sometimes covered with canvas to prevent slivering. The bed of the chute can be shaped to accommodate the products to be handled. In spiral chutes centrifugal force is the second controlling factor. When bodies on a spiral move too fast, they are thrown out toward a guard rail, and contact with the rail increases the friction thereby causing the bodies to slow down somewhat and settle back into the center of the runway and continue their descent at a controlled rate. Spirals with roller beds or wheels provide smooth descent of an article and tend to maintain the position of the article in its original starting position. Rollers may be of metal, wood, or plastic and can be arranged in an optimum position, depending upon the articles to be carried.

Changes in direction can be effected by turntables, ball transfer tables, or gradual S curves (**Fig. 2**). Generally speaking, wheel-type conveyors are less expensive than the roller varieties; however, the latter can withstand severer service. For successful use of wheeled conveyors, the conveyed article must have a smooth and firm riding surface.

Chain conveyors. There are three basic types of chain conveyors: (1) those that support the product being conveyed, (2) those that carry actuating elements between the two chains, and (3) those that operate overhead or are set into the floor (**Fig. 3**).

In the sliding chain conveyor either plain links or links with such special attachments as lugs are made up into the conveyors to handle cases, cans, pipes, and other similar products.

Slats or apron conveyors are fitted with slats of wood or metal, either flat or in special shapes, between two power chains. The slats handle such freight as barrels, drums, and crates. With the addition of cleats these conveyors carry articles up steep inclines. In this type of conveyor the article rides on the top strand of the slats.

Push-bar conveyors are a variation of the slat conveyor, in which two endless chains are cross-connected at intervals by pusher bars which propel the load along a stationary bed or trough of the conveyor.

Powered conveyors. Gravity conveyors are limited to use in conditions where the material is to be lowered in elevation. The horizontal conveying distance capabilities of the gravity conveyor depend on the difference in elevation and the angle of sliding or rolling friction of the material to be conveyed.

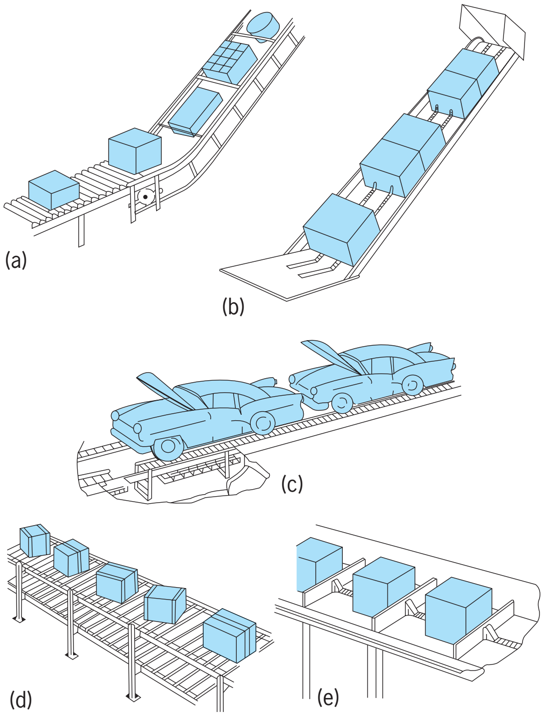

Fig. 3. Five examples of the basic types of chain conveyors. (*a*) Push-bar conveyor. (*b*) Twin chains carrying cartons. (*c*) Heavy-duty plates for assembly conveyor. (*d*) Apron or slat conveyor to carry miscellaneous articles. (e) Push-bar or cleat conveyor. (*After Conveyor Equipment Manufacturers Association*, *Conveyor Terms and Definitions*, *3d ed*., *1966*)

To move loads on level or inclined paths, or declining paths that exceed the angle of sliding or rolling friction of the particular material to be conveyed, powered conveyors must be employed. The following are various types of powered conveyors.

Belt conveyors. Loads are moved on a level or inclined path by means of power-driven belts. Belt conveyors with rough-top belts make possible inclines up to 28°; cleated belts are limited on degree of incline only by the position of the center of gravity of the conveyed item.

Essential components of belt conveyors in addition to the belt itself are (1) a bed, which may be a combination bed and frame; (2) end rollers; (3) a take-up to adjust belt tension as it varies with age and atmospheric conditions; and (4) a power unit (**Fig. 4**). The bed of a fabric belt conveyor may be wood, or more usually flat or concave sheet metal; or it may be made up of rollers. The former are called slide beds, the latter roller beds. Slide beds provide quiet, smooth conveying, but they require more power than roller beds. The two end rollers are mounted in antifriction bearings with provision for lubrication.

Where the tail roller is mounted in adjustable end arms to provide take-up, the length of the conveyor is not constant. Where this feature is objectionable, automatic gravity, screw, or spring take-ups can be used. Another required adjustment is provided by mounting the rollers so that their bearings can be shifted slightly either forward or backward to train the belt to run true.

Belts can be powered in several ways. A gear-head motor can be connected directly to the head roller, or the drive may be through a chain and sprockets. These arrangements necessitate placing the drive outside the frame. When this is undesirable, one of two drives can be located under the frame. Power units usually provide fixed or variable speeds from a few feet per minute to over 50 ft/min (15 m/min); 50 ft/min is usual with package conveyors. Normally $^1/_4$-hp (190-W) motors powers these units, but there are other, more powerful motors which are available for heavier duty.

Powered package conveyors can be combined in various ways to meet specific conditions. Powered curves are used, but wheel and roller sections are more usually employed to change direction. Inclined belt conveyors usually have a hump at the upper end to reduce the slapping by packages on the belt as they move from inclined to horizontal travel (**Fig. 5**). Cleats can be used, but they complicate the feeding of packages onto the line and require special construction features so that the cleats can pass around pulleys and be properly supported on the return portion of the conveying cycle.

Metal belts made of woven and flat wire, linked rods, and steel bands are engineered to make up conveyors, which are essentially the same as fabric belt conveyors. For example, woven wire belts can be driven by pulleys and these may be lagged, that is, covered with a material to improve traction.

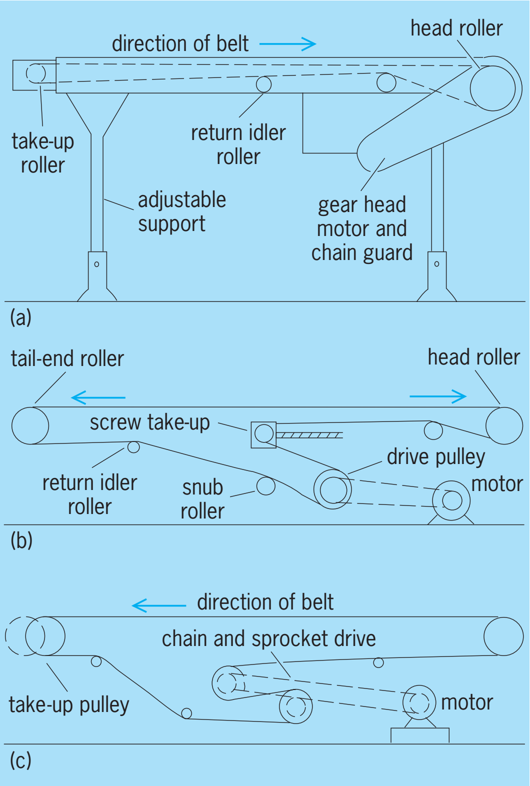

Fig. 4. Diagrams of three driven-belt conveyors. (*a*) Components of a fabric belt conveyor. (*b*) Wrap drive. (*c*) Tandem drive.

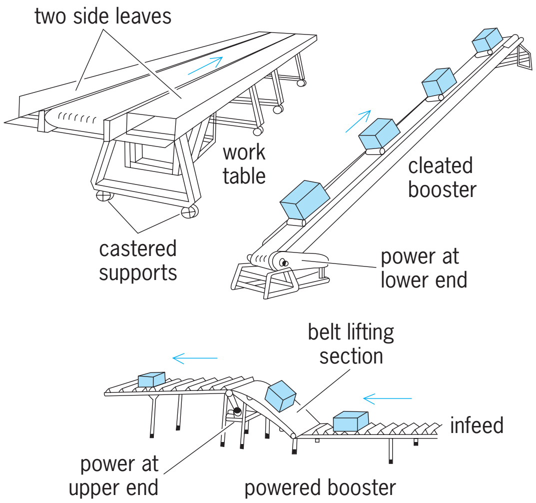

Fig. 5. Fabric belt conveyors.

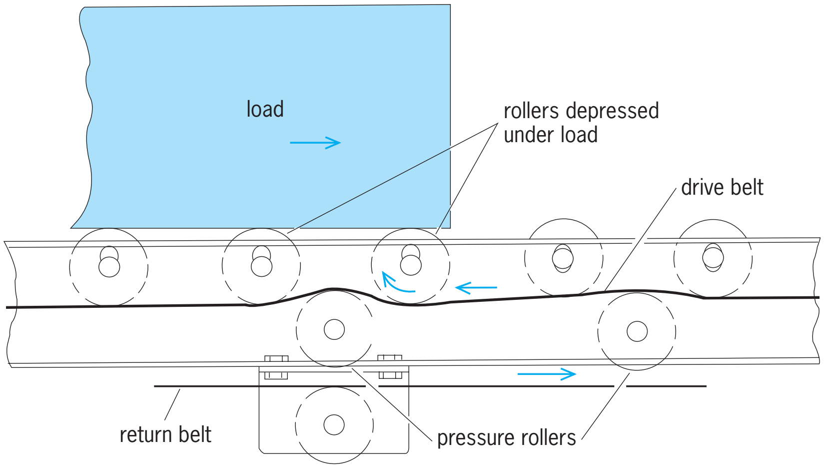

Fig. 6. Live rollers provide power for gravity curves.

Contact with the drive pulley can be increased by snubbing with small-diameter idler pulleys which guide the belt to increase the angle of contact. Flat wire, linked rod, and woven wire belts with chain edges are driven positively by pulleys with sprocket teeth or by true sprockets. Steel band conveyors are driven by pulleys with unusually large diameters. Other components are similar to those used in fabric belt conveyors but are more rugged in construction to handle the heavier carriers and to meet the more exacting conditions under which metal belts operate. Metal belts are used, for example, in high-temperature operations such as baking, annealing, brazing, and heat-treating.

The choice of a belt for a given situation depends on the effect of the belt's surface on the product, amount of drainage required, and similar factors.

Live-roller conveyors. Objects are moved over series of rollers by the application of power to all or some of the rollers. The power-transmitting medium is usually belting or chain. In one arrangement a belt drive running under and in contact with the rollers turns them to propel the load forward (**Fig. 6**). In another variation small sprockets are attached to the ends of some or all of the roller shafts, the sprockets being powered by a chain drive.

Arthur M. Perrin

Vibrating conveyors. These mechanical devices are designed to move bulk materials along a horizontal, or almost horizontal, path in a controlled system (**Fig. 7**). They can be used to simply transport material from one point to another or to perform various functions en route, such as cooling, drying, blending, metering, spreading, and, by installing a screen, scalping or dedusting.

They can be fed by a belt conveyor or, more commonly, used to provide a precisely controlled outlet from a bin, hopper, or chute. In all cases they have the ability to take a vertical flow of material and change the direction of movement up to 90° with only a small change in the handling level.

A vibrating conveyor basically consists of a base or reaction mass and a driven mass connected to each other by springs. The base is excited by a power source such as an electromagnetic or electromechanical drive. A trough or pan forms part of the driven mass and serves as the material carrying surface. In operation, the trough is moved alternately forward and up, then down and back. This causes the conveyed material to move along the trough surface in a series of short hops.

Amplitude or frequency of vibration can be adjusted to control conveyor speed and output. Electromagnetic conveyors operating at 3600 vibrations per minute with a low amplitude [a displacement of 0.09 in. (0.2 cm), for example], provide a gentle motion to the conveyed product and are frequently used to handle fragile or friable materials. Electromechanical conveyors normally operate at a lower frequency but a much higher amplitude [a displacement of 0.5 in. (1.2 cm), for example], which results in rougher handling of the product but greatly

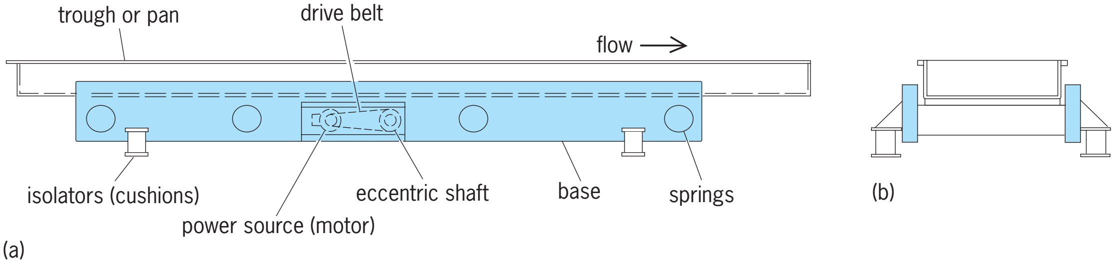

Fig. 7. Vibrating conveyor. (*a*) Side view. (*b*) End view.

increased capacity. The volume of material which can be handled ranges from a few pounds per hour up to thousands of pounds per hour. *See* VIBRATION MACHINE. R. F. Merwin

Cooling tower

A tower- or buildinglike device in which atmospheric air (the heat receiver) circulates in direct or indirect contact with warmer water (the heat source) and the water is thereby cooled. A cooling tower may serve as the heat sink in a conventional thermodynamic process, such as refrigeration or steam power generation, or it may be used in any process in which water is used as the vehicle for heat removal, and when it is convenient or desirable to make final heat rejection to atmospheric air. Water, acting as the heat-transfer fluid, gives up heat to atmospheric air, and thus cooled, is recirculated through the system, affording economical operation of the process.

Basic types. Two basic types of cooling towers are commonly used. One transfers the heat from warmer water to cooler air mainly by an evaporation heat-transfer process and is known as the evaporative or wet cooling tower. The other transfers the heat from warmer water to cooler air by a sensible heat-transfer process and is known as the nonevaporative or dry cooling tower. These two basic types are sometimes combined, with the two cooling processes generally used in parallel or separately, and are then known as wet-dry cooling towers.

Cooling process. With the evaporative process, the warmer water is brought into direct contact with the cooler air. When the air enters the cooling tower, its moisture content is generally less than saturation; it emerges at a higher temperature and with a moisture content at or approaching saturation. Evaporative cooling takes place even when the incoming air is saturated, because as the air temperature is increased in the process of absorbing sensible heat from the water, there is also an increase in its capacity for holding water, and evaporation continues. The evaporative process accounts for about 65–75% of the total heat transferred; the remainder is transferred by the sensible heat-transfer process.

The wet-bulb temperature of the incoming air is the theoretical limit of cooling. Cooling the water to within 5 to 20°F (−15 to −6.7°C) above wet-bulb temperature represents good practice. The amount of water evaporated is relatively small. Approximately 1000 Btu (1055 kilojoules) is required to vaporize 1 lb (0.45 kg) of water at cooling tower operating temperatures. This represents a loss in water of approximately 0.75% of the water circulated for each 10°F (6°C) cooling, taking into account the normal proportions of cooling by the combined evaporative and sensible heat-transfer processes. Drift losses may be as low as 0.01–0.05% of the water flow to the tower (recent performance of 0.001% has been achieved) and must be added to the loss of water by evaporation and losses from blowdown to account for the water lost from the system. Blowdown quantity is a function of makeup water quality, but it may be determined by regulations concerning its disposal. Its quality is usually expressed in terms of the allowable concentration of dissolved solids in the circulating cooling water and may vary from two to six concentrations with respect to the dissolved solids content of the cooling water makeup.

With the nonevaporative process, the warmer water is separated from the cooler air by means of thin metal walls, usually tubes of circular cross section, but sometimes of elliptical cross section. Because of the low heat-transfer rates from a surface to air at atmospheric pressure, the air side of the tube is made with an extended surface in the form of fins of various geometries. The heat-transfer surface is usually arranged with two or more passes on the water side and a single pass, cross flow, on the air side. Sensible heat transfer through the tube walls and from the extended surface is responsible for all of the heat given up by the water and absorbed by the cooling air. The water temperature is reduced, and the air temperature increased. The nonevaporative cooling tower may also be used as an air-cooled vapor condenser and is commonly employed as such for condensing steam. The steam is condensed within the tubes at a substantially constant temperature, giving up its latent heat of vaporization to the cooling air, which in turn is increasing in temperature. The theoretical limit of cooling is the temperature of the incoming air. Good practice is to design nonevaporative cooling towers to cool the warm circulating water to within 25 to 35°F (14 to 20°C) of the entering air temperature or to condense steam at a similar temperature difference with respect to the incoming air. Makeup to the system is to compensate for leakage only, and there is no blowdown requirement or drift loss.

With the combined evaporative-nonevaporative process, the heat-absorbing capacity of the system is divided between the two types of cooling towers, which are selected in some predetermined proportion and usually arranged so that adjustments can be made to suit operating conditions within definite limits. The two systems, evaporative and nonevaporative, are combined in a unit with the water flow arranged in a series relationship passing through the dry tower component first and the wet tower second. The airflow through the towers is in a parallel-flow relationship, with the discharge air from the two sections mixing before being expelled from the system. Since the evaporative process is employed as one portion of the cooling system, drift, makeup, and blowdown are characteristics of the combined evaporative-nonevaporative cooling tower system,

Fig. 1. Counterflow natural-draft cooling tower at Trojan Power Plant in Spokane, Washington. (*Research–Cottrell*)

generally to a lesser degree than in the conventional evaporative cooling towers.

Of the three general types of cooling towers, the evaporative tower as a heat sink has the greatest thermal efficiency but consumes the most water and has the largest visible vapor plume. When mechanical-draft cooling tower modules are arranged in a row, ground fogging can occur. This can be eliminated by using natural-draft towers, and can be significantly reduced with modularized mechanical-draft towers when they are arranged in circular fashion.

The nonevaporative cooling tower is the least efficient type, but it can operate with practically no consumption of water and can be located almost anywhere. It has no vapor plume.

The combined evaporative-nonevaporative cooling tower has a thermal efficiency somewhere between that of the evaporative and nonevaporative cooling towers. Most are of the mechanical-draft type, and the vapor plume is mitigated by mixing the dry warm air leaving the nonevaporative section of the tower with the warm saturated air leaving the evaporative section of the tower. This retards the cooling of the plume to atmospheric temperature; visible vapor is reduced and may be entirely eliminated. This tower has the advantage of flexibility in operation; it can accommodate variations in available makeup water or be adjusted to atmospheric conditions so that vapor plume formation and ground fogging can be reduced.

Evaporative cooling towers. Evaporative cooling towers are classified according to the means employed for producing air circulation through them: atmospheric, natural draft, and mechanical draft.

Atmospheric cooling. Some towers depend upon natural wind currents blowing through them in a substantially horizontal direction for their air supply. Louvers on all sides prevent water from being blown out of these atmospheric cooling towers, and allow air to enter and leave independently of wind direction. Generally, these towers are located broadside to prevailing winds for maximum sustained airflow.

Thermal performance varies greatly because it is a function of wind direction and velocity as well as wet- and dry-bulb temperatures. The normal loading of atmospheric towers is about 1–2 gal/min (3.7–7.5 liters/min) of cooling water per square foot of cross section. They require considerable unobstructed surrounding ground space in addition to their cross-sectional area to operate properly. Because they need more area per unit of cooling than other types of towers, they are usually limited to small sizes.

Natural draft. Other cooling towers depend for their air supply upon the natural convection of air flowing upward and in contact with the water to be cooled. Essentially, natural-draft cooling towers are chimneylike structures with a heat-transfer section installed in their lower portion, directly above an annular air inlet in a counterflow relationship with the cooling air (**Fig. 1**), or with the heat-transfer section circumscribing the base of the tower in a cross-flow relationship with the cooling airflow (**Fig. 2**). Sensible heat absorbed by the air in passing over the water to be cooled increases the air temperature and its vapor content and thereby reduces its density so that the air is forced upward and out of the tower by the surrounding heavier atmosphere. The flow of air through the tower varies according to the difference in specific weights of the ambient air and the air leaving the heat-transfer surfaces. Since the difference in

Fig. 2. Cross-flow mechanical-draft cooling towers. (*Marley Co.*)

specific weights generally increases in cold weather, the airflow through the cooling tower also increases, and the relative performance improves in reference to equivalent constant-airflow towers.

Normal loading of a natural-draft tower is 2–4 gal/(min)(ft^2) [1.4–2.7 liters/(s)(m^2)] of ground-level cross section. The natural-drafting cooling tower does not require as much unobstructed surrounding space as the atmospheric cooling tower does, and is generally suited for both medium and large installations. The natural-draft cooling tower was first commonly used in Europe. Then a number of large installations were built in the United States, with single units 385 ft (117 m) in diameter by 492 ft (150 m) high capable of absorbing the heat rejected from an 1100-MW light-water-reactor steam electric power plant.

Mechanical draft. In cooling towers that depend upon fans for their air supply, the fans may be arranged to produce either a forced or an induced draft. Induced-draft designs are more commonly used than forced-draft designs because of the lower initial cost, improved air-water contact, and less air recirculation (**Fig. 3**). With controlled airflow, the capacity of the mechanical-draft tower can be adjusted for economic operation in relation to heat load and in consideration of ambient conditions.

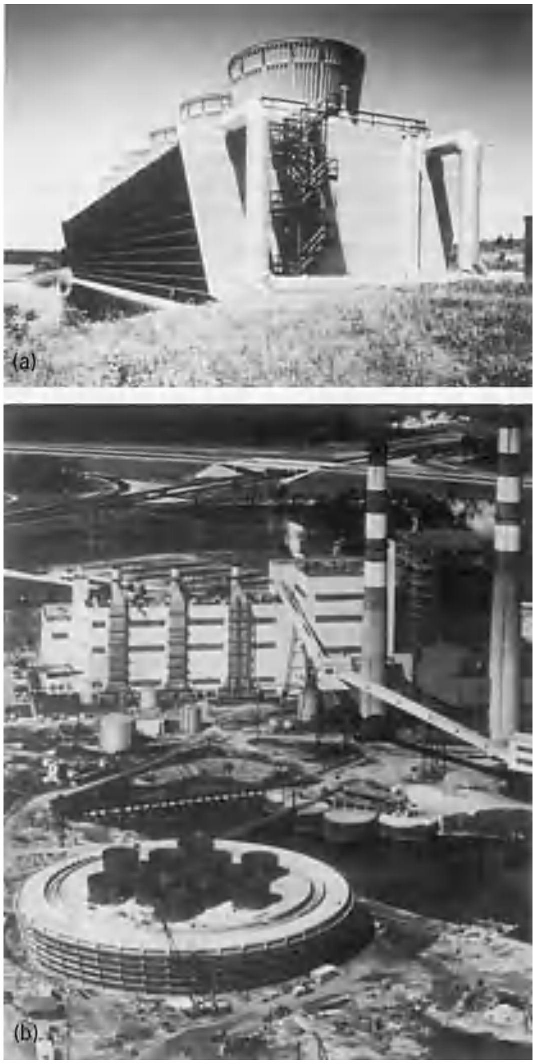

Fig. 3. Mechanical-draft cooling towers. (*a*) Conventional rectangular cross-flow evaporative induced-draft type; (*b*) circular evaporative induced-draft type. (*Marley Co.*)

Normal loading of a mechanical-draft cooling tower is 2–6 gal/(min)(ft^2) [1.4–4.1 liters/(s)(m^2)] of cross section. The mechanical-draft tower requires less unobstructed surrounding space to obtain adequate air supply than the atmospheric cooling tower needs; however, it requires more surrounding space than the natural-draft towers do. This type of tower is suitable for both large and small installations.

Nonevaporative cooling towers. Nonevaporative cooling towers are classified as air-cooled condensers and as air-cooled heat exchangers, and are further classified by the means used for producing air circulation through them. *See* HEAT EXCHANGER; VAPOR CONDENSER.

Air-cooled condensers and heat exchangers. Two basic types of nonevaporative cooling towers are in general use for power plant or process cooling. One type uses an air-cooled steam surface condenser as the means for transferring the heat rejected from the cycle to atmospheric cooling air. The other uses an air-cooled heat exchanger for this purpose. Heat is transferred from the air-cooled condenser, or from the air-cooled heat exchanger to the cooling air, by convection as sensible heat.

Nonevaporative cooling towers have been used for cooling small steam electric power plants since the 1930s. They have been used for process cooling since 1940; a complete refinery was cooled by the process in 1958. The nonevaporative cooling tower was formerly used almost exclusively with large steam electric power plants in Europe. Interest in this type of tower gradually increased in the United States, and a 330-MW plant in Wyoming using nonevaporative cooling towers was completed in the late 1970s.

The primary advantage of nonevaporative cooling towers is that of flexibility of plant siting. There is seldom a direct economic advantage associated with the use of nonevaporative cooling tower systems in the normal context of power plant economics. They are the least efficient of the cooling systems used as heat sinks.

Cooling airflow. Each of the two basic nonevaporative cooling tower systems may be further classified with respect to type of cooling airflow. Both types of towers, the direct-condensing type and the heat-exchanger type, can be built as natural-draft or as mechanical-draft tower systems.

Design. The heat-transfer sections are constructed as tube bundles, with finned tubes arranged in banks two to five rows deep. The tubes are in a parallel relationship with each other and are spaced at a pitch slightly greater than the outside fin diameter, either in an in-line or a staggered pattern. For each section, two headers are used, with the tube ends secured in each. The headers may be of pipe or of a box-shaped cross section and are usually made of steel. The bundles are secured in an open metal frame.

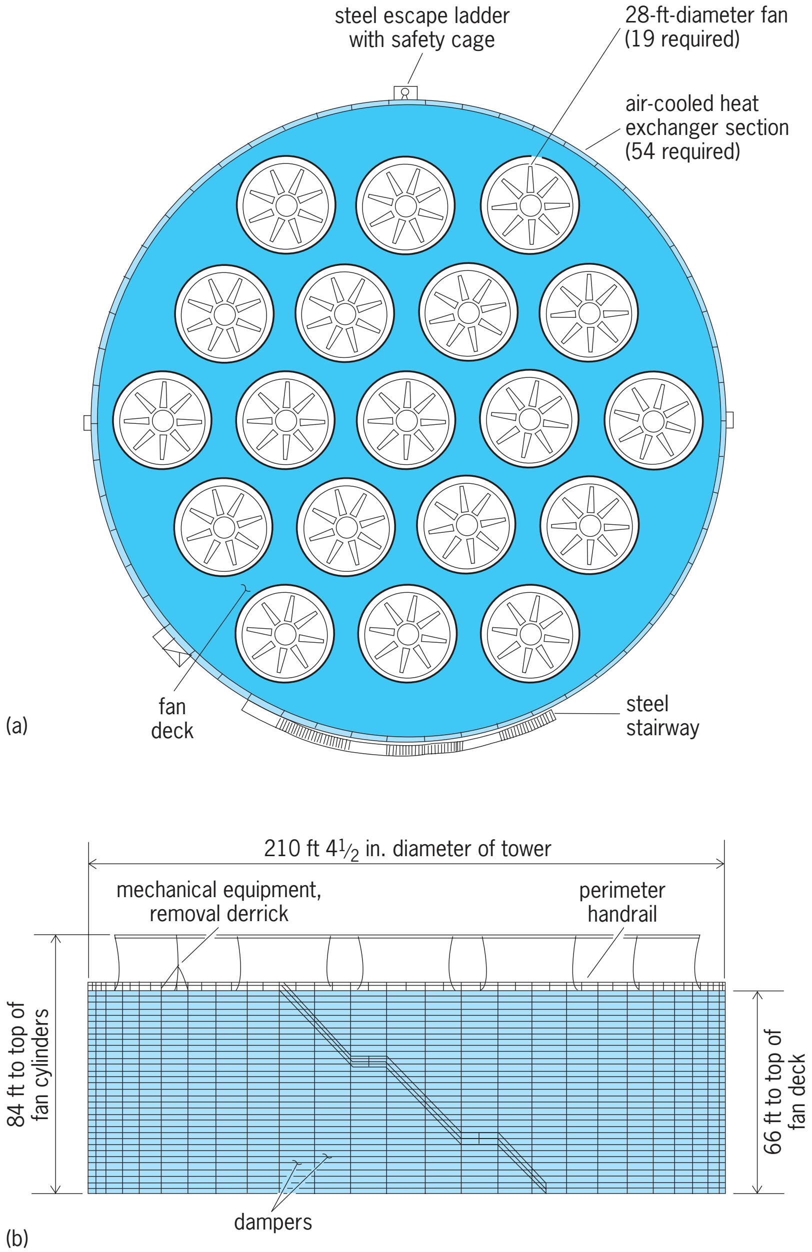

Fig. 4. Multifan circular nonevaporative tower. (*a*) Plan. (*b*) Elevation. 1 ft = 0.3 m; 1 in. = 2.5 cm. (*Marley Co.*)

The assembled tube bundles may be arranged in a V shape, with either horizontal or inclined tubes, or in an A shape, with the same tube arrangement. A similar arrangement may be used with vertical tube bundles. Generally, inclined tubes are shorter than horizontal ones. The inclined-tube arrangement is best suited to condensing vapor, the horizontal-tube arrangement best for heat-exchanger design. The A-shaped bundles are usually used with forced-draft airflow, the V-shaped bundles with induced-draft airflow. With natural-draft nonevaporative cooling towers there is no distinction made as to A- or V-shaped tube bundle arrangement; the bundles are arranged in a deck above the open circumference at the bottom of the tower, in a manner similar in principle to that used in the counterflow natural-draft evaporative cooling tower (Fig. 1). A natural-draft cooling tower with a vertical arrangement of tube bundles has been built, but this type of structure is not generally used.

Modularization of the bundle sections has become general practice with larger units; an installation of a circular module-type unit is shown in **Fig. 4**.

Combined evaporative-nonevaporative towers. The combination evaporative-nonevaporative cooling tower is arranged so that the water to be cooled first passes through a nonevaporative cooling section which is much the same as the tube bundle sections used with nonevaporative cooling towers of the heat-exchanger type. The hot water first passes through these heat exchangers, which are mounted directly above the evaporative cooling tower sections; the water leaving the nonevaporative section flows by force of gravity over the evaporative section.

Fig. 5. Wet-dry cooling tower at Atlantic Richfield Company. (*Marley Co.*)

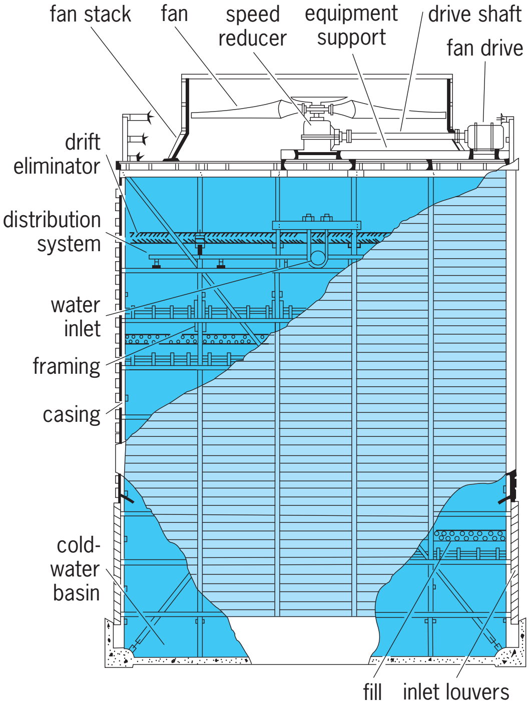

Fig. 6. Induced-draft counterflow cooling tower, showing the component parts.

The cooling air is divided into two parallel flow streams, one passing through the nonevaporative section, the other through the evaporative section to a common plenum chamber upstream of the induced-draft fans. There the two airflow streams are combined and discharged upward to the atmosphere by the fans. A typical cooling tower of this type is shown in **Fig. 5**.

In most applications of wet-dry cooling towers attempts are made to balance vapor plume suppression and the esthetics of a low silhouette in comparison with that of the natural-draft evaporative cooling tower. In some instances, these cooling towers are used in order to take advantage of the lower heat-sink temperature attainable with evaporative cooling when an adequate water supply is available, and to allow the plant to continue to operate, at reduced efficiency, when water for cooling is in short supply.

The more important components of evaporative cooling towers are the supporting structure, casing, cold-water basin, distribution system, drift eliminators, filling and louvers, discharge stack, and fans (mechanical-draft towers only). The counterflow type is shown in **Fig. 6**; the cross-flow type is shown in **Fig. 7**.

Treated wood, especially Douglas-fir, is the common material for atmospheric and small mechanical-draft cooling towers. It is used for structural framing, casing, louvers, and drift eliminators. Wood is commonly used as filler material for small towers. Plastics and asbestos cement are replacing wood to some degree in small towers and almost completely in large towers where fireproof materials are generally required. Framing and casings of reinforced concrete, and louvers of metal, usually aluminum, are generally used for large power plant installations. Fasteners for securing small parts are usually made of bronze, copper-nickel, stainless steel, and galvanized steel. Distribution systems may be in the form of piping, in galvanized steel, or fiber glass–reinforced plastics; and they may be equipped with spray nozzles of noncorrosive material, in the form of troughs and weirs, or made of wood, plastic, or reinforced concrete. Structural framing may also be made of galvanized or plastic-coated structural steel shapes. Natural-draft cooling towers, especially in large sizes, are made of reinforced concrete. The cold-water basins for ground-mounted towers are usually made of concrete; wood or steel is usually used for roof-mounted towers. Fan blades are made of corrosion-resistant

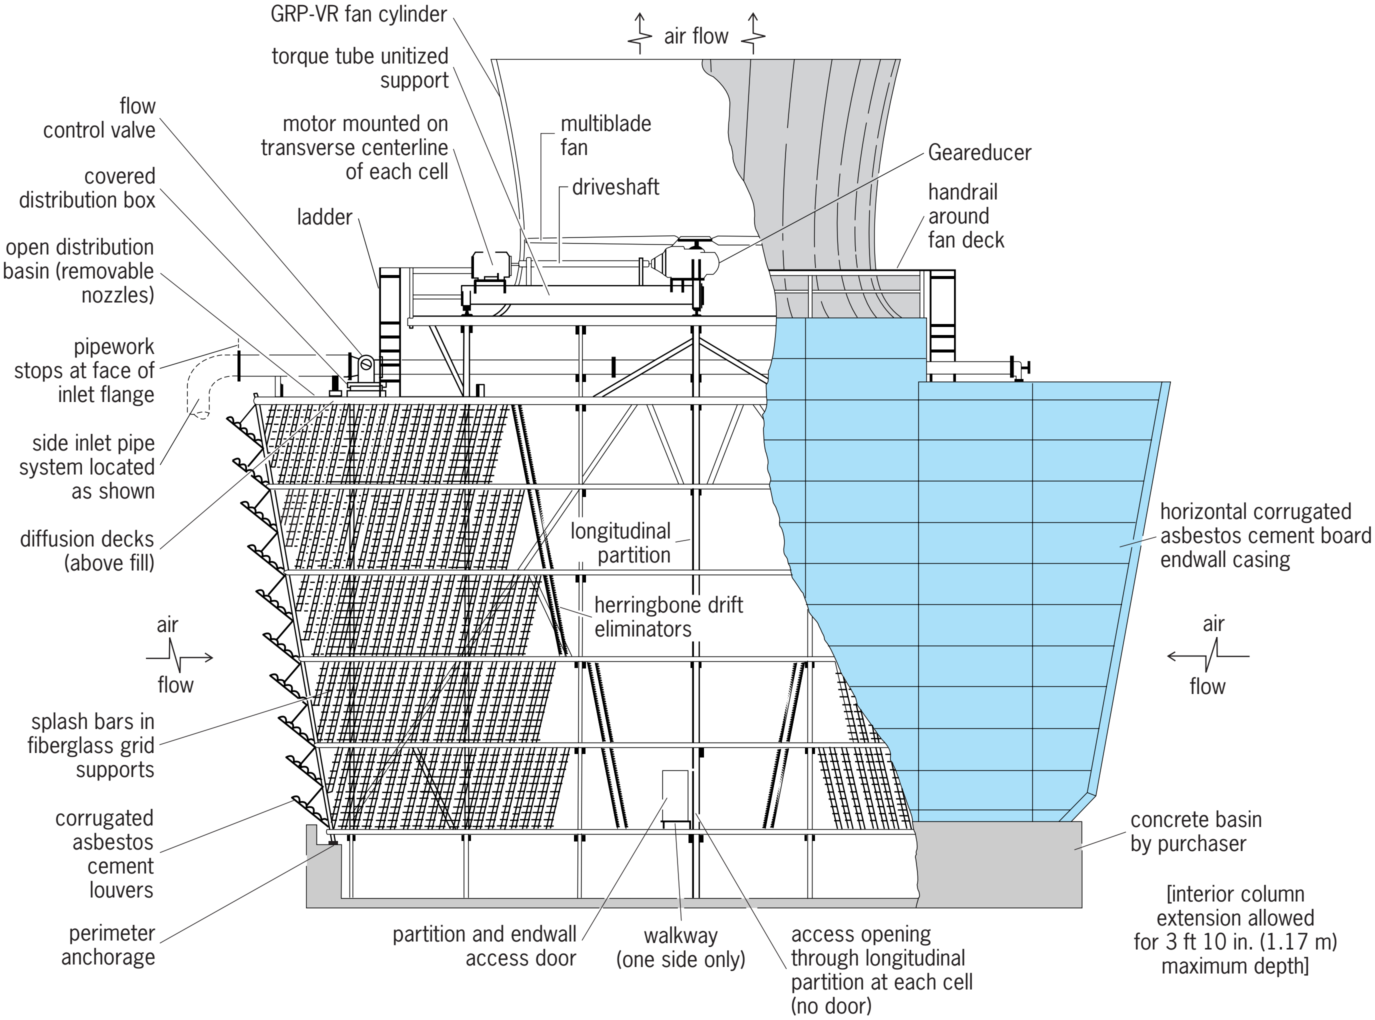

Fig. 7. Transverse cross section of a cross-flow evaporative cooling tower.

material such as monel, stainless steel, or aluminum; but most commonly fiber glass–reinforced plastic is used for fan blades.

The heat-transfer tubes used with nonevaporative cooling towers are of an extended-surface type usually with circumferential fins on the air side (outside). The tubes are usually circular in cross section, although elliptical tubes are sometimes used. Commonly used tube materials are galvanized carbon steel, ferritic stainless steel, and various copper alloys. They are usually made with wrapped aluminum fins, but steel fins are commonly used with carbon steel tubes and galvanized. Most designs employ a ratio of outside to inside surface of 20:25. Outside-diameter sizes range $^3/_4$–$1^1/_2$ in. (19–38 mm).

Tube bundles are made with tube banks two to five rows deep. The tubes are in parallel relationship with each other and secured in headers, either of steel pipe or of weld-fabricated steel box headers. The tube bundle assemblies are mounted in steel frames which are supported by structural steel framework. The bundle assemblies may be arranged in a V pattern, requiring fans of the induced-draft type, or in an A pattern, requiring fans of the forced-draft type (**Fig. 8**). Fans and louvers are similar to those described for evaporative cooling towers.

Nonevaporative cooling towers may also be used with natural airflow. In this case, the tube bundles are usually mounted on a deck within the tower and just above the top of the circumferential supporting structure for the tower. In this application, the tower has no cold-water basin, but otherwise it is identical with the natural-draft tower used for evaporative cooling with respect to materials of construction and design.

Performance. The performance of an evaporative cooling tower may be described by the generally accepted equation of F. Merkel, as shown below,

$$\frac{KaV}{L} = \int_{T2}^{T1} \frac{dT}{h'' - h}$$

where a = water-air contact area, ft^2/ft^3; h = enthalpy of entering air, Btu/lb; h'' = enthalpy of leaving air, Btu/lb; K = diffusion coefficient, lb/(ft^2)(h); L = water flow rate, lb/(h)(ft^2); T = water temperature, °F; T_1 = inlet water temperature, °F; T_2 = outlet water temperature, °F; and V = effective volume of tower, ft^3/ft^2 of ground area. The Merkel equation is usually performed graphically, by Simpson's rule, or with a suitable computer program. *See* PERFORMANCE RATING.

The performance of a nonevaporative cooling tower may be described by the generally accepted equation of Fourier for steady-state unidirectional heat transfer, using the classical summation of resistances formula with correction of the logarithmic temperature difference for cross-counterflow design in order to calculate the overall heat transfer. It is usual practice to reference the overall heat-transfer coefficient to the outside (finned) tube surface.

Evaluation of cooling tower performance is based on cooling of a specified quantity of water through a given range and to a specified temperature approach

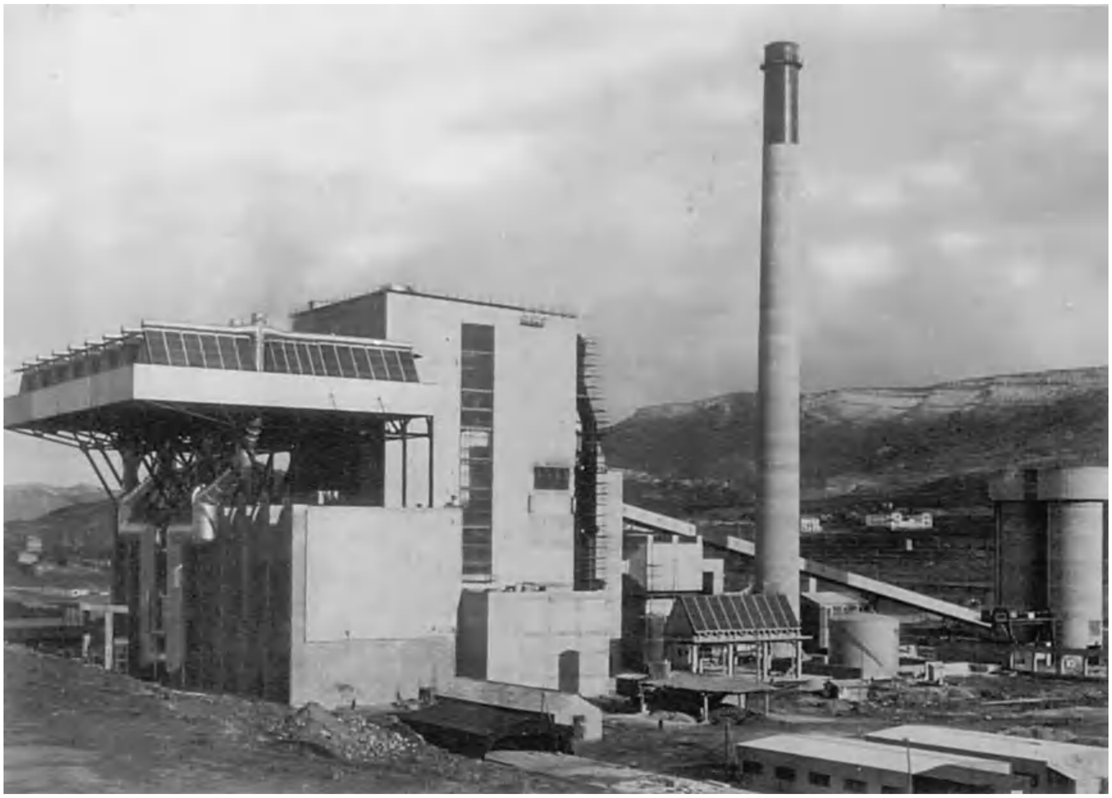

Fig. 8. Nonevaporative cooling tower, Utrillas, Spain. (*GEA*)

to the wet-bulb or dry-bulb temperature for which the tower is designed. Because exact design conditions are rarely experienced in operation, estimated performance curves are frequently prepared for a specific installation. These provide a means for comparing the measured performance with design conditions. Joseph F. Sebald

Coordinate systems

Schemes for locating points in a given space by means of numerical quantities specified with respect to some frame of reference. These quantities are the coordinates of a point. To each set of coordinates there corresponds just one point in any coordinate system, but there are useful coordinate systems in which to a given point there may correspond more than one set of coordinates.

A coordinate system is a mathematical language that is used to describe geometrical objects analytically; that is, if the coordinates of a set of points are known, their relationships and the properties of figures determined by them can be obtained by numerical calculations instead of by other descriptions. It is the province of analytic geometry, aided chiefly by calculus, to investigate the means for these calculations.

The most familiar spaces are the plane and the three-dimensional euclidean space. In the latter a point P is determined by three coordinates (x, y, z). The totality of points for which x has a fixed value constitutes a surface. The same is true for y and z so that through P there are three coordinate surfaces. The totality of points for which x and y are fixed is a curve and through each point there are three coordinate lines. If these lines are all straight, the system of coordinates is said to be rectilinear. If some or all of the coordinate lines are not straight, the system is curvilinear. If the angles between the coordinate lines at each point are right angles, the system is rectangular.

Cartesian coordinate system. This is one of the simplest and most useful systems of coordinates. It is constructed by choosing a point O designated as the origin. Through it three intersecting directed lines OX, OY, OZ, the coordinate axes, are constructed. The coordinates of a point P are x, the distance of P from the plane YOZ measured parallel to OX, and y and z, which are determined similarly (**Fig. 1**). In this system the coordinate lines through P are straight lines respectively parallel to the three coordinate axes. Usually the three axes are taken to be mutually perpendicular, in which case the system is a rectangular cartesian one. Obviously a similar construction can be made in the plane, in which case a point has two coordinates (x, y). It is this system that is used in the construction of graphs and charts of various data, whether observed or computed.

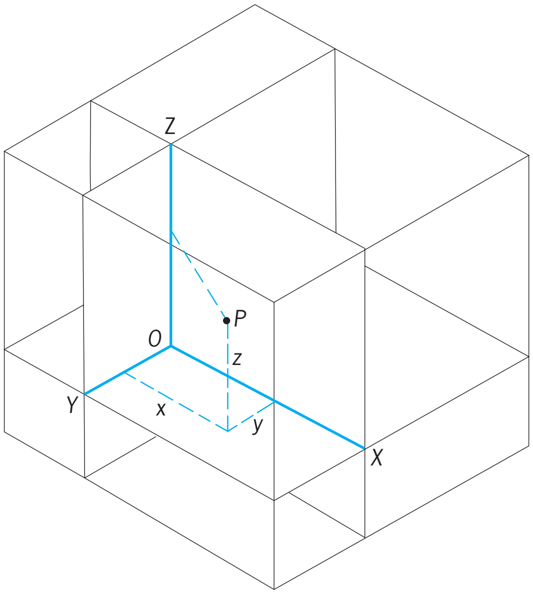

Fig. 1. Cartesian coordinate system.

Polar coordinate system. This system is constructed in the plane by choosing a point O called the pole and through it a directed straight line, the initial line. A point P is located by specifying the directed distance OP and the angle through which the initial line must be turned to coincide with OP in position and direction (**Fig. 2**). The coordinates of P are (r, θ). The radius vector r is the directed line OP, and the vectorial angle θ is the angle through which the initial line was turned, + if turned counterclockwise, − if clockwise. To each pair of values (r,θ) there corresponds just one point, but any point has an endless number of sets of coordinates. The coordinate lines in this case are radial lines through the pole (θ =

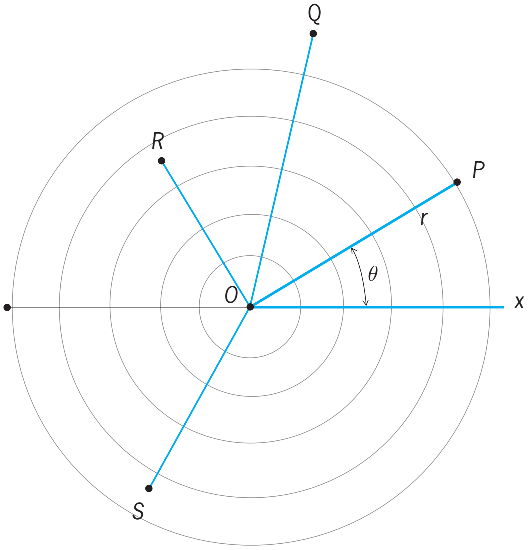

Fig. 2. Polar coordinate system.

constant) and concentric circles with center at the pole (r = constant). In spite of this lack of unique reciprocity between points and their coordinates, the polar system is useful in the study of spirals and rotations and in the investigation of motions under the action of central forces such as those of planets and comets.

Spherical coordinates. In three-dimensional euclidean space this system of coordinates is constructed by choosing a plane and in it constructing a polar coordinate system. At the pole O a polar axis OZ is constructed at right angles to the chosen plane. A point P, not on OZ, and OZ determine a plane. The spherical coordinates of P are then the directed distance OP denoted by ρ, the angle θ through which the initial line is turned to lie in ZOP and the angle $\phi = ZOP$ (**Fig. 3**). The coordinate lines are radial lines through O (θ and ϕ constant), meridian circles (ρ and ϕ constant), and circles of latitude (ρ and θ constant). This is an example of a curvilinear rectangle coordinate system. It is used in locating stars, in the study of spherical waves, and in problems in which there is spherical symmetry.

Cylindrical coordinates. These are constructed by choosing a plane with a pole O, an initial line in it, and a polar axis OZ, as in spherical coordinates. A point P is projected onto the chosen plane. The cylindrical coordinates of P are (r, θ, z) where r and θ are the polar coordinates of Q and $z = QP$ (Fig. 3). This is also a curvilinear rectangular system, the coordinate lines being mutually perpendicular. This system is used in problems of fluid flow and in others in which there is axial symmetry.

What has been done above in the plane and in euclidean space of three dimensions can be extended to curved spaces of any number dimensions. For a space S of n dimensions with some known geometrical or physical properties, a coordinate system in which a point has coordinates $(u_1, u_2, \ldots, u_n)$ is chosen. The coordinate lines are curves along which only one coordinate varies. When the known properties of S are expressed in terms of these coordinates, it is then the province of differential geometry to investigate their consequences. *See* DIFFERENTIAL GEOMETRY.

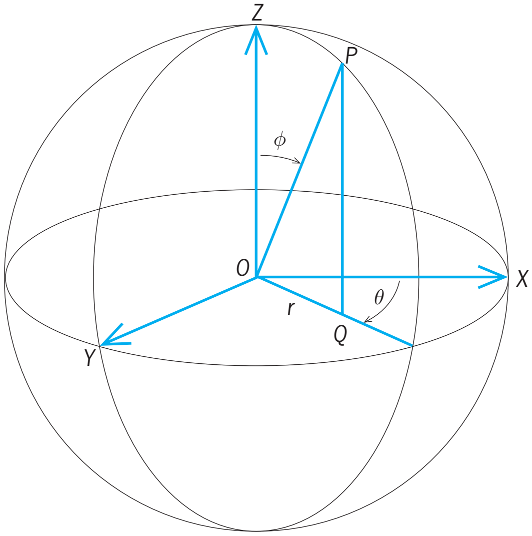

Fig. 3. Spherical coordinate system.

Transformation of coordinates. By means of a system of equations the description of a geometrical object in one coordinate system may be translated into an equivalent description in another coordinate system. Thus in a given space of n dimensions if there is a coordinate system A in which a general point P has coordinates $(u_1, u_2, \ldots, u_n)$ and a coordinate system B in which P has the coordinates $(v_1, v_2, \ldots, v_n)$, the transformation from system A to system B is the set of equations $u_i = f_i(v_1, v_2, \ldots, v_n)$, for $i = 1, 2, \ldots, n$, which expresses each u in terms of the v's. These functions are obtainable from the relation between the two coordinate systems. They are not completely arbitrary, for they must be single-valued, independent, and such that if in the B system P has another set of coordinates, say $(v'_1, v'_2, \ldots, v'_n)$, then $f_i(v_1, v_2, \ldots, v_n) = f_i(v'_1, v'_2, \ldots, v'_n)$. Then if a geometrical locus in the space S is described by one or more equations of the form $F(u_1, u_2, \ldots, u_n) = 0$ in system A, the equivalent description in system B is one or more of the equations of the form

$$F[f_1(v), f_2(v), \ldots, f_n(v)] = 0$$

Other geometrical objects such as vectors and areas have more complicated laws of transformation, but each such law is expressible in terms of the equations of transformation. As remarked above, a coordinate system is a mathematical language; a transformation of coordinates plays the role of a dictionary that translates from one language to another.

The most important transformations of coordinates are between rectangular cartesian coordinate systems. One such set of coordinate axes is obtainable from another by a translation (in the physical sense) and a rotation. Consider a coordinate system A with coordinate axes OX, OY, OZ, and coordinates of a point $P(x,y,z)$. System B *is* obtained by moving the axes without turning to a point O' with coordinates (a, b, c). The new axes are $O'X'$, $O'Y'$, $O'Z'$ and the coordinates of P in this system are (x', y', z'); then the equations of transformation are $x = x' + a$, $y = y' + b$, $z = z' + c$. If the new system is obtained from A by a rotation of the coordinate axes, let $\alpha_1, \alpha_2, \alpha_3; \beta_1, \beta_2, \beta_3; \gamma_1, \gamma_2, \gamma_3$ be the angles which the new axes OX', OY', OZ' make with the original axes (only three of these angles are independent); then the equations of transformation are

$$x = x' \cos\alpha_1 + y' \cos\beta_1 + z' \cos\gamma_1$$

$$y = x' \cos\alpha_2 + y' \cos\beta_2 + z' \cos\gamma_2$$

$$z = x' \cos\alpha_3 + y' \cos\beta_3 + z' \cos\gamma_3$$

The equations of transformation may be differently interpreted. The equations of transformation make the point P of coordinates (x, y, z), in the same coordinate system, correspond to a point P' of coordinates (x', y', z'). This constitutes a mapping of the space upon itself which maps a figure into some other figure. In applications one usually seeks a mapping that carries some pertinent loci into simpler loci while preserving some relevant properties. *See* ANALYTIC GEOMETRY; BARYCENTRIC CALCULUS; CALCULUS; CONFORMAL MAPPING; CURVE FITTING; SPHERICAL HARMONICS.

Morris S. Knebelman

Coordination chemistry

A field which, in its broadest usage, is acid-base chemistry as defined by G. N. Lewis. However, the term coordination chemistry is generally used to describe the chemistry of metals and metal ions in their interactions with other molecules or ions. For example, reactions (1)–(3) show Lewis acid-base-type reactions, which result in the formation of coordinate covalent bonds.

$$\mathrm{Mg^{2+} + 6H_2O \rightarrow Mg(H_2O)_6^{2+}} \qquad (1)$$

$$\mathrm{Ni + 4CO \rightarrow Ni(CO)_4} \qquad (2)$$

$$\mathrm{Fe^{2+} + 6CN^- \rightarrow Fe(CN)_6^{4-}} \qquad (3)$$

The products formed are coordination complex ions or compounds, and this area of chemistry is known as coordination chemistry.

It follows that coordination complex ions or compounds are ions or compounds that contain a central metal atom or ion and a group of ions or molecules bonded to it. Such an ion or compound tends to retain its identity, even in solution, although partial dissociation may occur. The charge on the coordinated species may be positive, zero, or negative, depending on the charges carried by the central atom and the coordinated groups. These groups are called ligands, and the total number of ligands bound to the central metal atom is called the coordination number. Other names commonly used for these compounds include complex compounds, complex ions, Werner complexes, coordinated complexes, chelate compounds, or simply complexes. *See* ACID AND BASE; CHELATION; COORDINATION COMPLEXES.

Experimental observations as early as the middle of the eighteenth century reported the isolation of coordination compounds. During that time and for the following 150 years, the valence theory could not adequately account for such materials. As a result, they were referred to as complex compounds, a term which is still in common usage, but not for the same reason. The correct interpretation of these compounds was finally given by Alfred Werner in 1893. He introduced the concept of residual or secondary valence, and suggested that elements have this type of valence in addition to their normal or primary valence. Thus, platinum(IV) has a normal valence of 4 but a secondary valence or coordination number of 6. This then led to the formulation of $\mathrm{PtCl_4 \cdot 6NH_3}$ as $\mathrm{[Pt(NH_3)_6]^{4+}, 4Cl^-}$ and of $\mathrm{PtCl_4 \cdot 5NH_3}$ as $\mathrm{[Pt(NH_3)_5Cl]^{3+}, 3Cl^-}$. The compound with five ammonias has only three ionic chlorides; the fourth is inside the coordination sphere, and therefore is not readily precipitated upon the addition of silver ion. Although the exact nature of the coordinate bond between metal and ligand remains the subject of considerable discussion, it is agreed that the formulations of Werner are essentially correct.

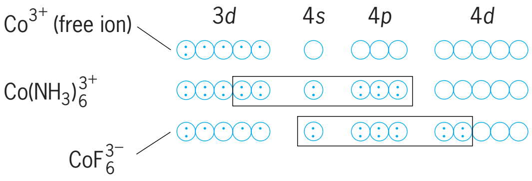

Fig. 1. Cobalt(III) complexes.

Coordinate bond. Three theories have been used to explain the nature of the coordinate bond. These are the valence bond theory, the electrostatic theory, including crystal field corrections, and the molecular orbital theory. Currently, the theory used almost exclusively is the molecular orbital theory. The valence bond theory for metal complexes was developed chiefly by Linus Pauling. This theory considers that the pair of electrons on the ligand enter the hybridized atomic orbitals of the metal and that the bond is essentially covalent. Several of the properties of these substances can be explained on the basis of this theory. For example, cobalt(III) complexes are represented by **Fig. 1**. The orbital hybridization of $\mathrm{Co(NH_3)_6}^{3+}$ is designated as d^2sp^3, and the complex is referred to as an inner orbital complex. Such a representation is consistent with the diamagnetic properties of this cation, for all electrons are paired. The orbital hybridization of $\mathrm{CoF_6}^{3-}$ is designated as sp^3d^2, and it is called an outer orbital complex. This ion is known to be paramagnetic, which is in keeping with the four unpaired electrons in the 3*d* orbitals. The term inner orbital is applied if the *d* orbitals of a lower quantum number than the *s* and *p* orbitals are used in bonding, whereas outer orbital has reference to systems in which the *d* orbitals used have the same quantum number as the *s* and *p* orbitals. *See* ELECTRON CONFIGURATION; MOLECULAR ORBITAL THEORY; QUANTUM NUMBERS.

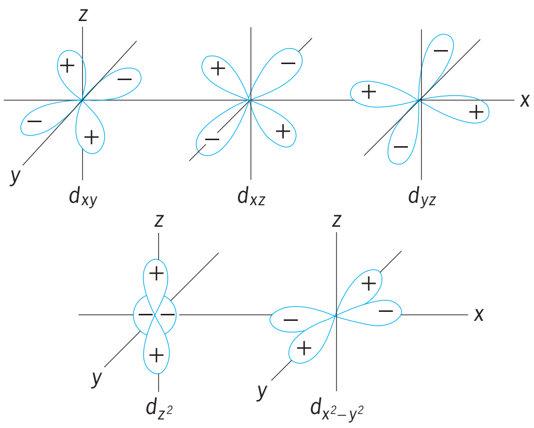

Fig. 2. Orientation of *d* orbitals in space.

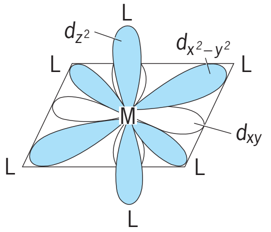

Fig. 3. Spatial orientation of *d* orbitals in coordination complex.

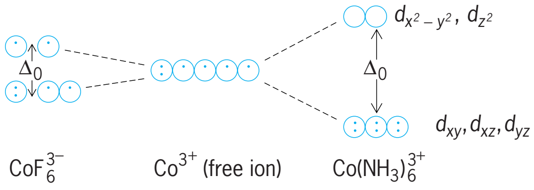

Fig. 4. Cobalt(III) complexes on the basis of crystal field theory.

The electrostatic theory, plus the crystal field theory for the transition metals, assumes that the metal-ligand bond is caused by electrostatic interactions between point charges and dipoles and that there is no sharing of electrons. Physicists have made good use of this theory to explain the properties of ionic crystalline solids, and it has now been extended to the metal complexes. For the nontransition metals, the parameters needed to determine the strength of the metal ligand bond are the charges and sizes of the central ions and the charges, dipole moments, polarizabilities, and sizes of the ligands. In order to give an adequate explanation of the bonding for transition metals, it is also necessary to consider the orientation of the *d* orbitals in space. The five possible spatial configurations are shown in **Fig. 2**. For the gaseous ion M, all five of the *d* orbitals are of equal energy. However, as shown in **Fig. 3**, the $d_{x^2-y^2}$ and d_{z^2} orbitals are pointing directly toward the six ligands at the corners of an octahedron and, because of repulsive interaction with the ligands, are at a higher energy than the d_{xy}, d_{xz}, and d_{yz} orbitals which do not point toward the ligands. *See* LIGAND FIELD THEORY.

Thus, on the basis of the crystal field theory, the cobalt(III) complexes referred to above are designated as in **Fig. 4**. The Co(NH$_3$)$_6^{3+}$ is called a spin-paired, or low-spin, complex, whereas CoF$_6^{3-}$ is called spin-free, or high-spin. This refers to the fact that the electrons are all paired in the former because of the larger crystal field splitting, Δ_0, whereas in the latter, Δ_0 is small, and the electrons are not paired. In addition to explaining the structure and magnetic properties, this theory affords an adequate interpretation of the visible spectra of metal complexes.

The molecular orbital theory assumes that the electrons move in molecular orbitals which extend over all the nuclei of the metal-ligand system. In this manner, it serves to make use of both the valence bond theory and crystal field theory. The molecular orbital theory is therefore the best approximation of the nature of the coordinate bond because it is sufficiently flexible to permit both covalent and ionic bonding as well as the splitting of *d* orbitals into various energy levels. The complexes CoF$_6^{3-}$ and Co(NH$_3$)$_6^{3+}$ can be represented by the molecular orbital energy diagrams shown in **Fig. 5**.

It is apparent from these molecular orbital diagrams that this theory combines the desirable features of both the valence bond and the crystal field theories. The covalent bonding of the valence bond theory appears as the sigma (σ) bonded molecular orbitals, designated here as σ_s, σ_p, and σ_d. Likewise the crystal field splitting (Δ_0) of the crystal field

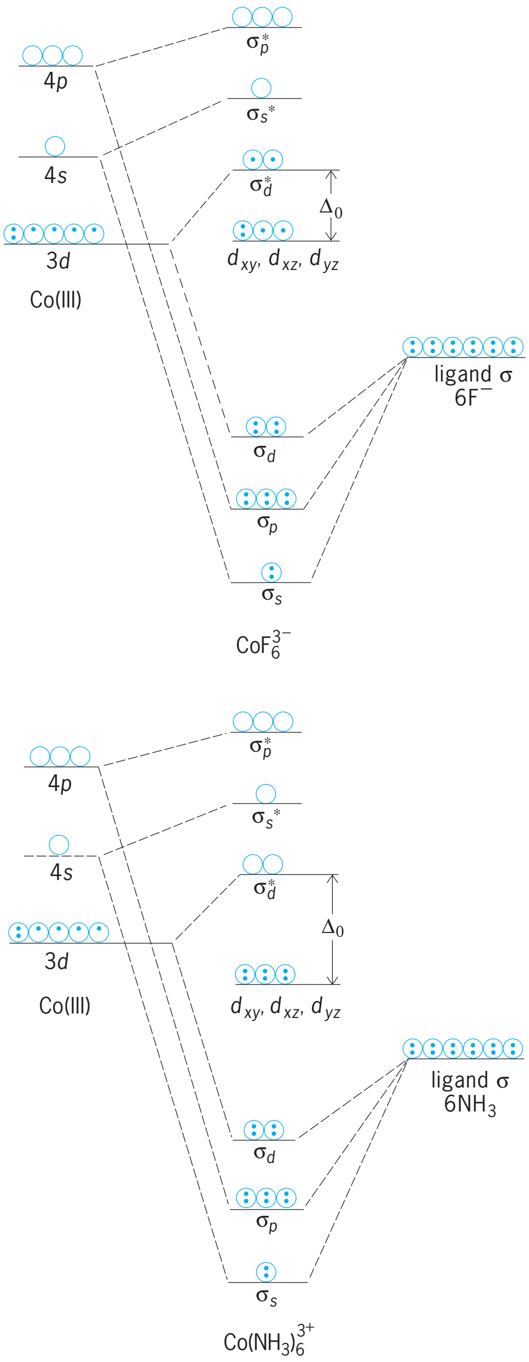

Fig. 5. Cobalt complexes CoF$_6^{3-}$ and Co(NH$_3$)$_6^{3+}$ according to molecular orbital theory.

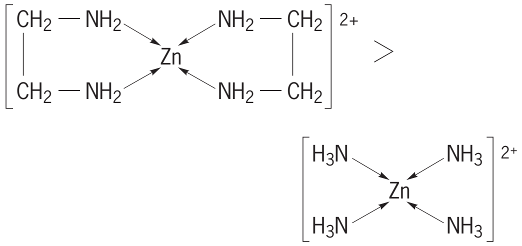
theory now is the energy difference between the nonbonding d orbitals d_{xy}, d_{xz}, d_{yz} and the antibonding sigma orbital σ_d^*. More complicated molecular orbital diagrams would include the contribution of π bonding in these systems.

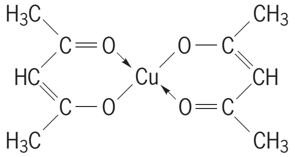
Stability of complexes. The stability of metal complexes depends both on the metal ion and the ligand. There is a great deal of quantitative information on the stability of coordination compounds. These data show that, in general, the stability of metal complexes increases if the central ion increases in charge, decreases in size, and increases in electron affinity. Thus, alkali-metal ions have the least tendency to form complexes, and the highly polarizing transition-metal ions have the greatest tendency. However, even in the least favorable cases of the alkali-metal ions, there is ample evidence that coordination with certain ligands does occur. For the transition-metal ions, it also appears that the electronic configuration of the ion is significant with regard to the stability of its complexes. For example, regardless of the nature of the ligand, the stability of complexes of bivalent transition metals is $\mathrm{Mn} < \mathrm{Fe} < \mathrm{Co} < \mathrm{Ni} > \mathrm{Cu} > \mathrm{Zn}$. This so-called natural order of stability is explained in terms of the crystal field theory, which indicates that a maximum stabilization effect in spin-free complexes is realized with d^8 systems, such as exists in Ni^{2+}. The platinum metals, because of their large polarizing ability, generally form the most stable metal complexes.

Effect of ligand. Several characteristics of the ligand are known to influence the stability of complexes: (1) basicity of the ligand, (2) the number of metal-chelate rings per ligand, (3) the size of the chelate ring, (4) steric effects, (5) resonance effects, and (6) the ligand atom. Since coordination compounds are formed as a result of acid-base reactions where the metal ion is the acid and the ligand is the base, it follows that generally the more basic ligand will tend to form the more stable complex. Much of the available quantitative data on the formation constants of coordination compounds gives a good linear correlation with the base strength of the ligand. It is also known that a polydentate ligand, one attached to the metal ion at more than one point, forms more stable complexes than does an analogous monodentate ligand. For example, ethylenediamine forms more stable complexes than does ammonia, as shown in the following inequality.

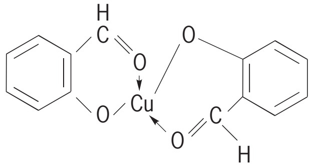


The ethylenediamine complex is referred to as a chelate complex. In general, an increase in the extent of chelation results in an increase in the stability of the complex. Ethylenediaminetetraacetate ion, a sexadentate ligand, is an excellent chelating agent and has found numerous applications as a sequestrant for metal ions. **Figure 6** is the structural formula of the chelate complex of calcium ion and ethylenediaminetetraacetate.

The size of the chelate ring is likewise an important factor. For saturated ligands such as ethylenediamine, five-membered rings are the most stable, whereas six-membered rings are the most stable for chelates containing one or more double bonds, for example (**1**) and (**2**). Examples of smaller and of larger chelate ring systems are known, but these are much less common and less stable. It has been observed that for analogous systems an increase in double bonding in the chelate ring increases the stability of the complex. For ligands of comparable base strengths, the acetylacetonate complexes of type (**1**) are more stable than the salicylaldehyde compounds of type (**2**). There are in effect two double bonds per chelate ring in (**1**) compared to one and a half in (**2**). This same phenomenon is believed to be responsible for the marked stability of the porphyrin complexes such as chlorophyll, hemoglobin, and the phthalocyanine dyes.



(**1**)



(**2**)

Steric factors often have a very large effect on the stability of metal complexes. This is most frequently observed with ligands having a large group attached

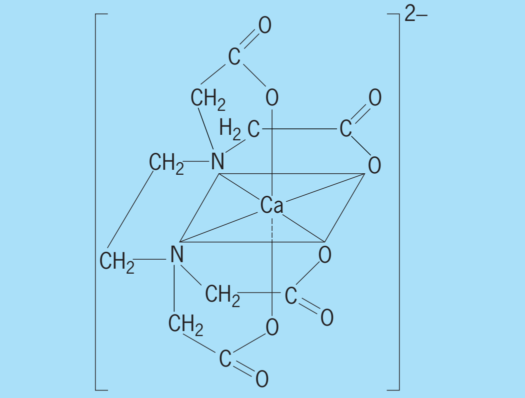


Fig. 6. Structural formula for the chelate complex formed from a calcium ion and ethylenediaminetetraacetate.

to the ligand atom or near it. Thus complexes, of the type shown in **Fig. 7**, with alkyl groups R in the position designated are much less stable than the parent complex where R = H. This results from the steric strain introduced by the size of the alkyl group on or adjacent to the ligand atom. In contrast to this, alkyl substitution at any other position results in the formation of more stable complexes because the ligand becomes more basic, and the bulky group is now removed from a position near the coordination site.

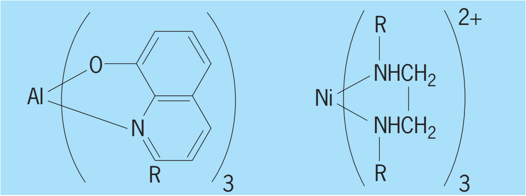

Fig. 7. Structural formulas of metal complexes which are affected by steric factors.

Finally, the ligand atom itself plays a significant role in controlling the stability of metal complexes. For most of the metal ions, the smallest ligand atom with the largest electron density will form the most stable complex. This means that the second period elements form more stable metal-ligand bonds than do other members of the same group, for example, N > P > As > Sb; O > S > Se > Te; F > Cl > Br > I. It is also known that for this same class of metal ions the stability order is N > O > F. These trends are in accord with the coordinate bond strengths expected on the basis of electrostatic interactions. These metal ions and the ligand atoms they prefer are not very polarizable, and are designated as hard Lewis acids and bases, respectively. A different trend in stability is found for a second class of metal ions, for example, Cu(I), Rh(I), Pd(II), Ag(I), Pt(II), and Hg(II). The stability trends observed for these metal ions are N < P > As > Sb, O < S > Se > Te, and F < Cl < Br < I. These metal ions and the ligand atoms they prefer are polarizable, and are designated as soft Lewis acids and bases, respectively. Thus, Pearson has proposed the HSAB theory of acids and bases, which states that hard Lewis acids prefer hard bases and soft Lewis acids prefer soft bases. Since the soft metal ions also have a large number of *d* orbital electrons and the third-period ligand atoms have vacant *d* orbitals, the enhanced stability is attributed to the formation of *dd-π* bonding. This means that the filled *d* orbitals of the metal ion overlap with the empty *d* orbitals of the ligand atom. This is illustrated by **Fig. 8**. This same class of metal ions is the one that forms olefin complexes such as Zeise's salt, K[Pt(CH_2=CH_2)Cl_3]. The stability of these compounds is likewise attributed to *π* bonding.

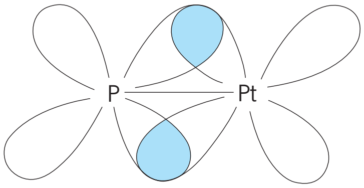

Fig. 8. Overlap of *d* orbitals of platinum with empty *d* orbitals of phosphorus ligand.

Stability and reactivity. Often the most stable complex is also the least reactive or most inert. Therefore, the platinum metal complexes as well as cobalt(III) and chromium(III) complexes are usually very slow to react. However, there are exceptions to this, for instance, the rapid exchange of radiocyanide with the coordinated cyanide in the stable tetracyano complexes $Hg(CN)_4^{2-}$ and $Ni(CN)_4^{2-}$. Several factors, such as the electronic configuration of the central metal ion, its coordination number, and the extent of chelation, all have a marked effect on the rate of reaction of a given compound.

There are sufficient data available to permit a fairly reliable classification for the relative reactivities of six-coordinated systems. Metal complexes are said to be labile if they have reacted completely at room temperature within the time of mixing, such as the instantaneous formation of the deep-blue color of $Cu(NH_3)_4^{2+}$ upon the addition of excess ammonia to $Cu(H_2O)_4^{2+}$. Complexes are designated as being inert if their reactions at room temperature proceed at a detectable rate and have half-lives longer than 2 min. On the basis of such a definition, it is possible to classify the labile complexes as being those of either the outer orbital type, such as CoF_6^{3-}, $Al(C_2O_4)_3^{3-}$, $SnCl_6^{2-}$, $Ni(NH_3)_6^{2+}$, or the inner orbital type with one or more vacant *d* orbitals, such as TiF_6^{2-}, $V(CN)_6^{3-}$, $Mo(SCN)_6^{2-}$. The inert complexes are then the inner orbital type with no vacant *d* orbitals; for example, $Co(NH_3)_6^{3+}$, $Cr(H_2O)_6)_6^{3+}$, $RhCl_6^{3-}$. A similar classification based on the crystal field theory is done in terms of the labile systems being those that are not stabilized greatly by the crystal field.

Reactions of complexes. The reactions referred to above are acid-base reactions, where one basic ligand replaces a less basic ligand coordinated to the acidic metal ion, for example, reaction (4). A reaction of this type is called a nucleophilic substitution reaction and is designated by the symbol S_N. There are at least two fundamentally different pathways conceivable for such a reaction. These are the dissociation and displacement mechanisms which are designated as S_N1 and S_N2, respectively. An S_N1 reaction goes by two-step process, where the first step is a slow unimolecular heterolytic dissociation, reaction (5), followed by the rapid coordination of the entering group, reaction (6). An S_N2 reaction is one involving a bimolecular rate-determining step in

$$Co(NH_3)_5Cl^{2+} + H_2O \rightarrow Co(NH_3)_5H_2O^{3+} + Cl^- \qquad (4)$$

$$Co(NH_3)_5Cl^{2+} \xrightarrow{\text{slow}} Co(NH_3)_5{}^{3+} + Cl^- \qquad (5)$$

$$Co(NH_3)_5{}^{3+} + H_2O \xrightarrow{\text{fast}} Co(NH_3)_5H_2O^{3+} \qquad (6)$$

which one nucleophilic reagent displaces another [reaction (7)]. Examples of both types of substitution are known for the reaction of metal complexes.

$$\mathrm{Co(NH_3)_5Cl^{2+} + H_2O \xrightarrow{slow} H_2O \cdots Co(NH_3)_5 \cdots Cl^{2+} \xrightarrow{fast} Co(NH_3)_5H_2O^{3+} + Cl^-} \qquad (7)$$

The specific reaction just cited, as well as analogous reactions of $Co(NH_3)_4Cl_2^+$ and $Co(NH_3)_4OHCl^+$, appears to proceed by an S_N1 mechanism. However, reactions of platinum(II) complexes are believed to involve an S_N2 process, for example, reaction (8).

$$\mathrm{Pt(NH_3)_3Cl^+ + NO_2^- \xrightarrow{slow} O_2N \cdots Pt(NH_3)_3 \cdots Cl \xrightarrow{fast} Pt(NH_3)_3NO_2^+ + Cl^-} \qquad (8)$$

The symbols AID were introduced in order to better designate the mechanisms of these reactions. A = association and relates to S_N2, where the entering group becomes associated with the complex [slow step of Eq. (8)]; I = interchange and signifies that a group just outside the complex interchanges positions with a ligand on the metal; D = dissociation and relates to S_N1, where the leaving group dissociates away from the complex [Eq. (5)]. In general, I_d is similar to S_N1 and designates a dissociative interchange mechanism, whereas I_a is similar to S_N2 and designates an associative interchange mechanism.

Finally, coordination may have the effect of stabilizing an unusual oxidation state of the coordinated metal. For example, ligands such as CO, CN^-, CNR, 2,2′-bipyridine, and PR_3 are most effective in stabilizing low-valent states. Thus, compounds of the type $Na_2[Fe(CO)_4]$, Na[V(2,2′-bipyridine)$_3$], $K_4[Ni(CN)_4]$, and $Pt(PR_3)_4$ are known where the assigned oxidation states are Fe (2−), V (1−), Ni (0), and Pt (0). It is believed that the low oxidation states in these systems are stabilized by the formation of π-type molecular orbitals between the metal and ligand atoms. If the ligand orbitals are of low energy and vacant, they can accommodate the *d*-orbital electrons of the metal and permit the addition of other electrons leading to the reduction of the complex. In contrast, ligands such as O^{2-}, OH^-, and F^- tend to stabilize high-valence states giving complexes of the type K_2FeO_4, Na_3BiO_4, K_2NiF_6, and K_3CuF_6, where the oxidation states are Fe (6+), Bi (5+), Ni (4+), and Cu (3+). These ligands have no *d* orbitals but only filled *p* orbitals. One explanation for the stabilization of higher-valent states by such ligands is that in these systems the π-type molecular orbitals cannot be formed so the metal electrons are forced into higher-energy antibonding orbitals from which they may be readily removed. *See* CHEMICAL BONDING; MAGNETOCHEMISTRY; SOLID-STATE CHEMISTRY; STEREOCHEMISTRY; SUBSTITUTION REACTION.

Merbach (eds.), *Perspectives in Coordination Chemistry*, 1992.

Coordination complexes

A group of chemical compounds in which all or a part of the molecular bonding is of the coordinate covalent type.

This article summarizes the different types of compounds that are known and discusses their nomenclature, structure, stereochemistry, and synthesis. For a discussion of the nature of the coordinate bond and the stability and reactivity of complex compounds *see* CHELATION; COORDINATION CHEMISTRY.

Complex compounds contain a central atom or ion and a group of ions or molecules bonded to it. Many simple hydrates, such as $MgCl_2 \cdot 6H_2O$, are best formulated as $[Mg(H_2O)_6]Cl_2$ because it is known that the six molecules of water are bound to the central magnesium ion. Therefore, $[Mg(H_2O)_6]^{2+}$ is a complex ion, and $[Mg(H_2O)_6]Cl_2$ is a complex compound. The charge on this complex ion is 2+, because this is the charge on the magnesium ion and the coordinated water molecules are neutral. However, if the coordinated groups are charged, then the charge on the complex is represented by the sum of the charge on the metal and that of the coordinated ions. See, for example, the progression of charges on the platinum(IV) complexes listed below. Thus the charge is 4+ for $[Pt(NH_3)_6]^{4+}$ because Pt is 4+ and NH_3 is neutral. But the charge is 2− for $[PtCl_6]^{2-}$ because of the 6 Cl^-, that is, $+4 - 6 = -2$ (that is, 2−).

Nomenclature. The metal complex may be a cation, have zero charge, or be an anion, as is exemplified by the following series of complexes:

$[Pt(NH_3)_6]Cl_4$	Hexaammineplatinum(IV) chloride
$[Pt(NH_3)_5Cl]Cl_3$	Chloropentaammine-platinum(IV) chloride
$[Pt(NH_3)_4Cl_2]Cl_2$	Dichlorotetraammine-platinum(IV) chloride
$[Pt(NH_3)_3Cl_3]Cl$	Trichlorotriammine-platinum(IV) chloride
$[Pt(NH_3)_2Cl_4]$	Tetrachlorodiammine-platinum(IV)
$K[Pt(NH_3)Cl_5]$	Potassium pentachloro-ammineplatinate(IV)
$K_2[PtCl_6]$	Potassium hexachloro-platinate(IV)

These compounds are named according to rules set up by the Nomenclature Committee of the International Union of Pure and Applied Chemistry. Some of the rules are the following: (1) Name the cation first as one word followed by the anion as one word. (2) For a cationic complex, name the negative ligands first with an ending of -o, then the neutral ligands, and finally the metal followed by a Roman numeral in parentheses to designate its oxidation state. Neutral ligands are named as the molecule, except that H_2O is aqua and NH_3 is ammine. (3) The prefixes such as di, tri, and tetra are used before simple names such as chloro, aqua, and oxalato. Prefixes such as bis, tris, and tetrakis are used before complex names such as ethylenediamine, 2,2′-bipyridine, and trialkylphosphine. (4) Neutral complexes are named in the same way except that only one word is required. (5) Anionic complexes are also named according to these same rules except that an -ate ending is used. Additional rules are available to name the more complicated compounds, and some of these will be used in the discussion that follows.

Coordination numbers of 2–10 have been observed for different complex compounds. The most common coordination numbers are 6 and 4. Complexes having coordination number 6 generally have an octahedral structure, but may also be trigonal prismatic. Complexes having coordination number 4 are either square planar or tetrahedral. **Table 1** gives examples of complexes having coordination numbers other than 4 or 6.

TABLE 1. Metal complexes with coordination numbers other than 4 or 6

Coord. number	Complex	Structure
2	$[Ag(CN)_2]^-$ $[Ag(NH_3)_2]^+$	Linear
3	$[Cu(PR_3)_2I]$ $[Au(AsR_3)_2I]$	Planar
5	$[Fe(CO)_5]$ [Zn(2,2′,2″-terpyridine)Cl_2]	Trigonal bipyramid
	$[Ni(PR_3)_2Br_3]$ {Pd[*o*-phenylene-bis-(dimethylarsine)]$_2$I}I	Tetragonal pyramid
7	$ZrF_7{}^{3-}$	Pentagonal bipyramid
	$NbF_7{}^{2-}$	Face-centered trigonal prism
	$TaF_7{}^{2-}$	
8	$Mo(CN)_8{}^{4-}$	Dodecahedral
	$TaF_8{}^{3-}$	Archimedean antiprism
9	$Nd(H_2O)_9{}^{3+}$	Face-centered trigonal prism
10	$Cd_2[Mo(CN)_8(H_2O)_2]$	Unknown structure

Structures. Metal complexes exhibit various types of isomerism. In many ways, inorganic stereochemistry is similar to that observed with organic compounds. Geometrical isomers are common among the substitution inert complexes of coordination numbers 4 and 6. Square planar complexes of the type $Pt(NH_3)_2Cl_2$ exist in two forms, cis and trans. Likewise, cis-trans isomers of the $Pt(NH_2CH_2COO)_2$ type have been isolated (**Fig. 1**). It is apparent from the above examples that the isomer with the same ligands or ligand atoms in adjacent positions is called cis, whereas the trans isomer has its like groups in opposite positions. There are also examples of geometrical isomers of complexes containing four different ligands (**Fig. 2**). Although geometrical isomerism of square complexes is most common with platinum(II), it has also been observed with compounds of nickel(II), palladium(II), and gold(III). *See* STEREOCHEMISTRY.

There are many examples of geometrical isomers for 6-coordinated complexes of cobalt(III), chromium(III), and the platinum metals. Most of the examples are of the type $[Co(NH_3)_4Cl_2]^+$ (**Fig. 3**). If three of the ligands differ from the other three, then only two isomers are possible (**Fig. 4**). Similar isomers are obtained with an unsymmetrical bidentate ligand (**Fig. 5**). The complex with 6 different ligands, such as $[Pt(NH_3)(py)(NH_2OH)(Cl)(Br)(NO_2)]$,

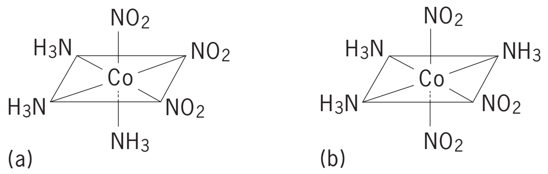

Fig. 4. Structure of (*a*) *cis*- (or facial-) trinitrotriamminecobalt(III) and (*b*) *trans*- (or meridial-) trinitrotriamminecobalt(III).

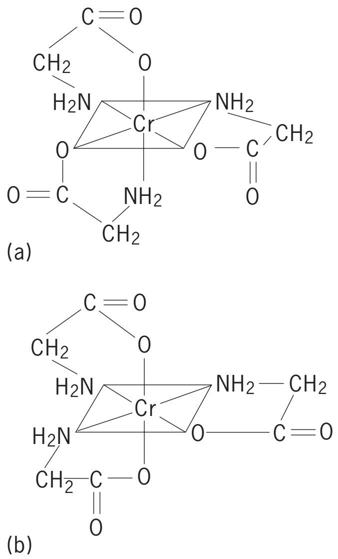

Fig. 5. Structure of (*a*) *fac*-triglycinatochromium(III) and (*b*) *mer*-triglycinatochromium(III).

can exist theoretically in 15 different geometrical forms.

Optical isomerism is also fairly common among these compounds. For example, 4-coordinate tetrahedral complexes containing unsymmetrical bidentate ligands, such as bis(benzoylpyruvato)beryllate (II) ion, have been resolved (**Fig. 6**). Optically active complexes of this type are likewise reported for boron(III) and for zinc(II). Most of the examples of optical activity occur with 6-coordinated systems containing three bidentate ligands, for example, trioxalatorhodiate(III) ion (**Fig. 7**). The resolution of 6-coordinated complexes of this type has been reported for the metal ions Al(III), As(V), Cd(II), Co(III), Cr(III), Ga(III), Ge(IV), Ir(III), Fe(II),(III), Ni(II), Os(II),(III), Pt(IV), Rh(III), Ru(II),(III), Ti(IV), and Zn(II).

The cis isomer of a complex containing two bidentate ligands and two monodentate ligands is asymmetric, and therefore exists in the form of mirror-image isomers, whereas the trans form is symmetrical and cannot be optically active (**Fig. 8**). Since the cis isomer of this type is optically active and the trans isomer is not, the successful resolution of one of the isomers has historically been used as a proof of its cis structure. Other types of isomerism are known for metal complexes (**Table 2**).

Synthesis. The synthesis of metal complexes containing only one kind of ligand generally involves simply the reaction of the metal salt in aqueous solution with an excess of the ligand reagent, reaction (1).

$$[Ni(H_2O)_6](NO_3)_2 + 6NH_3 \longrightarrow [Ni(NH_3)_6](NO_3)_2 + 6H_2O \quad (1)$$

The desired complex salt can then be isolated by removal of water until it crystallizes, or by addition of a water-miscible organic solvent to cause it to separate. Many reactions, such as the one cited above, occur readily at room temperature. For the substitution-inert complexes (those slow to react), prolonged treatment at more drastic conditions is often necessary.

The preparation of geometrical isomers is much more difficult, and in most cases, the approach used

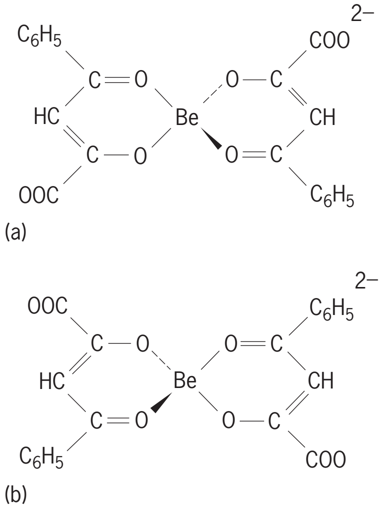

Fig. 6. Optical isomers of bis(benzoylpyruvato)beryllate(II) ion: (*a*) dextro and (*b*) levo.

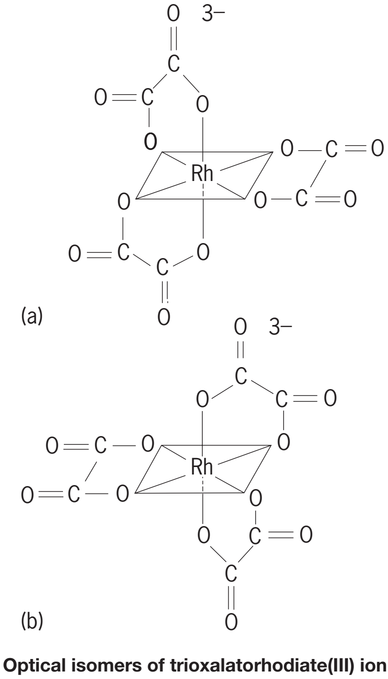

Fig. 7. Optical isomers of trioxalatorhodiate(III) ion: (*a*) lambda and (*b*) delta.

is rather empirical. Generally, reactions yield a mixture of cis-trans products, and these are separated on the basis of their differences in solubility. The trans isomers of platinum(IV) complexes are prepared by the oxidation of the appropriate platinum(II) compound (**Fig. 9**). The cis isomers of cobalt(III) complexes can sometimes be prepared by the reaction of a carbonato complex with the desired acid (**Fig. 10**).

TABLE 2. Types of isomerism for complex compounds

Isomerism	Examples
Geometrical	*cis*- and *trans*-$[Pt(NH_3)_2Br_2]$
Optical	Δ-and Ω-$[Ir(NH_2CH_2CH_2NH_2)_3]Cl_3$
Coordination	$[Co(NH_3)_6][Cr(CN)_6]$ and $[Cr(NH_3)_6][Co(CN)_6]$
Coordination position	 $[(R_3P)_2Pt(\mu\text{-}Cl)_2PtCl_2]$  and $[Cl(R_3P)Pt(\mu\text{-}Cl)_2Pt(PR_3)Cl]$
Hydrate	$[Cr(H_2O)_6]Cl_3$ and $[Cr(H_2O)_5Cl]Cl_3 \cdot H_2O$
Ionization	$[Pt(NH_3)_4Cl_2]SO_4$ and $[Pt(NH_3)_4SO_4]Cl_2$
Linkage	$[(NH_3)_5Co—NO_2]SO_4$ and $[(NH_3)_5Co—ONO]SO_4$
Polymerization	$[Co(NH_3)_3(NO_2)_3]$ and $[Co(NH_3)_6][Co(NO_2)_6]$
Conformation	$[Ni(P(C_6H_5)_2CH_2C_6H_5)_2Br_2]$ square-planar and tetrahedral

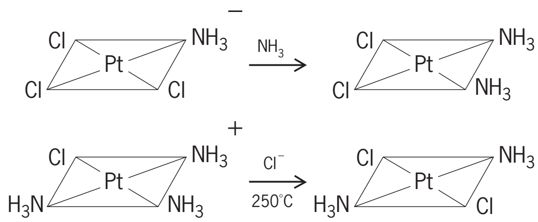

Fig. 11. Cis and trans isomer formation of platinum(II).

The easiest geometric isomers to prepare are those of platinum(II). For example, the cis and the trans isomers of $[Pt(NH_3)_2Cl_2]$ are prepared as shown in reactions (2). The second step in each of these reac-

$$K_2[PtCl_4] + 2NH_3 \longrightarrow cis\text{-}[Pt(NH_3)_2Cl_2] + 2KCl$$
$$[Pt(NH_3)_4]Cl_2 \xrightarrow[(392^\circ F)]{250^\circ C} trans\text{-}[Pt(NH_3)_2Cl_2] + 2NH_3 \qquad (2)$$

tions results in the replacement of the ligand trans to a chloro group (**Fig. 11**). This phenomenon, that a negative ligand often has a greater labilizing effect on a group in the trans position than does a neutral group, for example, $Cl^- > NH_3$, is called the trans effect. Extensive use has been made of this trans effect in the synthesis of desired platinum(II) complexes. The complex *cis*-$[Pt(NH_3)_2Cl_2]$ (Fig. 11) is used as an antitumor drug for certain types of cancer.

Finally, the separation of optical isomers of metal complexes involves techniques similar to those used for organic compounds. The usual procedure is to convert the racemic mixture into diastereoisomers by means of an optically active resolving agent and then to separate the diastereoisomers by fractional crystallization. Nonionic complexes have been resolved by preferential adsorption on optically active quartz or sugars. *See* AMMINE; HYDRATE.

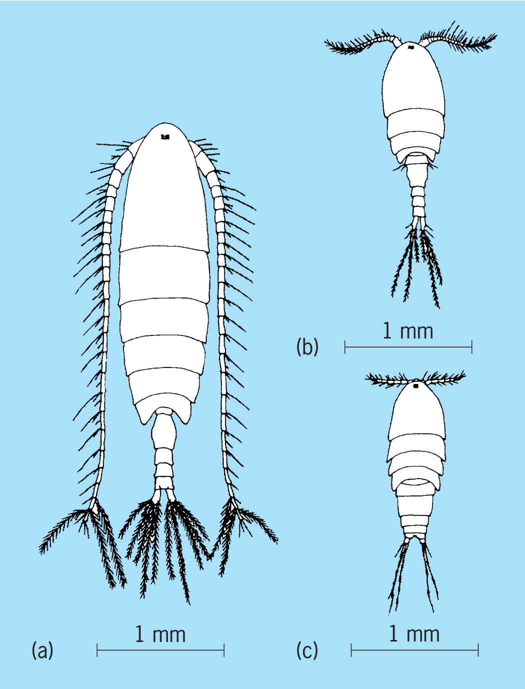
Copepoda

A subclass of Crustacea with eight orders. There are over 6000 species, most of which are free-living in aqueous environments, though many are parasitic or symbiotic with other aquatic animals. The free-living forms are the most abundant of all animals in the sea and directly constitute the main food for vast numbers of fishes, many invertebrates, and also at times for baleen whales.

Structure. The structure of copepods, although similar in basic pattern, varies greatly. In free-living forms the body is composed externally of a series of small chitinous cylinders, or segments, some of which may be more or less fused. The head bears two pairs of antennae. The first antennae are used for stabilizing, retarding sinking, olfactory functioning, and usually in the male for grasping the female. The second antennae are used for creating water currents for food straining and slow locomotion in the Calanoida, and for food grasping in the Cyclopoida and Harpacticoida. The feeding appendages are one pair of mandibles, two pairs of maxillae, and one pair of maxillipeds. During the nauplius larval stage, the second antennae are commonly provided with masticatory hooks for feeding. The thorax, consisting of six segments, bears the swimming feet. The genital aperture occurs on the sixth thoracic segment. The abdomen consists of one to five segments and bears no appendages except a pair of terminal processes known as caudal rami. The sexes are separate and sexual dimorphism is frequently evidenced, especially by modification in the male by one or both of the first antennae for clasping, and in many by marked specialization in the fifth pair of feet for the transfer of spermatophores, or packets of spermatozoa, to the female. Free-living species usually range in size from less than 0.02 in. (0.5 mm) to about 0.4 in. (10 mm) in length. A deep oceanic species, *Bathycalanus sverdrupi,* attains a length of 0.68 in. (17 mm). Some parasitic copepods, such as *Penella,* are greatly elongate, reaching up to 10 in. (250 mm) in length. *See* SEXUAL DIMORPHISM.

Classification. Seven orders of copepods are usually recognized. Three of these, Calanoida, Cyclopoida, and Harpacticoida, are wholly or primarily free-living and because of overwhelming numbers are of greatest general interest. The anatomical differences that set these three apart are, among others, the shape of the body and the position of the movable articulation separating the forebody (metasome) from the hindbody (urosome). In the calanoids and the cyclopoids the urosome is distinctly narrower than the metasome (**illus.** *a* and *b*). In the calanoids the movable articulation falls between the fifth and sixth thoracic segments, whereas in the cyclopoids, it is between the fourth and fifth segments. In the harpacticoids the urosome is commonly not narrow (illus. *c*), and the movable articulation falls between the fourth and fifth thoracic segments. In many harpacticoids there is considerable flexibility also between other segments. The length of the first antennae relative to body length is very useful in distinguishing these three orders. The first antennae in the Calanoida have 20–25 segments, usually extending to or beyond the caudal rami. In the Cyclopoida they have 6–17 segments, extending to the posterior border of the metasome or even the first body segment. In the Harpacticoida they have 5–9 segments, usually not extending to the posterior border of the first body segment. *See* CALANOIDA; CYCLOPOIDA; HARPACTICOIDA.



Free-living copepods. (*a*) *Calanus finmarchicus*, a calanoid. (*b*) *Cyclops*, a cyclopoid. (*c*) *Harpacticus*, a harpacticoid.

In the adult state the remaining orders (Poecilostomatoida, Siphonostomatoida, Monstrilloida, Misophrioida, and Mormonilloida) are parasitic at least part of their lives. Many adult stages are so greatly modified that their crustacean relationship is obscure. Their numbers are relatively small, but they may be conspicuous and important as “fish lice,” burrowing deep into the flesh or feeding externally upon the skin and gills. *See* MISOPHRIOIDA; MONSTRILLOIDA; MORMONILLOIDA; POECILOSTOMATOIDA; SIPHONOSTOMATOIDA.

Life history. The life histories of copepods differ in details, but in nearly all, development takes place from fertilized eggs which are either attached to the genital segment or are cast free in the water. The spermatozoa, transferred to the female genital segment in spermatophores, are stored in spermathecal sacs in the female. Usually one mating suffices for all subsequent eggs laid by the female. A nauplius larva hatches from the egg. This larva usually undergoes five molts in its growth. Most nauplii are self-sustaining, gathering their own food, but some nauplii hatched from yolky eggs are sustained by the yolk through one or more stages. The sixth naupliar stage metamorphoses into the first of six copepodid stages, the last of which is the adult. Only a few life histories have been studied completely. In *Calanus finmarchicus,* a calanoid, a summer brood in boreal waters requires about 2–3 months to reach maturity, but broods produced in the autumn live longer because they winter in deep water as subadults. The number of broods produced is related to latitude, fewer being produced in the far north.

In *Tisbe furcata*, a bottom-living harpacticoid, individual females may live for 70 days, producing 5–10 broods averaging 43 eggs per brood. The young may produce the first batch of eggs in 15 days. Because of their high fecundity and early sexual maturity certain harpacticoids have proved useful for genetic studies.

Habitats. Copepod habitats are extremely varied, but the vast majority of species live in the sea. They are mostly planktonic throughout their lives, some occurring only in coastal waters while others live in the open sea. Many frequent only the upper layers to about 650–1000 ft (200–300 m) depth. Others are bathypelagic at great depths. The harpacticoids, however, are primarily a benthic, or bottom-dwelling, group, though many are truly planktonic. A great many harpacticoid species live upon aquatic vegetation to which they cling with tiny claws. Others are found on the bottom feeding upon detritus. Some are especially adapted by slender wormlike bodies to burrow or creep into the bottom among the grains of sand. There are also many fresh-water copepods living in ponds, lakes, and streams in all parts of the world. Their wide dispersal to isolated bodies of water is probably brought about largely through transport on birds' feet. A few copepods live naturally in damp moss.

Economic biology. The role of copepods in the economy of the sea consists mainly of converting plant into animal substance. Many species are adapted to graze directly upon the chief synthesizers of organic material, the microscopic diatoms and dinoflagellates that constitute the great pasturage of the sea. Some species are predatory on other copepods, fish larvae, and other small animals, such as protozoa. Commonly copepods constitute about 70% of the zooplankton, and at times their numbers are so great as to impart a pinkish color to the sea. They are of sufficient size to be fed upon individually by young fishes and to be filtered from the water by the filtering apparatus (gill rakers) of such fishes as the herring, sardines, and others that require animal protein as food. At higher trophic levels these fishes in turn are, directly or indirectly, food for the more predatory fishes and mammals. *See* MARINE ECOLOGY.

Copolymer

A macromolecule in which two or more types of monomer are incorporated into the polymer chain. This contrasts with a homopolymer, which consists of only one type of monomer. Copolymerization offers the ability to alter the properties of a homopolymer by introducing an appropriately chosen second repeating unit, or to combine the desirable properties of two different homopolymers in a single molecule. The properties of a copolymer depend on the nature of the monomers and their distribution in the chain. Thus, monomers A and B can polymerize randomly (ABBAABA), they can alternate (ABAB), they can form blocks (AAABBB), or one polymer can be grafted onto another polymer (**Fig. 1**). Copolymers can be prepared by all the known methods of polymerization, including addition polymerization of vinyl monomers (by conventional or living free-radical, anionic, cationic, or coordination catalysis), ring-opening polymerization, or condensation polymerization. Copolymers can also be formed by the chemical reaction of functional groups (usually end groups) on the constituent polymer chains. *See* FREE RADICAL; MACROMOLECULAR ENGINEERING; POLYMER; POLYMERIZATION; RING-OPENING POLYMERIZATION.

Statistical copolymers. The simplest method of producing a copolymer is to polymerize a mixture of two (or more) different monomers. Assuming that they are both polymerizable via the same mechanism, the different types of repeat unit will be incorporated into the polymer chain according to their concentration in the monomer feed and their relative reactivities. If the comonomers (A and B) have similar reactivities, a random distribution of the alternative repeat units (BABBAABA) is obtained. If A prefers to add to B and B prefers to add to A, an alternating sequence (ABABABAB) is expected. If A prefers to add to A (and/or B prefers to add to B), one might expect a greater concentration of AAAA or BBBB blocks, or in the extreme case no copolymer at all but a mixture of homopolymers. In reality, the copolymer will have a composition and sequence distribution somewhere between these extremes that can be manipulated by varying the ratio of the comonomers in the feed and by varying the reactivities themselves (for example, by varying the temperature, catalyst, or solvent).

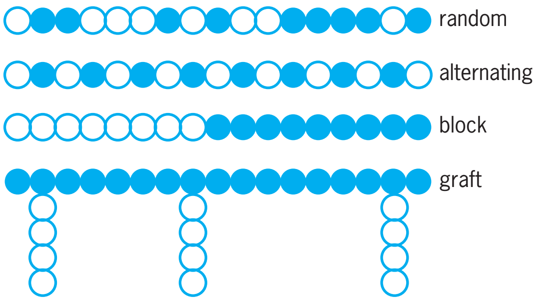

Fig. 1. Different types of copolymers.

Copolymerization models are equations for predicting the composition, sequence distribution, and polymerization kinetics as a function of the monomer feed fractions and a small set of characteristic constants. One of the simplest models is the terminal model. It is assumed that for a given type of polymerization mechanism (radical, anionic, cationic, metallocene-catalyzed, and so on), the reactivity of the propagating species depends only on the nature of its terminal monomer unit. As shown below, there are four types of reaction to consider, with the reacting chains ending in either monomer unit (A* or B*) with each of the comonomers (A or B).

$$\sim\!\sim A^* + \begin{cases} A \xrightarrow{k_{AA}} \sim\!\sim AA^* \\ B \xrightarrow{k_{AB}} \sim\!\sim AB^* \end{cases} \qquad r_A = \frac{k_{AA}}{k_{AB}}$$

$$\sim\!\sim B^* + \begin{cases} A \xrightarrow{k_{BA}} \sim\!\sim BA^* \\ B \xrightarrow{k_{BB}} \sim\!\sim BB^* \end{cases} \qquad r_B = \frac{k_{BB}}{k_{BA}}$$

The reactivity ratios r_A and r_B measure the selectivity of each propagating species toward the alternative monomers, and can be determined experimentally by fitting the terminal model equations to composition or sequence distribution data. Hundreds of reactivity ratios have been measured in this way, and numerous studies have attempted to explain their values in terms of the chemical structure. In recent years, it has been shown that the terminal model rarely holds, and much more complicated copolymerization models are generally required. In radical copolymerization, for instance, models that include additional factors, such as the influence of the penultimate unit of the propagating species, the depropagation reaction, or various types of solvent effects, have been introduced to describe various systems.

Tapered copolymers. An interesting feature of statistical copolymerization is the possibility of composition drift. If the comonomers are consumed at different rates, the comonomer feed ratio will vary through the polymerization process. As a result, the composition of the copolymer will also vary as a function of conversion. In a nonliving process, such as conventional free-radical copolymerization, chains are initiated and grow at different stages of the reaction, resulting in compositional variation among the polymer chains. In contrast, in a living process (such as ionic, coordination-catalyzed, or living free-radical copolymerization) the individual chains are initiated together and continue to grow over the entire polymerization process. As a result, changes in the instantaneous copolymer composition are frozen into the growing polymer chain, and a tapered composition results. For instance, if A is a more reactive monomer, the polymer is initially richer in A; but since monomer A is consumed at a faster rate, the polymer becomes progressively poorer in A. As a result, one end of the polymer chain is richer in A than the other end. Depending on the reactivity ratios and the initial monomer feed fractions, a variety of interesting tapered compositions can be produced. Tapered, or gradient, copolymers have properties that are different from either block copolymers or random copolymers, and are particularly useful as blend compatibilizers and vibration-dampening materials.

Random copolymers. Random copolymers were among the first copolymers produced, and remain to this day among the most commercially important as they offer a means of improving the properties of a homopolymer via the incorporation of a small amount of a second type of repeat unit into the polymer chain. The first commercially important copolymers were developed in Germany in the 1930s, where it was discovered that the properties of synthetic rubber could be markedly improved via the copolymerization of butadiene with small amounts of other monomers. Buna N (now known as nitrile rubber or ABR) is a copolymer of butadiene with acrylonitrile, and combines the elastomeric properties of rubber with the solvent resistance of polyacrylonitrile, while Buna S (now known as SBR) is a copolymer of butadiene with styrene that has improved mechanical properties. Both copolymers continue to find widespread commercial use; in particular, SBR (reinforced with carbon black) is used in vehicle tires and still accounts for approximately 40% of the world market for elastomers. *See* ACRYLONITRILE; CARBON BLACK; POLYACRYLONITRILE RESINS; RUBBER; STYRENE.

Countless other applications for random copolymers exist. Low-density polyethylene is a highly branched homopolymer of ethylene obtained via conventional radical polymerization. Various properties of this homopolymer can be improved through copolymerization with small amounts of other monomers, including vinyl acetate which is used to improve clarity and flexibility for food packaging applications, acrylate or methacrylate monomers which can improve thermal stability for applications in cable insulation and medical packaging, and acrylic or methacrylic acids which offer improved abrasion resistance, flexibility, and adhesion for applications such as packing film and laminates. *See* POLYOLEFIN RESINS.

Emulsions of polymers based on acrylic or methacrylic esters are used extensively in adhesives, caulks, paints, and other surface coatings. A significant number of them are copolymers of acrylic and methacrylic esters, and/or combinations of ester and acid monomers. The copolymer composition is varied to optimize the gloss, adhesion, flexibility, impact strength, and other coating properties. *See* EMULSION POLYMERIZATION.

Alternating copolymers. Alternating copolymers are obtained in a statistical copolymerization if the cross-propagation reactions are very strongly favored over the respective homopolymerizations (that is, r_A and

$r_B \approx 0$). In a radical copolymerization, this will be the case if the comonomers are pairs of strongly electron-accepting and electron-donating monomers (such as styrene with acrylonitrile). Unless both reactivity ratios are exactly zero, the ratio of the comonomers also needs to be finely balanced. Alternating copolymers can also be obtained if just one of the comonomers does not readily homopolymerize (such as SO_2 or maleic anhydride), provided the polymerization is carried out in a large excess of this monomer. Pairs of monomers (such as styrene with methyl methacrylate) that might naturally form random copolymers can sometimes be forced to alternate through complexation of one of the comonomers with a Lewis acid. The complexation alters the reactivity of the propagating species and favors the cross-propagation reaction.

Some commercially important examples of alternating copolymers include the propylene-butadiene elastomer, which has improved mechanical properties and resistance to oxidative degradation compared with polybutadiene, and the vinylidene fluoride–hexafluoroisobutylene copolymer, which has improved abrasion resistance and better processability than the tetrafluoroethylene homopolymer (Teflon®). Copolymers of styrene with 10–40% acrylonitrile (SAN) are also of major commercial significance. Strictly speaking, they are statistical copolymers, with a high alternating tendency that peaks at the 50% copolymer composition. In SAN, the acrylonitrile improves the solvent resistance and tensile strength, compared with polystyrene, and raises the temperature of use. Alternating copolymers of chromophore units and saturated segments are showing promise as tunable electroluminescent devices as, unlike their fully conjugated counterparts (like polyacetylene), the conjugation length is well defined, and the optical properties can be more easily adjusted through variation of the chromophore. *See* CONJUGATION AND HYPERCONJUGATION.

Block copolymers. Copolymers containing block sequences can be prepared in a statistical copolymerization if both of the monomers show a tendency to homo-propagate rather than cross-propagate. However, it is difficult to prepare well-defined block copolymers in this way, since typically one monomer either yields statistical copolymers with blocks of varying length or (if there is no cross-propagation at all) a mixture of homopolymers.

There are three main strategies for preparing true block copolymers. Sequential addition of monomers to a living polymerization is perhaps the simplest method of block copolymer formation, but relies upon the two constituent monomers being polymerizable by the same mechanism. Until recently, this was a limitation, owing to the highly selective nature of ionic and coordination catalysts. However, with the development of controlled radical polymerization, a broader range of block copolymers can now be made. A second, more versatile approach is to prepare the first block as an end-functionalized macroinitiator that is added to the second monomer at a later stage. The advantage of this approach is that it is possible to prepare block copolymers from monomers that would not undergo polymerization via the same mechanism. For instance, step polymers (such as polyesters or polysulfones) can be converted to macroinitiatiors for atom transfer radical polymerization (ATRP) through treatment with 2-bromopropionyl bromide in the presence of pyridine. This introduces bromide end groups that, in conjunction with an appropriate ATRP catalyst, can be used to initiate controlled radical polymerization of styrene or acrylates, resulting in a BAB triblock copolymer. A third approach to preparing block copolymers is to chemically bond the constituent polymer chains as a postpolymerization reaction of functional end groups. *See* CONTROLLED/LIVING RADICAL POLYMERIZATION; POLYESTER RESINS; POLYSULFONE RESINS.

Block copolymers have a wide range of applications. Block copolymers of two otherwise immiscible polymers can function as compatibilizers, while block copolymers of hydrophobic and hydrophilic polymers can self-assemble into stable spherical or cylindrical micelles for use as emulsifiers, dispersants, and even drug delivery devices (**Fig. 2**). Block copolymers of hard (rigid) and soft (flexible) units function as thermoplastic elastomers (**Fig. 3**). *See* MICELLE.

In normal elastomers (such as rubber), the polymer chains are chemically bonded (cross-linked) together to prevent chains from slipping past each other under mechanical stress. This increases the strength of the polymer and allows for rapid recovery after deformation. However, the chemical cross-linking step is irreversible and has to be performed as an additional processing step after fabrication. In the thermoplastic elastomers, the cross-links are not chemical bonds but physical bonds. The hard blocks of these copolymers aggregate together to form rigid domains that act as physical cross-links to keep the rubbery phase in a network structure. At high temperature, the rigid domains melt allowing for reprocessing of the polymer. Thermoplastic elastomers are cheaper to process but offer less resistance to solvents and deformation at high temperatures. As a result, they tend to be used in applications such as wire insulation, footwear, wheels, and adhesives.

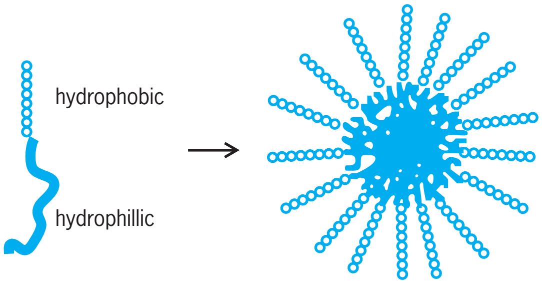

Fig. 2. Micelle formed from block copolymers.

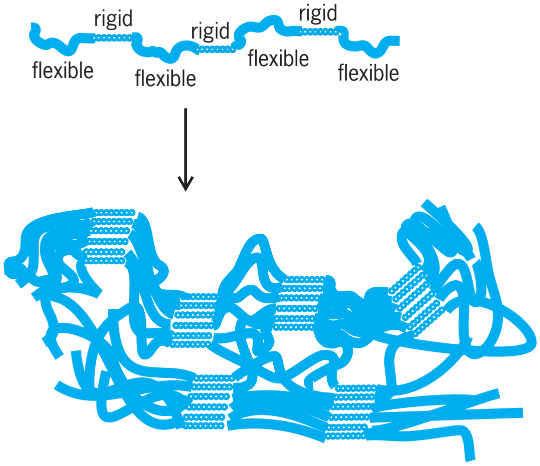

Fig. 3. Thermoplastic elastomer formed from block copolymers.

Graft copolymers. Graft polymers are a type of block copolymer in which one type of polymer chain is chemically attached to the side of the other chain (rather than the chain end). Typically, a single backbone supports several grafts, at either regular or random intervals along the chain. Highly grafted polymers (containing grafts at every repeat unit) are sometimes called bottle-brush polymers, while graft polymers with lower grafting densities are sometimes called comb polymers. *See* BRANCHED POLYMER.

As in the case of block-copolymer formation, grafting offers the possibility of introducing additional favorable properties to a homopolymer (such as improved mechanical properties or adhesion, or special additional functionalities such as antimicrobial action). For example, the impact resistance of polybutadiene (rubber) can be improved by grafting styrene onto it to make high-impact polystyrene, while grafting both styrene and acrylonitrile to make acrylonitrile-butadiene-styrene (ABS) polymers improves solvent resistance. Other commercially important examples include graft copolymers containing acrylic monomers which are used as pressure-sensitive adhesives, self-plasticizing poly(vinyl chloride) [PVC] which is produced by grafting poly(butyl acrylate) onto the PVC backbone, and blend compatibilizers which are obtained by grafting two otherwise immiscible polymers. When copolymers of hydrophilic and hydrophobic blocks are grafted onto a polymer backbone, they can function as unimolecular cylindrical micelles, and are of interest as potential nanoreactors and in drug delivery applications. *See* POLYVINYL RESINS.

Graft copolymers can be prepared using three main strategies: grafting onto, grafting from, and grafting through. In the grafting-onto approach, a preformed polymer with an active end group is attached onto the backbone of another preformed polymer at functional groups along the polymer chain. For example, polystyrene can be chlormethylated via treatment with chloromethyl ether in the presence of a catalyst, and then reacted with living polymeric chains. The grafting-from approach also begins with a polymer backbone but then grows the grafts from initiation sites along this backbone. These sites can be introduced to the backbone during its original preparation, via polymerization or copolymerization of a monomer that contains initiation sites. For example, a graft copolymer can be formed by the copolymerization of propylene with a monomer containing an alkoxyamine functional group. This functional group (which is inert at the temperature of the first polymerization) can then be used to initiate nitroxide-mediated polymerization of styrene in a controlled fashion. Alternatively, one can prepare a normal homopolymer and introduce the initiation sites as a separate reaction. For example, polystyrene can be treated with *N*-bromosuccinimide to brominate the polymer backbone at random intervals; the resulting bromide groups can then act as initiating sites for the polymerization of various vinylic monomers (by ATRP). *See* POLYSTYRENE RESIN.

In the grafting-through approach, one first prepares a macromonomer that is, a polymer with an end group that can be copolymerized with a second monomer. Macromonomers can be prepared using functional initiators or chain terminating agents. For example, polymers containing terminal olefinic bonds [carbon-carbon double bonds ($C{=}C$)] can be prepared in conventional radical polymerization in the presence of a catalytic chain-transfer agent. These monomers can then undergo radical copolymerization with a second olefinic monomer to yield graft copolymer.

Step copolymers. In a step polymerization process, a polymer is formed via the stepwise reaction of two different types of functional groups (such as an acid and an alcohol, or an acid and an amine) on multifunctional monomers. In many instances, the different types of functional groups are located on separate types of monomer (for example, a polyester is often made by reacting a diacid with a dialcohol), and a step homopolymer might be thought of as an alternating copolymer. However, in practice the entire ester linkage is defined as the repeating unit, and the term "copolymer" is reserved for polymers containing different types of repeat units.

As in the case of chain polymerization, statistical copolymers are formed from mixtures of monomers, such as two different types of acid with one or more types of alcohol, or two or more types of amine with one or more types of alcohol. For example, the crystallization and processing rates of poly(ethylene terephthalate) [PET] is improved by copolymerizing ethylene glycol and 1,4-butanediol with dimethyl terephthalate, while flame-retardant polycarbonates can be obtained by copolymerizing bisphenol A and its tetrabromo derivative.

In step polymerization, it is possible to make statistical copolymers not only from a mixture of monomers but also from a mixture of homopolymers. For example, if two different polyesters are heated under vacuum they will transesterify, resulting in the scrambling of their repeat units. Depending on how far the reaction is driven, one can obtain a range of sequence distributions ranging from blocks to fully random copolymers. This scrambling via interchange makes it difficult to synthesize block copolymers from homopolymers containing the same type of functional group. However, as seen above, it is possible to produce block or graft copolymers involving step polymers and various types of chain polymers. One important example is the multiblock copolymers of polyurethanes and butadiene, which function as thermoplastic elastomers. Michelle L. Coote

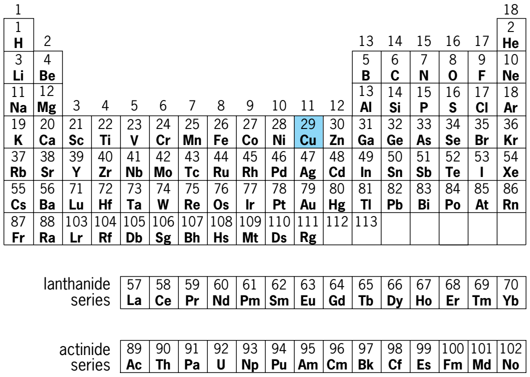
Copper

A chemical element, Cu, atomic number 29, atomic weight 63.546. Copper, a nonferrous metal, is the twentieth most abundant element present in the Earth's crust, at an average level of 68 parts per million (0.22 lb/ton or 0.11 kg/metric ton). Copper metal and copper alloys have considerable technological importance due to their combined electrical, mechanical, and physical properties. The discoveries that mixed-valence Cu(II)/Cu(III) oxides exhibit superconductivity (zero electrical resistance) at temperatures as high as 125 K (−234°F; liquid nitrogen, a cheap coolant, boils at 90 K or −297°F) have generated intense international competition to understand these new materials and to develop technological applications. Although some pure copper metal is present in nature, commercial copper is obtained by reduction of the copper compounds in ores followed by electrolytic refining. The rich chemistry of copper is restricted mostly to the valence states Cu(I) and Cu(II); compounds containing Cu(0), Cu(III), and Cu(IV) are uncommon. Soluble copper salts are potent bacteriocides and algicides at low levels and toxic to humans in large doses. Yet copper is an essential trace element that is present in various metalloproteins required for the survival of plants and animals. *See* COPPER ALLOYS.



Copper is located in the periodic table between nickel and zinc in the first row of transition elements and in the same subgroup as the other so-called coinage metals, silver and gold. The electronic configuration of elemental copper is [$1s^2 2s^2 2p^6 3s^2$] $3d^{10}4s^1$ or [argon]$3d^{10}4s^1$. At first glance, the sole $4s$ electron might suggest chemical similarity to potassium, which has the [argon]$4s^1$ configuration. However, metallic copper, in sharp contrast to metallic potassium, is relatively unreactive. The higher nuclear charge of copper relative to that of potassium is not fully shielded by the 10 additional d electrons, with the result that the copper $4s$ electron has a higher ionization potential than that of potassium (745.5 versus 418.9 kilojoules/mole, respectively). Moreover, the second and third ionization potentials of copper (1958.1 and 3554 J/mole, respectively) are considerably lower than those of potassium, and account for the higher valence-state accessibility associated with transition-metal chemistry as opposed to alkali-metal chemistry. *See* PERIODIC TABLE; TRANSITION ELEMENTS; VALENCE.

Copper is a comparatively heavy metal. The density of the pure solid is 8.96 g/cm^3 (5.18 oz/in.^{3}) at 20°C (68°F). The density of commercial copper varies with method of manufacture, averaging 8.90–8.92 g/cm^3 (5.14–5.16 oz/in.^{3}) in cast refinery shapes, 8.93 g/cm^3 (5.16 oz/in.^{3}) for annealed tough-pitch copper, and 8.94 g/cm^3 (517 oz/in.^{3}) for oxygen-free copper. The density of liquid copper is 8.22 g/cm^3 (4.75 oz/in.^{3}) near the freezing point.

The melting point of copper is 1083.0 $\mp$ 0.1°C (1981.4 $\mp$ 0.2°F). Its normal boiling point is 2595°C (4703°F).

The coefficient of linear expansion of copper is 1.65×10^{-5}/°C at 20°C.

The specific heat of the solid is 0.092 cal/g at 20°C (68°F). The specific heat of liquid copper is 0.112 cal/ g, and of copper in the vapor state about 0.08 cal/g.

The electrical resistivity of copper in the usual volumetric unit, that of a cube measuring 1 cm in each direction, is 1.6730×10^{-6} ohm · cm at 20°C (68°F). Only silver has a greater volumetric conductivity than copper. On a relative basis in which silver is rated 100, copper is 94, aluminum 57, and iron 16.

The mass resistivity of pure copper for a length of 1 m weighing 1 g at 20°C (68°F) is 0.14983 ohm. The conductivity of copper on the mass basis is surpassed by several light metals, notably aluminum. The relative values are 100 for aluminum, 50 for copper, and 44 for silver.

By far the largest use of copper is in the electrical industry, and therefore high electrical conductivity is its most important single property, although for industrial use this property must be accompanied by suitable characteristics in other respects. *See* CONDUCTOR (ELECTRICITY); ELECTRICAL CONDUCTIVITY OF METALS.

Copper-containing proteins provide diverse biochemical functions, including copper uptake and transport (ceruloplasmin), copper storage (metallothionen), protective roles (superoxide dismutase), catalysis of substrate oxygenation (dopamine β-monooxygenase), biosynthesis of connective tissue (lysyl oxidase), terminal oxidases for oxygen metabolism (cytochrome *c* oxidase), oxygen transport (hemocyanin), and electron transfer in photosynthetic pathways (plastocyanin). *See* BIORGANIC CHEMISTRY; ENZYME. Copper alloys

Solid solutions of one or more metals in copper. Many metals, although not all, alloy with copper to form solid solutions. Some insoluble metals and nonmetals are intentionally added to copper alloy to enhance certain characteristics. Copper alloys form a group of materials of major commercial importance because they are characterized by such useful mechanical properties as high ductility and formability and excellent corrosion resistance. Copper alloys are easily joined by soldering and brazing. Like gold alloys, copper alloys have decorative red, pink, yellow, and white colors. Copper has the second highest electrical and thermal conductivity of any metal. All these factors make copper alloys suitable for a wide variety of products.

Wrought alloys. Copper and zinc melted together in various proportions produce one of the most useful groups of copper alloys, known as the brasses. Six different phases are formed in the complete range of possible compositions. The relationship between composition and phases alpha, beta, gamma, delta, epsilon, and eta are graphically shown in the well-established constitution diagram for the copper-zinc system. Brasses containing 5–40% zinc constitute the largest volume of copper alloys. One important alloy, cartridge brass (70% copper, 30% zinc), has innumerable uses, including cartridge cases, automotive radiator cores and tanks, lighting fixtures, eyelets, rivets, screws, springs, and plumbing products. Tensile strength ranges from 45,000 lb/in.^{2} (310 megapascals) as annealed to 130,000 lb/in.^{2} (900 MPa) for spring temper wire. *See* BRASS; PHASE EQUILIBRIUM.

Lead is added to both copper and the brasses, forming an insoluble phase which improves machinability of the material. Free cutting brass (61% copper, 3% lead, 36% zinc) is the most important alloy in the group. In rod form it has a strength of 50,000–70,000 lb/in.^{2} (340–480 MPa), depending upon temper and size. It is machined into parts on high-speed (10,000 rpm) automatic screw machines for a multiplicity of uses.

Increased strength and corrosion resistance are obtained by adding up to 2% tin or aluminum to various brasses. Admiralty brass (70% copper, 2% aluminum, 0.023% arsenic, 21.97% zinc) are two useful condenser-tube alloys. The presence of phosphorus, antimony, or arsenic effectively inhibits these alloys from dezincification corrosion.

Alloys of copper, nickel, and zinc are called nickel silvers. Typical alloys contain 65% copper, 10–18% nickel, and the remainder zinc. Nickel is added to the copper-zinc alloys primarily because of its influence upon the color of the resulting alloys; color ranges from yellowish-white, to white with a yellowish tinge, to white. Because of their tarnish resistance, these alloys are used for table flatware, zippers, camera parts, costume jewelry, nameplates, and some electrical switch gear.

Copper forms a continuous series of alloys with nickel in all concentrations. The constitution diagram is a simple all alpha-phase system.

Nickel slightly hardens copper, increasing its strength without reducing its ductility. Copper with 10% nickel makes an alloy with a pink cast. More nickel makes the alloy appear white.

Three copper-base alloys containing 10%, 20%, and 30% nickel, with small amounts of manganese and iron added to enhance casting qualities and corrosion resistance, are important commercially. These alloys are known as cupronickels and are well suited for application in industrial and marine installations as condenser and heat-exchanger tubing because of their high corrosion resistance and particular resistance to impingement attack. Heat-exchanger tubes in desalinization plants use the cupronickel 10% alloy.

Copper-tin alloys (3–10% tin), deoxidized with phosphorus, form an important group known as phosphorus bronzes. Tin increases strength, hardness, and corrosion resistance, but at the expense of some workability. These alloys are widely used for springs and screens in papermaking machines.

Silicon (1.5–3.0%), plus smaller amounts of other elements, such as tin, iron, or zinc, increases the strength of copper, making alloys useful for hardware, screws, bolts, and welding rods.

Sulfur (0.35%) and tellurium (0.50%) form insoluble compounds when alloyed with copper, resulting in increased ease of machining.

Precipitation-hardenable alloys. Alloys of copper that can be precipitation-hardened have the common characteristic of a decreasing solid solubility of some phase or constituent with decreasing temperature. Precipitation is a decomposition of a solid solution leading to a new phase of different composition to be found in the matrix. In such alloy systems, cooling at the appropriate rapid rate (quenching) from an equilibrium temperature well within the all-alpha field will preserve the alloy as a single solid solution possessing relatively low hardness, strength, and electrical conductivity.

A second heat treatment (aging) at a lower temperature will cause precipitation of the unstable phase. The process is usually accompanied by an increase in hardness, strength, and electrical conductivity. Some 19 elements form copper-base binary alloys that can be age- or precipitation-hardened. *See* HEAT TREATMENT (METALLURGY).

Two commercially important precipitation-hardenable alloys are beryllium- and chromium-copper. Beryllium-copper (2.0–2.5% beryllium plus cobalt or nickel) can have a strength of 200,000 lb/in.^{2} (1400 MPa) and an electrical conductivity of less than 50% of IACS (International Annealed Copper Standard). Cobalt adds high-temperature stability, and nickel acts as a grain refiner. These alloys find use as springs, diaphragms, and bearing plates and in other applications requiring high strength and resistance to shock and fatigue.

Copper chromium (1% chromium) can have a strength of 80,000 lb/in.^{2} (550 MPa) and an electrical conductivity of 80%. Copper-chromium alloys are used to make resistance-welding electrodes, structural members for electrical switch gear, current-carrying members, and springs.

Copper-nickel, with silicon or phosphorus added, forms another series of precipitation-hardenable alloys. Typical composition is 2% nickel, 0.6% silicon. Strength of 120,000 lb/in.^{2} (830 MPa) can be obtained with high ductility and electrical conductivity of 32% IACS.

Zirconium-copper is included in this group because it responds to heat treatment, although its strength is primarily developed through application of cold deformation or work. Heat treatment restores high electrical conductivity and ductility and increases surface hardness. Tensile strength of 70,000 lb/in.^{2} (500 MPa) coupled with an electrical conductivity of 88% can be developed. Uses are resistance welding wheels and tips, stud bases for transistors and rectifiers, commutators, and electrical switch gear.

Fabrication. Copper alloys have a long history because of their ease of fabrication into utensils and products.

Melting. Alloys are initially prepared by melting the various elements involved in low-frequency induction furnaces. Usually the melt is protected from oxidation by covering it with charcoal. Copper-rich alloys are also deoxidized by adding elements such as phosphorus, lithium, or boron. The melt is usually poured at 100–200°F (38–93°C) above its melting point into oil- and graphite-dressed, water-cooled copper molds of suitable shape. The dressing protects the mold surfaces, produces a reducing gas that aids in the suppression of oxidation, and brings dirt and dross to the molten surface, preventing their inclusion in the casting.

Continuous casting of copper and its alloys is common practice and is accomplished by pouring the melt into the top of an open-end mold as the solidified casting is withdrawn from the bottom. Various mold designs are used, but all use water to cool the mold proper in addition to cooling sprays and tanks of water below the mold. Casting can be performed in either a vertical or a horizontal plane.

Mechanical properties of castings can be affected by such defects as large grain size, directional grain growth, and segregation. Either hot-working of the casting by rolling, forging, piercing, or extrusion, or cold-working by rolling or drawing with necessary intermediate annealing corrects these defects and markedly improves properties.

Processing. Processing varies with alloy, form, and size. Flat products are cast in heavy cakes for initial hot-rolling or in bars for cold-rolling. Copper and lead-free brasses are readily hot-rolled in a single heating from a 9-in. (23-cm) thick cake to a $^1/_2$ in. (1.25-cm) thick slab. Further rolling is done cold with intermediate anneals. Leaded brasses, tin bronzes, and other hot short alloys (alloys that are brittle when heated above red heat) must be cold-rolled from the casting to final size, using intermediate anneals that heat the particular alloy above its recrystallization temperature.

Round copper rods and wire are started by hot-rolling castings (wire bar) in grooved rolls, but most copper alloys are extruded. Both are subsequently reduced in size by cold-rolling, drawing, or both. In extrusion, a billet placed in a press is forced through a lubricated die by a ram.

Tin and tin-lead bronzes which are hot short are continuously cast in rod form and are cold-rolled or drawn to finish sizes using intermediate anneals as necessary.

Copper and high-copper-content lead-free brass tubes are started by hot piercing wherein the solid billet is driven with a helical motion over a rotating mandrel to form a seamless tube. Tubes of most other alloys are formed by extrusion because the alloys do not stand piercing. In extrusion of tube, a mandrel is pushed through a billet forming the inside of the tube, and a ram pushes the billet over the mandrel and through a die to form a seamless tube.

Cast alloys. Copper alloy castings of irregular and complex external and internal shapes can be produced by various casting methods, making possible the use of shapes for superior corrosion resistance, electrical conductivity, good bearing quality, and other attractive properties. High-copper alloys with varying amounts of tin, lead, and zinc account for a large percentage of all copper alloys used in the cast form. Tensile strength ranges from 36,000 to 48,000 lb/in.^{2} (250–330 MPa) depending upon composition and size. Leaded tin-bronzes with 6–10% tin, about 1% lead, and 4% zinc are used for high-grade pressure castings, valve bodies, gears, and ornamental work. Bronzes high in lead and tin (7–25% lead and 5–10% tin) are mostly used for bearings. High tin content is preferred for heavy pressures or shock loading, but lower tin and higher lead for lighter loads, higher speeds, or where lubrication is less certain. A leaded red brass containing 85% copper and 5% each of tin, lead, and zinc is a popular alloy for general use.

High-strength brasses containing 57–63% copper, small percentages of aluminum and iron, and the balance zinc have tensile strengths from 70,000 to 120,000 lb/in.^{2} (490–830 MPa), high hardness, good ductility, and resistance to corrosion. They are used for valve stems and machinery parts requiring high strength and toughness.

Copper alloys containing less than 2% alloying elements are used when relatively high electrical conductivity is needed. Strength of these alloys is usually notably less than that of other cast alloys.

Aluminum bronzes containing 5–10.5% aluminum, small amounts of iron, and the balance copper have high strengths even at elevated temperature, high ductility, and excellent corrosion resistance. The higher-aluminum-content castings can be heat-treated, increasing their strength and hardness. These alloys are used for acid-resisting pump parts, pickling baskets, valve seats and guides, and marine propellers.

Additives impart special characteristics. Manganese is added as an alloying element for high-strength brasses where it forms intermetallic compounds with other elements, such as iron and aluminum. Nickel additions refine cast structures and add toughness, strength, and corrosion resistance. Silicon added to copper forms copper-silicon alloys of high strength and high corrosion resistance in acid media. Beryllium or chromium added to copper forms a series of age- or precipitation-hardenable alloys. Copper-beryllium copper alloys are among the strongest of the copper-base cast materials. *See* ALLOY; COPPER; METAL CASTING; METAL FORMING.

Copper loss

The power loss caused by the flow of current through copper conductors. When an electric current flows through a copper conductor (or any conductor), some energy is converted to heat. The heat, in turn, causes the operating temperature of the device to rise. This happens in transformers, generators, motors, relays, and transmission lines, and is a principal limitation on the conditions of operation of these devices. Excessive temperature rises lead to equipment failure. *See* CONDUCTOR (ELECTRICITY).

If the resistance R (in ohms) and the current I (in amperes) are both known, the copper loss in watts may be found from the equation $P = I^2R$. An alternative form is to know the voltage across the resistor V (in volts) and to determine the power loss by the equation $P = V^2/R$. V and I are effective values of the voltage and current, respectively. The resistance R varies with both frequency and temperature. *See* ELECTRICAL RESISTANCE.

In electric machines, there are typically constant losses, as well as those that vary with the square of the load, such as the copper loss. Maximum efficiency is obtained when the load is adjusted so as to make the constant and varying losses equal.

Since the discovery of superconductivity in 1911, much effort has been directed toward the development of devices based on superconducting principles, with superconductors replacing the copper coils in electrical devices and systems in order to reduce or eliminate copper loss. Since superconductors have traditionally operated at temperatures close to absolute zero (0 K or −459.67°F), such devices are practical only if the power required to operate the refrigeration equipment is less than the copper loss that is supplanted. In 1986, a ceramic superconductor, lanthanum barium copper oxide, was discovered whose superconducting temperature was 30 K (−406°F), and by 1988 another ceramic, thallium barium calcium copper oxide, was shown to have a superconducting temperature of 125 K (−235°F). The rapid increase of superconducting temperatures has given new hope to the idea of reducing copper loss. However, the process of going from a scientific discovery to technological realization requires solutions to many technical problems as well as complex problems involving economic, reliability, safety, and related considerations. *See* SUPERCONDUCTING DEVICES; WIRING.

Copper metallurgy

The economic production of pure copper metal, suitable for fabrication and use, from copper ores containing as little as 0.5% Cu. Over 90% of the consumption of primary copper in the Western world is produced from ores containing sulfide minerals (chalcopyrite, $CuFeS_2$; chalcocite, Cu_2S; and bornite, Cu_5FeS_4) that can be economically treated only by pyrometallurgical processes. *See* PYROMETALLURGY, NONFERROUS.

Production. The main processes used in the production of copper from sulfide ores are shown in **Fig. 1**. The mined ore (0.5–2.0% Cu) is finely ground, and then concentrated by flotation to form copper concentrates containing 20–30% Cu. The concentrates are then smelted at high temperatures (about 2280°F or 1250°C) to form a molten mixture of copper and iron sulfides called matte. The molten matte

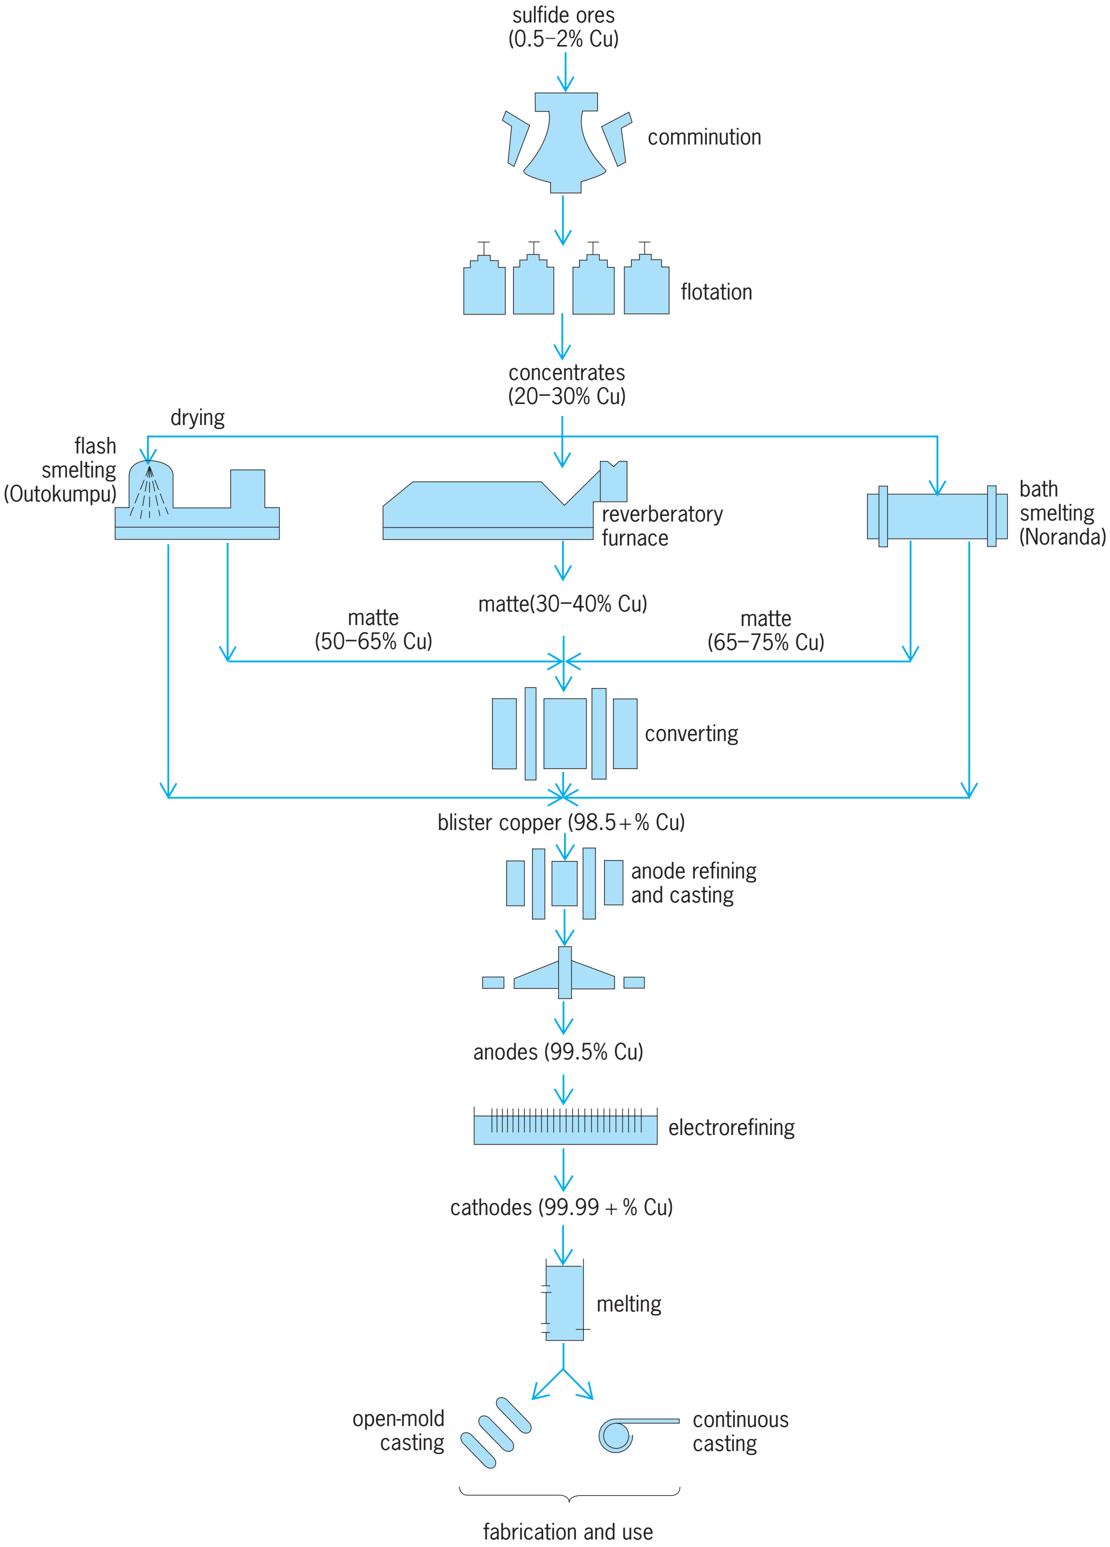

Fig. 1. Flow sheet of copper production from sulfide minerals.

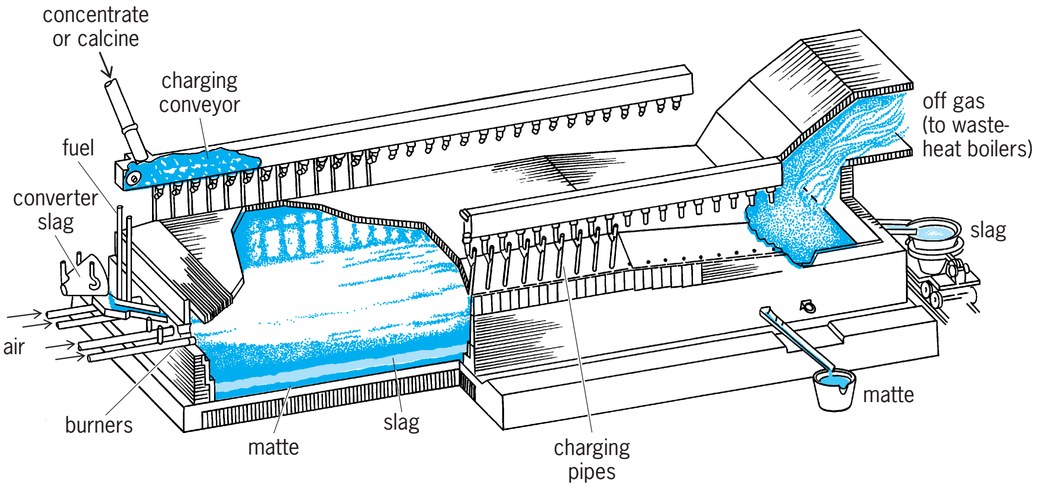

Fig. 2. **Cutaway view of a reverberatory furnace for the production of copper matte from sulfide concentrates or roasted calcines. (*After A. K. Biswas and W. D. Davenport, Extractive Metallurgy of Copper, Pergamon Press, 1980*)**

is converted to blister copper (about 99% Cu) by oxidizing the remaining iron and sulfur. After removing the residual sulfur and oxygen in an anode furnace, copper anodes are cast and then refined electrolytically to produce high-purity cathode copper (99.99% Cu), which is suitable for most uses. *See* ORE DRESSING.

Smelting processes. The reverberatory furnace (**Fig. 2**) is the oldest and most widely used smelting process. It consists of a refractory-lined chamber, typically 100 ft (30 m) long by 30 ft (10 m) wide, into which copper concentrates and silica flux are charged. Fuel-fired burners melt the charge, driving off the labile sulfur by reaction (1). Little iron sulfide is oxidized, so that fuel requirements are high, about 5.4 × 10^6 Btu per ton (6.3 × 10^6 kilojoules per metric ton) of Cu concentrate. Two molten layers are formed in the furnace: an upper layer slag of iron silicate with little copper (≤0.5% Cu); and a lower layer of matte (30–40% Cu), containing most of the original copper value. The slag and matte are drained separately from the furnace through tapholes into ladles. The slag is discarded, while the matte is transferred to the converting step. The sulfur evolved during smelting leaves the furnace in a 1–2% SO_2 gas stream, which is too dilute for economic treatment.

$$2CuFeS_2 \rightarrow Cu_2S \cdot 2FeS(l) + {}^1/_2S_2(g) \qquad (1)$$

The reverberatory furnace cannot meet today's requirements for low-energy consumption and stringent environmental control. Therefore more efficient smelting processes have been developed since the 1960s. These processes use much less energy (typically 0.7–1.8 × 10^6 Btu per ton or 0.8–2.1 × 10^6 kJ per metric ton of Cu concentrate) and produce a strong SO_2 gas stream (10% SO_2) to reduce treatment costs. These processes use oxygen enrichment, and oxidize more iron sulfide to generate more heat and produce mattes with higher copper levels (50–75% Cu). The smelting reaction for these processes can be represented by reaction (2), where

$$2CuFeS_2 + 2\alpha \cdot SiO_2 + (1 + 3\alpha)O_2 \rightarrow$$
$$Cu_2S \cdot 2(1 - \alpha)FeS + 2\alpha \cdot FeO \cdot SiO_2 + (1 + 2\alpha)SO_2 \qquad (2)$$

α is the fraction of FeS reacted (typically, in range $\alpha = 0.5$ to 0.9).

Modern smelting processes fall into two categories: flash smelting (Outokumpu flash smelting furnace) and bath smelting (Noranda process reactor). In flash smelting, dry concentrate is dispersed in an oxidizing gas stream, and the smelting reactions occur very rapidly as the particles fall down a reaction shaft. The molten matte and slag are collected in a hearth, and the SO_2-containing gases exit through an uptake shaft. In bath smelting, moist concentrate is smelted continuously in a molten bath of matte and slag, which is vigorously stirred by the injection of air or oxygen-enriched air. In the Noranda process reactor, the air is injected through tuyeres into a vessel similar to an elongated converter.

Matte converting. The molten matte is converted to blister in Peirce-Smith converters. The converter is a refractory-lined, cylindrical vessel, typically 30 ft (10 m) in length and 13 ft (4 m) in diameter (**Fig. 3**). The converter can be rotated about its axis, and is fitted on one side with a row of about 50 tuyeres through which air is injected. The top of the converter has a large mouth for charging molten matte and removing slag and product copper. Converting is a batch operation; initially several ladles of matte are charged, the air turned on, and the converter rotated until the tuyeres are submerged. The air, bubbling violently through the bath, gradually oxidizes the matte in two stages. In the first or slag-forming stage, iron sulfide is oxidized and fluxed with silica to form a fluid slag by reaction (3). The converter

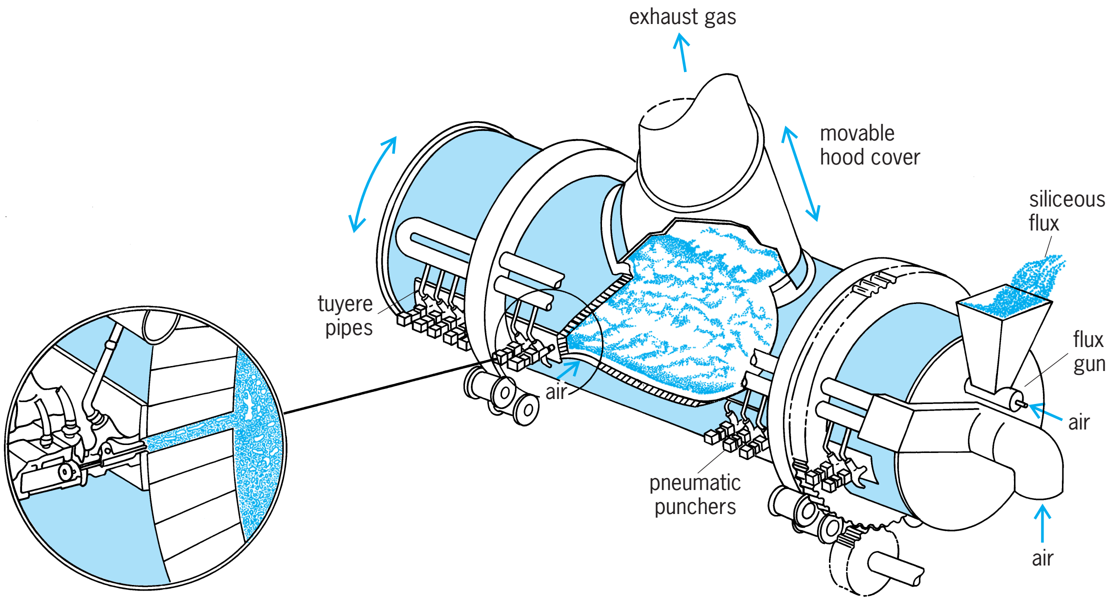

Fig. 3. Cutaway view of a horizontal side-blown Peirce-Smith converter for producing blister copper from matte. (*After A. K. Biswas and W. G. Davenport, Extractive Metallurgy of Copper, Pergamon Press, 1980*)

$$2FeS(l) + 2SiO_2(s) + 3O_2(g) \rightarrow 2FeO \cdot SiO_2(l) + 2SO_2(g) \qquad (3)$$

slag contains some copper (1–5% Cu), and is recycled to the smelting furnace or treated in a separate process. When all the iron has been removed, the remaining copper sulfide is further oxidized to blister copper by reaction (4). The converting process

$$Cu_2S(l) + O_2(g) \rightarrow 2Cu(l) + SO_2(g) \qquad (4)$$

is sufficiently exothermic that no additional fuel is required. The blister copper from the converter is transferred by ladle to the anode furnace, where the residual sulfur and oxygen levels in the copper are reduced further. The copper is then cast into anodes for electrorefining.

Sulfur fixation. Smelting and converting a typical copper concentrate generates over 0.50 ton SO_2 per ton concentrate (0.50 metric ton SO_2 per metric ton concentrate), and the resulting SO_2 emissions must be controlled to meet local environmental standards. This is generally achieved by converting the SO_2 to sulfuric acid in a contact acid plant, as long as the SO_2 concentration exceeds 4% and a viable market for acid exists. If local conditions are favorable, it is also possible to make liquid SO_2 or elemental sulfur from strong SO_2 gases. *See* SULFUR.

Electrorefining. The objective of electrorefining is to remove the remaining impurities in the anode copper (principally As, Bi, Ni, Pb, Sb, and Se) and produce a pure cathode copper (99.99+% Cu). Also, many copper ores contain appreciable amounts of precious metals (Ag, Au, Pt, and so on), which are concentrated into the anode copper during smelting and are recovered as valuable by-products in electrorefining. The impure anodes are suspended alternately with pure copper cathodes in tanks through which an electrolyte of copper sulfate and free sulfuric acid is continuously circulated. When direct current is applied, the copper in the anodes is electrochemically dissolved and then plated as pure copper on the cathodes. Some of the anode impurities, such as arsenic and nickel, are less noble than copper and dissolve in the electrolyte, but they do not plate out at the cathode as long as their concentrations are controlled. The other impurities, such as silver, lead, and selenium, are virtually insoluble in the electrolyte and fall as slimes to the bottom of the tank. These slimes are recovered and processed for eventual recovery of selenium and the precious-metal values. *See* ELECTROCHEMICAL PROCESS; ELECTROMETALLURGY.

Hydrometallurgical processes. Oxidized copper ores are more effectively treated by hydrometallurgical processes. The ore is crushed, ground if necessary, and leached with dilute sulfuric acid, either by percolation through heaps of ore or by agitation in tanks. Copper is recovered from the resulting solution by either cementation or solvent extraction–electrowinning. In cementation, copper is precipitated by contact with scrap iron to form an impure cement copper, which is smelted, then refined. Solvent extraction–electrowinning has become the preferred process. In solvent extraction special organic reagents are used to selectively extract copper from solution. The resulting copper-containing organic phase is then stripped to give a pure and more concentrated aqueous copper solution for electrowinning. Electrowinning is similar to electrorefining except that an inert anode is used and more energy is required. Although electrowon cathode copper is generally not as pure as electrorefined copper, it is still suitable for many applications. *See* HYDROMETALLURGY; SOLVENT EXTRACTION.

Future trends. Considerable progress has been made in improving the efficiency of copper smelting since the 1960s through new process innovations and the use of oxygen in large tonnages. The trend toward the production of higher-matte grades (up to 75% Cu) is expected to continue in order to minimize energy requirements and SO_2-fixation costs. Pyrometallurgical processes will continue to dominate primary copper production, and it is anticipated that the ultimate goal of direct copper production from chalcopyrite concentrates in a single smelting and converting vessel will be achieved. *See* COPPER.

Copulatory organ

An organ utilized by the male animal for insemination, that is, to deposit spermatozoa directly into the female reproductive tract. Various types of copulatory organs are found among the vertebrates, whereas cloacal apposition occurs in most other vertebrates which lack these structures. Amplexus, or false copulation, is peculiar to amphibians.

In fish, internal fertilization is restricted to certain groups. The pelvic fin of male elasmobranchs and holocephalians is modified for the transmission of sperm and is known as the clasper or clasping organ. A pair of anterior claspers (**Fig. 1***a*) and a frontal clasper which protrudes from the head occur among holocephalians in addition to the modified pelvic clasper of elasmobranchs. The anal fin of teleosts, in which copulation occurs, may be elongated to form a gonopodium. Copulatory organs are lacking in amphibians, even in those in which internal fertilization occurs. Among caecelians, the cloaca of the male is muscular and protrusible; however, it is questionable that this structure is a true copulatory organ. Hemipenes which can be everted during copulation are common to both snakes and lizards; however, these structures lack erectile tissue. Turtles and crocodiles possess a single penis with associated erectile tissue, the corpora cavernosa, which becomes distended with blood. A few species of birds have a penis; among these are the ostriches and anseriforms. The penis is present in all mammals.

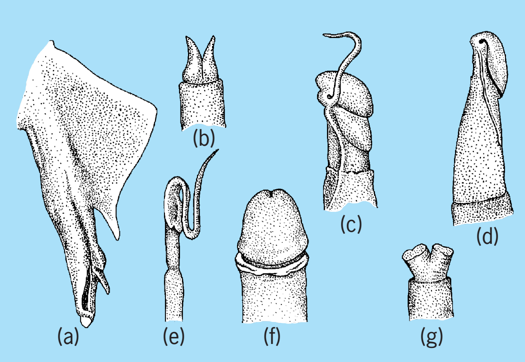

Fig. 1. Vertebrate copulatory organs. (*a*) Clasper of dogfish (*Squalus*). Glans penis of (*b*) opossum, (*c*) ram, (*d*) bull, (*e*) short-tailed shrew, (*f*) man, (*g*) Echidna.

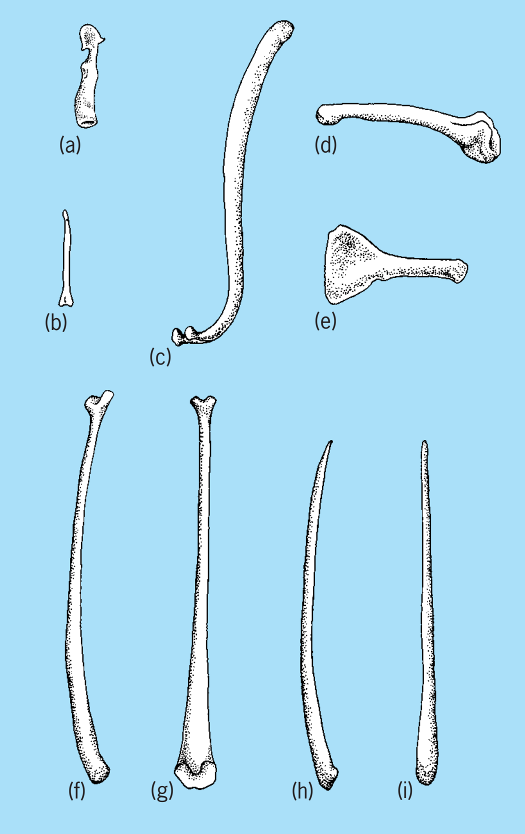

Fig. 2. Bacula of (*a*) fox squirrel, (*b*) cotton mouse, (*c*) otter, (*d*) *Neotoma lepida*, (*e*) *N. micropus*, (*f, g*) *Perognathus hispidus*, showing lateral and ventral views, (*h, i*) *P. baileyi*, showing lateral and ventral views.

This copulatory organ (Fig. 1*b–g*) is variously modified morphologically. Among certain mammals such as rodents, bats, whales, some carnivores, and lower primates, a penis bone, known as the os priapi or baculum (**Fig. 2**), occurs, increasing the rigidity of the penis. *See* FERTILIZATION; PENIS; REPRODUCTIVE SYSTEM.

Charles B. Curtin

Coquina

A calcarenite or clastic limestone whose detrital particles are chiefly fossils, whole or fragmented. The term is most frequently used for an aggregate of large shells more or less cemented by calcite. If the rock consists of fine-sized shell debris, it is called a microcoquina. Encrinite is a microcoquina made up primarily of crinoid fragments (see **illus.**). Some coquinas show little evidence of any transportation by currents; articulated bivalves are preserved in

Coquinoid limestone, encrinite, showing many entire fossils in fine-grained matrix. Note lack of assortment and diversity of types. (*From F. J. Pettijohn, Sedimentary Rocks, 3d ed., Harper and Row, 1949, 1957*)

entirety and the shells are not broken or abraded. *See* LIMESTONE. Raymond Siever

Coraciiformes

A diverse order of land birds found mainly in the tropics. The interrelationships of several families have been disputed, with no resolution. The closest affinities of the coraciiforms may be with other land birds, such as the Piciformes and Passeriformes. *See* PASSERIFORMES; PICIFORMES.

Classification. The Coraciiformes are divided into four suborders and families: Alcedines, including the families Alcedinidae (kingfishers; 91 species; worldwide, but mainly Old World tropics to Australasia), Todidae (todies; five species; West Indies), and Momotidae (motmots; nine species; New World tropics); Meropes, with the single family Meropidae (bee-eaters; 24 species; Old World to Australia, mainly tropics); Coracii, containing the families Coraciidae (rollers; 12 species; Old World to Australia, mainly tropics), Brachypteraciidae (ground-rollers; five species; Madagascar), Leptosomatidae (cuckoo-rollers; one specie; Madagascar); and Bucerotes, with the families Upupidae (hoopoes; one specie; Old World), Phoeniculidae (wood-hoopoes; eight species; Africa) and Bucerotidae (hornbills; 45 species; Old World tropics to New Guinea).

Several of these families, such as the different groups of rollers, are sometimes merged into a single family, and several groups, such as the kingfishers (**Fig. 1**) and hornbills (**Fig. 2**), are divided into subfamilies or even families.

Fossil record. The fossil record of this group of basically forest birds is rather poor; however, there are a number of specimens known that appear to belong to the Coraciiformes. A better picture of the history and relationships of this order may appear once these fossils are better studied. Most interesting is a fossil tody (a group now restricted to the Greater Antilles) from the Oligocene of Wyoming, and a second fossil tody from the Eo-oligocene of France, and a fossil motmot (a group that is now restricted to the American tropics) from the Oligocene of Switzerland. The identification of these fossils as such is controversial, but, if correct, suggests an earlier, broader distribution of several coraciiform families.

Characteristics. Coraciiform birds are characterized by a syndactyl foot in which the three anterior toes are joined at the base, although the cuckoo-rollers have evolved secondarily a zygodactyl foot

Fig. 1. Malachite kingfisher (*Alcedo cristata*), Africa. (*Photo by H. Vannoy Davis; © 2001 California Academy of Sciences*)

(in which the toes are arranged two in front and two behind). Most groups are tropical or warm temperate and are brilliantly colored. Except for bee-eaters and wood-hoopoes, coraciiforms are generally solitary. Most temperate species are migratory; the tropical ones are permanent residents. Most coraciiforms feed on insects and other animal prey, including fish; hornbills are omnivorous and some feed mainly on fruit. All nest, either solitarily or in colonies, in holes burrowed in earthen banks or in tree cavities. Wood-hoopoes and bee-eaters have young adults serving as helpers at the nest. The chicks are born naked and cared for by both parents until they can fly. The pair of central tail feathers of most motmots have racquet tips formed by the falling off of more anterior, weakly attached barbs.

Todies, motmots, and one small subfamily of kingfishers are found in the New World, but all other coraciiforms live in the Old World, suggesting the origin of this order in that part of the world. The kingfishers (Fig. 1) are the largest and most diversified family, with many members catching their prey on dry land. The largest and most famous kingfisher is the kookaburra or laughing jackass (*Dacelo novaeguinaea*) of Australia. Rollers are widespread throughout the Old World tropics, but the ground-rollers and the cuckoo-rollers are restricted to Madagascar. Wood-hoopoes are confined to the tropical forests of Africa, while the related hoopoes are widespread throughout Europe and Asia.

The hornbills (Fig. 2) are the largest of the coraciiforms, feed in forests, and are excellent soarers. A number of species possess a large casque on the base of the upper jaw which may serve in courtship or species recognition. The male helmeted hornbill (*Rhinoplax vigil*) of the Malay Peninsula and Indonesia has a solid casque of a thick rhamphotheca (horny covering of the beak) backed by massive bone, making its skull the heaviest of all known Recent birds. Male hornbills seal up the female with her eggs in the nesting cavity in a large tree, and feed her and the chicks until the young birds are ready to fly. During this period, the female undergoes a complete molt. Some species of hornbills are threatened because of habitat destruction, especially the loss of large trees with suitable nesting cavities. *See* AVES.

Corallimorpharia

An order of cnidarian subclass Hexacorallia commonly known as mushroom anemones. These polyps are morphologically intermediate between members of the hexacorallian orders Scleractinia (corals), with which they share features of internal anatomy, weak musculature, and certain types of nematocysts (intracellular stinging capsules used in food capture and defense), and Actiniaria (anemones), which they resemble in lacking a calcareous skeleton. All three animals have paired, coupled mesenteries that are added around the entire periphery of the polyp. Like Actiniaria and Scleractinia, Corallimorpharia contains some members that are solitary and some that are clonal (reproduce asexually to produce genetically identical individuals that live physically separate from one another); however, by contrast with Scleractinia, Corallimorpharia has no colonial members (clonemates that remain attached to one another). *See* CNIDARIA.

Morphology. There are two distinct morphological variants of corallimorpharians. Members of one group live primarily at high altitudes in shallow water and in deep water (to about 5-km or 3-mi depth) at all latitudes. A typical polyp has a well-defined cylindrical column and an oral disc not much broader than the column. The unbranched tentacles are arranged in radial rows on the disc, and commonly each has a spherical tip (that is, it is capitate). Examples are *Corynactis* (**Fig. 1**), which has a typical oral disc diameter of about 10 mm, and *Corallimorphus*, which may attain a diameter of 100–150 mm (4–6 in.).

In members of the other, primarily tropical, group, the oral disc is much broader than the small column, and the tentacles, which may be arranged in rows or in cycles, can be branched or be mere bumps. Members of this group harbor symbiotic dinoflagellates (zooxanthellae), so they occur only in shallow water. Examples are *Actinotryx* (**Fig. 2**), which may have an oral disc diameter of 20–25 mm (1 in.), and *Amplexidiscus*, the largest corallimorpharian, which can reach an oral disc diameter of 250 mm (10 in.).

Phylogeny. Based on preliminary phylogenetic analyses using both morphological and molecular data, it is likely that the two morphological variants

Fig. 1. *Corynactis californica.* (*Photograph by George Miller*)

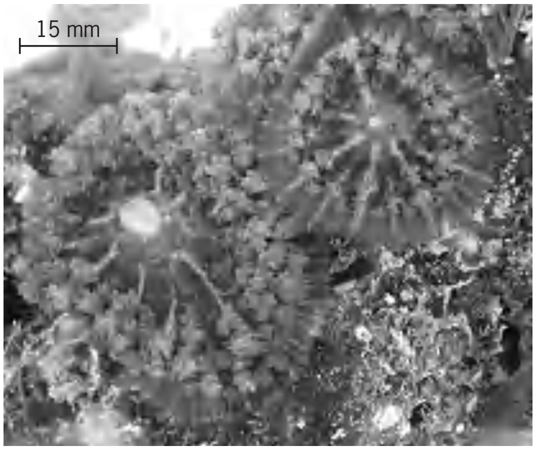

Fig. 2. ***Actinotryx sanctithomae.*** **(*Photograph by Ha-Rim Cha*)**

represent separate evolutionary lineages (that is, are polyphyletic). It seems likely that Corallimorpharia represents at least two taxa, derived independently from different types of scleractinians by loss of the skeleton. Indeed, it may be that corallimorpharians should be considered naked (askeletal) members of the order Scleractinia. Corallimorpharians have no fossil record because the animals lack skeletons. *See* ACTINIARIA; HEXACORALLIA; SCLERACTINIA.

Ecology. Corallimorpharians live in habitats typical of actiniarians and scleractinians. Some species proliferate on stressed coral reefs, attaching to skeletons of dying corals; it is uncertain whether the corallimorpharians merely take advantage of the dead coral skeleton as a substrate on which to grow, but they may kill the corals, for corallimorpharians can aggress toward other cnidarians by extruding their mesenterial filaments (the longitudinal band along the free edge of each mesentery). Like all cnidarians, corallimorpharians eat only animal prey, being opportunistic predators of small animals, such as crustaceans and fishes. The flat, shallow-water species have zooxanthellae, from which they presumably derive photosynthate as well. *See* REEF.

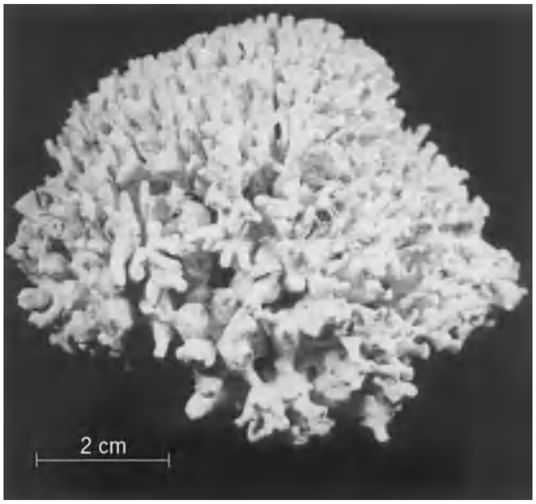
Corallinales

An order of red algae (Rhodophyceae), commonly called coralline algae. Only one family is recognized, the Corallinaceae, which formerly was assigned to the order Cryptonemiales. These algae are distinguished by the impregnation of cell walls with calcite, a form of calcium carbonate, which causes the thallus to be stony or brittle (see **illus.**). The few other red algae that are calcified are much softer than corallines and are impregnated with aragonite, another form of calcium carbonate. Many early biologists (including C. Linnaeus) thought that these plants were related to corals. *See* RHODOPHYCEAE.

Coralline algae, comprising about 40 genera and 500 species, are widespread, abundant, and ecologically important. They are divisible into two groups on the basis of the presence or absence of uncalcified, moderately flexible joints (genicula) between calcified segments (intergenicula). Those with genicula are called articulated coralline algae, while those totally lacking genicula are called nonarticulated or, with reference to their usual habit, crustose coralline algae. The erect portions (fronds) of articulated corallines usually arise from a crustose base. They vary in height from a few millimeters to 30 cm (12 in.) and are pinnately, dichotomously, or proliferously branched. Segments are cylindrical or flattened.

Structure. The most simple nonarticulated coralline algae are individual crusts of varying extent and thickness (to 20 cm or 8 in. thick). These often become confluent and cover large expanses of substrate. Many crusts bear rounded or pointed, branched or unbranched protuberances that can break off and continue to grow as free nodules known collectively as maerl. In some species, only part of the crust is attached to the substrate, the main portion growing free and resembling lichens or bracket fungi. In three genera of nonarticulated corallines, the thallus is ribbonlike, the linear segments being dichotomously branched, dorsiventrally organized, and flexible.

Coralline algae are cytologically similar to other red algae except for calcification of the cell wall. The wall consists of three layers: a thin, uncalcified inner layer; a thick, calcified middle layer; and a thin,



Coralline algae of the Pacific Ocean.

calcified outer layer or middle lamella. The calcite apparently is transported in vesicles from the cell lumen to the outer layers. Growth, which is restricted to uncalcified or decalcified areas or tissues, is usually very slow, especially at sites of low light intensity. Most corallines are perennial.

Reproduction. The life history follows the *Polysiphonia*-type, in which male and female plants alternate with a tetrasporophyte, all three phases being free-living and vegetatively identical or nearly so. Reproductive structures are produced in sunken or elevated chambers (conceptacles) with a roof penetrated by one or many pores. Tetraspores are produced by simultaneous zonate cleavage, a process unique to the order. They are relatively large and in most genera germinate in special patterns of cell division.

Habitat. Coralline algae are exclusively marine, although some species can tolerate a reduction in salinity to 13 parts per thousand. Some species thrive only where light is intense, as at the crest of a coral reef, while others grow only in shaded habitats or in deep water. Most species require constant immersion. Rock is the most common substrate in cold water, with some species preferring particular aspects, such as broad ledges, crevices, cobbles, or pebbles. Other hard substrates include shells, dead coral (the most common substrate in the tropics), and such artifacts as bottles and metal plates. Many corallines are obligate epiphytes, growing on other algae and on seagrasses, and a few overgrow such soft animals as sponges. An inconspicuous layer of corallines often underlies a turf of algae that at first glance appears to be growing directly on rock.

Unlike corals, coralline algae are equally abundant in cold or warm water, occurring from the Arctic to the Antarctic. At high latitudes, crustose corallines pave vast expanses of ocean floor. Along temperate shores, both crustose and articulated corallines are often abundant in tide pools. In areas of rough water, they typically form a broad band in the lowermost intertidal and uppermost subtidal zone. They may dominate deeper sites where herbivores consume fleshy algae. Stands of crustose corallines are made conspicuous by their bright pink or bluish-pink color.

The ecosystem in which coralline algae are most important is the coral reef, where they are primary producers, adding carbon to the ecosystem, adding new material to the reefs, and cementing together other calcareous organisms. They have been engaged in similar activities through the millennia, with modern genera recognizable in limestones at least as old as 150 million years (Jurassic). Paul C. Silva; Richard L. Moe

Fossils. Coralline algae are important frame builders and sediment producers in tropical reefs throughout Cenozoic time. Although scleractinian corals are volumetrically more important in most living reefs, crustose coralline algae are essential binding and cementing agents. Prominent coralline algae of tropical reefs today are *Neogoniolithon, Porolithon*, and *Lithoporella. Mesophyllum* and *Lithothamnium* are mainly cold-water genera, but they do occur in low-latitude regions in deep-water environments.

Coralline algae have a rather complete fossil record consisting of numerous genera and species. The earliest definite representatives of the Corallinaceae appeared in Jurassic time, although fossil forms with similar morphologies are known from late Paleozoic rocks. Coralline algae are some of the more common and widespread skeletal constituents in Cretaceous and Cenozoic marine rocks. *See* ALGAE; ATOLL; REEF.

Corbino disk

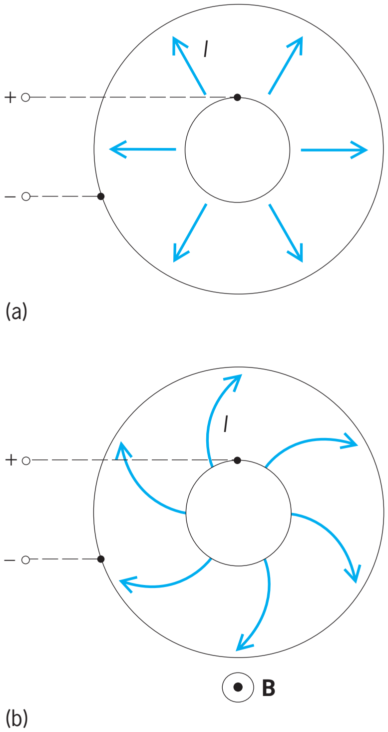
A conducting disk with concentric inner and outer electrical contacts, which can be placed in a magnetic field parallel to its axis. The disk is named after O. M. Corbino, who in 1911 reported magnetoresistance measurements on several metals by using this configuration. In zero applied field the lines of current are simply radial (**illus.** *a*), but in the presence of an axial magnetic field they lengthen by spiraling (illus. *b*). This spiraling occurs because the geometry of the disk is such that the Lorentz force acting on the charge carriers is not counterbalanced by a Hall-effect electric field. The resistance of the disk increases as the field increases, largely as a result of the geometrical magnetoresistance effect associated with the lengthening of the current path.

If B is the magnetic induction, the resistance of the Corbino disk can be expressed by Eq. (1). Here the Hall angle θ is defined by Eq. (2), where ρ_{yx} is

$$R(B) = R(0)(1 + \tan^2\theta)\frac{\rho_{xx}(B)}{\rho_{xx}(0)} \qquad (1)$$

$$\tan\theta = \frac{\rho_{yx}}{\rho_{xx}} = \mu B \qquad (2)$$

the Hall resistivity, ρ_{xx} is the usual resistivity (that is, the resistivity measured on a long wire of the material), and μ is the carrier mobility. For a disk material characterized by high mobility (as is the case for many semiconductors), the factor $1 + \tan^2\theta$, describing the geometrical magnetoresistance effect in Eq. (1), can be very large. The factor $\rho_{xx}(B)/\rho_{xx}(0)$, which measures the intrinsic magnetoresistance, is then relatively much smaller. With conformal mapping methods it is possible to demonstrate that the Corbino disk is equivalent to a very wide or very thin rectangular element of the material in which the Hall voltage is completely shorted and the geometrical magnetoresistance is maximized. Corbino disks have been used only rarely in practical devices



Corbino disk with voltage *V* and current *I* between inner and outer electrodes. (*a*) Current paths are radial in the absence of an applied magnetic field. (*b*) With an axial magnetic induction B directed out of the paper, the current paths become spirals, and the increased path length leads to increased resistance.

since they have a low overall resistance and correspondingly large power dissipation. For background information *see* HALL EFFECT; MAGNETORESISTANCE.

Cordaitales

An extinct order of the class Pinopsida comprising a natural grouping of Paleozoic forest trees or shrubs that first appeared in the Lower Pennsylvanian. They became an important component of the tropical vegetation during the Middle and Upper Pennsylvanian and diminished during the basal Permian. The Cordaitales were divided into three families, Cordaitaceae, Pityaceae, and Poroxylaceae. However, members of the Pityaceae and Poroxylaceae are now known to be either seed ferns or progymnosperms, so only the Cordaitaceae remain. Detailed information about these prominent Paleozoic gymnosperms comes from impression-compression fossils and sandstone casts. However, coal balls, which are mineral nodules in which the plants are preserved with three-dimensional anatomy, have been essential to establishing whole-plant concepts of cordaitean species. *See* COAL BALLS.

Some of the first fossil plant reconstructions were based on the consistent co-occurrence of plant parts at numerous localities. Reconstructions are based on numerous specimens of anatomically preserved, interconnected organs from single localities. This approach has resulted in several species of cordaitean plants constituting two distinct lineages, characterized by a diversity of life cycle and habitat. For example, although cordaites from mesic environments were tall, slender trees, those that grew in or close to peat-forming swamps were scrambling shrubs and small, possibly mangrovelike trees.

Features. *Mesoxylon* and *Cordaixylon* are cordaitean stem genera that have been expanded to whole-plant concepts. There are some features common to both genera. Cordaitean stems typically have a septate pith, although in some species it is solid (**Fig. 1**). Pith casts typically are 1.6–4 in. (4–10 cm) in diameter and provide evidence of the diaphragms separating the pith cavities. The wood is simple and has the basic structure found in modern Araucarian conifers with radial files of tracheids, mostly uniseriate rays, and no resin canals. Cordaites lack growth rings. Main-stem diameters range from 1.75 in. (4.4 cm) [shrubs] to more than 3 ft (1 m) [trees], with trees attaining heights of up to 100 ft (30 m).

Cordaitean leaves are sessile, are helically arranged, and appear to have been coriaceous and heavily cutinized with acuminate-to-rounded tips (**Fig. 2**). Most leaves are linear, up to 40 in. (100 cm) long and 0.75–2 in. (2–5 cm) wide, with numerous parallel veins but no midrib, much like those of the conifer *Agathis* or the angiosperm *Amaryllis*. However, needle leaves with a single vein are produced in the basal regions of branches in some species. There is no evidence of an abscission layer.

Some trees apparently formed highly branched, shallow root systems similar to many living conifers, while the shrublike forms had numerous

Fig. 1. Cross sections of cordaitean stems with simple wood. Left, *Cordaixylon iowensis* with septate pith. Right, *Mesoxylon priapi* with solid pith. (*Photographs by M. L. Trivett*)

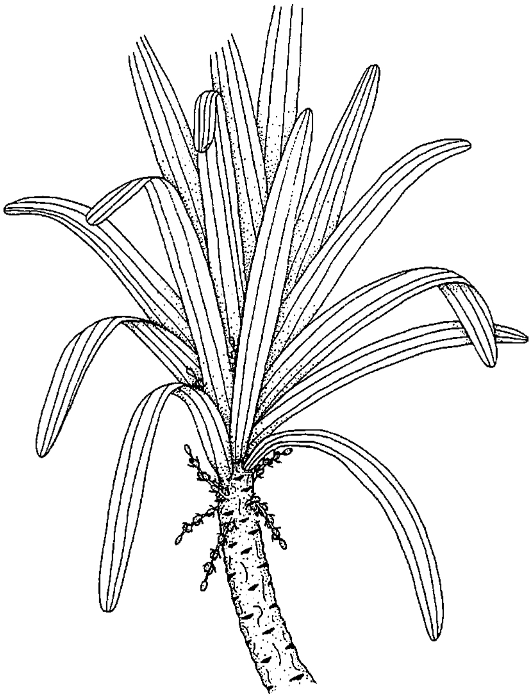

Fig. 2. Shoot of *Cordaixylon dumusum* illustrating strap leaves and nonaxillary *Cordaitanthus*-type cones. (*Courtesy of G. W. Rothwell*)

adventitious roots. Other roots have a combination of aerenchyma, periderm, lenticels, and medullated protosteles reminiscent of the stilt roots of some modern mangrove plants.

Vegetative and fertile branching is almost exclusively axillary. In most species, a single vegetative or fertile branch occurs in the axil of a leaf, although occasionally a vegetative and fertile branch or two fertile branches occur together. In a few species (such as *C. birame*), paired fertile branches are the norm. In others (for example, *C. dumusum*), single fertile branches are borne as nonaxillary, epicormic branches (Fig. 2).

Cordaitean reproductive organs are unisexual compound cones with a bilateral primary axis bearing four ranks of bracts, each subtending a secondary shoot. Secondary axes have numerous helical scale leaves, with some of the apical ones bearing pollen sacs or ovules at their tips.

Features of cauline primary xylem and reproductive structures are important generic characters within the Cordaitales. *Cordaixylon* stems have interconnected cauline strands and leaf traces, while *Mesoxylon* stems lack cauline bundles at the pith margin and have primary xylem present only as leaf traces. *Mesoxylon* cones (*Gothania*) [**Fig. 3**] are larger with more rectangular primary axes than *Cordaixylon* cones (*Cordaitanthus*) [Fig. 2] and produce pollen (*Sullisaccites* or *Felixipollinites*) in a line of pollen sacs. *Cordaixylon* cones produce pollen (*Florinites*) in rings of pollen sacs. *Mesoxylon* ovules (*Mitrospermum*) are winged, and *Cordaixylon* ovules (*Cardiocarpus*) are cordate. *See* FOSSIL SEEDS AND FRUITS.

Growth architecture and ecological interpretations. Integrating depositional information with architectural analyses can provide evidence of plant community structure and ecological partitioning. Delicate organs that show little, if any, transport damage indicate deposition at or near the growth site. Aerial organs of *Mesoxylon priapi* and *C. dumusum* are plentiful. Roots of *C. dumusum* are small but abundant, and *M. priapi* roots are lacking. *Cordaixylon dumusum* is reconstructed as a shrub inhabiting the stressed peat swamp environment, while *M. priapi* trees edged or perhaps grew on hummocks in the swamp. In addition, pollen sacs of *M. priapi* cones matured simultaneously, while those of *C. dumusum* appear to have matured over time, perhaps contributing to its role as a weedy colonizer.

Although most cordaites have leaves uniformly closely spaced, *C. iowensis* leaves are tightly packed in the bud but widely separated on mature stem sections and the pith is disrupted, indicating extensive internodal elongation. Needle leaves develop at the base of some branches. Such features typify rhythmic growth found in many temperate trees, resulting in a somewhat tiered architecture. Although growth rings (evidence of seasonality) are not present, rhythmic growth may have been induced by fluctuating environmental stress. The Cordaitales are an important group in understanding paleocommunity physiognomy, and in determining gymnospermous phylogeny through their relationships to both seed

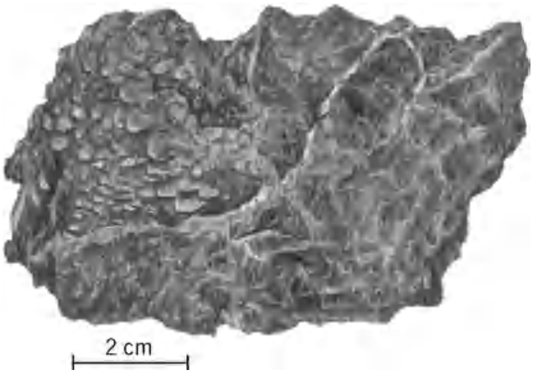
Cordierite

An orthorhombic magnesium aluminosilicate mineral of composition $Mg_2[Al_4Si_5O_{18}]$, $a = 1.710$ nanometers, $b = 0.973$ nm, $c = 0.936$ nm, $Z = 4$, space group *Cccm*. The crystal structure is related to beryl; magnesium is octahedrally coordinated by oxygen atoms, and the tetrahedrally coordinated aluminum and silicon atoms form a pseudohexagonal honeycomb, admitting limited amounts of K^+ and Na^+ ions and water molecules in the open channels. Limited amounts of Fe^{2+} may substitute for Mg^{2+}, and Fe^{3+} for Al^{3+}. The hardness is 7 (Mohs scale), specific gravity 2.6; luster vitreous; cleavage poor; and color greenish-blue, lilac blue, or dark blue, often strongly pleochroic colorless to deep blue (see **illus.**). Transparent pleochroic crystals are used as gem material. The disordered cordierite structure, $Mg_2[(Al,Si)_9O_{18}]$, is called indialite and is hexagonal, space group *P6/mcc*, isotypic with beryl. Osumilite, $KMg_2Al_3\cdot [(Al,Si)_{12}O_{30}]\cdot H_2O$, is also related but has a structure built of double six-membered rings of tetrahedrons. Cordierite, indialite, and osumilite are difficult to distinguish. Pale colored varieties are often misidentified as quartz, since these minerals have many physical properties in common. *See* BERYL; SILICATE MINERALS.

Cordierite possesses unusually low thermal expansion, and synthetic material has been applied to thermal-shock-resistant materials, such as insulators for spark plugs and low-expansion concrete. Cordierite is an important phase in the system $MgO–Al_2O_3–SiO_2$. Between 800 and 900°C (1470–1650°F), glasses of cordierite composition crystallize. Below 500°C (930°F) at pressures up to 500 bars (50 megapascals), cordierite in the presence of water breaks down to form chlorite + pyrophyllite. Indeed, it is often found naturally altered to these minerals. Cordierite melts incongruently at 2000 bars (200 MPa) and 1125°C (2057°F) to mullite + spinel + liquid. Natural cordierites break down at temperatures of about 800°C (1470°F) and pressures above 8 kilobars (800 kilopascals) to form enstatite, sillimanite, and quartz.



Cordierite, from Tsilaizina, Madagascar. (*Specimen from Department of Geology, Bryn Mawr College*)

Cordierite frequently occurs associated with thermally metamorphosed rocks derived from argillaceous sediments. A common reaction in regional metamorphism resulting in gneisses is garnet + muscovite → cordierite + biotite. It may occur in aluminous schists, gneisses, and granulites; though usually appearing in minor amounts, cordierite occurs at many localities throughout the world. Paul B. Moore

Cordilleran belt

A mountain belt or chain which is an assemblage of individual mountain ranges and associated plateaus and intermontane lowlands. A cordillera is usually of continental extent and linear trend; component elements may trend at angles to its length or be nonlinear.

The term cordillera is most frequently used in reference to the mountainous regions of western South and North America, which lie between the Pacific Ocean and interior lowlands to the east (see **illus.**). The term was first applied to the Andes Mountains of South America in their entirety (Cordillera de los Andes), but individual mountain ranges within the Andean belt are now called cordilleras by some authorities. Farther north, the extensive and geologically diverse mountain terrane of western North America is formally known as the Cordilleran belt or orogen. This belt includes such contrasting elements within the United States as the Sierra Nevada, Central Valley of California, Cascade Range, Basin and Range Province, Colorado Plateau, and Rocky Mountains. *See* MOUNTAIN SYSTEMS.

Cordilleras represent zones of intense deformation of the Earth's crust produced by the convergence and interaction of large, relatively stable areas known as plates. J. F. Dewey and J. M. Bird have analyzed mountain belts in terms of different modes of plate convergence. They contrast cordilleran-type mountain belts, such as the North American Cordillera, with collision-type belts, such as the Himalayas. The former develop during long-term convergence of an oceanic plate toward and beneath a continental plate, whereas the latter are produced by the convergence and collision of one continental plate with another or with an island arc. Characteristics of cordilleran-type mountain belts include their position along a continental margin, their widespread volcanic and plutonic igneous activity, and their tendency to be bordered on both sides by zones of low-angle thrust faulting directed away from the axis of the belt. The deformational, igneous, and metamorphic characteristics of cordilleran belts appear to be largely related to crustal compression, to melting of

The arrangement of the mountains and the continents of the world. (*After P. E. James, An Outline of Geography, Ginn and Co., 1935*)

rocks at depth along the inclined plate boundary, and to attendant thermal effects in the overlying continental plate. *See* OROGENY. Gregory A. Davis

Sci.*, Rodgers Volume, vol. 275A, 1975; J. F. Dewey and J. M. Bird, Mountain belts and the new global tectonics, *J. Geophys. Res.*, vol. 75, no. 14, 1970; C. J. Schmidt and W. J. Perry, Jr. (eds.), *Interaction of the Rocky Mountain Foreland and the Cordilleran Thrust Belt*, 1989.

Core loss

The rate of energy conversion into heat in a magnetic material due to the presence of an alternating or pulsating magnetic field. It may be subdivided into two principal components, hysteresis loss and eddy-current loss. *See* EDDY CURRENT.

Hysteresis loss. The energy consumed in magnetizing and demagnetizing magnetic material is called the hysteresis loss. It is proportional to the frequency and to the area inside the hysteresis loop for the material used. Hysteresis loss can be approximated empirically by using Eq. (1), where K_h is a constant

$$P_h = K_{ith} f B^n_{\max} \tag{1}$$

characteristic of the material, f is the frequency, $B_{\max}$ is the maximum flux density, and n, called the Steinmetz coefficient, is often taken as 1.6 although it may vary from 1.5 to 2.5. *See* MAGNETIZATION.

Most rotating machines are stacked with silicon steel laminations, which have low hysteresis losses. The cores of large units are sometimes built up with cold-reduced, grain-oriented, silicon iron punchings having exceptionally low hysteresis loss, as well as high permeability when magnetized along the direction of rolling.

Eddy-current loss. Induced currents flow within the magnetic material because of variation in the flux. This eddy-current loss may be expressed to close approximation by using Eq. (2), where K_e is

$$P_e = K_e (B_{\max} f \tau)^2 \tag{2}$$

a constant depending on the volume and resistivity of the iron, $B_{\max}$ the maximum flux density, f the frequency, and τ the thickness of the lamination in the core. For 60-cycle rotating machines, core lamination of 0.014–0.018 in. (0.35–0.45 mm) are usually used to reduce eddy-current loss.

Measured core loss. The measured core loss in a rotating machine also includes eddy-current losses in solid structural parts, such as the frame, ventilating duct spacers, pole faces, and damper windings, as well as those due to burrs or other contacts between punchings. A number of precautions are taken to minimize these components, which become appreciable in large machines. Structural parts close to the core, including clamping plates, I-beam spacers, dovetail bars, and shields, may be made of nonmagnetic material. Some of these parts may be shielded from the variable flux by low-resistance plates or by flux traps of laminated, high-permeability, low-loss steel. The core punchings are deburred and are coated with a baked-on insulating varnish. The finished cores are often tested with an ac magnetizing coil to locate and correct hot spots caused by damage during assembly. Pole-face losses are reduced by avoiding excessive slot-width to air-gap ratios, by surface grooving of the poles, and by low-resistance amortisseur windings. *See* ELECTRIC ROTATING MACHINERY.

Leon T. Rosenberg

Coriander

A strong-scented annual herb. Coriander is cultivated in many places throughout the world for both seeds and leaves. The two forms are quite different in taste from one another, and both are used for flavor in a variety of foods. Only one species, *Coriandrum sativum*, is cultivated. Coriander is a member of the carrot family, Apiaceae (Umbelliferae), and is closely related to other spice seed plants such as cumin, caraway, anise, dill, and fennel. A number of distinct cultivars have been developed. Some, with longer maturity times and resulting higher leaf yield, are grown for cilantro, also called Chinese parsley. Other seed-producing types, having a more uniform seed set, and types that resist splitting have been developed in Russia and India. *See* ANISE; APIALES; CARAWAY; CUMIN; DILL; FENNEL.

The growing of cilantro from seed to a harvestable size takes 40–60 days, and full maturity as coriander (dry ripe fruit) is reached in approximately 120 days. Coriander occurs as an erect herbaceous plant with one to many stems that reach about 4 ft (1.2 m) in height. When the plant is young, small deeply segmented leaves are formed, but as the plant ages the leaves become more and more divided until they become feathery in appearance, similar to dill.

The term coriander comes from the Greek *koris,* meaning bedbug, because the leaves and green fruit of this plant have an odor similar to bedbugs. Although some find it objectionable, it imparts a distinctive authentic taste to Mexican and Asian foods. Coriander seeds are used in pickling, curries, and for flavoring alcoholic beverages such as gin. The "seed," which is actually the whole fruit, is a two-seeded schizocarp borne in umbels and is approximately 0.1–0.3 in. (3–7 mm) in diameter. Longitudinal ridges run from top to bottom.

Cultivation is accomplished by planting seed in the spring at a rate of 9–14 lb/acre (10–15 kg/hectare). Pollination and weed control are similar to that of dill. *See* APIALES; SPICE AND FLAVORING.

Coriolis acceleration

An acceleration which arises as a result of motion of a particle relative to a rotating system. Only the components of motion in a plane parallel to the equatorial plane are influenced. Coriolis accelerations are important to the circulation of planetary atmospheres, and also in ballistics. They are so called after G. de Coriolis, the French engineer and mathematician whose analysis of the phenomenon was published in 1835. *See* ACCELERATION; BALLISTICS.

Newton's second law of motion is valid only when the motions and accelerations are those observed in a coordinate system that is not itself accelerating, that is, an inertial reference frame. In order to utilize familiar concepts in mathematical treatment, the Earth is commonly treated as if it were fixed, as it appears to one observing from a point on the surface, and the Coriolis force is introduced to balance the acceleration observed by virtue of the observer's motion in the rotating frame. *See* FRAME OF REFERENCE; NEWTON'S LAWS OF MOTION.

As with the influenced components of motion, the Coriolis force is directed perpendicularly to the Earth's axis, that is, in a plane parallel to the equatorial plane. Since the direction of its action is also perpendicular to the particle velocity itself, the Coriolis force affects only the direction of motion, not the speed. This is the basis for referring to it as the deflecting force of the Earth's rotation. The magnitude of the Coriolis force is equal to the product of twice the projection of particle velocity into the equatorial plane, with the angular velocity of the Earth's rotation ($7.292 \times 10^{-5}\ s^{-1}$).

The Coriolis force is directed to the right of the direction toward which the horizontal wind blows or the missile flies in the Earth's Northern Hemisphere, and to the left in the Southern. The horizontal component of the deflecting force is zero at the Equator, and a maximum at the poles. While negligible for the dynamics of small-scale phenomena such as cumulus convection and thunderstorms, Coriolis effects are critical to the dynamics of the Earth's large-scale wind currents. Indeed, the general circulations of planetary atmospheres owe their zonal nature and some other characteristics largely to the forces that arise by virtue of planetary rotation.

A simple illustration of a Coriolis effect in the Northern Hemisphere is afforded by a turntable in counterclockwise rotation, and an external observer who moves a marker steadily in a straight line from the axis to the rim of the turntable. The trace on the turntable is a right-turning curve, and obviously this is also the nature of the path apparent to an observer who rotates with the table. Now consider the contrasting case of an air parcel near the North Pole that moves directly south (away from the Earth's axis of rotation) so that its motion to an observer on the Earth is in a straight line. To a nonrotating observer in space, this same motion appears curved toward the east because of the increased linear velocity of the meridian at lower latitudes. The force necessary to produce the eastward acceleration in the inertial frame is equal to the Coriolis force and would be produced by a gradient of air pressure from west to east, and shown by north-south–oriented isobars. In the absence of the pressure gradient force, the Coriolis force would cause the trajectory of the southward-moving air to curve westward on the Earth's surface. Then an air parcel moving uniformly away from the North Pole along a line which appears straight to an observer in space would appear to earthbound observers to curve westward. *See* GEOSTROPHIC WIND; ISOBAR (METEOROLOGY). Edwin Kessler

Corn

Zea mays occupies a larger area than any other grain crop in the United States, where 60% of the world production is grown.

Production

Production is widely distributed throughout the United States, but it reaches its greatest concentration in the states of Iowa, Illinois, Indiana, Ohio, Nebraska, Minnesota, Wisconsin, Michigan, and Missouri. This area, called the Corn Belt, is characterized by moderately high temperature, fertile, well-drained soils, and normally adequate rainfall. The Corn Belt accounts for approximately 80% of corn production in the United States. Although corn is grown in the United States primarily for livestock feed, about 10% is used for the manufacture of starch, sugar, corn meal, breakfast cereals, oil, alcohol, and several other specialized products. In many tropical countries, corn is used primarily for human consumption.

Origin and description. From its presumed origin in Mexico or Central America, corn has been introduced into all the countries of the world that have suitable climatic conditions. However, the corn of today is far different from the primitive types found in prehistoric sites excavated in Arizona, Mexico, and Peru. The origin of corn is still unsettled, but the most widely held hypothesis assumes that corn developed from its wild relative teosinte (*Z. mexicana*) through a combination of favorable mutations, recognized and selectively propagated by early humans. Corn migrated from its center of origin and was being cultivated by the Indians as far north as New England upon the arrival of the first European colonists, whose survival was due largely to the use of corn as food.

Botanically, corn is a member of the grass family. Certain seed types within the species *Z. mays* were given subspecific rank by early investigators. Among these types are the dents (*indentata*), flints (*indurata*), soft or flour (*amylaceae*), sweet (*saccharata*), pop (*everta*), and pod (*tunicata*). Each form (botanical variety) is conditioned by fairly few genetic differences, and each may exhibit the full range of differences in color, plant type, maturity, and so on, characteristic of the species. All types have the same number of chromosomes (10 pairs), and all may be intercrossed to produce fertile progeny. Dent corns are the most important in the United States. Kernel texture is less homogeneous in other areas of the world. Soft types tend to predominate at higher elevations, flint types at lower elevations. This pattern is due, in part, to differences in methods of food preparation, but it has also been influenced by the greater resistance of flint types to stored-grain insect pests, which are more prevalent at lower elevations. Sweet corn is grown more extensively in the United States than in any other country. It is eaten as fresh corn or canned or frozen. In other countries, flint, dent, or flour corns may be eaten fresh, but at a much more mature stage than the sweet corn eaten in the United States. The commercial production of popcorn is almost exclusively American. Pod corn is grown only as a genetic curiosity. *See* CYPERALES; GENETICS; REPRODUCTION (PLANT).

Varieties and types. Corn is a cross-pollinated plant; the staminate (male) and pistillate (female) inflorescences (flower clusters) are borne on separate parts of the same plant (**Fig. 1**). Plants of this type are called monoecious. The staminate inflorescence is the tassel; it produces pollen that is carried by the wind to the silks produced on the ears. Natural cross-pollination permits maintenance of a high degree of genetic variability. As corn was carried by the Indians to different environments in North, Central, and South America, a large array of varieties ultimately was developed. Many of these primitive varieties still exist today. Extensive efforts have been devoted to the collection, classification, and maintenance of this valuable reservoir of genetic variability. Settlers migrating westward took with them their corn seed (botanically fruits). In time, by both planned and natural selection, a large number of varieties and local strains became established and adapted to the new ecological conditions. These strains varied in color of grain, plant, and ear characteristics, and in length of time required to reach maturity. Because of the variability associated with cross-pollination, corn is a highly plastic species, and varieties have been developed that are well adapted to a frost-free growing season of less than 90 days or, in contrast, grow 12–15 ft (3.5–4.5 m) tall and require more than 200 days to reach maturity, as in certain areas in Guatemala. *See* FLOWER; INFLORESCENCE; POLLINATION.

Hybrids. The development of varieties and strains of corn made possible the extension of its culture under diverse soil and climatic conditions. However, modern research methods, used for its further improvement, led to the present widespread use of hybrid corn. Essentially all of the corn grown in the United States is planted to hybrid seed, and this technology is being adopted in other areas of the world as rapidly as suitable hybrids are developed. *See* BREEDING (PLANT); HETEROSIS.

Fig. 1. A corn plant in full tassel and silk. The tassel produces pollen that is blown by wind to the silks. (*Courtesy of J. W. McManigal*)

Hybrid corn is the first generation of cross involving inbred lines. Inbred lines are developed by controlled self-pollination. When continued for several generations, self-pollination leads to reduction in vigor but permits the isolation of types which are genetically pure or homozygous. Intense selection is practiced during the inbreeding phase to identify and maintain genotypes having the desired plant and ear type and maturity characteristics, and relative freedom from insect and disease attacks. After the inbred lines have become fairly pure, they are further evaluated in hybrid combinations. Crosses involving any two unrelated lines will exhibit heterosis, that is, yields above the means of the two parents. Only a very few combinations, however, exhibit sufficient heterosis to equal or surpass hybrids in current commercial use. Hence large-scale experimental testing is required to identify new useful combinations.

The first commercial hybrids were double crosses produced by crossing two single crosses, each, in turn, having been produced by the crossing of two inbred lines. Hybrid seed for commercial planting is produced in special crossing blocks (isolated fields). The field is planted with the parents (inbred lines or single crosses) in alternating groups of rows.

The plants in blocks to be used as female parents are detasseled before silk emerges. Thus all seed produced will be pollinated by the male parent. After drying, sizing, and treatment, the seed harvested from the female rows becomes the hybrid seed of commerce. Since the early 1960s the use of single-cross hybrids has been increasing, and in the Corn Belt today probably accounts for 80% or more of the seed used.

Several techniques have been used to control pollination. Initially, manual removal of the tassels was used exclusively. Then cytoplasmic male sterility was used. This type of male sterility is transmitted only through the cytoplasm of the female parent. Since no fertile pollen is produced, no detasseling is required. With this system, pollen production in the farmers' fields is provided either by blending (artificial mixing of sterile and fertile types) or by the use of genetic fertility-restoring factors introduced through the male parent. In 1970 possibly 90% of the hybrid seed used in the United States utilized a single type of cytoplasmic sterility: the Texas type. This cytoplasmic type proved to be susceptible to a new mutant race (race T) of one of the leaf-blight fungi, *Helminthosporium maydis*, and thus the use of this type of sterility was distincontinued. Investigations of other types of cytoplasmic sterility are under way. Machines which cut or pull tassels in the seed fields have been developed and are being used extensively. Other types of genetic control of pollen production have been developed, and some attention is being given to the possible use of chemical sterilants.

Companies specializing in hybrid seed production produce and market the entire seed supply. Gains from the use of hybrid seed have been spectacular. The shift from open-pollinated varieties to hybrids, beginning in the 1930s, accounted for a yield increase of 25%. In succeeding years these first hybrids have been replaced by newer, higher-yielding types which have greater disease and insect resistance. Hybrid succession is a continuing process; few hybrids have a commercial life of more than 5 years. The per-acre yield of corn has increased about threefold since the first introduction and use of hybrid seed. *See* AGRICULTURAL SCIENCE (PLANT).

Planting. Planting dates depend upon temperature and soil conditions. Germination is very slow at soil temperatures of 50°F (10°C), and seedling growth is limited at temperatures of 60°F (16°C) or below. Because of these temperature relations, planting begins in Florida and southern Texas in early February and is completed in New York and New England by late May or early June. Planting rates are influenced by water supply, soil type, and fertility and by the maturity characteristics of the hybrid grown. Planting rates for full-season hybrids may vary from 8000 to 12,000 plants per acre (20,000 to 30,000 per hectare) in eastern Texas to 20,000 to 24,000 (50,000 to 59,000) in the central Corn Belt. Check-planting, with hills and rows spaced 38–42 in. (95–105 cm) apart, has been almost completely replaced by drilling. With planting rates above 16,000 plants per acre (40,000 per hectare), drilling in rows 24–36 in. (60–90 cm) apart has become common practice. The use of nitrogen fertilizer has increased greatly; lesser amounts of phosphorus and potash are applied as needed. Soil tests and experience provide useful guides to economic rates of fertilizer use under different environmental conditions.

There has been a marked trend toward reducing the amount of tillage in seedbed preparation. The variations in the planting systems used are influenced by soil type and topography, amount of crop residues on the soil surface, and the weed-control system to be employed. The use of the minimum tillage system, in which all soil preparation as well as planting is performed in one passage across the field, is increasing. This system, and less extreme modifications of the conventional system, reduces total energy costs. *See* AGRICULTURAL SOIL AND CROP PRACTICES.

Weed control. Weed control may be effected by cultivation or herbicides or both. With minimum tillage planting methods, weed control may be more difficult than with conventional seedbed preparation because of crop residues left on or near the surface. Weeds are easiest to control mechanically when they are small, preferably before they emerge. The most efficient and economical tool for killing weeds at this stage is the rotary hoe. Unfortunately this or other mechanical cultivation systems are relatively ineffective during extended periods of rainy weather. Disk or shovel cultivators are used after the corn is 6–8 in. (15–20 cm) in height.

Increasing use has been made of selective herbicides. Most broadleaf and grassy weeds may be controlled without damage to corn. Herbicides may be applied either "preplant" or "preemergence." If applied prior to planting, herbicides may be left on the soil surface or incorporated into the soil. Preemergence applications may be made as the seed is planted, or at any time prior to crop emergence. The choice of the many herbicides available is dependent upon many factors, including the type of weeds to be controlled and the farming system used. Under unfavorable early-season weather conditions, neither mechanical nor chemical control nor their combination may be completely effective, and sizable yield reductions may result. *See* HERBICIDE.

Harvesting. Harvesting of corn has undergone a major revolution since 1930. In the 1930s most corn was husked by hand, and the ears were stored in slatted cribs. Harvesting began when the moisture content of the grain had been reduced, by natural drying, to 20–24%. The mechanical picker supplanted hand harvesting. The mechanical picker, in turn, has been replaced by the picker-sheller or corn combine, which harvests the crop as shelled grain (**Fig. 2**). Energy requirements, however, have increased materially over the years. When harvested as shelled grain, at a relatively high moisture content (20–30%), the grain must be dried artificially for safe storage. High-moisture corn to be used for livestock feed may be stored in airtight silos or may be treated with certain chemical preservatives such as propionic acid. Corn stored under either of these systems is not suitable either for industrial processing or for seed. *See* AGRICULTURAL MACHINERY.

G. F. Sprague

Fig. 2. Two-row mounted picker for harvesting corn.

Productivity. Corn is highly productive largely because it can use solar energy so efficiently. It is classed as a C-4 species, which means that its leaves use the more efficient of the two photosynthetic processes found in crop plants. This is the same photosynthetic system used by sugarcane, sorghum, other tropical grasses, and many persistent weeds. In addition to relatively efficient leaves, corn's growth habit allows planting densities thick enough to almost completely shade the soil. Thus, a well-managed cornfield receives almost all the solar energy the environment provides and uses it as efficiently as any plant known. *See* PHOTOSYNTHESIS.

The higher productivity of modern corn hybrids, as compared with earlier hybrids, when both are grown under disease-free conditions, results to a considerable degree from their ability to tolerate higher plant populations without excessive barrenness. This capability is largely due to the greater plant-to-plant uniformity introduced by single cross hybrids and to the development of varieties with more erect leaves. Such foliage minimizes mutual shading and permits more uniform illumination of all leaf surfaces.

The actual rate of dry matter production by an area of corn with ample water and fertility depends on the average amount of light and on the temperature. The highest value reported, 2 oz (52 g) of dry matter per 11 ft^2 (1.0 m^2) of land area per day, was for high-population corn under cloudless conditions at Davis, California. A more representative range of values for the Corn Belt of the United States would be 0.9–1 oz (26–32 g) of dry matter per 11 ft^2 (1.0 m^2) per day. Day-to-day variation is large because of differences in cloudiness and in temperatures. Such estimates suggest dry matter growth rates of 230–285 lb per acre per day (258 to 319 kg per hectare per day).

The corn plant grows vegetatively until about silking, after which all weight increase is in the form of grain. There is little transfer of earlier growth to grain, so almost the entire grain yield results from photosynthesis during the grain growth period, which runs from silking to maturity. Thus, grain yield results from a combination of the rate of dry matter production after silking and the duration of the grain growth period. Contrary to much popular opinion, grain yields are highest under cool conditions, when the lengthened grain growth period more than compensates for the slower growth rate. Thus, yields for single planting are much greater at higher altitudes in the tropics than at warmer, lower locations. Highest average grain yields are in favored areas of Washington and Oregon in the United States, in the North Island of New Zealand, and in cooler long-season locations in Europe. Consistently high yields in the Corn Belt of the United States result more from favorable soil moisture and excellent management than from climatic superiority.

Relationships among solar radiation, temperature, growing-season length, soil moisture, day length, soil fertility, and corn genotype in producing grain yields are complex and not well understood. Attempts to study the system as a whole, using simulation models on digital computers, may add considerably to knowledge of the subject. William G. Duncan

Diseases

More than 100 diseases of corn are known worldwide; yet damage or yield loss from disease seldom forces a grower out of production. World reduction in grain production due to disease is estimated to average 9% and in the Corn Belt to average 7–17%. The widespread practices of continuous cropping, increased fertilization, high plant populations, and relative genetic uniformity of hybrids have sometimes resulted in epidemics: Stewart's bacterial wilt, northern corn leaf blight epidemics in 1939–1943, the maize dwarf mosaic epidemics in the 1960s, and the southern corn leaf blight epidemic of 1970–1971.

Diseases are caused by bacteria, fungi, nematodes, viruses, several mycoplasma-like organisms, and one parasitic seed plant (*Striga* spp.). Pollutants, pesticides, and unfavorable climatic and soil factors are responsible for still other diseases.

Seedling diseases. Seed decay and seedling blight caused by seed- and soil-borne *Diplodia, Fusarium, Penicillium,* and *Pythium* species are troublesome when grain is planted in cool, moist soil. Planting sound, mature, and chemically treated seed reduces these problems.

Leaf diseases. Of approximately 25 leaf blights, only a few are economically important in the United States. Southern corn leaf blight, caused by *Helminthosporium maydis,* accounted for a 15% loss in yield in the 1970 epidemic in the nation. Yellow leaf blight, caused by *Phyllosticta maydis,* occurred about the same time, and both blights are found most commonly in hybrids with the Texas male-sterile cytoplasm. Northern corn leaf blight, caused by *Helminthosporium* (*=Exserohilum*) *turcicum,* has been destructive and can cause 50% loss in yield if the disease strikes before pollination. With new conservation tillage practices, other leaf diseases have become increasingly important due to fungi that overwinter on crop debris left on the ground. Resistant hybrids and, sometimes, crop rotation are generally used for control. Two of the bacterial leaf blights are of major concern. Stewart's wilt, caused by *Erwinia stewartii,* results in a severe wilt of sweet corn and a leaf blight of dent corn in eastern North America. Control is obtained by use of resistant hybrids or by insecticides that control the flea beetle vector. Goss's bacterial wilt and blight, or leaf freckles, occurs in Colorado, South Dakota, Nebraska, and Kansas, and is caused by *Corynebacterium nebraskense*. All types of corn are susceptible, and various degrees of blighting and stunting occur.

Smuts and rusts. Common or boil smut, caused by *Ustilago maydis,* is found wherever corn is grown, but losses in yield seldom exceed 2% over a wide area. Galls may appear on any part of the plant and are most prevalent in vigorously growing plants in soil high in organic matter and nitrogen, often under dry conditions, and increase with hail and other

Fig. 3. Corn smut on various parts of plant. (*University of Minnesota Agricultural Experimental Station*)

mechanical injuries (**Fig. 3**). Large galls on or above the ear are more destructive than galls below the ear. Control is to plant resistant hybrids. The small cinnamon brown to black pustules of common rust, caused by *Puccinia sorghi,* on leaves are found wherever corn is grown. Most widely used hybrids have good field resistance. Southern rust, *P. polysora,* found mainly in the southeastern United States and other countries, appears to be spreading to northern states of the Corn Belt.

Stalk and root diseases. Stalk rots are universally important and among the most destructive diseases of corn in the world (**Fig. 4**). They are caused by *Fusarium moniliforme, F. roseum* "Graminearum" (*Gibberella zeae*), *Macrophomina phaseolina,* and to a lesser extent by *Diplodia zeae* and *Colletotrichum graminicola,* and several dozen other fungi and bacteria. Losses vary by season and region, but yield losses of 10–20% can occur among susceptible hybrids in the United States and 25–33% in other countries. Conditions favoring disease may cause plants to die before maturity. This results in poorly filled ears, but the greatest loss may come from stalk lodging that interferes with harvesting, or from ears fallen to the ground. Many factors affect stalk rot: unbalanced soil fertility, high plant populations, dry weather, leaf diseases, insect damage, hail, and, sometimes, continuous cropping to corn. The best control is to grow resistant hybrids and to follow good management practices. Root rots are caused usually by the same organisms that cause stalk rot, except that nematodes (eel- or roundworms) are sometimes involved. In fact, more than 40 species of nematodes have been reported to feed on corn roots. They can stunt plants, cause yellowing, and aid root-infecting fungi. *See* NEMATA.

Ear diseases. Considerable damage to ears from ear and kernel infection occurs in humid regions where rainfall is above normal late in the season, and from insect and bird feeding, early frosts, and fallen stalks (**Fig. 5**). Infected grain reduces yield and lowers grain quality, and grain may contain mycotoxins (aflatoxins, estrogens, and vomitoxin) which makes animals ill when used as feed. Infections occur in the field from fungi such as *Diplodia, Fusarium* (*Gibberella*), *Helminthosporium,* and *Nigrospora,* or in storage from such fungi as *Aspergillus, Cladosporium,* and *Penicillium*. Storage fungi can be controlled if grain is stored at 13–15% moisture and at uniform temperatures between 39 and 50°F (4 and 10°C), with provision for adequate aeration.

Viral and mycoplasma diseases. Prior to 1963, viruses were not a factor in corn production except in localized areas outside the United States. That year, maize dwarf mosaic virus (MDMV) caused economic losses in the United States. Almost complete destruction of susceptible corn occurred in some areas. MDMV has been identified in 15–20 states in the Corn Belt, as well as in the East and South. Aphids are vectors of MDMV, but leafhoppers are vectors for maize chlorotic dwarf virus (MCDV). Wheat streak mosaic virus (WSMV), widespread on certain inbred lines and hybrid corns in the Corn Belt, is transmitted by the mite *Eriophyes tulipae*. Other naturally occurring viruses of corn are sugarcane mosaic (a complex of Potyviruses that contain the MDMV subgroup), maize mosaic virus, maize chlorotic mottle virus (MCMV), and maize rayado fino virus. Corn lethal necrosis is a synergistic interaction between MCMV and either MDMV or WSMV, and is potentially destructive in the United States, but is currently confined to Kansas and Nebraska.

Some diseases once thought to be caused by viruses are now known to be caused by a spiroplasma or a mycoplasma-like organism. Corn stunt, transmitted by a leafhopper, occurs in Texas and in the Rio

Grande Valley, and is caused by a spiroplasma. The maize bushy stunt pathogen is a similar organism and has the approximate range of corn stunt in the United States and South America. The economic importance of virus diseases of corn has increasingly been recognized. *See* PLANT PATHOLOGY; PLANT VIRUSES AND VIROIDS.

Thor Kommedahl

Processing

Corn kernels (seeds) are subjected to both wet and dry milling. The goal of both processes is to separate the germ, the endosperm, and the pericarp (hull). The mean moisture content of corn kernels is 17% (range 7–23%). Kernel composition on a percent dry basis is given in **Table 1**. *See* CELLULOSE; HEMICELLULOSE; LIGNIN.

TABLE 1. Composition of corn kernels, on percent dry basis

Components	Mean value,%	Range,%
Starch	71	64–78
Protein	9.9	8–14
Fiber	9.5	8.3–11.9
Hemicelluloses	6.2	5.8–6.6
Cellulose	3.1	3.1–4.1
Lignin	0.2	
Oil	4.5	3.1–5.7
Ash	1.4	1.1–3.9
Sugars	2.6	1.0–3.0

Wet milling. Wet milling separates the chemical constituents of corn into starch, protein, oil, and fiber fractions (**Fig. 6**), the primary objective being to produce refined corn starch. The world production of corn grain in 1996–1997 was approximately 640 million tons (580 million metric tons) with more than 40% being produced in the United States. Products from milling of the United States crop are shown in **Table 2**. The amount wet-milled in 1997 was 16.5% of the crop.

There are variations in the equipment used for wet milling from plant to plant and within processing plants. The process begins with shelled No. 2 yellow dent corn being cleaned on vibrating screens to remove both coarse and fine material. The kernels are then placed in steep tanks that hold 2000–13,000 bushels (60–360 tons or 55–330 metric tons) and covered with steepwater (8–9 gal/bushel or 1.2–1.3 liter/kg) heated to 118–125°F (48–52°C). The steepwater is transferred in a countercurrent system, usually through batteries of about 12 tanks, with as many as 50 being used. The original steepwater contains 0.12–0.20% of added sulfur dioxide (SO_2). Dissolution of sulfur dioxide in water produces sulfurous acid, which assists in breaking down the starch-protein matrix. Kernels release about 6.5% of their dry substance as solubles into the steepwater. From the solubles, bacteria in the steepwater produce lactic acid, an important component for pH control. As the steepwater advances through the tanks in stages, the SO_2 content decreases to 0.01% or less and the lactic acid content increases to

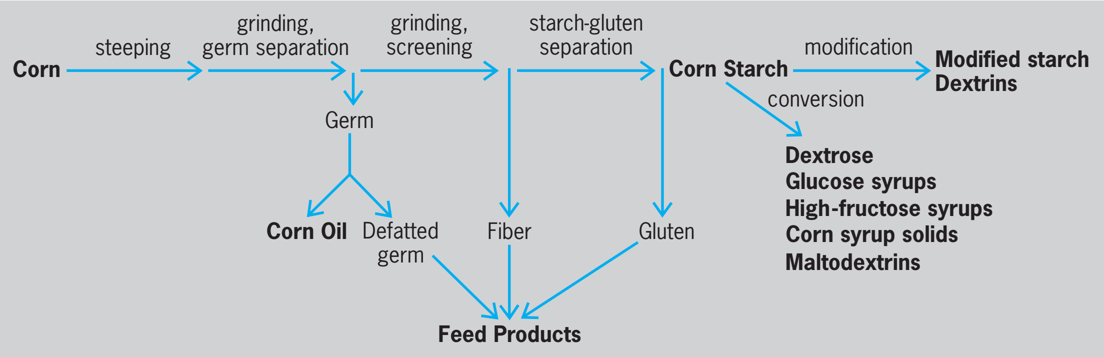

Fig. 6. Corn wet-milling process.

TABLE 2. Products obtained from corn in the United States[*]

Products	Production, 10^6 lb	Percent of nonfeed use
Wet-milled products	37,885	56.8
Starch products[†]	5,938	13.2
Conversion products[‡]	31,947	43.6
Fuel ethanol		28.4
Dry-milled products		7.5
Beverage alcohol		7.3
Coproducts of wet milling[§]		
Corn oil	1,284	
Corn gluten feed and corn oil meal	12,547	
Corn gluten meal	2,593	
Steepwater	1,118	

[*] Based on 1997 data; Corn Refiners Association, Washington, DC.
[†] Corn starches, modified corn starches, and dextrins.
[‡] Dextrose (d-glucose), glucose syrups, high-fructose syrups, D-fructose, syrup solids, maltodextrins.
[§] Does not include coproducts from fuel alcohol (ethanol) production.

1.6–1.7%. However, the pH remains a rather constant 4.0–4.1 throughout the process. The steeping process usually takes 20–40 h. At its end, the kernels are hydrated (45% moisture), swollen, and softened. The final steepwater is evaporated to 45–50% solids and mixed with corn fiber. The mixture is sold as corn gluten feed after drying. *See* PH.

The remainder of the process is continuous. The softened corn kernels are passed through coarse grinding mills that have one stationary and one rotating disk. The clearance between the disks is adjusted to minimize both the number of whole kernels and the number of broken germs. The discharge is pumped through banks of hydroclones to remove the germs, which have a lower density. The germs are washed on screens, dewatered in screw presses to about 50% solids, and dried. To recover the oil, the germs are heated to 250°F (120°C), steamed or passed through an extruder, and pressed in an oil expeller which reduces the oil content from 45% to 6%. Alternatively, after reducing the oil content to 13–20%, the germs are flaked and extracted with hexane. Crude corn oil is shipped to refiners. The remaining corn germ meal contains 23–25% protein. *See* FAT AND OIL (FOOD).

The slurry of corn kernels minus their germs is screened to separate "fiber" (mostly the pericarp) from the starch and protein. At this point, the fiber contains some attached starch. The slurry of fiber is again passed through rotating disk mills that free the starch with a minimum of fiber destruction. The milled slurry is again screened to separate the starch from the fiber. The fiber fraction remaining on the screens is dewatered to 42–48% moisture, mixed with evaporated steepwater, dried to 8–11% moisture, and sold as corn gluten feed (21% protein), often after pelletizing.

The starch slurry now contains only starch, protein, and some solubles. Because the protein has a specific gravity of 1.06 and the starch a specific gravity of 1.5, they can be separated in centrifuges. This separation produces a gluten fraction of more than 68% protein, which is dried to about 12% moisture and sold as corn gluten meal. *See* CENTRIFUGATION.

Most of the remaining protein (3–5% of the weight of starch) is removed from the starch by countercurrent washing in stages using banks of hydroclones 0.4 in. (10 mm) in diameter. The slurry of refined starch (40% solids) is centrifuged or vacuum-filtered to produce a cake that is dried in belt or flash driers and milled; or is pumped into tanks for various modifications; or is pumped through jet cookers for various conversions.

A typical composition of commercial common corn starch is starch 88%, moisture 11%, protein 0.35%, ash 0.1%, lipid 0.87%, and crude fiber 0.1%. A typical yield distribution of products obtained from the wet-milling process is starch of 11% moisture (74% yield), corn gluten feed of 21% protein (27%), corn gluten meal of 60% protein (6%), and corn oil (4%). Corn gluten feed and meal are used as animal feed. *See* ANIMAL FEEDS.

While by far the majority of the corn subjected to wet milling is common corn, waxy maize (less than 1% apparent amylose) and high-amylose corn (class V around 55% apparent amylose, and class VII around 73% apparent amylose) are grown under contract for wet millers and used for specialty starch production.

Corn starch. The United States produces almost 60% of the world's starch. Since corn is the source of more than 90% of the starch produced in the United States and starch is also produced from corn in other countries, by far the primary source of starch is corn. The world production of starch was around 40 million tons (36 million metric tons) in 1996, with 80% coming from corn. A large proportion (80–85%) of this starch is converted into other products such as sweeteners. Some is hydrolyzed to D-glucose which is used as the carbon source in fermentation to produce ethanol, a fuel additive; one-third of the starch produced by wet-milling of corn in the United States in 1997 was used to produce fuel ethanol. *See* ALCOHOL FUEL; ETHYL ALCOHOL; STARCH.

Not only does the source of starch vary from country to country, so does the ratio of products going to the various end uses. In the United States the starch of commerce is predominantly corn starch, and the primary market for corn starch, other than for the production of sweeteners and ethanol, is in the paper industry. Manufacture of paper, paper board, and corrugated board products consumes about 60% of the starch produced in the United States. About 20% of the starch is used in prepared foods. Approximately 20% of corn starch products are used as a textile size, in building materials, and in various other consumer and industrial products. The great majority of all corn starch used in any of these applications is first modified by etherification, esterification, acid-catalyzed depolymerization, oxidation, or a physical process (**Fig. 7**). It is not uncommon for a starch product to have been doubly, triply, or quadruply modified to

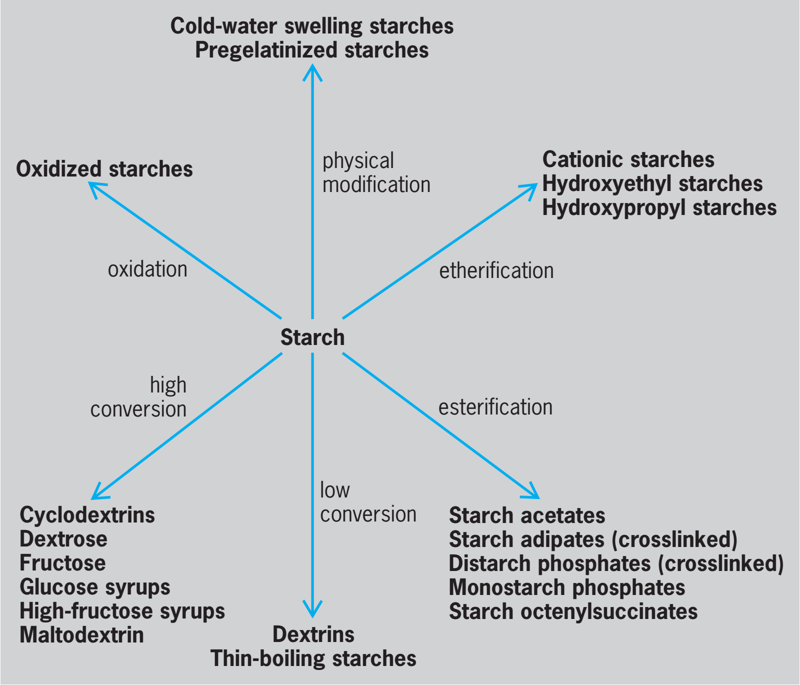

Fig. 7. Starch modification.

give it more desirable attributes for a particular application. Most modified food starch products made in the United States are based on waxy maize starch. For other corn starch products, the base starch is common corn starch.

Sweeteners. Worldwide, the production of nutritive sweeteners is the largest use for the starch obtained from corn. Residents of the United States consume more sweetener derived from corn than they do sucrose (sugar). *See* SUGAR.

Sweeteners can be made from any starch and are essentially identical regardless of which starch is used as the raw material, but in the United States all such products are made from corn starch and are often referred to as refinery products. The manufacture of corn sweeteners begins with the wet milling process. The starch, obtained as a slurry of granules in water, is first cooked, or pasted (**Fig. 8**). Then, the starch polymers are hydrolyzed (depolymerized) to the desired extent using an acid, an enzyme, a combination of enzymes, or an acid-enzyme combination. In all-enzyme conversion processes (the most commonly used), the starch paste is first rapidly thinned with an alpha-amylase (liquefying enzyme), then treated with one or more so-called saccharifying enzymes to convert partially degraded polymers into lower-molecular-weight carbohydrates—for example, to make high-glucose or high-maltose products, that is, solutions containing primarily D-glucose or maltose, respectively. The resulting solutions are refined and concentrated to 70–80% solids. These syrups, of whatever composition, are known worldwide as glucose syrups, but in the United States are often called corn syrups.

The syrups and all other breakdown products of starch are characterized by a value known as dextrose equivalency (DE). The DE value of a hydrolysis product is its reducing power expressed as a percentage of the reducing power of pure dextrose (D-glucose) and is inversely proportional to its

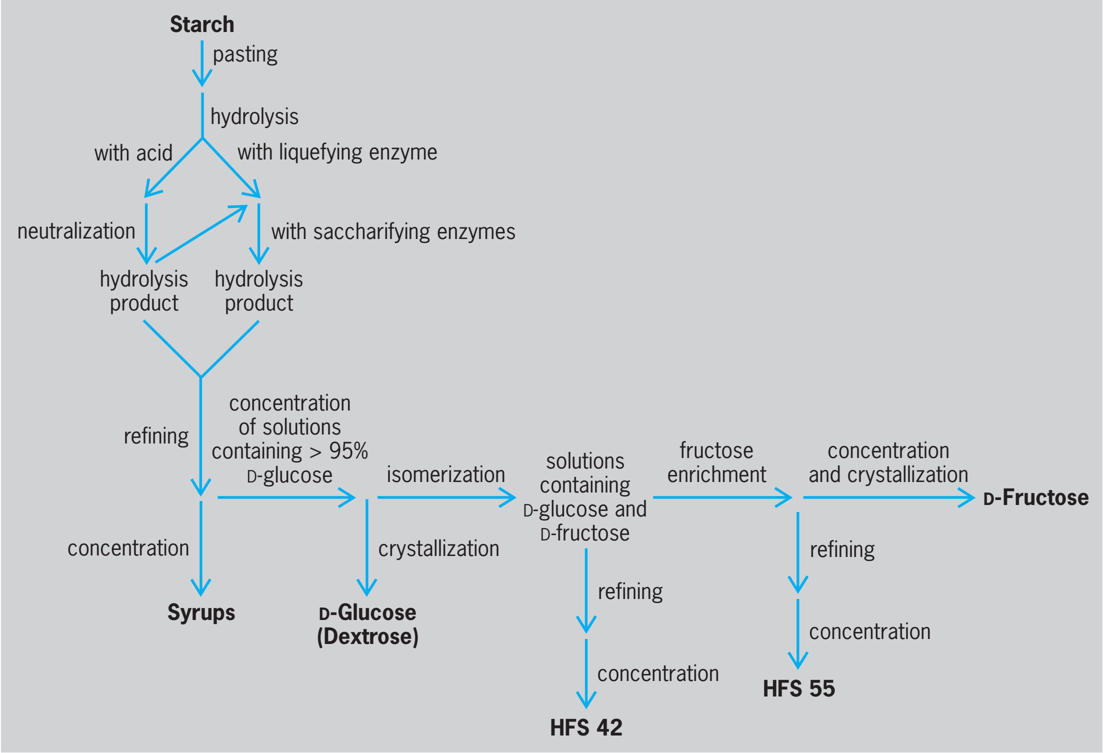

Fig. 8. Sweetener manufacture from starch.

average molecular size. Starch has a DE value of 0, while a solution of D-glucose has a DE value of 100. (Glucose and dextrose are interchangeable terms for the same substance, with D-glucose being the formal chemical name and dextrose being a term of commerce. Commercial products which contain less than 98% of the substance are usually referred to as glucose syrups, and the pure crystalline material is usually called dextrose.) Liquid solutions of nutritive saccharides obtained from starch (glucose syrups) have DE values of 20 or more. Their degree of sweetness is a function of the types and amounts of saccharides they contain. The degree of hydrolysis, that is, the composition of the hydrolyzate, also determines viscosity, fermentability, flavor enhancement, and freezing-point depression.

Glucose syrups are used in a wide variety of products. Besides having different sweetness levels, the functionalities they impart vary with saccharide composition. They may provide body (viscosity) or desirable mouthfeel to certain liquid products such as pancake and waffle syrups and certain beverages. They bind and hold water, providing desirable texture and mouthfeel to other products; for example, a 65 DE syrup is often used in soft cookies to help retain chewiness. Glucose syrups may also be used in bakery products to generate crust color and flavor or to provide texture to reduced-fat products without making them too sweet. They are often used in icings and glazes. A major use can be in candy manufacture, but relative amounts used in various applications vary from country to country. In addition to food uses, glucose syrups are a feedstock for fermentation processes that produce ethanol and other alcohols, vitamins, amino acid feed supplements, citric acids, and antibiotics. High-glucose syrups are hydrogenated to produce the polyol sorbitol; high-maltose syrups are hydrogenated to produce the polyol maltitol; and other syrups are used to produce hydrogenated starch hydrolyzates.

When starch is completely hydrolyzed, that is, converted into its monomer units, the only product is D-glucose (dextrose), which can be crystallized from concentrated solutions. Crystalline dextrose is produced in several different forms. It is about 60% as sweet as sucrose and has limited food applications. Dextrose monohydrate absorbs heat as it dissolves, so it imparts a cooling sensation when used in a sugar coating, and is used in donut glazes and sandwich cookie and sugar wafer fillings. It is used to make polydextrose, a food bulking agent and dietary fiber with reduced caloric value. Dextrose is used in preparing solutions for intravenous injection and for renal dialysis, in tableting, and in oral medications.

Isomerization of some of the D-glucose in a high-glucose hydrolyzate to D-fructose produces high-fructose corn syrups (HFCS), which are known simply as high-fructose syrups (HFS) outside the United States. Fructose is approximately 20% sweeter than sucrose on an equal weight basis. Converting some of the D-glucose to D-fructose makes a product similar to invert sugar, which is the 50:50 mixture of glucose and fructose made by hydrolysis of sucrose and is sweeter than sucrose. Two major products are HFCS 42 and HFCS 55, which contain, respectively, 42% and 55% fructose. HFCS is the sweetener for almost all soft drinks made in the United States that do not use a high-intensity sweetener. Most of the HFCS in colas is HFCS 55, which is made by enriching HFCS 42 with fructose. Many fruit-flavored drinks use HFCS 42. HFCS 42 is also used in most commercially produced yeast-raised breads, rolls, and cakes. The sugars in HFCS are fermentable. When HFCS is used in breadmaking, for example, yeast preferentially ferments glucose, leaving a higher percentage of fructose and the desired slight sweetness. HFCS is used in ice creams, frozen desserts, yogurt, chocolate milk, and other dairy products. It is blended with sucrose and a glucose syrup for use in fruit canning. The world production of high-fructose syrups was 12.5 million tons (11.3 million metric tons) in 1998–1999, with three-fourths of that amount (9.5 million tons or 8.6 million metric tons) being produced in the United States.

Crystalline (pure) fructose provides a rapid but short sweet taste, allowing other flavors to be sensed. For this reason, it is used in some fruit and fruit-flavored products such as jams, jellies, drinks, and sorbets.

Other starch conversion products. Corn starch is less extensively depolymerized to make products other than sweeteners. Very slight hydrolysis makes products known as acid-modified or thin-boiling starches. These products are still granular but cook more easily than the native starch. Their primary use is as film formers and adhesives; they also form gels with increased clarity and strength. A little more modification with an acid produces dextrins. Dextrins have some degree of cold-water solubility and generally have the same applications as thin-boiling starches. One application is as remoistenable adhesives on envelopes.

Hydrolysis catalyzed by acid or enzymes to DE values less than 20 produces starch oligomers, which are known as maltooligosaccharides or maltodextrins. Maltodextrins are easily dispersible and rapidly soluble, form films, have low hygroscopicity, and are generally bland, although some have slight sweetness. They are used extensively in foods for their bulking and binding properties and the protection they give to frozen foods. Special maltodextrins have properties that make them useful as fat replacers or sparers. Hydrolysis to DE 20–60 gives mixtures of breakdown products that, when dried, are known as corn syrup solids. Corn syrup solids dissolve rapidly, are mildly sweet, and are used as bulking materials in food.

Any one and often mixtures of the sweetener and other starch conversion products—that is, mixtures of dextrose, fructose, glucose or corn syrups, corn syrup solids, maltodextrins, hydrogenated sugars or syrups, and polydextrose—may be used to prepare functional, isotonic and oral rehydration beverages, enteral and parenteral fluids, infant formulas, and adult diet supplements.

TABLE 3. Typical compositions of products of corn dry milling in percent

Product	Mesh size	Moisture	Protein	Lipid	Crude fiber	Ash	Starch	Other polysaccharides
Coarse grits	−10 to +15	11.5	7.5	0.7	0.2	0.3	78	1.8
Regular grits	−15 to +30	11.5	7.5	0.7	0.2	0.3	78	1.8
Flaking grits	−3.5 to +6	11.7	7.0	0.6	0.2	0.2	78	2.0
Corn flour	−60 to +325	13.0	5.2	2.0	0.5	0.4	76	2.5

Dry milling. The amount of corn dry-milled in the United States in 1997 was 1.45% of the produced crop. Most of the processing is done by tempering-degerming systems. Corn, usually No. 2 yellow dent, but also white and other corns, is cleaned to remove metal, fines, pieces of cob, and broken corn. The whole kernels are then washed. Cleaned kernels are transferred to a tempering bin, where they are held for various times at various temperatures depending on the miller and the desired product. Tempered kernels at 20% moisture are passed through a degerminator, which removes the bran (pericarp) and germ while leaving the endosperm intact. But some bran and germ remain and must be removed by subsequent milling and aspiration; some endosperm remaining associated with the germ + bran fractions is also subsequently obtained.

Large pieces of endosperm, known as tail hominy, are dried, cooled, and sifted. Part of this fraction is isolated as large flaking grits which are used to make corn flakes breakfast cereal. The remainder is sent through roller mills for reduction to smaller fractions (coarse, medium, and fine grits; meals; flours).

The bran + germ fraction is dried, cooled, and aspirated to remove the bran. Corn oil is obtained from the germ by expelling or hexane extraction. The residue is the germ cake. Fines from the bran + germ fraction, the germ cake, the bran, and broken corn are combined, dried, and milled to produce hominy feed, the main by-product.

The endosperm may be converted into as many as 16 different fractions. The main products are regular grits, coarse grits, flaking grits, and corn flour (**Table 3**). Other products are corn cones and corn meal, −40 to +80 and −30 to +60 Standard U.S. mesh, respectively.

Nixtamalization. Nixtamalization is the process of cooking and soaking corn kernels in water containing calcium hydroxide (lime) to soften the pericarp and hydrate the protein matrix and starch of the endosperm. Subsequent washing removes leached solubles and excess lime. The cooked, steeped product, called nixtamal, is then ground, using stone attrition mills. The product, masa, is sheeted, cut into pieces, and baked, producing tortillas, tortilla chips, taco shells, and corn chips. The temperature, and particularly the time of each step, is varied depending on the desired product. The general process is as follows. Yellow, white, or blue corn (700 lb or 320 kg; alone or in mixtures) is cooked (200–212°F or 95–100°C) for around 4 to more than 30 min under alkaline conditions produced by adding 7 lb (3.2 kg) of powdered lime (calcium hydroxide; 1% based on the weight of corn) to 110 gal (415 liters) of water. Cooking is stopped by adding unheated water to drop the temperature to 150°F (65°C) or below. The corn kernels are then usually steeped for 8–16 h in this solution at about 105–115°F (40–45°C). Rotating drums equipped with pressurized water sprayers are used to wash the swollen kernels and remove the pericarp, lime, and solubles. The washed nixtamal is then ground in attrition mills with one stationary and one rotating stone to form masa. Subsequent processes vary, depending on the product desired. Masa may be dried for later tortilla making. *See* FOOD ENGINEERING; FOOD MANUFACTURING.

Cornales

An order of flowering plants, division Magnoliophyta (Angiospermae), in the superordinal Asteridae group of Eudicotyledon. The order consists of 5 families (Cornaceae, Grubbiaceae, Hydrangeaceae, Hydrostachyaceae, and Loasaceae), approximately 50 genera, and about 600 species. The members of the order show dramatic differences in habitat, ranging from temperate and tropical trees, to herbaceous perennials (Loasaceae), to submerged aquatics (Hydrostachyaceae). The order is mostly characterized by opposite leaves and flowers with four or five perianth parts that usually grow from the top of the ovary (epigynous) (see **illus.**). The fruit is either a fleshy berry or dehiscent capsule. The various species of dogwoods (*Cornus*) and sour gum (*Nyssa sylvatica*, family Cornaceae) are well known. Various species of Hydrangeaceae (deutzia, hydrangea, mock-orange)

Bunchberry or dwarf colonel (*Cornus canadensis*), a common dwarf, woody plant of the boreal forest of North America. (*a*) Four, large, white bracts surround the cluster of small flowers. (*b*) Each flower produces a red berry at maturity. (*Ken Sytsma, University of Wisconsin*)

are important cultivated shrubs. *See* ASTERIDAE; DOGWOOD; PLANT KINGDOM; TUPELO. K. J. Sytsma

Corner reflector antenna

A directional antenna consisting of the combination of a reflector comprising two conducting planes forming a dihedral angle and a driven radiator or dipole which usually is in the bisecting plane. It is widely used both singly and in arrays, gives good gain in comparison with cost, and covers a relatively wide band of frequency. Corner reflector antennas are used in very high-frequency (VHF) and ultrahigh-frequency (UHF) communications systems, telemetry systems, and electronic intelligence gathering systems.

The **illustration** shows the general configuration for a 90° corner reflector. The distance S from the driven radiator D to edge E need not be critically chosen with respect to wavelength; for a 90° reflector D may lie between 0.25 and 0.7 wavelength. The overall dimensions of the reflector need not exceed 2 wavelengths in order to approximate the performance obtained with very large reflectors. Gain, as compared with an isotropic radiator, is about 12 dB.

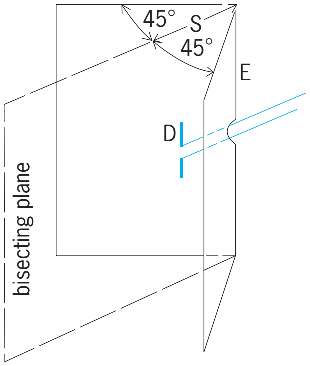

Diagram of corner reflector antenna.

The reflecting planes may be metal sheets or parallel wires separated by a small fraction of a wavelength and extending in the direction of current flow. *See* ANTENNA (ELECTROMAGNETISM). J. C. Schelleng

Bibliography. J. D. Kraus, *Antennas*, 2d ed., McGraw-Hill, 1988.

Corona discharge

A type of electrical conduction that generally occurs at or near atmospheric pressure in gases. A relatively strong electric field is needed. External manifestations are the emission of light and a hissing sound. The particular characteristics of the discharge are determined by the shape of the electrodes, the polarity, the size of the gap, and the gas or gas mixture.

In some cases corona discharge may be desirable and useful, whereas in others it is harmful and attempts are made to minimize it. The effect is used for voltage division and control in direct-current nuclear particle accelerators. On the other hand, the corona discharge that surrounds a high-potential power transmission line represents a power loss and limits the maximum potential which can be used. Because the power loss due to i^2r heating decreases as the potential difference is increased, it is desirable to use maximum possible voltage.

The shape of the electrodes has a very profound effect on the potential current characteristic. If the radius of curvature of the positive electrode is small compared to the gap between electrodes, the transition from the dark current region to the field-sustained discharge will be quite smooth. The effect here is to enable the free electrons to ionize by collision in the high field surrounding this electrode. One electron can produce an avalanche in such a field, because each ionization event releases an additional

Breakdown streamers in positive-point corona crossing from positive point to cathode below. (*From L. B. Loeb, Fundamental Processes of Electrical Discharge in Gases, Wiley, 1939*)

electron, which can then make further ionization. To sustain the discharge, it is necessary to collect the positive ions and to produce the primary electrons far enough from the positive electrode to permit the avalanche to develop. The positive ions are collected at the negative electrode, and it is their low mobility that limits the current in the discharge. The primary electrons are thought to be produced by photoionization (see **illus.**). For a discussion of ionic mobility *see* ELECTRICAL CONDUCTION IN GASES; DARK CURRENT.

The situation at the negative electrode is quite important. The efficiency for ionization by positive ions is much less than for electrons of the same energy. Most of the ionization occurs as the result of secondary electrons released at the negative electrode by positive-ion bombardment. These electrons produce ionization as they move from the strong field at the electrode out into the weak field. This, however, leaves a positive-ion space charge, which slows down the incoming ions. This has the effect of diminishing the secondary electron yield. Because the positive ion mobility is low, there is a time lag before the high field conditions can be restored. For that reason the discharge is somewhat unstable.

From the preceding it may be seen that the electrode shape is important. The dependence on the gas mixture is difficult to evaluate. Electronegative components will tend to reduce the current at a given voltage, because heavy negative ions have a low mobility and are inefficient ionization agents. The excess electron will not be tightly bound, however, and may be released in a collision. The overall effect is to reduce the number of electrons that can start avalanches near the positive electrode. Further, if a gas with low-lying energy states is present, the free electrons can lose energy in inelastic collisions. Thus it is more difficult for the electrons to acquire enough energy to ionize. In electrostatic high-voltage generators in pressurized tanks, it is quite common to use Freon and nitrogen to take advantage of this effect to reduce corona. In a pure monatomic gas such as argon, corona occurs at relatively low values of voltage.

In the potential current characteristic, the corona region is found above the dark current region and is field-sustained. Near the upper end it goes into either a glow discharge or a brush discharge, depending on the pressure. Higher pressure favors the brush discharge. *See* GLOW DISCHARGE.

For still higher potential difference, breakdown takes place and a continuously ionized path is formed. *See* ELECTRIC SPARK. **Glenn H. Miller**

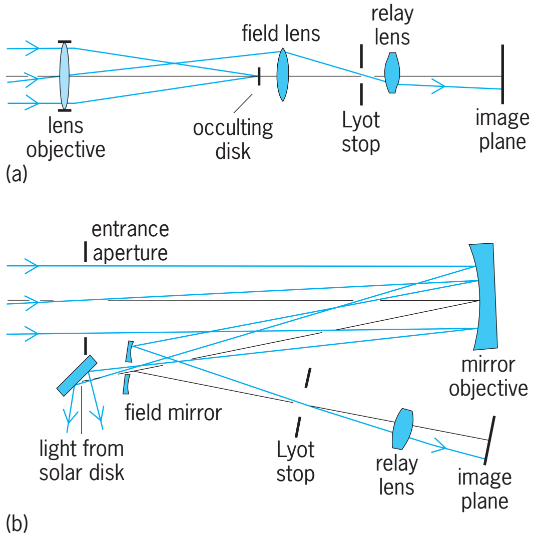
Coronagraph

A specialized astronomical telescope substantially free from instrumentally scattered light, used to observe the solar corona, the faint atmosphere surrounding the Sun. Coronagraphs can record the emission component of the corona (spectral lines emitted by high-temperature ions surrounding the Sun) and the white-light component (solar photospheric light



Basic designs of coronagraphs. (*a*) Lyot coronagraph with lens objective. (*b*) Reflecting coronagraph.

scattered by free electrons surrounding the Sun) routinely from high mountain sites under clear sky conditions. The emission and white-light components are typically only a few millionths the brightness of the Sun itself. Hence, the corona is difficult to observe unless the direct solar light is completely rejected, and unless instrumentally diffracted and scattered light that reaches the final image plane of the coronagraph is small relative to the coronal light. *See* SOLAR CORONA; SUN.

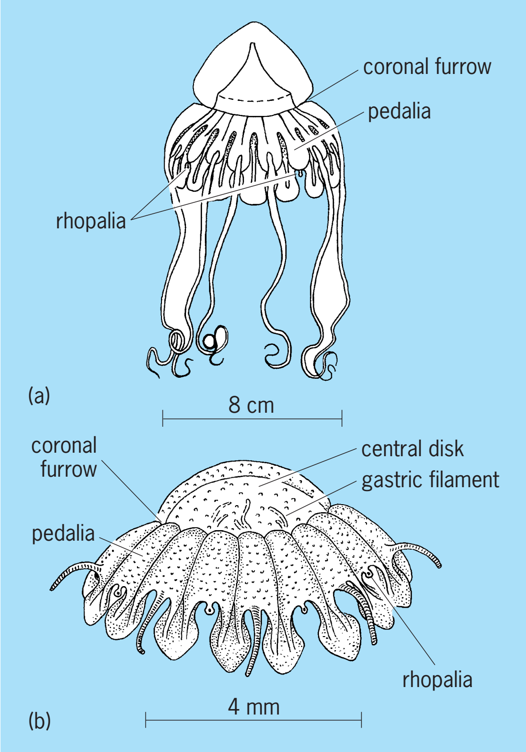
The basic design (**illus.** *a*), as invented by B. Lyot, has an occulting disk in the primary image plane of the telescope to block the image of the Sun itself. In addition, the primary objective (a lens or superpolished mirror) is specially fabricated to minimize scattered light. Also, light diffracted by the objective rim must be suppressed. For this, an aperture (Lyot stop) is placed at an image of the objective as produced by a field lens, with the aperture diameter slightly smaller than that of the objective image. A relay lens behind the Lyot stop forms the coronal image at the final image plane.

To observe the emission corona, optical filters or spectrographs are used to isolate the wavelengths corresponding to the various coronal emission lines and thus minimize the contribution due to the sky. To observe the white-light corona with ground-based coronagraphs, polarization subtraction techniques are required to discriminate the coronal electron-scattered light (polarized with the electric vector tangential to the limb) from the variably polarized sky background. Coronagraphs designed for operation on satellites usually have a circular mask out in front of the objective to completely shade it. This external occulting is more efficient in terms of instrumentally scattered light, when no sky background is present, than if only an internal occulting disk is used, but the inner corona is then vignetted, reducing the angular resolution in this region.

The development of superpolished mirror technology allowed the construction of coronagraphs based on mirror objectives, with significant advantages compared with the singlet-lens objectives used in traditional Lyot coronagraphs. For example, achromaticity allows high imaging quality independent of wavelength, simultaneous multiwavelength observations of the inner solar corona can be achieved, and large apertures are possible. In an off-axis design (illus. *b*), an annular field mirror is located at the image plane formed by the primary objective. The image of the solar disk passes through the hole in the annular mirror and is reflected out to the sky, while the field mirror reflects the coronal field to the lens system that forms the final image. A Lyot stop is located at the image of the entrance aperture, as formed by the field mirror. Raymond N. Smartt

Coronatae

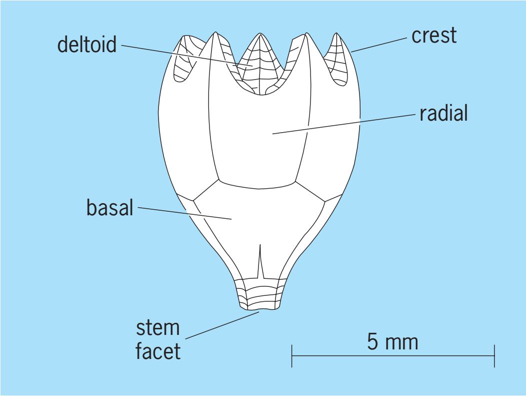
An order of the cnidarian class Scyphozoa which includes mainly abyssal species. The exumbrella is divided by a circular or coronal furrow into two parts, an upper central disk and a lower coronal part (see **illus.**). The central disk is usually domelike, but in *Periphylla* it often narrows toward the top. The coronal part has gelatinous thickenings, or pedalia, situated on the radii running from the center of the umbrella to the tentacles and the sensory organs. The pedalia are separated from one another by clefts, running down the radii, that are halfway between each tentacle and rhopalium (a sensory organ). The mouth has four lips. There are four groups of gastral filaments within the central stomach. Abyssal forms of this group are dark brown or reddish purple. The littoral species of *Nausithoë* is reported to show alternation of generations, but the life history of abyssal forms remains unknown. *See* SCYPHOZOA. Tohru Uchida



Coronatae. (*a*) *Periphylla*. (*b*) *Nausithoë*. (*After L. H. Hyman, The Invertebrates, vol. 1, McGraw-Hill, 1940*)

Coronoidea

A small class of “arm”- and brachiole-bearing, stemmed echinoderms in the subphylum Crinozoa, based on five genera known from the Middle Ordovician to Late Silurian of Europe and North America. Coronoids have a crested theca or body with well-developed pentameral symmetry and plate arrangement very similar to that found in blastoids (see **illus.**). Skeletal plates include three basals (two large and one smaller), five radials extending up to form the crests and bearing central notches for the ambulacra, five small plates supporting the arms, and four regular deltoids plus two anal deltoids in the fifth position around the mouth. The mouth is central on top of the theca and has five ambulacral



***Stephanocrinus gemmiformis*, Middle Silurian, Tennessee; side view of the theca.**

grooves radiating from it. A coiled arm is attached to a mounting plate at the end of each ambulacral groove; each arm has biserial plating with smaller biserial branches (=brachioles) on both sides. The projecting crests have internal canals that connected with the body cavity and apparently served as respiratory structures. A thin stem supported the theca above the sea floor, allowing coronoids to live as attached, low- to medium-level suspension feeders. Coronoids had previously been assigned to the blastoids, eocrinoids, or crinoids by different researchers, but they have been elevated in rank to a separate class. Coronoids appear to be most closely related to the Blastoidea and may have been the ancestors of this class. *See* BLASTOIDEA; ECHINODERMATA; EOCRINOIDEA.

Correspondence principle

A fundamental hypothesis according to which classical mechanics can be understood as a limiting case of quantum mechanics; or conversely, many characteristic features in quantum mechanics can be approximated on the basis of classical mechanics, provided classical mechanics is properly reinterpreted. This idea was first proposed by N. Bohr in the early 1920s as a set of rules for understanding the spectra of simple atoms and molecules.

Bohr's formulations. In 1913 Bohr used classical mechanics to calculate the energy levels of the electron in the hydrogen atom, but this result could not be understood in the conventional manner. Although the electron presumably orbits the proton like a planet around the Sun, Bohr had to assume that its electric charge radiates (or absorbs) light only when it makes a transition from one energy level to another. The frequency ν of the light is always the difference between the two energy levels divided by Planck's constant h.

Bohr's original quantization rules are readily applied to the simplest spectra, in particular to the electrons of hydrogenlike atoms and ions, as well as the vibrations and rotations of small molecules. The classical motions in these simple dynamical systems can be understood as composed of independent partial motions, each with its own degree of freedom, like the motion of the electron toward and away from the nucleus, and its motion around the nucleus. Each degree of freedom accumulates its own classical action-integral. This is the integral defined by Eq. (1), calculated along a closed orbit in terms of

$$I = \int p\,dq \tag{1}$$

the position q and momentum p. The classical energy is a function of these action integrals. Every action I is then related to the quantum number n by the Bohr-Sommerfeld rule, given by Eq. (2). A complete

$$I = nh \tag{2}$$

classification of the spectrum in quantum mechanics is obtained in terms of the quantum numbers. *See* ACTION; ATOMIC STRUCTURE AND SPECTRA; DEGREE OF FREEDOM (MECHANICS); MOLECULAR STRUCTURE AND SPECTRA.

The frequency ν of the classical motion for any particular degree of freedom is given by the partial derivative of the energy function with respect to the corresponding action. Bohr noticed that this classical result yields the correct quantum-theoretical result for the light frequency in a transition from one energy level to another, say from $n + 1$ down to n, provided the derivative is replaced by the difference in the energies. Moreover, precise information about the possibility of such transitions and their intensities is obtained by analyzing the related classical motion. This information becomes better as the quantum numbers involved become larger. The apparent inconsistencies in Bohr's quantum theory are thereby overcome by a set of rules that came to be called the correspondence principle.

This approach to the interpretation of spectra turned out to be very useful to the experimenters. Moreover, in 1925 W. Heisenberg's program of replacing all classical derivatives systematically by the corresponding differences led to the new quantum mechanics, as opposed to the old quantum theory. The complete and overwhelming success of the new quantum mechanics, particularly the equivalent approach of E. Schrödinger (wave mechanics), reduced the correspondence principle to a somewhat vague article of faith among physicists.

Use in statistical mechanics. The appeal to classical mechanics is still convenient for some rather crude estimates such as the total number $N(E)$ of levels below a given energy E. As in statistical mechanics, $N(E)$ depends on the volume of phase space, wherein every point gives the complete information on the state of the dynamical system. The phase space of a system with f degrees of freedom has $2f$ dimensions: f for the position in ordinary space, and f for the momentum. If E is sufficiently large, $N(E)$ approaches the volume of phase space with energy less than E divided by h^f. This estimate helps in finding the approximate shape of large atoms and large nuclei in the Thomas-Fermi model; each particle experiences the average effect of all the others, and only the exclusion principle, not the wavelike nature of the particles, is invoked. *See* EXCLUSION PRINCIPLE; STATISTICAL MECHANICS.

Application to quantum chaos. The correspondence principle, however, has assumed a more profound significance. Experimental techniques in atomic, molecular, mesoscopic, and nuclear physics have improved dramatically. High-precision data for many thousands of energy levels are available where the traditional methods of quantum mechanics are not very useful or informative. However, the basic idea behind the correspondence principle must still be valid: Quantum mechanics must be understandable in terms of classical mechanics for the highly excited states, even in difficult cases like the three-body problem, where the classical motion cannot be resolved into independent partial motions. In these cases, two trajectories that started out at almost the same initial position and with almost the same initial momentum do not stay together in the long run, and their overall behavior seems unpredictable and chaotic.

The challenge of extracting quantum information from classical data is called the problem of quantum chaos. The structure of the trajectories in phase space is fractal; that is, the same patterns occur repeatedly as the scale is reduced. Quantum mechanics does not allow this kind of self-similarity because it describes atoms, objects that cannot be subdivided into ever smaller pieces, and electrons and nuclei are, therefore, represented by waves. Nevertheless, these waves follow the classical rays or trajectories very closely, and their amplitudes act like a bunch of classical particles. These "semiclassical" waves can be superimposed on one another, and thereby manifest all the interference phenomena that are typical of wave optics, and are the essence of quantum mechanics. They yield surprisingly good approximate numerical results as well as intuitive insight, where the standard methods yield only numerical results, often massive calculations. *See* FRACTALS; INTERFERENCE OF WAVES.

The wider application of Bohr's correspondence principle allows many basic but difficult problems to be seen in a new light. The spectra of the hydrogen atom in a strong magnetic field, of the helium atom when both electrons are excited, and of the donor impurity in a semiconductor, and the fluctuations in the electric conductivity for a mesoscopic device are all closely related to the structure of closed orbits in the corresponding classical problem. The statistical properties and the correlations among the energy levels, as well as the fluctuations in the scattering cross sections, for the more complicated nuclei are now understood in terms of the underlying chaos in their classical analogs. *See* CHAOS; MESOSCOPIC PHYSICS; NONRELATIVISTIC QUANTUM THEORY; QUANTUM MECHANICS.

Corrosion

In broad terms, the interaction between a material and its environment that results in a degradation of the physical, mechanical, or even esthetic properties of that material. More specifically, corrosion is usually associated with the oxidation and/or dissolution of a metal, oxide, or semiconductor. For example, immersing a piece of iron in a moderately acidic solution is a typical example of corrosion; the vigorous reaction is the electrochemical oxidation of iron from the zero valence state to divalent ferrous ions (Fe^{+2}) dissolved in the water. Corrosion encompasses principles from diverse fields such as electrochemistry, metallurgy, physics, chemistry, and biology.

Economic impact. The cost of corrosion in the United States and other industrial countries has been estimated to be about 4% of the gross national product. This cost represents both the replacement of structures or components and the protection against corrosion. Such direct losses are relatively easy to assess in comparison to indirect losses, which include the cost of shutdown, loss of product or efficiency, contamination, and even loss of life. Another economic consideration is the source of corrosion-resistant metals. For example, chromium is considered to be of critical importance since it is responsible for the high-temperature oxidation resistance and aqueous corrosion resistance of a wide range of iron- and nickel-based alloys. Much of the chromium being used is considered irreplaceable. Since chromium ores occur primarily in South Africa and Russia, the Western industrialized nations often express concern regarding a perceived vulnerability in supply. *See* CHROMIUM.

Engineering systems for service environments require materials that are chemically stable or that can be made chemically stable. Moreover, modern technology continues to demand materials that can perform in increasingly hostile environments such as high-temperature coal gasification plants, deep sour-gas [natural gas containing hydrogen sulfide (H_2S)] wells, magnetohydrodynamic channels, and fusion reactors. Additionally, as engineering systems continue to evolve, they will use new or advanced materials. Thin-film electronic, magnetic, and optical devices will require special attention to corrosion issues. Likewise, it is necessary to deal with problems associated with traditional systems, such as the aging transportation infrastructure, underground tanks and pipelines, structures exposed to salt water, and conventional coal-burning power stations.

Thermodynamic stability of metals. Metals that are thermodynamically stable in their environment exhibit the best corrosion resistance, but only rarely are such metals of practical use. The stability of a metal in aqueous solutions can be assessed from data on the equilibrium potential that is established by an electrochemical reaction. The relationship between the equilibrium potential of a reaction and the activities of each species is determined by the Nernst equation. By convention, all electrochemical reactions are written in terms of reduction, reaction (1).

$$\mathrm{Fe}^{+2} + 2e^- \rightarrow \mathrm{Fe} \qquad (1)$$

The Nernst equation for these reactions is given in general terms by Eq. (2), where E is the equilibrium

$$E = E^\circ + \frac{2.303RT}{nF} \log \frac{\prod [a_O]^q}{\prod [a_R]^p} \qquad (2)$$

potential, E° is the equilibrium potential under standard conditions, $\Pi[a_R]^p$ and $\Pi[a_O]^q$ are the products of the activities of the reduced and oxidized species, respectively, where p and q are the coefficients for each term in the reaction; n is the number of moles of electrons transferred; F is Faraday's constant; R is the gas constant; and T is temperature. The activities are related to concentration, and in Eq. (2) a_R is the activity of the metal ions (for example, Fe^{2+}). The standard condition is unit activity, which means pure metals or 1 mole/liter for dissolved ions.

The standard reduction potentials for various reactions are given in the **table**. Also included are the standard potentials for the hydrogen evolution and oxygen reduction reactions. The equilibrium potential for the hydrogen evolution reaction at pH 0 is arbitrarily designated as zero volts, and all other potentials are referenced to this value.

This table can be used to predict the thermodynamic tendency of a metal to corrode by comparing the equilibrium potential of the metal dissolution reaction to that of a cathodic reaction. For example, comparing gold dissolution and oxygen reduction would lead to the conclusion that gold is thermodynamically stable under standard conditions. Alternatively, the equilibrium potential for iron (Fe^{2+}/Fe) is more negative than the equilibrium potentials for both cathodic reactions (oxygen evolution and hydrogen ion reduction); iron will, therefore, dissolve to form ferrous ions in solution. Copper has an equilibrium potential more positive than that of the hydrogen reaction and will dissolve only with oxygen reduction under standard conditions.

Standard reduction potentials* for various reactions

Metal	Electrode reaction	E°, V
Gold	$\mathrm{Au}^{3+} + 3e^- \rightarrow \mathrm{Au}$	1.50
Oxygen reduction	$\mathrm{O_2} + 2\mathrm{H_2O} + 4e^- \rightarrow 4\mathrm{OH}^-$	1.23
Copper	$\mathrm{Cu}^{2+} + 2e^- \rightarrow \mathrm{Cu}$	0.34
Hydrogen evolution	$2\mathrm{H}^+ + 2e^- \rightarrow \mathrm{H_2}$	0.00
Tin	$\mathrm{Sn}^{2+} + 2e^- \rightarrow \mathrm{Sn}$	−0.14
Nickel	$\mathrm{Ni}^{2+} + 2e^- \rightarrow \mathrm{Ni}$	−0.25
Iron	$\mathrm{Fe}^{2+} + 2e^- \rightarrow \mathrm{Fe}$	−0.44
Chromium	$\mathrm{Cr}^{3+} + 3e^- \rightarrow \mathrm{Cr}$	−0.74
Zinc	$\mathrm{Zn}^{2+} + 2e^- \rightarrow \mathrm{Zn}$	−0.76
Aluminum	$\mathrm{Al}^{3+} + 3e^- \rightarrow \mathrm{Al}$	−1.66

* $T = 25^\circ\mathrm{C}$ (77°F), $a = 1$ mol/liter.

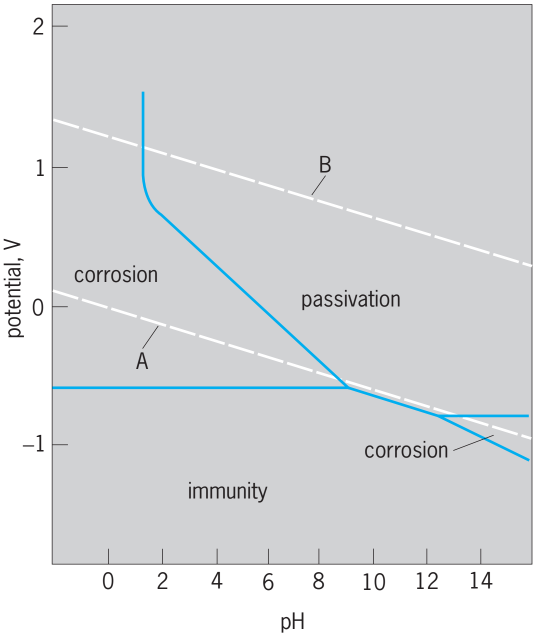

Fig. 1. Potential–pH diagram for the iron–water system: A = hydrogen equilibrium [see reaction (4)]; B = oxygen equilibrium [see reactions (5) and (6)]. (*After M. Pourbaix, ed., Atlas of Electrochemical Equilibria in Aqueous Solutions, NACE, Houston, 1974*)

The pH–potential diagram is an alternative way of representing thermodynamic data that also accounts for the important variable pH. For example, **Fig. 1** shows a potential–pH diagram for the iron–water system at 25°C (77°F). Such diagrams are also known as Pourbaix diagrams. The lines on the diagram are derived from the application of the Nernst equation to reactions involving coexisting phases, both solids and dissolved species. Therefore, areas bounded by these lines represent regions of potential and pH values where the various species predominate. For application to corrosion, the activity of dissolved ions is taken (arbitrarily) as 10^{-6} mole/liter, a value small enough to represent very small, or trivial, corrosion. Also superimposed on the diagram are lines, A and B, representing the limit of stability of water. Therefore, from a consideration of the dominant reactions expected for given values of potential and pH, one can infer whether corrosion, thermodynamic stability (immunity), or passivation is likely. For example, in Fig. 1 in the region of stability of ferric [iron (III)] oxide ($\mathrm{Fe_2O_3}$), iron is protected from corrosion by a thin film of this oxide, a phenomenon known as passivation. In regions where the ferrous ions (Fe^{2+}) or other soluble species are stable, iron will corrode.

Similar diagrams have been compiled for a wide variety of metal-solution systems. However, it is noted that these diagrams allow only thermodynamic predictions and cannot predict the kinetics (rate) of a particular reaction. *See* ACTIVITY (THERMODYNAMICS); CHEMICAL THERMODYNAMICS.

Reactions. Electrolytic corrosion consists of two partial electrochemical reactions: anodic (oxidation) and cathodic (reduction) [**Fig. 2**]. For thermodynamic considerations (as in the table), the cathodic

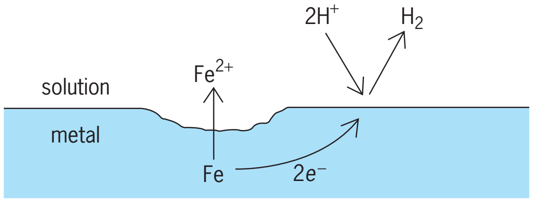

Fig. 2. Diagram of a corrosion cell showing the anodic and cathodic partial processes for a piece of iron in an acidic solution.

reaction is the reverse of the anodic reaction. However, in most aqueous corrosion situations, the anodic reaction is the dissolution of metal and the cathodic reaction is the reduction of a different species—for example, the reduction of dissolved oxygen or hydrogen ions. The loss of metal that is the usual manifestation of the corrosion process is a result of the anodic reaction (3), and the cathodic reaction could be reaction (4). Reaction (4) is often

$$\mathrm{Fe(S)} \rightarrow \mathrm{Fe}^{+2} + 2e^- \qquad (3)$$

$$2\mathrm{H}^+ + 2e^- \rightarrow \mathrm{H_2(g)} \qquad (4)$$

the dominant cathodic reaction in systems at low pH. The hydrogen-evolution reaction can itself cause corrosion-related problems, since atomic hydrogen (H) can enter the metal, causing embrittlement, a phenomenon that results in the degradation of the mechanical properties and can cause catastrophic failure. *See* EMBRITTLEMENT.

At steady state, the rates of each reaction will be such that the electrons (e^-) produced by the oxidation reaction will be consumed by the reduction reaction. The anodic reaction can occur uniformly over a metal surface or can be localized to a specific area. If the dissolved metal ion can react with the solution to form an insoluble compound, a buildup of corrosion products can accumulate at the anodic site. *See* OXIDATION-REDUCTION.

The second important cathodic reaction is the oxygen reduction, given by reactions (5) and (6). These

$$\mathrm{O_{2(dissolved)}} + 4\mathrm{H}^+ + 4e^- \rightarrow 2\mathrm{H_2O} \qquad (5)$$

$$\mathrm{O_{2(dissolved)}} + 2\mathrm{H_2O} + 4e^- \rightarrow 4\mathrm{OH}^- \qquad (6)$$

represent typical reactions in acidic and alkaline solutions, respectively. Equation (6) is usually dominant in solutions of neutral and alkaline pH. In order for this reaction to proceed, a supply of dissolved oxygen is necessary; hence, the rate of this reaction is sometimes limited by the transport of oxygen to the metal surface.

Equations (4), (5), and (6), in practice, can occur by a sequence of reaction steps. In addition, the reaction sequence can be dependent upon the metal surface, resulting in significantly different rates of the overall reaction on different metals. The cathodic reactions are important to corrosion processes since many methods of corrosion control depend on altering the cathodic process. Although the cathodic reactions can be related to corrosion processes, which are usually unwanted, they are essential for many applications such as energy storage and generation.

Rate of corrosion. Corrosion rates can be expressed in several different ways, reflecting the method of measurement. Loss of thickness per unit time [for example, mils (1/1000 in.) per year (MPY)], is commonly used in published data tables, but equivalent corrosion rates can be expressed as weight change per unit area–time (mg/cm^2-day) or as a current density (amperes per unit area). For many applications, 1–5 MPY is considered excellent corrosion resistance. General (uniform) corrosion rates can vary from centimeters per year [for example, iron in sulfuric acid (H_2SO_4)] to micrometers per year. Relatively large corrosion rates can be tolerated for some large structures, whereas for other structures small amounts of corrosion can result in catastrophic failure. For example, with the advent of technology for making extremely small devices, future generations of integrated circuits will contain components that are nanometers (10^{-9} m) in size, and even small amounts of corrosion could cause device failure. For medical devices implanted in the body, one meaningful measure of corrosion reflects the release rate of certain corrosion products into the body, such as milligrams of Ni^{2+} (from stainless steel) per unit area of device per day. The limitation on corrosion due to toxicity might be much more stringent than limitations based on structural damage.

Passivation. Many metals and alloys that exhibit a thermodynamic tendency to corrode actually have remarkable corrosion resistance in many environments due to the formation of a passive film. Passivation is the formation of a thin protective oxide on the surface of a metal. Passive films are usually less than 10 nm thick, but are highly stable and can prevent severe corrosion of the underlying metal. Stainless steels, such as Fe, 18% Cr, 8% Ni, form a highly stable, thin chromium oxide layer. This is the main reason for the widespread application of stainless steels in industry as corrosion-resistant alloys. Likewise, Al_2O_3 passive films protect aluminum alloys in solutions that are not extremely acidic or basic.

The electrochemical characteristics of a metal or alloy usually are measured by a combination of experimental techniques of which the current density–potential behavior is the most common. **Figure 3** shows a current density–potential diagram for AISI (American Iron and Steel Institute) 304 stainless steel (18–20% Cr, 8.0–10.5% Ni, <0.08% C) in 1 N H_2SO_4 solution at 25°C (77°F). The current density is often plotted on a logarithmic scale, as in this figure, due to the exponential relationship between current density and potential for many electrochemical reactions. In Fig. 3, it can be seen that the open-circuit potential, or corrosion potential, is about −0.38 V; and as the potential is increased, the current density increases rapidly to a maximum. At this point, a stable passive film is formed on the surface, and increasing the potential further results in a decrease in current density to a low value. At more positive

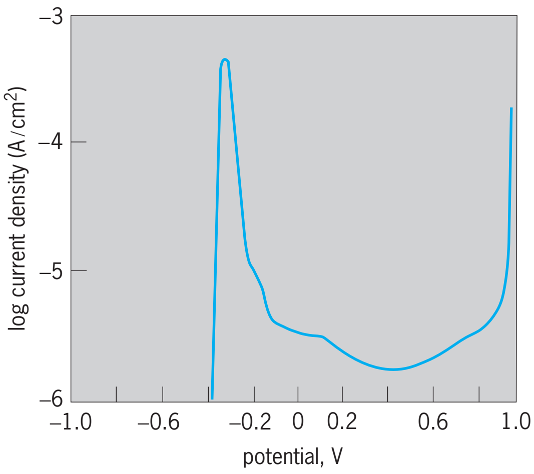

Fig. 3. Current–potential diagram for AISI 304 stainless steel in sulfuric acid (1 *N* H_2SO_4), $T = 25°C$ (77°F), scan rate = 0.3 mV/s.

potentials, the current density increases again at about 1 V because of oxygen evolution from the surface. This plot is typical for alloys that exhibit passivation over a range of potential in a given solution.

The continuous stability of the passive film is critical for most corrosion-resistance applications. A passive film can become unstable in an environment in which it can dissolve chemically or in the presence of certain aggressive anions. Halide ions, and in particular chloride ions, are the most common species that can cause passive film breakdown, and consequently many types of corrosion problems are related to exposure to seawater or other chloride-containing environments. This type of corrosion attack usually is characterized by localized breakdown of the film. For many common engineering alloys, the sites of localized attack usually are related to inhomogeneities such as precipitates or secondary phases.

Types. In some situations, corrosion can occur only at localized regions on a metal surface. This type of corrosion is characterized by regions of locally severe corrosion, although the general loss of thickness can be relatively small. Common types of localized corrosion are pitting corrosion and crevice corrosion. Other types of localized corrosion include galvanic corrosion, stress corrosion cracking, and hydrogen embrittlement.

Pitting. This type of corrosion is usually associated with passive alloys, although this is not always the case. Pit initiation is usually related to the local breakdown of a passive film, and pitting is often related to the presence of halide ions in solution (**Fig. 4**). The local environment within a pit can become extremely acidic, resulting in a high rate of corrosion within this small region. For the common situation of a metal in salt water, the dissolution of metal within the pit results in the formation of metal chlorides. When sufficiently concentrated, these salts react with water (hydrolyze) to form hydrochloric acid (HCl) within the pit, as shown in reaction (7).

$$Fe^{+2} + 2Cl^- + 2H_2O \rightarrow Fe(OH)_2 + 2H^+ + 2Cl^- \qquad (7)$$

The decrease in pH within the pit caused by acid formation further increases the rate of metal dissolution, and such self-accelerating reactions are often called autocatalytic.

Crevice corrosion. This type of corrosion occurs in restricted or occluded regions, such as at a bolted joint, and are often associated with solutions that contain halide ions (**Fig. 5**). Crevice corrosion is initiated by a depletion of the dissolved oxygen in the restricted region. For this situation to occur, the dimension of the restricted region is typically less than 1 mm. As the supply of oxygen within the crevice is depleted, cathodic oxygen reduction from the region adjacent to the crevice takes over, allowing the anodic current on the interior metal surface to continue. The ensuing reactions within the crevice are the same as those described for pitting corrosion; that is, halide ions migrate to the crevice, where they are then hydrolyzed to form metal hydroxides and hydrochloric acid. In neutral salt solutions, the pH within a crevice can fall to a value as low as 2.

Galvanic coupling. Corrosion can also be accelerated in situations where two dissimilar alloys are in electrical contact with each other and with the same solution. This form of corrosion is known as galvanic corrosion. Because the two alloys have different corrosion potentials, a voltage difference arises which drives the anodic reaction on one alloy and the cathodic reaction on the other. The possibility of galvanic corrosion and the identification of the alloy that will become the anode (and hence will experience accelerated corrosion rates) can best be determined from a galvanic series, which is a table of corrosion potentials in a particular solution. The alloy with the more negative potential becomes the anode, while the alloy with the more positive potential sustains the cathodic reaction. For example, a copper water pipe connected to a steel water pipe constitutes a galvanic couple, with the water

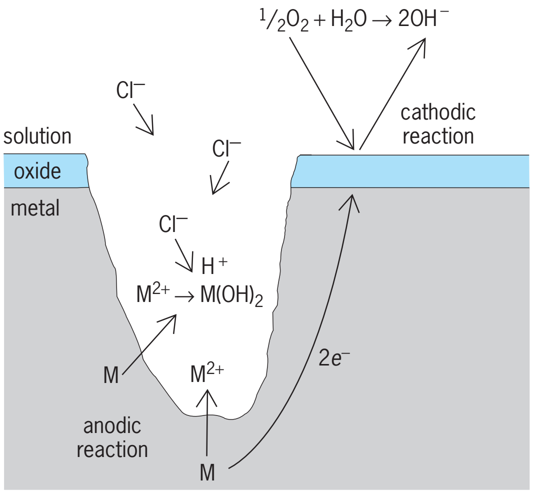

Fig. 4. Diagram of pitting corrosion. The diffusion of chloride ions into the pit to maintain electroneutrality is followed by hydrolysis of metal chlorides, resulting in the formation of hydrochloric acid (HCl).

inside acting as the corroding solution. The steel pipe (anode) will corrode rapidly at locations close to the copper/steel joint. A useful example of galvanic corrosion is the application of a zinc coating to steel (galvanized steel). Zinc has the more negative corrosion potential, so it selectively corrodes, protecting the steel (**Fig. 6**). Another example is the use of magnesium alloy anodes to protect steel ships and steel underground pipelines from corrosion.

Stress corrosion cracking. Stress corrosion cracking (SCC) and hydrogen embrittlement are corrosion-related phenomena associated with the presence of a tensile stress. Stress corrosion cracking results from a combination of stress and specific environmental conditions so that localized corrosion initiates cracks that propagate in the presence of the tensile (stretching) stress. Stress corrosion cracking is particularly dangerous because alloys that normally are quite ductile, and that are used at normally safe design stresses, can fail suddenly without warning by brittle fracture. There are many examples of the specificity of the combination of alloy/environment leading to stress corrosion cracking. For example, mild steels are susceptible to stress corrosion cracking in strongly basic environments (often called caustic cracking). Austenitic stainless steels are susceptible in the presence of chloride ions (Cl^-) and hydroxyl ions (OH^-). For example, in the medical device field stainless-steel implants used to mechanically support broken or diseased bones have been known to fail by stress corrosion cracking, because the environment is a warm, low-oxygen, high-chloride solution. Other alloys that are susceptible under specific conditions include certain brass, aluminum, and titanium alloys.

Hydrogen embrittlement is caused by the entry of hydrogen atoms into a metal or alloy, resulting in a loss of ductility and cracking promotion if the stress is sufficiently high. The source of the hydrogen is usually from corrosion (that is, cathodic hydrogen evolution) or from cathodic protection. Metals and alloys that are susceptible to hydrogen embrittlement include certain carbon steels, high-strength steels, nickel-based alloys, titanium alloys, and some aluminum alloys. *See* ALLOY; STAINLESS STEEL; STEEL.

Other types. Corrosion can be stimulated by biological organisms (such as microbially induced corrosion in soil and pitting induced corrosion beneath barnacles in seawater), where the local chemistry at the metal surface is altered by secretions from the organisms. Contaminants in the air also can accelerate corrosion rates. For example, sulfate particles or acidic droplets (acid rain) accelerate the corrosion of outdoor structures. Dust particles indoors have been shown to corrode unprotected microelectronic circuit boards. *See* ACID RAIN.

Control. In general, the resolution of a corrosion problem starts with the identification of the predominant type of corrosion and a determination of an acceptable design lifetime. Many corrosion problems can be solved simply by modifying the solution composition (pH control) or by selecting a more resistant alloy composition (stainless steel versus mild steel) to achieve a lower rate of corrosion. If large reductions in the rate of corrosion are needed, a useful approach is to separate the aqueous solution from the metal surface with a barrier, for example, using a passivated alloy (stainless steel), applying an overlayer (chrome plating), or adding an inhibitor to the solution. Inhibitors operate by controlling the metal/solution interface. Inorganic salts, such as chromates (CrO_4^{2-}), nitrites (NO_2^-), and phosphates (PO_4^{3-}), either form a barrierlike layer by reacting with the metal surface or stimulate film formation. Organic inhibitors are generally long-chain polar molecules with nitrogen, sulfur, oxygen, or

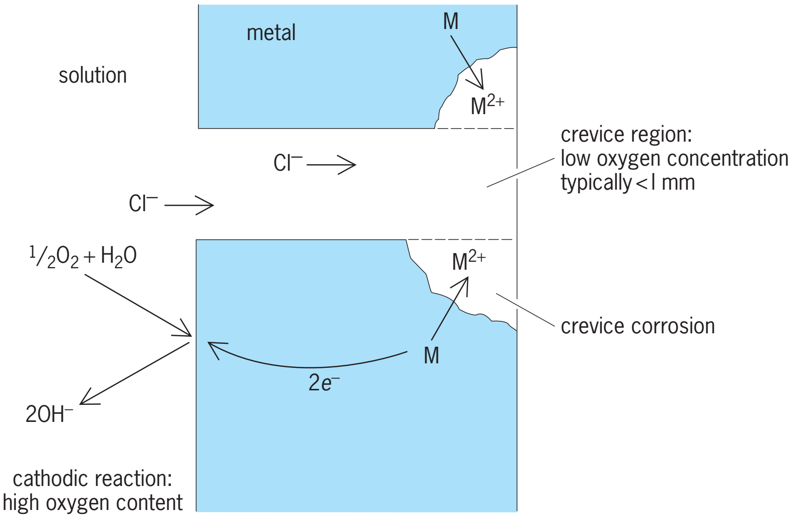

Fig. 5. Diagram of crevice corrosion, showing the mechanisms involved.

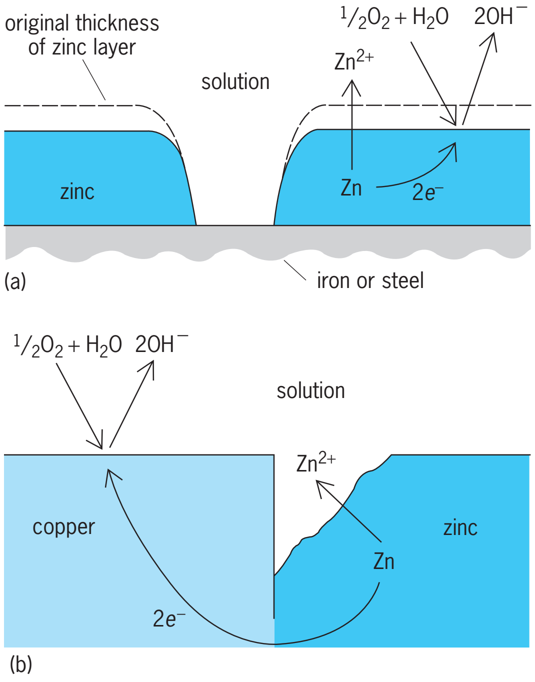

Fig. 6. Reactions of dissimilar metals in contact in the same solution. (*a*) Iron or steel protected from corrosion by a galvanic zinc coating. (*b*) Galvanic corrosion.

hydroxyl groups that strongly chemisorb to the metal surface and thereby separate metal and solution. For some specialized applications, such as protecting parts while they are being stored or shipped, adding a vapor-phase inhibitor to the package can be effective. *See* INHIBITOR (CHEMISTRY); METAL COATINGS.

A different approach is needed for pitting and crevice corrosion problems. Modifying the alloy's surface by cleaning or polishing or by adding a coating may help reduce or avoid the initiation of pits. Crevice corrosion usually can be avoided by redesigning to avoid crevices (for example, joining by welding instead of bolts) or by applying a watertight gasket to the joints. Galvanic corrosion problems can be avoided by choosing alloys with similar corrosion potentials or, if the design allows, by electrically isolating the parts. Designing to avoid stress concentrations (fair out corners) and removing residual stresses that arise from welding can reduce the risk of stress corrosion cracking.

In practice, the application of the above principles often is complicated by additional constraints. Materials selected might need to meet mechanical property specifications and cost restrictions. Clearly, it is impractical to gold-plate automobiles for corrosion resistance, but gold is routinely used for dental crowns, in part because of its corrosion resistance. In some applications, such as the chemical and food-processing industries, the composition of the corroding solution can be quite inflexible, or the solution cannot realistically be altered (for example, seawater). In the biomedical field, the cost of the material chosen for an implant is secondary to achieving the intended function with an appropriate service lifetime; however, the rate of release of potentially toxic corrosion products can be a stringent corrosion limitation. This is one of the newer, challenging areas of corrosion engineering.

Electrochemical techniques also can be used for corrosion control in some applications. For example, cathodic protection is the application of a cathodic current to a structure that prevents it from sustaining an anodic reaction. This can be achieved either by coupling the metal to be protected with a metal having a more negative open-circuit potential (sacrificial anode, such as magnesium) or by applying a cathodic current through an auxiliary electrode (impressed current).

For large structures, such as an underground pipeline, cathodic protection is usually applied in conjunction with a coating, since the current required to protect a large, uncoated structure would be uneconomical. Large marine structures, such as oil drilling platforms, are frequently cathodically protected.

Future. Traditional corrosion engineering problems have included systems such as steam generators, heat exchangers, reaction vessels, bridges, oil platforms, and motor vehicles. These areas will continue to be important in terms of materials selection and corrosion control. Corrosion and its control also will continue to be important in energy systems. The continuing development of alternative energy sources, such as geothermal energy and sour oil and gas wells, require processing in highly corrosive environments. In addition, there is a continuing search for more efficient and less costly materials for fuel cells, batteries, photoelectrolysis, and other emerging technologies.

The current generation of thin-film devices for integrated circuits and magnetic storage, using submicrometer scale ($<10^{-6}$ m) features, pose significant challenges because a small amount of corrosion will cause a device failure. Microprocessors are being used in increasingly aggressive environments, such as process plants and automobiles, where the importance of corrosion control in terms of device packaging will become critical. The current and continuing emphasis on cost reduction is being applied to many different kinds of devices. Corrosion control is increasingly difficult in these circumstances and will require new and ingenious solutions from corrosion scientists and engineers.

All engineering materials are susceptible to some form of environmental degradation. Users of such materials must be aware of the limits of chemical stability of these materials in service environments. *See* ELECTROCHEMISTRY.

Cortex (plant)

The mass of primary tissue in roots and stems extending inward from the epidermis to the phloem. The cortex may consist of one or a combination of three major tissues: parenchyma, collenchyma, and sclerenchyma. In roots the cortex almost always consists of parenchyma, and is bounded, more or less distinctly, by the hypodermis (exodermis) on the periphery and by the endodermis on the inside.

Cortical parenchyma is composed of loosely arranged thin-walled living cells. Prominent intercellular spaces usually occur in this tissue. In stems the cells of the outer parenchyma may appear green due to the presence of chloroplasts in the cells (**Fig. 1**). This green tissue is sometimes called chlorenchyma, and it is probable that photosynthesis takes place in it.

In some species the cells of the outer cortex are modified in aerial stems by deposition of hemicellulose as an additional wall substance, especially in the corners or angles of the cells. This tissue is called collenchyma, and the thickening of the cell walls gives mechanical support to the shoot.

The cortex makes up a considerable proportion of the volume of the root, particularly in young roots, where it functions in the transport of water and ions from the epidermis to the vascular (xylem and phloem) tissues (**Fig. 2**). In older roots it functions primarily as a storage tissue. The cells of the root cortex generally are similar in appearance and may occur in radial files, but histochemical tests reveal a variety of cell types in root cortex.

In addition to being supportive and protective, the cortex functions in the synthesis and localization of many chemical substances; it is one of the most fundamental storage tissues in the plant. The kinds of cortical cells specialized with regard to storage and synthesis are numerous.

Because the living protoplasts of the cortex are so highly specialized, patterns and gradients of many substances occur within the cortex, including starch, tannins, glucosides, organic acids, crystals of many kinds, and alkaloids. Oil cavities, resin ducts, and laticifers (latex ducts) are also common in the midcortex of many plants. *See* SECRETORY STRUCTURES (PLANT).

The young cortex in roots is functional in the selection and passage of solutes and ions into the plant. Experiments with radioactive ions indicate a pileup of solutes in the innermost cells of the cortex next to the endodermis. Radioactive isotopes used in experimental work accumulate just outside the endodermis by a screening action of the endodermis and the innermost cells of the cortex. Cortical cells next to the endodermis apparently act as a selective barrier with the endodermis to the kinds of ions taken into the stele and vascular tissue.

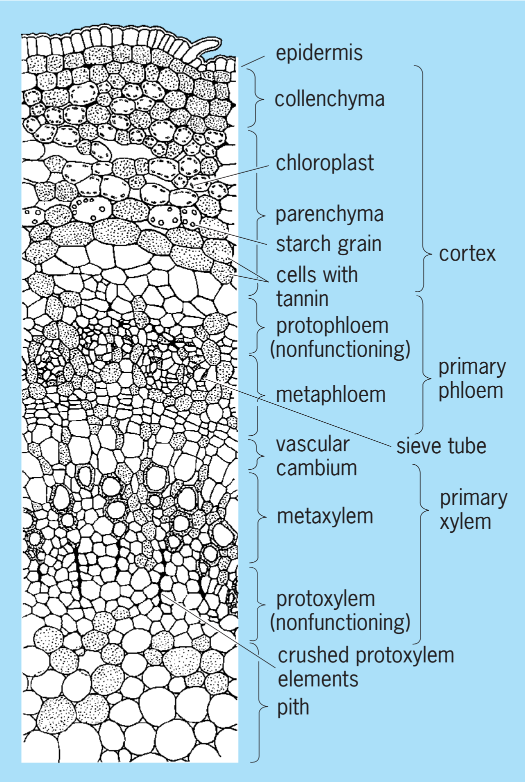

Fig. 1. Transverse section of the *Prunus* stem showing the cortex which is composed of collenchyma and parenchyma. The parenchyma has cells containing chloroplasts, starch grains, and tannin. (*After K. Esau, Plant Anatomy, 2d ed., John Wiley and Sons, 1967*)

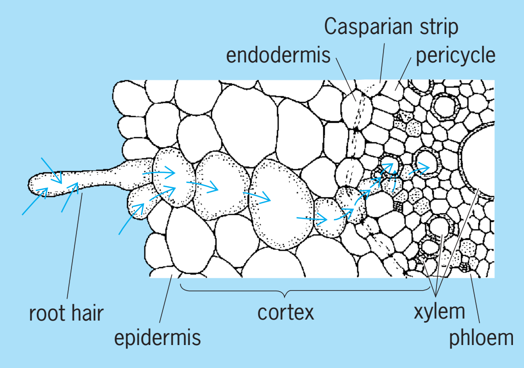

Fig. 2. Transverse section of wheat root, illustrating the kinds of cell that may be crossed by water and salts absorbed from the soil before they reach the tracheary elements of the xylem. The arrows indicate the direction of the movement through a selected series of cells. Among these, the living cells are partly stippled. The Casparian strip in the endodermis is shown as though exposed in surface views of the end walls. (*After K. Esau, Plant Anatomy, 2d ed., John Wiley and Sons, 1967*)

There appears to be complete freedom of movement of water, solutes, and ions through the cortex from the epidermis, but the Casparian strips limit freedom of movement through the endodermis into the stele. The piling up of solutes in the inner cortex limits freedom of movement and may function in the selection of the kinds of ions that pass from the cortex through the endodermis into the stele. Numerous substance gradients, as well as gradients of oxidizing potential across the cortex, may be significant in the uptake of solutes in the active growing portion of young roots. The passage and transport of solutes and ions from the cortex into the vascular system is most pronounced in the cortex just back of the growing tip of the root. In this zone of nutrient absorption, it is believed that passage of solutes into the vascular tissue is effected by an active metabolic transport system in the inner cells of the cortex, with an active system of selection in the endodermis.

The gradient of decreasing oxygen and increasing carbon dioxide across the cortex and into the vascular tissue is associated with a low level of metabolic activity in the cells around the vascular xylem vessels. Cells around the xylem with low metabolic activity would be expected to lose salts, since energy is required to hold salts, into the open vessels of the xylem. Diffusion of solutes back into the cortex is prevented by the impervious Casparian band between all endodermal cells. A unidirectional movement of solutes into the xylem vessels of the plant is a result of the action of the cortex and endodermis. *See* CELL WALLS (PLANT); COLLENCHYMA; ENDODERMIS; HYPODERMIS; PARENCHYMA; ROOT (BOTANY); SCLERENCHYMA; STEM.

Cosmic background radiation

The blackbody radiation left over from the origin of the universe, also known as the cosmic microwave background (CMB). This radiation was emitted before any astronomical objects such as stars, galaxies, or quasars existed, and is now observed to be like the thermal emission from a black object with a temperature of 2.725 K (degrees above absolute zero, or −454.8°F). Blackbody radiation is emitted by an isothermal object that absorbs all incident radiation. Its spectrum, or amount of power at different frequencies, depends only on its temperature and is given by the Planck function. The energy density of this radiation, which peaks at wavelengths near 1 mm, is larger than that of any other cosmic radiation field. Its existence was predicted in 1947 and 1948 by George Gamow, Ralph Alpher, and Robert Herman as part of their model for the formation of the elements during a hot dense phase in the early history of the universe. *See* HEAT RADIATION.

The properties of the cosmic microwave background rule out almost all cosmological models except for these hot big bang models. Observations of the spectrum of the cosmic microwave background show that less than 60 parts per million of the energy in the cosmic microwave background was generated later than 2 months after the creation of the universe and thus indicate that the universe started in a very hot and dense state. The anisotropy of the cosmic microwave background—the difference in the temperature of the blackbody radiation from point to point on the sky—reveals the structure of the universe at the time of recombination, 380,000 years after the big bang, when the free electrons and protons of the cosmic plasma combined into transparent hydrogen and helium gas. After recombination, the photons could freely travel very long distances, so that the small inhomogeneities that existed 380,000 years after the big bang became the small anisotropies that are now observed. *See* BIG BANG THEORY.

History of observations. The model for elememt formation developed by Gamow, Alpher, and Herman encountered difficulties accounting for the creation of elements heavier than lithium. These difficulties led to a general neglect of the model's prediction of the cosmic microwave background, even though the development of radar during World War II and the invention of a sensitive radiometer by Robert Dicke provided the tools necessary for the direct detection of the cosmic microwave background, and Dicke had placed a limit of less than 20 K on the temperature of the sky. The first indirect evidence for the cosmic microwave background was the rotational excitation of the interstellar cyanogen (CN) radical seen in 1939 by Andrew McKellar, but this observation was not connected to Gamow's prediction, except in a review by Fred Hoyle of a book by Gamow. Hoyle, who was co-inventor of the steady-state model of the universe, which was then a rival of the big bang model, felt that the 2.3 K measured by McKellar was too low for the big bang model, but Alpher and Herman had published detailed calculations allowing a current temperature of 1 to 5 K. Unfortunately, neither the big bang proponents nor the steady-state proponents followed up this discrepancy. Thus, the effective discovery of the cosmic microwave background was made by Arno Penzias and Robert Wilson in 1965, as they systematically tried to identify all the sources of noise in a very sensitive antenna used by Bell Labs for early communication satellite experiments. In every direction of sky they saw a nearly constant level of excess noise (**Fig 1*a***), and neither instrumental noise nor atmospheric emission could account for this emission. Dicke, James Peebles, Peter Roll, and David Wilkinson were building a radiometer to look for the cosmic microwave background when they heard of the Penzias and Wilson discovery.

Searches were carried out for the anisotropy of the cosmic microwave background, that is, for temperature differences in the cosmic microwave background in different directions on the sky. These searches led to a tentative detection of a dipole pattern by E. K. Conklin in 1969 which was confirmed

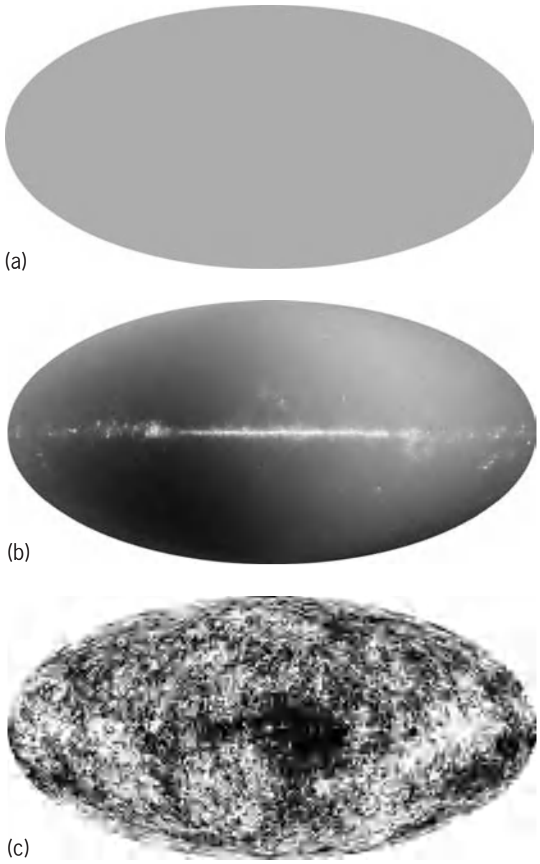

Fig. 1. Plots of the cosmic microwave background (CMB) temperature in a Molleweide projection in galactic coordinates. (*a*) CMB temperature from the *Cosmic Background Explorer* (*COBE*) Differential Microwave Radiometer (DMR), plotted without contrast enhancement. (*b*) Contrast enhanced by a factor of 400 to show the dipole anisotropy and emission from the Milky Way. (*c*) Dipole-subtracted linear combination of different frequency maps chosen to cancel the Milky Way emission, showing the CMB temperature fluctuations with contrast enhanced by a factor of 20,000.

by Paul Henry (a graduate student working with Wilkinson) in 1971, Brian Corey and Wilkinson in 1976, and George Smoot and his colleagues in 1977. A dipole pattern has two poles, with one side of the sky hotter than average, peaking at a hot pole, and the other side cooler than average, giving a cold pole. This dipole pattern is a measure of the motion of the solar system at 368 km/s (823,000 mi/h) relative to the observable universe (Fig 1*b*). After the dipole pattern was subtracted out of the observed temperature map, the anisotropy was less than the sensitivity of these early experiments, which was a few hundred parts per million.

The *Cosmic Background Explorer* (*COBE*) project, proposed in 1974 but not launched by the National Aeronautics and Space Administration (NASA) until 1989, carried an instrument to search for deviations of the cosmic microwave background spectrum from a blackbody, the Far-InfraRed Absolute Spectrophotometer (FIRAS), and an instrument to search for anisotropy, the Differential Microwave Radiometers (DMR). The FIRAS instrument limited distortions of the cosmic microwave background spectrum to less than 50 parts per million root-mean-square. The detection of nondipole anisotropy by the *COBE* DMR at a level of 11 parts per million was described as the "discovery of the century, if not of all time" by Stephen Hawking in 1992.

A second satellite to study the cosmic microwave background was launched by NASA in 2001. This satellite project was led Charles Bennett and Wilkinson, and after Wilkinson's death in 2002, the satellite was renamed the *Wilkinson Microwave Anisotropy Probe* in 2003. *Planck*, a third satellite to study the cosmic microwave background, is scheduled to be launched by the European Space Agency after 2007. *See* WILKINSON MICROWAVE ANISOTROPY PROBE.

Spectrum of CMB. The best measurement of the spectrum of the cosmic microwave background was made by the FIRAS instrument on *COBE*. This spectrometer compared the sky with a very good blackbody on the spacecraft and thus made a very sensitive measurement of deviations from a Planck function. The measured cosmic microwave background spectrum agrees with the spectrum of a blackbody to within 50 parts per million, and the temperature of the blackbody that best matches the sky is measured to be 2.725±0.002 K. **Figure 2** shows the spectrum of the cosmic microwave background plotted such that a blackbody is a horizontal line. The cosmic microwave background is remarkably close to a blackbody.

The expansion of the universe produces a redshift that preserves the blackbody character of the radiation. When the universe was 0.1% of its current size, the photons of the blackbody radiation field had 1000 times more energy than they do now. Since this time the wavelengths of the photons have increased by a factor of 1000, while the size of the universe has also increased by a factor of 1000. This ratio of the final wavelength λ_{obs} to the initial wavelength λ_{em} is used to define z, the redshift, via the formula $1 + z = \lambda_{obs}/\lambda_{em}$. Thus, when the universe was 0.1% of its current size, the color temperature deduced from the photon energy was 1000 times higher than T_0=2.725 K. However, the number density of the photons was 10^9 times higher than the current number density, and the energy density was 10^{12} times higher than the current energy density. This is exactly the energy density proportional to T^4 law seen for blackbodies. Thus, once a blackbody radiation field is produced, the expansion of the universe acts in a way that preserves the blackbody character of the radiation, with only the temperature changing. *See* REDSHIFT.

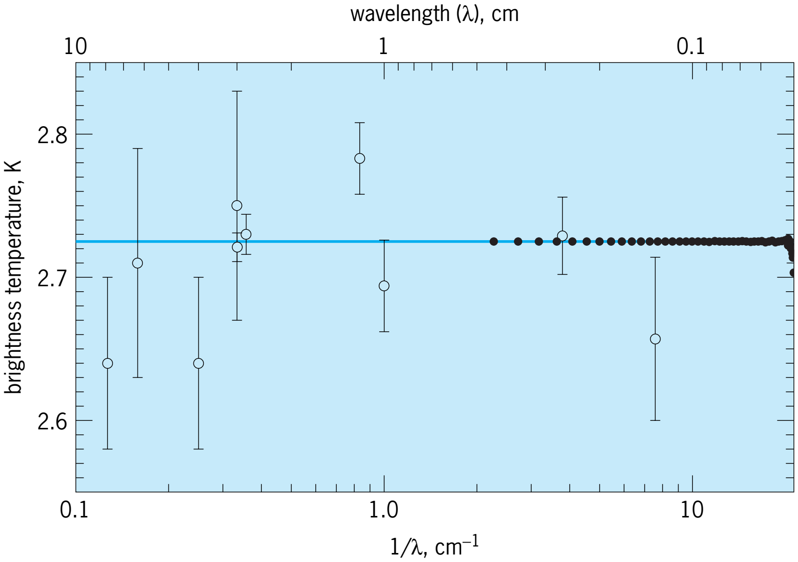

Fig. 2. Brightness temperature of the cosmic microwave background as a function of wavelength λ. For a perfect blackbody, the brightness temperature is independent of wavelength. The horizontal line is a blackbody at a temperature of 2.725 K. The closed points are the very precise Far-InfraRed Absolute Spectrophotometer (FIRAS) data.

Isotropy of CMB. The cosmic microwave background is completely isotropic to about 1 part per thousand and, except for the velocity of the solar system, would be isotropic to better than 40 parts per million. Figure 1*a* shows the temperature of the sky without any contrast enhancement, and no structure can be seen. This is quite a remarkable property that is best explained by the inflationary scenario which postulates an immense expansion of the universe during the first picosecond after the big bang. *See* INFLATIONARY UNIVERSE COSMOLOGY.

Anisotropy of CMB. When the contrast of the temperature map is increased by a factor of 400, as shown in Fig. 1*b*, a systematic variation across the sky can be seen. This figure uses an equal-area Molleweide projection to show the entire sky in an ellipse with a 2:1 aspect ratio, and the equator of the map is the galactic plane, with the center of the Milky Way Galaxy occupying the center of the map. The "dipole" pattern with a hot pole in the upper right and a cold pole in the lower left can be explained by a Doppler shift between the frame of reference of the solar system and a frame of reference at rest relative to the observable universe. *See* DOPPLER EFFECT; MAP PROJECTIONS.

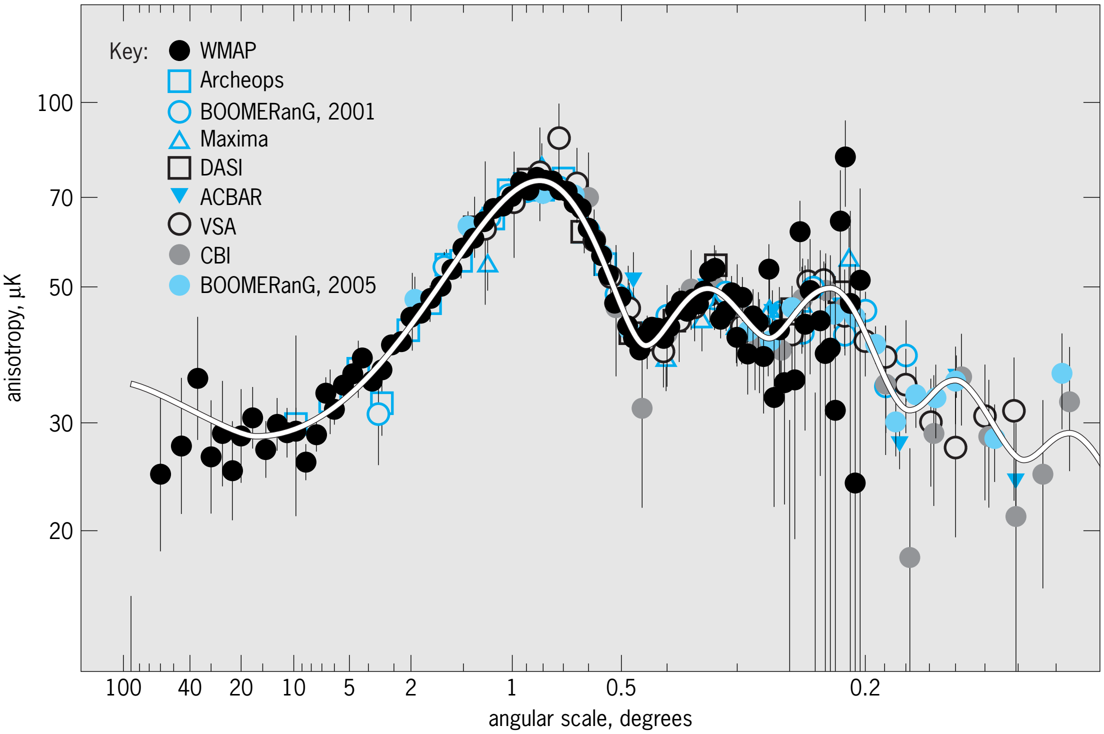

Fig. 3. Angular power spectrum of the cosmic microwave background as measured by the *Wilkinson Microwave Anisotropy Probe* (*WMAP*) and other experiments, including the balloon-borne Archeops, BOOMERanG (data published in 2001 and 2005), and Maxima experiments, the ground-based Very Small Array (VSA) and Cosmic Background Imager (CBI), and DASI and ACBAR at the South Pole. The curve shows the predicted angular power spectrum for a model of the universe with Euclidean (flat) geometry, dominated by vacuum energy (dark energy).

Since the pattern produced on the sky by a Doppler shift can be predicted, the dipole anisotropy can be removed from the map, giving a no-dipole map. After this, the largest signal that remains is due to the radio and millimeter wave emission from the Milky Way. This emission is much stronger at centimeter wavelengths than at millimeter wavelengths, so if a fraction of a long-wavelength map is subtracted from a short-wavelength map, almost all of the emission from the Milky Way can be canceled while still leaving a strong cosmic microwave background anisotropy signal. Figure 1*c* shows such a no-dipole, no-Galaxy map based on data from the *Wilkinson Microwave Anisotropy Probe*.

The dominant cause of the temperature fluctuations for large angular scales is the gravitational redshift. Dense regions have negative gravitational potential wells, and the photons of the cosmic microwave background lose energy as they leave the potential wells. This effect is larger than the normal density effect wherein gases become hotter when compressed. However, at small angular scales the situation changes, in part because the density fluctuations have time to change between the big bang and recombination. The photons and the baryons plus electrons (ordinary matter) are tightly coupled before recombination, so the density fluctuations travel as acoustic waves at the sound speed in the plasma. Because there are billions of photons for every baryon, the radiation pressure from the photons is large compared with the energy density from the baryon rest mass, so the speed of sound c_s is very high, and is comparable to the speed of light c, being given approximately by the formula $c_s{\sim}c/\sqrt{3}=170{,}000$ km/s (380,000,000 mi/h). If the wavelength of a fluctuation is set so that it goes through one-half cycle of oscillation before recombination, the effects of the photon density and the gravitational redshift are in phase at recombination instead of partially canceling. This wave has a frequency of 42 femtohertz (4.2×10^{-14} Hz, more than 52 octaves below middle C) and a wavelength of 400,000 light-years. It shows up on the sky as a 1.6° angle with peaks separated by 0.8° from adjacent valleys. Thus, there will be more anisotropy in bumps about 0.8° in size compared to other angular scales. This phenomenon is evident in **Fig. 3**, a plot of the amount of anisotropy versus angular scale, or the angular power spectrum, which has a peak at an angular scale of 0.8°.

Conclusions. Observations of the cosmic microwave background provide a wealth of information about the universe. The cosmic microwave background spectrum gives a picture of the universe from 2 months after the big bang. (Prior to 2 months any spectral distortions were eliminated, while after 2 months the distortions were modified by electron scattering but still survived.) The anisotropy of the cosmic microwave background shows the state of the universe 380,000 years after the big bang, but that state was established during the inflation epoch less than 1 picosecond (10^{-12} s) after the big bang.

From the heights of the peaks and the depths of the troughs in the angular power spectrum (Fig. 3), the density of baryons (protons and neutrons in atomic nuclei) and the density of cold dark matter in the universe have been found: 0.42 ± 0.02 yoctogram (1 yg $= 10^{-24}$ g) per cubic meter for baryons and 2.1 ± 0.2 yg/m^3 for dark matter. In combination with other data, the cosmic microwave background results also show that the universe has Euclidean (Flat) geometry, that 75% of the energy in the universe is vacuum energy (dark energy), and that the universe is 13.7×10^9 years old. *See* COSMOLOGY; DARK ENERGY; DARK MATTER; UNIVERSE. Cosmic rays

Electrons and the nuclei of atoms—largely hydrogen—that impinge upon Earth from all directions of space with nearly the speed of light. Before they enter the atmosphere they are typically referred to as primary cosmic rays, to distinguish them from the particles generated by their interaction with the terrestrial atmosphere. Secondary cosmic rays, comprising a large variety of species of charged and neutral particles, cascade down through the atmosphere all the way to the ground and below. Study of cosmic rays at high energy now is often referred to as particle astrophysics.

Cosmic rays are studied for a variety of reasons, not the least of which is a general curiosity over the process by which nature can produce such energetic nuclei. Apart from this, primary cosmic rays provide the only direct sample of matter from far outside the solar system. Measurement of their composition can aid in understanding which properties of the matter making up the solar system are typical of the Milky Way Galaxy as a whole and which may be so atypical as to yield specific clues to the origin of the solar system. Cosmic rays are electrically charged; hence they are deflected by the magnetic fields which are thought to exist throughout the Milky Way Galaxy, and may be used as probes to determine the nature of these fields far from Earth. Outside the solar system the energy contained in the cosmic rays is comparable to that of the magnetic field, so the cosmic rays probably play a major role in determining the structure of the field. Collisions between cosmic rays and the nuclei of the atoms in the tenuous gas which permeates the Milky Way Galaxy change the cosmic-ray composition in a measurable way and produce gamma rays which can be detected at Earth, giving information on the distribution of this gas. *See* GAMMA-RAY ASTRONOMY.

This modern understanding of cosmic rays evolved through a process of discovery which at many times produced seemingly contradictory results, the ultimate resolution of which led to fundamental discoveries in other fields of physics, most notably high-energy particle physics. At the turn of the century several different types of radiation were being studied, and the different properties of each were being determined with precision. One result of many precise experiments was that an unknown source of radiation existed with properties that were difficult to characterize. In 1912 Viktor Hess made a definitive series of balloon flights which showed that this background radiation increased with altitude in a dramatic fashion. Far more penetrating then any other known at that time, this radiation had many other unusual properties and became known as cosmic radiation, because it clearly did not originate in the Earth or from any known properties of the atmosphere.

Unlike the properties of alpha-, beta-, gamma-, and x-radiation, the properties of cosmic radiation are not of any one type of particle, but are due to the interactions of a whole series of unstable particles, none of which was known at that time. The initial identification of the positron, the muon, the π meson or pion, and certain of the K mesons and hyperons were made from studies of cosmic rays.

Thus the term cosmic ray does not refer to a particular type of energetic particle, but to energetic particles being considered in their astrophysical context. The effects of cosmic rays on living cells are discussed in a number of other articles: for example, *See* ELEMENTARY PARTICLE; RADIATION INJURY (BIOLOGY).

Cosmic-ray detection. Cosmic rays are usually detected by instruments which classify each incident particle as to type, energy, and in some cases time and direction of arrival. A convenient unit for measuring cosmic-ray energy is the electronvolt, which is the energy gained by a unit charge (such as an electron) accelerating freely across a potential of 1 V. One electronvolt equals about 1.6×10^{-19} joule. For nuclei it is usual to express the energy in terms of electronvolts per nucleon, since the relative abundances of the different elements are nearly constant as a function of this variable. Two nuclei with the same energy per nucleon have the same velocity.

Flux. The intensity of cosmic radiation is generally expressed as a flux by dividing the average number seen per second by the effective size or "geometry factor" of the measuring instrument. Calculation of the geometry factor requires knowledge of both the sensitive area (in square centimeters) and the angular acceptance (in steradians) of the detector, as the arrival directions of the cosmic rays are randomly distributed to within 1% in most cases. A flat detector of any shape but with area of 1 cm^2 has a geometry factor of π cm$^2 \cdot$ sr if it is sensitive to cosmic rays entering from one side only. The total flux of cosmic rays in the vicinity of the Earth but outside the atmosphere is about 0.3 nucleus/(cm$^2 \cdot$ s $\cdot$ sr) [2 nuclei/(in.$^2 \cdot$ s $\cdot$ sr)]. Thus a quarter dollar, with a surface area of 4.5 cm^2 (0.7 in.^{2}), lying flat on the surface of the Moon will be struck by $0.3 \times 4.5 \times 3.14 = 4.2$ cosmic rays per second.

Energy spectrum. The flux of cosmic rays varies as a function of energy. This function, called an energy spectrum, may refer to all cosmic rays or to only a selected element or group of elements. Since cosmic rays are continuously distributed in energy, it is meaningless to attempt to specify the flux at any exact energy. Normally an integral spectrum is used, in which the function gives the total flux of particles with energy greater than the specified energy [in particles/($cm^2 \cdot s \cdot sr$)], or a differential spectrum, in which the function provides the flux of particles in some energy interval (typically 1 MeV/nucleon wide) centered on the specified energy, in particles/[$cm^2 \cdot s \cdot sr \cdot$ (MeV/nucleon)]. The basic approach of cosmic-ray research is to measure the spectra of the different components of cosmic radiation and to deduce from them and other observations the nature of the cosmic-ray sources and the details of where the particles travel on their way to Earth and what they encounter on their journey.

Types of detectors. All cosmic-ray detectors are sensitive to moving electrical charges. Neutral particles (neutrons, gamma rays, and neutrinos) are studied by observing charged particles produced in the collision of the neutral primary with some type of target. At low energies the ionization of the matter through which they pass is the principal means of detection. Such detectors include cloud chambers, ion chambers, spark chambers, Geiger counters, proportional counters, scintillation counters, solid-state detectors, photographic emulsions, and chemical etching of certain mineral crystals or plastics in which ionization damage is revealed. The amount of ionization produced by a particle is given by the square of its charge multiplied by a universal function of its velocity, the Bethe-Bloch relation. A single measurement of the ionization produced by a particle is therefore usually not sufficient both to identify the particle and to determine its energy. However, since the ionization itself represents a significant energy loss to a low-energy particle, it is possible to design systems of detectors which trace the rate at which the particle slows down and thus to obtain unique identification and energy measurement. *See* GAMMA-RAY DETECTORS; GEIGER-MÜLLER COUNTER; IONIZATION CHAMBER; JUNCTION DETECTOR; PARTICLE TRACK ETCHING; PHOTOGRAPHIC MATERIALS; SCINTILLATION COUNTER.

At energies above about 500 MeV/nucleon, almost all cosmic rays will suffer a catastrophic nuclear interaction before they slow appreciably. Some measurements are made using massive calorimeters which are designed to trap all of the energy from the cascade of particles which results from such an interaction. More commonly an ionization measurement is combined with measurement of a physical effect that varies in a different way with mass, charge, and energy. Cerenkov detectors and the deflection of the particles in the field of large superconducting magnets (or the magnetic field of the Earth itself) provide the best means of studying energies up to a few hundred gigaelectronvolts per nucleon. Detectors of x-ray transition radiation are useful for measuring composition at energies up to a few thousand GeV per nucleon. Transition radiation detectors are also used to study electrons having energies of 10–200 GeV which, because of their lower rest mass, are already much more relativistic than protons of the same energies. *See* CERENKOV RADIATION; SUPERCONDUCTING DEVICES; TRANSITION RADIATION DETECTORS.

Above about 10^{14} eV, direct detection of individual particles is no longer practical, simply because they are so rare. Such particles are studied by observing the large showers of secondaries they produce in Earth's atmosphere. These showers are detected either by counting the particles which survive to strike ground-level detectors or by looking at the flashes of light the showers produce in the atmosphere with special telescopes and photomultiplier tubes. It is not possible to directly determine what kind of particle produces any given shower. Because of the extreme energies involved, which can be measured with fair accuracy and have been seen as high as 10^{20} eV (16 J), most of the collision products travel in the same direction as the primary and at essentially the speed of light. This center of intense activity has typical dimensions of only a few tens of meters, allowing it to be tracked (with sensitive instruments) like a miniature meteor across the sky before it hits the Earth at a well-defined location. In addition to allowing determination of the direction from which each particle came, the development of many such showers through the atmosphere may be studied statistically to gain an idea of whether the primaries are protons or heavier nuclei. The main idea behind these studies is that a heavy nucleus, in which the energy is initially shared among several neutrons and protons, will cause a shower that starts higher in the atmosphere and develops more regularly than a shower which has the same total energy but is caused by a single proton. *See* PARTICLE DETECTOR; PHOTOMULTIPLIER.

Atmospheric cosmic rays. The primary cosmic-ray particles coming into the top of the terrestrial atmosphere make inelastic collisions with nuclei in the atmosphere. The collision cross section is essentially the geometrical cross section of the nucleus, of the order of 10^{-26} cm^2 (10^{-27} in.^{2}). The mean free path for primary penetration into the atmosphere is given in **Table 1**. (Division by the atmospheric density in g/cm^3 gives the value of the mean free path in centimeters.)

TABLE 1. Mean free paths for primary cosmic rays in the atmosphere

Charge of primary nucleus	Mean free path in air, g/cm^2*
$Z = 1$	60
$Z = 2$	44
$3 \leq Z \leq 5$	32
$6 \leq Z \leq 9$	27
$10 \leq Z \leq 29$	21

*1 g/cm^2 = 1.42 × 10^{-2} lb/in.^{2}

When a high-energy nucleus collides with the nucleus of an air atom, a number of things usually occur. Rapid deceleration of the incoming nucleus leads to production of pions with positive, negative, or neutral charge; this meson production is closely analogous to the generation of x-rays, or bremsstrahlung, produced when a fast electron is deflected by impact with the atoms in a metal target. The mesons, like the bremsstrahlung, come off from the impact in a narrow cone in the forward direction. Anywhere from 0 to 30 or more pions may be produced, depending upon the energy of the incident nucleus. The ratio of neutral to charged pions is about 0.75. A few protons and neutrons (in about equal proportions) may be ejected with energies up to a few GeV. They are called knock-on protons and neutrons. *See* BREMSSTRAHLUNG; MESON; NUCLEAR REACTION.

A nucleus struck by a proton or neutron with energy greater than approximately 300 MeV may have its internal forces momentarily disrupted so that some of its nucleons are free to leave with their original nuclear kinetic energies of about 10 MeV. The nucleons freed in this fashion appear as protons, deuterons, tritons, alpha particles, and even somewhat heavier clumps, radiating outward from the struck nucleus. In photographic emulsions the result is a number of short prongs radiating from the point of collision, and for this reason it is called a nuclear star.

All these protons, neutrons, and pions generated by collision of the primary cosmic-ray nuclei with the nuclei of air atoms are the first stage in the development of the secondary cosmic-ray particles observed inside the atmosphere. Since several secondary particles are produced by each collision, the total number of energetic particles of cosmic-ray origin will at first increase with depth, even while the primary density is decreasing. Since electric charge must be conserved and the primaries are positively charged, positive particles outnumber negative particles in the secondary radiation by a factor of about 1.2. This factor is called the positive excess.

Electromagnetic cascade. Uncharged π^0 mesons decay into two gamma rays with a lifetime of about 9×10^{-17} s. The decay is so rapid that π^0 mesons are not directly observed among the secondary particles in the atmosphere. The two gamma rays, which together have the rest energy of the π^0, about 140 MeV, plus the π^0 kinetic energy, each produce a positron-electron pair. Upon passing sufficiently close to the nucleus of an air atom deeper in the atmosphere, the electrons and positrons convert their energy into bremsstrahlung. The bremsstrahlung in turn creates new positron-electron pairs, and so on. This cascade process continues until the energy of the initial π^0 has been dispersed into a shower of positrons, electrons, and photons with insufficient individual energies ($\leq$1 MeV) to continue the pair production. The shower, then being unable to reproduce its numbers, is dissipated by ionization of the air atoms. The electrons and photons of such showers are referred to as the soft component of the atmospheric (secondary) cosmic rays, reaching a maximum intensity at an atmospheric depth of 150–200 g/cm^2 and then declining by a factor of about 10^2 down to sea level. *See* ELECTRON-POSITRON PAIR PRODUCTION.

Muons. The $\pi^\pm$ mesons produced by the primary collisions have a lifetime about 2.6×10^{-8} s before they decay into muons: $\pi^\pm \rightarrow \mu^\pm +$ neutrino. With a lifetime of this order a $\pi^\pm$ possessing enough energy (greater than 10 GeV) to experience significant relativistic time dilatation may exist long enough to interact with the nuclei of the air atoms. The cross section for $\pi^\pm$ nuclear interactions is approximately the geometrical cross section of the nucleus, and the result of such an interaction is essentially the same as for the primary cosmic-ray protons. Most low-energy $\pi^\pm$ decay into muons before they have time to undergo nuclear interactions.

Except at very high energy (above 500 GeV), muons interact relatively weakly with nuclei, and are too massive (207 electron masses) to produce bremsstrahlung. They lose energy mainly by the comparatively feeble process of ionizing air atoms as they progress downward through the atmosphere. Because of this ability to penetrate matter, they are called the hard component. At rest their lifetime is 2×10^{-6} s before they decay into an electron or positron and two neutrinos, but with the relativistic time dilatation of their high energy, 5% of the muons reach the ground. Their interaction with matter is so weak that they penetrate deep into the ground, where they are the only charged particles of cosmic-ray origin to be found. At a depth equivalent of 300 m (990 ft) of water the muon intensity has decreased from that at ground level only by a factor of 20; at 1400 m (4620 ft) it has decreased by a factor of 10^3.

Atmospheric neutrinos. In the late 1990s, detectors became available with sufficient sensitivity to exploit atmospheric neutrinos. Neutrinos of different types are produced in association with muons and electrons, and it is possible to calculate the expected flux of each type with some accuracy. Production of other types of neutrinos is predicted to be quite small. The detected flux of muon neutrinos is significantly lower than the calculation, in analogy with a similar deficit in the neutrino flux from the Sun. Data from the large detector Super Kamiokande in Japan gave the first indication that the atmospheric deficit is due to transformation (known as oscillation) of muon neutrinos into other types of neutrinos. The Sudbury Neutrino Observatory in Canada has confirmed this transformation, demonstrating that the rest mass of the neutrino, while very small, is not zero. Astrophysical consequences of a nonzero rest mass are profound, as a particle with a rest mass interacts gravitationally in a way totally different from that of a particle (such as a photon) with no rest mass. Huge numbers of neutrinos permeate the universe, and details of their gravitational interaction are crucial to the understanding of galaxy formation. *See* NEUTRINO.

Nucleonic component. The high-energy nucleons—the knock-on protons and neutrons—produced by the primary-particle collisions and a few pion collisions proceed down into the atmosphere. They produce nuclear interactions of the same kind as the primary nuclei, though of course with diminished energies. This cascade process forms the nucleonic component of the secondary cosmic rays.

When nucleon energy falls below about 100 MeV, stars and further knock-ons can no longer be produced. At the same time the protons are rapidly disappearing from the cascade because their ionization losses in the air slow them down before they can make a nuclear interaction. Most of the hadrons in the lower atmosphere are thus neutrons, which are already dominant at 3500 m (11,550 ft), about 300 g/cm^2 (4.3 lb/in.^{2}) above sea level, where they outnumber the protons four to one. Thus the final stages of the cascade involve mainly neutrons in a sequence of low-energy interactions which convert them to thermal neutrons (neutrons of kinetic energy of about 0.025 eV) in a path of about 90 g/cm^2 (1.3 lb/in.^{2}). These thermal neutrons are readily detected in boron trifluoride (BF_3) and helium-3 (^{3}He) counters. The nucleonic component increases in intensity down to a depth of about 120 g/cm^2 (1.7 g/cm^3), and thereafter declines in intensity, with a mean absorption length of about 200 g/cm^2 (2.8 lb/in.^{2}).

The various cascades of secondary particles in the atmosphere are shown schematically in **Fig. 1**. About 48% of the initial primary cosmic-ray energy goes into charged pions, 25% into neutral pions, 7% into the nucleonic component, and 20% into stars. The nucleonic component is produced principally by the lower-energy (about 5 GeV) primaries. Higher-energy primaries put their energy more into meson production. Hence in the lower atmosphere, a Geiger counter responds mainly to the higher-energy primaries (about 5 GeV) because it counts the muons and electrons, whereas a BF_3 counter detecting thermal neutrons responds more to the low-energy primaries.

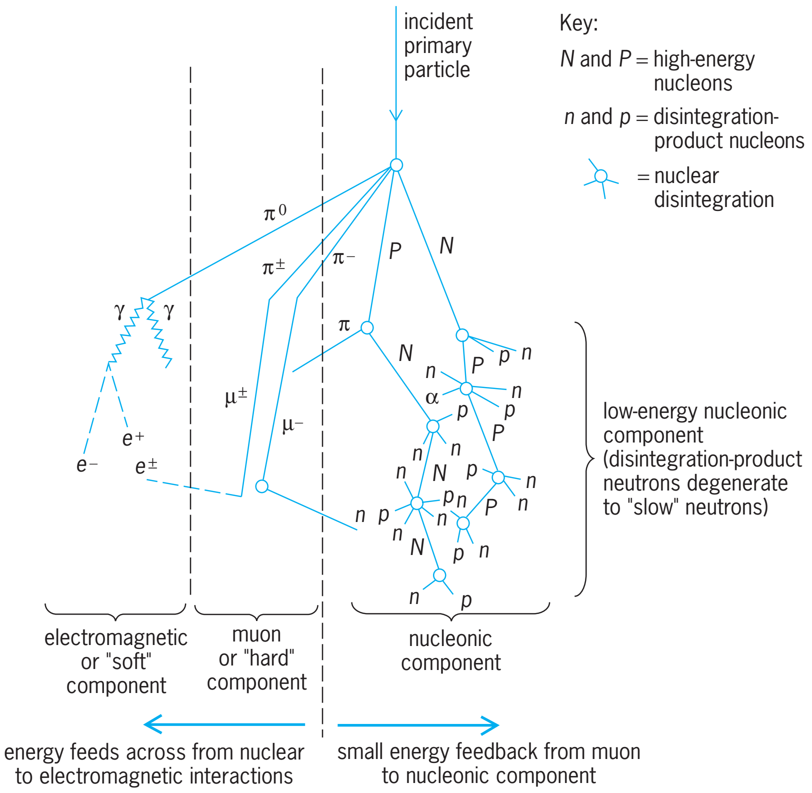

Fig. 1. Cascade of secondary cosmic-ray particles in the terrestrial atmosphere.

Neutrinos. Cosmic neutrinos, detected for the first time from the explosion of the supernova 1987A, provide confirmation of theoretical calculations regarding the collapse of the cores of massive stars. Although neutrinos are produced in huge numbers (over 10^{15} passed through a typical human body from this supernova), they interact with matter only very weakly, necessitating a very large detector. Detectors consisting of huge tanks containing hundreds of tons of pure water located deep underground to reduce the background produced by other cosmic rays recorded less than two dozen neutrino events. Still larger detectors, which are under construction in the Antarctic ice and underwater at several locations, will permit observation of more distant supernovae and allow sensitive searches for point sources of high-energy neutrinos. Additionally, by measuring the fraction of non-neutrino-induced events containing multiple muons, these new detectors can investigate the composition of cosmic rays at energies above 10^{15} eV. Some preliminary measurements indicate that these high-energy cosmic rays may consist primarily of iron nuclei rather than the protons that dominate at lower energies. Much of the interest in the new neutrino observatories derives from the success of the now maturing field of measurement of the flux of solar neutrinos, which is really quite a different problem. With the realization that neutrinos have mass, increasingly precise measurements of the solar neutrino flux, coupled with such techniques as helioseismology, continue to make fundamental contributions to the study of the internal structure of the Sun. *See* NEUTRINO ASTRONOMY; SOLAR NEUTRINOS; SUPERNOVA.

Relation to particle physics. Investigations of cosmic rays continue to make fundamental contributions to particle physics. Neutrino detectors, besides detecting oscillations of atmospheric neutrinos, have set the best limit yet (about 10^{32} years) on the lifetime of the proton. Cosmic rays remain the only source of particles with energies above 1000 GeV. With the continued increase in the size and sensitivity of detectors, study of cosmic rays should continue to provide the first indications of new physics at ultrahigh energies. *See* FUNDAMENTAL INTERACTIONS; PROTON.

Geomagnetic effects. The magnetic field of Earth is described approximately as that of a magnetic dipole of strength 8.1×10^{15} weber-meters (8.1×10^{25} gauss · cm^3) located near the geometric center of Earth. Near the Equator the field intensity is 3×10^{-5} tesla (0.3 gauss), falling off in space as the inverse cube of the distance to the Earth's center. In a magnetic field which does not vary in time, the path of a particle is determined entirely by its rigidity, or momentum per unit charge; the velocity simply determines how fast the particle will move along

TABLE 2. Properties of particles when all have a rigidity of 1 gigavolt

Particle	Charge	Nucleons	Kinetic energy		Momentum, MeV/*c*
			MeV	MeV/nucleon	
Electron	1	—	1000	—	1000
Proton	1	1	430	430	1000
^{3}He	2	3	640	213	2000
^{4}He	2	4	500	125	2000
^{16}O	8	16	2000	125	8000

this path. Momentum is usually expressed in units of eV/*c*, where *c* is the velocity of light, because at high energies, energy and momentum are then numerically almost equal. By definition, momentum and rigidity are numerically equal for singly charged particles. The unit so defined is dimensionally a volt, but the relationship to electric potential is neither obvious nor particularly useful in practice. **Table 2** gives examples of these units as applied to different particles with rigidity of 1 gigavolt. This corresponds to an orbital radius in a typical interplanetary (10^{-9} tesla or 10^{-5} gauss) magnetic field of approximately 10 times the distance from the Earth to the Moon. *See* RELATIVISTIC ELECTRODYNAMICS.

The minimum rigidity of a particle able to reach the top of the atmosphere at a particular geomagnetic latitude is called the geomagnetic cutoff rigidity at that latitude, and its calculation is a complex numerical problem. Fortunately, for an observer near the ground, obliquely arriving secondary particles, produced by the oblique primaries, are so heavily attenuated by their longer path to the ground that it is usually sufficient to consider only the geomagnetic cutoff for vertically incident primaries, which is given in **Table 3**. Around the Equator, where a particle must come in perpendicular to the geomagnetic lines of force to reach Earth, particles with rigidity less than 10 GV are entirely excluded, though at higher latitudes where entry can be made more nearly along the lines of force, lower energies can reach Earth. Thus, the cosmic-ray intensity is a minimum at the Equator, and increases to its full value at either pole—this is the cosmic-ray latitude effect. Even deep in the atmosphere the variation with latitude is easily detected with BF_3 counters (**Fig. 2**). North of 45° the effect is slight because the additional primaries admitted are so low in energy that they produce few secondaries.

TABLE 3. Geomagnetic cutoff

Geomagnetic latitude	Vertical cutoff, gigavolts
0°	15
±20°	11.5
±40°	5
±60°	1
±70°	0.2
±90°	0

Accurate calculations of the geomagnetic cutoff must consider the deviations of the true field from that of a perfect dipole and the change with time of these deviations. Additionally the distortion of the field by the pressure of the solar wind must often be accounted for, particularly at high latitude. Such corrections vary rapidly with time because of sudden bursts of solar activity and because of the rotation of the Earth. Areas with cutoffs of 400 MV during the day may have no cutoff at all during the night. This day-night effect is confined to particles with energies so low that neither they nor their secondaries reach the ground, and is thus observed only on high-altitude balloons or satellites.

Since the geomagnetic field is directed from south to north above the surface of Earth, the incoming cosmic-ray nuclei are deflected toward the east. Hence an observer finds some 20% more particles incident from the west. This is known as the east-west effect. *See* GEOMAGNETISM.

Solar modulation. **Figure 3** presents portions of the proton and alpha-particle spectra observed near the Earth but outside of the magnetosphere in 1973. Below 20 GeV/nucleon the cosmic-ray intensity varies markedly with time. S. Forbush was the first to show that the cosmic-ray intensity was low during the years of high solar activity and sunspot number, which follow an 11-year cycle. This effect is clearly seen in the data of Fig. 2 and has been extensively studied with ground-based and spacecraft instruments. While this so-called solar modulation is now understood in general terms, it has not been

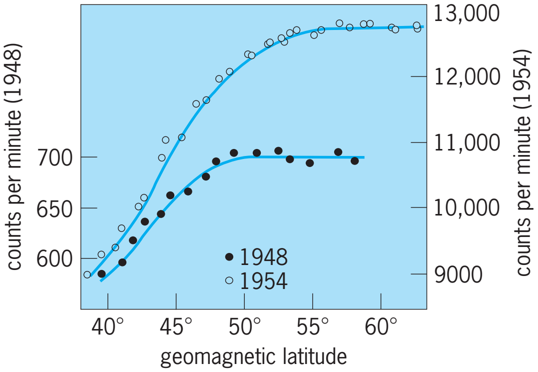

Fig. 2. Latitude variation of the neutron component of cosmic rays in 80°W longitude and at a height corresponding to an atmospheric pressure of 30 kPa (22.5 cm of mercury) in 1948, when the Sun was active, and 1954, when the Sun was deep in a sunspot minimum.

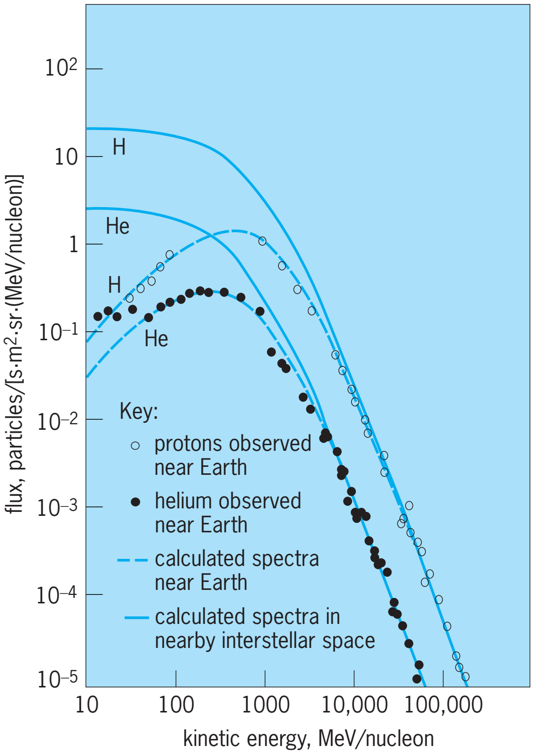

Fig. 3. Spectra of cosmic-ray protons and helium at Earth and in nearby interstellar space, showing the effect of solar modulation. Observations were made in 1973, when the Sun was quiet.

calculated in detail, in large part because there are few direct measurements out of the ecliptic plane and in the outer heliosphere.

The primary cause of solar modulation is the solar wind, a highly ionized gas (plasma) which originates from the solar corona and propagates radially from the Sun at a velocity of about 400 km/s (250 mi/s). The wind is mostly hydrogen, with typical density of 5 protons/cm^3 (80 protons/in.^{3}). This density is too low for collisions with cosmic rays to be important. Rather, the high conductivity of the medium traps part of the solar magnetic field and carries it outward. The rotation of the Sun and the radial motion of the plasma combine to create the observed archimedean spiral pattern of the average interplanetary magnetic field. Turbulence in the solar wind creates fluctuations in the field which often locally obscure the average direction and intensity. This complex system of magnetic irregularities propagating outward from the Sun deflects and sweeps the low-rigidity cosmic rays out of the solar system. *See* SOLAR MAGNETIC FIELD.

In addition to the bulk sweeping action, another effect of great importance occurs in the solar wind, adiabatic deceleration. Because the wind is blowing out, only those particles which chance to move upstream fast enough are able to reach Earth. However, because of the expansion of the wind, particles interacting with it lose energy. Thus, particles observed at Earth at 10 MeV/nucleon actually started out at several hundred megaelectronvolts per nucleon in nearby interstellar space, while those with only 100–200 MeV/nucleon initial energy probably never reach Earth at all. This is particularly unfortunate because at these lower energies the variation with energy of nuclear reaction probabilities would allow much more detailed investigation of cosmic-ray history. Changes in the modulation with solar activity are caused by the changes in the pattern of magnetic irregularities rather than by changes in the wind velocity, which are quite small. *See* MAGNETOHYDRODYNAMICS; PLASMA (PHYSICS).

Heliosphere. Solar modulation is important in a region around the Sun termed the heliosphere, a large bubble formed in the interstellar medium by the solar wind. The density, and therefore the energy and momentum, of the solar wind drop as the material expands with increasing distance from the Sun, eventually becoming too small to push back the interstellar material. The typical distance to the interface is thought to be approximately 100 AU, but the actual distance in any direction is determined by local variations in both the solar wind and the interstellar medium. (1 AU, or astronomical unit, is the average Earth-Sun separation, 1.49×10^8 km or 9.26×10^7 mi.).

The spacecraft *Voyager 1* crossed the termination shock of the solar wind on December 16, 2004, at some 94 astronomical units (AU) or more than 8.7×10^9 miles from the Sun, as evidenced by an abrupt increase in the magnetic field. The termination shock is the innermost, and probably the best-defined, structure in this boundary region. Outside the termination shock several centuries worth of decelerated solar wind are probably piled up, producing a region that is still capable of modulating cosmic-ray intensity. The Sun, carrying the heliosphere with it, is moving through the interstellar medium at approximately 20 km/s (12 mi/s). Eventually all of the solar material blends into the interstellar medium by turbulent interactions. The termination shock had been universally thought to be a prodigious accelerator of particles and *Voyager 1* largely confirmed this. At the shock there is a remarkable increase in particle intensity with a distinctive energy spectrum.

Forbush decreases. Apart from the 11-year modulation cycle, there are many different types of cosmic-ray variation associated with irregularities in the solar wind. The most dramatic is the Forbush decrease, wherein worldwide cosmic-ray intensity may drop as much as 20% in one day, followed by a slow recovery lasting many days or even weeks. Most Forbush decreases are associated with severe magnetic disturbances in the solar wind that result from massive ejections of material from the solar corona into interplanetary space. Often these ejections accompany solar flares. When magnetic disturbances encounter the Earth, they can cause geomagnetic storms and other phenomena that are disruptive to human activity. This complex set of interactions has come to be called space weather. Observing changes in cosmic-ray fluxes from several places on Earth simultaneously is one important tool for investigating the interaction of a magnetic disturbance with Earth. *See* SOLAR WIND; SUN.

Composition of cosmic rays. Nuclei ranging from protons to lead have been identified in the cosmic radiation. The relative abundances of the elements ranging up to nickel are shown in **Fig. 4**, together with the best estimate of the "universal abundances" obtained by combining measurements of solar spectra, lunar and terrestrial rocks, meteorites, and so forth. Most obvious is the similarity between these two distributions. However, a systematic deviation is quickly apparent: the elements lithium-boron and scandium-manganese as well as most of the odd-charged nuclei are vastly overabundant in the cosmic radiation. This effect has a simple explanation: the cosmic rays travel great distances in the Milky Way Galaxy and occasionally collide with atoms of interstellar gas—mostly hydrogen and helium—and fragment. This fragmentation, or spallation as it is called, produces lighter nuclei from heavier ones but does not change the energy/nucleon very much. Thus the energy spectra of the secondary elements are similar to those of the primaries. *See* SPALLATION REACTION.

Calculations involving reaction probabilities determined by nuclear physicists show that the overabundances of the secondary elements can be explained by assuming that cosmic rays pass through an average of about 5 g/cm^2 (0.07 lb/in.^{2}) of material on their way to Earth. Although an average path length can be obtained, it is not possible to fit the data by saying that all particles of a given energy have exactly the same path length; furthermore, results indicate that higher-energy particles traverse less matter in reaching the solar system, although their original composition seems energy independent. *See* ELEMENTS, COSMIC ABUNDANCE OF.

When spallation has been corrected for, differences between cosmic-ray abundances and solar-system or universal abundances still remain. The most important question is whether these differences are due to the cosmic rays having come from a special kind of material (such as would be produced in a supernova explosion), or simply to the fact that some atoms might be more easily accelerated than others. It is possible to rank almost all of the overabundances by considering the first ionization potential of the atom and the rigidity of the resulting ion, although this approach gives no prediction of the magnitude of the enhancement. Relative abundances of particles accelerated in solar flares are also far from constant from one flare to the next. Accounting for these abundance variations is one of the most important constraints on models of solar particle acceleration, the exact mechanism of which remains an unsolved problem. *See* IONIZATION POTENTIAL.

Isotopes. Much current cosmic-ray research is concentrated on determining isotopic composition of the elements, partly because this is less likely to be changed by acceleration than the elemental composition and thus is more accurately representative of the composition of the source material. As an example, the low-energy helium data in Fig. 3 are not well represented by the calculation. The excess flux, which is referred to as the anomalous component, is nearly all ^{4}He, whereas higher-energy cosmic rays are nearly 10% ^{3}He. A similar enhancement of low-energy nitrogen is pure ^{14}N, while at higher energies nitrogen is half ^{15}N. Measuring isotopes allows conclusive identification of the anomalous component as a sample of originally neutral interstellar material that has been ionized and energized by processes in the solar wind.

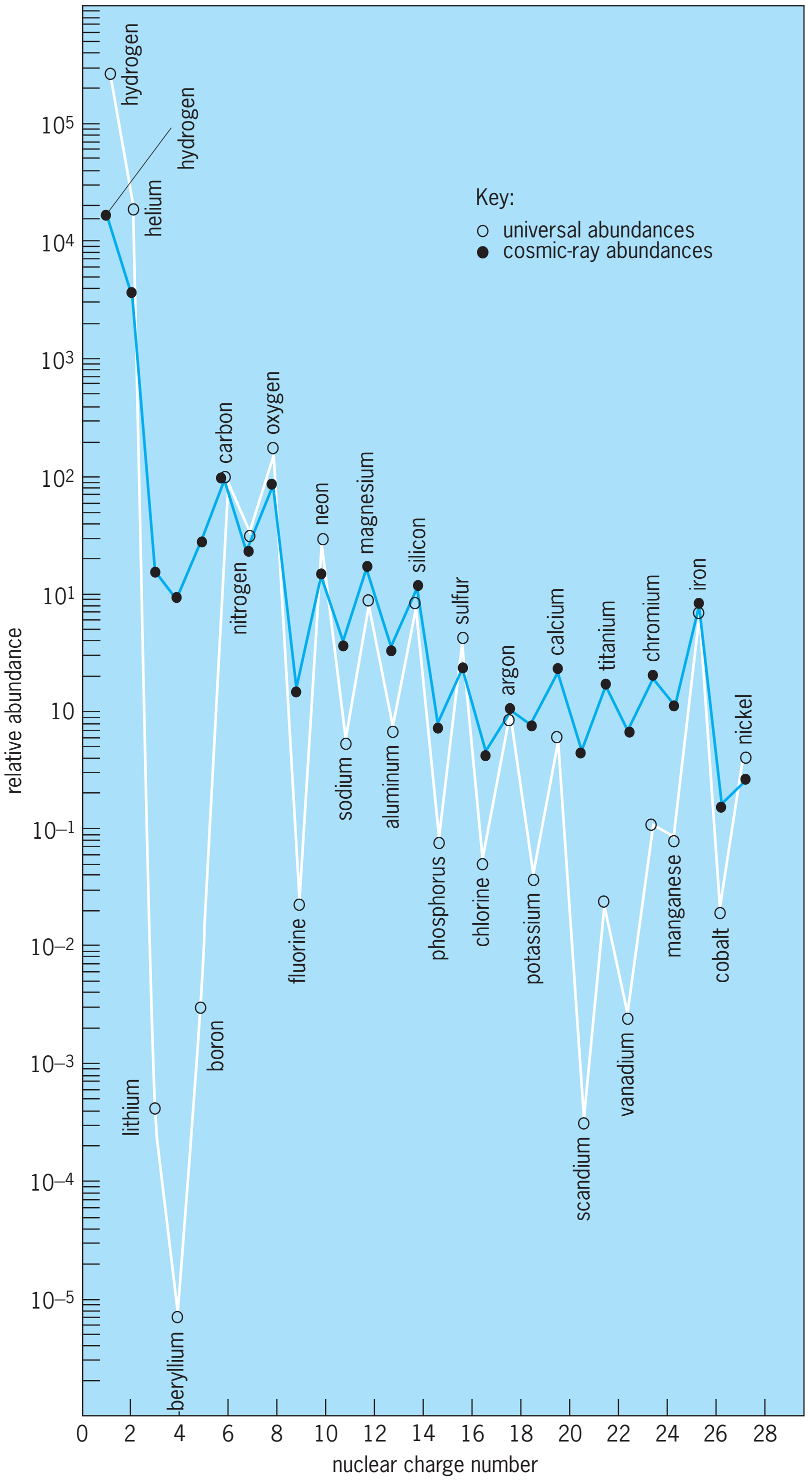

Fig. 4. Cosmic-ray abundances compared to the universal abundances of the elements. Carbon is set arbitrarily to an abundance of 100 in both cases.

Other variations in the isotopic composition are not currently understood. For example, the ratio of

^{22}Ne to ^{20}Ne in the cosmic-ray sources is estimated to be 0.37, while the accepted solar system value for this number is 0.12, which agrees well with the abundances measured in solar-flare particles. However, another direct sample of solar material—the solar wind—has a ratio of 0.08, indicating clearly that the isotopic composition of energetic particles need not reflect that of their source. Conclusions drawn from the observed difference in the solar and cosmic-ray values must be viewed as somewhat tentative until the cause of the variation in the solar material is well understood. *See* ISOTOPE.

Electron abundance. Cosmic-ray electron measurements pose other problems of interpretation, partly because electrons are nearly 2000 times lighter than protons, the next lightest cosmic-ray component. Protons with kinetic energy above 1 GeV are about 100 times as numerous as electrons above the same energy, with the relative number of electrons decreasing slowly at higher energies. But it takes about 2000 GeV to give a proton the same velocity as a 1-GeV electron. Viewed in this way electrons are several thousand times more abundant than protons. (Electrical neutrality of the Milky Way Galaxy is maintained by lower-energy ions which are more numerous than cosmic rays although they do not carry much energy.) It is thus quite possible that cosmic electrons have a different source entirely from the nuclei. It is generally accepted that there must be direct acceleration of electrons, because calculations show that more positrons than negatrons should be produced in collisions of cosmic-ray nuclei with interstellar gas. Measurements show, however, that only 10% of the electrons are positrons. As the number of positrons seen agrees with the calculated secondary production, added confidence is gained in the result that there is indeed an excess of negatrons. *See* ELECTRON.

Electrons are light enough to emit a significant amount of synchrotron radiation as they are deflected by the 10^{-10}-tesla (10^{-6}-gauss) galactic magnetic field. Measurement of this radiation by radio telescopes provides sufficient data for an approximate calculation of the average energy spectrum of electrons in interstellar space and other galaxies. Comparison of spectra of electrons and positrons measured at Earth with those calculated to exist in interstellar space provides the most direct measurement of the absolute amount of solar modulation. *See* RADIO ASTRONOMY; SYNCHROTRON RADIATION.

Properties of the energy spectrum. At energies above 10^{10} eV, the energy spectra of almost all cosmic rays are approximated over many decades by functions in which the flux decreases as the energy raised to some negative, nonintegral power referred to as the spectral index. Such a power-law relationship is of course a straight line when plotted using logarithmic axes. A steep or "soft" (that is, more rapidly falling with increasing energy) spectrum thus has a higher spectral index than a flat or "hard" spectrum. The straight-line regions of the spectra in Fig. 3 correspond to a variation of flux with a spectral index of -2.7. A spectral index of -2.7 provides a good fit with the data up to 10^{15} eV total energy. Between 10^{15} and 10^{19} eV a steeper spectrum, with an index around -3.0, seems to be well established. Above 10^{19} eV the spectrum hardens once more, returning to an index of about -2.7. The spectral index above 10^{20} eV has not been determined, because particles are so rare that they are almost never seen, even in detectors which cover several square kilometers and operate for many years. At such high energies, the individual particles are not identified, and changes in the measured-energy spectrum could be the result of composition changes. However, the evidence available indicates that the composition is essentially unchanged.

The Pierre Auger Observatory, which began operation in 2005, has a detection area the size of Rhode Island (over 3000 km^2 or 1200 mi^2) located in western Argentina's Mendoza Province. The Auger Observatory is a hybrid detector, employing two independent methods to detect and study high-energy cosmic rays. One technique is ground-based and detects high-energy particles through their interaction with water. Each of the 1600 detectors contains 11,000 L (3000 gals) of ultrapure, deionized water. The other technique tracks the development of air showers by observing ultraviolet light emitted high in the Earth's atmosphere.

Age. Another important result which can be derived from detailed knowledge of cosmic-ray isotopic composition is the "age" of cosmic radiation. Certain isotopes are radioactive, such as beryllium-10 (^{10}Be) with a half-life of 1.6×10^6 years. Since beryllium is produced entirely by spallation, study of the relative abundance of ^{10}Be to the other beryllium isotopes, particularly as a function of energy to utilize the relativistic increase in this lifetime, will yield a number related to the average time since the last nuclear collision. Measurements show that ^{10}Be is nearly absent at low energies, yielding an estimate of the age of the cosmic rays of approximately 10^7 years. An implication of this result is that the cosmic rays propagate in a region in space which has an average density of 0.1–0.2 atom/cm^3 (1.5–3 atoms/in.^{3}). This is consistent with some astronomical observations of the immediate solar neighborhood.

Very high energy particles cannot travel long distances in the 2.7 K blackbody-radiation field which permeates the universe. Electrons of 15 GeV energy lose a good portion of their energy in 10^8 years by colliding with photons via the (inverse) Compton process, yet electrons are observed to energies of 100 GeV and over. A similar loss mechanism becomes effective at approximately 10^{20} eV for protons. These observations are of course not conclusive, but a safe statement is that a cosmic-ray age of 10^7 years is consistent with all currently available data. *See* COMPTON EFFECT; COSMIC BACKGROUND RADIATION.

Several attempts have been made to measure the constancy of the cosmic-ray flux in time. Variations in ^{14}C production, deduced from apparent deviations of the archeological carbon-dating scale from that derived from studies of tree rings, cover a period of about 10^3 years. Radioactive ^{10}Be in deep-sea sediments allows studies over 10^6 years, whereas etching of tracks left by cosmic rays in lunar minerals covers a period of 10^9 years. None of these methods has ever indicated a variation of more than a factor of 2 in average intensity. There are big differences in these time scales, and the apparent constancy of the flux could be due to averaging over variations which fall in the gaps as far as the time scales are concerned. Nevertheless, the simplest picture seems to be that the cosmic rays are constant in time at an intensity level which is due to a long-term balance between continuous production and escape from the Galaxy, with an average residence time of 10^7 years. *See* COSMOGENIC NUCLIDE; RADIOCARBON DATING.

Although small, variations in cosmic-ray intensity show systematic patterns over historical and geologic time scales. Some of this variation is undoubtedly due to variability in the magnetic field of the Earth that results in changes in the geomagnetic cutoff. However, over the past several thousand years, when the magnetic field has been reasonably constant, cosmic-ray intensity has shown a distinct anticorrelation with measures of overall global temperature. Low cosmic-ray fluxes, indicative of enhanced solar activity, typically go together with warm periods. The relationship is far from understood, but this is one of many observations that must be considered in the complex, nonlinear problem of global warming.

Origin. Although study of cosmic rays has yielded valuable insight into the structure, operation, and history of the universe, their origin has not been determined. The problem is not so much to devise processes which might produce cosmic rays, but to decide which of many possible processes do in fact produce them.

In general, analysis of the problem of cosmic-ray origin is broken into two major parts: origin in the sense of where the sources are located, whatever they are, and origin in the sense of how the particles are accelerated to such high energies. Of course, these questions can never be separated completely.

Location of sources. It is thought that cosmic rays are produced by mechanisms operating within galaxies and are confined almost entirely to the galaxy of their production, trapped by the galactic magnetic field. The intensity in intergalactic space would only be a few percent of the typical galactic intensity, and would be the result of a slow leakage of the galactic particles out of the magnetic trap. It has not been possible to say much about where the cosmic rays come from by observing their arrival directions at Earth. At lower energies (up to 10^{15} eV) the anisotropies which have been observed can all be traced to the effects of the solar wind and interplanetary magnetic field. The magnetic field of the Milky Way Galaxy seems to be completely effective in scrambling the arrival directions of these particles.

For several decades in energy above 10^{15} a smoothly rising anisotropy is measured, ranging from 0.1 to 10%, but the direction of the maximum intensity varies in a nonsystematic way with energy. At these energies, particles have a radius of curvature which is not negligible compared to galactic structures, and thus their arrival direction could be related to where they came from but in a complex way. Above 10^{19} eV the radius of curvature in the galactic magnetic field becomes comparable to or larger than galactic dimensions, making containment of such particles in the disk of the Milky Way Galaxy impossible. Only a few hundred events greater than 10^{19} eV have been detected, with no systematic anisotropy. Clustering of events (of marginal statistical significance) in the data of individual observatories has been reported, but so far never confirmed by other detectors. The Pierre Auger Observatory should, over several years, increase the number of events observed by orders of magnitude and may possibly permit statistically definitive determinations of features in the arrival direction distribution. Actual identification of sources, however, will probably come only from detection of neutral radiation (photons and neutrinos) produced in cosmic-ray interactions.

Cerenkov telescopes, such as HESS in Namibia and MAGIC at the Roque de los Muchachos Observatory in the Canary Islands, have produced remarkable images of objects in the light of 10^{12}-eV gamma rays. Supernova remnants have been clearly resolved to show structures within them, and emission from x-ray binary systems has been definitively observed. Several sources unassociated with known objects are also being studied. It is generally believed that gamma rays of energy greater than 10^{12} eV can be produced only through interactions of high-energy protons or other hadrons. These gamma rays provide important information on the structure and operation of these exotic objects but the key question of whether these particles escape to become galactic cosmic rays remains unanswered. *See* ASTROPHYSICS, HIGH-ENERGY; BINARY STAR; CERENKOV RADIATION; X-RAY ASTRONOMY.

Direct detection of cosmic rays propagating in distant regions of the Milky Way Galaxy is possible by observing the electromagnetic radiation produced as they interact with other constituents of the Milky Way Galaxy. Measurement of the average electron spectrum using radio telescopes has already been mentioned. Proton intensities are mapped by studying the arrival directions of gamma rays produced as they collide with interstellar gas. Unfortunately, the amount of radiation in these processes depends upon both the cosmic-ray flux and the magnetic-field intensity or density of interstellar gas. Areas where cosmic rays are known to exist can be pointed out because the radiation is observed. But where no radiation is seen, it is not known whether its absence results from lack of cosmic rays or lack of anything for them to interact with. In particular, very little radiation is seen from outside the Milky Way Galaxy, but there is also very little gas or magnetic field there. There is therefore no direct evidence either for or against galactic containment.

A major difficulty with the concept of cosmic radiation filling the universe is the large amount of energy needed to maintain the observed intensity in the face of an expanding universe—probably more energy than is observed to be emitted in all other forms put together. *See* COSMOLOGY.

Confinement mechanisms. Three possible models of cosmic-ray confinement are under investigation. All assume that cosmic rays are produced in sources, discrete or extended, scattered randomly through the galactic disk. Most popular is the "leaky box" model, which proposes that the particles diffuse about in the magnetic field for a few million years until they chance to get close to the edge of the Milky Way Galaxy and escape. This is a phenomenological model in that no mechanism is given by which either the confinement time or the escape probability as a function of energy can be calculated from independent observations of the galactic structure. Its virtue is that good fits to the observed abundances of spallation products are obtained by using only a few adjustable parameters. Variations of the model which mainly postulate boxes within boxes—ranging from little boxes surrounding sources to a giant box or static halo surrounding the whole Milky Way Galaxy—can be used to explain variations from the simple predictions. However, all attempts to calculate the details of the process have failed by many orders of magnitude, predicting ages which are either far older or far younger than the observed age.

A second model is that of the dynamical halo. Like the earlier static-halo model, it is assumed that cosmic rays propagate not only in the galactic disk but also throughout a larger region of space, possibly corresponding to the halo or roughly spherical but sparse distribution of material which typically surrounds a galaxy. This model is based on the observation that the energy density of the material which is supposed to be contained by the galactic magnetic field is comparable to that of the field itself. This can result in an unstable situation in which large quantities of galactic material stream out in a galactic wind similar in some respects to the solar wind. In this case the outward flow is a natural part of the theory, and calculations have predicted reasonable flow rates. In distinction to the solar wind, in which the cosmic rays contribute almost nothing to the total energy density, they may provide the dominant energy source in driving the galactic wind.

A third model assumes that there is almost no escape; that is, cosmic rays disappear by breaking up into protons which then lose energy by repeated collision with other protons. To accept this picture, one must consider the apparent 5-g/cm^2 (0.07-lb/in.^{2}) mean path length to be caused by a fortuitous combination of old distant sources and one or two close young ones. Basically, the objections to this model stem from the tendency of scientists to accept a simple theory over a more complex (in the sense of having many free parameters) or specific theory when both explain the data. *See* MILKY WAY GALAXY.

Acceleration mechanisms. Although the energies attained by cosmic-ray particles are extremely high by laboratory standards, their generation can probably be understood in terms of known astronomical objects and laws of physics. Even on Earth, ordinary thunderstorms generate potentials of millions of volts, which would accelerate particles to respectable cosmic-ray energies (a few megaelectronvolts) if the atmosphere were less dense. Gamma rays and neutrons have, in fact, been detected from lightning strikes. Consequently, there are many theories of how the acceleration could take place, and it is quite possible that more than one type of source exists. Two major classes of theories may be identified—extended-acceleration regions and compact-acceleration regions.

Extended-acceleration regions. Acceleration in extended regions (in fact the Milky Way Galaxy as a whole) was first proposed by E. Fermi, who showed that charged particles could gain energy from repeated deflection by magnetic fields carried by the large clouds of gas which are known to be moving randomly about the Milky Way Galaxy. Many other models based on such statistical acceleration have since been proposed, the most recent of which postulates that particles bounce off shock waves traveling in the interstellar medium. Such shocks, supposed to be generated by supernova explosions, undoubtedly exist to some degree but have an unknown distribution in space and strength, leaving several free parameters which may be adjusted to fit the data.

Compact-acceleration regions. The basic theory in the compact-acceleration class is that particles are accelerated directly in the supernova explosions themselves. One reason for the popularity of this theory is that the energy generated by supernovas is of the same order of magnitude as that required to maintain the cosmic-ray intensity in the leaky box model.

However, present observations indicate that the acceleration could not take place in the initial explosion. Cosmic rays have a composition which is similar to that of ordinary matter and is different from the presumed composition of the matter which is involved in a supernova explosion. At least some mixing with the interstellar medium must take place. Another problem with an explosive origin is an effect which occurs when many fast particles try to move through the interstellar gas in the same direction: the particles interact with the gas through a magnetic field which they generate themselves, dragging the gas along and rapidly losing most of their energy. In more plausible theories of supernova acceleration, the particles are accelerated gradually by energy stored up in the remnant by the explosion or provided by the intense magnetic field of the rapidly rotating neutron star or pulsar which is formed in the explosion.

Acceleration of high-energy particles was first observed in the Crab Nebula, the remnant of a supernova observed by Chinese astronomers in 1054. This nebula is populated by high-energy electrons which radiate a measurable amount of their energy as they spiral about in the magnetic field of the nebula. So much energy is released that the electrons would lose most of their energy in a century if it were not being continuously replenished. Pulses of gamma rays also show that bursts of high-energy particles are being produced by the neutron star—the gamma rays coming out when the particles interact with the atmosphere of the neutron star. Particles of cosmic-ray energy are certainly produced in this object, but it is unlikely that they escape from the trapping magnetic fields in the nebula and join the freely propagating cosmic ray population. As noted above, observation of 10^{12}-eV gamma rays now allows mapping of energetic hadrons in these objects, but the issue of an escape mechanism remains. *See* CRAB NEBULA; NEUTRON STAR; PULSAR.

Acceleration in the solar system. The study of energetic particle acceleration in the solar system is valuable in itself, and can give insight into the processes which produce galactic cosmic rays. Large solar flares, about one a year, produce particles with energies in the gigaelectronvolt range, which can be detected through their secondaries even at the surface of the Earth. It is not known if such high-energy particles are produced at the flare site itself or are accelerated by bouncing off the shock fronts which propagate from the flare site outward through the solar wind. Nuclei and electrons up to 100 MeV are regularly generated in smaller flares. In many events it is possible to measure gamma rays and neutrons produced as these particles interact with the solar atmosphere. X-ray, optical and radio mappings of these flares are also used to study the details of the acceleration process. By relating the arrival times and energies of these particles at detectors throughout the solar system to the observations of their production, the structure of the solar and interplanetary magnetic fields may be studied in detail.

In addition to the Sun, acceleration of charged particles has been observed in the vicinity of the Earth, Mercury, Jupiter, and Saturn—those planets which have significant magnetic fields. Details of the acceleration mechanism are not understood, but certainly involve both the rotation of the magnetic fields and their interactions with the solar wind. Jupiter is such an intense source of electrons below 30 MeV that it dominates other sources at the Earth when the two planets lie along the same interplanetary magnetic field line of force. The anomalous component is known to be local interstellar material, accelerated by a mechanism that is not fully understood but probably is situated near the interface between the solar wind and the interstellar medium. However, there was no evidence in the *Voyager 1* crossing of the termination shock that this production occurs immediately at this particular structure. *See* JUPITER; MERCURY (PLANET); PLANET; SATURN.

Direct observation of conditions throughout most of the solar system will be possible in the next few decades, and with it should come a basic understanding of the production and propagation of energetic particles locally. This understanding will perhaps form the basis of a solution to the problem of galactic cosmic rays, which will remain for a very long time the main direct sample of material from the objects of the universe outside the solar system.

Cosmic spherules

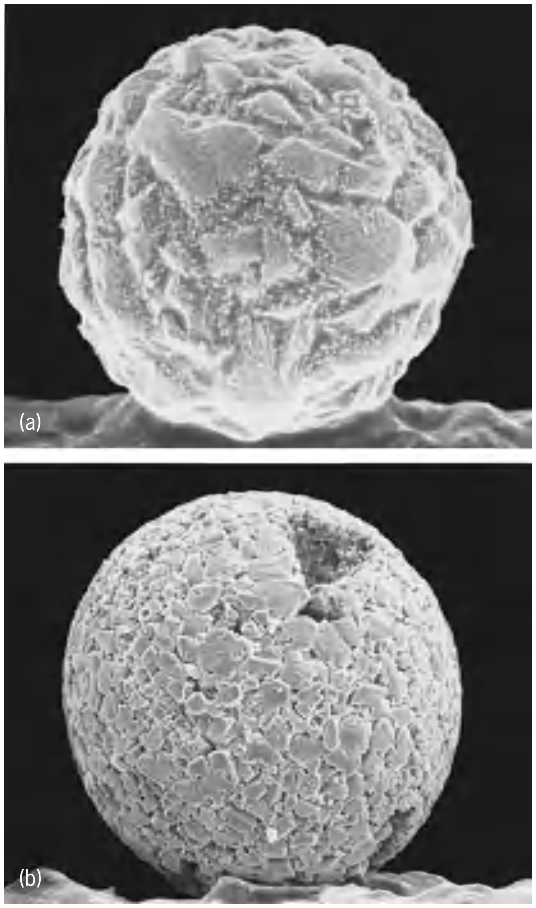
Solidified droplets of extraterrestrial materials that melted either during high-velocity entry into the atmosphere or during hypervelocity impact of large meteoroids onto the Earth's surface. Cosmic spherules are rounded particles that are millimeter to microscopic in size and that can be identified by unique physical properties. Although great quantities of the spheres exist on the Earth, they are ordinarily found only in special environments where they have concentrated and are least diluted by terrestrial particulates. *See* METEOR.

The most common spherules are ablation spheres produced by aerodynamic melting of meteoroids as they enter the atmosphere. Typical ablation spheres are produced by melting of submillimeter asteroidal and cometary fragments that enter the atmosphere at velocities ranging from 6.5 to 43 mi (11 to 72 km) per second. Approximately 10,000 tons of such particles collide with the Earth each year, and cosmic spheres in the size range of 0.004 to 0.04 in. (0.1 to 1.0 mm) are the most abundant form of this material that survives to reach the Earth's surface. The spheres are formed near 48 mi (80 km) altitude, where deceleration, intense frictional heating, melting, partial vaporization, and solidification all occur in only a few seconds time. During formation, the larger particles can be seen as luminous meteors or shooting stars. Impact spheres constitute a second and rarer class of particles that are produced when giant meteoroids impact the Earth's surface with sufficient velocity to produce explosion craters that eject molten droplets of both meteoroid and target materials.

Impact spheres. These are very abundant on the Moon, but they are rare on the Earth, and they have been found in only a few locations. Impacts large enough to produce explosion craters occur on the Earth every few tens of thousands of years, but the spheres and the craters themselves are rapidly degraded by weathering and geological processes. Meteoritic spherules have been found around a number of craters, including Meteor Crater in Arizona, Wabar in Saudi Arabia, Box Hole and Henbury in Australia, Lonar in India, and Morasko in Poland. They have also been found at the Sikhote-Alin meteorite shower site and at the location of the Tunguska explosion in Russia. Spheres from these craters include ablation spheres as well as true impact spheres produced either by shock melting of target and meteoroid or by condensation from impact-generated vapor. Impact spheres are also produced by the larger cratering events, some of which may have played roles in biological extinctions. Silica-rich glass spheroids (microtektites) are found in thin layers that are contemporaneous with the conventional tektites. Microtektites are believed to be shock-melted sedimentary materials that were ejected from large impact craters. They were ejected as plumes that covered substantial fractions of the surface of the Earth. The cumulative mass of microtektites in the 35-million-year-old North American tektite field is estimated to be equivalent in mass to 36 mi^3 (100 km^3) of solid rock. Microspherules of a different composition have been found in the thin iridium-rich layer associated with the global mass extinctions at the Cretaceous–Tertiary boundary. *See* TEKTITE.

Ablation spheres. These fall to Earth at a rate of one 0.1-mm-diameter sphere per square meter per year, and every rooftop contains these particles. Unfortunately they are usually mixed in with vast quantities of terrestrial particulates, and they are very difficult to locate. They can, however, be easily found in special environments that do not contain high concentrations of terrestrial particles that could be confused with cosmic spheres larger than 0.004 in. (0.1 mm) in diameter. Such environments include the mid-Pacific ocean floor and certain ice deposits in Greenland and Antarctica. In mid-Pacific sediments the accumulation of terrestrial sediments is only a few meters per million years, and the spherules larger than 0.004 in. (0.1 mm) than are found in concentrations of roughly 10–100 per kilogram of sediment. Cosmic spheres are easily extracted from the sediment because most spherules are ferromagnetic and much larger than typical sediment particles. The highest ablation spherule concentrations on Earth (over one per gram of sediment) are found in the melt zones of the Greenland ice cap, where melting ice leaves dust particles concentrated directly on the ice surface. *See* MARINE SEDIMENTS.

Cosmic ablation spherules can be grouped into two major types: type S (stony) and type I (iron). In polished sections it can be seen that the S spheres are composed of olivine, magnetite, and glass, with textures consistent with rapid crystallization from melt. Both of the type S spherules shown in the **illustration** have elemental compositions similar to those of stony meteorites. In general, types S spheres have compositions that are a close match with chondritic meteorites except for depletion of volatile elements such as sulfur and sodium that are lost during atmospheric entry. Many spheres are also depleted in nickel by a process that may also lead to the formation of the iron spheres. Typical type I spheres consist of iron oxide (magnetite and wustite) surrounding a core of either nickel-iron metal or a small nugget of platinum group elements. Nickel and the platinum group elements are concentrated during brief oxidation when the sphere is molten. Some of the iron spheres may be droplets of iron meteorites, but the most common ones appear to be droplets that separated from the stony spheres during atmospheric melting.



Scanning electron photomicrographs of stony cosmic spherules about 300 μm in diameter collected from the mid-Pacific ocean floor. (*a*) Sphere with so-called turtleback texture, indicative of rapid cooling from a very hot molten droplet. (*b*) Sphere with porphyritic texture, indicative of formation of a particle that was not so strongly heated during hypervelocity entry into the atmosphere as the sphere in *a*.

Identification. Cosmic spherules are of particular scientific interest because they provide information about the composition of comets and asteroids and also because they can be used as tracers to identify debris resulting from the impact of large extraterrestrial objects. The ablation spherules can be positively identified because of several unique properties, including distinctive oxygen isotope compositions and the presence of isotopes that are produced by cosmic rays such as aluminum-26 and manganese-53. Some spheres did not melt entirely, and they also retain high concentrations of noble gases implanted by the solar wind. In general, cosmic spherules can be confidently identified on the basis of their elemental and mineralogical compositions, which are radically different from nearly all spherical particles of terrestrial origin. Cosmic strings

Hypothetical thin tubes that carry very large amounts of vacuum energy. They belong to the class of objects known as topological defects. As the universe expands, its temperature decreases and its microscopic properties, such as the strength with which fundamental particles interact, sometime change abruptly in what are called phase transitions. A well-known example of such a transition is when water freezes into ice when the temperature drops below 0°C (32°F). Strings are predicted to form at these transitions. In this context, the lowest energy state of the universe, which is called the "vacuum" although it is not necessarily empty, can have a nontrivial structure in space, and strings appear as defects in this structure. *See* DARK ENERGY; ENERGY LEVEL (QUANTUM MECHANICS); PHASE TRANSITIONS.

Two possible kinds of strings are predicted, namely, local and global strings. The energy of local strings is concentrated within a very short distance of the defect tube, called the core. As a result, local strings have only contact interactions. They are predicted in almost all cosmologically realistic grand unified theories describing all interactions as a single one at high energies. The energy density of global strings, on the other hand, is not well localized along the core, so these strings have long-range interactions. Global strings are a consequence of many models based on superstring theories; they are often called axionic strings because they contain hypothetical particles, called axions, which appear naturally in the low-energy limit of these theories. In practice, both kinds of strings could exist. *See* DARK MATTER; GRAND UNIFICATION THEORIES; SUPERSTRING THEORY.

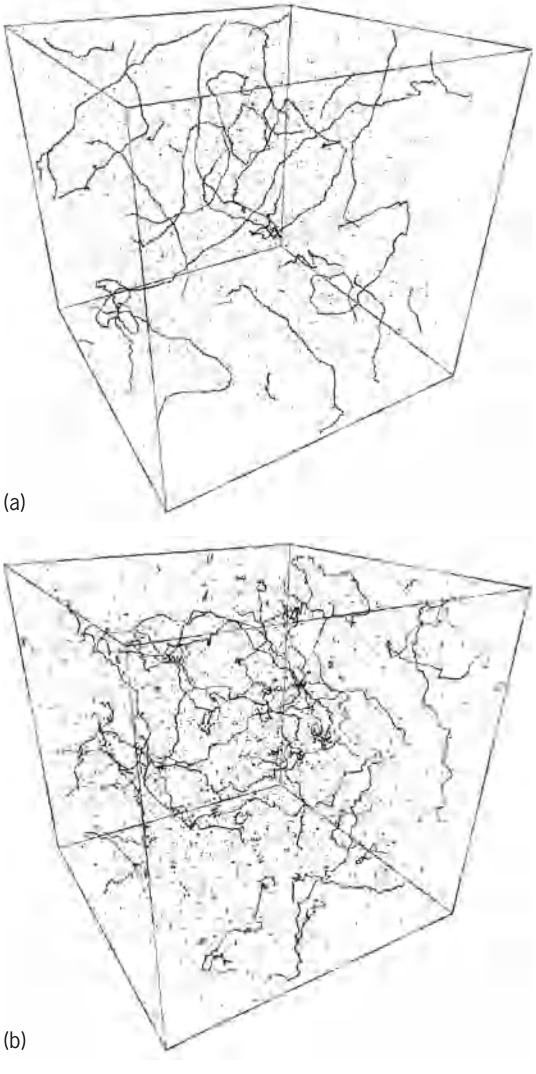
Formation. Phase transitions are believed to have taken place in the early universe, namely, immediately after the big bang, when the temperature was much higher than it is now. As such a phase transition proceeded in the early universe, regions having different microscopic properties grew independently. When their boundaries met, there could be mismatches in these properties, resulting in defects such as cosmic strings. The process was very similar to a phase transition that is observed in liquid crystals: At high temperature, molecules in such a material move rapidly and their relative orientations are random. When the temperature is lowered below a critical value, the forces between the molecules, which tend to cause them to be aligned, can overcome the thermal motion, and in any given region of space all the molecules end up pointing in the same direction. In uncorrelated locations of the crystal sample, those directions will be different, so that at various interfaces between such regions the molecules cannot have a preferred direction. The original, randomly distributed state persists in a region near such an interface; such a region is called a defect. The geometry of the defects is fixed by the original properties of the system. In the universe, although other defects, such as monopoles, domain walls, and textures, could in principle be formed, they are in practice ruled out as they would induce cosmological consequences that are not observed. *See* CRYSTAL DEFECTS; LIQUID CRYSTALS; SYMMETRY BREAKING.

Strings exist for topological reasons. Therefore, they are stable and cannot have ends, at least in simple models. In more sophisticated theories, strings can be terminated by monopoles or by connecting domain walls, but these theories are usually incompatible with cosmological observations. Therefore, strings can be seen in the form of either closed loops or infinite strings. The latter are often assumed to be, in fact, loops whose dimension is larger than the size of the observable universe, called the Hubble radius. *See* BIG BANG THEORY.

Evolution of string networks. Once a network of local strings has been formed at a phase transition, its cosmological consequences depend on its subsequent evolution. Initially, in what is called the friction-dominated phase, the network interacts very strongly with its environment, namely the very dense primeval plasma. The expansion of the universe makes the plasma density decrease, until the interactions between the strings and the particles become negligible. At this point, another effect comes into play: Whenever two pieces of strings cross each other, they have a large probability (set to unity in actual numerical simulations) to exchange extremities. This contact interaction is called intercommutation or reconnection. Long strings and loops then tend to fragment and produce large numbers of small loops. In turns, these loops lose their energy in gravitational radiation. This energy loss mechanism is compensated by the effect of the expansion, which pulls more and more strings within a Hubble volume as the Hubble radius, namely the size of the observable universe, increases. *See* GRAVITATIONAL RADIATION.

After some relaxation time, the string network eventually reaches a special configuration, known as a scaling solution: Snapshots of the string distribution (see **illustration**) taken at two different times would have similar statistical properties, with characteristic lengths increased because of expansion. The observable universe thus contains at any time an almost fixed number of long strings, somewhere between 10 and 100, separated by a typical distance of the order of the Hubble radius divided by the number of strings. Nowadays, that would be between 10^8 and 10^9 light-years. Thanks to the scaling, the density contained in the string network relative to the overall density of the universe is constant in time; it is evaluated to be of the order of 10^{-5}.

Observational consequences. The weak, strong, and electromagnetic forces appear to be very different at the low energies at which particle physics experiments can be performed. However, it is believed that they are in fact different faces of a single interaction, much in the same way as electric and magnetic effects are merged, at accelerator energies, into the



Snapshots of the simulated string distribution, that is, the string network, at two different times. (*a*) Radiation-dominated epoch. (*b*) Matter-dominated era. The size of the simulation box is that of the visible universe. (*C. Ringeval, after D. Bennett and F. Bouchet, High-resolution simulations of cosmic-string evolution: i. Network evolution, Phys. Rev. D, 41:2408–2433, 1990*)

electromagnetic interaction. Above a given energy scale, known as the grand unified scale, the differences among these three interactions disappear. If strings are formed at this grand unified scale, then their energy per unit length is of the order of the equivalent of 10^{15} tons per centimeter, concentrated in a radius of 10^{-29} cm. *See* FUNDAMENTAL INTERACTIONS.

Strings have a tension that is equal to the mass density times the velocity of light squared. As for any kind of string, transverse disturbances travel along strings at a velocity that is given by the square root of the tension divided by the mass per unit length. For a cosmic string, this velocity is therefore the speed of light, and strings are therefore very relativistic objects. Strings also move with respect to the cosmological frame (the frame in which the cosmic microwave background is at rest) with velocities comparable to that of light. As a consequence, the gravitational effects they induce are special to them, leading to specific signatures. In particular, although strings are extremely massive, the gravitational field around a string vanishes. This vanishing means that an observer at rest with respect to a string will experience no gravity. Test particles can, however, feel a gravitational disturbance provided that they move with respect to the string. Because of this disturbance, two particles are instantly projected toward one another at relativistic velocities whenever a string passes between them. This phenomenon was proposed in 1980 as a mechanism capable of seeding large-scale structure formation, namely galaxies, clusters of galaxies, and so on. Nowadays, it is believed that this mechanism is not the chief reason that the primordial featureless soup ended up with all the structures that are now observed, the basic seeds having resulted from another mechanism such as inflation. *See* INFLATIONARY UNIVERSE COSMOLOGY.

Light can be deflected by strings. This deflection is due to the fact that, if one circles around a string, the angle measured falls short of 2π by a very small but nonzero value called the missing angle. The first consequence of this deflection is that moving strings induce a Doppler-like shift in the frequency of a beam of light passing by; this phenomenon is called the Kaiser-Stebbins effect. Such shifts, being independent of the photon wavelength, are seen as temperature fluctuations in the cosmic microwave background radiation, superimposed over the primordial ones. Present studies indicate that these secondary fluctuations cannot contribute at a level higher than 10% of the total fluctuations. The remaining 90% were most probably produced during an inflationary epoch in the early universe and therefore did not result from cosmic strings. *See* COSMIC BACKGROUND RADIATION.

A light ray passing near a string would travel along a trajectory that takes into account the missing angle, and would be bent by half this amount. As a result, if a string is present between an observer and a point source, the source will be lensed and thus seen as two absolutely identical objects by the observer. Unambiguously observing such a double image would be a proof of the existence of cosmic strings. Obtaining such an observation is, however, a difficult task as even the most massive strings produce a missing angle of only a few seconds of arc. Moreover, actual pairs of almost identical objects are very common in the sky, so that, as yet, it has never been possible to distinguish between a coincidence and a lensing effect. Good candidates are currently being examined and the existence of cosmic strings might thus shortly be proven. *See* GRAVITATIONAL LENS.

Superconducting strings. The strings can be coupled to many particles, and in some cases the trapping of those particles in the string cores is energetically favored. In such cases, the trapped particles behave as current carriers, and the strings become superconducting, with currents up to 10^{20} ampères. It has been proposed that such high currents could be the sources for ultrahigh-energy cosmic rays. Current-carrying loops of strings can form equilibrium states (named vortons), which would not decay into gravitational radiation as do their non-current-carrying counterparts. The energy density they contain would then not be transferred into the radiation fluid, a condition necessary to reach scaling. Vortons would then come to dominate the universe and lead it to a premature collapse, a big crunch. Such scenarios lead to very strong constraints on the theories that predict them. *See* COSMIC RAYS; SUPERCONDUCTIVITY.

Cosmic superstrings. At energies higher than the grand unified scale, particle properties are expected to be described by superstring theory. This theory is based on the idea that the fundamental building blocks of nature are not pointlike particles. Rather, they are extended, one-dimensional objects, also called strings, which are so small that they appear to be pointlike in all conceivable experiments. However, under some conditions, some strings (not to be confused with the axionic strings, also produced by the same theories) could be of cosmological dimensions. In this case, their properties are expected to be similar to those of the local strings described above. The main difference is that the reconnection probability could be much lower, resulting in a network that could have difficulties reaching scaling, and in potentially observable cosmological consequences, currently under investigation. It is hoped that such consequences will perhaps provide the first testable prediction of superstring theory.

Cosmochemistry

The science of the chemistry of the universe, particularly that beyond the Earth. As currently practiced, cosmochemistry is concerned primarily with inferences on pre-solar-system events, solar nebular processes, and early planetary processes as deduced from minerals in meteorites and from chemical and isotopic compositions of meteorites and their parts. *See* ISOTOPE; METEORITE.

Minerals in Meteorites

Meteorites provide a great deal of otherwise unobtainable information about the formation and early history of the solar system. The solar system formed from the solar nebula, a large cloud of gas and dust. The chemical composition of the solar system, which can be assumed to be the same as that of the solar nebula, is known in detail from spectroscopic analysis of the Sun, which contains 99.9% of its mass. From a combination of this knowledge, an estimate of temperature and pressure from hydrodynamic models, and thermodynamic data for all possible gas, liquid, and solid species, it can be determined which minerals would have become stable as the gas cloud underwent gravitational collapse, spun down into a disk, and cooled. Pressure in the solar nebula was probably so low that condensation occurred at temperatures below the melting points of the minerals, and they condensed as solids. Different minerals became stable at different temperatures, giving rise to a condensation sequence, which can be calculated (**Table 1**). *See* ASTRONOMICAL SPECTROSCOPY; ELEMENTS, COSMIC ABUNDANCE OF; HYDRODYNAMICS; PROTOSTAR; SOLAR SYSTEM; SUN; THERMODYNAMIC PRINCIPLES.

Detailed chemical information, however, requires samples, and the Earth is too geologically active to provide samples dating to its formation. Meteorites are therefore studied because, in general, they have undergone much less modification than terrestrial rocks.

Carbonaceous chondrite inclusions. A certain type of meteorite, the carbonaceous chondrite, contains millimeter-sized rocklets, or refractory inclusions, that are composed of the very minerals (especially hibonite, perovskite, melilite, spinel, and fassaite; Table 1) believed to have been among the first to condense from the solar nebula. This finding indicates that assumptions used to calculate the condensation sequence are reasonably accurate. Corundum, the first major condensate, is very rare, however. Most of it probably reacted with the nebular gas to form hibonite, or it may have entered clumps of minerals that melted and crystallized other phases upon cooling. The absence of forsterite (FeO-free olivine; Table 1) and other lower-temperature phases from

most of these refractory inclusions indicates that they were somehow isolated from the nebular gas at very high temperatures. *See* CORUNDUM; MELILITE; PEROVSKITE; SPINEL.

The most abundant refractory inclusions that are thought to be condensates, found in the C3 group of carbonaceous chondrites, are the so-called fluffy type-A inclusions. These inclusions are mainly composed of melilite, with lesser amounts of spinel, perovskite, and hibonite. Most have very irregular shapes and appear to be aggregates of individually formed nodules. Many contain melilite crystals in which aluminum oxide (Al_2O_3), rather than magnesium oxide (MgO), increases from core to rim. This trend is opposite to that expected for crystallization from a liquid, but it could be produced by condensation from the nebular gas at about 1460 K (2170°F) during a period of falling pressure.

In contrast, type-B inclusions, also found in C3s, are round and contain spinel, melilite, fassaite, and anorthite. Results of experiments in which artificial refractory inclusions were crystallized from liquids at known temperatures and cooling rates suggest that these type B inclusions crystallized from liquids that formed by incomplete melting of preexisting solids, and cooled at rates ranging from a few tenths of a degree to tens of degrees per hour from temperatures of about 1400°C (2550°F). *See* CRYSTALLIZATION.

Unlike terrestrial rocks, most meteorites contain metallic iron-nickel alloys, indicative of formation in a reducing (oxygen-poor) environment. Other minerals within refractory inclusions can be used to estimate the oxygen abundance. On Earth, titanium is most commonly found as Ti^{4+}, but in refractory inclusions there are some minerals (for example, hibonite, fassaite) which also contain titanium in its more reduced form, Ti^{3+}. The Ti^{3+}/Ti^{4+} ratios in these minerals in many cases are quantitatively consistent with their formation in the highly reducing environment of a gas of solar nebular composition.

Formation of chondrites. Condensation probably continued at lower temperatures, after isolation of the refractory inclusions from the nebular gas. The C2 carbonaceous chondrites contain single crystals of forsterite and enstatite (Table 1) that are believed to be condensates, and the C3 chondrites contain ameboid olivine aggregates, which are irregularly shaped clumps of grains that also appear to be condensates. Based on the olivine compositions (FeO-bearing) and the presence of nepheline and sodalite, which contain sodium oxide (Na_2O) or potassium oxide (K_2O), these objects continued to react with the solar nebular vapor to temperatures as low as about 500 K (440°F). There is much olivine in the chondritic meteorites, but most of it is present in objects termed chondrules, which are millimeter-sized spheres of crystals and glass that once were molten droplets. Chondrules are found in carbonaceous and ordinary chondrite meteorites, the latter being aptly named since they are the most abundant type of meteorite. Chondrule formation was thus a major, widespread process in the early solar system. As is the case for many refractory inclusions, chondrules are thought to have crystallized from liquids formed by melting of preexisting solids, but the nature of the heat source that caused the melting is not well understood. *See* ENSTATITE; NEPHELINE; OLIVINE; PYROXENE.

In the C3 carbonaceous chondrites, the refractory inclusions and the chondrules are enclosed in a later-formed, fine-grained matrix dominated by FeO-rich olivine, plus Fe-sulfides and iron-bearing compounds. The matrix must have formed at a much lower temperature than the chondrules and refractory inclusions, because FeO is not sufficiently stable to enter silicates significantly above about 900 K (1160°F) and the carbonaceous materials require low temperatures in order to be stable as well. Thus, diverse components—condensate inclusions, melted inclusions, and chondrules—with different histories were all assembled without much reheating into objects that became carbonaceous chondrites.

In addition, components were efficiently sorted, giving rise to different chondrite groups. The C1 carbonaceous chondrites contain no chondrules or inclusions, just single olivine and pyroxene crystals in a fine-grained matrix of sheet silicates (a water-bearing mineral, similar to the clay minerals). These are the most primitive meteorites, containing solar proportions of all but the most volatile elements. The C2 carbonaceous chondrites contain small refractory inclusions that consist mostly of nonsilicate, oxide minerals (hibonite, perovskite, and spinel), and olivine-rich chondrules in a matrix dominated by sheet silicates. Many of the chondrules and inclusions were altered by some sort of FeO-water-rich fluid. This process may have occurred on the parent body. The C3 carbonaceous chondrites have more abundant chondrules and larger, more silicate-rich refractory inclusions than the C2 chondrites, in an anhydrous, olivine-rich matrix.

Ordinary chondrites consist mainly of chondrules, chondrule fragments, and very rare refractory inclusions in a very small amount of matrix. Many have been heated and have very uniform olivine and pyroxene compositions, especially with respect to their Mg/Fe ratios; these are the equilibrated ordinary chondrites. Others have not been heated and are known as unequilibrated ordinary chondrites. All chondrites contain FeO-bearing olivine, and determining how olivine with such compositions, especially that in ordinary chondrites and carbonaceous chondrite matrices, could have formed in the solar nebula is one of the major unsolved problems in the study of meteorites. Calculations show that, at the (low) temperature at which FeO becomes stable enough to enter olivine in a gas of solar composition, its rate of diffusion into grains would be so slow that negligible amounts, much lower than are observed, would enter olivine before diffusion stops altogether. The stability temperature of FeO would be higher, however, allowing more extensive diffusion, in a more oxygen-rich gas. One way this could have occurred would be if oxygen-bearing dust were added to the nebula, increasing the dust/gas ratio over the solar ratio. But only by using the maximum dust/gas ratio permitted by nebular models, with oxygen-rich, water ice-bearing dust, and olivine grains with radii of approximately 1 micrometer, do condensation models predict the formation of olivine with FeO contents within the range observed in ordinary chondrites. This set of requirements is not a satisfactory solution to the problem of accounting for the observed FeO contents of olivine in chondrites.

Some meteorites also contain trace amounts of grains of carbon-rich minerals (silicon carbide, diamond, and graphite) whose condensation requires a gas with a carbon/oxygen ratio greater than 1, whereas that of the Sun is 0.5. This finding, along with very large isotopic anomalies for many elements, provides strong evidence that these grains are interstellar in origin, predating the Sun by as much as about 2.4×10^9 years. These grains should have disappeared by reacting with the solar nebular gas, however; why they did not and how they survived long enough to be incorporated into meteorites are not yet understood. *See* DIAMOND; GRAPHITE; INTERSTELLAR MATTER; SILICON.

Meteorites from planets. The presence of a wide variety of objects in chondrites—interstellar grains, refractory inclusions, chondrules, and matrix— which date back to the formation of the solar system and have survived virtually unchanged, shows that these meteorites were generally not subjected to destructive geologic processes on their parent bodies. This fact indicates that those bodies were small and inactive. Some objects, presumably with chondritic bulk compositions, did grow large enough to become geologically active. In such bodies, heat from gravitational compression and radioactive decay caused interior melting. The first liquid produced by melting of chondritic rock consists mostly of metallic nickel-iron and sulfur. Since this liquid is twice as dense as silicates, it will sink, forming an iron-rich metallic core.

Iron meteorites are completely composed of metallic nickel-iron that was once molten. In some cases, as they cooled, the nickel preferentially entered one phase and the iron entered another, forming alternating bands in a process called exsolution. From the bulk composition of a meteorite and the iron-nickel phase diagram, the starting temperature for exsolution can be determined, and from the thicknesses and compositions of the bands, how far it progressed. Then, application of experimentally determined diffusion rates yields the cooling rate. Results for various iron meteorites fall between 1 and 100°C (2 and 180°F) per million years, evidence for origins deep within planets with radii between 100 and 300 km (60 and 180 mi). At least a dozen parent bodies appear to be represented. The pallasite meteorites, with coarse olivine crystals enclosed in a matrix of metallic nickel-iron, probably come from core-mantle boundaries of former planets.

Stony (silicate) meteorites called achondrites, which do not contain chondrules and do not have chondritic (near-solar) compositions, are from the silicate portions of planets that underwent internal melting. Just above the core-mantle boundary of such planets should be metal-poor zones of coarse-grained rocks that formed by settling of large crystals. Ureilites (olivine-rich meteorites) and diogenites (pyroxene-rich meteorites) probably formed in such zones.

The eucrites, another group of achondrites, are essentially basaltic rocks, and microscopic study shows that many of them consist of rock fragments that were broken up by meteorite impacts on their parent body. This finding indicates that they formed at or near the surface, as do terrestrial basalts. Other meteorites, termed howardites, appear to be lithified soils, and consist of rock, mineral, and glass fragments in a fine-grained matrix, as do lunar soils. In howardites the rock fragments are mainly diogenites and eucrites, showing that these meteorite types originated on the same parent body.

The irons and achondrites provide evidence of internal melting in small planets. Radiometric dating indicates that these meteorites are about as old as the solar system itself. Therefore, planet formation took place on a fairly short time scale, with bodies becoming large enough to undergo internal melting soon after the formation of the solar system. *See* MINERAL; PLANETARY PHYSICS.

A group of relatively young meteorites is also very important—the SNC (shergottite-nakhlite-chassignite) group. These are crystalline rocks with ages of less than 1.3 billion years, much younger than other igneous meteorites (4.5 billion years) or lunar samples (the youngest returned samples are about 3.1 billion years old; some unsampled units may be younger). The relatively young ages of the SNCs indicate that they had a fairly large parent body, because larger planets lose their internal heat more slowly and remain geologically active longer than small planets. Because all of the known asteroids are too small to have produced 1.3-billion-year-old internal melts, Mars was proposed as the source of the SNCs. This idea has become widely accepted. Strong evidence that Mars is the source of the SNCs, in addition to their young ages, comes from the rovers *Spirit* and *Opportunity*, which have analyzed rocks with compositions like those of basaltic shergottites. Additional evidence includes similarities between the compositions of shergottites and that of the soil at the *Viking*, *Spirit*, and *Opportunity* landing sites, and a close match between the composition of trapped gas in the SNCs and that of the Martian atmosphere as measured by *Viking* spacecraft. For some years an argument against Mars as the source of the SNCs was the absence of lunar meteorites from collections. But in 1983 the discovery of the first lunar meteorite was confirmed, on the basis of detailed comparison with analyses of lunar samples returned by the *Apollo* astronauts. *See* MARS; SPACE PROBE. Steven B. Simon

Chemical Compositions of Meteorites

The chemical composition of meteorites and independently formed objects within them have taught much about pre-solar-system events, solar nebular processes, and early planetary processes.

Cosmochemical properties of elements. Before discussing examples of the results of meteorite studies, it is necessary to understand a few basic properties of the elements.

Cosmochemical affinity. The elements can be divided into four groups based on their cosmochemical affinity: siderophile or metal-seeking elements; chalcophile or sulfide-seeking elements; lithophile or oxide and silicate-seeking elements; and atmophile elements, which do not condense and are found in atmospheres (**Fig. 1**). This classification of elements applies to the highly reducing conditions of the solar nebula, which is dominated by hydrogen. Conditions on the surface of the Earth and other planets are more oxidizing, so that some elements classified here as siderophile or chalcophile, such as lead, have lithophile characteristics in the Earth's crust and mantle. *See* ELEMENTS, GEOCHEMICAL DISTRIBUTION OF.

Volatility. The elements show a wide range of volatility in a gas of solar composition (**Fig. 2**). The refractory elements are generally considered to be those that are totally condensed in about the first 5% of the total condensable matter of the solar system, corresponding to about 1475 K (2195°F) in a gas of solar composition at a total pressure of 10^{-3} atmosphere (10^2 pascals). A subset of the refractory trace elements are sometimes referred to as the ultrarefractory elements, because they are already completely condensed before the first major mineral, hibonite, condenses at 1743 K (2677°F). The moderately volatile elements show variable degrees of depletion in chondrites and planets compared to cosmic abundances; they have condensation temperatures between 1475 and 700 K (2195 and 800°F). The highly volatile elements are strongly depleted in chondrites and planets and have condensation temperatures below 500 K (440°F). The solar nebula is highly reducing, because of the high abundance of hydrogen compared to other elements. The relative volatilities of some elements change under more oxidizing conditions. For example, under oxidizing conditions cerium becomes a moderately volatile element, whereas all remaining rare-earth elements remain refractory.

Compatibility. Some lithophile elements have large ionic radii and do not fit readily into the crystal structures of the major minerals that make up most rocks: olivine, pyroxene, and plagioclase. These elements are often referred to as incompatible elements. They tend to be enriched in the melt when a rock is partially melted. Examples of incompatible elements are potassium, rubidium, light rare-earth elements, and uranium.

Presolar events. As mentioned above, a number of types of interstellar grains have been separated from primitive meteorites. Presolar grains identified include silicon carbide, graphite, diamond, titanium carbide, zirconium carbide, molybdenum carbide, ruthenium carbide, metallic iron, aluminum oxide, titanium oxide, hibonite, and spinel. While chemistry alone has not unambiguously identified any of these grains as presolar, chemistry does help to understand the formation conditions of objects whose isotopic composition proves a presolar origin. A good example is silicon carbide, most of which is believed, on the basis of isotopic arguments, to come from the circumstellar envelopes of asymptotic

giant branch stars. The silicon carbide with isotope anomalies that is separated from meteorites is enriched in a number of trace elements that are predicted to condense at high temperatures as carbides in reducing environments, such as zirconium, titanium, molybdenum, strontium, barium, and the rare-earth elements. These enrichments are entirely consistent with the proposed origin of silicon carbide by high-temperature condensation in the circumstellar envelopes of carbon-rich stars. *See* CARBON STAR; GIANT STAR.

Solar nebular processes. Chemistry has been used to infer a number of important processes in the solar nebula. These include high-temperature condensation and vaporization, melting and crystallization of millimeter- to centimeter-sized objects in the solar nebula, separation of metal from silicate grains, and reaction of condensed grains with solar nebular gas. Investigation of these processes helps determine important properties of the solar nebula, such as its temperature, how long it lasted, and what the planets, which formed from the nebula, are made of.

Condensation and evaporation. As mentioned above, most carbonaceous chondrites contain refractory inclusions, which are enriched in refractory elements relative to cosmic abundances. The most common type is enriched by about 20 times relative to cosmic abundances in all refractory elements, regardless of whether they are lithophile or siderophile. Some other refractory inclusions show evidence for volatility fractionation of refractory elements from one another. This fractionation requires higher temperatures and is likely to have occurred within a few degrees of condensation of hibonite, above 1700 K (2600°F). Thermodynamic calculations done to model this fractionation assume equilibrium, so they cannot distinguish between volatilization and condensation.

Kinetically controlled processes can lead to isotopic and chemical fractionation effects that would not have occurred under equilibrium. One example comes from the refractory inclusions. The bulk chemical compositions of refractory inclusions are depleted in magnesium and silicon compared with the calculated bulk composition of material condensing from a gas of solar composition. These inclusions also display isotopic mass fractionation effects, in which they are enriched in heavy isotopes of magnesium and silicon relative to normal solar system material. Both effects have been reproduced in the laboratory by melting and evaporating synthetic refractory inclusions in vacuum or in low-pressure hydrogen. It now seems likely that most refractory inclusions have experienced heating and evaporation in the solar nebula under kinetically controlled conditions. In contrast, chondrules in chondritic meteorites generally do not display isotopic fractionation effects and are likely to have been heated under conditions that were closer to equilibrium.

Depletion of volatile elements. Relative to cosmic abundances, the terrestrial planets and many types of meteorites are depleted in the moderately volatile elements, with the depletions growing larger with increasing volatility. A useful element pair for seeing this fractionation comprises potassium, a moderately volatile element, and uranium, a refractory element. Both are incompatible elements. Within a single planet or meteorite parent body, the potassium/uranium ratio is relatively constant, because igneous fractionation processes tend to exclude both elements from major minerals. Both have long-lived radioactive isotopes that are gamma-ray emitters, so measurements are available from Mars and Venus. Chondritic meteorites have potassium/uranium ratios near the cosmic value of about 65,000, whereas the Earth, Moon, Venus, Mars, and the parent body of the basaltic achondrites [probably the 500-km-diameter (300-mi) asteroid Vesta] have lower potassium/uranium ratios. The potassium depletion in the terrestrial planets is strong evidence for a nebula-wide event that swept away the volatile elements before they could condense.

Planetary processes. A number of important planetary processes, such as separation and differentiation of a metallic core and differentiation of the silicate portion of a planet into mantle and crust, can be studied through the chemical compositions of meteorites.

Core formation. The siderophile elements are powerful recorders of metal-silicate fractionation processes in parent bodies, that is, core formation. Some elements, such as tungsten, are strongly but not completely partitioned into metal during core formation. In igneous differentiation processes, the tungsten that remains behind in the silicate is highly incompatible, such that its ratio to other incompatible but strongly lithophile elements, such as lanthanum, remains constant. In each major planetary body, such as the Earth, Moon, the parent body of the igneous SNC (shergottite-nakhlite-chassignite) meteorites (probably Mars, as discussed before), and the basaltic achondrite parent body, the ratio of tungsten to lanthanum remains constant, although the absolute concentrations can be quite variable among different samples. There are differences from one parent body to the next in the tungsten/lanthanum ratio, which are due to differences in how metallic cores separated from the silicate mantle of each parent body.

Core differentiation. When the core of a planet forms, it is initially molten (otherwise the mechanical properties of metal and silicate would not have allowed it to separate). The process of crystallization of cores of now-disrupted small parent bodies can be followed through the chemical compositions of some classes of iron meteorites. About 800 iron meteorites are known. About 80% of them can be classified into 12 groups, based primarily on the concentrations of four diagnostic elements: nickel, gallium, germanium, and iridium. During crystallization of an initially molten core, some elements, such as gold, tend to partition into solid metal while others, such as iridium, tend to remain in the liquid. Several of the 12 groups of iron meteorites show correlations between siderophile trace elements that are consistent with slow crystallization of planetary cores.

Asteroid melting. The chondritic meteorites, which have textures indicating that they never melted, show variable depletions of moderately volatile elements, but these depletions are independent of whether a trace element is incompatible or not. In contrast, the basaltic achondrites are composed of basalt, which is a rock that can form by partial melting of a chondritic source composition. The eucrites, which are igneous basaltic achondrites, show a range of trace-element concentrations that indicate that they crystallized from a melt enriched in incompatible elements compared to cosmic abundances. This range of trace-element concentrations is due to fractional crystallization, where, compared to the melt, the first eucrites to crystallize are depleted in incompatible elements and the last eucrites are enriched in incompatible elements. *See* ASTEROID.

Sampling the solar system. Much of what is known about the chemistry of the solar system comes from meteorites, which are believed to have sampled asteroids, Mars, and the Moon. Now, more that 30 years after the Apollo missions to return lunar samples, new missions are sampling the Sun, a comet, and an asteroid, and further sample-return missions are in the planning stages.

Genesis. The first of the new generation of sample-return missions, *Genesis*, exposed high-purity materials such as silicon, aluminum oxide, and diamond film to the solar wind for over 2 years. The spacecraft crashed in Utah when its parachute failed to open, but the solar wind collectors survived. Analyses will measure the chemical and isotopic compositions of many elements in the samples, allowing tests of how well spectroscopic methods measure solar composition and whether the Sun has the same isotopic composition as the Earth and meteorites.

Stardust. The *Stardust* mission flew close to the nucleus of comet Wild 2 in January 2004 and collected dust particles in silica aerogel. The spacecraft returned to Earth in January 2006. Dust grains as small as 1 μm across were extracted from the aerogel and analyzed for their crystal structure and chemical and isotopic composition. The mission should dramatically increase our knowledge of comets. It is currently unknown whether the dust in comets is formed mostly within the solar system or is an aggregation of presolar material that was never significantly modified during formation of the solar system.

Hayabusa. In early February 2006, the *Hayabusa* spacecraft was orbiting the asteroid Itokawa after having landed twice on the surface of the asteroid, with the purpose of collecting a sample to return to Earth. The spacecraft had a number of problems: it may not have collected a sample; it will not return to the Earth until at least 2010, three years later than previously planned; and scientists were attempting to resume communication, which was interrupted in December 2005. It will be of great interest to see how closely asteroids resemble the meteorites in the world's collections, and, regardless of the fate of *Hayabusa*, other robotic sample return missions to asteroids are being proposed and planned. *See* SPACE PROBE.

Andrew M. Davis

Isotopic Compositions of Meteorites

Studies of the relative abundances of isotopes in meteorites provide a unique source of information about the age of the solar system, the time scales for formation of the first solid bodies in the solar system and the growth and evolution of small planets, the prehistory (nucleosynthesis) of the material out of which the solar system formed, and the interaction of solar and galactic cosmic rays with matter.

Chronology: age of solar system and formation of planets. Meteorites are the oldest objects available for scientists to study in the laboratory and provide the best indication of the age of the solar system. Nineteen radioactive decay schemes with half-lives ranging from a remarkably short 53 days to more than 100 billion years (**Table 2**) have been utilized to determine the ages of samples varying in size from individual mineral grains less than 1 μm across to whole meteorites. The radionuclide systems in Table 2 are generally divided into two classes according to the half-life of the radioactive parent isotope: short-lived radionuclides have half-lives of less than about 100 million years, while long-lived radionuclides have half-lives of greater than 500 million years. This distinction is based on the practical issue of observability. Radioactive species with half-lives shorter than about 100 million years are now extinct in the sense that whatever amount may have existed at the birth of the solar system has completely decayed away. For this reason conventional dating of terrestrial rocks is based solely on the long-lived radionuclides listed at the bottom of Table 2. Most meteorites, in contrast, formed sufficiently early to preserve evidence of the short-lived radionuclide parents, and chronologies based on these short-lived radionuclides provide a powerful tool for examining time scales during the first 50 million years of solar system history.

The oldest meteoritic samples are the refractory, calcium-aluminum-rich inclusions found in carbonaceous chondrites. The 4.567-billion-year age of these objects provides the best estimate for the condensation of the first solid material in the solar system. Chondrules, millimeter-size spherules of glass and crystals, began to form 1 to 3 million years after refractory inclusions as the solar nebula cooled. The oldest basaltic meteorites crystallized from molten lavas on small asteroids within roughly 3 million years following the formation of the carbon-aluminum-rich inclusions (that is, ages of 4.564–4.552 billion years). Most chondritic meteorites have less precisely determined ages encompassing the range covered by chondrules and basaltic achondrites. The tight clustering of ages of the oldest meteorites reflects a period of very rapid growth during the first 5 million years of solar system history, as millimeter-to-centimeter-size objects collided and coalesced to form meter-to-kilometer-size planetesimals. The younger ages of some meteorites indicate that disturbances due to shock and thermal metamorphism began as early as 4.55 billion years ago and continued for several hundred million years. Collisions between planetesimals led to coagulation and differentiation, the growth of larger bodies, and the eventual formation of the terrestrial planets, including the Earth-Moon system, within about 50 million years following the solar system's birth. *See* EARTH, AGE OF; ROCK AGE DETERMINATION.

TABLE 2. Radionuclides and solar system chronology

Nuclide[*]	Half-life, 10^{9} years	Daughter	Abundance[†]
^{7}Be	1.5×10^{-10}	^{7}Li	^{7}Be/^{9}Be $\sim 6 \times 10^{-3}$
^{41}Ca	0.00010	^{41}K	^{41}Ca/^{40}Ca $\sim 1.4 \times 10^{-8}$
^{36}Cl	0.00030	^{36}S	^{36}Cl/^{35}Cl $\sim 2 \times 10^{-4}$
^{26}Al	0.00072	^{26}Mg	^{26}Al/^{27}Al $\sim 5 \times 10^{-5}$
^{10}Be	0.0015	^{10}B	^{10}Be/^{11}Be $\sim 1 \times 10^{-3}$
^{60}Fe	0.0015	^{60}Ni	^{60}Fe/^{56}Fe $\sim 1 \times 10^{-6}$
^{53}Mn	0.0037	^{53}Cr	^{53}Mn/^{55}Mn $\sim (0.9\text{-}4) \times 10^{-5}$
^{107}Pd	0.0065	^{107}Ag	^{107}Pd/^{108}Pd $\sim 2 \times 10^{-5}$
^{182}Hf	0.009	^{182}W	^{182}Hf/^{180}Hf $\sim 1 \times 10^{-4}$
^{129}I	0.016	^{129}Xe	^{129}I/^{127}I $\sim 1 \times 10^{-4}$
^{244}Pu	0.081	Xe fission	^{244}Pu/^{238}U ~ 0.007
^{146}Sm	0.103	^{142}Nd	^{146}Sm/^{142}Sm ~ 0.008
^{235}U	0.704	^{207}Pb	^{207}Pb/^{204}Pb $= 10.29$
^{40}K	1.25	^{40}Ar	^{40}Ar/^{36}Ar $= 295.5$
^{238}U	4.47	^{206}Pb	^{206}Pb/^{204}Pb $= 9.307$
^{232}Th	13.9	^{208}Pb	^{208}Pb/^{204}Pb $= 29.48$
^{187}Re	41.6	^{187}Os	^{187}Os/^{188}Os $= 0.0956$
^{87}Rb	48.8	^{87}Sr	^{87}Sr/^{86}Sr $= 0.6988$
^{147}Sm	106	^{143}Nd	^{143}Nd/^{146}Nd $= 0.5068$

[*] Short-lived radionuclides, listed above in the top of the table, have half-lives shorter than 100 million years; long-lived radionuclides appear in the bottom half.

[†] Short-lived radionuclides: inferred initial abundance of the parent nuclide 4.566 billion years ago. If the initial abundance is not well established, the range of values is shown. Long-lived radionuclides: initial abundance of daughter isotope.

One unusual group, the SNC meteorites, whose appearance and composition is similar to that of terrestrial basalts, is the exception to the rule with much younger crystallization ages of approximately 1.3 billion years. The young ages of the SNCs require an origin on a planetary body larger than the Moon, on which radioactive heating could sustain igneous activity for at least 3 billion years. It is now generally accepted that this group of meteorites originated on Mars, an argument strengthened by recent evidence that the isotopic compositions of hydrogen, nitrogen, and noble gases in the SNC meteorites and the Martian atmosphere are strikingly similar and distinct from those in the Earth and other meteorites.

The first short-lived radionuclide, ^{129}I, was discovered in the early 1960s by way of the observation that some meteorites have a greater abundance of daughter ^{129}Xe than do others. Twelve short-lived species with half-lives ranging from 53 days to 103 million years (Table 2) are now confirmed to have existed at the birth of the solar system. Suggestive evidence of three additional radionuclides has been reported but awaits confirmation. The evidence of short-lived radionuclides is distributed across all classes of meteorites and provides a compelling argument not only that meteorites are the oldest objects in the solar system but also that they formed rather quickly over a very short interval. Although these nuclides can no longer be observed directly, evidence that they were present during the earliest epoch of solar system history is preserved as variations in the relative abundances of the daughter isotopes of the extinct radionuclides. For example, large excesses of ^{26}Mg, produced by the decay of ^{26}Al (half-life of 0.72 million

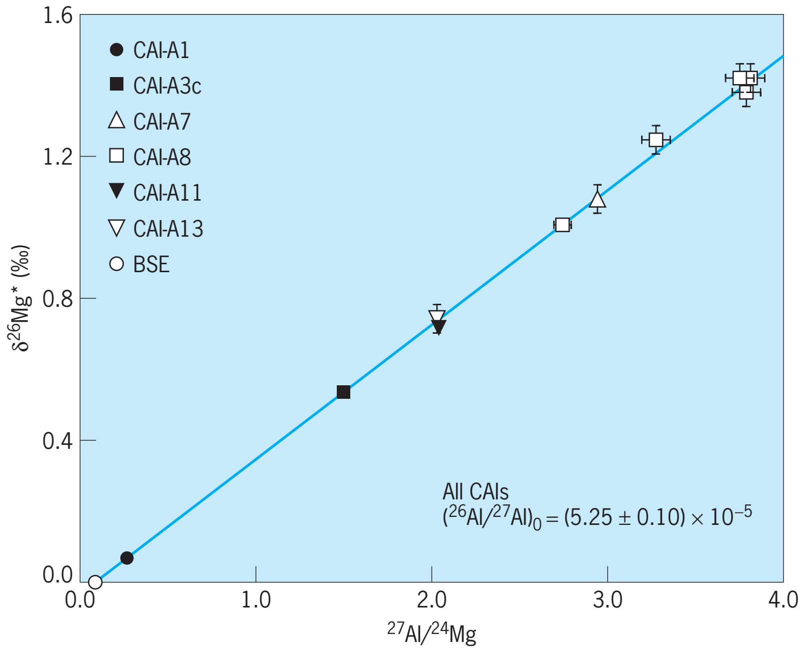

Fig. 3. Correlation of the $^{26}Mg/^{24}Mg$ ratio, expressed as $\delta^{26}Mg$ (the deviation in parts per thousand from normal Mg), with the $^{27}Al/^{24}Mg$ ratio for a group of calcium-aluminum-rich inclusions (CAIs) from the Allende meteorite. The correlation line is generated by the ingrowth of radiogenic ^{26}Mg, produced by the decay of ^{26}Al within the inclusions. The slope of the correlation line, corresponding to $^{26}Al/^{27}Al = 5.25 \times 10^{-5}$, indicates the abundance of the short-lived radionuclide ^{26}Al at the beginning of the solar system, 4.567 billion years ago. The point labeled BSE represents the Mg isotope composition of the silicate portion of the Earth. The fact that all six inclusions lie along a single line indicates that most CAIs formed at the same time, within ~50,000 years. (*After M. Bizzarro, J. A. Baker, and H. Haack, Nature, 431:275–278, 2004*)

years), are found in aluminum-rich, magnesium-poor minerals in refractory inclusions in carbonaceous chondrites (**Fig. 3**). The correlation between the relative abundance of ^{26}Mg and the Al/Mg ratio shown in Fig. 3 indicates that the inclusion crystallized before the ^{26}Al had decayed, while the slope of the line provides the relative ^{26}Al abundance at the time of formation, $^{26}Al/^{27}Al \sim 5 \times 10^{-5}$. The nearly uniform abundance of ^{26}Al among refractory inclusions suggests that the majority of these objects formed over an interval no longer than 100,000 years. No material formed in the solar system is known to have higher $^{26}Al/^{27}Al$, that is, to have formed prior to refractory inclusions.

The short-lived nuclides are not restricted to primitive chondritic meteorites but are also prominent in meteorites produced by planetary-scale melting. Asteroids similar to Vesta must have grown and differentiated within a few million years after the formation of refractory inclusions. A similar time scale is found for parent-body metamorphism of undifferentiated chondritic meteorites. These observations require an efficient and fast-acting heat source to drive planetary melting and differentiation. The long-lived radionuclides ^{40}K, ^{232}Th, ^{235}U, and ^{238}U decay much too slowly to produce melting on small planets within a few million years, and the short-lived nuclides ^{26}Al and ^{60}Fe are the most plausible sources. The abundances of ^{26}Al and ^{60}Fe found, respectively, in refractory inclusions ($^{26}Al/^{27}Al \sim 5 \times 10^{-5}$) and chondrules ($^{60}Fe/^{56}Fe \sim 1 \times 10^{-6}$) are sufficient to melt the interiors of parent bodies larger than a few kilometers. A new wealth of new data from the Hf-W, Fe-Ni, Mn-Cr, and Al-Mg parent-daughter systems in differentiated meteorites provides conclusive evidence for the dominant role of short-lived radionuclides for melting and core formation on small planetesimals.

The discovery of short-lived radionuclides also has important implications for what may be called presolar chronology, or the time-scale of events immediately preceding the birth of the solar system. The widespread presence of short-lived nuclides indicates that the time interval between nucleosynthesis and the formation of the solar system was extremely short. The upper limit to this interval is set by the lifetime of ^{41}Ca (Table 2). The refractory inclusions containing ^{41}Ca must have formed within a few mean lives, that is, a few hundred thousand years of the time of ^{41}Ca production. This time scale is so short that it suggests the formation of the solar system may have been triggered by a shock wave from a nearby exploding star containing freshly synthesized nuclear material. The one radionuclide with an even shorter half-life of 53 days, ^{7}Be, must have been produced by energetic particle interactions between gas and dust within the nascent solar nebula and cannot be used to limit the time since nucleosynthesis.

Isotope anomalies and presolar grains. Except for the variations in isotopic abundances related to decay of radionuclides discussed above, for the most part there is a close similarity between the isotopic compositions of meteorites, the Moon, and the Earth. For many years this apparent homogeneity was taken as evidence that the solar nebula was chemically and physically well mixed before the formation of the first solid bodies. The development of new analytical techniques permitting the determination of isotopic compositions in small (<1 μm) constituents of meteorites has, however, led to the discovery of large differences in isotopic abundances for many elements which cannot be explained in terms of radioactive decay or cosmic-ray interactions. These isotope anomalies provide unequivocal evidence that dust grains that condensed around a variety of different stars were incorporated into primitive meteorites and offer a window through which nucleosynthesis and stellar evolution are revealed with unprecedented clarity.

Two distinct types of meteoritic material with isotope anomalies can be distinguished: (1) samples closely related to chondritic meteorites but containing unusual isotope abundances for selected elements, and (2) authentic interstellar grains. Refractory inclusions are the primary example of the first type of material. These inclusions unquestionably formed within the solar system but exhibit unusual isotope abundances for a number of elements, including oxygen, magnesium, silicon, calcium, titanium, chromium, iron, zinc, strontium, barium, neodymium, and samarium. The variations in O-isotope abundances are particularly significant, because they hold an important clue to understanding nebular and planetary processes in the early solar system. Oxygen in refractory inclusions is enriched in ^{16}O by up to 4% relative to the average solar composition; no other element exhibits such a large variation in terms of the total number of atoms.

Aside from oxygen, the most prominent nucleosynthetic isotope effects in refractory inclusions are excesses and deficits of the neutron-rich isotopes in elements of the iron abundance peak. Correlated effects for these isotopes provide definitive evidence for the preservation of an exotic component, produced in a supernova during neutron-rich nucleosynthesis. These same inclusions also contain large (percent-level) oxygen, magnesium, and silicon anomalies due to mass-dependent shifts in relative isotope abundance. The connection between isotope anomalies reflecting stellar nucleosynthesis and those due to fractionation processes is poorly understood and remains a subject of current investigation.

Oxygen isotope anomalies are found on all scales studied, from less than a micrometer to many kilometers. The characteristic patterns of oxygen isotopes are similar to those found in refractory inclusions—large variations in the ^{16}O abundance with very small changes in the ^{17}O/^{18}O ratio. Different meteorite classes [the H (heavy), L (light), and LL chondrites] have distinct oxygen isotope compositions, requiring at least two different oxygen reservoirs in the solar nebula. The ^{16}O-rich reservoir most plausibly consisted of dust grains, while the ^{16}O-poor reservoir, containing the greater part of the solar system's oxygen, was gaseous. Mixing and exchange between these reservoirs as the solar nebula evolved gave rise to the heterogeneous array of oxygen-isotope compositions seen today. The only group of meteorites to have bulk oxygen isotope abundances similar to those of the Earth and Moon are the enstatite chondrites.

The isotope anomalies found in refractory inclusions represent a mixture of exotic stardust from other stars diluted with normal solar system material; the inclusions themselves clearly are not presolar material. A major new discovery in meteorite research is the identification in primitive chondrites of whole interstellar grains, formed outside the solar system in stellar atmospheres and incorporated into primitive meteorites essentially intact. These grains survived transit through the interstellar medium and injection into the forming solar system and preserve the isotopic and chemical compositions of the stellar nuclear sources for both major and trace elements. Presolar grains show isotope anomalies for all elements, and the size of the anomalies is at least a factor of 100 times larger than that of anomalies found in refractory inclusions.

At least 11 distinct types of presolar grains have been identified in meteorites: diamond, silicon carbide (SiC), titanium carbide (TiC), rutile (TiO_2), graphite, hibonite ($CaAl_{12}O_{19}$), corundum (Al_2O_3), spinel ($MgAl_2O_4$), silicon nitride (Si_3N_4), and, most recently, the common magnesium-rich silicate minerals, olivine and forsterite. These presolar grains have high formation temperatures and, with the exception of diamond, are generally about 1 micrometer in size. The abundance of the different types of grains varies widely among different meteorites, but diamond is always most abundant, while titanium carbide, rutile, and silicon nitride are least abundant. Presolar grains were originally incorporated into all classes of chondritic meteorites. Today, primitive meteorites of low petrologic type (for example, CI or CM chondrites) that never experienced high metamorphic temperatures contain the highest abundance of presolar grains. The pattern of decreasing abundance with increasing petrologic grade of the host meteorite reflects the selective destruction of presolar grain populations during parent body metamorphism. The abundance of presolar grains (diamond and silicon carbide, primarily) now provides a useful measure of the extent of meteorite parent body metamorphism.

With an abundance of approximately 0.05% by mass in carbonaceous chondrites, diamond is by far the most prevalent interstellar material. Interstellar diamonds are exquisitely small (mean size of only about 3 nanometers) and can be analyzed only as aggregates containing hundreds of thousands of grains. The carbon isotope composition of nanodiamonds is very similar to that of average solar system material, and the presolar origin of nanodiamonds is indicated by large enrichments in ^{14}N and Xe-HL (an exotic xenon component characterized by excesses of both the light and heavy Xe isotopes). Despite their small size, diamonds contain 50–90% of the Xe-HL in bulk chondrites. A supernova environment provides the best explanation for the observed properties of presolar diamonds.

Presolar SiC is much less abundant, about 10–15 parts per million (ppm), and much larger (about 0.1–20 μm) than the nanodiamonds. Carbon and nitrogen in SiC exhibit an extraordinary range in isotopic composition; ^{12}C/^{13}C ratios extend from 2 to 7000, compared to the range in terrestrial materials of 88 to 90, while ^{14}N/^{15}N ratios vary from 5 to more than 20,000, compared to the range in terrestrial materials of 260 to 284. Presolar SiC exhibits isotope anomalies for all elements measured, including helium, neon, magnesium, aluminum, silicon, potassium, calcium, titanium, zirconium, barium, and molybdenum. These isotope abundance patterns cannot be found anywhere in the solar system and indicate that most SiC grains formed as condensates in the atmospheres of carbon-rich, red-giant stars. Approximately 1% of SiC exhibits particularly unusual isotopic properties indicative of supernova origin; the few silicon nitride grains are also related to supernovae.

Interstellar graphite is slightly less abundant, about 10 ppm, than SiC and occurs as micrometer-size spherules which, in turn, often contain even smaller grains of Ti-, Zr-, and Mo-carbide. Presolar graphite exhibits a wide range in carbon and nitrogen isotope compositions, similar to SiC, and also contains essentially pure ^{22}Ne, extreme enrichments in ^{18}O, and large excesses of ^{26}Mg from the decay of extinct ^{26}Al. The inferred initial ^{26}Al/^{27}Al ratios range up to about 0.2, compared to a maximum of 5×10^{-5} in refractory inclusions. The diverse array of isotopic compositions cannot be explained by a single type of stellar source, and requires several different sources, including Wolf-Rayet stars, novae, and carbon-rich giant stars. *See* NOVA; WOLF-RAYET STAR.

Interstellar oxide grains are nearly 1000 times less abundant than presolar SiC, range from 0.5 to 5 μm in size, and are identified as presolar by their extremely anomalous oxygen isotope ratios. The $^{16}O/^{18}O$ ratio extends from 100 to greater than 5000, compared to the solar value of 499. Most presolar oxide grains contain excess ^{26}Mg from the decay of ^{26}Al and have isotope compositions, indicating a red giant branch star (RGB) progenitor.

Of particular interest is the discovery of presolar silicate grains whose chemical composition (rich in magnesium, silicon, and oxygen) is nearly indistinguishable from that of normal meteoritic and terrestrial minerals. Although astronomical observations indicated the presence of silicate grains in dust shells surrounding young stars, previous searches for presolar silicates proved unsuccessful. The presolar silicates were identified using a new type of imaging mass spectrometer to locate small grains displaying extreme oxygen isotope ratios, up to 100-fold enrichments in ^{17}O and ^{18}O relative to solar system matter. These presolar silicates are also found in interplanetary dust particles (IDPs) and have a surprisingly high abundance, ~70 ppm of the whole meteorite, making silicates the second most abundant type of presolar material. Like SiC and graphite, presolar silicates appear to have originated from intermediate-mass asymptotic giant branch stars.

Nucleosynthesis. Studies of isotope anomalies and presolar grains in primitive meteorites have yielded important new clues to nucleosynthesis and the types of stars contributing material to the nascent solar nebula. The very large range of isotope abundances measured in presolar grains cannot be generated by a single stellar source, and is ample proof that the solar system is the product of contributions from disparate stars. Hydrogen and the bulk of the helium in the solar system are relicts of big bang nucleosynthesis, while the elements carbon through iron were produced dominantly in charged particle reactions in massive stars. The radionuclides ^{129}I, ^{232}Th, ^{235}U, ^{238}U, and ^{244}Pu are all produced by neutron-rich nucleosynthesis, the *r*-process, in supernovae. The abundance of short-lived radionuclides requires the late addition of fresh nucleosynthetic material, most plausibly from massive, red-giant stars, to the solar nebula less than a few hundred thousand years prior to the formation of the first meteorites. The short-lived beryllium nuclei, ^{7}Be and ^{10}Be, cannot be produced in stellar nucleosynthesis and must the product of energetic particle interactions in the protosolar nebula. *See* BIG BANG THEORY; NUCLEOSYNTHESIS; STELLAR EVOLUTION; SUPERNOVA.

Cosmogenic nuclide

A rare nuclide produced by nuclear reactions between high-energy cosmic radiation and terrestrial or extraterrestrial material. Cosmogenic nuclides may be used to examine the history of exposure to cosmic rays, and have numerous applications in earth science and archeology.

Origin of terrestrial nuclides. Primary cosmic radiation is present in space and consists of nuclear particles (mostly protons and alpha particles) with energies that are greater than typical nuclear binding energies. Collisions between cosmic-ray particles and atomic nuclei produce fragments, including cosmogenic nuclides, and also alter the characteristics of the cosmic radiation. As cosmic radiation enters the atmosphere, its flux decreases and its composition becomes dominated by neutrons rather than protons and alpha particles (which react with atmospheric gases). This reduction in flux continues through the atmosphere; at ground level, small but measurable quantities of cosmogenic nuclides are produced in solid material within about 1 m (3.3 ft) of the Earth's surface. The cosmogenic nuclides produced in these two reservoirs (atmosphere and lithosphere) may be employed for examination of different geological processes. Because of their wide range of half-lives and chemical properties, cosmogenic nuclides have a wide range of applications in geological, geomorphological, and biogeochemical studies. *See* ALPHA PARTICLES; COSMIC RAYS; COSMOCHEMISTRY; PROTON.

Production. Production of cosmogenic nuclides varies over both space and time. The flux of cosmic rays, and hence cosmogenic nuclide production rates, decreases exponentially (by a factor of 2 for every ~100 g/cm^2 increase in pressure) with depth into the atmosphere (**Fig. 1**). In addition, the Earth's magnetic field—weakest at the magnetic poles and strongest at the Equator—diverts charged particles before they enter the upper atmosphere. As a result, production rates are greater at high geomagnetic latitude than at low geomagnetic latitude (Fig. 1).

Production of cosmogenic nuclides also varies with time. The three major potential variables are solar activity, the primary flux of galactic cosmic rays, and the Earth's magnetic field. Solar activity has an ~11-year cycle, varying around a mean that is fairly constant over longer periods. The galactic cosmic-ray flux is believed to have been relatively constant for at least the past 10^7 years. Therefore, geomagnetic field variability is probably the most important source of production rate changes over the past 10^3–10^6 years.

The earliest measurements of cosmogenic nuclides utilized radioactive decay counting and established the bases of many present-day studies. The development of exceptionally sensitive techniques (accelerator mass spectrometry and static mass spectrometry) during the 1980s improved detection limits by factors of up to 10^6 and greatly broadened the range of applications of these nuclides. *See* ACCELERATOR MASS SPECTROMETRY.

Atmospheric nuclides. Numerous nuclides are produced in measurable quantities in the atmosphere (**Table 1**). Their half-lives and their chemical reactivities determine their applications in earth science. *See* RADIOISOTOPE (GEOCHEMISTRY).

Short-lived nuclides. Short-lived nuclides, including beryllium-7 (^{7}Be), sodium-22 (^{22}Na), phosphorus-32 (^{32}P), and phosphorus-33 (^{33}P), have been employed in studies of atmospheric circulation, particularly stratospheric-tropospheric exchange. Because production rates are far higher in the stratosphere than in the troposphere, concentrations of these nuclides in atmospheric aerosol particles are related to the extent of exchange processes. *See* STRATOSPHERE; TROPOSPHERE.

These nuclides also have applications in oceanography. Phosphorus is an essential nutrient element in the surface ocean; its isotopes ^{32}P and ^{33}P have half-lives appropriate for studies of surface-layer oceanic biological productivity. The tendency for beryllium in aquatic systems to adsorb onto particle surfaces makes ^{7}Be useful in tracing sediment transport and accumulation, on time scales up to several months, in estuarine and coastal regions.

Longer-lived nuclides. Because of its highly successful applications in dating, carbon-14 (^{14}C; radiocarbon) is the best-known cosmogenic nuclide. Essentially all atmospheric ^{14}C is in the form of gaseous carbon dioxide ($^{14}CO_2$); it thus has an atmospheric residence time long enough for the ratio of ^{14}C to ^{12}C (the stable isotope) to become homogeneous throughout the atmosphere. Living organisms and inorganic carbonates incorporate carbon with an isotope ratio reflecting that of the atmosphere. Upon removal from contact with the atmosphere, the ratio ^{14}C/^{12}C decreases through radioactive decay of ^{14}C. With knowledge of the initial ratio and the half-life of ^{14}C, measurement of ^{14}C/^{12}C allows calculation of the age of a sample. This technique has been extensively used in archeology and geology for samples as old as 4 × 10^4 years. High-precision ^{14}C dates of inorganic carbon dissolved in seawater are also used to deduce global oceanic circulation rates and patterns by determining the time since a particular water mass had contact with the atmosphere. *See* OCEAN CIRCULATION; RADIOCARBON DATING; SEAWATER.

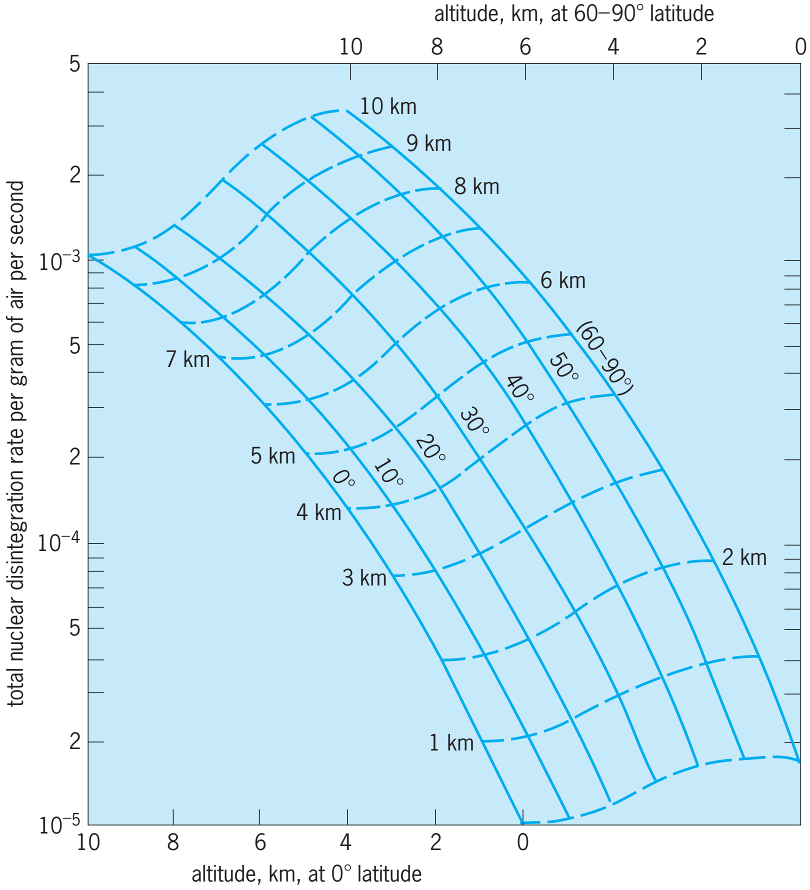

Fig. 1. Total rate of nuclear disintegrations in the atmosphere (with energy release greater than 40 MeV) is plotted as a function of altitude for various geomagnetic latitudes. Curves for each latitude (0–90°, in steps of 10°) are successively displaced by 1 km (0.6 mi) along the abscissa. It can be seen that disintegration rates increase exponentially with altitude and are lower at low geomagnetic latitude. The relationship between the total nuclear disintegration rate and the production rate differs slightly for each nuclide. (*After D. Lal and B. Peters, Cosmic ray produced radioactivity on the earth, in S. Flugge, ed., Handbuch der Physik, vol. 46/2, pp. 551–612, Springer-Verlag, 1967*)

Production rates of cosmogenic nuclides play a key role in setting the initial value of isotope ratios used in calculating ages. The record of the ^{14}C/^{12}C ratio in annual tree rings allowed reconstruction of production rate variations over the past 10^4 years. This range has been extended to about 3 × 10^4 years by measurements of the ^{14}C/^{12}C ratio in independently dated corals. These results indicate that the ^{14}C/^{12}C ratio in the atmosphere was ~1.4 times the present value during the period between 2–3 × 10^4 years ago. *See* DENDROCHRONOLOGY.

Unlike ^{14}C, most other cosmogenic nuclides have atmospheric residence times on the order of months, and thus they may provide information on cosmogenic nuclide production rate variations on time

TABLE 1. Principal cosmogenic nuclides produced in the atmosphere and their applications

Nuclide	Major target elements	Half-life	Main applications
Beryllium-7 (^{7}Be)	Nitrogen, oxygen	53 days	Tracing of atmospheric mixing Sediment transport and deposition
Beryllium-10 (^{10}Be)	Nitrogen, oxygen	1.5×10^6 years	Dating and tracing of marine sediments Examination of soil formation Ice core studies
Carbon-14 (^{14}C)	Nitrogen	5730 years	Dating of organic carbon, shells, and so forth Determination of rates of oceanic circulation
Sodium-22 (^{22}Na)	Argon	2.6 years	Tracing of atmospheric mixing
Silicon-32 (^{32}Si)	Argon	130 years	Upper-ocean biological processes and mixing
Phosphorus-32 (^{32}P)	Argon	14.3 days	Tracing of atmospheric mixing Upper-ocean biological processes
Phosphorus-33 (^{33}P)	Argon	25 days	Tracing of atmospheric mixing Upper-ocean biological processes
Chlorine-36 (^{36}Cl)	Argon (chlorine in aerosols)	3.0×10^5 years	Dating and tracing of ground waters

scales of years to decades. Records of ^{10}Be concentrations in ice cores drilled in Antarctica and Greenland extend as far back as $\sim 1.5 \times 10^5$ years. These results are useful for determining precipitation rates and establishing chronologies. However, with careful normalizations they also may be used to examine past variability in production rates. Similarly, a record of beryllium-10 (^{10}Be) fluxes combined from several marine sediment cores provides a 200,000-year history of cosmogenic nuclide production.

Beryllium-10 has also been used for dating marine sediment cores and manganese encrustations up to 1.5×10^7 years old. If ^{10}Be is homogenized with the stable isotope (^{9}Be) in the oceanic water column, the beryllium incorporated into sediments will have a known isotope ratio. Any changes in the ^{10}Be/^{9}Be ratio down the sediment core can then be assumed to be due to radioactive decay of ^{10}Be. The tendency of beryllium to adsorb onto particles in aqueous systems gives it a relatively short oceanic residence time, making it necessary to consider the possibility of past variation in the oceanic ^{10}Be/^{9}Be ratio. Details of the incorporation of beryllium into marine sediments have been obtained by comparison of ^{10}Be with thorium-230 (^{230}Th) and protactinium-231 (^{231}Pa), other so-called particle-reactive radionuclides. *See* MANGANESE NODULES; MARINE SEDIMENTS.

Atmospheric cosmogenic nuclides can be used to trace mixing between geological reservoirs. For example, the ratio of cosmogenic chlorine-36 (^{36}Cl) to stable chlorine differs greatly in atmospheric, continental, and marine material; chlorine isotopes are thus used to examine the relative contributions of these possible sources to salts in saline lakes and ground waters. Similarly, because ^{10}Be has very high concentrations in marine sediments, its presence within mineral matrices of arc volcanic rocks provides evidence for the role of subducted young sediment in the associated magma. In addition, ^{10}Be concentrations in fluids emitted by ocean-ridge hydrothermal systems can quantify the extent of interaction between those fluids and marine sediments.

Cosmogenic nuclides also have applications in examining soils and ground waters. Chlorine-36 produced in the atmosphere and brought to the Earth's surface in precipitation remains in solution; it is used for tracing and dating ground waters. In contrast, beryllium has very low mobility in neutral-to-alkaline ground waters. The inventory of ^{10}Be in a soil profile is related either to the age of the profile or to the residence time (relative to removal in ground water or by erosion) of beryllium in the profile.

Ground-level nuclides. A small but significant flux of cosmic rays is present at ground level (Fig. 1). This radiation produces cosmogenic nuclides within mineral lattices of exposed rock. In-situ-produced cosmogenic nuclides are used to examine geological problems (**Table 2**). In contrast to the case of cosmogenic nuclides produced in the atmosphere, in which applications are linked to the geochemical behavior of each element as well as the half-life of the nuclide, the uses of in-situ-produced cosmogenic nuclides in exposed rock surfaces depend primarily on the half-lives of the nuclides.

In-situ-produced cosmogenic nuclides are useful for dating periods of surface exposure. Their production rates decrease by a factor of 2 for every ~40 cm (16 in.) depth below an exposed rock surface, so accumulation of cosmogenic nuclides can date geological events that bring material to the Earth's surface. For example, the theoretical evolution of the concentration of ^{10}Be as a function of time for various erosion rates can be calculated (**Fig. 2**). The method has been used to date exposure of rocks brought to the surface by processes including glaciation, volcanic activity, and meteor impact. It has also been used to date the formation of geomorphological features (such as alluvial fans or glacial moraines) deposited over active faults and subsequently offset by fault movement. This provides a quantitative

TABLE 2. Principal cosmogenic nuclides produced in situ within surface rock

Nuclide	Half-life, years	Major target elements	Advantages	Disadvantages
Helium-3 (^{3}He)	Stable	Oxygen, magnesium, silicon, iron	High production rate; low analytical detection limits	Loss by diffusion; corrections for primordial and nucleogenic ^{3}He
Beryllium-10 (^{10}Be)	1.5×10^{6}	Oxygen, magnesium, silicon, iron	Production fairly independent of rock composition	Potential contamination by atmospheric ^{10}Be
Carbon-14 (^{14}C)	5730	Oxygen, magnesium, silicon, iron	Less influence of exposure before current episode	Only for exposure ages under 15,000 years
Neon-21 (^{21}Ne)	Stable	Magnesium, aluminum, silicon, iron	Stable isotope with low diffusive loss rate	Corrections for atmospheric, primordial and nucleogenic ^{21}Ne
Aluminum-26 (^{26}Al)	7.2×10^{5}	Silicon, aluminum, iron	Minimal atmospheric production	Significant noncosmogenic production
Chlorine-36 (^{36}Cl)	3.0×10^{5}	Iron, calcium, potassium, chlorine	Ease of chemical purification	Production rates highly dependent on rock composition

approach to determine slip rates on faults and earthquake recurrence intervals. Such results could not have been obtained by conventional methods. *See* GEOMORPHOLOGY.

Erosional losses of in-situ-produced nuclides limit their use in certain cases. In fact, outside of Antarctica (where erosion rates are exceedingly slow), cosmic-ray-exposure dating is generally applicable only to exposures of less than a few hundred thousand years. However, in cases where independent evidence indicates that exposure has been sufficiently long for nuclides to reach their steady-state concentrations, cosmogenic nuclide concentrations may be used to calculate mean physical erosion rates (Fig. 2). In some cases, this approach may be extended to the scale of a watershed by assuming that the cosmogenic nuclide content of sediment discharged by a river represents the average concentration—weighted for area and denudation rate of the various erosional environments present—for the basin as a whole. In addition, spatial distributions of in-situ-produced nuclides and ratios of nuclides with differing half-lives can provide criteria for understanding whether rocks have undergone previous episodes of exposure and burial. *See* ROCK AGE DETERMINATION.

Erik Thorson Brown

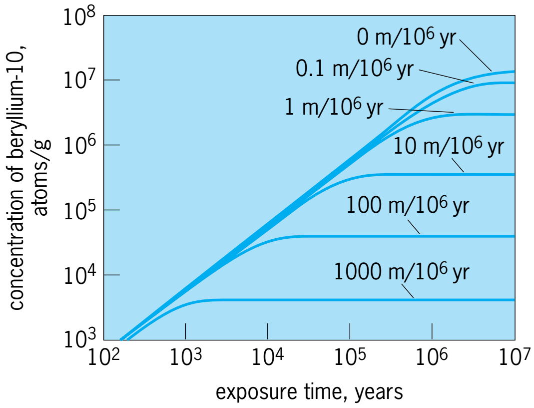

Fig. 2. Theoretical accumulation of in-situ-produced ^{10}Be as a function of time for various erosion rates. These curves are based on calculations using present-day production rates for sea level and high latitude. Concentrations increase with time to reach steady-state values with respect to radioactive decay and erosional loss. Nuclides with other half-lives have similar behavior, but with different time scales. (*After E. T. Brown et al., Examination of surface exposure ages of moraines in Arena Valley, Antarctica using in-situ-produced beryllium-10 and aluminum-26, Geochim. Cosmochim. Acta, 55:2269–2283, 1991*)

Meteorites. Collisions among the solid bodies of the solar system produce many small fragments. A fragment from a collision that finds its way to the top of the Earth's atmosphere is known as a meteoroid. A meteoroid becomes a meteorite when it lands on the Earth. While a meteoroid is in space, cosmic rays bombard its surface and penetrate to depths of a few meters. The exposure age of an extraterrestrial object is the time during which cosmic rays bombarded it in space.

Because cosmic rays penetrate just a few meters of solid matter, cosmogenic nuclides cannot form deep in the interiors of large bodies such as asteroids. The accumulation of cosmogenic nuclides begins when a collision lifts deep-seated material to the surface or ejects it into space as part of a small body. When a meteorite hits the Earth, the accumulation of cosmogenic nuclides effectively stops. The reason is that the Earth's atmosphere and magnetic field screen out most cosmic rays.

Identification. The total amounts of the cosmogenic nuclides in a meteorite are related to its exposure age. They also indicate the size of the meteoroid. To get this information, it is necessary to be able to identify cosmogenic nuclides as such and measure their concentrations. Many of the nuclides found in terrestrial materials are radioactive. All of them have lifetimes of a few million years or less. Most bodies in the solar system solidified about 4.5×10^{9} years ago. Thus, even if an asteroid contained some noncosmogenic ^{10}Be when it formed, that ^{10}Be would long since have vanished. Accordingly, when ^{10}Be is found in a meteorite today, it is likely that cosmic rays produced it recently. The same conclusion applies to other radioactive nuclides found in terrestrial materials.

The stable nuclides pose a different kind of problem in identification. For example, the total concentration of purely cosmogenic neon-21 (^{21}Ne) seldom reaches 1 part per billion, an extremely low value. If a meteorite parent body contained much noncosmogenic ^{21}Ne when it formed, then that ^{21}Ne would drown any later contribution due to cosmic rays. As it happens, the parent bodies of meteorites crystallized with very few atoms of neon. Indeed, the low "primordial" abundance of neon is one reason why ^{21}Ne is such an important stable cosmogenic nuclide. Some meteorites do contain measurable concentrations of primordial neon. For them, a general knowledge of isotope abundance patterns can help in sorting out the cosmogenic and noncosmogenic components (**Table 3**). *See* ISOTOPE.

Measurement of exposure ages. The concentrations of cosmogenic nuclides in meteorites are so low that very sensitive techniques are needed to measure them. Formerly, the only practical method for measuring the radioactive nuclides was to observe their rates of decay, a slow process requiring large samples. With the development of accelerator mass spectrometry, it became possible to measure directly the number of atoms of cosmogenic nuclides. Accelerator mass spectrometry has largely replaced decay counting for cosmogenic radionuclides with half-lives greater than a few thousand years. Conventional methods of mass spectrometry give reliable results for the stable cosmogenic nuclides. *See* MASS SPECTROMETRY.

If the concentration of a stable cosmogenic nuclide N grows at a constant rate P in a meteoroid, then after an exposure lasting t years the meteorite will contain a concentration N equal to $P \times t$. The value t for a meteorite can be calculated by measuring the concentration N, provided that the value of the production rate P is known. One way to obtain a value for production rate is to calculate it from basic physical principles. Another is to use the information given by the radioactive cosmogenic nuclides.

TABLE 3. Some important cosmogenic nuclides in extraterrestrial materials

Isotope	Half-life
Hydrogen-3 (^{3}H)	12.3 years
Helium-3 (^{3}He)	Stable
Beryllium-7 (^{7}Be)	53 days
Carbon-14 (^{14}C)	5730 years
Neon-21 (^{21}Ne)	Stable
Sodium-22 (^{22}Na)	2.6 years
Aluminium-26 (^{26}Al)	7.1×10^5 years
Magnesium-26 (^{26}Mg)	Stable
Chlorine-36 (^{36}Cl)	3.0×10^5 years
Argon-36 (^{36}Ar)	Stable
Argon-38 (^{38}Ar)	Stable
Argon-37 (^{37}Ar)	35 days
Argon-39 (^{39}Ar)	269 years
Potassium-40 (^{40}K)	1.3×10^9 years
Potassium-39 (^{39}K)	Stable
Potassium-41 (^{41}K)	Stable
Calcium-41 (^{41}Ca)	1×10^5 years
Manganese-53 (^{53}Mn)	3.5×10^6 years
Manganese-54 (^{54}Mn)	312 days
Nickel-59 (^{59}Ni)	7.6×10^4 years
Iron-60 (^{60}Fe)	1.5×10^6 years
Cobalt-60 (^{60}Co)	5.27 years
Krypton-81 (^{81}Kr)	2.1×10^5 years
Krypton-78 (^{78}Kr)	Stable
Krypton-80 (^{80}Kr)	Stable
Krypton-82 (^{82}Kr)	Stable
Krypton-83 (^{83}Kr)	Stable
Iodine-129 (^{129}I)	1.6×10^7 years
Xenon-124 (^{124}Xe)	Stable
Xenon-132 (^{132}Xe)	Stable

The values for meteorite exposure ages range from times too short to measure to 2.5×10^9 years. Stony meteorites generally have exposure ages of $2–20 \times 10^6$ years. Iron meteorites have much longer exposure ages, about 5×10^8 years on average, than do stony meteorites, perhaps because iron meteorites resist destruction better. Many groups of meteorites have several members with the same exposure age. The stony meteorites known as H-chondrites provide a striking example of exposure age clustering at about 7×10^6 years. The existence of such clusters suggests that the meteorites involved originated in the same body in a single collision. Interestingly, many of the meteorites known as diogenites, eucrites, and howardites seem to have a common exposure age of about 2×10^7 years. This observation supports the idea that all three groups come from the same object, even though they differ in chemical and mineral composition.

Lunar meteorites have some of the shortest exposure ages measured, no doubt because they had only a short distance to travel. Research related to the problem of meteorite exposure ages is focused on improving the values of production rates, determining the exposure ages of rare but important new meteorites, refining existing values, deciphering exposure histories of objects that underwent more than one episode of irradiation, and understanding the behavior of cosmic rays from the Sun and from the stars over time. *See* METEORITE. Cosmological constant

The constant gravitational source added to the general theory of relativity by Einstein to balance the gravitational field equations necessary for a static universe. In formulas it is denoted Λ (lambda) and has units of curvature, or $(\text{length})^{-2}$. The existence of the cosmological constant would mean that empty space gravitates as if it were filled by a static, uniform energy density $\rho = \Lambda c^4/8\pi G$, where G is the newtonian constant of gravitation, and pressure $p = -\rho$. It is speculated to be responsible for dark energy, since a sufficiently large cosmological constant would cause the accelerated expansion of spacetime. However, the physical origin of the cosmological constant is not understood. Quantum theory predicts the existence of the cosmological constant, but with an energy density that is approximately 10^{120} times too large to be compatible with observations. This gross mismatch between theory and observation, known as the cosmological-constant problem, is a deep enigma of astrophysics and physics. It is thought that a resolution requires a quantum theory of gravity. Testing for the existence of the cosmological constant is a major goal of current physics and astronomy research. *See* ACCELERATING UNIVERSE; DARK ENERGY; QUANTUM GRAVITATION; RELATIVITY.

Introduction by Einstein. The cosmological constant was introduced by Albert Einstein in 1917, in the first application of general relativity to cosmology. In order to balance theoretical and practical considerations in constructing a mathematical model of the universe, Einstein found it necessary to invoke a new cosmological term, Λ. He regarded this term as a universal constant whose value would be determined empirically. The effect of adding the Λ was to cut off the gravitational influence of distant matter and balance the field equations for a static universe. This cosmological model was consistent with contemporary observations of the slow kinetic motions of stars and nebulae. Though the 1929 discovery of the cosmic redshift-distance by Edwin Hubble, soon interpreted as expansion, invalidated Einstein's construction, the cosmological constant survived. Later, when discussing the discovery of the expanding universe with George Gamow, Einstein is reputed to have called the introduction of the cosmological constant "the greatest blunder" of his life.

De Sitter model. Shortly after Einstein's introduction of the cosmological constant, Willem de Sitter proposed a theoretical model universe containing the cosmological constant but no other forms of matter. This solution of the gravitational field equations is an idealization of the present-day universe, wherein the stars and galaxies are regarded as test particles that sit atop a perfect sea of static, uniform energy. Since general relativity dictates that pressure gravitates in addition to mass-energy, the negative pressure or tension of the cosmological constant causes spacetime to expand at an accelerating rate. Hence, test particles recede from each other as if under the influence of a repulsive gravitational potential. The theoretical prediction of a cosmological redshift can be traced back to this work, also. In the big bang cosmology, the inflationary universe is well described by de Sitter's solution, as is the distant future of the universe filled with dark energy in the form of the cosmological constant. *See* BIG BANG THEORY; INFLATIONARY UNIVERSE COSMOLOGY.

Quantum vacuum as a source. The quantum vacuum was proposed as the source of the cosmological constant by Yakov Zeldovich in 1967. He showed that the irreducible, quantum zero-point energy of elementary particles—a foaming sea of virtual particles—contributes a static, spatially uniform source of gravitation. Consequently, the cosmological constant is interpreted to represent the cosmological vacuum, the lowest energy state of the universe. The magnitude of this energy density depends sensitively on the maximum particle energy allowed in the quantum theory. Zeldovich found that any reasonable estimate for this energy scale, based on the known properties of particles, results in a cosmological energy density that is too large by many orders of magnitude.

There has been debate whether the cosmological constant is a consequence of the geometry of spacetime or of the gravitating sources, traditionally corresponding to the left- and right-hand sides of the gravitational equations, respectively. Einstein placed Λ on the left-hand side, identifying it as a property of the spacetime. Zeldovich placed Λ on the right-hand side, advocating the view that the cosmological constant, as well as gravitation itself, traced their origins to the quantum properties of particles and fields. The difference is largely semantic, since general relativity dictates that the gravitating sources are balanced by the curvature of spacetime.

Arguments for zero value. Prior to the discovery of the cosmic acceleration, most efforts to solve the cosmological constant problem sought to explain that Λ must be identically zero. One such proposal suggested that under a quantum theory of gravity Λ is a quantum-mechanical variable with a vanishing expectation value. Alternatively, it was argued that boundary conditions at the big bang set Λ to zero. In neither case are there additional, testable consequences of the proposed solution. Supersymmetry, a theory of fundamental interactions beyond the standard model of particle physics, offers a solution which can be tested by laboratory experiments. If this new symmetry of nature is valid, it implies that the cosmological vacuum, and hence Λ, is zero. *See* QUANTUM MECHANICS; SUPERSYMMETRY.

Relation to cosmic acceleration. The discovery of cosmic acceleration puts these arguments in limbo. Current observations are consistent with a nonvanishing cosmological constant, although they are not precise enough to eliminate other possibilities. If observations prove that dark energy can be explained only by the cosmological constant, the challenge will be to explain why the magnitude of Λ is so much smaller than the naive estimate.

Energy scales. The cosmological constant based on Zeldovich's calculation can be expressed as $\Lambda = E^4/2\pi(E_P\hbar c)^2$, where E is the maximum allowed zero-point energy, $\hbar$ is Planck's constant divided by 2π, and c is the speed of light. The natural choice for this energy is the Planck energy, $E_P \equiv \sqrt{\hbar e^5/G} \approx 10^{19}$ GeV, the energy scale at which quantum and gravitational effects are thought to unify. However, the resulting value of Λ is approximately 120 orders of magnitude too large. Consistency with the observed accelerating expansion requires that $\Lambda = 3\Omega_\Lambda H_0^2/c^2$, where $\Omega_\Lambda \approx 0.7$ gives the fraction of the total energy density of the universe contributed by the cosmological constant, and $H_0 \approx 70$ km/s/Mpc is the Hubble constant. These figures give $\Lambda \approx (3000\ \text{Mpc})^{-2}$ and an energy $E \approx 0.008$ eV $\approx 10^{-21}$ J. The significance of this energy is unclear, since virtual particles exist at energies well above this scale. The proximity of this energy to an energy scale associated with neutrino masses has prompted speculation of new physics. Other proposals have linked this energy scale with novel theories of gravity beyond Einstein's general relativity. *See* HUBBLE CONSTANT; NEUTRINO.

Consequences of nonzero value. The existence of the cosmological constant would imply the existence of a cosmological event horizon, a spherical boundary centered on any observer marking a distance beyond which no causal contact is possible. A light signal sent from the center could never reach the boundary because the expansion of spacetime is so rapid. This horizon is similar to the event horizon surrounding a black hole, viewed from within. If the dark energy is a cosmological constant, the horizon is located at a radius $r = \sqrt{3/\Lambda} \sim 5000$ Mpc. Correspondingly, no rocket or light signal that we may send can reach objects currently beyond a redshift $z \approx 1.7$ within the lifetime of the universe. *See* BLACK HOLE; REDSHIFT.

Prospects. Precision measurements of cosmic distances and the evolution of the universe will help refine the evidence for the cosmological constant. Current evidence is ambiguous as to whether Λ is dark energy. If not, it will likely be accepted in practice that Λ is zero. Confirmation of the existence of a nonzero cosmological constant would have a tremendous impact on physics and our view of the universe. *See* COSMOLOGY; UNIVERSE.

Cosmology

The study of the structure and the origin of the universe, including the origin of galaxies, the elements, and matter itself.

Big bang model. When Albert Einstein proposed his theory of general relativity, the universe was believed to be static. Einstein had to modify his equations so that general relativity would allow a static universe by adding a cosmological constant term. Today, this term is incorporated into the current cosmological model. *See* COSMOLOGICAL CONSTANT; RELATIVITY.

At the time of Einstein's work, astronomers were uncertain about the nature of the faint spiral nebulae and the size of the visible universe. Some contended that they were regions of star formation that were part of the Milky Way Galaxy, while others argued that they were distant galaxies much like the Milky Way. This debate was settled in 1923 by E. Hubble's discovery of 12 Cepheid variable stars in M31, the Andromeda Nebula. There is a simple empirical relationship between the period of the Cepheids and their luminosity. Thus, Hubble's observations allowed him to determine that the Andromeda Nebula was at a very large distance and was a galaxy much like the Milky Way. *See* ANDROMEDA GALAXY; CEPHEIDS; GALAXY, EXTERNAL; MILKY WAY GALAXY.

Hubble continued his study of galaxies and found that most were receding from the Earth. Hubble proposed a simple linear relationship between the distance to a galaxy and its recessional velocity Eq. (1),

$$v = Hr \tag{1}$$

where v is the recessional velocity of the galaxy, usually measured in kilometers per second, and r is the distance to the galaxy, usually measured in megaparsecs (1 Mpc = 3.26×10^6 light-years = 3.1×10^{19} km = 1.9×10^{19} mi). Various techniques now yield consistent measurements of the Hubble constant, $H \sim 70$ (km/s)/Mpc. *See* HUBBLE CONSTANT.

Hubble's observations of the expanding universe then implied that the addition of a cosmological constant to the equations of general relativity was unnecessary. In the 1920s, G. Lemaître and A. Friedmann independently proposed a general relativistic model of the expanding universe. One of the simplest solutions to Einstein's relativity equation, this model assumes that the universe is homogeneous and expanding. When Lemaître and Friedmann made their proposal, there was no real evidence for their simplifying assumptions. Only since the late 1980s have observations become sensitive enough to confirm them.

The Friedmann-Lemaître model, often called the big bang model, implies that the universe began in an extremely dense state and expanded and cooled. In this model, the Hubble law is predicted as an approximate description of the expansion valid for galaxies within a few hundred megaparsecs of the Milky Way Galaxy. The model implies that radiation is redshifted as the universe expands. Thus, radiation from distant objects should appear at lower frequencies than those at which it was emitted. Observations of atomic lines from distant quasars confirm that radiation is redshifted just as predicted. *See* QUASAR; REDSHIFT.

The Friedmann-Lemaître model, while fully relativistic, can be described in the language of newtonian physics. The Hubble law implies that a shell of galaxies of radius R and mass m expands with velocity HR. Thus, the kinetic energy of the shell is $m(HR)^2/2$. If M is the mass interior to the shell, then the gravitational binding energy of the shell is GMm/R, where G is the newtonian constant of gravitation. The total energy E of the shell is therefore given by Eq. (2). Since it has been assumed that the

$$E = \frac{m(HR)^2}{2} - \frac{GMm}{R} \tag{2}$$

universe is uniform, the mass M within the shell can be replaced with the quantity $4\pi R^3/3$, where ρ is the density of the universe and $4\pi R^3/3$ is the volume of a shell of radius R. Then Eq. (2) can be rewritten as Eq. (3), where Ω is the ratio of the density of

$$\frac{E}{mR^2} = \frac{H^2}{2}\left(1 - \frac{8\pi G\rho}{3H^2}\right) = \frac{H^2}{2}(1 - \Omega) \qquad (3)$$

the universe to the critical density of the universe, $3H^2/(8\pi G)$. If $\Omega < 1$, the total energy of the shell is positive, and the universe will continue to expand forever. If $\Omega > 1$, the total energy of the shell is negative, gravity will eventually stop the expansion, and the universe will eventually collapse. Some physicists speculate that this so-called big crunch will be followed by a future big bang. If $\Omega = 1$, the total energy is zero, and the universe stands on the balance between open and closed and corresponds to a special solution called the Einstein-de Sitter model. *See* GRAVITATION.

This simple newtonian model, while accurately describing the dynamics of the expanding universe, can lead to a conceptual error. The newtonian shell has a center, since newtonian theory cannot deal with a uniform mass density. General relativity, however, allows the universe to be isotropic and to be expanding uniformly without having a special center point. In the Friedmann-Lemaître model, the Milky Way Galaxy is not a special place in the universe.

Geometry of the universe. The density of the universe determines not only the final fate of the universe but also its geometry. If $\Omega > 1$, the universe is closed and its geometry is that of a three-dimensional sphere. (A circle is a one-sphere and the surface of the Earth is a two-sphere.) If two pilots leave New York in opposite directions, one heading east and the other heading west, they will meet somewhere over the Pacific. If the Earth were flat, the two pilots would continue to head directly away from each other. Similarly, if the universe is closed, two light rays sent off in opposite directions will eventually bend toward each other. If $\Omega = 1$, the universe is flat and the two light rays will continue to move away from each other. If $\Omega < 1$, the geometry of the universe is hyperbolic, much like that of a saddle. A common misconception is that if the universe is open it must be spatially infinite. This relationship need not be true, as general relativity does not constrain the topology of the universe. If $\Omega < 1$, the universe could be either infinite or finite and periodic.

Microwave background radiation. One of the most dramatic discoveries of modern physics was the detection of the microwave background radiation by A. Penzias and R. Wilson. Most cosmologists believe that this radiation is the leftover heat from the big bang.

In the hot big bang model, the universe started in an extremely hot dense state. In this state, the universe was composed of electrons, positrons, quarks, neutrinos, and photons. As the universe expanded, most of the matter annihilated with antimatter into photons. These photons then cooled as the universe expanded. Thermal physics predicts that the spectrum of radiation from the big bang would be similar to that emitted by a blackbody, a so-called Planck spectrum. The Friedmann-Lemaître model predicts that this radiation should be uniform since the big bang started in a uniform state. *See* HEAT RADIATION.

The observations of the *Cosmic Background Explorer* (*COBE*) satellite, launched in 1989, provided strong confirmation of the hot big bang model. The observed spectrum of the microwave background radiation agrees closely with the predicted Planck spectrum. The *COBE* experiment also confirmed that the microwave background radiation is uniform to nearly 1 part in 50,000, consistent with the homogeneity assumption of the hot big bang model.

Observations of small fluctuations in the temperature of the microwave background have become a powerful tool for studying the basic properties of the universe. Since most of the microwave background photons last interacted with matter when the universe was only 500,000 years old, these tiny fluctuations in temperature are directly probing variations in the density of the universe soon after the big bang. *See* COSMIC BACKGROUND RADIATION.

Nucleosynthesis. Within the context of the hot big bang model, the conditions in the universe now can be extrapolated back to the first moments after the big bang. The temperature of the cosmic background radiation now is 2.73 kelvins above absolute zero. When the universe was half its present size, the background temperature was twice as high. One second after the big bang, the universe was only 3×10^{-11} of its present size and the temperature of the microwave background was roughly 10^{10} K (1.8×10^{10} °F). At this high temperature, the universe consisted of a thermal sea of photons, electrons, positrons, and neutrinos. In addition, there were a handful of protons and neutrons. There was approximately 1 baryon (proton or neutron) for every 10^{10} photons. *See* BARYON; ELECTRON; NEUTRINO; NEUTRON; POSITRON; PROTON.

As the universe cooled, the protons and neutrons combined to make deuterium. Most of this deuterium then interacted to make helium, while trace amounts combined to make lithium. One of the successes of the big bang model is its ability to account for the observed abundances of light elements. The universe today consists of roughly 28% helium, 70% hydrogen, and 2% other elements, calculated by their masses. Nucleosynthesis in stars produces roughly equal amounts of helium and heavier elements from hydrogen. Thus, it is difficult to understand the helium abundance without big bang nucleosynthesis. *See* DEUTERIUM; HELIUM; HYDROGEN; LITHIUM.

The amounts of deuterium, helium, and lithium produced in the big bang depend sensitively on the number of baryons per photon in the early universe and on the number of neutrino flavors. Based on the observed abundances of this isotope and these elements in old stars, it was predicted that there should be only three flavors of neutrino. Experiments at particle accelerators have confirmed this prediction based on the first moments of the early universe. *See* FLAVOR.

The observed light-element abundances also lead to a prediction for the density of protons and neutrons. The current best estimates suggest that the density in atoms is 5×10^{-31} gram/cm^3. Measurements of the amplitude of microwave background fluctuations also measure the density in atoms as the pattern of fluctuations depends on the atomic density. The best fit value for the density of atoms based on microwave background fluctuations agrees with the estimate based on light-element abundances to better than 10% (and well within the current statistical errors). *See* BIG BANG THEORY; NUCLEOSYNTHESIS.

Lambda cold dark-matter model. Over the past few decades, a simple cosmological model called the lambda cold dark-matter (lambda CDM) model has emerged as the best fit to the current observational data. The lambda CDM model is a version of the standard hot big bang model. The big bang model assumes that general relativity is valid on cosmological scales and that the distribution of matter on large scales is homogeneous. This set of assumptions implies that the universe is expanding: the distances between galaxies are constantly growing. Since the universe is expanding, it is constantly getting cooler and less dense. In the standard big bang model, the shape and evolution of the universe depend on its composition.

The lambda CDM model assumes that the universe is composed of atoms, dark matter, and vacuum energy. The total energy density of the universe is very close to the critical density so that the geometry of the universe is flat. *See* DARK ENERGY; DARK MATTER.

This model has five basic parameters: the expansion rate of the universe (the Hubble constant), the density of matter in the universe, the density of atoms in the universe, the amplitude of the primordial density fluctuations, and how the amplitude of fluctuations varies with scale. With these five parameters, the model can fit a host of astronomical data, including measurements of positions of millions of galaxies, observations of microwave background fluctuations, measurements of distances to both nearby galaxies and distant supernovae, as well as a host of other astronomical observations. While simple, the lambda CDM model posits the existence of two novel forms of matter: cold dark matter and vacuum or dark energy.

Evolution of structure. The inflationary universe model is an attractive scenario for simultaneously explaining the homogeneity of the universe on large scales and the fluctuations in density observed on the smaller scales. In this scenario, the universe in its first few moments underwent a period of exponential expansion. This rapid expansion, which took place before nucleosynthesis, stretched out any initial density variations and eliminated any monopoles or other unwanted objects that formed before the inflationary epoch. During this inflationary epoch, quantum fluctuations generated new density fluctuations that are predicted to be the initial source of structure. The inflationary scenarios predict that the density parameter Ω should be extremely close to 1. *See* INFLATIONARY UNIVERSE COSMOLOGY.

Since different regions of space underwent different amounts of inflationary expansion, this process generated large-scale variations in the density of the universe. The inflationary universe model predicts that the variations in density should be gaussian random-field fluctuations. This implies that the statistical properties of both fluctuations in the microwave background and the fluctuations in the galaxy density distribution are characterized by its overall amplitude and its dependence on scale.

Observations of the microwave background radiation probe these conditions in the early universe. In most cosmology models, the microwave photons that are detected on Earth last interacted with electrons when the universe was one-thousandth its present size. Thus, fluctuations in the microwave background temperature reflect the density fluctuations in the early universe.

During its first 500,000 years, the early universe was a hot plasma of electrons, protons, electromagnetic and radiation (photons). The density fluctuations generated by inflation set up sound waves that propagated as long as the universe was ionized. When the universe cooled and atoms formed, radiation was able to travel freely to our telescopes and satellites. These density variations and the sound waves that they generated produced a characteristic pattern of fluctuations. Since the early universe was nearly uniform, simple linear physics describes the generation and evolution of these fluctuations. The characteristic size of these fluctuations equals the distance that sound waves can travel in 500,000 years. The amplitude of the fluctuations depends on the amount of matter and the density of atoms in the early universe.

The cosmic microwave background temperature fluctuations are very small: variations of only a few millionths of a degree. Over 25 years of searches for these fluctuations were rewarded in 1992, when the *COBE* satellite detected fluctuations in the microwave background temperature of about 2 parts in 100,000. NASA's *Wilkinson Microwave Anisotropy Probe* (*WMAP*) satellite and several ground and balloon-based measurements have been making ever more accurate measurements of these fluctuations (**Fig. 1**). With the launch of the European Space Agency's *Planck* satellite and a new generation of more sensitive ground-based experiments in development, the accuracy of these measurements will continue to rapidly improve. *See* WILKINSON MICROWAVE ANISOTROPY PROBE.

These inflationary density fluctuations grew to form the observed pattern of galaxies. Regions that were slightly overdense expanded more slowly; thus, these overdense regions collapsed and formed galaxies and clusters. On the other hand, underdense regions expanded more rapidly than the surrounding universe. These underdense regions eventually developed into voids. Astronomers using wide-field surveys such as the Sloan Digital Sky Survey and the 2dF

Galaxy Redshift Survey have now measured the positions of several hundred thousand galaxies. They have found that the clustering pattern matches the predictions of the lambda CDM model. *See* SLOAN DIGITAL SKY SURVEY.

Cosmologists now use massive computer simulations to model the clustering of matter and the formation of galaxies. These simulations are compared with observations of the large-scale distribution of galaxies and with observations of galaxy and cluster properties. Simulations based on the lambda CDM model match a wide range of astronomical observations. Remarkably, the inflationary model successfully describes the statistical properties of both galaxies and the microwave background and fits astronomical observations over a range of 10^4 in scale and 10^{12} in mass (**Fig. 2**).

Measuring the size of the universe. Measuring the distance to astronomical objects remains a great scientific challenge. Astronomers are able to measure the distances to the nearest stars by using parallax. They then must rely on empirical properties of stars to extrapolate to more distant objects. Observations of globular clusters and open clusters in the Milky Way Galaxy are needed to calibrate the luminosity–period relation for Cepheid variable stars. *See* PARALLAX (ASTRONOMY); STAR.

Primary extragalactic distance indicators are used to measure the distance to nearby galaxies such as the Magellanic Clouds and the Andromeda Galaxy. Variable stars, such as Cepheids and RR Lyrae stars, are still important tools in determining the distances to these objects. Observations of the expansion of the dust shell around Supernova 1987A in the Large Magellanic Cloud have provided an alternative method for measuring distances. All these techniques imply that the Large Magellanic Cloud is at a distance of roughly 50,000 parsecs. *See* MAGELLANIC CLOUDS; SUPERNOVA; VARIABLE STAR.

Secondary distance indicators are then used to determine the relative distance to the Virgo Cluster. For example, the brightest red and blue stars in a distant galaxy in the Virgo Cluster are assumed to have the same luminosity as the brightest stars in Andromeda. Other secondary distance indicators include the brightness of typical globular clusters or planetary nebulae. *See* VIRGO CLUSTER.

Tertiary distance indicators are then used to extrapolate from the Virgo Cluster to more distant clusters. Galaxies in the Virgo Cluster are observed to have a simple relationship, noted by B. Tully and R. Fisher, between their gas velocities and their luminosity. This relation is used to measure the relative distance to distant galaxies. Together with Doppler-shift measurements of recessional velocity, this technique yields estimates of the Hubble constant. *See* DOPPLER EFFECT.

Observations using the *Hubble Space Telescope* have significantly improved our measurements of the Hubble constant. These observations suggest that the Hubble constant is 65–80 (km/s)/Mpc. If the lambda CDM model is assumed, the *Wilkinson Microwave Anisotropy Probe's* measurements of primordial fluctuations imply a Hubble constant of 68–76 (km/s)/Mpc. Estimates of the Hubble constant using other techniques (for example, time delays from multiple imaged quasars) yield consistent results.

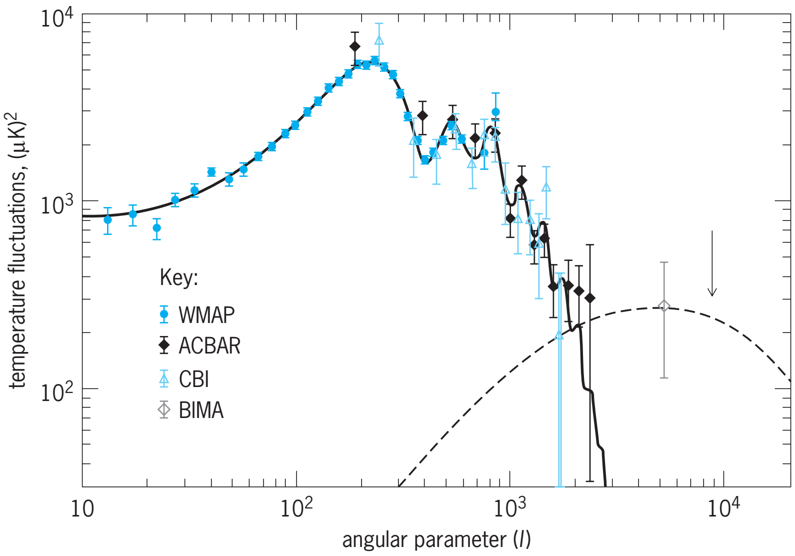

Fig. 1. Measurements of the amplitude of temperature fluctuations as a function of angular scale. The solid line is the predictions of the lambda CDM model. The data points are from the *Wilkinson Microwave Anisotropy Probe* (*WMAP*) and three ground-based experiments. The broken line shows an estimate of the expected level of contamination from hot gas in clusters. The horizontal axis is an angular parameter, *l*, and the angular scale measured is 180°/*l*. The vertical axis shows the amplitude of the temperature fluctuations in millionths of a degree (μK). (*A. Readhead; CBI team*)

Observations of supernovae have become a powerful tool for measuring distances to distant galaxies. Type Ia supernovae, supernovae produced by the explosive burning of a white dwarf star, have nearly the same luminosity. By measuring the time evolution of these supernovae, astronomers can correct for variations in their absolute luminosities and use these standard candles to determine the distances to galaxies. By measuring the distances to supernovae as a function of their redshifts, astronomers have been able to determine the geometry and expansion history of the universe. Current data suggest that the universe is accelerating and is well fit by the basic parameters of the lambda CDM model. *See* ACCELERATING UNIVERSE.

Ground-based supernova observations have found that supernovae at redshifts of 0.3–0.8 are systematically dimmer than predicted in cosmological models without dark energy (**Fig. 3**). The observations imply that the universe is now accelerating. Hubble telescope observations of supernovae at redshifts greater than 1 (not shown in Fig. 3) find that these more distant supernovae are actually brighter than expected in a universe without dark energy. The observations of these more distant supernovae imply that, earlier in its history, the expansion of the universe was slowing and that dark energy has been dominating the expansion only during the past 5×10^9 years. The current supernova data fit the lambda CDM model well and are one of the key pieces of evidence for the existence of dark energy.

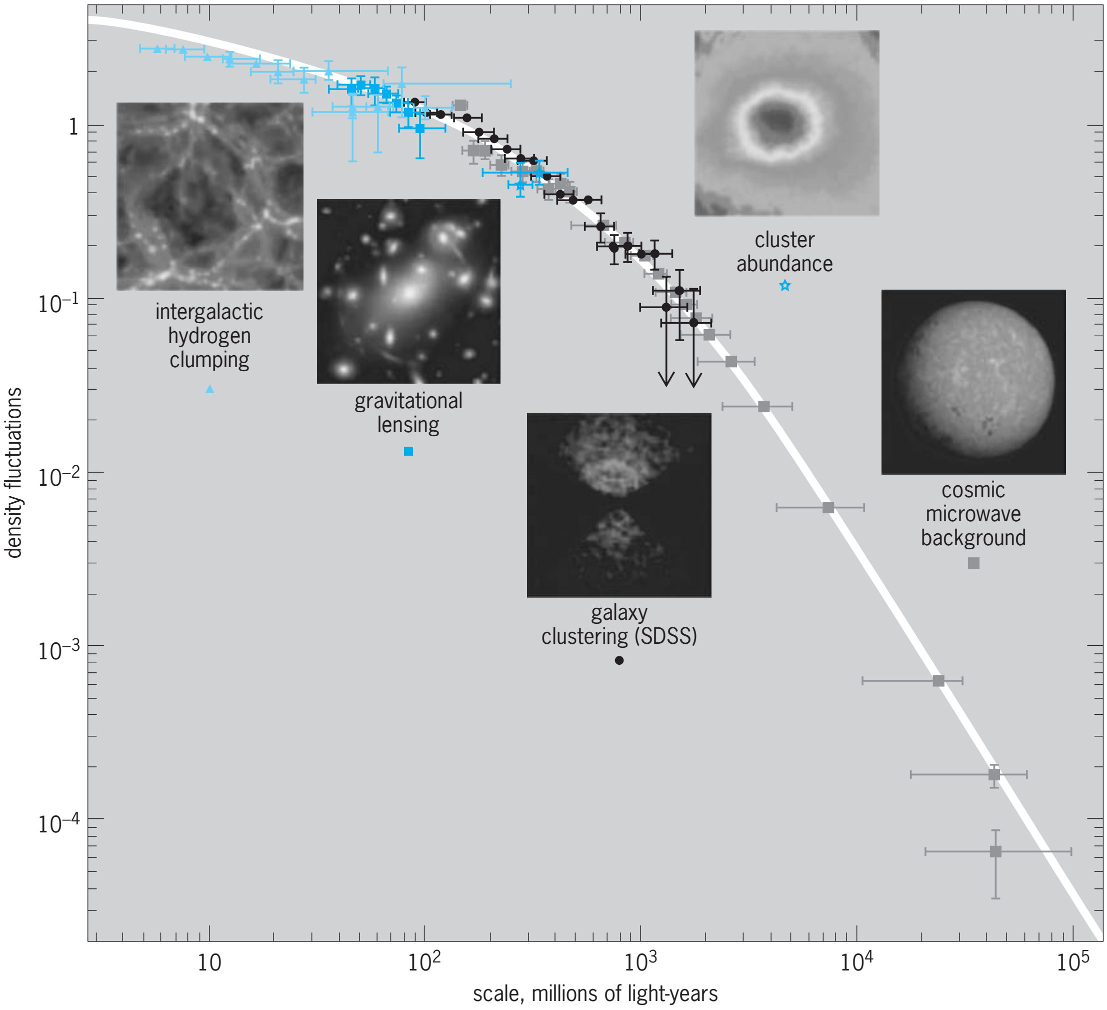

Fig. 2. Amplitude of density fluctuations as a function of scale. The insets indicate the various types of observations that measure the fluctuations and the data points that represent them in this figure. The microwave background observations measure the amplitude of fluctuations 500,000 years after the big bang; the clumping of gas measures the amplitude of fluctuations 2 × 10^9 years after big bang; and the galaxy and clustering measurements and gravitational lensing observations measure the amplitude of clustering in the nearby universe. The galaxy clustering measurements are based on the Sloan Digital Sky Survey (SDSS). The intergalactic hydrogen abundance is based on measurement of the absorption by its Lyman alpha line of light from distant quasars and galaxies. Cluster abundance is illustrated by an image of x-ray emission from a cluster. The amplitudes have been extrapolated to today using the lambda CDM model. The curve shows the prediction of the model. (*Max Tegmark*)

Age of the universe. The universe ought to be older than any visible star; thus, the inferred ages of the stars in the Milky Way Galaxy place a lower limit on the age of the universe. The oldest known stars are in globular clusters, dense concentrations of roughly 100,000 stars, believed to be 12–20 × 10^9 years old. These age estimates are based on models of stellar evolution that predict when a star of a given mass becomes a red giant. *See* STAR CLUSTERS; STELLAR EVOLUTION.

Distant elliptical galaxies are composed almost entirely of old stars. Measurements of their spectra constrain the age of the universe as a function of redshift. Measurements of the age of the universe provided the first strong hints of the existence of dark energy. The current measurements of the Hubble constant imply that a flat universe without dark energy would be only 9 × 10^9 years old, much younger than some of the stars in our galaxy. In a flat universe without dark energy, light from objects with a redshift of 2 was emitted when the universe was only 1.7 × 10^9 years old, which is difficult to reconcile with observations showing the existence of 2.5 × 10^9-year-old stars in galaxies with this redshift. On the other hand, models with dark energy provide a good fit to measurements of stellar and galactic ages (**Fig. 4**).

Just as radioactivity lifetimes can be used to date archeological artifacts, nuclear dating provides an alternative independent measure of the age of the Milky Way Galaxy. By using these techniques, the minimum age of the Galaxy has been estimated to be 10 × 10^9 years. The oldest white dwarf stars detected are 9 × 10^9 years old, and the Sun is believed to be 4.5 × 10^9 years old. These age measurements place a firm lower limit on the age of the universe. *See* SOLAR SYSTEM; WHITE DWARF STAR.

Observations of the microwave background fluctuations yield a direct geometric measurement of the age of the universe. The fluctuations have a characteristic size set by the distance that sound waves can travel in 500,000 years. By measuring the angular size of the typical fluctuation, cosmologists have determined an age of the universe as 13–14 × 10^9 years.

Dark-matter problem. Astronomers have been in an embarrassing situation for several decades: the amount of mass measured dynamically in galaxies by observing stellar and gas motions is roughly 10 times the mass observed in dust, gas, and known stars. This discrepancy suggests that either there is a basic flaw in newtonian physics or 90% of the mass in galaxies is in some yet unknown form, usually referred to as dark matter.

Evidence for dark matter. Some of the strongest evidence for existence of dark matter comes from radio observations of hydrogen gas and optical observations of star motions in spiral galaxies like the Milky Way Galaxy. The neutral gas and stars in the disks of galaxies are moving in nearly circular orbits. The centrifugal acceleration of the gas (and stars), v^2/r outward (where v is the velocity of motion and r is the orbit radius), must balance the gravitational acceleration of the galaxy, yielding Eq. (4), where $M(r)$

$$v^2 = \frac{GM(r)}{r} \qquad (4)$$

is the mass of the galaxy within radius of the gas or stellar orbit. Thus, observations of the gas or stellar velocity are a direct measure of the mass interior to its orbit. Most of the light in a galaxy like the Milky Way Galaxy is located in the inner 15,000 parsecs. (The Sun is roughly 8000 parsecs from the galactic center.) If mass were distributed as light, the gas rotation velocity should begin to fall off outside the optical edge of the galaxy. In all optical and radio observations of spiral galaxies, the gas rotation velocity is not falling but is either flat or slowly rising. This situation implies that there is mass where there is no light.

Observations of hot x-ray-emitting gas in elliptical galaxies provide a method for measuring their mass distribution. Since the gas pressure gradients must balance the force of gravity, gas density and temperature profiles can be directly related to the elliptical galaxy mass profiles. Data from x-ray satellites suggest that the galactic dark-matter problem is ubiquitous: all galaxies, whether spiral or elliptical, dwarf or normal, seem to have halos of dark matter. *See* X-RAY ASTRONOMY.

Observations of groups and clusters of galaxies provide an alternative method of weighing galaxies. The velocities of galaxies in clusters can be used to determine the mass of the entire cluster. This technique for measuring galactic mass, first applied in the 1930s, also implies a dynamical galactic mass that vastly exceeds the mass in luminous material.

General relativity implies that mass curves space. Thus, the path of light rays moving through a cluster of galaxies is bent by the mass within the cluster (**Fig. 5**). Hence, dense clusters of galaxies can act as gravitational lenses that distort the images of galaxies behind the cluster into arcs. Measurements of these distorted arcs confirm the evidence for enormous amounts of dark matter in clusters. *See* GRAVITATIONAL LENS.

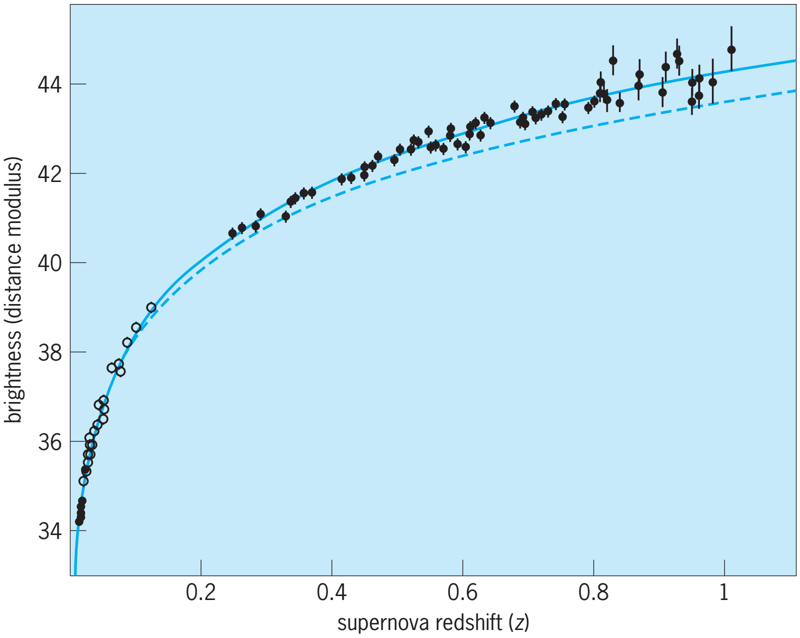

Fig. 3. Brightness of supernovae as a function of their redshift. The supernova brightnesses are measured in terms of the distance modulus, which is related to the magnitude (it is the difference between the apparent and absolute magnitudes), and are corrected for variations in supernova properties. The broken line shows the predictions for a flat universe with no dark energy. The solid line shows the predictions of the lambda CDM model. (*P. Astier; Supernova Legacy Survey*)

Candidates for dark matter. Candidates for the dark matter range in mass from microelectronvolt axions to 10^6-solar-mass black holes. Many groups of physicists and astronomers are actively searching for various candidates for the dark matter.

Baryons (such as ordinary protons and neutrons) make up most of the mass of the Earth and the Sun. Baryons are the most obvious dark-matter candidate. These baryons cannot be bound into luminous stars, nor can they be in either hot or cold gas. Cold gas can be detected through hyperfine and molecular lines. Hot gas is detectable by ultraviolet and x-ray satellites. Current observations constrain the gas mass to be much less than the mass needed to account for the dark matter. Within our galaxy, baryons could have escaped direct detection if they were bound together into clumps, either as comets, bound by atomic forces, or as planets or very low mass stars, bound by gravitational forces. However, microwave background observations provide a more direct total accounting of the composition of the universe. These observations imply that the total density in atoms is only one-sixth of the density in matter, so ordinary matter is no longer considered a likely candidate for the dark matter.

Black holes have been proposed as another possible candidate for the dark matter. If the first generation of star formation consisted of very massive stars, these objects would rapidly burn hydrogen to

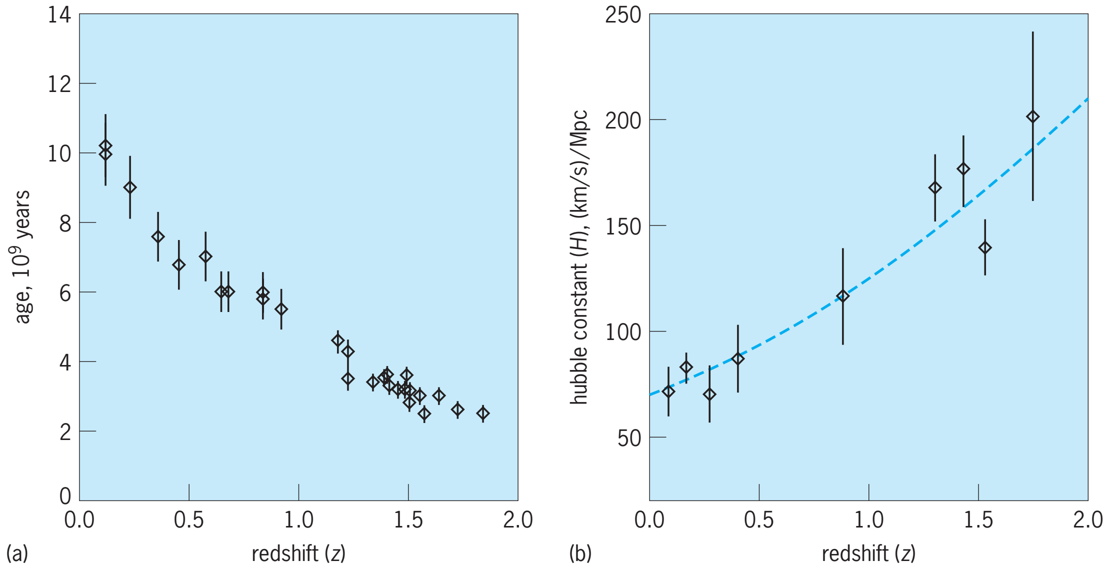

Fig. 4. Comparison of galactic ages with predictions of the lambda CDM model. (*a*) Ages of the oldest galaxies as a function of redshift. (*b*) Data points and bars show the Hubble constant inferred from the galactic ages. The curve shows the predictions of the lambda CDM model. (*J. Simon, L. Verde, R. Jimenez*)

heavier elements and then collapse to black holes. Observational constraints on element abundance require that these massive stars not lose much of the carbon, oxygen, or iron produced during their stellar evolution to the interstellar medium. Models of very massive star evolution suggest that these stars could swallow most of their mass and form a halo of black holes. This scenario is rather tentative, since very little is understood about pregalactic star formation. These black holes could also be detected in the current gravitational lensing searches. *See* BLACK HOLE.

The currently favored hypothesis is that the dark matter consists of some as yet undetected particle. Particle physicists have suggested several possible candidates for the dark matter. The most popular of these particles is predicted in an extension of standard physics called supersymmetry. This particle, named a WIMP (weakly interacting massive particle), could potentially be detected in deep underground experiments or created in particle accelerators. The upcoming generation of dark-matter experiments at CERN may be able to produce these particles in the laboratory. *See* ELEMENTARY PARTICLE; SUPERSYMMETRY; WEAKLY INTERACTING MASSIVE PARTICLE (WIMP).

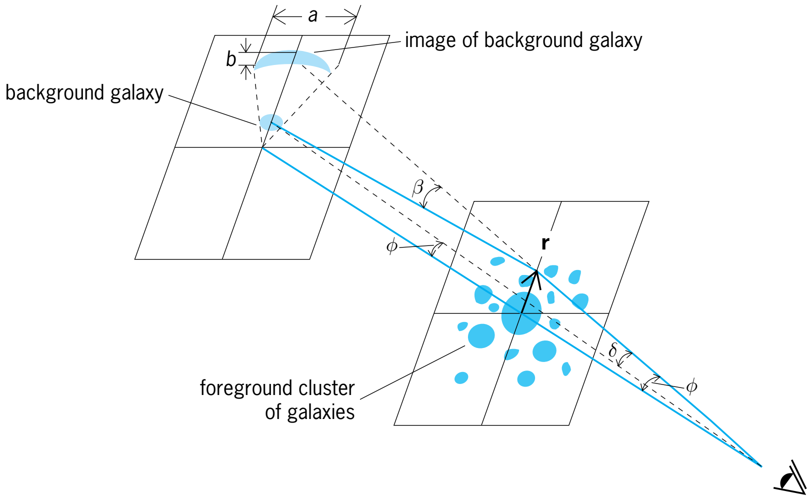

Fig. 5. Gravitational displacement and distortion (lensing) of a distant background galaxy by a compact foreground cluster of galaxies. A light ray passing the cluster plane at an impact parameter vector r is gravitationally bent through an angle β. Thus, it is seen displaced (through an angle δ) from ϕ, its true angular distance from the cluster centroid, to the larger angle ϕ. Because of its finite width, the image also is distorted into a circular arc (of length *a* and width *b*) concentric with the cluster. (*After A. Tyson, Mapping dark matter with gravitational lenses, Phys. Today, 45(6):24–32, June 1992*)

Dark energy. Measurements of distances to supernovae, galaxies, and the microwave background imply that most of the energy in the universe is not in the form of matter but dark energy. Measurements of the evolution of the clustering of galaxies confirm the existence of this dark energy and imply that it does not cluster gravitationally.

The most popular current idea for the dark energy is that it is energy associated with the vacuum. Einstein first posited the existence of this vacuum energy (or cosmological constant); however, the current model of fundamental physics cannot explain its measured value.

Other possible explanations for the dark energy include extremely weakly interacting ultralight fields or modifications of general relativity. Understanding the dark energy and measuring its properties is one of the most active areas of research not only in cosmology but also in all of physics.

Alternatives to the hot big bang. There have been a variety of models proposed as alternatives to the hot big bang. Historically, the most important alternative model was the steady-state model, which assumes a homogeneous expanding universe that is not evolving because matter is continuously being created out of the vacuum. This model has great difficulty accounting for the observed shape of the microwave background radiation and cannot account for the observed abundance of helium.

Another alternative is the cold big bang model in which the universe began in a big bang that started at absolute zero. It has been suggested that in this model the microwave background radiation could be due to reemitted light from iron needles. This model requires special dust grains and also cannot explain the abundances of light elements.

In H. Alfvén's plasma universe, the Milky Way Galaxy is part of a finite cloud of material expanding into empty flat space. It is very difficult for this model to explain the observed uniformity of the microwave background spectrum or the light-element abundances.

E. Segal has proposed an alternative to cosmology based on general relativity. In this chronometric theory, there is a quadratic rather than a linear relationship between redshift and distance. Modern measurements of the distances to rich clusters find that these objects obey Hubble's linear relationship rather than Segal's quadratic law. Observations of the correlation between jet expansion velocity and redshift are a direct test of the chronometric hypothesis, which it fails.
