The reaction was complete at 90 minutes. A sample was analysed to determine any residual PCB content as well as the complete range of chlorobenzene isomers and benzene. Trace quantities of 1,2,3-trichlorobenzene, tetraCBz, pentaCBz were found at sub ppb levels while hexaCBz was 4.3 ppb. Trichloro- and lower chlorinated benzenes were below the method detection limit of 0.3 ppb.

Other work by the author has shown that the action of sodium reagents on PCBs causes the sequential removal of chlorine atoms from the biphenyl molecule until a polymerized polyphenyl sludge is obtained. The change in the relative peak heights shown in the chromatograms of samples taken at different times was clearly indicated. The later peaks contain $C_{12}H_3Cl_7$ isomers which appear to lose chlorine and add to the earlier peaks with six, five and fewer chlorine atoms. The PCBs which elute at shorter retention times probably contain five and four chlorine atoms. Both of these peaks are relatively larger than in the starting material which indicates that the more highly chlorinated PCB congeners react faster than the less chlorinated congeners. The kinetics of the process were not established in detail because the dechlorination process takes place too rapidly under the conditions used to allow precise correlations to be developed.

The reduction in concentration by three orders of magnitude in 30 minutes reaction time is very similar to the reduction observed in the HCBz experiment.

Chemical reaction from a relatively concentrated PCB solution of Aroclor 1260 has been found to be reduced from an initial value of 254 ppm PCB to 4.6 ppm PCB in 30 minutes.

At this point in time it is uncertain whether the final product is polyphenyl hydrocarbons or whether the reaction continues to break the phenyl-phenyl bond. There is no observable precipitation of polyphenyls or other organic residue. The turbidity of the initial solution caused by the emulsion is completely eliminated and points to the probable elimination of organics from the water. This is supported by the observation that total organic carbon (TOC) is reduced simultaneously with PCB dechlorination.

A further experiment was conducted with a 3,300 ppm Aroclor 1260 emulsion in water. The process reduced the concentration to 0.2 ppm in 30 minutes.

The following table summarises the data (Table 58).

The electrochemical process by its nature is easily controlled and safe. The system is closed and has no emissions, it operates at ambient temperature.

In any chemical dechlorination system in which there is a possibility of the formation of hydroxyl radicals or hydroxylated species there is a possibility that incomplete reaction might produce hydroxylated species which are more water soluble than the original PCB. While the toxicity of the hydroxylated product might be less than that of the original PCB it is much more likely to be dispersed into the environment because of its increased water solubility. The electrochemical process yields products which do not contain chlorine as evidenced by the chromatograms of samples taken from the process at different reaction times.

No mechanistic studies have so far been done to determine the formation of intermediate reaction products.

Once an hydroxylated product has been formed in a dechlorination reaction, there is a possibility that, given the right conditions for reaction, PCDFs or PCDDs might be formed. Such reactions are known to occur under pyrolysis conditions and also when hydroxyl radicals are produced during the course of a reaction such as ozone oxidation and the interaction of solutions with high energy electrons generated by a Van der Graff machine or Sr^{90} β^--particles. These reactions have been discussed in an earlier section.

The dimerization of chlorophenate precursors to yield dibenzofurans is a bimolecular reaction and therefore the products formed should be highly dependent upon the chlorophenate concentrations. The particular PCDD isomers formed in the system, and their quantities, will depend upon the relative kinetics of alternative reaction routes.

The data in Table 59 indicate that aqueous samples which contained PCDFs and PCDDs can be dechlorinated to below the method detection limit of 0.03 parts per trillion. Work to determine the efficiency and optimal treatment parameters of the method towards the elimination of PCDFs and PCDDs has not been specifically addressed. The sample analyses shown in the table derive from real samples which contained PCDF and PCDD contamination together with other contaminants. All of the contaminants were successfully removed. During this experiment the system was not intended to specifically reduce PCDF and PCDD compounds but rather to remove other components of concern. Since these classes of compounds are chemically more reactive than chlorobenzenes it is expected that PCBs/PCDFs/PCDDs would also react to the observed low levels found in the current research.

Analytical chemistry at the time of the ‘Yusho’ incident in 1968 was at a stage of development in which the determination of compounds of concern at the parts per million level was considered to be the state-of-the-art. Vos showed in 1970 that PCDFs could be determined in the presence of a matrix of PCBs but it was not until about 10 years later that analytical methodology had advanced to the point that PCDFs and PCDDs could be determined with a standard, quality assured protocol.

The analysis protocol used to determine the PCDF data in Table 59 is designed to precisely and accurately quantitate the 2,3,7,8-TCDF and 2,3,7,8-TCDD isomers which are of greatest health concern. The remaining congeners are classified according to the number of chlorine atoms contained in the isomeric group. The concentration of the isomeric group is reported as the sum of the concentrations of the unseparated isomers.

The technology might be designed into a closed loop system. For example, the excavated soil is washed, the solvent mixed with supporting electrolyte and fed into the electrochemical cell. Compounds of concern are destroyed and the wash water and solvent regenerated and recirculated for further use.

The cost-efficiency of the process can be optimized by reducing the concentration of contaminants of concern to an intermediate level in the closed-loop system. The incompletely reacted mixture can be re-used to extract the excavated soil for a second pass treatment. The solvent is re-loaded with contaminants and treated in a second pass. Finally, the mixture is completely reacted to a prescribed level which will allow the clean soil to be returned to the site. The solvent need not be treated to extremely low levels because it is used in the closed-loop system to re-extract subsequent batches of contaminated soil.

TABLE 58
PCB emulsions in water are reduced to low parts per trillion

	Time (min.)/PCB Concentration (ppm)			
Initial (ppm PCB)	10 min.	20 min.	30 min.	90 min.
22.5			0.028	0.007
254	13.2	8.7	4.6	
3,300	25.5	2.9	0.2	

TABLE 59

	Polychlorinated dioxins (ppt)		Polychlorinated dibenzofurans (ppt)	
Component	Untreated	Treated	Untreated	Treated
2,3,7,8-TCDF	N.D.	N.D.	0.5	<0.03
Tetra-chloro-	1.2	0.15	1.5	0.21
Penta-chloro-	0.95	0.48	1.5	0.12
Hexa-chloro-	1.1	0.17	1.5	0.15
Hepta-chloro-	1.7	0.37	2.8	0.32
Octa-chloro-	1.3	0.22	1.6	N.D.

N.D. = not detected.

The process is operated at ambient temperature. There are no emissions from the closed-loop system and only clean water, solvent and soil leave the process. The vessel is not pressurised and does not require a high capital cost to construct. The operation is conducted with a low power requirement of 25 or fewer amps and 8 volts which can be generated in the field. If a power outage occurred, the reaction would stop instantaneously. All of these factors make for a safe working environment.

The electrochemical process has been used on effluent samples from various industry groups. Amongst these is the effluent from the pulp and paper industry which is known to contain large quantities of chlorinated organic materials, referred to as AOX components, which may include PCBs, PCDFs and PCDDs. The particular sample treated contained originally a total of 43,000 ppb AOX. The electrochemically treated solution showed a final concentration of 970 ppb which was below the required AOX industrial discharge limits. The process could have been continued to further reduce the AOX if that had been required.

The electrochemical process, whether intended for the breaking of emulsions, the removal of dissolved or suspended organic compounds, the destruction of chlorinated synthetic organic compounds including PCBs, PCDFs and PCDDs, operates on all of the contaminants simultaneously. The application of the process is mobile and safe.

The electrochemical cell is not pressurised and does not require expensive materials of construction to avoid chemical corrosion. Operating parameters are simple and safe—no hazardous by-products are formed since all of the chlorinated organic compounds are completely dechlorinated. The system is self-contained and has no emissions—the discharge of clean soil and the reuse of water and solvent are key products of the operation.

The capital cost of construction of this alternative technology is much lower than incineration. The extent of treatment, expressed in terms of electrolytic conditions and time, can be controlled to achieve a required level of destruction of organochlorine compounds of concern.

APPENDIX

COD	Chemical oxygen Demand
DBPC	Di-tertiary Butyl-P-Cresol
DRE	Destruction and Removal Efficiency
ESR	Electron Spin Resonance
HRGC	High Resolution Gas Chromatography
HTFW	High Temperature Fluid Wall
NaNp	Sodium nephthalenide
NAPEG	Sodium polyethylene glycol
NMR	Nuclear Magnetic Resonance
NCI-MS	Negative Chemical Ionization-Mass Spectrometry
PCB	Poly Chlorinated Biphenyl
PCBZ	Poly Chloro Benzene
PCBP	Poly Chloro Bi Phenylene
PCCY	Poly Chlorinated Chrysene
PCDD	Poly Chloro Diberizo-p-Dioxin
PCDF	Poly Chlorinated Dibenzo Furan
PCDPE	Poly Chlorinated Di Phenyl Ether
PCN	Poly Chlorinated Naphthalene
PCPY	Poly Chlorinated Pyrene
PCQ	Poly Chlorinated Quaterphenyl
PIC	Product of Incomplete Combustion
POHC	Principal Organic Hazardous Constituent
RCRA	Resource Conservation and Recovery Act
TSCA	Toxic Substances Control Act

PESTICIDES

INTRODUCTION

Man employs pesticides as purposeful environmental contaminants in order to improve environmental quality for himself and his domesticated animals and plants. In agriculture, pesticides are used to increase the cost/benefit ratio in favor of the farmer and of the ultimate consumer of food and fiber products, the citizen. It has been widely estimated that the U.S. farmer receives an average net return of about $4 for every $1 invested in pesticides (PSAC, 1965, Pimentel and Levitan, 1986). In our present era of managed ecology of monocultures, of farm mechanization, and of the complex system of food harvesting, processing, distribution and storage, the use of pesticides often represents the slender margin between crop production and crop failure, and between economic profit and economic loss. In the developing countries where food supplies are marginal, pesticide use may represent the margin between survival and starvation.

In public health, pesticides often provide the only feasible means for the control of the invertebrate vectors of human and animal diseases. It is difficult to place monetary values on human health, but for malaria in India, the World Health Organization has estimated that an investment of $200 million in malaria control by DDT residual house spraying during 1956–66 saved 179.5 million man days of labor or an estimated saving of $490 million. The cost/benefit ratio has thus been about $2.7 return for every $1 invested. In addition, during this period the annual number of cases of malaria has decreased from 75 million to 150,000 and deaths from about 750,000 to 1500 (World Health, 1968).

In surveying the role of pesticides in environmental quality it must be remembered that pests themselves generally affect adversely the quality of the environment. The spectrum ranges from a mosquito in the bedroom or a cockroach in the pantry to a plague of locusts or the tsetse flies (*Glossina* spp.) which as vectors of trypanosomiasis have effectively prevented the development of 4.5 million square miles of Central Africa. The presence of vicious biting black flies (*Simulium* spp.) or wide-spread defoliation of forest and shade trees by the gypsy moth (*Porthetria dispar*) or other defoliators are effective deterrents to the resort industry in many northland vacation sites. Who can place a realistic value on the loss to environmental quality from the chestnut blight or the Dutch elm disease which have destroyed millions of North America's finest shade trees? Therefore it must be recognized that the purposeful environmental contamination by pesticides generally provides environmental benefits substantially greater than the risk of environmental pollution. It is also necessary to distinguish carefully between *environmental contamination*, which may not pose any risk or hazard to the environment, and *environmental pollution* where the health or well being of man or other animals and plants may be severely threatened. Environmental contamination is often a matter of degree, as for example with selenium, which at very low levels is essential for the normal growth and development of vertebrates yet at higher levels is an extremely poisonous pollutant. What is wanted then in an exploration of "pesticides in the environment" is a scientific appraisal of all these elements, a judicious weighting of risk/benefit ratios, and where deleterious effects on environmental quality are detected, the prompt substitution of remedial measures and/or alternative pesticides which pose no environmental hazard (Brown, 1978, McEwen and Stevenson, 1979).

Another measure of the economic value of pesticides is the total extent to which they are used. Pesticide production in the United Sates over the period of 1962–1986 is shown in Table 1. The average annual increase in total production from 1962 to 1976 was about 5% per year but since that time growth has averaged only about 1% per year. Over this period, there have been major changes in use patterns with herbicide use doubling from 1962 to 1968 and doubling again by 1980. The use of insecticides grew slowly from 1962 to 1974 and since that time has decreased about 5% per year. Agricultural use represents about 68% of the market, industrial use 17%, home and garden use 8%, and governmental use 7% (Storck, 1984, 1987). In global terms, the United States uses about 26% of total production, W. Europe 25%, the Far East 22%, E. Europe and USSR 10%, Latin America 9%, and the other regions about 8% (Chem. Week, 1985).

The most recent major inventory of pesticide use in United States agriculture was made in 1976 when it was estimated that 295 million kilograms of pesticide active ingredients were applied to 84 million hectares of cropland or about 61% of the total crop acreage. Herbicides were applied to 56%, insecticides to 18%, and fungicides to 2% of cropland. Corn was the most heavily treated crop with about 36% of total farm use, followed by soybean 13%, and cotton 12%. These three crops accounted for 61% of the total farm use of pesticides (Eichers *et al.,* 1978).

TABLE 1
Production of synthetic organic pesticides in the United States[a]

Year	Millions of kilograms			
	Fungicides	Herbicides	Insecticides	Total
1962	70	85	216	370
1964	70	118	208	396
1966	76	124	256	455
1968	87	183	265	534
1970	64	184	223	410
1972	65	205	256	526
1974	74	275	295	644
1976	65	298	257	620
1978	67	302	275	644
1980	71	366	230	667
1982	50	285	172	506
1984	56	325	159	540
1986	51	330	155	536

TABLE 2
Estimated farm use of pesticides in the United States[a]

Pesticide	Millions of kilograms			
	1966	1971	1976	1982
Alachlor	—	6.7	40.2	37.7
Atrazine	10.7	26.1	41.0	34.1
2,4-D	18.2	15.2	17.5	9.5
Trifluralin	2.4	5.2	12.9	15.9
Toxaphene	15.7	16.8	14.0	1.4
DDT	12.3	6.5	—	—
Aldrin	7.1	3.6	0.4	—
Carbaryl	5.6	8.1	4.2	—
Carbofuran	—	1.3	5.3	3.2
Methyl parathion	3.6	12.5	10.4	4.1
Parathion	3.8	4.3	3.0	—

[a] Data from USDA Agr. Econ. Repts. 254 (1974), 418 (1979), Council Environ. Qual. Rept. 15 (1984).

An estimate for 1982 indicated that 113 million hectares of cropland were treated with 337 million kilograms of pesticides, with herbicides applied to 59%, insecticides to 18%, and fungicides to 3% of cropland. It was estimated that 16% of the total area of the United States received some direct application of pesticide annually (Pimentel and Levitan, 1986).

Major changes have occurred in the types of pesticides applied in the United States during the last half of the 20th Century. Available data for the farm use of major pesticides during the last two decades is presented in Table 2. The organochlorine insecticides DDT, BHC, toxaphene, aldrin, dieldrin, endrin, heptachlor, and chlordane dominated the market for about 25 years following their introduction after World War II. These persistent and broad-spectrum insecticides proved to be environmentally uncontrollable, and legal restriction of the use of DDT in 1973 was followed by restrictions on the use of aldrin and dieldrin in 1974, chlordane and heptachlor in 1976, and toxaphene in 1983. As a result the use of these organochlorines, which comprised 46% of all farm insecticides in 1971, declined to 29% in 1976 and was nearly phased out by 1984 (Table 2). Similar regulation of use has occurred in Western Europe, USSR, China, and Japan, although extensive use of these insecticides still occurs in developing countries of Asia, Africa, and South America. The organochlorine insecticides were almost entirely replaced during the last decade with biodegradable organophosphate insecticides such as parathion, methyl parathion, diazinon, malathion, and chlorpyrifos; and with the carbamate insecticides carbaryl, carbofuran, methomyl, and aldicarb. During the past decade a new group of insecticides, the synthetic pyrethroids permethrin, deltamethrin, cypermethrin, fenvalerate, and flucythrinate have become used extensively.

The use of herbicides has increased four-fold since 1960 as the preplanting technology of weed control developed. There has been a decrease in the use of the chlorinated phenoxyacetic acids and chlorinated benzoic acid herbicides. Presently the market is dominated by the triazines such as atrazine and cyanazine, the acetamides such as alachlor, the nitroanilines such as trifluralin and pendimethalin, the carbamate butylate, and the urea linuron.

There are approximately 600 individual chemical compounds registered as pesticides in the United States including 80 fungicides, 200 insecticides and 300 herbicides. These are available in about 50,000 formulations. On a world basis more than 900 chemicals are in commercial use as pesticides and the number of different formulations is estimated to exceed 100,000 (Melnikov, 1971, Büchel, 1983). However, as shown in Table 2, about 10 individual pesticides comprise 50% of the total farm use in the United States and the herbicides alachlor and atrazine comprise about 36% of the total herbicide use.

The chemical properties, biological behavior, and environmental fate of this large array of pesticides are exceedingly complex and are beyond the scope of this discussion (Melnikov, 1971, White-Stevens, 1971, Büchel, 1983). The role of these chemicals in pest control and crop production has been studied intensively and their use has become virtually indispensable to modern agriculture. Nevertheless, for the majority of the individual pesticides thee is only superficial knowledge of the effects of their long term use on the quality of the environment (Brown, 1978, McEwen and Stevenson, 1979).

During the 1980s the introduction of several groups of pesticides with 10- to 100-fold greater activity than conventional pesticides that are normally applied at about 1 kg per ha, provided for major improvements in the effects of pesticides on environmental quality. The synthetic pyrethroids are now widely used to control cotton insects at dosages of 20 to 50 g per ha. The sulfonyl urea herbicides such as chlorsulfuron are effective in preplanting applications at doses as low as 4 to 8 g per ha. There is increasing use of microbiological insecticides that are highly specific and do not leave persisting residues. The *delta*-endotoxin of *Bacillus thuringiensis* (BT insecticide) and nuclear polyhedrosis viruses (NPV insecticides) are both highly specific and essentially nonpolluting. The avermectins from *Streptomyces avermitilis* are parasiticides and insecticides that control certain agricultural pests at doses of a few grams per ha.

PESTICIDES AS ENVIRONMENTAL CONTAMINANTS

Pesticides are microchemical environmental contaminants, and their rates of utilization are such that they contaminate soil, water and food in terms of parts per trillion (0.000001 ppm) to parts per million (ppm).* Thus a pesticide applied at 1 lb/acre (1.12 kg/ha) contaminates the top 1 foot (30 cm) of soil (approximately 4 million lb. or 1800 metric tons) to 0.25 ppm. Where such contamination is deleterious to environmental quality the pesticide becomes a microchemical pollutant, exhibiting such objectionable properties as (1) high physiological and ecological specificity, (2) resistance to biochemical degradation, (3) sequential concentration in organisms of the trophic web, and (4) capacity for delayed onset of intoxication (Warner, 1967).

Pesticides in Air

The widespread application of pesticides in particulate sprays and dusts insures that appreciable contamination of the air is a consequence of pesticide use. Much of the total application of pesticides is from aircraft (about 80% of pesticide application in California in 1963 was by aircraft; Mrak, 1969) where the propeller wash and wing vortices characteristically throw small particles high into the air and wind currents may drift them for miles away from the target site. When released 10 ft above the ground into a 3 mph wind, 2μ dia. particles drifted 21 miles, 10μ particles 1 mile, and 50μ particles 200 ft (Akesson and Yates, 1964). It is evident that air applications produce increased air pollution, and Wasserman *et al.* (1960) found air concentrations in forests after air application of DDT at 18.9–170.9 mg/m^3 as compared with 4.6–25.5 mg/m^3 for ground application. Comparative values for BHC were: air 4.1–53.7 mg/m^3 and ground 4.6–25.5 mg/m^3. It has been estimated that 50% of the pesticide released in aerial spraying of forest drifts away from the target site.

The use of more than 200 million individual aerosol spray dispensers annually in the United States discharges substantial amounts of such pesticides as pyrethrinspiperonyl butoxide, dichlorvos, malathion, methoxychlor, chlordane, diazinon, propoxur, and so on indoors in homes, stores, warehouses, and aircraft, in the $5-30\mu$ dia range. Organic insecticides have appreciable vapor pressures, ranging from 1.5×10^{-7} mm Hg for DDT, 1.2×10^{-2} for dichlorvos and 1420 mm for methyl bromide. Thus volatilization is a major factor in dispersal of pesticides into the air, and accounts for much of the dissipation of pesticides from treated plant surfaces and buildings and from soil (Harris and Lichtenstein, 1961). Wind erosion of dust from treated soil and so on is also a substantial factor in the dispersal of pesticides through the air.

Occupational Exposure The degree of air pollution resulting from a variety of occupation uses of pesticides is shown in Table 3 (Jegier, 1969). These values illustrate the maximum air-borne concentrations to which humans are likely to be exposed and demonstrate the substantially higher exposures experienced indoors as compared to outdoors. Spray operators during average spraying operations are exposed to minute fractions of the combined dermal and respiratory toxic dose: 0.29% for endrin, 0.43% for parathion, 0.72% for azinphos, and 1.43% for demeton; four highly toxic insecticides. The greatest hazards from air borne exposure to highly toxic materials are found during filling spray tanks with wettable powders.

Residential Exposure Agricultural spraying operations, especially those from aircraft produce considerable air pollution and traces of pesticides have been identified for many miles downwind. Where highly toxic pesticides such as tetraethyl pyrophosphate have been dusted on orchards by air, typical cholinergic symptoms of poisoning have been observed in inhabitants of neighbouring rural communities

TABLE 3

Occupation exposure to insecticides in air[a]

Insecticide	Use	Mean concentration μm/m^3
Azinphos	Orchard spraying	670
Carbaryl	Orchard spraying	600
Malathion	Orchard spraying	590
Parathion	Orchard spraying	150–360
Endrin	Vegetable spraying	50
Demeton	Greenhouse spraying	9150
Chlordane	Household spraying	440
Diazinon	Household spraying	2680
Methoxychlor	Barn and cattle spraying	7680
Lindane	Household vaporizer	100
Azinphos	Tank filling	2270
Parathion	Tank filling	530

[a] Data from Jegier (1969).

---

* Contamination of a substrate at 1 ppm represents 1 μg of contaminant per gram of substrate.

(Quinby and Doornick, 1965). Spraying of apple orchards from ground air blast equipment has resulted in concentrations in nearby residential areas of azinphos, carbaryl, malathion, and parathion as high as 0.5 mg/m^3 (Jegier, 1969). Studies of the effect of DDT spraying operations upon air pollution of rural and urban communities have produced values ranging from <0.1 ng/m^3 (0.000001 mg/m^3) to >8500 ng/m^3. Ranges observed in specific localities included: Fresno, California 0.3–19; Sacramento, California 0–2; Florida City Florida 0.1–7.6; Fort Valley, Georgia 0.3–9.9; Leland, Mississippi 0.4–22; and Lake Apopka, Florida 0.3–8500 (Jegier, 1969). Pesticides are apparently present in the air everywhere as Risebrough *et al.* (1968) measured the concentrations in the air over Barbados as ranging from 13×10^{-6} to 380×10^{-6} ng/m as compared to that of La Jolla, California where the average was 7.0×10^{-2} ng/m^3.

A comprehensive study by Stanley (1968) to determine the atmospheric contamination by pesticides in urban and rural sites of 9 U.S. cities showed that only DDT was present in all localities. The maximum concentrations found were DDT 1560 ng/m^3, toxaphene 2520 ng/m^3, and parathion 465 ng/m^3. The pesticides were mostly present in the atmosphere as particulates and the levels were generally correlated with spraying practices on particular crops.

In another study of pesticides in the air near 10 urban communities (Tabor, 1966), the maximum concentrations found near the center of town and at least a mile from agricultural operations were: DDT 22 ng/m^3, chlordane 6, aldrin 4, and toxaphene 15. Where communities were being fogged for control of pests DDT was found up to 8000 ng/m^3 and malathion up to 140.

Pesticides in Dust The windblown erosion of dust from agricultural lands treated by pesticides can become a substantial source of air pollution. Cohen and Pinkerton (1966) investigated the transport of pesticides to Cincinnati in a violent dust storm originating in the southern high plains of Texas in 1965. The major pesticide components of the dust and their concentrations in the dried dust particles after precipitation by rain in Cincinnati were: DT 0.6 ppm, chlordane 0.5 ppm, ronnel 0.2 ppm, DDE 0.2 ppm, heptachlor epoxide 0.04 ppm, 2,4,5-T 0.004 ppm, and dieldrin 0.003 ppm.

Pesticides in Rainwater Many analyses of rainwater have shown substantial content of various pesticides indicating their general distribution in the atmosphere. As an example, the following mean concentrations of pesticides were found in three locations in Ohio in ppt: DDT 0.07–0.34, DDE 0.005–0.03, and BHC 0.006–0.05. Chlordane, heptachlor, aldrin, dieldrin, and 2,4,5-T isoctyl ester were also found in rainwater samples (Cohen and Pinkerton, 1966).

Recent investigations have shown that persistent residues of toxaphene, a chlorinated camphene with at least 177 separate components, have permeated the Great Lakes ecosystem. More than 2.5×10^8 kg of toxaphene were applied to cotton in the southern United States between 1947 and 1977. The characteristic gas chromatographic "fingerprints" of the multiple components indicate that lake trout, *Salvelinus namaychush* from Lake Michigan contain 6–10 ppm of these toxaphene components and trout from remote Lake Siskowit on Isle Royale in Lake Superior, contain 1.7–4.5 ppm (Rice and Evans 1984). This contamination of the Great Lakes and its biota could only have resulted by airborne transport and precipitation in rain.

Study and the evaluation of pesticide pollution in air has been less intensive than comparable investigations of water and food. However, it is clear that pesticide residues are constantly being transported and redistributed from their sites of application through the atmosphere and are present in some degree in the air everywhere. The degree of human exposure is related to occupation and to geographic location and is highest for workers in pesticide plants, spray operators, and users of household aerosol sprays. Inhabitants of rural regions or those dwelling in houses where spraying operations are conducted for agricultural or public health purposes are obviously exposed to substantially higher concentrations of airborne pesticides than are typical urban dwellers.

Pesticides in Water

The water environment provides the ultimate sink for pesticide residues which enter it by direct contamination from rain precipitating pesticide aerosols or atmospheric codistillates, by direct application to surface waters, by runoff from treated plants and soils, by industrial and household sewage effluents, and by residues in human and animal excreta. An intrinsic property of most pesticidal molecules in high lipid solubility and low water solubility and this property strongly favors concentration from water to the lipids of living animals through partitioning through the animal cuticle and the gills. Such absorption and subsequent storage and concentration may result in aquatic animals accumulating pesticide residues hundreds and even thousands of times greater than that in the surrounding aquatic medium. This concentration process is dependent upon the initial pesticide residue in water, the length of animal exposure, i.e. lifetime, and the rate of metabolism or breakdown of the pesticide in the organism, i.e. biological half-life. Thus this subject has assumed great ecological importance.

Ground Waters Pesticide residues in ppt to ppb quantities eventually percolate into ground waters. This problem has become a major environmental concern because of greatly increased soil applications of pesticides (more than 100 million ha are treated annually), improper waste disposal, and the enhanced analytical capability provided by gas chromatography/mass spectrometry. The Safe Drinking water Act of 1974 (Public Law 95–523) requires EPA to promulgate and enforce nonpolluting drinking water standards by establishing maximum contamination levels at which no adverse health effects are observable. The Act requires EPA to publish such non-polluting drinking water standards for some 83 water contaminants by Jan. 1991.

An EPA survey of 1988 has disclosed the presence of 74 different pesticides in the ground waters of 38 states. Aldicarb insecticide has been detected as the sulfoxide and sulfone derivatives in ground waters of 15 states and 29%

of the wells in the potato growing area of Suffolk Co. New York had aldicarb residues of 7 ppb with maximum concentrations reaching 600 ppb. In Massachusetts 220 drinking water wells were closed because of aldicarb contamination from 1–50 ppb (Pesticide & Toxic Chemical News 1985). Ethylene dibromide soil fumigant has been detected in the ground waters of 8 states and in 11% of more than 1000 wells in Florida, with exposure of more than 50,000 people (Pesticide & Toxic Chemicals News 1985). Iowa ground water has been found to be contaminated with the herbicides atrazine, cyanazine, metalochlor, alachlor and the insecticides terbufos and sulprofos; all applied as preplanting applications to corn and soybeans. In California, more than 50 different pesticides were detected in water sampled from over 8,000 wells in 24 counties. In Ontario, Canada the herbicides alachlor, butylate, dalapon, dicamba, MCPA and simazine were detected in the waters of 159 of 237 wells analyzed (Frank *et al.,* 1979).

This widespread pollution of drinking water sources is one of the most important environmental problems of the 1990s. Many of the soil applied pesticides migrate very slowly through the soil and even if annual applications were discontinued, water pollution levels are expected to increase for another 5 to 10 years. Pesticides have long residence times in ground water because of the absence of light, air, and microorganisms that are primarily involved in degradation. The number of persons exposed for long periods of time is very large. The mandatory provisions of the Safe Drinking Water Act may change forever how pesticides are applied.

Surface Waters The Mrak Commission (Mrak, 1969) observed that the current U.S. annual production of pesticides, ca. 1×10^9 lb, applied to the annual U.S. runoff, ca. 1×10^6 gal/day, could result in a maximum concentration of 0.3 mg/l (0.3 ppm). Fortunately, most of the environmental contamination with pesticides is directly or indirectly to the soil where the various compounds are often tightly bound to soil colloids and/or degraded by soil microorganisms. The average runoff concentrations of 9 organochlorine insecticides, obtained from analysis of 6000 samples at 100 locations in all major U.S. river basins from 1958–65, is summarized in Table 4 (Breidenback *et al.*, 1967). The maximum amounts determined, dieldrin 0.122 ppb, endrin 0.214 ppb, DDT 0.144 ppb, aldrin 0.006 ppb, heptachlor 0.002 ppb heptachlor epoxide 0.008 ppb, and BHC 0.022 ppb were well below the suggested Federal Drinking Water Standards (USPHS, 1968) of dieldrin 17 ppb, endrin 1 ppb, DDT 42 ppb, heptachlor 19 ppb, heptachlor epoxide 18 ppb and lindane 56 ppb, except for endrin. The yearly analyses showed dieldrin to be the dominant contaminant but declining, DDT and congeners virtually constant, endrin reaching a peak in 1964 and declining.

In another study of 12 organochlorine pesticides in 11 streams in Western United States (Brown and Nishioka, 1967) the contaminants, positive samples, and range detected were: DDT—82, 0.01–0.12 ppb; DDE—49, 00–0.06; DDD—35, 0.0–0.04; 2,4-D–41, 0.01–0.35; 2,4,5-T—28, 0.01–0.07; heptachlor–27, 0.01–0.04; dieldrin—24, 0.01–0.07; silvex—14, 0.01–0.21; lindane—11, 0.01–0.04; aldrin—11, 0.01–0.07; endrin—4, 0.01–0.07; and heptachlor epoxide—2, 0.02–0.04.

A major source of pesticide pollution of ground water is from soil particles contaminating attached pesticide residues through erosion runoff, or flooding. Application of aldrin to rice fields at 415 g/ha by seeding with treated rice seeds resulted in 1.6 ppb aldrin plus dieldrin in the water after 2 days and 0.07 ppb 14 weeks after seeding. Draining of the fields after 14 weeks produced 0.027 ppb in the ditches, 0.44 ppb in the stream receiving the ditches, and concentrations as high as 0.023 ppb in the river into which the stream flowed (Sparr *et al.,* 1955). In a companion study runoff from a cotton field treated 7 days before with 450 g/ha of endrin, contained 0.66 ppb endrin after a 1.15 in. rain. Used irrigation water contained 0.11 ppb endrin 3 days after spraying.

Lakes and Reservoirs These bodies of water often represent the sites of the most serious environmental pollution problems resulting from the applications of pesticides to both land and water. The direct application of pesticides to water for the control of mosquito or black fly larvae, snails,

TABLE 4
Organochlorine pesticides in major river basins of the United States[a]

Pesticide	Positive samples of 537	Range ppb	Area of highest concentration
Dieldrin	495	0.008–0.122	lower Miss. 1964
Endrin	217	0.008–0.214	Lower Miss. 1963
DDT	145	0.008–0.144	W. Gulf Basin 1963
DDE	176	0.002–0.011	lower Miss. 1965
DDD	231	0.004–0.080	N. Atlantic basin 1963
Aldrin	31	<0.001–0.006	S.W. basin 1964
Heptachlor	6	0–0.002	lower Miss. 1965
Heptachlor eposice	26	<0.001–0.008	N. Atlantic basin 1963
BHC	44	0.003–0.022	S.E. basin 1960

[a] From Breidenback *et al.* (1967).

or water weeds is an obvious source of contamination. Rates of application commonly range from 0.1–1 kg/ha of water surface for insecticides to as much as 100 kg/ha for 2,4-D herbicide. In water 0.3 m deep these rates would range from 2 ppm to 2000 ppm.

One of the first examples of serious water pollution by pesticides resulted from the application of the larvicide DDD to Clear Lake, California for the control of Clear Lake gnat *Chaborus astictopus* which was a severe nuisance. In 1949, 14,000 gal of emulsive concentrate of DDD was applied to the lake at a rate of 14 ppb. The gnats were nearly exterminated and it appeared that no damage to fish occurred. Reinfestation from nearby lakes resulted in retreatment with DDD at 20 ppb in 1954 and 1957. Dying Western Grebes (*Aechmophorus occidentalis*) in areas around the lake were observed in 1954, 1955, and 1957 and they had tremors characteristic of DDD poisoning. Their body tissues showed as much as 1600 ppm DDD. Subsequent study showed DDD residues of up to 10 ppm in plankton, and as much as 2375 ppm in the body fat of the white catfish, *Ictalurus catus* (Hunt and Bischoff, 1960). Thus this episode provided the first well studied example of ecological magnification of a pesticide from water through a food chain of plankton→fish→birds, which died from chronic DDD poisoning.

Large fresh water lakes may have astonishingly long water retention times, which magnify pesticide contamination problems. In the Great Lakes system Lake Superior with an area of 82,366 km^2 and a volume of 12,221 km^3 has an average water retention time of 189 yrs, and Lake Michigan with an area of 58,016 km^2 has an average water retention time of 30.8 yrs. Rainey (1967) has pointed out that in such bodies of water contamination is a major disaster for which there is no apparent solution. Thus the times for 90% waste removal are $>$500 yrs for Lake Superior and 100 yrs for Lake Michigan, as compared to 20 yrs for Lake Ontario and 6 yrs for Lake Erie. Lake Michigan is exposed to pesticide contamination from intensive agriculture and from effluents from the densely populated urban areas within its 117,845 km^2 watershed. Analyses of Lake Michigan surface waters in 1968–1969 showed DDT $2.0–2.8 \times 10^{-6}$ ppm, DDE $0.8–1.4 \times 10^{-6}$ ppm, and DDD $0.3–0.5 \times 10^{-6}$ ppm; while grab samples at the Chicago filtration plant had DDT $0.034–0.058 \times 10^{-3}$ ppm, lindane $0.01–0.02 \times 10^{-3}$ ppm, aldrin 0.019×10^{-3} ppm, and heptachlor epoxide $0.019–0.049 \times 10^{-3}$ (Mrak, 1969). The ecological significance of these trace amounts is shown by studies reporting concentrations of DDT in the Lake Michigan ecosystem of 0.014 ppm in bottom muds, 0.410 ppm in amphipods, 3.22 ppm in yellow perch, 6.9 ppm in lake trout, 6.71 ppm in lake herring, and 99 ppm in herring gulls (Reinert, 1970; Harrison *et al.,* 1970). The overall concentration of DDT from water to fish-eating bird is $>10^7$. Dieldrin was present in lake trout and lake herring to 0.20 ppm (Reinert, 1970), for an overall concentration of about 2×10^5.

Estuaries The importance of estuarine waters to commercial and sports fishing makes these locations especially vulnerable targets to the runoff of pesticides in streams and rivers from agricultural practices and industrial operations. It has been estimated (PSAC, 1965) that more than 50% of the total harvest of sea foods from waters of the United States is composed of species whose existence of spawning grounds are in the estuarine zone, and this harvest includes some of the most valued sea foods—shrimp, lobster, crabs, oysters, salmon, menhaden, and game fish. Agricultural pesticides are more toxic to the marine life than any other group of chemicals, and lethal concentrations for the organochlorine insecticides aldrin, dieldrin, heptachlor, endrin, DDT, lindane, and toxaphene range from 0.0006–0.06 ppm. Mollusks in particular can concentrate extraordinary quantities of stable pesticides, and oysters have been found to accumulate DDT to 70,000 times the amount in the surrounding water. Thus these organisms are especially useful as biological indicators of pesticide pollution. Woodwell *et al.* (1967) estimated that the Carmans River estuary of Long Island contained about 0.00005 ppm DDT in the water, with concentrations of 0.04 ppm in plankton, 2–3 ppm in small fish, and up to 75.5 ppm in the ring-billed gull (*Larus delawarensis*).

Oceans Little information exists about pesticide residues in the oceans. As these compounds are leached from the land or precipitated by rains, they circulate initially in the mixed layer above the thermocline and may eventually be transferred slowly into the abyss which provides a reservoir of virtually infinite capacity (Woodwell *et al.,* 1971). The organochlorine compounds such as DDT with their high lipid solubility and very low water solubility must be largely absorbed into organic matter. Woodwell *et al.* (1971) estimate concentrations of DDT in algae of the oceans ranging from 0.1–1.0 ppm and a maximum accumulation in the mixed layer of the ocean of about 15 ppt. Scattered observations suggest that DDT is present in most marine animals, with levels in whales of 0.4–6 ppm, tuna up to 2 ppm, oysters 0–5.4 ppm, and sea birds up to 10 ppm (Butler, 1966; Wolman and Wilson, 1971). Virtually nothing is known of the presence of other pesticides in marine organisms. Trapping of pesticides in petroleum slicks, which may contain up to 10,000 ppm DDT, provides another facet to marine pollution.

Pesticides in Soils

Pesticides are most frequently applied directly to soil or to plant surfaces above it and concern for the persistence of pesticide residues in soils has existed since the first widespread use of lead and calcium arsenate. A study by Jones and Hatch (1937) reported that 3500 lb of lead arsenate was applied to a commercial apple orchard over a 25 yr period. Most of the lead and arsenic was confined to the upper 6–8 in of soil and did not harm the roots of the fruit trees. However, the residual levels were highly toxic to cover crops or to young newly planted trees.

Pesticides are applied to crops and soils in most of the agricultural areas of the United States. Estimates in 1982 suggest that of the 113 million ha of cropland, herbicides were applied to 59%, insecticides to 18%, and fungicides to 13% (Pimentel and Levitan, 1986).

Soil Residues of Pesticides Monitoring studies made of pesticide residues in soils of the heavily treated cotton growing areas of the Mississippi Delta (Gentry, 1966) have given a general picture of the extent to which agricultural soils may be contaminated. In an area where a cumulative total of 30 kg of DDT/ha had been applied over a 9 yr period 1955–63, the level in the top soil in 1964 was 1.3 ppm or about 1.3 kg/ha. In another area where 13 applications of endrin at 0.2 kg/ha were applied since 1956, the average level in the soil in 1964 was 0.05 ppm. Aldrin and dieldrin, although not used since about 1955, were found in the study area in 1964 at levels of up to 0.06 ppm dieldrin and 0.13 ppm aldrin, and benzene hexachloride was found at about 0.02 ppm. Toxaphene was a present in the soils at 0.8–3.7 ppm, and calcium arsenate, although not used for many years, had left an arsenic level of 2.18–12.8 ppm.

The occurrence of residues of chlorinated hydrocarbon insecticides in soils from 31 farms in Southern Ontario has been explored by Harris *et al.* (1966). Orchard soils contained the highest levels of DDT 19.9–118.9 ppm, DDE 3.4–15.7 ppm, DDD 0.2–3.5 ppm, and dicofol 2.4–6.9 ppm. A vegetable farm where radishes were grown on muck soil had the highest concentrations of dieldrin 1.6 ppm, aldrin 2.1 ppm, endrin 3.8 ppm, together with DDT 13.8 ppm, DDE 0.8 ppm, and DDD 0.4 ppm. The highest levels of other pesticides found were: heptachlor 0.2 ppm, chlordane 0.6 ppm, and endosulfan 1.4 ppm. The average levels found in soils from 16 farms in this area in 1966 were aldrin 0.47 ppm, dieldrin 0.78 ppm, endrin 0.12 ppm, and DDT 23.9 ppm (Harris, 1971).

The rate of degradation of any pesticide in the soil is a function of its chemical structure and the formulation applied whether emulsion, granular, or seed treatment. Most pesticide degradation in soil is accomplished by the wide range of soil microorganisms which can use the compound as an energy source, although hydrolysis and photochemical oxidations may also play a role. Soil factors which determine the actual rate of persistence are (1) soil type, (2) soil moisture, (3) temperature, (4) uptake by plants, (5) leaching by water, (6) wind erosion. Thus it is difficult to generalize about soil persistence of pesticides, which is, however, greater in muck soils heavy in organic matter than in light sandy soils. Some idea of the relative persistence of various pesticides in soils is given in Table 5, from data by Edwards (1964), Lichtenstein (1969), and Harris (1971).

Uptake of Pesticides by Plants Plants obviously absorb pesticides from the soil and translocate them throughout the leaves and fruits or pre-emergent herbicides would have little activity in killing weeds and systemic insecticides would fail to protect plants against insect attack. The actual amounts absorbed by plant roots are dependent upon the solubility of the pesticide in the lipids of the root cuticle, and the amounts translocated are a function of the water solubility of the pesticide in the translocation stream.

The organochlorine insecticides are absorbed in trace amounts by root crops such as carrots, radishes, and potatoes, and these crops grown in soil treated with 1 kg/ha of aldrin contained as much as 0.03–0.05 ppm of the pesticide (Lichtenstein, 1969). Residues of these pesticides also enter above ground portions of crops and Lichtenstein (1969) has calculated that alfalfa grown on soil treated with aldrin and heptachlor at 1 kg/ha would contain approximately 0.005 ppm aldrin and dieldrin and 0.015 ppm of heptachlor and heptachlor epoxide. In contrast, residue studies made of the results of soil and seed treatments with phorate and disulfoton showed residues in the leaves after 39 days ranging from 5–12 ppm in alfalfa, 32–137 ppm in cotton, and 7–46 ppm in sugar beets (Reynolds *et al.,* 1957). These residues dissipated rapidly as the plants grew older and in practical use conform to the residue tolerance levels in hay and cottonseed.

Pesticides in Foods

The most direct avenue for pesticide contamination of the human body is through ingestion of pesticide residues on food products. Perhaps 75% of all pesticides production is used for the production or protection of agricultural commodities and wide-spread contamination of food products is the inevitable result. However, much of the initial pesticide load is lost by "weathering", through action of rain and dew and by photochemical oxidations, by enzymatic destruction in the tissues of plants or animals and through losses in harvesting and food processing. The processes of degradation and persistence of pesticide residues usually follow first

TABLE 5
Persistence of pesticides in soils

Pesticide	Approximate time for 70–95% loss[a]
DDT	4–10 yrs
Toxaphene	2–10 yrs
Dieldrin	3–8 yrs
Lindane	3–6 yrs
Chlordane, heptachlor	3–5 yrs
Aldrin	2–3 yrs
Picloram	1–2 yrs
Simizine, atrazine	10–12 months
Monuron, fenuron, diuron	8–10 months
Trifluralin	6 months
Carbaryl, carbofuran	4–6 months
2,4,5-T	3–5 months
Parathion, chlorpyrifos, diazinon	3–6 months
Amiben, dicamba, MCPA	2–3 months
Dalapon, propham, CDAA, CDEC, EPTC	1–2 months
Phorate, disulfoton	2–6 weeks
2,4-D	4–6 weeks
Captan	3–6 weeks
Malathion	1–2 weeks

[a] Data from Edwards (1961), Kearney, Nash and Isensee (1969).

order chemical kinetics and can be plotted semilogarithmically as straight lines of log. residue in ppm vs. time elapsed since treatment. Such residue persistence curves give values for residue half-lives or RL_{50} (Gunther and Blinn, 1965) which are independent of initial concentration and thus represent a characteristic of each pesticide on or in a particular substrate such as leaf surface, fruit peel, plant wax or juice, and so on This concept then supports the empirically derived practice of observing a "safe period" after pesticide application and before harvest to permit the pesticide residue to attenuate to levels which long term animal feeding studies have shown to be innocuous to animal health. Based on these animal feeding studies and incorporating a safety factor, ideally 100-fold to allow for peculiar human metabolic idiosyncrasies and sensitivities, together with the potential daily intake in foods, the U.S. Food and Drug Administration has established pesticide residue tolerances for each registered pesticide used on a food commodity. The range of tolerances for commonly used pesticides is shown in Table 6.

The actual occurrence of pesticide residues in human foods has been studied by the FDA from 1964–1966, through the examination of 26,326 samples including raw agricultural products, milk and dairy products, processed animal feeds, shell eggs, fish and shell fish, meat, canned and frozen foods, vegetable oils, and special dietary products (Duggan, 1969). Residues of 81 different pesticide chemicals were detected, with 11 chemicals accounting for 95% of the residues found. Those most commonly detected in domestic foods were, in order of importance: DDT 25%, DDE 24%, dieldrin 17%, DDD 9%, heptachlor epoxide 7%, lindane 4.5%, BHC 2.6%, endrin 2.3%, aldrin 1.8%, toxaphene 1.4% and dicofol 0.7%. Animal tissues contained, in addition, methoxychlor and chlordane. Approximately 95% of the residues were below 0.5 ppm, 78% below 0.1 ppm and 58% below 0.03 ppm. Excessive residues, above tolerances, were found in 3.6% of the samples. It is apparent that the chlorinated organics provided the great majority of readily detectable residues in food products, because of their high stability and fat solubility.

The exposure of humans to pesticide residues in a well balanced diet has been studied by FDA since 1962. For 1964–1966 this was calculated to contain an average of 0.025 ppm chlorinated organics, 0.003 ppm organophosphates, 0.003 ppm chlorophenoxy acids, and 0.05 ppm carbamates. The average daily intake of 15 pesticides in 516 diet composites sampled by FDA is shown in Table 7 (Duggan, 1969).

Increasingly sophisticated evolution procedures have shown that a number of pesticides traditionally considered safe are in fact carcinogens when fed to laboratory animals over their lifetimes. There is much public concern about the long term hazards of eating processed foods containing trace residues of such pesticides. In the United States pesticide residues in food are regulated under the 1954 Food Drug and Cosmetic Act (FDCA) and the 1947 Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) as modified in 1978. Under these laws, the Environmental Protection Agency grants approval for the presence of certain levels of a particular pesticide on a specific agricultural commodity, that is, a "tolerance". Typical pesticide residue tolerances are given in Table 6. However, the Delaney Clause of the FDCA states that no tolerance may be set for any pesticide found to be oncogenic. Based on risk studies determined from carcinogenic effects in laboratory animals together with human dietary contamination levels, a

TABLE 6

Typical pesticide residue tolerances in the United States[a]

Pesticide	Crops, commodities	Tolerance ppm
Alachlor	Forage	0.2–0.75
Atrazine	Forage	0.1–0.25
Azinphos methyl	Fruits, vegetables, forage	0.3–5
Butylate	Fruits, vegetables	0.1
Captan	Fruits, vegetables	100
Carbaryl	Fruits, vegetables, forage	5–100
Carbofuran	Forage	0.1–1.0

[a] Data from Duggan (1969).

National Academy of Sciences study (1987) concluded that nearly 80% of the estimated oncogenic risk to humans is from residues to 10 pesticides. The study concluded that 98% of the oncogenic dietary risk could be eliminated by revoking the registrations of 28 carcinogenic pesticides.

PESTICIDES IN WILDLIFE

The widespread use of pesticides has occasioned much concern about adverse affects on wildlife. Significant reviews of this important subject include Hunt (1966), Dustman and Stickel (1966, 1969), and Cope (1971). Concern in this area has moved from studies of acute toxicity (Rudd and Genelly, 1956) to physiological, behavioral, and ecological implications of the toxicity to non-target organisms (Cope, 1966; Newsom, 1967; Johnson, 1968; Pimentel, 1971). Despite the implications of selective toxicity inherent in pesticide application it is evident that pesticide usage often has deleterious effects on non-target organisms. As Pimentel (1971) points out, pesticide usage in the United States is aimed at about 2000 pest species of plants and animals, but many of the remaining 200,000 non-target plants and animals, the great majority of which are necessary for human survival, are affected directly or indirectly. The anthropomorphic concepts of pest and beneficial species are not valid ecologically and it is obvious that both target and non-target organisms respond to pesticide contamination in a variety of essentially similar ways (Newsom, 1967).

Acute Toxicity of Pesticides

An important first step in assessing pesticide effects on organisms is the determination of the acute toxicity as LD_{50} in terms of dose applied, eaten, or injected; or LC_{50} in terms of concentration in the water, causing 50% mortality of an animal population. Knowledge of the comparative toxicities of a variety of pesticides to representative organisms is important in selecting pesticides for various uses and in assessing risks to non-target species. Unfortunately most of the large amount of data on quantitative toxicology deals with effects of a few compounds on a wide variety of species and there is little uniform data on a wide representation of species for the important pesticides. Table 8 presents a selection of toxicity values to a variety of organisms for the widely used pesticides for which adequate data is available. From the comparative viewpoint, the table shows the impossibility of profound generalizations about pesticide toxicity. Methoxychlor and malathion, two of the very safest materials to mammals and birds, are highly toxic to fish and invertebrates. Carbaryl, with low toxicity to mammals, birds, and fish is highly toxic to invertebrates. Zectran and carbofuran, among the most toxic compounds to mammals and birds, are of low toxicity to fish. Endrin, phorate, disulfoton, and parathion are general biocides, highly toxic to nearly all animals. Only the herbicides such as dalapon, dicamba, diquat, diuron, endothall, paraquat, 2,4-D, 2,4,5-T and simazine seem relatively safe to all the animals listed.

Ecological Magnification

This descriptive term applies to the ability of living organisms to concentrate stable, lipid soluble, water insoluble substances in their bodies either through successive accumulation in food chains or directly from water by partitioning. In this manner residues of substances such as DDT and dieldrin have been concentrated in fish $>1 \times 10^6$ and $>1 \times 10^5$ fold respectively over the concentration of the water. The first demonstration

of this remark-able phenomenon resulted from the treatment of Clear Lake, California with DDD at 0.014–0.02 ppm and the observance of DDD residues in Western grebes and predaceous fish at 1600–2500 ppm. The overall magnification was about 120,000-fold (Hunt and Bishoff, 1960). Woodwell *et al.* (1967) describe a Long Island, New York estuary where a DDT concentration of 0.00005 ppm became successively magnified in plankton (0.04 ppm), invertebrates (0.16–0.42 ppm), fish (0.17–2.07 ppm), and predatory birds (3.15–75.5 ppm). The DDT level was concentrated about 10-fold in each trophic level and appeared in the upper levels of the food web largely as DDE the most stable metabolite. The overall magnification was about 120,00 fold. The magnification of aldrin through a terrestrial ecosystem where Missouri cornfields were treated over a 15 yr period with a total of about 25 kg/ha was studied by Korschgen (1970). The soil contained an average residue of 0.06 ppm aldrin, earthworms averaged 1.49 ppm; seed-eating ground beetles *Harpalus* contained 1.1 ppm; the predaceous beetle *Poecilus* 9.67 ppm; the seed-eating mice *Peromyscus, Mus,* and *Reithrodontomys* averaged 0.98 ppm; toads, *Bufo americanus,* feeding on insects and other invertebrates, 4.60 ppm; and garter snakes *Thamnophis sirtailis* which eat salamanders, toads, earth-worms, and small birds and mammals, accumulated 10.3–14.4 ppm. Most of the aldrin was stored as the more stable metabolic oxidation product dieldrin and the overall magnification was about 200-fold.

The aquatic habit favors the concentration of trace residues in the stable organochlorine compounds in invertebrates and fish. Dustman and Stickel (1969) cite examples such as: fathead minnows concentrated endrin 10,000 ×; croakers concentrated DDT 20,000 ×; trout concentrated dieldrin 3300 × ; oysters concentrated lindane 60 ×; DDT 15,000 ×; and heptachlor 17,600 ×. In these cases, the water and the animal tissue, especially the lipids, seem to form a system of liquid-liquid partitioning between two immiscible solvents and Hamelink *et al.* (1971) suggest that in fish the pesticide passes through two partitions from water→ blood, and from blood→fat. They suggest that the partition coefficients for the various organo-chlorine pesticides are roughly proportioned to their solubility in fat (ca. 10 g/l)→ solubility in water (DDT 0.0012, γ-chlordane 0.009, aldrin 0.027, heptachlor 0.056, dieldrin 0.186, endrin 0.23, heptachlor epoxide 0.35, and lindane 10 ppm). Calculated partition coefficients for fat/water are: DDT ca. 10^6, dieldrin 5×10^4, heptachlor epoxide 3×10^4, and lindane 10^3 which are remarkably close to the actual levels of concentration observed in nature.

Pesticides and Fish

It will be noted from Table 8 that many of the organic insecticides are extremely toxic to fish in the ppb range, e.g. endrin, dieldrin, aldrin, heptachlor, toxaphene, chlordane and DDT. The synthetic pyrethroids are also toxic to fish in the ppb range. Disastrous fish kills have resulted from industrial effluents, accidental spillages and unwise disposal of spray tank residues into ponds and streams where fish and invertebrates may be killed for many miles downstream. Examples of such accidents include massive fish kills in the lower Mississippi River in 1963 attributed to effluents from the manufacture of endrin (Barthel *et al.,* 1969) and in the lower Rhine River from the sinking of a barge load of endsulfan.

DDT spraying of the Yellowstone River System in 1955 at 1 lb/acre by air for spruce budworm control was responsible for widespread mortality of mountain white-fish (*Proposium williamstoni*), brown trout (*Salmo trutta*) and longnose sucker (*Coatostomus catostomus*). After subsequent spraying in 1957, dead fish were analyzed for DDT and the trout contained from 0.186–14.0 ppm DDT and 0–6.53 ppm DDE, and the whitefish 0.06–6.9 ppm DDT and 0–5.6 ppm DDE (Cope, 1961). The prolonged and deleterious effects of such spraying on important invertebrate sources of fish food are shown in Table 9 (Cope, 1961). DDT aerial spraying of the Lake George region of New York for gypsy moth control was responsible for widespread contamination of the lake and total loss of lake trout fry in 1955–1958. The affected fry were observed to float upside down and then to sink and die. The symptoms always occurred after absorption of the yolk sac and subsequent study showed that DDT was present at 4.75 ppm or more in the fish eggs which displayed this syndrome and that as the yolk sac was absorbed the fish were poisoned and subsequently died (Burdick *et al.,* 1964).

Many other examples of the adverse effects of the organochlorine pesticides on fish could be cited, and the entire problem is reviewed by Johnson (1968).

Pesticides and Birds

The effects of pesticides on bird populations have been more intensively considered than any other aspect of the impact of pesticides on the environment. As with fish in the aquatic environment, most of the concern has been directed at the use of the persistent organochlorine insecticides (Moore, 1965; Rudd and Genelly, 1956). Massive spraying of elms with DDT to control the elm bark beetle vectors (Scolytidae) of Dutch elm disease has resulted in dying robins and other birds (Barker, 1958; Hickey and Hunt, 1960). Such spraying contaminated the soil up to 18 ppm and earthworms contain 53–204 ppm DDT and DDE. Robins feeding on the contaminated earthworms suffered as much as 80% mortality and their bodies contained a median residue of 3 mg DDT, an amount which could be obtained by eating less than 100 earthworms. The widespread use of cereal seeds treated with dieldrin, DDT and other organo-chlorine insecticides has been an important cause of bird mortalities. Sowing of DDT-treated rice seed in California resulted in residues in pheasants averaging 740 ppm in body fat and lowered survival rates (Hunt, 1966). Spring seeding with dieldrin, aldrin, and heptachlor treated seed in Great Britain produced substantial evidence of birth mortality and the use of seeds treated with the organochlorine insecticides has been restricted in both the U.S. and Great Britain (Moore, 1965).

Many of the pesticides listed in Table 8, especially aldicarb, carbofuran, diazinon, disulfoton, endrin, parathion, and

TABLE 9

phorate are acutely toxic to birds but their use patterns are such that damage to bird populations has not been extensive.

Thin eggshell syndrome Drastic reductions in the populations of North American and European raptorial birds such as the peregrine falcon, (*Falco peregrinus*), sparrowhawk (*Accipiter niger*), kestrel (*Falco tinnuncujlus*), osprey (*Pandion haliaetus*), bald eagle (*Haeliaetus leucocephalus*), and golden eagle (*Aquila chrysactos*) have been observed during the past 2 decades and these population declines coincided with the period of large scale use of DDT and other chlorinated organic insecticides. Although the complex reasons for these population declines are highly controversial, there is ample evidence that reproductive failure is a major factor (Pimentel, 1971). Egg shell fragility or thin egg shells is the most common cause and on Anacapa Island of California, where the complete reproductive failure of the brown pelican (*Pelecanus occidentalis*) was observed, egg shells were found to average 0.38 mm in thickness, or a decrease of 34% over normal (0.57 mm). Residues of DDT and DDE as high as 1200 ppm (85% DDE) were found and the fat of the adult birds, contained from 738–2603 ppm DDT and DDE (Pimentel 1971). A similar effect has been shown for the Scottish golden eagle where egg shell thickness has declined from an index of 3.146 over the period of 1848–1946, to 2.839 during 1951–1965, or a decrease of 9.9% (Ratcliffe, 1970). Bald eagle eggshells in Florida declined in weight from an average of 12.15 g in the pre-DDT era to 9.96g in 1947–1962 or an 18% decrease, and this has been associated with a decline in the eagle population in Florida (Pimentel, 1971) although other factors must also be considered.

Laboratory experiments summarized by Pimentel (1971) show that feeding DDE to mallard ducks at 40 ppm induced a 14% decrease in eggshell thickness and in cracking of eggs. Eggshell thinning occurred at DDE levels as low as 10 ppm and duckling production per hen was reduced as much as 75% when these levels of DDE were fed. DDT was less effective in producing the thin-eggshell effect than DDE although this occurred in coturnix fed DDT at 10 ppm and 25 ppm.

After the cancellation of registrations of DDT in 1973, the average body concentration in the lake trout of Lake Michigan declined from 19.2 ppm in 1970 to 2.2 ppm in 1984. However, the cancellation of aldrin and dieldrin registrations in 1974 had little effect on the average body concentration of dieldrin in lake trout, which was 0.27 ppm in 1970 and 0.38 in 1984. There has also been a decrease in the residues of DDT in herring gull eggs from 33.4 ppm in 1986 to 7.1 ppm in 1986, and in dieldrin residues from 0.82 ppm in 1976 to 0.28 in 1986 (Council Environ. Qual. 1987).

Methylmercury Fungicides These compounds, especially Panogen$^{®}$ or methylmercury dicyandiamide, have been very widely used as fungicidal treatments for small grains. In Sweden, as much as 80% of the spring wheat sown from 1940–1965 was treated with such alkylmercury fungicides. As a result, mercury became very widely distributed in wild birds. Borg *et al.* (1966) studied the mercury content of the livers of seed eating birds, pheasants, partridges, pigeons, finches, and so on, which were found dead. Of 253 birds investigated, 48% had Hg levels above 2 ppm and 20% above 10 ppm. There was a remarkable increase in the incidence of high levels of Hg in these bird livers during May–June and October–November, which related to the planting of seed dressed with alkylmercury fungicides during these months (Borg *et al.,* 1968). When pheasants were fed wheat treated with 20 ppm methylmercury dicyandiamide, a normal rate of agricultural use, the eggs had reduced hatchability with Hg residues of 1.3–2.0 ppm and the birds died in 29–61 days with liver residues of Hg ranging from 30 to 130 ppm. Wild pheasants and partridge eggs in Sweden contained about 30 ppm Hg (Borg *et al.,* 1966).

Predatory birds, hawks, falcons, eagles, and owls were also examined for Hg content of the liver. Of a total of 412 predators found dead, shot, or trapped for examination, 62% had Hg levels above 2 ppm and 19% above 10 ppm (Borg *et al.,* 1966).

The methylmercury readily entered food chains and it was found that hens in Sweden fed grain grown from wheat whose seed was treated with alkylmercury fungicides produced eggs abnormally contaminated with Hg. Swedish eggs on the open market, 1964–1966, averaged 0.029 ppm Hg as compared with 0.007 ppm Hg in eggs on the market in Continental Europe (Westöö, 1969). Thus a daily consumption of two Swedish eggs could exceed the FAO/WHO recommended safe level for Hg intake of 0.00005 mg per kg body weight. As a result of the wildlife contamination and the dietary egg problem, alkylmercury fungicides were banned in Sweden on February 1, 1966. Subsequently, the Hg contents of Swedish hens' eggs decreased to an average of 0.009 ppm by September 1967 (Westöö, 1969).

Pesticides and Bees

The honeybee *Apis mellifera* is not only an important domesticated animal producing honey and bees wax valued at $50 million annually in the U.S., but also is the primary agent responsible for the pollination of fruit, vegetable, and field crops valued in excess of $12 billion annually. As representative insects, bees are highly susceptible to insecticides and are a prime non-target victim of pesticides applied during blossom time when the bees' foraging patterns take them to sprayed orchards and field; or from pesticides carefully applied near apiaries. As an example of the damage that insect control programs can do to bee colonies, the repeated application of carbaryl to cotton in the Imperial Valley of California as part of an eradication program for the pink boolworm *Pectinophora gossypiella,* is estimated to have killed 30,000 colonies of bees in 1967.

Anderson and Atkins (1968) have classified the toxicity of pesticides to the honeybee *Apis mellifera* in groups as follows:

Group I *highly toxic* LD_{50} 0.001–1.99 μg per bee: includes the organophosphorus esters parathion, methyl parathion, azinphos, malathion, dimethoate, dichlorvos, diazinon, chlorpyrifos, fenthion, mevinphos, phosphamidon, naled, and fenitrothion; the carbamates carbaryl, carbofuran, aldicarb, propoxur, and Zectran®; and the organochlorine compounds aldrin, dieldrin, heptachlor, lindane; and the arsenicals. The newer synthetic pyrethroids such as permethrin, fenvalerate, deltamethrin, and flucythrinate are extremely toxic to bees with LD_{50} values <0.01 μg per bee.

Group II *moderately toxic* LD_{50} 2.0–10.99 μg per bee includes DDT, endrin, endosulfan, mirex, chlordane, disulfoton, phorate, demeton, ronnel, coumaphos, temephos, and carbophenothon.

Group III *relatively non-toxic* LD_{50} greater than 11.0 μg per bee includes all the common acaricides, trichlorfon, cryolite, DDD, methoxychlor, rotenone, ryania, toxaphene, the fungicides, the herbicides, and the defoliants.

Simple precautions such as avoiding insecticide applications during bloom, or applying toxic insecticides only as soil and seed treatments can greatly minimize bee losses.

PESTICIDES AND HUMANS

Humans, in an ecological sense, are consumers at the top of the food pyramid and are exposed to pesticide residues contained nearly everywhere in cereals, fruits and vegetables, and in meat, fish and poultry. Additionally humans are exposed directly to pesticides from occupational use of aerosol products in the home, from home and garden sprays, and from effluents from agricultural operations. Therefore it is not surprising that traces of the stable organochlorine insecticides are found in the body fats of humans everywhere.

DDT in Humans

Elaborate monitoring studies of pesticide residues in humans have been reported by Hayes (1966), Durham (1969) and Mrak (1969). DDT was first found in human fat in 1948 and at least 9 general surveys of the DDT content of human fat have been made in various areas of the United States. These show that DDT is stored in the body fat of everyone in the United States, with a mean storage level in the 1960's of about 8 ppm combined DDT and its principal metabolite DDE. With the revoking of the registrations of DDT in 1973 and aldrin and dieldrin in 1974, the levels of these insecticide residues in human body fat have declined slowly over the next decade as shown in Table 10. However, detectable tissue levels of oxychlordane, the principal persistent metabolite of chlordane, very widely used for household pest control have persisted unchanged (Table 10).

TABLE 10
Insecticide residues in human body fat—United States[a]

Year	DDT-T	dieldrin	oxychlordane
		ppm in fat	
1972	6.97	0.18	0.10
1974	5.15	0.14	0.12
1976	4.35	0.09	0.11
1978	3.52	0.09	0.11
1980	2.82	0.10	0.12
1983	1.67	0.06	0.10

[a] Council on Environmental Quality, 17th Report, 1987.

The storage levels of DDT and DDE in people in other countries have also been investigated (Durham, 1969). The levels were lowest in countries where little DDT is used, for example Denmark with DDT 0.6 and DDE 2.7 ppm; and highest in countries such as India, DDT 16 and DDE 10 ppm, where large amounts of DDT are used in malaria eradication.

The storage of DDT in human fat is a direct function of level of intake and is lowest in meat abstainers, DDT 2.3 and DDE 3.6 ppm; and Eskimos, DDT 0.8 and DDE 2.2 ppm, whose diets contained the lowest amounts of DDT. Volunteers given 35 mg per day orally stored DDT 281 and DDE 40 ppm, and a formulator in a DDT factory had DDT 648 and DDE 483 ppm; yet these men remained in good health (Hayes, 1966).

DDT and its metabolites DDE and DDD are also found in other human tissues: blood DDT 0.0068 and DDE 0.0114 ppm, milk 0.08–0.13 ppm, adrenal glands 0.7 ppm (Durham, 1969). DDT ingested by humans is excreted slowly as 4,4-dichlorodiphenyl acetic acid (DDA) which is present in the urine of the general U.S. population at <0.02–0.18 ppm (Hayes, 1966). The levels of DDA in human blood and urine roughly parallel the rate of intake and can be used to monitor the exposure (Mrak, 1969).

The significance of levels of DDT and its metabolites DDE and DDD in the general population is complex.

Food is generally believed to contribute as much as 89% of the total intake of DDT but recent studies showing substantial fat storage of DDT in Eskimos and in institutional patients where DDT intake is very low suggest that non-dietary sources such as house dust may contribute up to 50% of the total body burden (Mrak, 1969). The non-white population of the U.S. has significantly higher fat storage of DDT than the white population suggesting the influence of dietary factors and socioeconomic factors resulting in greater use of house-hold insecticides. Fat storage of DDE increases with the age of the population, especially in non-whites where the level increased from 4.06 ppm in the 0–5 yrs category to 8.61 ppm in 41–50 years, and 15.50 ppm at 90+ yrs. Accumulation in states with cooler climates averaged 4.85 ppm as compared with 9.21 ppm in warmer States. There is no clear cut evidence of a sex difference in fat storage of DDT or in positive association with specific disease conditions (Mrak, 1969).

Other Pesticides in Humans

Other stable organochlorine insecticides or their stable metabolites are also found in human tissues. Surveys of the U.S. population have shown levels of these materials in fat and blood: BHC isomers—fat 0.20–0.60 ppm, blood 0.0031–0.0019 ppm; heptachlor epoxide—fat 0.10–0.24 ppm, blood 0.0008–0.0011 ppm (Hayes, 1966; Durham, 1969). In addition to these pesticides demonstrated in the blood of the general U.S. population, trace levels of chlordane, toxaphene, endrin, aldrin, pentachlorophenol, and 2,4-D have been found in tissues of humans with unusual occupational or accidental exposure.

Most of the other types of pesticides widely used, the organophosphorus esters, carbamates, phenoxy- and benzoic-acids, triazines, ureas are less persistent in the environment than the organochlorine compounds and are rapidly metabolized by enzymes in the human liver and converted to predominantly water-soluble products eliminated in the urine. Therefore there is little evidence of fat storage of these compounds. Monitoring of the urinary content of water-soluble metabolities is a very sensitive measure of intake of such pesticides and has been studied for parathion, malathion and related organophorus esters, the carbamates carbaryl and propoxur, dinitro-*o*-cresol, lead, arsenic, and mercury (Hayes, 1966).

Acute Toxicity in Humans

The substitution of the more hazardous organophosphate and carbamate insecticides for the organochlorines has greatly increased the incidence of acute human poisoning. WHO has estimated that worldwide there are as many as 500,000 accidental poisonings annually with 20,000 deaths (Copplestone, 1977). In the United States, EPA estimates suggest that there are 45,000 accidental poisonings with 3000 hospitalizations and 200 deaths annually (Pimentel and Levitan, 1986).

GLOSSARY

alachlor, 2-chloro-2′,6′-diethyl-*N*(methoxymethyl) acetanilide
aldicarb, 2-methyl-2-methylthiopropionaldoxime *0-N* methylcarbamate
aldrin, 1,2,3,4,10,10-hexachloro-1,4,4a,5,8,8a-hexachloro-1,4-*endo,exo*-5,8-dimethanonaphthalene
amiben, 3-amino-2,5-dichlorobenzoic acid
atrazine, 2-chloro-4-ethylamino-6-isopropylamino-*s*-trianzine
azinphos, methyl, *0,0*-dimethyl S-[4-oxo-1,2,3-benzotriazine-3(4H)-ylemthyl] phosphorodithioate
bendiocarb, 2,3-(isopropylidenedioxy)- phenyl *N*-methylcarbamate
BHC, mixture of stereoisomeric 1,2,3,4,5,6-hexachloro-cyclohexane
butylate, *S*-ethyl diisobutylthiocarbamate
captan, *N*-trichloromethylmercapto-4-cyclohexane 1,2-dicarboximide carbaryl, 1-naphthyl *N*-methylcarbamate
carbofuran, 2,2-dimethyl-2,3-dihydro-7-benzofuranyl *N*-methylcarbamate
carbophenothion, *S*- [*p*-chlorophenyl] thiomethyl] *0,0*'-diethyl phosphorodithioate
CDAA, 2-chloro-*N,N*-diallyl acetamide
CDED, 2-chloroallyl-*N,N*-diethyldithiocarbamate
chlorbenzilate, ethyl 4,4′-dichlorobenzilate
chlordane, 2,3,4,5,6,7,8,8-octochloro-2,3,3a,4,7,7a-hexa-hydro-4,7-methanoindene
chlordimeform, *N*′-(4-chloro-2-methyl)-*N,N*-dimethylmethanimidamide
chlorpyrifos *0,0*-diethyl *0*-(3,5,6-trichloro-2-pyridylphosphorothionate
chlorsulfuron, 2-chloro-*N*-[(4-methoxy-6-methyl-1,3,5-triazin-2-yl)-aminocarbonyl]-benzenesulfonamide
Ciodrin, α-methylbenzyl-3-hydroxy-*cis*-crotonate dimethylphosphate coumaphos, *0,0*-diethyl *0*-(3-chloro 4-methyl-7-coumarinyl)
Phosphorothionate
cryolite, sodium fluoaluminate
cypermethrin, cyano-(3-phenoxyphenyl)-methyl-3-(2,2-dichloroethenyl)-2,2-dimethyl-cyclopropanecarboxylate
cyanazine, 2-[[4-chloro-6-(ethylamino)-*s* triazine-2-y]-amino]-2-methylpropionitrile
dalapon, 2,2-dichloropropionic acid
2,4-D, 2,4-dichlorophenoxyacetic acid
DDA, 4,4′- dichlorodiphenylacetic acid
DDD, 1,1-dichloro-2,2-bis- (*p*-chlorophenyl)-ethane
DDE, 1,1-dichloro-2,2-bis- (*p*-chlorophenyl) ethylene
DDT, 1,1,1-trichloro-2,2-bis- (*p*-chlorophenyl) ethane
deltamethrin, cyano-(3-phenoxyphenyl)-methyl-3-(2,2-dichloroeth-enyl)-2,2-dimethyl-cyclopropanecarboxylate
demeton, 40:60 mixture of *0,0*-diethyl *S*-(2-ethylthio—ethyl phophorothiolate with *0,0*-diethyl *0*-(2-ethylthio)ethyl phosphorothionate
diazionon, *0,0*-diethyl-*0*-(2-isopropyl-4-methyl-6-pyrimidinyl) phosphorothionate
dibromochloropropane, 1,2-dibromo-3-chloropropane
dicamba, 2-methoxy-3,6-dichlorobenzoic acid
dichloran, 2,6-dichloro-4-nitroaniline
dichlorvos, 2,2-dichlorvinyl dimethylphosphate
dicofol, 4,4′-dichloro-α-(trichloromethyl) benzhydrol
dieldrin, 1,2,3,4,10,10-hexachloro-*exo*-6,7-epoxy-1,4,4a,5,6,7,8,8a-octahydro-1,4-*endo, exo*-5,8-dimethanonaphtha-lene
Dilan, mixture of one part 1,1-bis(*p*-chlorophenyl)-2-nitro-propane and two parts 1,1-bis(*p*-chlorophenyl)- 2-nitrobutane
dimethoate, *0,0*-dimethyl *S*-(*N*-methylcarbamoylmethyl) phosphorodithioate
dinitro-*o*-cresol (DNOC), 4,6-dinotro-*o*-cresol
diquat, 1,1′-ethylene-2,2′-dipyridylium dibromide
disulfoton, *0,0*-diethyl *S*-2(ethylthio)ethyl phosphorodithioate
diuron (DCMU)*, N*-3,4-dichlorophenyl-*N*′, *N*″-dimethyl urea
endosulfan, 6,7,8,9,10,10-hexachloro-1,5,5a,6,9,9a-hexahydro-6,9-methano-2,4,3-benzodioxathiepin 3-oxide
Endothall, 7-oxabicyclo (2,2,1)heptane-2,3-discarboxylic acid
endrin, 1,2,3,4,10,10-hexachloro-*exo*-6,7-epoxy-1,4,4a,5,6,7,8,8a-octahydro-1,4,5,8-*endo, endo*-dimethanonaphthalene
EPTC, *S*- ethyl,*N,N*- dipropylthiocarbamate
fenitrothion, *0,0*-dimethyl *0*-(4-nitro-*m*-tolyl) phosphorothionate
fenthion, *0,0*-dimethyl *0*[4-(methylthio)-*m*-tolyl] phosphorothionate
ferbam, ferric dimethyl dithiocarbamate
fenvalerate, cyano-(3-phenoxyphenyl-methyl-4-chloro-*α* (1-methylethyl)-benzeneacetate
flucythrinate, cyano-(3-phenoxyphenyl)-methyl-4difluoromethoxy)-*α*-(1-methylethyl)-benzeneacetate
heptachlor, 1,4,5,6,7,8,8-heptachloro-3a,4,5,5a-tetrahydro-4,7-*endo*-methanoindene
heptachlor expoxide, 1,4,5,6,7,8,8-heptachloro-3a,4,5,5a-tetrahydro-2,3-epoxy-4,7-*endo*- methanoindene
lindane, *gamma*-isomer of 1,2,3,4,5,6-hexachlorocyclohexane
linuron, 3-(3,4- dichlorophenyl)-1-methoxy-1-methylurea
malathion, *0,0*-dimethyl *S*-(1,2-dicarbethoxyethyl) phosphorodithioate
maneb, manganese ethylene bis(dithiocarbamate)
MCPA, 4-chloro-2-methylphenoxyacetic acid
methomyl, S-methyl-*N*-[(methylcarbamoyl)-oxy]-thioacetimidate
methoxychlor, 1,1,1-trichloro-2,2-bis(*p*-methoxyphenyl) ethane
methyl parathion, *0,0-dimethyl 0-p*-notrophenyl phosphorothionate
mevinphos, 2-methoxycarbonyl-1-methylvinyl dimethyl-phosphate
mirex, dodecachlorooctahydro-1,2,3-metheno-2H-cyclo-buta (cd) pentalene
monuron, 3- (*p*-chlorophenyl)-1,1-dimethylurea
naled, 1,2-dibromo-*2,2*-dichloroethyl dimethylphosphate
nicotine, 1–1-methyl-2-(3*α*-pyridyl)-pyrrolidine
Panogen, methylmercury dicyandiamide
Paraquat, 1,1′-dimethyl-4,4′-bipyridynium ion

parathion, *0,0*-diethyl *0-p*-nitrophenyl phosphorothionate
pendimethalin, *N*-(1-ethylpropyl)-3,4-dimethyl-2,6-dimitrobenzeamine
permethrin, (3-phenoxyphenyl)-methyl-3-(2,2-dichloroethenyl)-2,2-dimethyl-cyclopropane carboxylate
o-phenylphenol
phorate, *0,0*-diethyl *S*-(ethylthio)-methyl phosphorodithioate
Phosphamidon, dimethyl diethylamido-1-chlorocrontonyl-(2) phosphate
picloram, 4-amino-3,5,6-trichloropicolinic acid
propachlor, 2-chloro-*N*-isopropyl-*N*-phenylacetamide
propham, isopropyl carbanilate
propoxur, *o*-isopropoxyphenyl *N*-methylcarbamate
pyrethrins, insecticidal compounds in pyrethrum flowers, *Chrysanthemum cineraniaefolium*
ronnel, *0,0*-dimethyl *0*-2,4,5-trichlorophenyl phosphorothionate
rotenone, extracts of *Derris* or *Lonchocarpus* plants
ryania, roots and stems of *Ryania speciosa*
silvex, 2-(2,4,5-trichlorophenoxy) propionic acid
simazine, 2-chloro-4,6-bis-(ethylamino)-3-triazine
2,4,5-T, 2,4,5-trichlorophenoxyacetic acid
temephos, *0,0,0′,0′*-tetramethyl *0,0′*-thiodi-*p*-phenyclene phosphorothionate
terbufos, *0,0*-diethyl *S*- 2-(*tert*-butylthio)-methyl phosphorodithionate
tetradifon, *S-p*-chlorophenyl 2,4,5-trichlorophenyl sulfone
tetraethyl pyrophosphate (TEPP)
thiram, tetramethylthiuram disulfide
toxaphene, mixture of isomers of octachlorocamphence (67–69% chlorine)
trichlorfon, dimethyl (2,2,2-trichloro-1-hydroxyethyl) phosphonate
trifluralin, *α,α,α*-trifluoro-2,6-dinitro-*N,N*-dipropyl-*p*-toluidine
warfarin, 3-(1′-phenyl-2′-acetylethy)-4 hydroxycoumarin
Zectran, 4-dimethylamino-3,5-xylyl *N*-methylcarbamate
zineb, zinc ethylene-1,2-bisdithiocarbamate

PHYSICAL AND CHEMICAL TREATMENT OF WASTEWATERS

INTRODUCTION

The substances in domestic and industrial wastewater having significance in water-pollution control, disposal, and reuse are (1) dissolved decomposable organic substances resulting in dissolved oxygen depletion in streams and estuaries and/or causing taste and odor; (2) suspended organic solids resulting in dissolved oxygen depletion; (3) inert suspended solids (SS) causing turbidity and resulting in bottom sediment deposits; (4) toxic synthetic organic substances and heavy metals; (5) oil, grease, and floating materials; (6) acids and alkalis; and (7) dissolved salts, including nutrients like phosphorus and nitrogen.

Conventional wastewater-treatment practices have been oriented to the removal of grit and floating matter followed by the removal of suspended and dissolved organic matter. The removal of suspended matter has been achieved by sedimentation, and the bulk of the soluble organic matter is removed by biological oxidation and flocculation. These processes, when carried out in combination, have proved to be economical and effective means for removing organic matter from wastewaters. However, there are certain disadvantages associated with them. These include the following:

1. Biological process require considerable operating control and often generate operating problems of a complex nature.
2. Biological processes are easily upset by shock loads and require time to regain efficient operation.
3. Biological processes are unable to remove certain nutrients, heavy metals, and inorganic salts, whenever there is a requirement for their removal.
4. Many waste streams contain certain compounds that do not respond to biological treatment or, alternatively, require extensive pretreatment.

In the last decades, physical-chemical treatment of wastewater has been studied both on laboratory and pilot-plant scales with important industrial and municipal wastewater-treatment applications. This type of treatment is used either as a pretreatment, tertiary treatment, or advanced treatment given to the effluent from secondary treatment, or as a substitute for conventional biological treatment. In the latter case, it is found to produce effluent of a quality at least equal to that produced by conventional biological treatment.

The first study on the treatability of raw wastewater by physical-chemical processes was reported by Rudolfs and Trubnick in 1935. In this study, solids were removed by chemical coagulation with ferric chloride followed by absorption of dissolved impurities with activated carbon.

Stander and Van Vuuren (1969) investigated the treatment of raw wastewater in a pilot plant where solids removal was achieved by primary sedimentation and chemical coagulation with lime, and adsorption with activated carbon. Rizzo and Schade (1969) have also reported results on the pilot-plant treatment of raw wastewater with chemical coagulation and anionic polymer and adsorption with activated carbon.

Zuckerman and Molof (1970) studied the efficiency of a treatment system in which raw wastewater was lime-clarified at high pH and then activated-carbon-treated: their results showed that the chemical oxygen demand (COD) values of the final effluent were significantly lower than those associated with good conventional treatment. Moreover, they concluded that the removal of soluble organics with activated carbon was enhanced because of the hydrolytic breakdown of high-molecular-weight organic compounds, at a higher pH value, which are absorbed more readily by activated carbon.

Weber et al. (1970) investigated the chemical clarification of primary effluent with ferric chloride followed by activated-carbon adsorption. Their results showed that 65% of the organic matter present in primary effluent was removed by chemical treatment with ferric chloride. Overall removal of biochemical oxygen demand (BOD) was reported as being consistently in the range of 95 to 97%. Final effluent from the system contained approximately 5 mg/l BOD as compared to 30 mg/l for the same wastewater treated conventionally.

In another study, Villiers et al. (1971) showed that the treatment of primary effluent by lime clarification and activated carbon, in a steady flow system, produced an effluent with total organic carbon (TOC) averaging 11 mg/l and turbidity averaging less than 2. Phosphates and SS removal were consistently 90% or better. These product characteristics are comparable to those associated with products from well-operated conventional treatment plants.

Shuckrow (1971) had developed a sewage-treatment process involving chemical coagulation for SS removal, followed by adsorption of soluble organics on powdered carbon. The advantages cited for this process were (1) a total treatment time of less than one hour, (2) a high-quality effluent,

(3) lower initial plant cost, (4) ability to remove nitrogen and phosphorus, and (5) a final sludge reduction to sterile ash in a centrifuge-incineration process combined with a chemical regeneration step to recover both the coagulant and the carbon. While the estimated operational costs were high, the overall costs during a 20-year plant life were considered to be significantly less than costs for comparable biological facilities.

Ecodyne Corporation's first complete physical-chemical treatment plant in Rosemount, Minnesota, with 0.04 to 0.08 m^3/sec peak capacity, consisted of bar screening, phosphate removal with sludge recirculation, dual media filtration, carbon absorption to remove dissolved organics, secondary filtration, and ammonia removal by ion exchange with zeolite. The plant included facilities for regenerating the carbon, recovering ammonia, and regenerating brine from the ion-exchange system (Ecodyne, 1972).

Examples of more recent research include an exhaustive review on the treatment of pulp- and paper-mill wastewater published by Pokhrel and Viraraghavan in 2004. This includes the different processes involved with their effluents, the different methods for treatment of these effluents, the integration of biological and physico-chemical processes, a comparison of them, and conclusions from this review. An article by Van Hulle and Vanrolleghem (2004) presents the development, calibration, and application of a model for the simulation and optimization of a wastewater-treatment plant. The constructed model proved to be able to predict large variations in influent composition. This could be an important tool for production scheduling when applied to industrial wastewater-treatment plants. Recent research in specific areas is included in for each process.

The number of water-treatment facilities in the United States by treatment capacities is presented in Table 1. Many of these facilities include some sort of physical-chemical treatment technology. A diagram of alternative technologies for wastewater treatment is shown in Figure 1; it includes most of the processes to be discussed in the next section. As environmental regulations, space availability, and cost factors affect the treatment of waste streams, more and more physical-chemical treatment will be needed to meet these constraints. This is an important research area that will continue to grow in the next years.

TABLE 1

Number of wastewater-treatment facilities in the United States (1996)

Flow ranges m^3/s	Number of facilities	Total existing flowrate m^3/s
0–0.00438	6444	12.57
0.0044–0.0438	6476	101.78
0.044–0.438	2573	340.87
0.44–4.38	446	511.12
>4.38	47	443.34
Other	38	—
Total	16204	1409.68

PHYSICAL AND CHEMICAL PROCESSES USED IN WASTEWATER TREATMENT

The following important unit operations and unit processes involved in the physical and chemical treatment of wastewater are discussed in detail:

Flow equalization and neutralization
Chemical coagulation, flocculation, and sedimentation
Filtration
Gas stripping
Ion exchange
Adsorption
Flotation
Chemical processes
Oxidative, photochemical, and electron-beam processes

Flow Equalization and Neutralization

Both domestic and industrial wastewater flows show considerable diurnal variation, and it is considered necessary to significantly dampen these variations in inflow to relieve hydraulic overload on both biological and physical-chemical plants. This process will also smooth out variations in influent characteristics.

Flow-equalization basins are basically flow-through or side-line holding tanks, and their capacity is determined by plotting inflow and outflow mass curves. These tanks are generally located after preliminary treatment and should be designed as completely mixed basins, using either diffused air or mechanical surface aerators, to prevent settling of suspended impurities. If decomposable organic matter is present in the wastewater, aeration will prevent septicity. The preaeration can also reduce the BOD on subsequent treatment units.

Flow-equalization basins can also be used to neutralize the acidity or alkalinity in incoming wastewater. The neutralizing chemicals are added to the inflow wastewater stream before entering the flow-equalization basins, and the retention period in these basins provides sufficient time for reaction. Any precipitates produced during neutralization are separated in subsequent sedimentation basins.

Chemical Coagulation, Flocculation, and Sedimentation

The use of chemical treatment appeared early in the development of sewage- and wastewater-treatment technology. Aluminum sulfate, lime, and ferrous sulfate, when used in the manner usually adopted for water clarification, were successful in producing an effluent of quality better than that obtained by plain sedimentation. An effluent that is generally fairly clear, with only very fine suspended or colloidal solids but with practically all of the dissolved solids remaining, can be produced. Under most favorable conditions and with skilled operation, SS may be reduced in an amount of up to 90% and BOD up to 85%. However, the

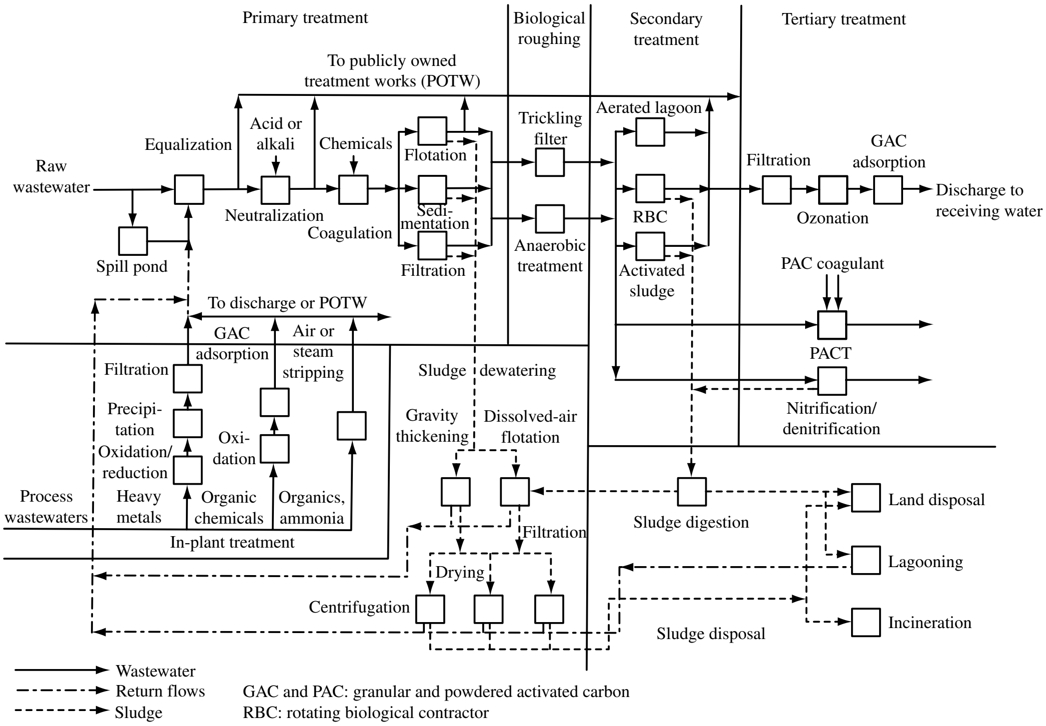

FIGURE 1 Alternative technologies for wastewater treatment (From Eckenfelder, 2000. Reprinted with permission from McGraw-Hill.)

cost of the coagulants and the difficulty of disposing of the larger amount of the sludge produced by this process caused it to be abandoned. The revival of chemical treatment can be attributed to a number of factors that accumulated as a result of continuous investigations and reevaluation of the process. These are (1) the decrease in cost of chemicals; (2) better understanding of floc formation and the factors affecting it; (3) the development of methods of sludge filtration and processing that overcome, in part, the difficulty of greater sludge bulk; and (4) the establishment of the relationship between eutrophication in streams and nutrients, particularly phosphorus, nitrogen oxides, and organic matter. This relation establishes the need of final effluent wastes free of such pollutants regardless of the cost of additional treatment.

The settling velocities of finely divided and colloidal particles in wastewaters are so small that removing them in a settling tank under ordinary conditions is impossible unless very long detention periods are provided. Therefore, it has been necessary to devise means to coagulate these very small particles into larger ones that will have higher settling velocities. The aggregation of dispersed particles in wastewater is induced by addition of chemical coagulants to decrease the effects of stabilizing factors such as hydration and zeta potential, and by agitation of the medium to encourage collisions between particles.

Because of the greater amount of suspended matter in sewage, the doses for chemical coagulants are generally considerably greater. Therefore, in order to keep costs down, it is important that the chemical reaction involved with each coagulant should be known and enhanced and that optimum pH values be obtained by adjustment with acid or base to get more efficient coagulation and clarification with least sludge production.

Coagulation Coagulation is a process in which chemicals are added to an aqueous system for the purpose of creating rapid-settling aggregates out of finely divided, dispersed matter with slow or negligible setting velocities. The potential applications of this process in treating wastewater are: (1) direct coagulation of organic matter present mostly as colloidal particles in wastewater; (2) the removal of colloidal substances prior to such tertiary treatment processes as ion exchange, carbon adsorption, and sand filtration; (3) the removal of colloidal precipitates formed in phosphate precipitation processes; and (4) the removal of dispersed microorganisms after a brief biooxidation process.

The majority of colloids in domestic wastewater or in organic wastes are of a hydrophilic nature; that is, they have an affinity for water. The affinity of hydrophilic particles for water results from the presence of certain polar groups such as $-COOH$ and $-NH_2$ on the surface of the particles. These groups are water-soluble and, as such, attract and hold a sheath of water firmly around the particle. The primary charge on hydrophilic colloidal particles may arise from ionization of the chemical groups present at the surface of the particles, e.g., carboxyl, amino, sulfate, and hydroxyl. This charge is dependent upon the extent to which these surface groups ionize, and thus the particle charge depends upon the pH.

The precise zeta potential that yields optimum coagulation must be determined for a given wastewater by actual correlation with jar test or plant performance. The control point has been reported to be in the range of 0 to −10 mV when raw sewage is coagulated by alum. It is important that coagulants contribute polyvalent ions of charge opposite to the zeta potential of the dispersion. On a molar basis, bivalent ions seem to be about 10 to 50 times and trivalent ions about 300 to 700 times as effective as monovalent ions for destabilization of dispersion in wastewater (Rich, 1963). The zeta potential is unaffected by pH in the range of 5.5 to 9.5 (Eckenfelder, 2000).

Since most dispersions encountered in wastewaters are stabilized by negative charges, coagulants required are polyvalent cations such as aluminum, ferric, ferrous, or calcium. Organic polyelectrolytes are also effective coagulants. Dispersions stabilized principally by electrostatic force are in general amenable to coagulation inasmuch as addition of small doses of suitable electrolytes may effect a significant change in zeta potential of the particles. The most widely used chemicals for coagulation of wastewater are the salts of aluminum and iron. Lime alone has also been used for precipitation of phosphates.

Aluminum Sulfate In order to form flocs, aluminum sulfate requires the presence of alkalinity, which, if naturally present in wastewater in the form of bicarbonate, would lead to the following reaction:

$$Al_2(SO_4)_3.xH_2O + 3Ca(HCO_3)_2 \rightarrow \\ 2Al(OH)_3 \downarrow + 3CaSO_4 + xH_2O + 6CO_2 \qquad (1)$$

In case of insufficient alkalinity in the wastewater, lime is generally added, and the reaction with alum becomes:

$$Al_2(SO_4)_3.xH_2O + 3Ca(OH)_2 \rightarrow \\ 2Al(OH)_3 \downarrow + 3CaSO_4 + xH_2O \qquad (2)$$

In the presence of phosphate, the following reaction also occurs:

$$Al_2(SO_4)_3.xH_2O + 2PO_4^{-2} \rightarrow \\ 2AlPO_4 \downarrow + 3SO_4^{-2} + xH_2O \qquad (3)$$

Aluminum hydroxide flocs are least soluble at a pH of approximately 7.0. The floc charge is positive below pH 7.6 and negative above pH 8.2 (Eckenfelder, 1966). The solubility of $AlPO_4$ is related to the pH and the equilibrium constant for the salt. Stumm and Morgan (1970) state that the solubility of aluminum phosphate is pH-dependent, and the optimum pH for phosphorus removal lies in the range of 5.5 to 6.5. Generally, at pH above 6.3, the phosphate removal occurs either by incorporation in a complex with aluminum or adsorption on the aluminum hydroxide flocs. According to Yuan and Hsu (1970), the reaction mechanism for precipitation of phosphates by aluminum hydroxide is very complex. They have proposed that the positively charged hydroxy-aluminum polymers are the species that accounts for the precipitation of phosphates and that effective phosphate precipitation can occur only when the positive charges on the polymers are completely neutralized. It is also reported that the effectiveness of aluminum is related to the nature and concentration of the foreign components present and to the ratio of phosphate to aluminum.

Alum has been used extensively for phosphate removal in raw wastewaters. Bench-scale tests of alum addition were conducted at Springfield, Ohio, and Two Rivers, Wisconsin (Harriger and Hoffman, 1971 and 1970, respectively). Raw wastewater at Springfield required an average Al:P mass ratio of 1.9:1 to achieve 80% removal, while at Two Rivers the average mass ratio was 0.93:1 to obtain phosphate removal of 85%. The stoichiometric equation (3) indicates that each kilogram of phosphorus requires 0.87 kg of aluminum for complete precipitation.

Ferrous Sulfate and Lime If ferrous salts are used for wastewater coagulation, addition of a small amount of base, usually sodium hydroxide or lime, is essential. The required dosage is related to the alkalinity of water. Ferrous sulfate reacts with calcium bicarbonate in water, but this reaction is much delayed and therefore cannot be relied on (Steel, 1960). Caustic alkalinity, due to the addition of lime to the wastewater, produces a speedy reaction. The lime is added first, and the following reaction takes place:

$$FeSO_4.7H_2O + Ca(OH)_2 \rightarrow Fe(OH)_2 + CaSO_4 + 7H_2O \qquad (4)$$

The ferrous hydroxide is not an efficient floc, but it can soon be oxidized by the dissolved oxygen in wastewater as ferric hydroxide:

$$4Fe(OH)_2 + O_2 + 2H_2O \rightarrow 4Fe(OH)_3 \downarrow \qquad (5)$$

An insoluble hydrous ferric oxide is produced over a pH range of 3 to 13. The floc charge is positive in the acid range and negative in the alkaline range, with a mixed charge over a pH range of 6.5 to 8.0. This process is usually cheaper than the use of alum but needs greater skill to dose with the two chemicals.

Ferric Chloride Ferric chloride has been used successfully for wastewater coagulation because it works well in a wide pH range (Steel, 1960; Wuhrmann, 1968). The reactions of ferric chloride with bicarbonate alkalinity and lime are, respectively:

$$2FeCl_3 + 3Ca(HCO_3)_2 \rightarrow 2Fe(OH)_3 \downarrow + 3CaCl_2 \\ + 6CO_2 \qquad (6)$$

$$2FeCl_3 + 3Ca(OH)_2 \rightarrow 2Fe(OH)_3 \downarrow + 3CaCl_2 \qquad (7)$$

Wuhrmann (1968) was successful in removing phosphates from sewage effluent by precipitation with a mixture of ferric salt and lime. The ferric dosages varied between 10 and 20 mg/l and the lime dosages from 300 to 350 mg/l in order to raise the pH to values between 8 and 8.3. The actual lime dosage required is related to the alkalinity of the water. According to Wuhrmann, the dominant reaction product between the phosphate ion and the ferric ion at pH above 7 is believed to be $FePO_4$, with a solubility product of about 10^{23} at 25°C. The colloidal particle size of the $FePO_4$ requires a sufficient excess of ferric ion for the formation of a well-flocculating hydroxide precipitate, which includes the $FePO_4$ particles and acts as an efficient adsorbent for other phosphorous compounds.

It has been reported that for efficient phosphorus removal (85 to 95%), the stoichiometric amount of 1.8 mg/l Fe required per mg/l P should be supplemented by at least 10 mg/l of iron for hydroxide formation. Also, the use of anionic polymer is considered desirable in order to produce a clear supernatant (Wukash, 1968).

Lime Lime reacts with the bicarbonate alkalinity of wastewater to form calcium carbonate, which precipitates, under normal conditions:

$$Ca(OH)_2 + Ca(HCO_3)_2 \rightarrow 2CaCO_3 \downarrow + 2H_2O \qquad (8)$$

Normally, 70 to 90% of the phosphorus in domestic sewage is in the form of orthophosphates or polyphosphates that may hydrolyze orthophosphates. The remaining phosphorus is present in the form of organic-bound phosphorus. The removal of phosphorus can be achieved by direct adsorption on the surface of calcium carbonate particles. Orthophosphates can also be precipitated in the alkaline range by reaction with calcium salts to form hydroxyapatite, according to the following reaction:

$$10Ca(OH)_2 + 6H_3PO_4 \rightarrow 10Ca + (PO_4)_6(OH)_2 \downarrow + 18H_2O \qquad (9)$$

Schmid and McKinney (1969) observed that hydroxyapatite was present in soluble form at a pH value above 9.5. They also found that at pH values of 9.5 or less, phosphorus was adsorbed onto the growing faces of calcium-carbonate particles, thereby inhibiting their growth. Buzzell and Sawyer (1967) have shown that at pH levels of 10 to 11 in the primary sedimentation tanks, BOD removal of 55 to 70%, nitrogen removal of 25%, phosphate removal of 80 to 90%, and coliform removal of 99% can be expected. Bishop et al. (1972) have reported that precipitation of domestic wastewater with lime removed approximately 80% of the TOC, BOD, and COD; 91% of the SS; 97% of the total phosphorus; and 31% of the total nitrogen. Phosphates from secondary effluent have been removed successfully at Lake Tahoe by precipitation with lime (Slechta and Culp, 1967). Albertson and Sherwood (1967) found that by recirculating calcium-phosphate solids, previously formed due to the addition of lime, it was possible to reduce the lime dosage by about 50%.

Galarneau and Gehr (1997) present experimental results of their studies on phosphorous using aluminum hydroxide. de-Bashan and Bashan (2004) present an extensive review of recent advances in phosphorous removal from wastewaters and its separation for use as a fertilizer or as an ingredient in other products.

In wastewater-treatment practices, it is detrimental to form large floc particles immediately in the flocculation step because it reduces the available floc surface area for adsorption of phosphorus. Therefore, it is essential to maintain fine pinpoint flocs in order to get a maximum phosphate removal by surface adsorption, and this can be achieved by minimizing the time of their flocculation. This is not the case if the goal is one of colloidal-solids removal, as is often the case in water treatment.

The process of coagulation and flocculation in wastewater treatment can be summarized in the following three steps:

1. As the coagulant dissolves, positive aluminum and ferric ions become available to neutralize the negative charges on the colloidal particles including organic matter. These ions may also react with constituents in solution such as hydroxides, carbonates, phosphates, sulfides, or organic matter to form complex gelatinous precipitates of colloidal dimensions that are termed "microflocs." This is the first stage of coagulation, and for greatest efficiency a rapid and intimate mixing is necessary before a second reaction takes place.
2. After the positively charged ions have neutralized a large part of the colloidal particles and the zeta potential has been reduced, the resulting flocs are still too small to be seen or to settle by gravity. The treatment, therefore, should be flocculation, slow stirring so that very small flocs may agglomerate and grow in size until they are in proper condition for sedimentation. Some evidence suggests that aggregation of microflocs with dispersed waste constituents is the most important mechanism affecting coagulation in water treatment (Riddick, 1961).
3. During the third phase, surface adsorption of particles takes place on the large surface area provided by the floc particles. Some of the bacteria present will also become entangled in the floc and carried to the bottom of the tank.

Electrocoagulation Electrocoagulation is a process in which the coagulating ions are produced by electrolytic oxidation of sacrificial electrodes. This technique has been successfully used in the removal of metals, suspended particles, colloids, organic dyes, and oils. An interesting review of this technique is presented by Mollah et al. (2001). In it the advantages and disadvantages of electrocoagulation are presented as well as a description and comparison with chemical coagulation. His group studied its use in the treatment of a synthetic-dye solution with a removal of 99% under optimal conditions (Mollah, Morkovsky, et al., 2004). Another publication (Mollah, Pathak, et al., 2004) presents the fundamentals of electrocoagulation and the outlook for the use of this process in wastewater treatment. Lai and Lin (2003) studied the use of electrocoagulation for the treatment of chemical mechanical polishing wastewater, obtaining a 99% copper removal and 96.5% turbidity reduction in less than 100 minutes.

Sedimentation Sedimentation basins are important components in water- and wastewater-treatment systems, and their performance greatly depends upon proper design. In chemical treatment of wastewater, the separation of chemically coagulated floc depends on the characteristics of the floc in addition to the factors normally considered in the design of conventional primary and secondary clarifiers. Field experience indicates that the usual values for surface overflow rates used in separating chemical floc in water-treatment plants must be reduced in order to obtain a good efficiency in the removal of floc from chemically coagulated wastewater (Weber et al., 1970; Convery, 1968; Rose, 1968; Kalinske and Shell, 1968). In wastewater-treatment practices, the recommended overflow rate for removal of alum floc is 30 m/day, while with use of lime or iron salts, it can be increased up to 40 m/day.

Filtration

Filtration of wastewater can be accomplished by the use of (1) microscreens, (2) diatomaceous earth filters, (3) sand filters, (4) mixed media filters, or (5) membranes. The filtration of sludges, on the other hand, is achieved by sand beds or vacuum filters.

The filtration characteristics of the solids found in a biological treatment plant effluent are greatly different from those of the floc formed during chemical coagulation for the removal of organic matter and phosphates. Tchobanoglous and Eliassen (1970) have noted that the strength of the biological floc is much greater than that of the flocs resulting from chemical coagulation.

Accordingly, biological flocs can be removed with a coarser filter medium at higher filtration rates than can the weaker chemical flocs, which may shear and penetrate through the filter more readily. Lynam et al. (1969) had observed that the chemical floc strength can be controlled, to some degree, with the use of polymers as coagulant aids. Their experiments yielded higher SS removal by filtration when 1 mg/l of anionic polymer A-21 was used along with alum.

The filterability of solids in a conventional biological plant effluent is dependent upon the degree of flocculation achieved in the biological process. For example, filtration of the effluent from a trickling-filter plant normally cannot yield more than 50% removal of the SS due to the poor degree of biological flocculation in trickling filters. On the other hand, the activated sludge process is capable of a much higher degree of biological flocculation than the trickling-filter process. The degree of biological flocculation achieved in an activated sludge plant was found to be directly proportional to the aeration time and inversely proportional to the ratio of the amount of organic material added per day to the amount of SS present in the aeration chamber (Culp and Hansen, 1967a). It has also been reported that up to 98% of the SS found in the effluent from a domestic sewage-treatment plant after a 24-hour aeration time could be removed by filtration without the use of coagulants (Culp and Hansen, 1967b).

Microscreening Microscreens are mechanical filters in which flow is passed through a special metallic filter fabric placed around a drum. The filter traps the solids and rotates with the drum to bring the fabric under backwash water sprays fitted to the top of the machine, in order to wash the solids to a hopper for gravity removal to disposal. The rate of flow through the microscreen is determined by the applied head, normally limited to about 150 mm or less, and the concentration and nature of the SS in the effluent.

Extensive tests at the Chicago Sanitary District showed that microscreens with a 23 μm aperture could reduce the SS and BOD of a good-quality activated sludge effluent, 20–35 mg/l SS and 15–20 mg/l BOD, to 6–8 mg/l and 3.5–5 mg/l, respectively (Lynam et al., 1969). It was noted that the microscreens were more responsive to SS loading than to hydraulic loading and that the maximum capacity of the microscreens was reached at the loading of 4.3 kg/m^2/day at 0.27 m/min.

Diatomaceous Earth Filtration Diatomite filters found their widest application in the production of potable waters, where the raw water supply was already of a relatively good quality, i.e., of low turbidity. Operating characteristics of diatomite filters can now be predicted under a wide range of operating conditions by utilizing several mathematical models (Dillingham et al., 1966, 1967). Several investigators have studied the filtration of secondary effluent by diatomite filters whose ability to produce an excellent-quality effluent is well established (Shatto, 1960; R. Eliassen and Bennett, 1967; Baumann and Oulman, 1970). However, the extremely high cost and their inability to tolerate significant variations in SS concentration limit the usage of diatomite filters in sewage-treatment practices.

Sand Filtration Sand filters have been operated as slow sand filters or as rapid sand filters made with one or more media. A slow sand filter consists of a 150- to 400-mm-thick layer of 0.4-mm sand supported on a layer of a coarser material of approximately the same thickness. The underdrainage system under the coarser material collects the filtrate. The rate of flow through the filter is controlled at about 3 m/day. This rate is continued until the head loss through the bed becomes excessive. Then the filter is thrown out of service and allowed to partially dry, and 25 to 50 mm of the sand layer, which includes the surface layer of sludge, is manually scraped from the top for washing. Disadvantages of slow sand filtration system are: (1) the filters may become inoperative during the cold winter weather, unless properly housed; (2) slow sand filters may not be effective due to the rapid clogging of filters (the normal frequency of cleaning filters varies from once to twice a month; Truesdale and Birkbeck, 1996); (3) the cost of slow sand filtration is three times the cost of rapid sand filters and twice the cost of microscreens (anonymous, 1967); and (4) the large space requirement.

Rapid sand filters consist of about a 400-mm-thick layer of 0.5- to 0.65-mm sand supported on coarser gravel. The rate of filtration ranges between 80 and 120 mm/min. At this high filtration rate, the filter beds need backwashing when the head loss becomes excessive.

Lynam et al. (1969) reported results of detailed tests conducted on filtration of secondary effluent from an activated sludge plant of the Chicago Sanitary District. They used a filter bed of 0.85-mm-effective-size sand in a 280-mm depth and a filtration rate of 120 mm/min, and analyzed the data in terms of both hydraulic and SS loadings. Poor correlations were obtained between effluent quality and hydraulic loading, effluent quality and solids loading, and solid removal and hydraulic loading. However, an excellent correlation existed between SS loading and SS removals. It was also observed that the sand filtration of alum-coagulated solids was no better than that of uncoagulated solids, and the optimum SS removal was obtained by alum and polymer coagulation in combination with sand filtration.

A review of the retention of pathogenic bacteria in porous media is presented by Stevik et al. (2004). The review includes the factor affecting bacteria retention and the factors that effect elimination of bacteria from porous media. The authors also suggest priority areas of research in this field.

Multimedia Filtration The limitation of the single medium rapid sand filter follows from its behavior as a surface filtration device. During filter backwashing, the sand is graded hydraulically, with the finest particles rising to the top of the bed. As a result, most of the material removed by the filter is retained at or very near the surface of the bed. When the secondary effluent contains relatively high solids concentrations, the head loss increases very rapidly, and SS clog the surface in only a few minutes. One approach to increase the effective filter depth is to use dual-media beds consisting of a discrete layer of coarse coal placed above a layer of fine sand.

More recently, the concept of mixed-media filters has been introduced in order to achieve a filter performance that very closely approaches an ideal one. In this case a third layer of a very heavy and fine material, garnet (with specific gravity of 4.2) or illmenite (with specific gravity of 4.5), is placed beneath the coal and sand. Conley and Hsiung (1965) have suggested the optimum design values for these filters. The selection of media for any filtration application should be based on the floc characteristics. An example of a typical dual-media filter is shown in Figure 2.

Moving-Bed Filters These types of filters were put on the market by the Johns-Manville Corporation in the late 1960s. It is a continuous sand filter in which influent wastewater passes through the bed and becomes product water. Solids trapped on the filter face and within the bed move with the filter media, countercurrent to the liquid. Solids and small amounts of filter media regularly removed from the filter face are educted to the filter media tower without stopping operations. Solids are scrubbed from the media and discharged as a waste sludge, while the washed media is fed back into the bed.

The filter medium usually used is 0.6- to 0.8-mm sand with a maximum sand-feed rate of 5 mm/min and maximum filtration rate of 85 m/day (2100 U.S. gal/day/ft^2). The advantages claimed for this system are (1) automatic and continuous operation, (2) that the filter allows much higher and variable solids loadings than is permissible with a sand bed, and (3) that through an efficient use of coagulant chemicals, the system has the flexibility to reduce turbidity, phosphorus, SS, and BOD to the desired level (Johns-Manville Corporation, 1972).

Membrane Filtration Membrane filtration is being applied more extensively as membrane materials are becoming more resistant and affordable. Fane (1996) presents a description of membrane technology and its possible applications in water and wastewater treatment. An extensive study on microfiltration performance of membranes with constant flux for the treatment of secondary effluent was published by his research group in 2001 (Parameshwaran et al., 2001). Kentish and Stevens (2001) present a review of technologies for the recycling and reuse of valuable chemicals from wastewater, particularly from solvent-extraction processes.

A feasibility study on the use of a physico-chemical treatment that includes nanofiltration for water reuse from printing, dyeing, and finishing textile industries was performed by Bes-Pia et al. (2003). In this work jar tests were conducted for flocculation using commercial polymers followed by nanofiltration. Their results show that the combination reduces COD from 700 to 100 mg/l. Another treatment approach by the same authors (2004) uses ozonation as a pretreatment for a biological reactor with nanofiltration as a final step. A combined approach is presented by Wyffels et al. (2003). In this case a membrane-assisted bioreactor for the treatment of ammonium-rich wastewater was used, showing this to be a reliable technology for these effluents.

Galambos et al. (2004) studied the use of nanofiltration and reverse osmosis for the treatment of two different wastewaters. For their particular case the use of reverse osmosis was more convenient due to the high quality of the effluent, but the permeate of the nanofiltration can only be released into a sewer line or would have to be treated, resulting in an economic compromise. A comparison between a membrane bioreactor and hybrid conventional wastewater-treatment systems at the pilot-plant level is presented by Yoon et al. (2004).

The removal of volatile organic compounds (VOCs) using a stripper-membrane system was studied by Roizard et al. (2004). Their results show that this hybrid system can be used for the removal of toluene or chloromethane with a global efficiency of about 85%.

Vildiz et al. (2005) investigated the use of a coupled jet loop reactor and a membrane for the treatment of high-organic-matter-content wastewater. The main function of the membrane is the filtration of the effluent and the recycle of the biomass to the reactor. One advantage of the system is its reduced size as compared with traditional treatment systems, as well as a better-quality effluent.

A comprehensive review on the use of nanofiltration membranes in water and wastewater use, fouling of these membranes, mechanisms of separation, modeling, and the use of atomic force microscopy for the study of surface morphology is presented by Hilal et al. (2004). The future of

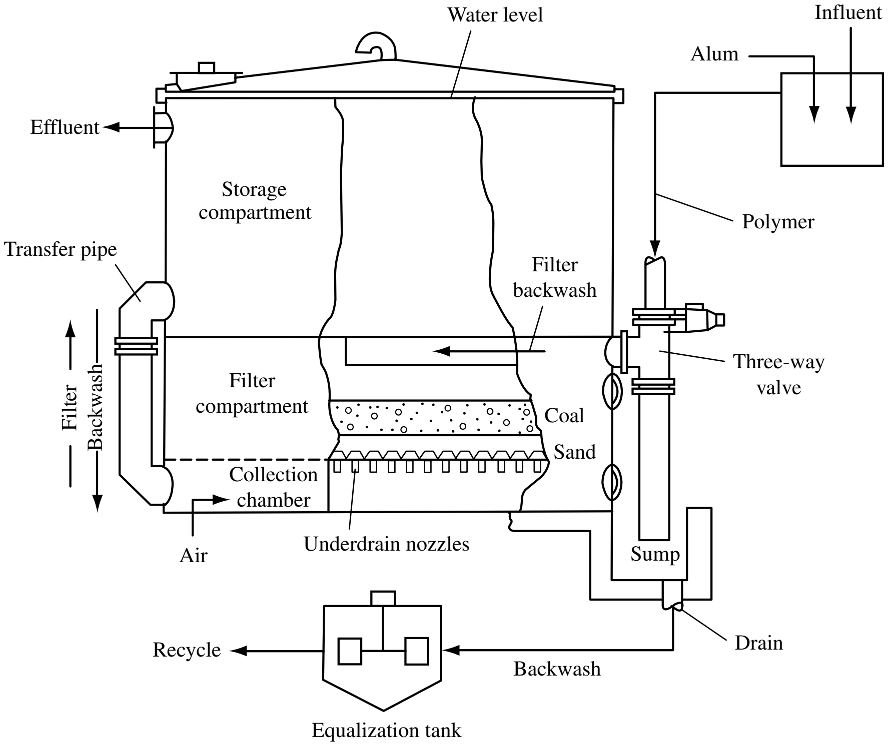

FIGURE 2 Typical dual-media filter (From Eckenfelder, 2000. Reprinted with permission from McGraw-Hill.)

membranes and membrane reactors in green technology and water reuse was published by Howell (2004). In it, water problems in different regions of the world are discussed, different membrane systems are presented, and different approaches for new research are introduced.

Reverse Osmosis There are several reverse-osmosis units currently in use to produce freshwater from seawater. With recent improvements in membranes, this process is also being used for purification of wastewater. Substantial removal of BOD, COD, total dissolved solids, phosphate, and ammonia by this process has been reported (Robinson and Maltson, 1967).

In a reverse-osmosis process, wastewater containing dissolved materials is placed in contact with a suitable semipermeable membrane in one of the two compartments of the tank. The pressure on this compartment is increased to exceed the osmotic pressure for that particular waste in order to cause the water to penetrate the membrane, carrying with it only a small amount of dissolved materials. Therefore, the dissolved material in the wastewater gets concentrated continuously, while highly purified water collects in the other compartment.

The performance of the reverse-osmosis process depends mainly on (1) the membrane semipermeability or its efficiency to separate dissolved material from the wastewater, and (2) the membrane permeability or the total amount of water that can be produced with appropriate efficiency for the removal of dissolved materials. It has been reported that the conventional cellulose-acetate membranes give adequate separation efficiency, but the flow rate of water is too small to be of practical interest. However, cellulose-acetate membranes allow a much higher flow rate of product water, at the same separation efficiency, which makes it applicable in wastewater-treatment practices (Goff and Gloyne, 1970).

The operating pressure, as well as the rejection performance of the membrane, is dependent on the membrane porosity. Rejection performances of three graded membranes with secondary sewage effluent were investigated by Bray et al. (1969).

Merten et al. (1968) evaluated the performance of an 18.9 m^3/day pilot reverse-osmosis unit in removing small amounts of organic material found in the effluent of carbon columns treating secondary effluent. With a feed pressure of 2760 kPa and water recovery of 80 to 85%, 84% removal of COD present in the carbon column effluent, averaging 10.8 mg/l, was achieved. Problems of clogging have occurred when operating with waters containing high concentrations of bicarbonate, and as such, adjustment of pH to prevent calcium-carbonate precipitation is normally required.

Sadr Ghayeni et al. (1996) discuss issues such as flux control and transmission in microfiltration membranes and biofouling in reverse-osmosis membranes in their use for the reclamation of secondary effluents. The process used for the study consisted of a microfiltration membrane followed by a reverse-osmosis membrane. The performance of this combined system was evaluated by Sadr Ghayeni et al. (1998b), as was the study of the adhesion of bacteria to reverse-osmosis membranes (1998a).

A study on the processing of composite industrial effluent by reverse osmosis was published by Sridhar et al. in 2003. The effluent used in the study was from combined bulk drug and pharmaceutical companies, obtaining a removal of 88% of dissolved solids, COD, and BOD, with reasonable water recovery. They also present a comparison between aerobic and reverse-osmosis treatment for this effluent.

A physical-chemical process for the treatment of chemical mechanical polishing process wastewater is presented by Lin and Yang (2004). In it the authors used chemical coagulation using different coagulants followed by reverse osmosis, obtaining water capable of being reused in the process due to its characteristics.

Electrodialysis Electrodialysis involves the removal of inorganic ions from water by creating an electrical potential across two electrodes dipped in water. One of the two strips serves as a cathode and the other as an anode. The treatments that can be achieved by electrodialysis include:

1. Removal of inorganic ions: Under the effect of applied potential, cations and anions migrate to the cathode and anode, respectively. By alternating membranes, a series of concentrating and diluting compartments can be created. For a long run and better efficiency, it is essential that turbidity, SS, colloids, and trace organics are removed from the wastewater before it enters the electrodialysis unit.
2. Effective bacteria reduction in wastewater: Most of the municipal wastewaters contain a high concentration of chloride ions. Oxidation of chloride at the anode produces chlorine, hypochlorite, or chloramines, depending on the nature of the wastewater. Chlorine in these forms is a good disinfectant and also provides an effective means of reducing soluble BOD.

In order to reduce the operating cost of the electrodialysis process, the eroding anodes made of aluminum or iron are now being replaced by nonconsumable noble anodes, which appear to have more potential in wastewater treatment (Culp and Culp, 1971). The cost of disinfection by electrodialysis is reported to be 0.053 \$/m^3 of wastewater as compared to 0.095 \$/m^3 for the conventional chlorination (unpublished proposal, 1970). However, some other sources have reported that the cost of electrolytic treatment of wastewater was too high for the removal of a large percentage of secondary effluent COD.

Grimm et al. (1998) present a review of electro-assisted methods for water purification, including electrodialysis. Fukumoto and Haga (2004) applied this technique for the treatment of swine wastewater with removal rates for NO_3^- and PO_4^{-3} ions of 99% and an average color reduction of 58%.

Gas Stripping

In domestic wastewaters, most of the nitrogen that gets converted to ammonia during biological degradation is present either as ammonia or in organic form. When the carbon concentration in wastewater becomes low and the nitrifying bacteria are populous, this ammonia can be oxidized by bacteria to nitrites and nitrates in the presence of dissolved oxygen. The stripping process can be employed either before or after secondary treatment for removing high levels of nitrogen that is present as ammonia. If it is to be used as pretreatment prior to a biological system, enough nitrogen, N:BOD = 5:150, must be left in the effluent to satisfy the nutritional requirement (Eckenfelder and Barnhart, 1963).

In wastewater, ammonium ions exist in equilibrium with ammonia and hydrogen ions:

$$NH_4^+ \leftrightarrow NH_3 \uparrow + H^+ \tag{10}$$

At pH levels of 6 to 8, ammonia nitrogen is mostly present in the ionized form NH_4^+. Increasing the pH to above 10 changes all the nitrogen to ammonia gas, which is removable by agitation. The stripping of ammonia from wastewater is carried out with air. In this operation, wastewater is agitated vigorously in a forced-draft countercurrent air-stripping tower when the ammonia is driven out from the solution and leaves with the air exhausted from the tower. The efficiency of ammonia removal in the stripping process depends upon the pH, airflow rate, tower depth, and hydraulic loading to the tower.

Slechta and Culp (1967) have shown experimentally that the efficiency of the ammonia-stripping process is dependent on the pH of the wastewater for pH values up to 10.8. However, no significant increase in ammonia removals was achieved by elevating the pH above 10. Kuhn (1956) had come to the same conclusion. It has also been reported that the efficiency of the ammonia-stripping process depends on maximizing the air–water contact within the stripping tower. Higher ammonia removals and lower air requirements were obtained with a 40 × 50-mm packing than with a 100 × 100-mm packing. Increased tower depth, which provides additional air–water contact, results in greater ammonia removals and lower air requirements. Ammonia removals of 90%, 95%, and 98% were obtained at airflow rates of 1875, 3000, and 6000 m^3 per cubic meter of wastewater, respectively.

Gas stripping is also used for removal of H_2S and VOCs from wastewater.

Ion Exchange

The ion-exchange process has been adopted successfully in wastewater-treatment practice for removing most of the inorganic dissolved salts. However, the cost of this method for wastewater treatment cannot be justified unless the effluent water is required for multiple industrial municipal reuse. One of the major applications of this technique is the treatment of plating-industry wastewater, where the recovery of chrome and the reuse of water make it an attractive choice (Eckenfelder, 2000).

Gaffney et al. (1970) have reported that the modified DESAL process, developed for treating acid mine drainage waters, can be applied successfully to the treatment of secondary sewage effluent. This process consists of passing secondary sewage-plant effluent upflow through an ion-exchange unit filled with a weak base anion exchange resin, Amberlite IRA-68, operated on a bicarbonate cycle. The effluent with a pH of 6.0 is then treated with a small quantity of bentonite and cationic flocculant, Prima floc C-7, followed first by aeration to drive out carbon dioxide, and then lime softening in proportion to its hardness concentration. A dosage of 30 mg/l of bentonite, 3 to 5 mg/l of polyelectrolyte, and normal lime levels are required. The effluent that is partially desalinated and essentially free of nitrates, phosphates, chlorides, alkyl benzene sulfonate (ABS), and COD can be produced. If the salinity is too high, it may be reduced further by passing a portion of the effluent through a weak acid cation, Amberlite IRC-84. It has been observed that IRA-68 can remove much of the organic contents and COD, thereby eliminating or markedly reducing the need for carbon treatment.

Slechta and Culp (1967) tested a cationic resin, Duolite C-25, for the removal of ammonia nitrogen from the carbon column effluent that was containing ammonia nitrogen in the range of 18 to 28 mg/l as nitrogen. A 100-mm-diameter Plexiglas cylinder filled to a depth of 700 mm with the resin served as the pilot ion-exchange column. The rate of application of influent waste to the ion-exchange column was 0.4 m^3/min per cubic meter of resin. Following breakthrough of the ammonia nitrogen to 1 mg/l, the bed was backwashed and the resin was regenerated. On the average, about 400 bed volumes of carbon column effluent had been passed through the ion-exchange resin prior to a breakthrough to 1 mg/l ammonia nitrogen. However, considering the operating and capital costs, they concluded that the ammonia-stripping process was more efficient.

Nitrate nitrogen, present in the effluent from the activated sludge process, has been removed by anion exchange regenerated with brine by R. Eliassen and Bennett (1967). This ion-exchange process also removes phosphates and some other ions; however, pretreatment by filtration is essential. The resin is restored by treatment with acid and methanol.

The removal of heavy metals with Mexican clinoptilolite was studied by Vaca Mier et al. (2001). In this study the interactions of lead, cadmium, and chromium competed for the ion-exchange sites in the zeolite. The authors also studied the influence of such factors as the presence of phenol and the pH of the solution to be treated.

Adsorption

Application of adsorption on granular active carbon, in columns of counterflow fluidized beds, for the removal of traces or organic pollutants, detergents, pesticides, and other substances in wastewater that are resistant to biological degradation has become firmly established as a practical, reliable, and economical treatment (Slechta and Culp, 1967; Weber, 1967; Parkhurst et al., 1967; Stevens and Peters, 1966; Presecan et al., 1972).

Adsorption can also be accomplished with powdered carbon (Davies and Kaplan, 1964; Beebe and Stevens, 1967), which is mixed in wastewater, flocculated, and ultimately settled. However, there are certain problems associated with the use of powdered carbon. These are: (1) that large quantities of activated carbon are needed in wastewater treatment, because it is used only on a once-through basis, and handling of such large quantities of carbon also creates a dust problem, and (2) problems in disposal of precipitated carbon unless it is incinerated along with the sewage sludge.

Carbon-Adsorption Theory Less polar molecules, including soluble organic pollutants, are removed by adsorption on a large surface area provided by the activated carbon. Smaller carbon particles enhance the rate of pollutant removal by providing more total surface area for adsorption, partial deposition of colloidal pollutants, and filtration of larger particles. However, it is almost always necessary to remove finely divided suspended matter from wastewater by pretreatment prior to its application on a carbon bed.

Depending on the direction of flow, the granular carbon beds are either of the downflow-bed type or upflow-bed type. Downflow carbon beds provide the removal of suspended and flocculated materials by filtration beside the absorption of organic pollutants. As the wastewater passes through the bed, the carbon nearest the feed point eventually becomes saturated and must be replaced with fresh or reactivated carbon. A countercurrent flow using multiple columns in series is considered more efficient. The first column is replaced when exhausted, and the direction of flow is changed to make that column the last in the series. Full countercurrent operation can best be obtained in upflow beds (Culp and Culp, 1971).

Upflow carbon columns for full countercurrent operations may be either of the packed-bed type or expanded-bed type. Packed beds are well suited to treatment of wastes that contain little or no SS, i.e., turbidity less than 2.5 JTU. However, the SS invariably present in municipal and industrial wastewaters lead to progressive clogging of the carbon beds. Therefore, expanded-bed upflow columns have certain potential advantages in operation of packed-bed adsorbers for treating wastes that contain SS. In expanded-bed-type adsorbers, water must be passed with a velocity sufficient to expand the bed by about 10%, so that the bed will be self-cleaned.

Experiments conducted by Weber et al. (1970) have shown that expanded-bed and packed-bed adsorption systems have nearly the same efficiency with regard to the removal of soluble organic materials from trickling-filter effluent, under otherwise similar conditions. The packed-bed system was found to be more effective for removal of SS, but the clogging that resulted from these solids required higher pumping pressure and more frequent cleaning of the carbon beds. Because of the time elapsed in cleaning, the expanded-bed production was about 9% more than the packed-bed production.

The Lake Tahoe Water Reclamation Facilities, described by Slechta and Culp (1967), included pretreatment of secondary effluent by chemical clarification and filtration, thereby providing a highly clarified feed and permitting an extended operation of carbon beds. Carbon beds were of the upflow full-countercurrent columns and were usually operated as packed types since the turbidity of the applied water was always less than 0.3 JTU. The columns were also operated at times as expanded beds by drawing 10% of the carbon.

The efficiency of carbon bed treatment depends on:

1. Contact time between the carbon and the wastewater
2. The pH of the wastewater (below pH of 9.0, the rate of adsorption of organics in wastewater increases with decreasing pH)
3. Temperature of the wastewater
4. Quality of the influent.

Carbon-Bed Design The following are the important design parameters used in the design of activated-carbon beds:

1. Properties of filtering material: The two most common sizes of granular carbon normally used for wastewater treatment are 8 × 30 mesh and 12 × 14 mesh; 8 × 30 mesh carbon is preferable, although its surface area is less, because it reduces losses during regeneration, head loss is less, and the operation of the filter becomes easier. Culp and Culp (1971) have reported the desirable physical properties for granular activated carbon for use in wastewater treatment.
2. Depth of carbon bed: 3 to 10 m.
3. Flow rates: 140 to 700 m^3/min per square meter of column cross-sectional area. For optimum performance of the bed, the actual depth and rate of flow should be determined by a dynamic pilot-plant test in the laboratory.
4. Activated carbon contact time: 15 to 35 mm, depending on the objective of treatment and the impurities to be removed from the wastewater.

A diagram of a carbon-gas-adsorption process is presented in Figure 3.

In the 1970s, over 30 granular activated-carbon plants were designed in the United States for use at municipal wastewater-treatment plants (DeJohn and Edwards, 1981). Thirteen of the plants are classed as physical-chemical and 15 as tertiary treatment plants, and 4 use carbon to dechlorinate. According to the authors, there have been some problems encountered at certain physical-chemical and tertiary treatment plants, but in their opinion, granular activated carbon is a viable treatment alternative when applied under proper conditions (Grieves et al., 1964).

One of the changes in conventional treatment technology is the use of the PACT (Powdered Activated Carbon Treatment) process using powdered carbon in the aeration tank of an activated sludge system (Meidl, 1981). The development

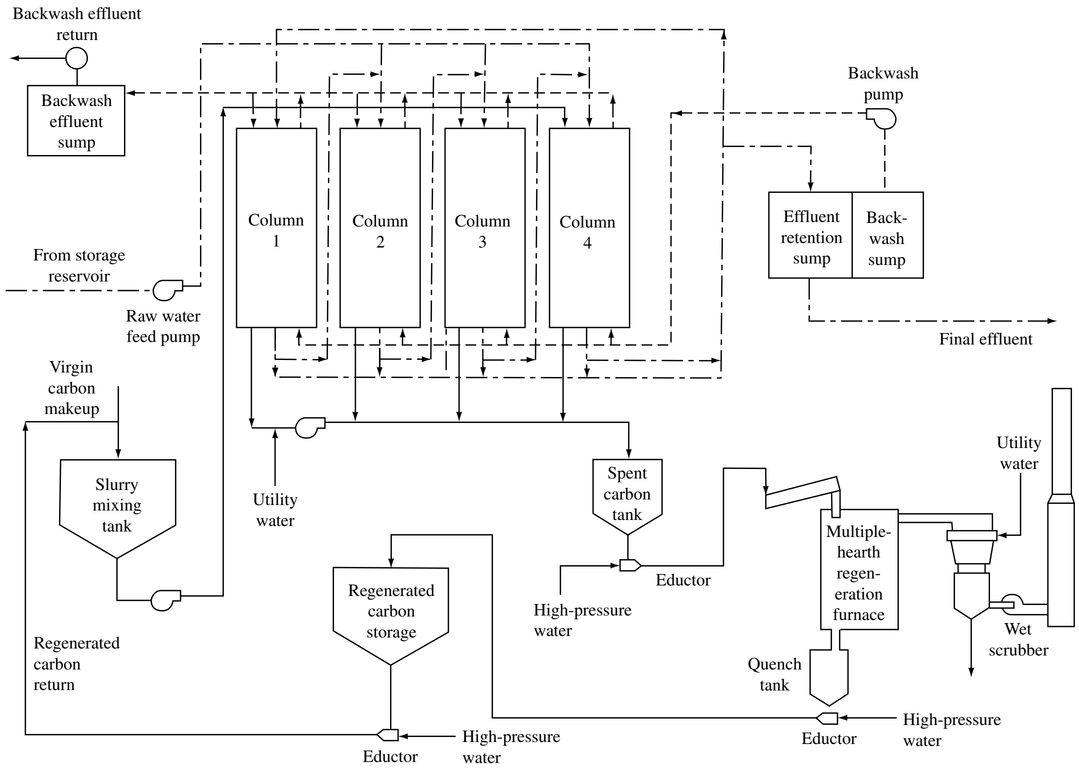

FIGURE 3 Carbon-adsorption process diagram (From Eckenfelder, 2000. Reprinted with permission from McGraw-Hill.)

of PACT in municipal wastewater treatment resulted from the inability of the physical-chemical treatment process to adequately treat wastewater. This process has been used successfully to treat domestic wastewater from a residential population of 30,000 in Vernon, Connecticut, and many other plants have been under construction. Similar applications of combined powdered-carbon and activated-sludge treatment to various industrial wastewaters, particularly coal-gasification wastewaters, are shown to be successful.

Miyake et al. (2003) studied the adsorption equilibrium isotherms of trichloroethylene (TCE) vapor stripped from TCE-polluted waters. These results can be used for wastewater treatment of waters with the same pollutant. A combined Al(III) coagulation/carbon adsorption process for the treatment of reactive dyes in synthetic wastewater was proposed by Papic et al. (2004). This process achieved 99.9% reduction of the dyes in the wastewater as well as 95.7 and 91.3% COD reduction for the two waters used. They conclude that the proposed process has many advantages, such as high efficiency, low use of coagulant, minimal sludge production, and high-quality product water with reuse potential.

Adsorption of Pollutants on Biomaterials A review of potentially low-cost adsorbents for heavy metals was presented by Bailey et al. (1999). Minamisawa et al. (2004) investigated the adsorption of cadmium and lead ions on different biomaterials, concluding that this is a promising alternative for the removal of these ions. Another review was published in 2004 by Gardea-Torresdey et al., concluding that Cd, Cu, Ni, Cr, and other ions have been successfully removed from solutions using different biomaterials. Gong et al. (2005) studied the use of peanut hull as a biosorbent for the removal of anionic dyes in a solution, obtaining sorption capacities of between 13.99 and 15.60 mg per gram of biosorbent for three different dyes.

Flotation

Surface-active contaminants, if present in wastewater, will produce foam upon aeration. This foam rises to the surface of the wastewater and can be separated and concentrated. Moreover, as the foam generates and rises, certain suspended impurities also get removed by entrainment. Thus, the foam-separation process can be developed to provide a selective removal of soluble and colloidal pollutants in various concentrations from water or wastewater. The process may either utilize the surface-active impurities present in the wastewater or may require the addition of a specific surface-active agent prior to aeration; soluble or colloidal impurities of interest may be precipitated to improve their removal.

Factors affecting the efficiency of the process of foam separation are:

1. Airflow rate/surface-active agent or airflow-rate-to-waste-flow-rate ratio (the removal efficiency increases when increasing the airflow rate, but yields wetter foam)
2. Air-bubble size (fine-bubble aeration improves the efficiency of foam separation, whereas coarse bubbles or deck aeration are not efficient)
3. Nature and concentration of surface-active agents
4. Foam stability
5. pH of the wastewater
6. Detention period (a short aeration time, 5 minutes or so, is considered sufficient)
7. Surface-to-volume ratio (a large surface-to-volume area is conducive to higher efficiency)

The process of foam separation has been used successfully in a number of waste-treatment applications. These include (1) removal of surface-active materials such as ABS from secondary effluent sewage (Klein and McGauhey, 1963; Grieves et al., 1964; Brunner and Lemlich, 1963; Fldib, 1963); (2) removal of radioactive ions from dilute aqueous solutions by the addition of anionic surface agents (Schoen and Mazella, 1961; Schoen et al., 1962; Schnepf et al., 1959); (3) removal of specific surfactants from refining and petrochemical wastewaters (Grieves and Wood, 1963); (4) foam fractionation of phenol (phenolate) from aqueous solutions using a cationic surfactant, ethyl hexadecyl dimethylammonium bromide, as the foaming agent (Grieves and Aronica, 1966); (5) the treatment of cyanide and acid chromate wastes (cyanide is precipitated with ferrous ions, and the ferrocyanide precipitates are floated with a cationic surfactant in a pH range of 5 to 7; acid chromate is reduced and precipitated as $Cr(OH)_3$, and these precipitates are floated with an anionic surfactant [Grieves, 1972]); (6) the treatment of liquid wastes from the scrubbing of phosphate and fluoride from air-pollution emissions of the phosphoric-acid-manufacturing industry (these include precipitation by lanthanum (III), followed by flotation with an anionic surfactant [Grieves, 1972]); (7) clarification of turbid raw water supplies by microflotation-activated carbon process (Grieves, 1972); and (8) physical separation of SS and coagulated dissolved organic impurities from wastewaters. ABS serves as activator for bubble attachment in flotation treatment of sewage (Klein and McGauhey, 1963). Other applications include the treatment of mine-drainage wastes combined with secondary sewage effluents and removal of H_2S from sour wastes.

An overview on flotation in wastewater treatment was published by Rubio et al. in 2002. The authors explain the process, present conventional and emerging flotation techniques and processes, and discuss the applications of the technique to different compounds. An example of a dissolved air flotation (DAF) process is presented in Figure 4.

Chemical Processes

An extensive review on catalytic abatement of water pollutants was published by Matatov-Meytal and Sheintuch in 1998. In it they present the oxidation and reduction processes involved as well as a discussion on catalyst support and deactivation. A discussion on the use of iron for wastewater treatment was published by Waite (2002). This article presents the research challenges and the new possibilities in

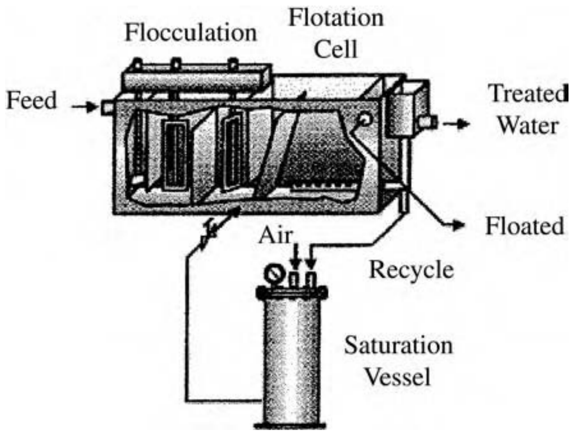

FIGURE 4 Conventional DAF unit with water recycle to the saturator (From Rubio et al., 2002, with permission from Elsevier).

this area. A review on the use of ferrate (VI) salt as a coagulant and oxidant for water and wastewater treatment is presented by Jiang and Lloyd (2002). In this paper the authors demonstrate the advantages of this approach in the treatment of microorganisms, heavy metals, and SS, as well as present the difficulties associated with this technique.

Ghoreishi and Haghighi (2003) propose a combined bisulfite catalyzed sodium borohydride reduction followed by activated sludge for the treatment of nonbiodegradable textile effluent, reposting reductions of BOD, COD, and TSS of 74–88%, 76–83%, and 92–97% respectively. Lin and Wang (2004) investigated the performance of a proposed granulated activated carbon bed combined with ozonation and preceded by chemical coagulation, obtaining interesting results. Akcil (2003) discusses the advantages of using biological methods for the treatment of cyanide in gold-mill effluents as compared to well-established chemical methods. Chung et al. (2003) evaluated the performance of a combined chemical absorption–biological oxidation system for the removal of H_2S from gaseous streams such as those produced by livestock wastewater-treatment plants. They demonstrated the potential of this technique and obtained reductions on the order of 85%. Another combined approach is presented by Libra and Sosath (2003). In this case they used ozonation followed by a biological process for the treatment of textile wastewater, comparing two configurations of treatment processes, concluding that the most attractive alternative is the simplest: ozonation followed by aerobic treatment as compared to anaerobic, aerobic, ozonation, and aerobic treatments for their effluent and conditions.

A comprehensive review on the properties of alumina, the chemical reactions involved in its use in water treatment, and adsorption and catalysis using alumina was published by Kasprzyk-Hordern in 2004. An interesting review on the enhancement of biodegradability of industrial wastes by chemical-oxidation pretreatment is presented by Mantzavinos and Psillakis in 2004. This exhaustive review includes many different pollutants, trends, and process schemes used as segregation by effluent type; evaluation of the pretreatment steps; and modeling of the individual steps involved.

Aiyuk et al. (2004) propose a chemically enhanced primary treatment followed by a UASB reactor for the treatment of domestic wastewater. The chemical pretreatment consisted of the addition of $FeCl_3$ or $Al_2(SO_4)_3$ and polymers in a mixing tank, and a posttreatment of the biologically treated water was achieved by zeolite adsorption for NH_4^+ removal. Another combined solution was proposed by Bressan et al. in 2004. This approach includes the use of an enhanced Fenton process followed by biological treatment of olive-mill wastewater.

Oxidative, Photochemical, and Electron-Beam Processes

Oxidizing agents like chlorine, ozone, hydrogen peroxide, potassium permanganate, and ultraviolet irradiation have been used successfully in oxidizing and stabilizing certain impurities like hydrogen sulfide, phenol, cyanide, and selected refractory organic substances. The reaction of chlorine with certain organic matter present in wastewater to form a more harmful persistent chemical has raised a serious question of continuing the use of chlorine for disinfection of wastewater effluents. Ozone is gradually becoming more popular, because it has strong oxidizing and disinfecting capacity and leaves no harmful residuals. It has been shown that ozone in combination with photochemical oxidation economically removed inorganic, organic, and toxic refractory species and effectively destroyed phenol in a bubble column or a stirred cell (Wall, 1980; Otake, 1979). Ganes and Staubach (1980) have reported the kinetics of the reaction between ozone and nitrilotriacetate in water and the effects of pH, metal content, and natural organics on the rate and extent of degradation.

In 1993, Legrini et al. published an extensive review on photochemical processes for water treatment, including UV, H_2O_2/UV, ozone/UV, O_3/H_2O_2/UV, TiO_2/UV, vacuum UV, photochemical electron-transfer processes, and energy-transfer processes. In 1999, Andreozzi et al. published studies on the use of O_3/UV and O_3/H_2O_2 for the treatment of mineral-oil-polluted wastewaters, performing different experiments and achieving an 80 to 90% reduction of COD for the O_3/UV treatment (Andreozzi et al., 1999). A discussion of the different advanced oxidation processes (AOP), as well as experimental apparatus and working procedures for the study of the application of this technique, is presented in Andreozzi et al. (2000).

An extensive review on photocatalytic degradation was presented by Bhatkhande et al. (2001). In it they include a description of the process, the mechanisms implied, the compounds that can be degraded with it, and the variables that can affect this technique. Another review was published by Kabra et al (2004), concluding that this process can be used to treat industrial wastewater for the removal of metal ions and nonbiodegradable organics. Another conclusion is that the costs of this method are slightly higher than for conventional methods, but that future research can make a competitive option. An interesting article on the evaluation of the use of peracetic acid for the disinfection of the effluent of Montreal's wastewater-treatment plant was published by Gehr et al. in 2003. In this study the authors presented and evaluated the different alternatives (with the exception of chlorine, due to environmental regulations) arriving at the conclusion that using the current process, the economically viable alternative is UV, while if some changes are made upstream, the use of peracetic acid could be a viable alternative.

A study on the application of different AOPs to the treatment of textiles, Kraft bleaching, photoprocessing, and pharmaceutical wastewaters was published by Balcoglu et al. in 2003. They conclude that the efficiency of the AOP process used for a particular application depends upon the pretreatment used, and concentrations and types of pollutants present in the influent.

Adesina (2004) investigated the use of photocatalysis for the treatment of spent industrial Bayer liquor and detoxification of paper-mill effluents, among others. The use of sunlight as an energy source is also discussed. A comparison of different AOPs and chemical-treatment options was conducted by Azbar et al. (2004) for the reduction of color and COD from an acetate- and polyester-dyeing process. They conclude that AOPs have better performances than chemical-coagulation methods for the parameters studied. They also found that UV/H_2O_2 achieved 99% and 96% COD and color removal, respectively. Their choice from the economic point of view was the Fenton's reagent process. The removal of the drug diclofenac by means of UV/H_2O_2 was studied by Vogna et al. (2004), showing that the proposed treatment was effective for the degradation of the drug. The behavior of the process Fe(III)/Air/UV was studied by Andreozzi and Marotta (2004) by using benzoic acid as the molecule to be treated, with the goal of developing kinetic models for this process. A study on the treatment of cork-processing wastewater was published by Acero et al. in 2004. They evaluated the use of different combinations of UV, H_2O_2, and O_3 and Fenton's reagent and photo-Fenton processes for the effluent under study and concluded that the best options that produce reusable water are those involving ozone.

Broad reviews on oxidation technologies at ambient conditions and on hybrid methods for wastewater treatment were published by Gogate and Pandit (2004a, 2004b). Tabrizi and Mehrvar (2004) present an interesting article on the integration of AOPs and biological processes, including recent developments, trends, and advances in this field. A review on the degradation of chlorophenols via AOP was published by Pera-Titus et al. in 2004. Among their conclusions is that although photocatalytic processes show higher half reaction times, they do not require oxidants or further separation of byproducts after the reaction.

Ding et al. (1996) present a review of catalytic oxidation in supercritical water, including the reactions involved, the processes available, a comparison with subcritical water oxidation, and an extensive review of the catalysts available. Kritzer and Dinjus (2001) published an interesting evaluation of the problems of supercritical water oxidation, with discussion and suggestions for its improvement.

Ultrasound Ultrasound is being studied as an alternative solution for environmental problems. This process works by generation of highly reactive oxidizing species, such as hydroxyl, hydrogen, and hydroperoxyl radicals as well as hydrogen peroxide by means of ultrasound waves (Vajnhandl and Majcen Le Marechal, 2005). In their review they include the use of ultrasound in the textile industry and its wastewaters.

Electrochemical Oxidation Panizza and Cerisola (2004) published results on a series of experiments using an electrochemical cell for the treatment of synthetic-tannery wastewater using two different electrodes under various experimental conditions, concluding that electrochemical methods can be effectively applied for the final treatment of these effluents, achieving total COD, tannin, and ammonium removals.

Electron-Beam Wastewater Treatment Water irradiation with ionizing radiation generates several very reactive ions and molecules. Getoff presents a review and the state of the art for radiation-induced degradation of water pollutants (1996). His group has studied the use of radiation for disinfection and decomposition of pollutants in water and wastewater for years. Among the experimental factors proposed to affect the efficiency of this process in pollutant degradation are: form of radiation, energy, absorbed dose and dose rate, pollutant concentration, pH, temperature, effect of oxygen and ozone, presence of ozone and TiO_2, and molecular structure of the pollutants (2002).

Pikaev et al. (2001) applied electron beams followed by coagulation for the treatment of mixed distillery and municipal wastewater; they conclude that the proposed scheme can treat the effluent at lower cost than the biological and sedimentation processes. In 2002 his group published pilot-plant experiments using electron-beam and biological oxidation for the treatment of dyeing wastewater. In this research they conclude that the proposed method reached the desired effluent characteristics in about 8 hours of treatment, as compared to 17 hours for biological treatment alone (Pikaev, 2002). In collaboration with researchers from Korea, he also used electron beams combined with coagulation, flocculation, and biological processes for the treatment of paper-mill effluents. This research concluded with the design of a commercial plant for the treatment of 15,000 m^3/day of wastewater with 80% of water reuse (Shin et al., 2002). In a final publication, Pikaev (2002) presents data on the treatment of different pollutants, including carboxylic acids, distillery slops, and petroleum products. In this work the author presents an economic evaluation of a commercial plant, concluding that the treatment costs for the proposed technology are about half of conventional methods.

PLANNING

Planning is a field of study which encompasses a number of related physical development and social and scientific functions including land use analysis, transportation planning, housing policy, economic analysis, environmental planning, urban and rural development and redevelopment. The broad goal of planning is to provide thoughtful examination of physical development and related public policy initiatives.

Planning has evolved from the early social concerns of 19th Century urban life—crowding, squalor and unhealthful living conditions focuses attention on such concepts as the public interest and on laws which protect the public health and safety. Controls on the location of unhealthful industrial uses such as slaughterhouses have evolved into land use planning and zoning controls. Concern for over crowding and provision of adequate light and air are now measured by housing analysis and population surveys.

Planning is an inter-disciplinary field which brings an understanding of public health, legal and social issues, and architectural design principles to develop theories of the history and future of development patterns. From principles of urban design appropriate street layout, open space and urban densities are derived which provide light and air. Traffic transportation planners identify the need for mass transit systems as well as traffic improvements. Standards in environmental planning provide a background to evaluate costs, benefits and impacts of new developments and initiatives.

Planners are a diverse and loosely defined group who identify themselves by the branch of planning they engage in, thus land use planners, public health planners, economic planners, housing planners and transportation planners working side by side and within their own particular area of expertise in government and private industry.

The advancement of the public interest and the protection of the public health, safety and welfare are two principles which continue to support a myriad of planning initiatives. The goals can be seen within the studies of environmental planning: wetland management and other conservation efforts are viewed as controls which protect the public interest; air quality controls protect the public health, safety and welfare.

Planners utilize academia as a home base, where the lessons of urban planning are taught, together with analytical methods for the determination of social and scientific standards and criteria urban design and aesthetic principles. Professional planning societies also provide information and forums for discussion on planning issues. The American Institute of Certified Planners (AICP) offers a membership admittance test which serves to provide a roster of qualified professionals. Ethics standards promulgated by the AICP attempt to self-police the profession. Only two states, New Jersey and Michigan, license professional planners.

The key analytical methods and models of planners include survey and sampling methods, ranking strategies, program evaluation, location planning, population forecasting and models for measuring impact of landuse actions including air quality analysis, transportation capacity, and employment, economic and fiscal impact.

Land use planners utilize planning principles to determine appropriate locations for land uses within a specified area. The land use planner may be employed by a town or city to conduct long range planning and maintain and advance the master plan through day to day land use decision-making. Comprehensive plans provide forecasting tools for a variety of resources, population trends and social service needs, resource projections and utility and infrastructure investments as well as transportation planning, roadway improvements, and conservation lands and sensitive environmental lands.

The role of government in planning in the United States is generally regarding as a local activity, for example, defining the appropriate use for the abandoned industrial plant in your home town is a local decision-making process. However, planners are engaged at each level of government; that is, the federal, State and local level. From these broad perspectives the role of a planner shifts to reflects the changing role of government.

The federal government provides planning through public policy initiatives and laws and regulation. The two functions adhere to the two pronged principles of planning; the public interest and the public health safety and welfare. The public interest is served through programs which promote a particular public policy initiative which is encouraged, such as open space or local park funding. Federal programs which administer funding for state and local actions, such as Community Development Block Grants for urban redevelopment promote the public interest. Promulgation and enforcement of regulations which protect the public health safety and welfare include the Clean Air Act, the Clean Water Act, and the Safe Drinking Water Act.

The National Environmental Policy Act of 1969 is a key milestone within the federal government, aimed at promoting the general welfare, in that it requires federal actions to be subject to both inter-governmental and public review. The intent of this law is to provide for a careful analysis of the likely effects of an action prior to use of federal funds. This law serves to open up the process of government decision-making to the public. In addition, the NEPA legislation provides a model for similar environmental scrutiny at the state and local level, thus providing a network of environmental planning at all levels of government.

In terms of land use decision-making, there is no central planning. The federal government role is confined to public policy, grants in aid and regulatory control (the environmental controls placed on filling of wetland areas is an issue which most closely approximates central planning in that the effect of these regulations can often nullify development proposals which may be encouraged at the local level).

Information gathering, such as census data provided by the Department of Commerce, is the key central planning function used universally by planners in all disciplines and sectors: statistics and forecasts are used by public agencies, private consultants and commerce and industry to understand and plan for communities with regard to population, transportation, housing, the economy and employment and a host of demographic and industrial data.

At the State level, planning functions are both assumed from the federal government and conveyed to local governments. State governments serve to administer federal programs and assume responsibility for enforcement of some key planning and environmental responsibilities such as the Clean Air Act. Often, compliance with federal goals in one area forms the basis for government aid or funding of related public initiatives, for example, efforts to comply with air quality goals are often related to transportation funding. The State works closely with federal agencies as a conduit for policy and funding of government programs, often creating mirror agencies for administration of transportation, historic preservation and environmental protection. Also parallel and in association with the federal government, States provide for the collection and dissemination of statistical information such as the census and economic forecasting.

The state government assigns and provides to local governments the authority to plan and zone. The power to plan in its narrow sense, land use control, is based upon the police power. Planning is seen to protect the health safety and general welfare of the public. The majority of planning work is done at the municipal level (a certain amount of master planning and regional coordination is provided at the country and state level). The first element in municipal planning is the formulation of the Master Plan. The Master Plan or comprehensive plan is an amalgam of public policy objectives and practical information for future planning such as existing demographic information and trends with projections of the future to the benefit of landuse plans, transportation plans, utilities, and education. The master plan should be a unique reflection of both the physical elements of the city and the people who live in it. Thus the master plan, which culminates in a landuse map becomes the guide to the development regulations of a city.

The zone plant sets forth the physical controls on uses and densities within the jurisdictional area. The physical layout of the city is assigned uses, densities and standards for development in a land use plan. A zone plan presents the regulations which carry out a given land use plan. The integrity of a zone plan is as strong as the development review boards. Planning Boards and Zoning Boards are charged with maintaining the integrity of the plan with the power to review subdivision, site plan and various requests.

The site plan review process illustrates the typical planning exercise and scope and range of municipal review powers. The site plan review, and variance requests, for example, a use variance, are subject to review and scrutiny from a municipal board with regard to the merits of the site plan, the need for the use, how the use is consistent with the master plan, how it advances planning goals of the community and what hardships or unique physical characteristics would justify a departure from set development standards and proscribed uses.

Many municipalities have established environmental commissions, architectural or historical resource review boards all which serve to advise in the site plan review pursuant to the general welfare. The environmental review at the municipal level should encompass the full range of relevant issues to asses the scope of the proposed activity and its likely impact on site and surrounding resources.

PLANNING FOR NEW PROCESSES: ENVIRONMENTAL ASPECTS

INTRODUCTION

Planning for a major new facility must address the environmental impact of both the construction and operational phases of the project. It is essential to optimize alternatives, while evaluating performance relative to regulated emissions and ambient standards and to develop a cost effective permitting strategy.

For large scale projects, Quig (1980) recommends a highly integrated project approach for environmental compliance early in the planning stage based upon historical siting, licensing, engineering and construction experience with similar sized plants.

Strong emphasis on early process work is necessary to understand environmental impacts. This and other front-end engineering and planning should be executed in very close coordination with the staff charged with documenting the licensing effort. Extensive use of specialists is generally required.

The major federal acts to be addressed are:

1) National Environmental Policy Act, (NEPA), 1969.
2) Clear Air Act Amendments, revised 1990.
3) Federal Water Pollution Control Act Amendments, 1972 (FWPCA).
4) Resources Conservation and Recovery Act (RCRA), 1976.
5) National Historic Preservation Act of 1966.
6) Historical and Archaeological Preservation Act of 1974.
7) Endangered Species Act, 1973.

These federal and selected state environmental acts essentially address the following: Land Use Aspects (fuel storage, exclusion or buffer zones, waste disposal, zoning, and demography); Water Resources (availability and competitive uses, wastewater complexities and water quality, hazardous wastes, and waste heat); Air Quality/Meteorology (attainment/nonattainment areas, in terms of offset policy and lowest achievable emission rate; newsource performance standard for particulates; NO_x and SO_2; prevention of significant deterioration in Class I, II, III; stack height credit; hazardous wastes; minor meteorologic changes); and Regulatory (multiple lead agency involvement, licensing strategy, feasibility of concept, permit requirements, and federal/state implementation).

The environmental, health safety, and socio-economic impacts discussed above highlight the areas of concern which must be considered in the site characterization studies and subsequent reporting of the project compatibility with the proposed location. Baseline conditions must be identified in the areas of potential impact. The characterization of the environment, the definition of the process operations and the identification of the potential impacts are the elements required for input to a comprehensive program of facility design for impact mitigation. As such, the development of an environmental statement of the project serves as feedback to the design effort with the result being a facility licensable from the environmental viewpoint.

To illustrate the procedure we shall present a typical example, namely planning a new coal gasification plant. Technical details of gasification are discussed elsewhere in this Encyclopedia under Coal Gasification Processes. The example will focus on regulatory requirements and siting considerations.

REGULATORY REQUIREMENTS

The first step in any program of this nature is to define the regulatory requirements associated with the construction and operation of the proposed facility. This will define specific limitations and establish generally the study requirements for the program as they relate to the environmental, safety, health, and socioeconomic aspects of the development.

AIR QUALITY RELATED REGULATORY REQUIREMENTS

Federal Requirements

At the Federal level, this project will be required to comply with the following air quality regulations and requirements. *Primary and Secondary National Ambient Air Quality Standards* (NAAQS) A demonstration showing compliance with NAAQS must be made to EPA for approval to commence construction. This would involve modeling the anticipated plant emissions and imposing the resultant concentration increases on representative ambient air quality conditions and comparing these with NAAQS. Information necessary for this demonstration would include the facility emissions as discussed earlier and the ambient air quality developed from a monitoring program or from representative data as available.

New Source Performance Standards (NSPS) The proposed air quality control system (AQCS) for the facility must be designed to comply with existing NSPS for the coal preparation facilities (e.g., particulates), the gas turbine component (e.g., NO_x) and the auxiliary boiler (e.g., SO_2) of the plant. Since NSPS do not exist for the coal gasification component, appropriate AQCS Best Available Control Technology (BACT) evaluations will be performed to select the control system. In addition the AQCS design will have to be reviewed with the EPA for approval to construct.

Prevention of Significant Deterioration (PSD) No construction can commence until the PSD permit has been obtained. The report and application for the permit would have to consider the following: the emissions from the total facility; a BACT review for any regulated pollutant (NAAQS, allowable increments, NESHAP), which the plant emties above "de minimis" values, an air quality review for all pollutants emitted, after controls are applied, over the "de minimis" emission rates unless it were demonstrated that the air impacts of those emissions would not exceed the air quality impact "de minimis" values. As part of these demonstrations ambient air quality monitoring would have to be conducted for the same pollutants for which BACT demonstrations would be required unless representative monitoring data are available.

National Emission Standards for Hazardous Air Pollutants (NESHAP) The discharge to the atmosphere of pollutants regulated under NESHAP is not anticipated for this type of facility. However, tracking of EPA's continued development of NESHAP should be carried out to ensure compliance with the regulations as they develop.

New stationary sources and modifications to major stationary sources are required by the Clean Air Act to obtain permits prior to construction of a new process facility. The stringency of permit requirements depends on the regional status of its compliance with ambient standards for particular pollutants. For example, in zones having acceptable air quality referred to as "attainment areas" for a specific pollutant, the permits are of the prevention of significant deterioration (PFD) type. The code of federal regulations, US EPA Title 40 CFR, 51.166, specifies the set of minimum PSD air quality permit requirements to warrant approval by the US EPA. The primary objective of PSD is to insure new major sources and modifications of existing sources comply with NAAQS. Specific public notice requirements and subsequent hearings allow for public comment to be part of the PSD review process. On the other hand, in a non-attainment area, NAA permits are required. NAA permits address area improvement of pollutant levels and falls under the state's supervision, through a State Implementation Plan (SIP) enforced by the US EPA and DOJ. Either type of permit is subject to New Source Review (NSR). The physical change triggering regulation of pollutants is usually 100 or 250 tons per year, depending on the industrial source category. As of early 2005 the definition of major modification for coal fired power plants has come under dispute in the courts (see the discussion at the end of this article for further information).

State Requirements

The state may have air quality related requirements which will affect the proposed project.

State requirements may include a permit to construct a facility if the construction of operation of the facility will release air contaminants into the atmosphere. The applicant must submit a completed application for Approval of Emissions and an Emission Inventory Questionnaire (along with a copy of the PSD Application) which show compliance with state air quality standards, toxic substance limitations and emission control requirements.

WATER QUALITY RELATED REGULATORY REQUIREMENTS

Federal Requirements

At the Federal level, the major laws affecting the discharge of liquid effluents from the proposed facility are as follows:

Clean Water Act (CWA) Under the CWA, the proposed project will require a National Pollutant Discharge Elimination System (NPDES) permit before commencing construction and operation. The application to the EPA for these permits would be based on the conceptual design of the wastewater control systems which could ensure compliance with effluent limitations and water quality standards. Where effluent limitations are not specified for discharges from certain facilities, limitations on discharges from similar operations would be used as a guideline for design of the wastewater control systems. These designs would be used to support the application for an NPDES permit. The NPDES permit and the work effort necessary for its preparation will also address the discharge of toxic pollutants listed on the Section 307(a) toxic pollutants list and any other toxics discharged from the plant.

A section 404 permit is required by the Corps of Engineers for the discharge of dredge or fill material in the navigable waters of the United States. This permit is required for the river structures associated with the facility and would be prepared and obtained concurrently with the Section 10 permit required under Rivers and Harbors Act (see discussion below) and the NPDES permit.

Application for either an NPDES permit from the EPA or a Section 404 permit from the Corps will trigger the NEPA review process and is the basis upon which the preparation of an environmental report (ER), in support of a Federal EIS, is considered necessary.

Rivers and Harbors Act of 1899 (RHA) Under Section 10 of the RHA, any construction activity in a navigable waterway requires a permit from the Corps of Engineers. This permit will be required for the construction of the intact and discharge structures and the barge loading/unloading facilities. It would be submitted jointly as a common permit application with the Section 404 Dredge and Fill Permit application.

State Requirements

The state often has water quality related regulations and requirements which must be complied with before approval to commence construction and/or operation of the proposed project can be obtained. They are typically as follows:

A state regulatory agency may require that a certificate of approval be obtained prior to construction of a treatment facility for handling industrial wastes. A report containing detailed information about the operation of the treatment facility must be developed and submitted prior to construction.

Regulations may also require the submission of a permit application prior to discharge from an industrial source. The State may also issue a certification in accordance with the Clean Water Act which confirms that discharges from the facility will comply with effluent limitations and water quality standards.

SOLID WASTE RELATED REGULATORY ACTIVITIES

Federal Requirements

The major Federal law governing the handling and disposal of solid waste is the Resource Conservation and Recovery Act of 1976 (RCRA). The most significant sections of RCRA are Subtitle C, which deals with Hazardous Waste Management and Subtitle D, which deals with Non-hazardous Waste Management. Regulations pursuant to Subtitle C of RCRA address identification and listing of hazardous waste, standards applicable to generators, transporters, and owners and operators of hazardous waste treatment, storage and disposal facilities and permit requirements for treatment, storage or disposal of hazardous waste. The project will require a permit for disposal of any solid wastes determined to be hazardous by the criteria in Section 3001 regulations. Operation practices of the solid waste management facility are also regulated. In this regard the work necessary to determine the nature of the solid waste generated by this facility must be carried out. If the wastes are determined to be hazardous (Section 3001 Criteria) the applicable requirements of Subtitle C or RCRA must be incorporated into the facility design.

Regulations promulgated under Subtitle D or RCRA establish criteria for the development of State plans for management of solid waste. No requirements are directly imposed at the Federal level.

State Requirements

State plans for the management of solid waste (Hazardous and Non-hazardous) may be at varying stages of development. An application for a permit to operate a hazardous waste management facility may be filed with the state's DNR if any solid wastes to be generated at the proposed facility can be classified as hazardous.

NATIONAL ENVIRONMENTAL POLICY ACT (NEPA)

The major provision of NEPA which significantly impacts the planning and scheduling for major industrial facilities is the need for Federal agencies contemplating major actions, such as issuing permits, to prepare an environmental impact statement (EIS).

In the case of this coal gasification facility, the requirement for a Federal EIS would be triggered by the application for an NPDES permit from EPA and/or a Section 404 or Section 10 permit from the Corps of Engineers for anticipated river structures. Upon designation of the lead agency based on discussions with the various Federal agencies and submittal of applications for permits, the EIS would be prepared according to CEQ final regulations.

SITING THE PROJECT

Geology, Topography, and Soils

Geology studies should be performed to describe the soils, geologic and topographic setting of the site, particularly with respect to structural and topographic control of the local and regional groundwater flow systems. A secondary, albeit very important, purpose is the identification of potential geological hazards within the site area.

Information sought includes physical and chemical soil characteristics, general topography, paleontology, and geological framework. Descriptions are sought for aquifer systems and characteristics including their name, thickness, depth, stratigraphy, and areal extent. Mineral production and unique geologic/geomorphic features will be documented. Pertinent data is summarized in tabular and/or graphic format.

The results of the geology studies primarily define the soils, topographic, and geologic setting of the site. Potential impacts references these descriptive settings to evaluate impact magnitudes. The impact of plant site preparations and construction or localized site topography, soils and erosion characteristics, and site physical and economic geology are assessed. Geological hazards discussed include excessive slopes, unstable soils and fault zones.

Groundwater Hydrology and Water Use

The purpose of the groundwater studies is to understand the physical and chemical characteristics of the groundwater regime. This allows for an accurate assessment of groundwater impacts resulting from the proposed action in addition to formulation of mitigative measures to help alleviate these impacts. In addition, information necessary for the design of solid waste handling facilities as prescribed under RCRA is developed.

Information sought includes general topography and geological framework, description of aquifer systems and characteristics including their name, thickness, depth, stratigraphy, and areal extent; seasonal groundwater levels, rate, and direction of flow; aquifer hydraulic properties including permeability, transmissivity, and storativity; surface water/groundwater inter-relationships; location of aquifer recharge and discharge areas; ground water quality; and domestic, industrial, and municipal groundwater well distribution and characteristics. Long and short term regional and site specific (within 5 miles of the site) data is sought. Special efforts are made to document the location of contaminated areas.

Groundwater sampling can be conducted in conjunction with surface water sampling. Samples are taken quarterly from monitoring wells.

This information can then be evaluated in light of the projected facility emissions and demands on the area's resources. The issues and concerns to be addressed include:

1) Use of groundwater by the plant, and the effects of lowering water levels or pressures for this reason or for construction purposes.
2) Changes in water quality, or effects on rocks/deposits, caused by accidental leaks or spills, effluent discharge, slag or scrubber sludge pits, surface water and the like. The potential impacts identified are evaluated in light of their magnitude and importance. Extra attention is paid to those judged significantly high in either value.

By early identification of stresses that might affect the natural systems, steps can be taken to minimize the impacts or alleviate them to an acceptable degree. Mitigative measures that can be taken during plant design, construction or operation, such as adding clay liners, for example, can be evaluated and described.

Using the results of plant design, the initial impact evaluation and the adopted mitigative measures, a final evaluation is made of the effects of the construction and operation of the proposed plant and ancillary facilities on the natural environmental systems.

This activity evaluates expected effects of the proposed plant both during and after construction of the groundwater hydrologic environment. Each effect is evaluated as to its unavoidable adverse effects and favorable effects.

Surface Water Hydrology and Water Use

The purpose of the surface water studies is to determine, develop and present the surface water quantity and quality characteristics of the site and its surrounding environs. These data and information are analyzed and evaluated in recognition of the proposed facility's operation and construction related characteristics to determine and project potential effects and impacts on the surrounding surface water. Specifically, the objectives are:

1) To provide a quantitative description of the hydrologic setting of the site and its vicinity including any stream flow characteristics (i.e., flood and low flow frequencies, seasonal ranges, averages, and historical extremes), and the physical and chemical water quality characteristics of source and receiving waters. Annual and seasonal ranges and averages are developed.
2) To identify the other water uses (withdrawals as well as discharges) and users including the location and quantities involved;
3) To identify the existing water quality criteria and regulations affecting plant discharges, and
4) To evaluate the impact of construction and operation of the proposed plant on adjacent surface waters, with regard to the applicable water quality criteria, and related permit requirements.

The data and information needed for the description of the hydrologic setting of the surface waters of the site and evaluation of the plant's impact include the following:

1) Geographic and topographic maps of the site area containing varying degrees of local and regional details to delineate the drainage basin and its drainage patterns.
2) Watershed characteristics such as geometry, slope, vegetation types and density, and soil types to derive rainfall-runoff relationships (empirical runoff coefficient).
3) Records of rainfall events to estimate overland flow.
4) Records of stream flows from gaging stations on local water courses. These data are used in defining statistical stream flow characteristics.
5) Meteorological data including air temperature, relative humidity, solar radiation, wind speed and evaporation data, and thermal plume calculations (as needed).
6) Records of various water users, locations of withdrawal, quality, and quantities involved.
7) Proposed plant site location map, grade elevation, drainage pattern, character of soil types, and cover.
8) The physical and chemical water quality characteristics of the surrounding surface waters.
9) The facility description and operational characteristics relating to the discharge quantity and quality. In addition, construction procedures, methods, schedules, and erosion control features are needed.

In addition to a water quality characterization program, the required data is collected through existing sources. This would involve a thorough search, review, and compilation of the existing hydrological data base. Appropriate Federal, State, and local agencies are contacted and interviewed and published regulatory materials is reviewed to gain information regarding other water users and water laws affecting the plant construction and operation.

A field monitoring program is carried out to obtain water quality characteristics of intake and discharge waters. Water quality samples are taken quarterly from selected stations.

A hydrological assessment of the construction phase is undertaken to:

1) identify changes in drainage patterns and possible effects on flooding potential,
2) identify changes in riparian terrestrial habitat areas,
3) identify the potential for erosion and local soil losses.

These impact areas are addressed, and mitigating measures are specified for their control.

For the operational phase, the various aqueous discharges from the plant are inventoried and evaluated. Results of plume analyses, if appropriate, are critiqued with respect to compliance with applicable water quality criteria and standards. Recommendations concerning the potential optimization of the plant water management plan are made to reduce or eliminate environmentally objectionable discharges. Consumptive water use for the plant is identified to determine the effects of plant operation on intake waters and downstream users. Recommendations concerning optimization of the plant water management plan and the use of alternate or supplemental sources of water are made, if warranted.

Ecology

The ecological studies are designed to generate and assemble pertinent data to determine the status of threatened and endangered species, and commercially or recreationally important wildlife species, and to identify and locate sensitive, unique, and critical aquatic, riparian, and terrestrial habitat areas in the site area. Additionally, the status of commercially or recreationally important fish in any site intake and discharge waters is determined. The biological setting is then analyzed in light of the proposed plant construction and operational characteristics to arrive at assessments of impact potential.

Terrestrial Ecology

In evaluating the impact of the project on the terrestrial environment, the work objective is to assess both construction and operation of the facility utilizing "baseline" data developed and secured from field programs, literature, and agency contacts. Animal species, occurrence, abundance, distribution, and preferred habitat associations and principal ecological interactions are determined. Habitats are identified and described as natural plant communities within the site. Additionally, discussions and data gathering activities focus on vertebrates and prominent otherwise important plant community components.

Construction-related effects largely result from vegetation and habitat removal, which often constitutes the major impact of a major industrial facility on terrestrial communities.

Assessment of vegetation loss due to land clearing is based on previous identification and mapping of regionally productive rare, or otherwise important vegetation types. In this regard, the role of plants in soil stability warrants detailed consideration. Effects of facility construction on wildlife is also evaluated in terms of important habitat areas. Attention is focused on those species which appear sensitive to habitat loss (e.g., species already limited by factors relating to habitat availability), which function as critical components of a community, or which are considered "important." The latter category refers to wildlife designated uncommon, threatened or endangered, or wildlife of recreational or economic value.

An assessment of project operation including existing and proposed effects on vegetation must consider stack and cooling tower emissions. Predicted ground-level concentrations of stack emissions and cooling tower salt are compared to exposure levels considered thresholds for possible injury or damage, and to exposure levels documented as injurious under filed conditions.

Potential effects of facility operation (existing and proposed units) on wildlife from stack emissions, dust, increased human activities, and noise are evaluated. Additionally, the potential for bird collisions with plant components is evaluated. The magnitude of a potential bird-collision problem is evaluated from data compiled during field studies. Included in the impact assessment analysis is the use of the plant site by wildlife during station operation. Collecting ponds and other waste bodies provide habitat for waterfowl and amphibians, while areas cleared during construction and allowed to revegetate (or which are replanted) potentially provide habitat for a variety of species.

Aquatic Ecology

The aquatic ecology of the site intake and discharge waters as well as habitat removal associated with barge facilities is addressed, habitat and food web relationships of the system characterized and potential impacts to the system estimated. Data requirements are met by literature review, interviews, and discussions with local fishermen and scientists and field collections. While data gathering focuses on fish species, particularly the commercially or recreationally important species, other biotic elements of the lotic and lentic environments are identified.

Evaluation of potential impacts of the construction and operation of the proposed facility consist of projecting the effects of the various activities on the description of existing environmental conditions developed as a result of the field program, literature review and agency contacts described above.

The primary construction impacts likely to affect the aquatic habitat are those associated with the construction of the intake facility and secondarily increased erosion due to construction. Impact assessment of construction activities centers primarily on habitat lost or denied due to actual physical placement of structures and habitat degradation. Attention is focused on those species which appear sensitive to habitat loss; which function as critical components of the aquatic community; or are considered "important" (rate, threatened or endangered, or of commercial or recreational value).

Assessment of operational impacts centers on the effects of water withdrawal and the associated losses to the fish community due to entrainment and impingement. Potential changes in the population structure all addressed. Losses are estimated from population densities and from the field sampling program. Entrainment losses are expressed as "adult-equivalents" if warranted for important species. Potential discharge effects (thermal and chemical) are based on information developed from the literature review and input of engineering parameters.

Land and Waterway Use

The purpose of the land and waterway use—demographics effort is to:

1) determine the existing land use of the site and existing and future land and waterway use patterns in the surrounding area in order to assess any conflicts which may exist and to evaluate any impacts on land use that may occur from the construction and operation of the plant; and
2) determine the population growth patterns of the area in order to assess the impact the plant will have on nearby towns and communities in the area.

Based on the existing land uses, and the analysis performed by other disciplines such as terrestrial and aquatic ecology and air quality, impacts upon adjacent land uses caused by construction and operation are estimated. This impact assessment includes the impact of storage pond construction, noise, dust, plant appearance, stack emissions, cooling tower fogging and salt depositions, and construction stage traffic activity on residential, recreational, agricultural, and other adjacent land uses in the area, as well as the compatibility of the proposed plant with local land use plans, aesthetics, and regulations. Specific attention is given to the type and relative value of the land uses to be preempted or adversely affected by plant construction and operation.

The impacts of the increase in activities on a river if applicable is estimated including additional barge traffic staging in the area and the impact of these activities on existing movements and facilities in the vicinity of the area.

The demographic impact assessment consists of comparing the population projections for the study area to the expected population influx to be caused by plant construction and operation. The comparison is done by taking the estimated plant-related population influx as a percentage of the total projected population of the area to be affected by the incoming workers and families.

Socioeconomics

The purpose of the socioeconomics studies is to determine and describe the existing socioeconomic base for the plant region and surrounding major towns and to assess the changes, either positive or negative, which would occur as a result of the construction and operation at the proposed site.

The existing socioeconomic based is described for those areas likely to be impacted by the influx of construction and operational employment for the plant. Information required to describe the socioeconomic base of the area includes the following:

1) peak number of construction workers by craft during each year of plant construction;
2) estimate of the number of immigrant construction workers expected during construction of the plant;
3) existing and future capacity of the schools, hospitals, fire, sewer, etc., facilities in site area;
4) local government fiscal capabilities and local tax structure and tax bases;
5) employment and income statistics; and
6) economic base studies.

Socioeconomic impacts can result from the influx of immigrant construction workers to the area around the plant. This occurs when the construction force required to build the plant is fairly large and there are a number of large construction projects competing for the labor supply in the area.

The socioeconomic demand analysis qualitatively compares the demand for service facilities, and employment during the construction and operation of the plant with the baseline socioeconomic projections. Any perceived increases in demand for local facilities is qualitatively evaluated with respect to the cost of the facilities and the ability of local units to finance them.

Impacts associated with plant operation to be assessed include an evaluation of the change in local tax structure as a result of a large influx of new tax revenues to the local governments and the impact associated with the relocation of plant operating personnel into the area.

Noise

The purpose of this effort is to sample the existing ambient noise levels surrounding the proposed site, and to estimate the environmental noise impact produced by the plant operation.

In order to properly assess the noise environmental impact, plant noise emissions should be evaluated in terms of any State or local noise regulations. Consequently, various State and local regulatory agencies are contacted to determine the status of the regulatory constraints that might be imposed on the plant operation and construction noise emissions. In the absence of any such constraints, US EPA's guidelines for the protection of "Public Health and Welfare," as indicated in the "Levels Document" (550/9-74-004) are followed.

A literature review is conducted to assist in identifying the major sources of noise of the plant and in quantifying them. The search includes various professional journals, other environmental reports, and manufacturers' publications. Construction schedule, equipment list, general arrangement drawings, project description manual, and operational parameters of major plant equipment (Forced Draft Fans, Turbine Generator, Pumps and Motors) are obtained from the appropriate sources.

The facility noise levels are then evaluated and assessed in terms of existing regulations or guidelines and any potential restrictive conditions in either the working environment or the general site environment are identified. In addition, potential limitations to equipment are identified as are appropriate mitigative measures.

Cultural Resources

Cultural resource studies involve a review of appropriate records, and site-related literature to identify sensitive archaeological, historical, recreational, and aesthetic resources in the project area.

Most of the information required for cultural resource studies is available from State and Federal cultural resource agencies and societies. An on-site survey is conducted to locate any cultural resources eligible for the National Register of Historic Places.

Project components which affect significant cultural resources are identified and the magnitude of the impact evaluated. Mitigation alternatives are addressed. If serious impacts are discovered they should be brought to the attention of the developers promptly so that policy decisions can be made at the earliest opportunity to rectify the situation.

Air Quality/Meteorology

The purpose of this program is to obtain and analyze Air Quality/Meteorology data so that: the site can be characterized; the air quality implications of the facility can be evaluated; mitigative and control measures can be developed; and an Environmental Report and PSD application can be prepared.

The data required for the Air Quality/Meteorological program work efforts relate to: (1) The air quality/meteorological characterization of the existing site and region; and (2) The facility's atmospheric emissions and operating characteristics. Specifically, the existing site and region must be characterized in terms of the regulated pollutant such as SO_2, Particulates, NO_x, CO, Photochemical Oxidants, and the local meteorology, including winds, stability, and other physical characteristics. In addition, the facility's emission characteristics including their quantity and quality must be developed so that their impacts can be established.

To establish the required data base it is necessary to gather and update existing emission inventory information, collate meteorological and air quality data, review present and proposed PSD Class I and nonattainment areas, evaluate topographic influences and monitor the region's air quality characteristics.

The task of establishing adequate meteorological and air quality data bases includes evaluating any existing local meteorological and air quality data. The validity of the data and its representativeness with respect to the proposed site must also be assessed. As required, data from other sources is evaluated as a basis for comparison with local data, or as a supplement to local data where necessary. The objective is to establish meteorological and air quality data bases which are most representative of the proposed site.

A report should be prepared to provide technical support for a construction permit application under the PSD provisions of the Clean Air Act of 1977. Described in the report are the data bases, methodologies and models utilized in the analyses. The PSD report also includes appropriate maps, summary tables and figures necessary to display relevant information such as locations of plant sites, PSD Class I and nonattainment areas, and resultant pollutant concentrations.

An atmospheric impact assessment of the proposed and alternative cooling tower types is included in the ER. Operational impacts of the tower to be considered include elevated visible plumes and deposition of cooling tower drift. Computer modeling is utilized to predict the impact of these occurrences.

Ground level fogging/icing is also addressed. Computer modeling is utilized to predict the frequency and duration of ground level fogging and icing for the alternative cooling towers. The potential for interaction of the cooling tower and stack plumes must also be addressed.

National Weather Service (NWS) data can be supplemented by any available meteorological data to the fullest extent possible to develop the estimates of cooling frequencies, and salt deposition rates are given on an area basis and include more detailed information, as necessary, for any sensitive receptors.

Health Implications

The purpose of this work effort is to identify and evaluate the potential health concerns, including estimates of offsite exposures that may result from facility operation at the site. Once the concerns are identified, the need for controls and the feasibility of the gasification plant at a particular site from a public health perspective can be evaluated. Changes in coal type, process or waste treatment systems can be addressed if needed to mitigate a potential health concern. This allows and insures that alleviation of potential health problems is an integral part of the facility planning.

The health implications to the offsite population are identified and assessed. Specific analytical measurements from pilot plant studies, available information from similar industrial plants, and other existing studies regarding the health implications from coal conversion processes are used. The overall approach involves scaling the results of specific pilot plant runs and other study results to approximate a commercial size facility; applying standard air dispersion models and waste dilution criteria in order to predict exposure concentration; and evaluating the predicted concentration against known information on the toxicity of each contaminant.

The identification of potential public health concerns requires not only the estimation of exposure levels but also the evaluation of the relative toxicity of each chemical species. Consequently, a review of the toxic properties of each identified chemical substance or chemical group is required. At the conclusion of this evaluation each contaminant or chemical group is categorized into one of four groups—potentially significant health problems, potentially minor health problem, no expected health problem, and those for which insufficient information is available.

The results of this evaluation is then utilized to develop control systems and/or mitigative actions for the facility. In addition, the results are presented in the ER and discussed in terms of a cost/benefit framework.

With regard to occupational health, worker exposure to toxic substances is a potentially serious problem which could significantly lessen and limit the benefits of alternative fuel technology. As such, its implications must be carefully evaluated in the planning and design phases of this project. The Occupational Safety and Health Act (OSHA) contains basic worker protection guidelines and specific regulations which establish industry procedures for the protection of workers from exposure to potentially toxic or health impairing substances.

However, the current regulations do not specifically address a coal gasification process and only limited operating experience is available from existing gasification plants. Consequently, identification of potential occupational health problems must be done in an indirect manner through comparison with other industries.

This occupational hazard analysis yields identification of potential hazards, definition of possible control measures for as many of those hazards as possible, and identification of areas of concern where insufficient knowledge or control methodologies exist. In addition it provides input to:

1) design of worker protection programs to be implemented at the plant,
2) design of engineering controls to minimize worker exposure to hazardous substances, for example, isolation of process steps, ventilation changes, pressure control, etc.

Most of the procedural information, repeated from the article by Quig and Granger (1983) remains valid today. For a more quantitative treatment of the effluent emissions observed during plant operation the reader is referred to the study of Holt (1988) on the Cool Water plant and to the current Encyclopedia article, Coal Gasification Processes.

PERMITTING FOR LANDFILL GAS ENERGY RECOVERY

Purpose

New York State Air Guide 41 (1996) provides guidance on the permitting of emissions from municipal solid waste landfills, including the use of landfill gas for energy recovery, flares and, also, passive venting, as per the following:

Background

Landfill gas (LFG) is generated by the decomposition of wastes in all municipal solid waste landfills, regardless of age or size. The total volume of gas generated is a direct function of the quantity of wet, decomposable refuse available; however, the rate of gas generation can vary greatly over time, depending on numerous factors (such as the volume of waste, the depth of the landfill and the amount of rainfall the landfill receives), most of which are uncontrollable. Landfills the accept waste water treatment plant sludge for disposal tend to generate more LFG than those that do not. LFG is not generated until the available oxygen supply has been consumed and the decomposition process becomes anaerobic. The typical composition of LFG is essentially the same at all landfills and at all points within the landfill. The typical composition of LFG is:

Methane	50–58%
Carbon Dioxide	35–45%
Hydrogen	1–2%
Oxygen	1–2%
Nitrogen	2–5%
Non Methane Organic Compounds (NMOCs)[1]	3–5%

LFG can, and should, be used for energy recovery. The energy content of LFG comes entirely from the methane component, which has a basic heating value of 1,000 Btu/standard cubic foot (scf). Since the nominal concentration of methane in LFG is approximately 55%, the heating value of raw LFG is approximately 550 Btru/scf, although this figure can, and will, vary somewhat. By comparison, natural gas is composed of 95% methane, giving it a basic heating value of 950 Btu/scf.

At the majority of landfills in New York State, LFG is currently uncontrolled or passively vented to the atmosphere. Recovering and combusting such gas into useful energy will virtually eliminate harmful emissions from a fuel that is otherwise wasted. This also prevents the pollution associated with the use of fossil fuels (i.e., SO_2). If LFG is not combusted, it will still escape to the atmosphere through the path of least resistance (diffused from landfill, vented or flared).

Federal Regulations

Air In accordance with the Clean Air Act, the U.S. Environmental Protection Agency (EPA) has proposed New Source Performance Standards (NSPS) under 40 CFR 60 Subpart WWW for municipal solid waste landfills. These NSPS will affect landfills that began construction or modification after the standard was proposed (5/30/91) or existing landfills that have accepted waste since November 8, 1987. It must be noted that this proposed rule is currently being developed. The rule is subject to change and it is possible that it will not be released. However, the guidelines contained in this proposed rule should be used in developing a permit for the use of landfill gas. Additional information regarding this proposed rule is included in Appendix A.

In a recent Federal court case in Pennsylvania (Ogden Products Inc. vs. New Morgan Landfill Co.), the court ruled that the landfill in question is subject to New Source Review since it has the potential to emit more than 50 tons per year of volatile organic compounds. This decision, combined with the NSPS for landfills proposed by the EPA, will make all new landfills subject to the requirements of the CAA, particularly if the landfill has the potential to emit volatile organic compounds at levels exceeding air quality standards.

Hazardous Waste When LFG is recovered, it tends to cool, and some condensate is formed. It is stated in Section

124 of the Superfund Amendments and Reauthorization Act (SARA) of 1986 that if the aqueous or hydrocarbon phase of the condensate removed from the gas recovered from a landfill meets any of the characteristics of a hazardous waste (i.e., it fails the TCLP test), the condensate shall be considered hazardous waste and regulated accordingly. This section is an amendment to the Resource Conservation and Recovery Act (RCRA), but is not part of RCRA. Since this provision of SARA is not actually part of RCRA and there are no implementing regulations in 40 CFR, it may be binding upon EPA, but RCRA-authorized states (such as New York) are not obligated to enforce its requirements. This issue could arise if LFG is to be recovered from a municipal landfill that meets the size and NMOC criteria cited in Appendix A and is included on the Superfund priority list of inactive hazardous waste sites.

State Regulations

Solid Waste 6 NYCRR Part 360 has requirements for the control of LFG during both the active life of the landfill and after the landfill is closed. While the landfill is in operation, the owner must periodically (i.e., quarterly) monitor for the presence of LFG at or above 25% of the lower explosive limit (LEL) at on-site structures and any off-site areas. When the landfill is closed, an LFG control system must be included in the closure plans to prevent the migration of concentrated LFG away from the site and to prevent damage to a landfill cap. LFG is lighter than air and will tend to rise causing the overlying cap to rise also. Generally the LFG is allowed to vent to the atmosphere through a porous gas vent layer that leads to gas vent risers spaced at approximately one vent per acre.

Part 360-2.16 contains the regulations regarding LFG recovery facilities. These regulations require that anyone proposing an LFG facility obtain a permit to construct and operate the facility. The application for a permit must contain an engineering plan, engineering report and an operation and maintenance plan.

Hazardous Waste As cited above, some LFG condensate may exhibit hazardous waste characteristics. In an October 20, 1992 declaratory ruling applying to the Freshkills Landfill, the Department excluded landfill gas condensate from being regulated as a hazardous waste. This ruling was based on the grounds that the LFG was derived from a household waste and therefore excluded from hazardous waste regulation under New York State law. However, if the landfill received both municipal and industrial or hazardous waste, the condensate may be hazardous. The condensate would need to be analyzed using the TCLP method to determine if it is a hazardous waste.

Air NYSDEC's proposed Part 201 operating permit program (proposed to comply with the federal Clean Air Act Amendments of 1990) contains an exemption for LFG emissions vented directly (i.e., without a flare or energy recovery device) to the atmosphere that fall beneath major source thresholds as long as the facility is operating in compliance with 6 NYCRR Part 360. Such an exemption will not apply to landfills subject to NSPS or National Emissions Standards for Hazardous Air Pollutants.

A number of landfills in New York State currently use flares or energy recovery for control of their LFG. These emission sources must have a permit from the Division of Air Resources. These permits are issued under 6 NYCRR Part 201. All energy recovery projects produce NO_x in the combustion of the LFG. These projects must control NO_x emissions as required under Part 227-2. For example, if a lean burn internal combustion engine running on LFG is used for energy recovery, the emission limit for NO_x is 9.0 grams/brake horse power-hour (Part 227-2.4(f)).

LFG recovery projects would be affected by either Prevention of Significant Deterioration (PSD) or New Source Review in Nonattainment Areas (Part 231) regulations depending on the location of the project. Projects in nonattainment areas are likely to be affected by NO_x and CO requirements (Note: the entire state is nonattainment for VOC and NO_x because the state is in the ozone transport region). This is because recovering energy with a combustion unit will create NO_x and CO that often require emission offsets to be obtain and the installation of Lowest Achievable Emission Rate (LAER) technology.

The EPA has issued interim guidance stating that sources may be exempt from New Source Review (NSR) provided that the project is environmentally beneficial and there are no adverse air quality impacts. This exemption from NSR is referred to as a pollution control project. The EPA presently expects to complete rulemaking on an exclusion from major NSR for pollution control projects by mid 1996. However, in the case of nonattainment areas, EPA believes that the state or the source must provide offsetting emission reductions for any significant increase in a non-attainment pollutant from a pollution control project.

Presently, 6NYCRR Part 231 allows a Pollution control project exemption only at existing electric utility steam generating units (>25 megawatts of electrical output). Consequently, LFG projects which exceed the applicability thresholds, would have to obtain NO_x offsets at a ratio of 1.3 or 1.15 to 1, depending on the location of the project (i.e., in a severe non-attainment area or in a moderate non-attainment area), and would be required to install LAER technology. Please note that this may change if the EPA determines that this type of project is eligible to become a pollution control project.

Approach to Permitting—DAR

When the economics of an energy recovery project using LFG are favorable, these projects are to be encouraged. The following is the hierarchy of preferred LFG uses:

1. Gas cleaning and upgrade to pipeline quality gas;
2. Energy recovery with gas pretreatment or conversion to a reusable chemical product;
3. Energy recovery without gas pretreatment;
4. Flares with high combustion efficiency (i.e., 98% or greater);
5. Vents, if no economically feasible use for the gas is available.

The following procedure will be used for permitting of energy recovery facilities that utilize LFG:

If the LFG Is Pretreated (i.e., if the constituents other than methane are removed from the gas), then permit as a combustion source with no further emission testing or ambient modeling necessary to satisfy toxic concerns. The permit should address traditional combustion contaminants such as NO_x and CO. However, the permit application for this type of option must include a detailed description of the method(s) to be used for gas pretreatment. LFG can contain up to 50%, by volume, CO_2 (35–45%) and air toxics (1–2%). The pretreatment employed must remove these compounds before the LFG can be permitted for just the traditional combustion contaminants. Note that gas pretreatment will minimize toxic products of incomplete combustion and minimize system corrosion.

If the LFG Is Not Pretreated, then permit as a combustion source and use the total concentration of NMOC emitted to address toxic issues. Note that if the gas is burned, either by a flare or energy recovery process, generally the air toxics will be destroyed. It will be easier and more efficient to regulate the NMOC (or total VOCs) than trying to identify and regulate all contaminants of LFG emissions, since they can vary greatly depending on the waste disposed at the landfill. The permit should address traditional combustion contaminants such as NO_x and CO. The EPA proposed standard of 20 ppmvd NMOC should be used as BACT for the control of untreated LFG used as a combustion source. Periodic stack testing of the emissions is recommended at the discretion of the permit writer.

With regard to compliance with Part 231, the LFG facility may need to obtain NO_x and CO offsets at the ratio applicable to its location (i.e., 1.3 or 1.15 to 1). This requirement may change if the EPA decides that LFG-type facilities are eligible for a pollution prevention exclusion. The permit reviewer will need to exercise judgment to determine if the LFG facility is required to obtain these offsets. As stated above, an LFG facility can be used for energy recovery. While a combustion turbine or internal combustion engine is not normally considered add-on pollution control devises, they do serve the same function as a flare, namely to reduce VOC emissions at the landfill with the incidental benefit of producing useful energy (energy that would otherwise be produced using higher polluting fossil fuels). For an LFG facility the reviewer should proceed as follows:

1. Verify that the NO_x increase has been minimized to the extent practicable;
2. Confirm (through modeling or other appropriate means) that the actual significant increase in NO_x emissions will not violate the applicable NAAQS, PSD increment or adversely impact any air quality related value;
3. Apply all otherwise applicable SIP and minor source and permitting requirements and ensure that NO_x offsets are provided in an area in which nonattainment review applies to NO_x emissions increases.

Coordination within the Department

The use of LFG will require coordination of efforts between the Divisions of Air Resources (DAR) and Solid and Hazardous Materials (DSHM). If a landfill meets the criteria cited above and the emissions from the site must be controlled, the proposed plan for this control should be submitted to both Divisions. DSHM should focus their review of the proposal, based on the requirements of Part 360-2.16. DAR should focus their review on evaluating and permitting the combustion sources that utilize the LFG, as outlined in the previous section. Both Divisions must keep in mind that LFG can be a valuable resource for energy generation and that using this resource will conserve the use of other fossil fuels and permit the re-use of material otherwise considered waste. Further, the respective project managers handling a particular facility's permit application should maintain communication to ensure that there are no unnecessary delays on developing a permit for an LFG facility.

APPENDIX A OF AIRGUIDE 41

NSPS for Municipal Solid Waste Landfills

In accordance with the Clean Air Act, the U.S. Environmental Protection Agency (EPA) has proposed New Source Performance Standards (NSPS) under 40 CFR 60 Subpart WWW for municipal solid waste landfills. These proposed NSPS will affect landfills that began construction or modification after the standard was proposed (5/30/91) or existing landfills that have accepted waste since November 8, 1987. It must be noted that this proposed rule is currently being developed. This proposed rule would require landfills to install active gas collection and control systems if they exceed both of the following criteria:

- design capacity in excess of 2.500,000 Mg (2,700,000 tons); and
- NMOC emission rate in excess of 50 Mg per year (50.05 tpy).

Landfills closed prior to November 8, 1987 or having design capacities less than 2.5 million metric tons will be exempt once this rule is finalized.

The NMOC emission rate is determined by the following equation:

$M_{NMOC} = 2L_0R(1-e^{-kt})\,C_{NMOC}\,(3.595 \times 10^{-9})$ where,
M_{NMOC} = mass emission rate for NMOC, Mg/yr
L_0 = refuse methane generation potential, m^3/Mg refuse (default value = 170 m^3/Mg)
R = average annual acceptance rate, Mg/yr
k = methane generation rate constant, 1/yr (default value = 0.05/yr)
t = age of the land fill in years

C_{NMOC} = concentration of NOMOC, ppmv as hexane (default value= 4,000 ppm)
3.595×10^{-9}= conversion factor

(Note: In the absence of site specific data, use the given default values to determine NMOC emission rate.)

Each landfill of design capacity greater than or equal to 2,500,000 Mg must determine its NMOC emission rate, using the above equation. If the NMOC mass emission rate is less than 50 Mg/yr, the landfill owner would submit this information to the NYSDEC as part of the Part 360 permit. No further action regarding control of the landfill emission would be required. The emission rate will be recalculated annually, with a report submitted to the Department. This report must be submitted to the Department within 90 days of the issuance of a construction or operating permit or initial acceptance of refuse, whichever is earlier.

If the NMOC mass emission rate is greater than 50 Mg/yr, the landfill owner must submit a design for, and install a collection and control system at the landfill. This control system must be designed to reduce, in accordance with 40 CFR 60 Subpart WWW, the emission of NMOCs by 98% by weight.

Wehland and Earl (2004) present the inconsistencies in legal and enforcement interpretations of the PSD requirement for NSR major modifications and hence the criteria by which to determine the need for a PSD permit and the installation of BACT. There is no need to install equipment if the modifications are of the routine maintenance, repair or replacement without increase in unit capacity. For each of the four cases involving coal fired power plants in which decisions were reached prior to 2004, the court's conclusions were different, and in some cases significantly different. In *U.S. vs. Southern Indiana Gas & Electric Co.* (S.D. Ind. 2003), the district court ruled that the utility had fair warning about EPA's decision to review the records of the affected unit, only, in determining if the maintenance was routine, but deferred its final determination to the more general NSR applicability. In *U.S. vs. Ohio Edison* (S.D. Ohio 2003), the court concluded that fair warning was given to the utility in the plain language of the CAA.

The court gave weight to establishing the routine nature of the maintenance by analyzing the all of the factors below for the projects:

(1) budgeting and accounting,
(2) purposes and costs, and the
(3) net emissions increase

In *U.S. vs. Duke Energy* (M.D.N.C. 2003), the district court ruled that EPA's past practices in other cases require that industry-wide rather than the individual unit's past practices were the criteria to be followed. Also the court favored an increase in emissions analysis to be on a "Projected actual", rather than on a "future potential" basis. They also indicated that when determining the applicability of a modification, the NSPS rule of not increasing the maximum hourly emissions rate should be followed.

In the case, *Tennessee Valley Authority vs. U.S.* (11th Cir. 2003), the decision by the circuit court side-stepped the primary differences and ruled against the EPA because of its use of an administrative procedures that deprived TVA of its rights to a hearing. In October 2003 the EPA defined a routine project as one that would cost less than 20% of the total cost of replacing an emitting unit. The new rules and lack of enforcement were being challenged as of 2004. An alternative to the current regulations offered by the authors, "is to eliminate the NSR and incorporate plant-wide emission limits in operating permits." They also recommend modeling and employing maximum achievable control technology (MACT) when modeling results determine controls are necessary to protect the air quality.

PLANNING WATER SUPPLY AND SANITATION PROJECTS IN DEVELOPING NATIONS

INTRODUCTION

It is estimated that over 1.5 billion people in the world are without adequate water supply and waste disposal facilities.[1] Waterborne diseases kill an average of 25,000 people every day, and millions suffer the debilitating effects of the diseases.[2] Concerned about the need for safe water supply and sanitation, the United Nations (UN) declared 1981–1990 as the *International Water Supply and Sanitation Decade* with the professed goal of supplying potable water for all the people of the world by 1990, and also of providing all people with the means to safe disposal of human excreta. This goal was highly optimistic in view of the fact the nearly 80 percent of the population in the developing countries does not have access to piped water supply, and even a large percentage lacks public sewers and household waste disposal systems.[3,4]

At the end of the International Water and Sanitation Decade, it was estimated that almost 31 and 44 percent of the world population was lacking safe water supply and adequate human waste disposal, respectively. The global population being 5.28 billions, total population currently having inadequate water supply and sanitation is therefore staggering.[5–7] Based on an assessment of the successes and failures of the Decade, it is believed that much has been accomplished, but progress is needed on all fronts: rehabilitation and operation of existing systems, training of personnel, financing, and new construction to achieve the goals of the Decade within a reasonable time in the future. In this article many factors that contribute to successes and failures of the Water Decade goals are reviewed. The discussion is divided into (1) understanding of the needs, (2) appropriate technology for water supply and waste disposal, (3) commitment, (4) financial resources, (5) training of people to plan, design, build, operate and maintain water and sanitary projects, and (6) role of developed nations.[8–10]

UNDERSTANDING THE NEEDS

Adequate supply of safe water and basic sanitation are the foundation of health. Water pollution and poor sanitation are probably responsible for 80 percent of the morbidity and mortality in the developing countries. It is estimated that over 900 million cases of diarrhea related illness occur each year, resulting in the death of over 3 million children. Common diseases associated with polluted water are grouped in Table 1.[11] Prevention of such diseases depends on the improvement of the quality of the water supply, personal hygiene, food handling and preparation; as well as the provision of adequate sanitation, including sanitary facilities for human waste disposal.

The importance of personal hygiene specially on the part of mothers and children is the key to beneficial results in disease prevention. Therefore, more intensive activities directed to improve personal hygiene should be emphasized in the developing countries. Furthermore, a meaningful program of providing safe water supply in developing countries must also include safe disposal of human excreta, basic education, and improvement of sanitary conditions.

The major constraints on the progress of the International Drinking Water Supply and Sanitation Decade have been operation and maintenance and rehabilitation of the systems that were built earlier. Broken-down and poorly functioning facilities waste money, are a threat to health, and discourage future investments. Also, inappropriate technology is at the root of many water supply and waste disposal problems in the developing countries.[12,14]

APPROPRIATE TECHNOLOGY

Water Supply

The goal of the UN Water Decade was to provide "clean water and adequate sanitation for all by 1990". It should be noted that this did not mean a tap and a flush toilet in every house. Reasonable access to safe water is usually understood to be within 500 m of the household; for many developing countries, adequate sanitation probably refers to some technology intermediate between the water flush toilet and the simple pit latrine. The scope of the task of the UN Water Decade was truly enormous considering that the two priority areas are the rural population (71%), who often have to travel long distances for water, and the crowded urban poor (25%), for whom water supply often is grossly inadequate; 87% of rural population and 47% of urban fringe areas lack adequate sanitation.[12] Naturally, achieving universal coverage would mean not only supplying almost one billion people currently without safe water supplies and the 1.7 billion people without sanitation, but matching population growth as well. Annual investment is currently in the range of 15 to 20 billion dollars per year—about 2 to 3 percent of gross investment in developing countries. If the share

TABLE 1
Common disease associated with contaminated water and poor sanitation

Disease	Common Vehicle
Water-borne diseases	
Amoebic dysentery	Diseases transmitted by ingesting contaminated water and food
Bacillary dysentery	
Cholera	
Criptospridiosis	
Gastroenteritis	
Giardiasis	
Hepatitis	
Leptospirosis	
Paratyphoid fever	
Salmonellosis	
Typhoid	
Water-washed diseases	
Conjunctivitis	Lack of adequate quantity of uncontaminated water, and poor personal hygiene create conditions favorable for their spread
Hookworm (Ankylostoma)	
Leprosy	
Scabies	
Skin sepsis and ulcers	
Trihcuriasis	
Whipworm (Enterobius)	
Yaws	
Water-based diseases	
Bilharziosis	Diseases caused by infecting agents by contact with or without ingestion of water. An essential part of the life cycle of the infection agent takes place in an aquatic animal
Dracunculosis	
Oncholersosis	
Philariosis	
Schistosomiasis	
Treadworm	
Fecal-disposal diseases	
Clonorchiasis	Diseases caused by infecting agent mostly contracted by eating uncooked fish and other food
Diphyllobothriasis	
Fasciolopsiasis	
Paragonimiasis	
Water-related vectors	
Arbovirus	Diseases transmitted by insects which live and breed close to water. Infections are spread by mosquitoes, flies, and insect bite
Bancroftian	
Dengue fever	
Encephalitis	
Filariasis	
Hemorrhagic fever	
Malaria	

Adapted in part from Ref. 11.

remains constant over the next fifteen to twenty years, economic growth will allow investment to double in real terms, to 30–40 billion a year.[13] Therefore, selection of appropriate technology and service levels must be established in bringing down the capital costs of water supply and sanitation projects. It was also demonstrated in the first half of the Decade that the biggest priority is correcting the inadequate training of the operating personnel.[14]

Selection of appropriate technology for use by the developing countries requires (1) understanding of the cultural background, regional environmental conditions, and local needs; (2) selection of appropriate systems that will be within the financial (minimizing initial investment cost as well as maintenance cost) and technical (minimizing operational failures) resources; (3) training paraprofessional rural water technicians (using available labor where possible instead of expensive imported equipment); (4) promoting complementary activities to help people to obtain the most benefits from the systems (so that users will receive long-term benefits of these basic services); and (5) selection of the most appropriate water source and the most appropriate energy source for conveying water to its users.

The different sources of small community water supply systems in developing countries can be categorized as follows: (1) groundwater, (2) rain water, (3) springwater, and (4) surface water. Depending on the sources of water supply, many techniques have been found effective and applicable to the water and sanitation programs in the developing countries. Some of these techniques are presented below.

Groundwater In areas where *groundwater* is readily available at moderate depth, constructing a number of wells fitted with hand pumps is by far the cheapest means of providing a good water supply.[14] Although, community water systems piped under pressure to households and public standposts may be an ultimate goal, many areas will realistically have to seek hand pumps as an interim if not an ultimate measure. The trouble with most hand operated water pumps used in developing countries is that they are not hardy enough and require frequent maintenance. Pump parts are usually expensive to buy and are difficult to make locally to fit the pump. Development work started at the Consumer Research Laboratory (CRL) in England has led to the *snappy* plastic pump: a simpler, cheaper and hardier device that has many beneficial features. A complete description of such hand pumps is given by Sattaur.[15] Additional information on other types of hand pump manufactured in developing countries may be found in Ref. 15. Hofkes provides some other techniques and methods of groundwater withdrawal used by small water supply systems in developing countries.[11]

Rainwater In developing countries rainwater is sometimes used to supplement the other water supply sources. In some tropical islands rainwater is the only source of domestic water supply. Rainwater harvesting requires adequate provision for the interception, collection and storage of the water. Generally, cisterns are built to collect the runoff from the roofs. Water quality preservation is very important and some basic measures should be followed to exclude bird droppings, insects and dirt from the stored water. Also, storage in cool conditions, exclusion of light, and regular cleaning is essential. Simple disinfection devices may be very useful.

Rainwater catchments are relatively simple to construct and maintain. It is expected that these systems will be widely used in the future. In Kenya, concrete jars used as storage tanks are said to be the most popular appropriate technology. Their popularity is growing among the villagers in Thailand where the construction and maintenance of these units is undertaken by technicians of the Sanitation Division of the Department of Health. The technician directs the voluntary labor of villagers in constructing concrete storage tanks reinforced with bamboo. The Villagers then repay the costs of the tanks in 12 monthly installments. The owners of these tanks, having contributed so much of their time and money into their construction are usually very keen to operate and maintain it properly.[16] Design details and economics of many cisterns, storage tanks, and other rainwater harvesting systems may be found in Refs.[17–21]

Spring and Surface Water There are many situations in the developing world where water is available from a nearby stream or spring. Various devices have been constructed to utilize the energy available in flowing streams to pump the water to the point of use.

The more successful devices, that will represent substantial savings in pumping water are the hydraulic ram pumps (hydram) and low-head turbine pumps. One converts pressure energy to mechanical work and the other converts kinetic energy to mechanical work. These two practical devices have been described and compared in detail by Schiller.[22] He observed that the hydram is easier to operate and maintain, but installation of the turbine pump is easier and simpler.

Before the Water Decade program started the water quality control was given least importance in developing countries. Perhaps, the major reason was inappropriate operation and maintenance of the equipment. The primary goal of any water project started in the Drinking Water Decade was to provide a facility and system that can be operated, maintained and managed at local levels giving self sufficiency with proper personnel and financial needs.[23] Local capabilities for operation and maintenance must be developed through training local maintenance personnel, establishing a locally managed maintenance fund, selecting an easily maintained technology, and requiring capital contributions from the community to increase local sense of ownership and responsibility for the systems.[24] Finally, a successful drinking water program requires extensive local participation (materials and labor) and minimize dependence on overseas materials and equipment for construction and operation of facilities.[25]

Human Waste Disposal

Rapid growth of the urban populations (mainly because of migration from rural areas) has led to severe problems in providing human waste disposal systems. Only 32 percent of the population in the developing countries is directly connected to sewer systems. Therefore, the collection and disposal of human wastes constitute a serious environmental and health problem.[26] Several alternatives are available; each has its own limitations and constraints. Certainly there is no single option appropriate to all situations. The range of options described below is sufficient to cover the vast majority of the situations within the low income communities of the developing countries.

One of the fundamental principles of community sanitation is to remove all putrescible matter, particularly human wastes. A satisfactory excreta disposal method must satisfy the following requirements:[26]

1) Should not be accessible to flies or animals
2) Should not cause odors or unsightly conditions

3) Should be simple and inexpensive to construct and operate
4) Should not cause ground water or surface water contamination
5) Should not cause soil contamination.

The appropriate technology for human waste disposal in developing nations fall into two major applications (1) rural, and urban areas without sewers, and (2) urban areas having municipal sewers. Appropriate technology for each of the above applications are discussed below:

Rural and Urban Areas without Municipal Sewers The environmentally acceptable methods of human waste disposal in rural areas include various types of sewerless composting toilets. Common examples of such toilets are bored-hole latrine, pit privy, vault privy, septic privy, chemical toilet, soil or composting toilet, methane forming toilet, and box-and-can privy.[26,27] These devices are simple and inexpensive to build and operate. Each of these devices is briefly discussed below.

Bored-hole Latrine: Bored-hole latrines consist of a hole in the ground 25 to 60 cm in diameter, and 2 to 3 meters deep. The hole may be braced to prevent it from caving. A concrete slab with a hole cut in it may be placed over it, and the entire assembly is made into an outhouse. When the hole is filled, the structure is moved to another hole. Fly and odor problems are controlled by keeping the hole covered, and dropping dry soil in the hole on a regular basis. Deep bored-hole latrines present danger of ground-water pollution.[26]

Pit or Vault Privy: Pit or vault privies can serve the needs of homes, schools or groups of homes. A concrete pit or vault is constructed in the ground and a toilet seat is located on the top. The seat cover must be kept closed to prevent flies from entering. Odor is a problem. A vent pipe raised over the roof has been helpful in odor control. In 3 to 4 months when the pit or vault becomes full, there is the unpleasant job of cleaning it. Some vaults have two compartments. When one compartment is full it is kept closed for 2 to 3 months while the other side is used. During this time, the excreta is decomposed, and cleaning becomes less objectionable. Pit or vault privies with separate back covers have also been used. These back covers help in the cleaning operation.[26]

Septic Privy: Septic privies utilize a liquefying tank similar to a septic tank. The waste is digested and overflow may be discharged into a percolation field. The toilet has a shallow trap. After use the toilet must be flushed by pouring 2 to 3 liters of water.[26]

Chemical Toilet: Chemical toilets consist of a tank in which waste accumulates. The toilet seat is provided directly over the tank. Caustic soda (sodium hydroxide (NaOH)) is most commonly used to kill the bacteria and to liquefy the wastes. The caustic soda dosage is 1 to 2 kg of sodium hydroxide per month for a family of four. The tank is emptied periodically. If caustic soda is used the tank contents can be carefully applied over farming land. Many types of chemical toilets are available from various manufacturers.[26,28,29]

Soil or Composting Toilet: This is dry toilet capable of being used indoors. The toilet consists of a wooden frame with toilet seat, and a bucket lined with a plastic bag. The toilet is started with a layer of dry soil 10 to 15 cm deep. Users must sprinkle several scoops of soil after each use. Once or twice a week, the bag is removed, tied and stored. After a decomposition of several weeks the contents are spread over farm land.[30]

A more involved is the *Clivus Multrum* composting toilet. This toilet was developed and has been successfully used for some time in Sweden and is now manufactured in the United States.[31] The toilet is capable of composting toilet waste, kitchen wastes, and even leaves and grass. It has three sloping chambers and is started with a layer of peat moss four to five inches thick. Design and operational details may be obtained in Ref. 31. Another toilet similar to *Clivus Multrum* toilet is the *Toa-Throne* compost toilet also developed in Sweden.

Another dry composting toilet that has been proven highly successful in Vietnam, offers a suitable system for all developing nations.[32] The toilet consists of two-holer outhouse in which only one hole is used at any one time. There is no raised seat, instead each hole is placed in a squatting plate at floor level. The urine flows out and soaks into the ground outside the outhouse. The fecal wastes go into the other hole. The user must drop dry soil or ash after use. When the toilet is two-thirds full, the rest is filled with soil, and the vault is tightly sealed. The other side is started. After a composting period of approximately 45 days the contents are taken out and used over the farm as rich compost.[33,34]

Methane Farming Toilet: In India small biogas plants are extensively built in rural areas. These biogas plants anaerobically digest animal manure and other organic wastes, and the methane is used to light, heat, and power the farms. Singh gave the basic design and construction details of such toilet.[34] Other designs of anaerobic digesters utilizing human, animal and other organic wastes are used in Kenya and Brazil.[35–37] Morris developed a package unit for methane generation from human wastes.[37] Khandelwal provided design and operational details on dome-shaped biogas plants used in India.[38] Eusebio and Rabino provided design of large biogas plants used in Philippines, India and Africa.[39]

Box-and-can Privy: The toilet system consists of a wooden box, the lid and toilet seat. The can or pail is removable through the top or side of the box. The cans are removed manually under regular scavenger service, emptied, cleaned, and replaced. This system is most commonly used in cities that do not have a sewerage system.

This type of system is associated with odors and serious fly problems if the lids are not tightly closed after use. For satisfactory operation there should be a regular scavenger service, preferably under a governmental supervision with ordinances covering types and size of box and can, method of emptying and cleaning of the cans, and ultimate disposal of the human waste. A speedy and convenient way is to use identical toilet boxes and cans for the entire community. The scavengers remover the can and place it in his vehicle without emptying, and replacing a clean can. The vehicle when full is taken to a central disposal facility for emptying, and replacing with clean cans. The disposal facility should be located in a remote area and should utilize anaerobic digesters whereby the recovery and sale of methane gas, and digested sludge as soil conditioner can be achieved. The central disposal facilities should be equipped with running water, hose, and chemical solution for washing and cleaning the cans.

Experience has shown that such systems based on payments by the residents to private scavengers have been unsatisfactory. The service is poor, irregular and wastes may be dumped uncontrolled upon land and in waters.

The box-and-can system should be used only as a temporary means of waste disposal with continued effort to replace it by other more acceptable methods. Furthermore, it should be carried out only under the supervision of trained personnel and under strict governmental control.

Urban Areas with Municipal Sewers The wastewater collected through municipal sewers contains large volumes of water. Therefore, treatment technology is much more complex than discussed above. Treatment schemes to achieve secondary level of treatment (90% organics and total suspended solids removal) include screening, grit removal, primary sedimentation, biological treatment (activated sludge or trickling filter), final clarification, and disinfection. Other physical, chemical and biological treatment processes may be added to remove phosphorus, nitrogen, and additional organics and suspended solids. The solids fraction (sludge) is digested aerobically or anaerobically.

Although, such treatment technology may be desirable for the developed nations, their use in developing nations may not be appropriate. Such treatment processes are costly to build, and complex to operate. Desirable treatment methods for developing nations may include the following:

1) stabilization pond followed by effluent reuse on farming lands,
2) Imhoff tanks followed by stabilization pond and effluent reuse on farming land, and
3) upflow anaerobic sludge blanket process.

Imhoff tanks provide primary sedimentation, and anaerobic digestion of settled sludge. The methane is collected for energy source and digested sludge is used as compost. The stabilization pond (oxidation pond or lagoon) is an earthen basin that retains the wastewater for sufficient time to stabilize the organic matter, and destroy large percentage of pathogens. The effluent is used for irrigation, or discharged into natural waters.[40–43] The *upflow anaerobic sludge blanket* process (UASB) was developed in Netherlands and is extensively used and tested in the developing nations.[44] In this process the wastewater enters the bottom of the reactor and percolates up through the sludge blanket where organics are converted to methane and carbon dioxide by anaerobic organisms. The gas is collected, and treated effluent is drawn off from the top.[34]

COMMITMENT

The water supply and sanitation schemes in developing countries cannot be successful without the willingness of the government to commit the resources to undertake water supply and sanitation projects. Unfortunately, the governmental priority in this area is quite low. Most of the developing countries set their priorities as follows: (1) agriculture, (2) industries, (3) energy resource development, (4) education, (5) commerce and transportation, (6) family planning, (7) housing and urban development, and (8) water supply, and sanitation, and environmental control.[45] Such priorities have been set on account of necessities. It is necessary that the developing countries give needed priority on water and sanitation.

FINANCIAL RESOURCES

The success of any program in any country depends upon the financial commitments of the respective governments. Developing nations (except for the oil exporting nations) are poor and have very limited funds. A 1975 study indicated that villagers if they have to pay more than 50 cents per month for water supply, they would not participate in the program.[45] Their ability to pay for water and sanitation is very limited. Success of the program will depend upon outside funds, and local labor.

TRAINING AND MANPOWER DEVELOPMENT

It is well recognized that the success of any program requires well trained people. Unfortunately, past experience has shown that many internationally supported training programs were not successful because the emphasis was incorrectly placed. Engineers from developing nations when trained in the western world generally learn the theory and design of most sophisticated unit operations and processes in water and wastewater treatment and environmental engineering. When they return to their countries, they are generally eager to utilize such technologies, although in most cases these may be quite inappropriate. Furthermore, foreign consultant's unfamiliarity with the cultural and operating competence of the people in developing countries have resulted in selection and design of technology that have not functioned.

What is really needed is a program where training at all levels may be effectively provided. The includes training of central government officials and engineers; local government officials, residents and technicians; on-the-job training of operators; and users education. Government officials set the priorities and make funding decisions. Engineers have responsibility to evaluate, select and implement the appropriate technology. Local officials participate and support the program. The technicians and operators have the responsibility for continued operation and maintenance of the system. And finally, users education is essential as they are the ultimate beneficiary.

In order to effectively provide such a complex training opportunity, programs must be developed in the developing nations. Such training programs must be developed as academic programs, short courses, seminars, and internships to address different audiences yet meet the specific needs of each. Brief discussion is given below.

Academic Programs

Academic programs include regular undergraduate and graduate programs at universities, and technology or vocational programs in polytechnics and colleges. Both programs have different objectives.

University Programs Regular academic programs such as master's and bachelor's degrees in civil, sanitary or environmental engineering, biology, public health, and so on. have been modeled along the lines of western universities. These programs often may not be directly applicable to the needs of the developing nations. It is necessary to modify or develop new programs tailored for their national needs. As an example, graduates in civil, sanitary or public health engineering must also know community interactions, socio-economic implications, relationships between service levels and health and well-being, that dictate the success or failure of any water supply and sanitation projects, especially in rural and urban settings of developing nations.

Technology Programs The technology or vocational programs should be directed towards training technicians, health inspectors, and community workers. Specialized training is needed so that these personnel can undertake field work, organize the community, conduct training, and assist the community in the selection and installation of water supply and sanitation facilities, and provide continued operation and maintenance of such facilities. Special training is needed for personnel to motivate people and implement the programs in rural areas where approximately 75% of the population lives.

Short Courses and Seminars

In corporation with the health ministry specialized short courses of one- or two-week duration should be conducted at universities, colleges, and high schools. These short courses should be designed to provide training to full-range of people including decision makers, engineers, operators and community workers.

Decision Makers The government officials who have the responsibility for setting up priorities, and allocation of funds must be aware of the relationship between service levels and health and other benefits, cost of construction and operation, and short-range and long-range implications of the investments in water supply and sanitation projects.

Engineers and Designers The intensive short courses designed for engineers and designers should cover the successes and failures of different projects, improvements needed in future systems, public education, and how to relate health conditions and project objectives in order to develop the most cost-effective system for the specific conditions.

Operators and Community Workers Intensive short courses should be conducted for operators and community workers in basic topics ranging from chemistry, biology, vectors, communicable diseases, to metal working, equipment repairs, operation and maintenance, leak repairs, book keeping, to management of public works projects.

On-the-job Training On-the-job training programs of varying periods with or without short courses should be developed to train field workers and inspectors and local people in construction techniques and operation of water supply and sanitation systems. Such practical training can be a powerful tool for manpower development.

Primary Health Care Workers Health education or sanitation education should be provided at village level. Villagers, literate or illiterate, should be trained as primary health care workers, or *barefoot doctors,* whose training should be emphasized on prevention, and curative care. Six to 12 months intensive training could be provided at local high schools or through health education service.

Users Education Training of villagers in water supply and sanitation must also be provided as part of user or adult education program. This can be achieved by mass campaigns by health education extension services. Health education must also be instituted in primary schools. This will provide the broadest, and most dependable coverage to younger groups. The program must include community sanitation; hygiene habits in home; fly rodent and other vector control; water contamination and use of water supply devices; and proper use and maintenance of various types of privies and latrines.

Training and Educational Material, and Education of Trainers

It is important that training, educational and technical material should be in the form of posters, technical books, manuals, photographs, slides, films and audio-visual aids. Audio-visual equipment has been highly successful in training personnel, and illiterate population in rural areas. A portable power generator may be necessary for rural areas without electrification.

Educational material must be carefully prepared for the specific audience. General health related material covering disease transmission, vector control, water and food protection, personal hygiene, should be prepared for general public with no education. Information on public use of water supply and sanitation devices should also be prepared for general audience. Technical and semitechnical information should cover the design and construction; and operation and maintenance of different types of water supply and sanitation devices presented earlier in this paper.

The other most important of all training program activities is the selection and training of instructors or trainers. Technicians and supervisors should be trained so that they can teach their colleagues, subordinates or interns on the job. Education of trainers should be provided in schools, through short courses, audio-visual aids, and job training.

ROLE OF DEVELOPED NATIONS

Developed nations can play a major role in helping the developing nations to achieve the original goals of the UN

Water Decade. The assistance may come in the form of funding of the international agencies (UN, World Bank, etc.) and international development agencies in their own countries.

The technical assistance and transfer of know-how can also be achieved in the form of advisory services to the governments, utilities, and institutions. The assistance can be provided by short-term and long-term consultants for on-job training, development of educational material, and training of personnel and manpower development.

POLLUTION EFFECTS ON FISH

INTRODUCTION

During the past twenty-five years, man has subjected the earth to an ever increasing variety of chemical substances never before encountered by living organisms. Many of these foreign substances, which originated from industrial, agricultural and municipal sources, are seriously threatening the natural environmental conditions established over geologic time by evolutionary processes. Organisms, including man, are finding it more and more difficult to escape the consequences of exposure to these compounds, many of which are known to interfere with life sustaining biochemical and reproductive mechanisms. Little is known, however, concerning the effects the vast majority of these pollutants will have on plants and animals that inhabit this planet.

The aquatic environment is the ultimate destination of most of these contaminants as a result of rainfall and runoff from the lands. The establishment of water quality requirements for the protection of fish life must, therefore, become an item of first priority. The task is complicated, however, by the fact that different species of fish as well as different developmental states of the same or different species exhibit wide variations in their sensitivity or tolerance to foreign materials. In addition, the basic biochemical and physiological information needed to evaluate the harmful effects foreign substances have on organisms is severely lacking for fish and other aquatic organisms.

It is the purpose of this chapter to briefly discuss the current state of knowledge in regard to the response of fishes to environmental contaminants. Because of the serious lack of information in the area of fish toxicology,[†] it is not possible, nor is it within the scope of this discussion, to present even an outline of the toxic effects of the many foreign substances which fish encounter. Instead, representative compounds have been selected to illustrate the principles that are believed to play a major role in determining how fish respond to environmental contaminants. Unfortunately, these principles are based almost entirely on research performed over the last several decades dealing with the toxicologic responses of mammalian species, including man, to drugs and foreign compounds. Until equivalent research is performed on fishes, we will be forced to rely on these mammalian principles when attempting to evaluate the effects foreign compounds have on fish species.

MECHANISMS OF TOXICITY

Foreign substances can injure organisms through a variety of mechanism but these can generally be grouped into two categories: specific and non-specific injury. Chemicals that produce non-specific injury usually do so at the site of exposure, such as skin, respiratory membranes, oral mucosa, and intestinal mucosa. Frequently, such injury is the result of the caustic or corrosive nature of the chemical with the cellular responses being directly related to the concentration of toxicant within the cell or tissue involved. Agents producing this type of injury are commonly referred to as "primary irritants" because they induce local, minor to severe inflammatory responses and occasionally extensive necrosis (death) of cells. Excellent examples of these chemicals are acids, bases and aldehydes, all of which are strong irritants to mucous and gill membranes.

Other compounds, unlike the non-specific action of the primary irritants, can have a high degree of specificity and act at low dose levels at certain receptor sites to produce pathological change in specific cells with subsequent alteration of the function of organ systems. The degree of injury is dependent on the efficiency of the repair mechanisms for the tissue involved. If a cell is not irreversibly damaged, functional and structural characteristics may return to normal. Cells that are permanently injured at usually replaced by fibrous (scar) tissue. Fibrosis can seriously impair the functional capability of the tissue or organ involved.

Examples of substances that exhibit specific toxicological actions are those that produce mutations by interfering with the genetic machinery of germ cells. Mutation of a dominant gene may express itself immediately and produce fatal abnormalities (teratogenic effects) or early fetal death. Other mutations may not express themselves for several generations and then suddenly appear creating serious abnormalities for that individual and its offspring. Chemicals may be carcinogenic (e.g. diethylnitrosamine and aflatoxin) and initiate the growth of malignant tumors in fish and mammals (Stanton, 1965; Ashley *et al.*, 1964). Many toxicants directly or indirectly affect reproductive mechanism, gonadal growth and development, spawning behavior, and fry survival by specific toxicological actions. This can frequently result in a depletion or extinction of a susceptible species.

[†] Toxicology is the scientific discipline that deals with the quantitation of injurious effects on living systems resulting from chemical and physical agents that bring about alterations in cell or organ structure and function.

FACTORS THAT INFLUENCE TOXICITY

Several biological, physical and chemical factors play a part in determining the ultimate toxicological consequences of a foreign compound on an organism. To produce injurious effects, a toxicant must achieve an adequate concentration at its sites of action. The concentration attained at these sites in the animal obviously depends on the amount of foreign compound present in the animal's environment. Equally important, however, are the extent and rate of the toxicant's absorption, distribution, binding or localization in tissues, inactivation, and excretion. These factors are depicted in Figure 1 (Goodman and Gilman, 1970).

The following sections discuss each of these aspects that play the major role in the response of organisms to foreign compounds.

Absorption of the Toxicant

Generally speaking, a compound with specific toxicological actions must first be absorbed and distributed (biological translocation) in an organism before it can reach its specific site of action and exert its toxic effect. The ease with which foreign substances are absorbed, therefore, is a significant factor in determining the toxicity of foreign compounds. Absorption of substances by fish occurs through the skin, oral mucosa, intestinal mucosa, and gills. Because it is necessary that gill surfaces be exposed to large volumes of water for the maintenance of adequate blood levels of CO_2 and O_2, this organ is an especially vulnerable site for the absorption of foreign materials. Fish are, therefore, exceptionally susceptible to toxicants that readily cross the gill epithelium. In addition, fish acquire many foreign substances from their diet by absorption across the gastrointestinal mucosa. It should be mentioned, however, that studies are severely lacking about this and other mechanisms of translocation of foreign substances in fishes.

The biochemical and physicalchemical properties of a compound determine both its ability to cross biological membranes and its distribution within an organism. In general, the non-ionized, non-polar forms of compounds are significantly soluble in fat, i.e. lipid soluble, and are therefore readily transported across the lipidal components which characterize animal-cell membranes (Whittaker, 1968). The chemical structure of a foreign compound also determines its ability to react with biological molecules as well as its susceptibility to biotransformation (metabolism) by organisms. The ability of an animal to metabolize foreign compounds is important to that organism because the products (metabolites) formed usually are less toxic (but occasionally greater) than the parent compound. A more detailed discussion of biotransformation mechanisms appears later in this chapter.

Distribution of the Toxicant

Once the toxicant is absorbed and has entered an organism's blood or lymphatic system, it is readily transported and distributed to sites of action, centers of metabolic breakdown or detoxication, storage, and excretion.

Most toxicants are transported reversibly bound to blood proteins with only a small portion existing in the free or unbound state. Compounds must usually exist in this unbound state to react with biological molecules (receptors) and interfere with biochemical mechanisms. Therefore, the total amount of plasma protein available for the binding and transport of toxic substances plays an important role in the toxicological consequences of these compounds (Petermann, 1961). It is interesting to note that fish, when compared to mammals, have a distinct disadvantage in this regard since

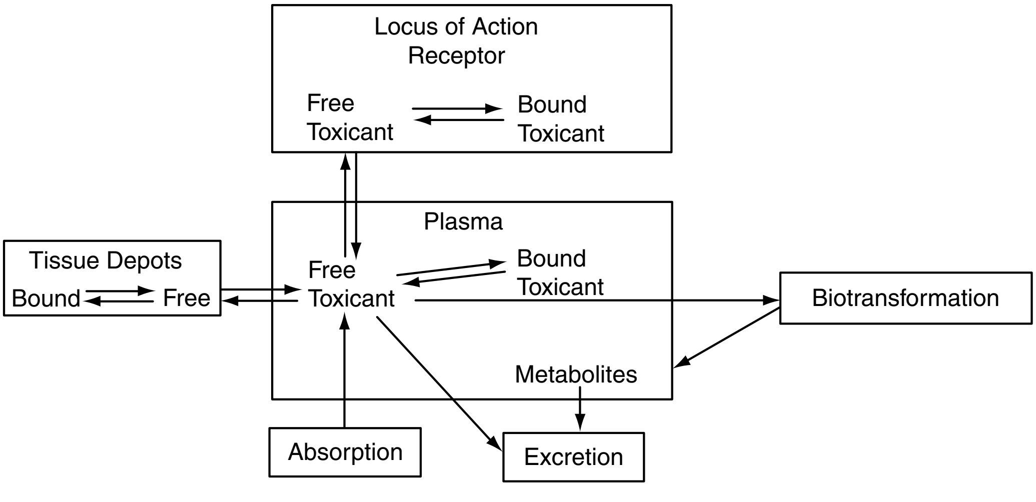

FIGURE 1

they have much less plasma protein. Compounds that have a high tendency to bind to plasma proteins may compete or displace one another from binding sites when they exist together in the blood. This may be the mechanism of dangerous toxic interactions because plasma protein binding sites become so saturated that a greater percentage of unbound toxicant exists in the blood than would normally be present with only one toxicant. When the degree of plasma binding is high and the rate of release is low, plasma proteins can act as a storage depot for the bound substances. Storage depots also frequently result from a particular affinity a toxicant may possess for certain organs or tissues. Examples of this are the chlorinated hydrocarbon pesticides which are stores in body fat and heavy metals such as copper and mercury which are stored in the liver and kidney of fish (Life, 1969).

Many foreign compounds are capable of producing a specific effect, that is, are selectivity toxic, on a specific biological system or systems. These systems are said to be the site of locus of action of the chemical. The site may be confined to one anatomic location within the animal, or may be diffusely located throughout the animal. Two fundamental types of mechanisms are responsible for the selective action of chemicals on cells or cellular mechanisms.

The first type is a result of factors that increase the concentration of the toxicant at specific cell or tissue sites. This is accomplished in the organisms by mechanisms of selective translocation and biotransformation. One good example is the renal tubular (kidney cell) injury produced in fish exposed to copper. Because copper is excreted by the kidney it accumulates at tubular cells. As the concentration rises injurious levels are reached and these cells are damaged or destroyed (Life, 1969).

A second mechanism in the selective toxicity of chemicals on cells involves the presence of specific targets or receptor systems in exposed cells. In this case, the concentration of the toxicant is the same for all cells, but only certain cells are affected. This is due to the specificity of action of the toxicant on receptors that are normally occupied by endogenous hormonal or neurohormonal substances. Organophosphorus compounds such as parathion and malathion are good examples of selectively toxic agents that act in this way. These cholinesterase inhibitors act to inhibit the enzyme responsible for hydrolysis of the neurotransmitter, acetylcholine. In this example cholinesterase is considered to be the receptor. Prevention of the hydrolysis of acetylcholine results in the continuous stimulation of post-synaptic sites throughout the central and peripheral nervous systems and rapid death due to respiratory paralysis is the usual outcome.

Biotransformation and Excretion of the Toxicant

The duration and intensity of injurious action of many foreign compounds are largely determined by the degree and speed at which an organism can eliminate these compounds (Conney, 1967). The kidneys of both marine and fresh water fishes have been shown to share with mammalian kidneys the primary role of ridding an animal of potentially toxic compounds (Forster, 1961, 1967).

The excretion of substances by the kidney is largely determined by lipid solubility characteristics of the compounds as they enter renal tubules. Molecules with a high degree of lipid solubility are readily re-absorbed from the renal tubule through lipoidal membranes back into the circulating blood and consequently are not excreted. It is only through certain specific biochemical transformations of these foreign compounds by the organism itself that lipid solubilities are altered and tubular excretion is successful (Brodie and Erdos, 1962). These reactions or transformations can be classified as oxidations, reductions, hydrolyses and syntheses (conjugation).

Most animals, including fish, transform (metabolize) foreign compounds in two successive phases, the first phase consisting of a variety of oxidations, reductions, and hydrolyses and the second phase of a limited number of syntheses or conjugations (Williams, 1967). Phase I reactions can result in:

1) The inactivation of a toxic compound;
2) The conversion of an initially inactive compound into a toxic compound; and
3) The conversion of a toxic compound into another toxic compound.

The second phase of biotransformation, consisting of synthetic reactions, most often results in the conversion of toxic compounds into inactive excretory products. This concept of the metabolism of foreign compounds can be represented as in Figure 2 (Williams, 1967).

Biochemical reactions of both phases of metabolism are catalyzed by enzymes located in various organ systems, and it is from the study of the qualitative and quantitative variations in these enzymes that an evaluation of detoxifying capacities can be made for an organism (Williams, 1967).

Phase I reactions are carried out by enzymes of normal metabolic routes and by enzymes which occur in the smooth endoplasmic reticulum of liver cells. When these cells are ruptured in the laboratory by homogenization the endoplasmic reticulum undergoes fragmentation. High-speed centrifugation separates these fragments from the remaining cell constituents. These fragments are referred to as microsomes and it is the microsomal enzymes that are involved in the metabolism of many drugs and foreign compounds. Microsomal enzymes do not generally act on lipid-insoluble compounds but rather convert lipid-soluble materials by oxidative and reductive processes to less lipid-soluble metabolites, which are more polar substances and, therefore, readily

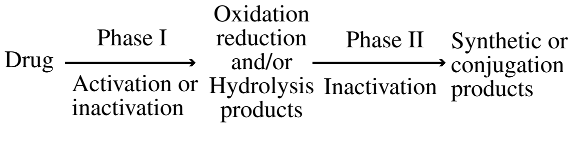

FIGURE 2

excretable by the kidney. Without these biotransformations, the effects of some foreign substances on organisms would last for months (Brodie *et al.,* 1965). Excretion of these lipid-insoluble metabolites can be achieved by active secretion at the tubules of the kidney or by passive transport across the glomerular membrane into the renal tubule (Forster, 1961, 1967). Since the metabolite has been transformed to a less lipid-soluble derivative, it will not diffuse back into the plasma for recirculation subsequent to passing through the glomerulus into the tubule.

The microsomal enzymes were, until recently, thought to be concerned only with the metabolism of compounds which are normally regarded as foreign to the body. Conney (1967) has recently shown that steroid hormones and other normal body constituents are also substrates of the drug-metabolizing enzymes in liver microsomes and he suggests that this enzyme system may play a significant role in their regulation and physiological action. These enzyme systems are thought to operate by a mixed function oxidase mechanism whereby NADPH reduces a component in microsomes which reacts with molecular oxygen to form an "active oxygen" intermediate. The "active oxygen" is then transferred to the drug or toxicant (Gillette, 1963). Key enzymes in the overall reaction are NADP-cytochrome *c* reductase, the flavin enzyme involved in the oxidation of NADP, cytochrome P-450, and NADPH cyctochrome P-450 reductase, which acts to reduce oxidized cytochrome P-450 (Gillette and Sasame, 1966).

Many foreign compounds can alter these key enzymes and enhance or impair the ability of liver microsomal enzymes to metabolize other foreign compounds and steroids (Conney, 1967). Halogenated hydrocarbon insecticides have long been known to be potent stimulators of mammalian drug-metabolizing enzymes (Hart and Fouts, 1963; Hart, Shultice and Fouts, 1963). Buhler (1966) selectively induced drug-metabolizing enzymes in rainbow trout by exposing these animals to DDT or phenylbutazone. Organophosphate insecticides are unlike the halogenated hydrocarbons in that they inhibit, rather than stimulate, the metabolism of drugs and steroids by liver microsomes, when given chronically to rats (Rosenberg and Coon, 1958; Welch *et al.,* 1967). Some heavy metals (Fe^{++}, Cu^{++}, Zn^{++} and Co^{++}) have also been shown to be inhibitory to drug metabolism in mice and rats (Peters and Fouts, 1970). Alterations in microsomal enzyme metabolizing capacities can substantially alter an animal's response to foreign compounds as well as its ability to hydroxylate steroid hormones and other normal body constituents (Conney, 1967). Altered steroid metabolism can directly affect the animal's ability to cope with environmental stresses as well as seriously impair reproductive mechanisms.

Other than Buhler's (1966) work on rainbow trout, little is known about the effects foreign compounds have on the microsomal drug metabolizing capacities of fishes. In addition, the current state of knowledge dealing with metabolism of foreign compounds in fishes is, at best, scanty (Adamson, 1967).

THE TOXICITY OF COMPLEX EFFLUENTS

Most industrial effluents contain mixtures of two or more substances. These complex effluents present special problems in evaluating their toxicities to fish and other organisms. In some cases two agents with similar pharmacologic actions can produce a response that is equal to the summation of the effects of the individual agents or greater than the summation of the independent effects of the two agents. The latter response is called "potentiation" and represents the condition whereby one compound is made more toxic in the presence of another compound which alone may produce minimal or no pharmacologic effect. Potentiation poses a special problem for the aquatic environment as well as the terrestrial environment for it is possible that a certain combination of relatively harmless substances may result in an unpredictable high level of toxicity that would seriously threaten the existence of one or many species. Usually, however, the effect of two agents is the summation of responses to each agent. Occasionally, the effect of a toxic substance is reduced on the addition of another substance, a phenomenon referred to as antagonism. In some cases the antagonistic substance may or may not be toxic when present by itself.

Synergism (potentiation and summation) and antagonism are poorly understood phenomena and greatly confuse the understanding and prediction of the toxic effects of industrial effluents. The majority of toxicological studies conducted in this and other countries on both mammals and fish deal with the effects of single substances on organisms; only a few studies are currently investigating the responses of organisms to complex mixtures of substances. Synergism and antagonism are worthy of further investigation, for little is known about the basic mechanisms governing these processes.

RESISTANCE OF FISH TO TOXICANTS

Resistance of animals to chemicals has been known to exist for some time now and has posed serious obstacles in the control of insects and bacteria. While the mechanisms of resistance remain thus far a mystery, we know that they are genetically based. Most susceptible populations of animals have an occasional individual which exhibits resistance and it is this member that provides the genetic material for selection pressures to act upon.

Resistance has best been demonstrated with various pesticides in several natural populations of fishes (Ferguson *et al.,* 1964, 1966), but these findings have attracted little attention. Many biologists have, in fact, believed this phenomenon to be beneficial to these animals, especially since they are useful to man.

Recently, some disturbing evidence has emerged suggesting that pesticide-resistant vertebrates pose a major hazard in natural ecosystems and that they may be creating serious toxicological problems for man (Ferguson, 1967). The reason for this is some resistant animals carry massive residues of unaltered pesticides in their tissues and aggravate the already serious problem of biological magnification.

Animals whose resistance is due to enhanced abilities to metabolize toxic substances to inactive metabolites do not, however, contribute to biological magnification.

Biological magnification results when a foreign substance enters plants and small animals and is then passed rapidly along food chains to larger animals. As this happens the substance becomes more and more concentrated until it reaches dangerous levels in the large predacious fish, many of which are consumed by birds and mammals including man. Clearly, the more resistance a fish has for the particular toxicant in its tissues the greater the likelihood it will be consumed by animals living on the land. Unfortunately, these animals may not have equivalent levels of resistance and may be unable to adequately deal with these toxicants.

CURRENT METHODS OF EVALUATING TOXICITY IN FISHES

The establishment of water quality standards for concentrations of toxic pollutants that will be safe for fish has recently become a major concern of Federal and State Governments in pollution control (Water Quality Criteria, 1968). Efforts in this regard have centered around determining lethal limits of toxicants by establishing a TLm (tolerance limit, median) of various species exposed to toxicants for periods of time up to 96 hr (Sprague, 1969).

These short term studies have been valuable in defining the upper limits of toxicity but have not considered the subtle deleterious effects of foreign compounds which may not be evident for weeks, months, or longer (Water Quality Criteria, 1963). These responses to toxicity may manifest themselves in appetite changes, metabolic alterations, disorders of the nervous system, reproductive changes, behavioral abnormalities, or alteration of vital functions which are not immediately lethal. For this reason, investigations have only recently been conducted to measure toxicity in terms of survival, growth, and reproductive alterations resulting from long-term exposure to sublethal levels of pollutants (Water Quality Criteria, 1968). The concept of a "maximum acceptable toxicant concentration (MATC)" has originated from these studies and is defined as the highest continuous concentration of a toxicant that does not significantly decrease the laboratory fish production index; an index developed by Mount and Stephen (1967) which takes into account survival, growth, reproduction, spawning behavior, viability of eggs, and growth of fry.

Because the toxicity of most pollutants varies with water characteristics and fish species, Mount and Stephen (1967) proposed the use of an "application factor," (calculated by dividing the MATC of the 96-hr TLm value), to determine safe concentrations of toxic pollutants which, when determined for one species of fish in one type of water, may be applicable to other waters and other species. Studies are currently underway to test the practicality of this approach (Mount, 1968; Mount and Stephen, 1969).

The "application factor" approach may improve upon present methods of estimating safe concentrations of toxicants. At best, however, this approach requires considerable time for collection and evaluation of data and measures only the end result of a multitude of biochemical, physiological, metabolic, pharmacological and pathological responses to toxicants. Little definitive information is gained concerning the mechanism which produces the gross changes upon which the "application factor" is based.

Because of the virtual impossibility of thoroughly assessing the individual, cumulative, synergistic and antagonistic effects of the numerous substances continually being introduced into our environment, it is imperative that we know the basic metabolic, physiologic and toxicologic responses of fish to compounds representative of broad categories of foreign substances. Only then will we be in a position to predict intelligently the biological effects of toxicants and regulate their concentrations to assure protection of this very important biological resource. If fish toxicologists continue to consider only the effect of a substance on the laboratory fish production index without understanding causative mechanisms, they will severely limit the amount of information available for making meaningful decisions so desperately needed in water pollution control programs.

Investigations of the disposition of foreign compounds in fish will shed valuable information on the evolution of enzymes that metabolize drugs, on drug metabolic pathways and excretion, and on factors affecting the biological half-life of foreign compounds in their lower species as well as higher vertebrates including man (Adamson, 1967). The editors refer the reader to numerous studies which have noted the collection of fishes with fin erosion or other deformities. A few concentrated on fresh water streams (Reash and Berra, 1989; Sindermann, 1979) whereas a preponderance focused on marine or estuarine environments with and without pollution (see Cross, 1985; Skinner and Kandrashoff, 1988) for example. Reash and Berra found that the incidence of fish erosion was significantly greater at polluted stream sites compared to unpolluted sites.

POLLUTION FROM MINE DRAINAGE

INTRODUCTION

All forms of mining cause some impact on the aquatic environment, just as any other earth disturbance will impact the local hydrology. Sometimes this impact is very adverse, in which case there is usually a considerable disruption of the natural life cycles in the affected water. Other, and less noted cases may even improve the local waters. Unfortunately, the adverse impacts greatly outnumber the advantageous circumstances so that the result of mining is to severely degrade the aquatic environment.

A generalized characterization of the impact of mining on water is rather difficult, as almost any specific change in the chemical qualities of the affected waters may be found at some specific point. In almost all cases, however, there is an increase in the total dissolved solids in the mine drainage waters. Additionally, the acidity of mine drainage is increased above normal ground water levels for the area, and the level of dissolved metal is increased. In some areas, however, the alkalinity levels are increased by mining. Many forms of mining also increase the suspended solids content of water.

Coal mining has received the greatest amount of attention as the mining which causes water pollution. This is perhaps deserved as the mining of coal has been a major operation for many years and more coal has been mined than any other single mineral. Water pollution from coal mining was known in medieval England and the mines in Wales were known to make the creeks run red. This fact was important to the exploration of the North American continent, as early explorers deduced the presence of large deposits of coal from the natural color and character of some of the streams and creeks. Similar conditions were sometimes noted in relation to other mineral deposits in the US. As the outcrop materials come into contact with the atmospheric conditions, oxidation and solubilization take place and the products are transported into the streams. Hence, the natural production of some mine drainage is a natural phenomena which has existed almost from the beginning of time.

Coal mine drainage may vary from waters pure enough to drink without treatment to waters containing more than 20,000 mg/l acidity with commensurate amounts of iron and other dissolved solids. Drainage from metal mines may vary over almost equally wide ranges of acidity but often contain substantial amounts of dissolved heavy metals. In most respects the acid drainages from metal mines are similar to acid coal mine drainages. This similarity is so great that most of the treatment processes and prevention mechanisms developed and applicable to coal mine drainage can also be applied to metal mine drainage.

ORIGIN OF ACID MINE DRAINAGE

The earth strata associated with and superjacent to coal and many other minerals almost always contain the iron sulfide mineral pyrite (FeS_2). Oxidation of the acidforming pyritic material associated with mining is necessary for the formation of mine acids and as oxygen is a necessary part of the oxidation of these materials, there can be no significant amount of oxidation until these are exposed to air. The process of mining greatly increases the exposure of these materials to atmospheric oxidation. Oxidation of the sulfide mineral begins as soon as it is exposed to the air and continues at a rate characteristic of the geologic and atmospheric conditions. Usually this oxidation causes spalling of the mineral substance with a progressive increase in the amount of surface area available for oxidation. Time then becomes a significant factor in the amount and rate of formation of acid mine drainage.

The exact nature of the pyritic mineral which oxidizes so rapidly and causes the acid drainage from mining has been sought for many years. In appearance, the mineral is often grey like marcasite, and its oxidation rate is even more rapid than that of marcasite. X-ray diffraction studies of the sulfide material associated with coal, however, have confirmed by the crystal structure that the material is pyrite rather than some other crystalline form of iron sulfide.

The intricate mechanism of oxidation of this pyrite and the formation of acid drainage has been the subject of many learned discussions and research efforts extending back over fifty years or so. The reaction will occur at normal room temperature and humidity conditions with the release of SO_2 into the atmosphere. Under more humid conditions, the reaction results in all of the sulfur being converted into sulfate. Typical reactions depicting some of the several paths possible for the reaction of the iron sulfide, air, water and alkali materials are listed.

This list is typical rather than all-inclusive to cover all possible reaction routes.

$$
\begin{aligned}
&\mathrm{FeS_2 + 3O_2 \rightarrow FeSO_4 + SO_2}\\
&\mathrm{2FeS_2 + 7O_2 + 2H_2O \rightarrow 2FeSO_4 + 2H_2SO_4}\\
&\mathrm{4FeSO_4 + 2H_2SO_4 + O_2 \rightarrow 2Fe_2(SO_4)_3 \downarrow + 2H_2O}\\
&\mathrm{4FeSO_4 + O_2 + 2H_2O \rightarrow 4Fe(OH)SO_4 \downarrow}\\
&\mathrm{Fe_2(SO_4)_3 + 2H_2O \rightarrow 2Fe(OH)SO_4 \downarrow + H_2SO_4}\\
&\mathrm{Ca(HCO_2)_2 + FeSO_4 \rightarrow CaSO_4 + Fe(HCO_3)_2}\\

&\quad \mathrm{Ca(HCO_2)_2 + Fe_2(SO_4)_3 + 4H_2O \rightarrow}\\
&\mathrm{CaSO_4 + 2Fe(OH)_3 \downarrow + 2CO_2 \uparrow + 2H_2SO_4}\\
&\mathrm{Ca(HCO_2)_2 + H_2SO_4 \rightarrow CaSO_4 + 2CO_2 \uparrow + 2H_2O.}
\end{aligned}
$$

There has been a continuing debate among the scientific community over the role which bacteria may play in the formation of acid mine damage. Bacteria of the Ferrobacillus ferroxidans family are almost always found in large pools of acid mine drainage. The bacteria have been shown to have the capability of oxidizing ferrous iron to the ferric state. However, they thrive in a very limited pH range (approximately pH 3.5) and there is no evidence to indicate that they contribute directly to the primary oxidation of the pyretic substance. Ferric ion can oxidize sulfide sulfur and this could possibly provide a mechanism for the bacteria to increase the rate of oxidation of pyrite in some circumstances. Other recent studies have shown that the transfer of oxygen from the atmosphere to the pyrite surface is the rate limiting factor of the reaction, making moot arguments put forth as to whether bacterial or chemical oxidation is the principal mechanism of acid drainage formation.

Bacteria may play a significant role in the oxidation of the ferrous to ferric ion in mine drainage. This fact can be of considerable importance in the treatment of mine drainage as ferrous iron tends to retard the rate of neutralization reactions. It almost appears that this is Nature's first step in the neutralization of acid drainage. The bacterial oxidization of iron allows the alkalinity of the associated earth strata and of diluting waters to be more readily reacted with the acidity of the mine drainage waters. This concept is rather radically at variance with former concepts that considered the sterilization of a mine as a possible method of reducing or eliminating the formation of acid drainage. Bacteria has been used deliberately as a step in the treatment of mine drainage. This process allows the ferrous iron to be oxidized and accelerate the neutralization of the acid salts.

The formation of acid drainages from surface and underground mines is essentially the same process, and the two drainages are indistinguishable on the basis of the chemical qualities of the waters. In general the iron contained in drainage from surface mines and also from coal refuse piles is in the ferric state. The drainage from surface mining may contain very substantial amounts of suspended solids or sediment. Because many of the drainage problems of strip and deep mines are directly interrelated there is almost no rational way of separating the treatment or preventive measures which may be applied to the two types of mining.

EXTENT OF ENVIRONMENTAL IMPACT

The problem of environmental degradation caused by mine drainage is widespread and serious. Some form of mining occurs in each of the fifty states and many states are extensively mined. The aquatic degradation caused by coal mining in the eastern and Appalachian region is best known and has been best documented. For this reason, most statements of the damages caused by mine drainage cite only the degradation in the Appalachian area. The Appalachian Regional Commission reported that some 10,500 miles of streams in that region are affected by mine drainage and acid drainage continually pollutes nearly 5700 stream miles. Since data are not available in many mining areas, particularly in the Rocky Mountain and western areas, firm total statements of the extent of the problem cannot be made. However, enough information is available to indicate that it is very substantial.

The extent and amount of degradation which may be caused by the presence of mine drainage, and the environmental and economic impacts which may be felt, vary, of course, with the type of mine, the strata surrounding it, and other localized conditions.

For example, coal mine drainage, which is usually acidic, kills fish and other forms of aquatic biota by lowering the pH of the water and also may have an adverse economic effect upon the human population. The acidity accelerates the corrosion of bridges, culverts, boats and navigational facilities, making replacement at shorter intervals necessary. High cost water treatment may be required to make the local water supply potable or suitable for industrial use. Water contact sports may not be possible in the area, causing a loss of potential tourist industry revenues.

Although metal mining may cause the same adverse effects, it usually occurs in less densely populated regions. Additionally, metal mine drainage may render the waters toxic to humans as well as aquatic life by the presence of heavy metals.

REMEDIES FOR MINE DRAINAGE POLLUTION

In the past a substantial number of investigators have simply discussed the problem and observed its extent so that more is known about the nature of the problem than about the mechanisms which may be applicable to correcting or mitigating it. Mine drainage may be characterized on the basis of its source and possible remedies considered by this categorization even though the chemical nature and biological impact of the drainage from the several sources is identical. For the purposes of this discussion let us consider three types of mine drainage by the source: drainage from active or operating mines, drainage from non-operating (sometimes called abandoned) mines and drainage which will be generated in the future from mines which have not yet begun operation.

Separating surface and underground mines is not feasible as they frequently occur together and interact to add to the problem.

Presently operating mines have certain characteristics which differentiate mines them from other mines. Primarily because they are now in operation a responsible owner or operator can be located and people, equipment, machinery and power are available at the mine site. This allows consideration of procedures to treat the mine drainage as well as procedures to reduce or minimize the amount of pollutants discharged both during the remainder of the mine's life and after mining has been terminated. Procedures presently available may be employed to minimize the amount of mine drainage pollution which issues from an operating mine, but no procedures are now available which can totally eliminate it.

Non-operating, or abandoned mines, generally do not have any responsible person readily available, or any other resources such as personnel and machinery, which makes abatement techniques more expensive for this type of mine than for one which is operating.

When a mine is still in the planning stage, it is easier to plan for future prevention of pollution and thereby reduce it. For instance, provisions can be pre-planned for a mine to have rapid and complete drainage during the mining operation, thereby reducing the pollutional discharges which otherwise may need to be treated. Additionally, improved mining methods can provide for minimum void spaces after mining; also water level control after mining ceases can be provided only during the mine pre-planning stages.

The methods for alleviating mine drainage may be divided into the two basic categories of treatment of mine drainage, and prevention of the formation of discharge of pollutants.

Treatment removes pollutants by physical/chemical means and generally results in only specific pollutants being removed or reduced. The process must continue for as long as the source produces pollution and usually in the case of mine damage this is tantamount to "treatment in perpetuity." Disposal of wastes and constant usage of power or chemicals made such treatment unduly consumptive of both human and physical resources. Treatment methods for coal mine drainage are summarized in Table 1 and many of the methods are applicable to other types of mine drainage pollution.

Prevention is the total cessation or massive reduction of the formation or discharge of pollutants during and after the operating life of the mine. Prevention of all forms of pollution, including dissolved and suspended materials, is obviously more desirable than simple treatment of pollution with its attendant problems. Provisions for prevention of the formation of pollution cab be planned into a mine while it is still on the drawing board. Specific techniques for prevention and correction of pollution from mines, both operating and non-operating, are shown in Table 2.

TABLE 1
Summary of treatment techniques

Pollutants removed[a]	Neutralization and aeration	Microbial iron oxidation	Reverse osmosis	Ion exchange	Flash distillation[d]	Electro-dialysis	Product recovery	Silt basins
Acidity	XXX	NA	XX	X[c]	XX	X[e]	X[f]	NA
Iron	XX	XX	XXX	X[c]	XXX	?	X[f]	NA
Aluminum	XXX	NA	XXX	X[c]	XXX	X[e]	X[f]	NA
Manganese	X[b]	NA	XXX	X[c]	XXX	X[e]	X[f]	NA
Copper	XX	NA	XXX	X[c]	XXX	X[e]	X[f]	NA
Zinc	X[b]	NA	XXX	X[c]	XXX	X[e]	X[f]	NA
Hardness	—	NA	XXX	X[c]	XXX	X[e]	X[f]	NA
Suspended solids	X	NA	NA	NA	NA	NA	X[f]	X
Dissolved solids	—	NA	XXX	X[c]	XXX	X[e]	X[f]	NA
State of art[g]	CU	PP	PP	R, PP, FSO[c]	FSD	R[e]	R	R, CU
Cost, $/1000[h]	0.05–4.55	UK	0.30–2.57	0.30–2.53	0.33–3.25	0.52–2.52	UK	0.02–1.0
Waste product[j]	S	S	B	B, R	B	B	S,B,R	S

[a] NA—Not applicable, ? Questionable, X-degree to which removed, the greater number of "X"s the higher the removal.
[b] Must be raised to very high pH.
[c] Various ion exchange techniques are under evaluation. Their effectiveness and which pollutant is removed depends on the technique.
[d] 5 mgd plant is under construction in Pennsylvania. Techniques has only a limited potential.
[e] Technique will not operate where iron is present in water.
[f] Various product recovery schemes are under consideration; however, all are still in research stage.
[g] R—Research, PP—Pilot Plant, FSD—Full Scale Demonstration, CU—Common Usage.
[h] Cost depends on the degree of pollution, size of plant, pre- and post-treatment requirements. UK—Unknown.
[j] Each treatment process has a waste product that must be disposed of and creates additional problem. S—insert sludge, B—highly mineralized brine, R—regenerate.

TABLE 2
Cost and effectiveness of various at-source prevention and corrective techniques

Control techniques	Effectiveness %	Cost	Remarks
Surface mine reclamation	25–90	$300–3000/acre	Includes backfilling, regarding, contouring, and water control structures. Prevents acid formation, erosion control, runoff of dissolved soils. Cost and effectiveness controlling factors are nature of surface and overburden, slope of land, and proposed use of land.
Mine sealing (air)	0–50	$1000–5000/seal. Additional cost of $5000–100,000/seal may be required to control entrance of air through subsidence holes, boreholes, outcrop, etc.	Sealing of an underground mine to prevent entrance of air. Prevents acid formation. Cost of effectiveness depend on the ability to locate and seal all air paths to the mine, type and condition of mine operating and type of seal. Most mines cannot be airsealed.
Mine sealing (flooding)	75–99	$1000–20,000/seal. Additional costs of $5000–20,000 may be required to control drainage through bore holes, outcrop, etc.	Sealing of an underground mine to completely and permanently flood the working. Prevents acid formation and sometimes all discharges. Cost and effectiveness depend on the ability to seal all discharges, size of mine, dip of seam, outcrop condition, condition of mine opening, type of seal, and amount of grouting required. Is not applicable to all mines.
Drainage diversion	25–75	$200–20,000/acre	The prevention of water from entering the mine area. Prevention of siltation and flushing of pollutants. Cost and effectiveness depend on ability to divert as much water as possible in properly designed structures.
Impoundment	50–95	$350–1000/acre-ft	Flooding of surface mine pits. Prevents acid production. Cost and effectiveness depend on complete and permanent flooding of the material responsible for acid production.
Refuse pile reclamation (reject material from mining and processing)	25–75	$1000–3000/acre	Stabilizing a refuse pile with soil, chemicals, vegetation, etc. Prevents acid production and siltation. Cost and effectiveness depend upon the availability of the land in which the refuse piles can be filled and also upon the availability of impervious materials such as clay, fly ash, or limestone for compaction over the surface of the filled area.
Reject tailing pond (reject material from mining and processing in slurry form)	25–95	$300–2000/acre	Stabilizing of tailings by flooding, soil covering, chemicals, vegetation, etc. Prevents air pollution and discharge of suspended and dissolved solids. Cost and effectiveness depend upon the size, location.
Revegetation	5–25	$70–700/acre	Establishment of vegetative cover on reclaimed surface mines, reject piles, and pond. Prevents erosion. Cost and effectiveness depend on the type of cover, soil conditioning, and thickness of cover required.
Controlled pumping and drainage	25–75	$0.190.23/1000 gallon	Involves rapid removal of water from a mine before it gets contaminated or discharge of contaminated water at regulated rate so that dilution provides minimum contamination effects. Cost and effectiveness depend upon the characteristics of the material in the mine, contact time between water and exposed materials, rate of pumping, pumping head, and amount of dilution water available.
Inert gas blanket	Under research and development		Filling of an underground mine with an inert gas to prevent acid production.
Sterilization	Under research		Control of the bacteria in a mining environment. Prevents acid production. Technique does not show merit at this time.
Internal sealing	Under research and development		Internal sealing of underground mine to prevent acid production and/or mine drainage discharge.
Longwall mining	Under research and development		Allows complete removal of the coal in an underground mine. Mine roof collapses behind the working face, eliminating "breathing" of the mine.
Daylighting	Under research and development		Strip mining of a previously mined underground seam. Removes pillars left before. Surface must be reclaimed.

It can be seen from Table 2 and Figure 1 that the cost of creating or preventing the formation of mine drainage is a wide ranging variable, dependent on the method(s) selected for use. The estimated costs for the limestone neutralization treatment of mine drainage are shown in Figure 1 as a function of acidity and quantity to be treated.

As can be seen in the figures, the number of methods of alleviation and control of mine drainage which are highly effective are few, and most treatment processes produce undesirable by-products, as well as being expensive over the long run. It would be highly desirable to lessen the sources of mine drainage and to be able to treat it effectively with a gain in desirable by-products.

New techniques for the prevention of pollution from mines are presently in the development and demonstration stage. For example, a new technique known as "daylighting" is being demonstrated. This procedure will use strip mining techniques to remove the residual coal from shallow, non-operating mines and consolidate the overburden to prevent the continued discharge of acid drainage. A variety of abatement techniques related to surface mine reclamation are being demonstrated in the Appalachia region. Also there are two major efforts directed toward the development of non-pollutional mining techniques. These are the mining of coal under oxygen free conditions within the mine to prevent the oxidation of pyrite and the formation of acid drainage and the application of a new mining technique called "longwall stripping." Longwall stripping will apply longwall mining techniques to shallow cover coals, which are now strip mined, to remove the coal without inverting or dismantling the overlying earth strata.

LITERATURE REFERENCES

Most discussions of this type are buttressed by an impressive listing of reference documents citing sources of the many facts contained therein. To the casual reader, these references are useless, except for their creation of an impression of authority. The serious worker will demand to have even more references and documentation. The field of coal mine drainage is somewhat unique in that the literature of the field is regularly collected, abstracted and these abstracts published. This publication, entitled "Mine Drainage Abstracts, a Bibliography" is prepared by the Bituminous Coal Research, Inc. for the Commonwealth of Pennsylvania. Copies may be purchased from B.C.R., Monroeville, Pennsylvania. A listing of the reports of the research in this field may be obtained from the Publications Branch, Office of Research and Monitoring, Environmental Protection Agency, Washington, DC 20460.

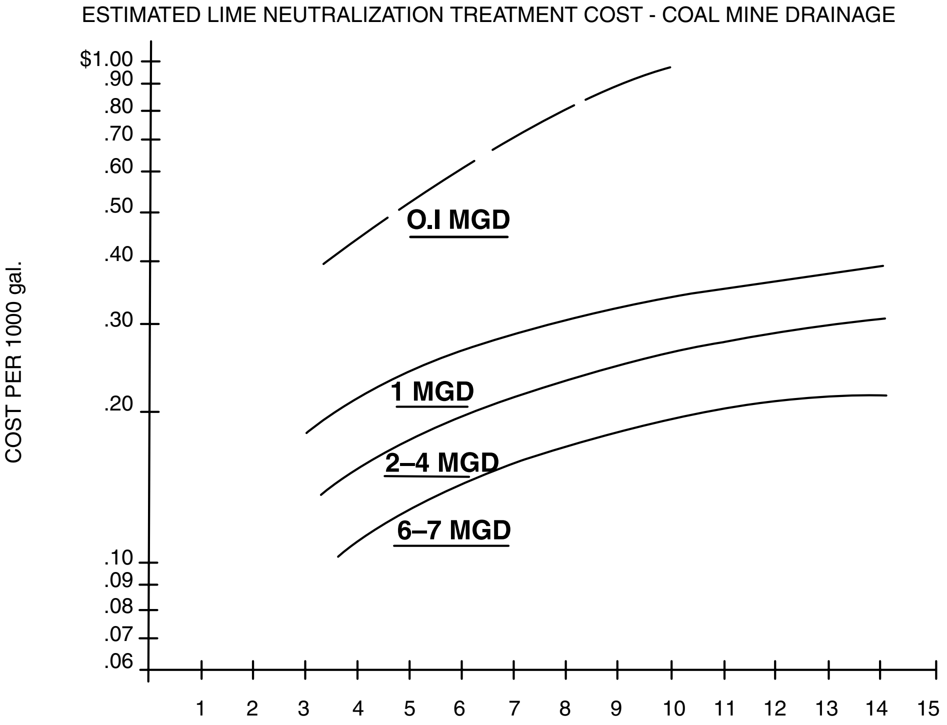

FIGURE 1 Estimated costs for treatment of coal mine drainage waters based upon a composite of published laboratory, pilot plant, and actual plant data. The estimate for the 0.1 MGD plant is preliminary and based upon limited information.

PREVENTION OF TOXIC CHEMICAL RELEASE

Purging of process vessels, tanks and piping before startup and after shutdown is imperative for pilot plants and large-scale plants in the process industries or wherever combustible gases and vapors are handled. Gases most often used for purging are nitrogen, carbon dioxide, or gases derived from the combustion of hydrocarbons. The reader is referred to the sections on Vapor and Gaseous Pollutant Fundamentals and to Fossil Fuel Cleaning for unit operations and incineration procedures involved in hazardous gas removal. To show how the purging procedure can be "mapped" a typical purging chart will be constructed and the salient points explained (see Appendix).

Inert gases such as nitrogen have the property of not only depressing or narrowing the explosive range of a combustible gas or vapor, but also of preventing the formation of explosive mixtures with air when these inert gases are mixed in suitable proportions with either air or with the combustible gas or with an explosive mixture of both. By displacing or mixing air contained in a vessel, tank or piping system to be placed into gas service, with a suitable amount of an inert gas such as nitrogen, a combustible gas may subsequently be introduced without the formation of an explosive mixture. Similarly, by displacing or mixing the combustible with a suitable amount of nitrogen, air may later be introduced without causing an explosive mixture to develop. During the purging procedure constant sampling of contents must be pursued using standard accepted methods of chemical analysis.

GAS FLAMMABILITY LIMITS

A flammable mixture of a gas, such as acetylene and air, may be diluted with one of the constituents (acetylene or air) until it no longer is flammable. The limit of flammability due to dilution is the borderline composition: a slight change in the direction will support burning, while in the other direction combustion cannot be supported and maintained.

At the ends of these two extremes there are well defined limits within which self-propagation of flame will take place on ignition. These are known as "upper" and "lower" limits as defined in terms of the percentage by volume of combustible gas present in a mixture of the gas and air. Table 1 below lists these limits for some of the more common gases and vapors for conditions of atmospheric pressure and temperature.

Within these limits, the combustible gas and air mixture liberates sufficient energy to continue to propagate flame from one mixture layer to the other. Mixtures above the upper limit may burn on contact with external air, since these layers are formed in the zone where gases mix. Certain conditions effect a shift in the two limits, either increasing or decreasing the spread between them as we will note later. These conditions include: ignition source, ignition intensity, direction of flame propagation (upward, downward, or across), size and shape of container, vessel, or piping orientation, temperature, pressure and humidity in the containing vessel, oxygen content and turbulence.

EXPLOSIONS

When a chemical reaction is accompanied by the liberation of heat, as the reaction progresses, it is followed by an increase in the amount of heat, which in turn helps to accelerate the reaction. Thus the two advance together, both in highly intimate connection and mutually helpful, until the entire mass has been heated and chemically converted.

When a burning substance, a match for instance, is placed in contact with the extreme outer limit of an explosive mix-

TABLE 1

Per cent gas or vapor in mixture—flammability limits

Gas or vapor	Lower	Upper	Gas or vapor	Lower	Upper
Acetylene	2.5	80.0			
Carbon monoxide	12.5	74.2	Acetone	2.6	12.8
Hydrogen	4.0	74.2	Ethane	3.2	12.5
Ethyl ether	1.9	48.5	Propane	2.4	9.5
Carburetted	6.4	47.7	Butane	1.9	8.4
Hydrogen sulfide	4.3	45.5	Benzene	1.4	8.8
Methyl alcohol	6.7	36.5	Gasoline	1.5	6.2
Coal gas	3.9	29.9	Turpentine	0.8	—
Ethylene	2.8	28.6	Ammonia	16.0	27.0
Pennsylvania	4.9	14.1	Ethyl alcohol	3.3	19.0
Natural gas	—	—	Methane	5.0	15.0

ture of gas and air, ignition takes place at the point of contact, i.e. incites chemical reaction. Combustion proceeds from the outside of the mixture towards the center, and thereby forms a plane of combustion which divides the gaseous mixture into two parts. On the one side are the highly heated products of combustion, and on the other, is the still unconsumed gas mixture.

The velocity at which this plane advances in different for each gaseous mixture, and depends both on the composition of the mixture and on the pressure to which it is subjected. The higher the velocity of propagation the greater the rise in temperature, and this latter, in turn, directly influences gas expansion and the products of combustion, which thereby exert such a high pressure on their environment that any opposing medium, vessels, tanks, piping, walls, etc. is ruptured.

APPLICABLE EXPLOSIBILITY DATA

Not all explosibility data reported in the literature are applicable to purging problems. From the safety standpoint, it is desirable to select the widest explosive limits for the purge operation. In addition, an ample safety factor be applied, especially to the lower explosive limit. For acetylene-air mixtures, at atmospheric pressure and temperature, the published and accepted values for the lower explosive limit (LEL) and upper explosive limit (UEL) are 2.5 and 80.0% acetylene in air respectively. These are the widest limits recording. See Table 1.

In every case involving combustible gas handling or processing, constant awareness of the inherent dangers to life and limb as well as property is imperative. In the case of acetylene, it is a well known fact that it has unstable characteristic at any pressure and whether or not a decomposition would take place depends on the intensity of the initial source of ignition. Higher pressures have the effect of lowering the initial energy necessary to initiate a decomposition.

ACETYLENE—CASE STUDY

Acetylene is inherently an unstable gas at any pressure and whether or not a decomposition would take place depends on the intensity of the initial source of ignition. Higher pressures have the effect of lowering the initial energy necessary to start a decomposition. Higher initial pressures will also result in an increase in the ratio of the maximum pressure developed in the decomposition to the initial pressure. As for acetylene-air mixtures, pretty much the same behavior is manifested. With decreasing ignition energies, the initial pressures must be correspondingly increased so as to bring the total gas mixture volume to decomposition.

The size, shape and orientation of a process vessel as well as its material of construction have a profound effect on the ignition limits of combustible gas mixtures. The same applies to acetylene decompositions. It is a matter of heat balance during the combustion process. Even the relative position of the source of ignition. The widest explosive range is obtained for vertical cylindrical vessels or tanks when the ignition source is located at its base.

The presence of water vapor and high humidity acts as a diluent and an inert gas. This effect is typical for all combustible gas–air mixtures.

As for the effect on explosion limits, the ratio of vessel surface to cross-sectional area from a cooling or heat balance point of view, long slender vessels (high ratio of surface to sectional area) narrow the limits of explosibility. It's all a matter of the rate at which heat is removed from the gas mixture inside the vessel. As for the temperature effect, higher temperatures induce convection currents within the vessel and increase turbulence and widen the limits.

Thus, only tests of actual operating setups can tell the effects on the widening or narrowing of the explosibility range. Then, once established, the LEL and UEL determined experimentally can be used to develop a purging graph hereinafter discussed and developed.

EFFECT OF INERT GAS

The effect of an inert gas on explosibility of combustible gases in air can be shown graphically on Figure 1 for acetylene–air mixtures. Once the conditions for actual operating conditions and configuration are determined experimentally, the graph can be set up as we shall see.

As nitrogen is added to mixtures of the gas and air within the explosive range, a series of new mixtures are formed each of which has a different UEL and LEL than the preceding mixture and the explosive range is narrowed along definite lines of demarcation. As the air and combustible gas contents are reduced by the addition of nitrogen, the line of LELs and the line of UELs converge and meet at a point, i.e., *D*. Here the range has degenerated to zero. No mixture of acetylene, air and nitrogen which contains less oxygen than the lowest point on the line *LDU* (point *D*) is explosive in itself, but all mixtures within the areas bound by *LUD* are within the limits of explosibility and are therefore explosive. Again, in Figure 1, line *ADE* is drawn tangent to *LDU* at *D*. Any mixture represented by point *X* to the right of line *DE* and below the upper explosive limits *DU* is not explosive in itself. However, on dilution of that mixture with air, a new series of mixtures will be formed having compositions falling along line *X A* which passes through the explosive area. Similarly, any mixture represented by a point to the left of line *LD* and *DE* will not form explosive mixtures on further dilution with air.

Note line *LD* is not vertical but swings to the right as falls.

APPLICATION OF GRAPH

At startup when placing gas equipment into service purging from air to inert gas, the object is to reduce the oxygen

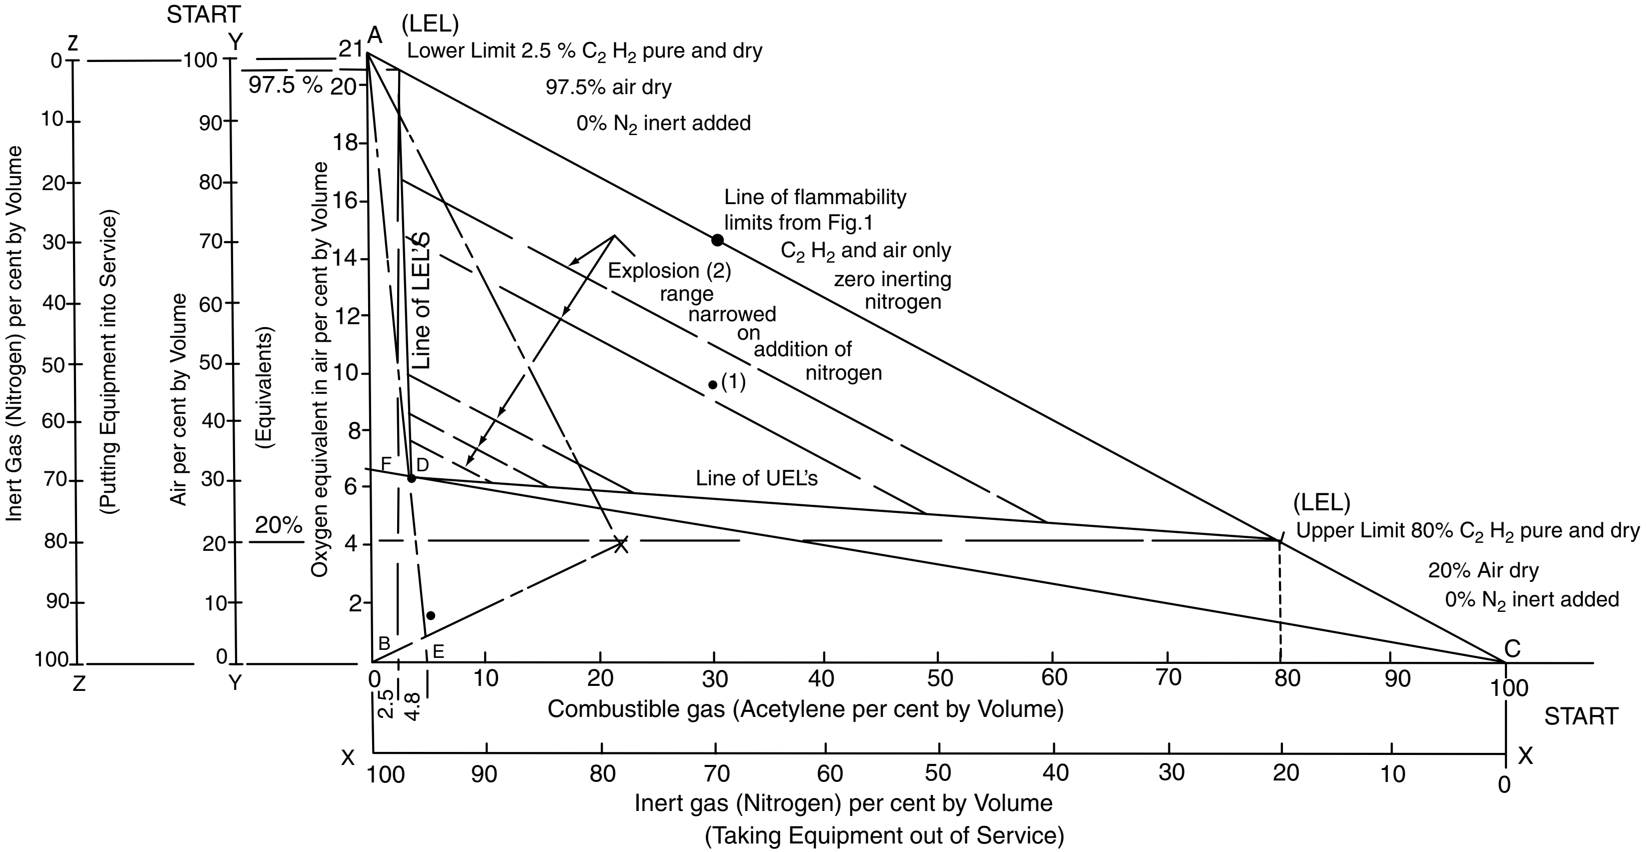

FIGURE 1 Acetylene-Air-Nitrogen purging chart (atmospheric temperature and pressure).

content of the air inside the equipment to a point that acetylene (or other gas) may be subsequently introduced without forming an explosive mixture. From Figure 1 it may be observed that the safe condition will be reached when the oxygen content within the vessel or equipment has been reduced by the introduction of nitrogen to below approximately 6.6% by volume, point *F* where *FC* drawn tangent to *LDU* at *D* intersects the vertical axis *AB*. Any mixture of this combustible gas, nitrogen and air having an oxygen content represented by a point below this line *FC* may be diluted with the combustible gas without forming an explosive mixture (see Appendix).

WHEN SHUTTING DOWN

Likewise, when shutting down or withdrawing equipment containing acetylene from service or when purging from combustible to inert gas, the object is to reduce combustible gas content to such a point that the air may subsequently be introduced without fear of forming an explosive mixture. Figure 1 shows that a safe condition will be reached when the combustible gas content within the equipment or piping has been reduced to below 4.8% by volume, denoted by point *E*.

On occasions the mixtures of acetylene, nitrogen and air are to be diluted with a further quantity of inert gas so as to render them nonexplosive or incapable of forming explosive mixtures on later addition of air. Object here is to add sufficient nitrogen to convert the existing composition of the mixture to some composition corresponding to a point to the left of *LD* and *DE*. If we assume that the mixture is again denoted by point *X*, then on addition of nitrogen, successive mixtures will be formed along *XB*. Point where *XB* crosses *DE* denotes the safe endpoint composition. Then on the further addition of air (intentional or accidental) the line of mixtures will fall to the left of *LDE*.

In practice, it is desirable to decrease the proportions of oxygen and combustible gas below the determined values to provide a factor of safety. To prevent explosion in chemical processing, it is necessary to keep the air–gas or–vapor or mixture of the gases, air and nitrogen, below the *LEL* within the equipment most likely to be affected. An established safe practice is to keep the mixture well blended with air or inert gas so that calculated or experimental values never reach more than 25% of the *LEL* or other low limit as determined from Table 1 in temperatures below 250°F. Placing system into service or out of service should be done when system has been depressurized to atmospheric pressure.

DEPRESSURIZING TO ATMOSPHERE

More often than not, combustible-gas releases to atmosphere do not contain air. When handling acetylene in its pure state a maximum pressure of 15 psig is usually used. Thus on release to atmosphere large quantities of the gas may be emitted through pressure relief valves to flares or high stacks. Then again the gas may be returned to gas holder storage. If released to atmosphere, inert gas purging should be provided. An excellent reference on inert-gas purges of stacks on pressure releasing has been published*; for process equipment see review.[12]

SAMPLING OF MIXTURE CONTENTS

During startup or shutdown of systems, sampling of mixtures within equipment should be conducted downstream of the point of injection of nitrogen to ensure proper mixing of gases before sampling. Taking samples from stratified streams should be avoided. For piping systems sampling should be taken downstream of elbows and open valves. In anticipation of this elbows and turns as well as valves should be designed into the system originally. In actual testing it has been observed that form 6 to 10 volume changes are necessary to purge equipment or piping systems. Sampling should begin after this purge.

Purging to a point below the LEL may be done using an explosimeter[†] that has been properly calibrated for the gas–air–nitrogen mixture. Laboratory testing procedures may also be used where samples are washed[†] with acetone and the volume of acetylene absorbed deducted from the entire sample to give volume of the remainder gases as air or nitrogen.

Spark-resisting tools should be used to prevent sparking and possible ignition of combustible gas. Work shoes with rubber soles and so steel studs should be used. In addition, continuous sampling of the workroom atmosphere should be conducted using explosimeters built for that purpose.

INERT GAS SUPPLY

Where rigid purity of inerting gas is not a requirement, the use of inert gases obtained from the combustion of hydrocarbon fuels may be used. This decision is one to be based on experience and processing needs.

Gas analysis can now be accurately measured and controlled in tenths of a percent range. These inert gas generators are provided with rugged instrumentation and controls for hazardous environments as found in desert and offshore installations. The analysis can even be accurately measured down to the ppm range where instrumentation maintenance is present. The same caliber of technician is needed whether or not the nitrogen source is cryogenic or hydrocarbon.

Such inert gas generators are currently supplied with automatic trimmer control which analyzes the discharge gas and automatically controls the air-to-fuel ratio. For critical installations they are even equipped with inexpensive automatic vent and alarm systems. For more information and their technical manual, write to C.M. Kemp Manufacturing Company, Glen Burnie, Maryland 21061.

[†] Explosimeters are available from Mine Safety Appliances Company, Pittsburgh, PA 15235 and Davis Emergency Equipment Company, Newark, New Jersey.

Skid-mounted units for applications in remote locations, or where onsite cryogenic facilities are too large to be cost-effective, are available. These units provide nitrogen at purities of 97 to 99.5%. They operate by pressure-swing absorption, in which a bed of activated carbon absorbs oxygen from air at high pressure and desorbs it at reduced pressure. The nitrogen produced by this cyclic process contains 5 ppm of water and CO_2. 400 to 20,000 cfh of nitrogen can be supplied, at a pressure of 100 psig. Write Airco Industrial Gases, Murray Hill, New Jersey.

Nitrogen for purging may also be supplied from cascade systems or directly from "bottle" trailers under pressure, normally 2000 psig. When drawn from large cascade systems or reservoirs the nitrogen is piped into a "running tank." The "run" tank is then pressurized and its contents are expanded through pressure regulators as desired for purging. When pressurized trailers are used, the high pressure gas is regulated down to the desired pressure for purging.

ACKNOWLEDGMENTS

This article appeared in its original form in *Chemical Engineering,* December 9, 1980, pp. 65–68. It has now been redone to provide more useful detail in the designation and use of the chart. A special section on checking points and areas on the graph has been included. This author gratefully acknowledges with thanks the permission by *Chemical Engineering* to update and republish.

APPENDIX

STEPS IN SETTING UP PURGING CHART

1) Draw right triangle *ABC* whose size is to accommodate ordinate and abscissa scales.
2) Fill in both ordinate and abscissa scales for the combustible of concern.
3) From Table 1 superimpose the explosive range of the combustible gas of concern on line *AC*, using the abscissa scale values.
4) Using the experimentally determined value equivalent of point, *E*, strike that value on line *BC*.
5) Draw line *AE*.
6) Draw lines *LD* and *UD*.
7) Draw line *FDC*.
8) Establish any point *X* below line *FDC*.
9) Draw lines *AX* and *BX* as shown.
10) Complete the chart by adding in the notes and other embellishments.

Draw chart carefully so that the various points can be determined with accuracy. And remember to use a safety factor in applying the chart figures, i.e. 25% of the chart values (points E and F) when taking equipment out of service and when putting equipment into service, respectively.

PURGING CHART DESIGNATIONS AND USE

Point D = No mixture of acetylene, air, and nitrogen which contains less than 6.4% oxygen is explosive.
LDU = All mixtures within area of triangle LDU are explosive.
Point X = Any mixture such as denoted by point X is not explosive.
Line XA = On dilution of mixture denoted by point X with air, new mixtures along XA are formed.
LDE = Any point to the left of LDE will not form explosive mixtures on dilution with air.
FDC = Any mixture of acetylene, nitrogen and air represented by a point below FDC may be diluted with acetylene without forming an explosive mixture when placing equipment into service.
Point F = fe point reached after air displaced with nitrogen and ready to add acetylene (6.6% oxygen) when placing equipment into service.
Point E = Safe point reached after acetylene displaced with nitrogen and ready to add air (4.8% acetylene). This is the situation when taking equipment out of service.

CHECKING POINT AND AREAS ON GRAPH

Purpose is to become better acquainted with the graph and to check various points.

UEL From UEL on AC read down vertically to 80% acetylene on BC. Then read horizontally left to YY and read 20% air by volume, with Zero inert nitrogen. Then by calculation and since composition of air is 21% oxygen and 79% nitrogen by volume: $O_2 = 4.2\%$; $N_2 = 15.8\%$.

LEL Likewise: 2.5% acetylene and 97.5% air and zero inerting nitrogen. In the air: 20.48% O_2 and 77.02 N_2%.

Point 1 This lies within area bound by LDU and should be explosive. Now from point 1 drop vertically and read 30% acetylene on BC. Move horizontally left to YY and read air per cent = 4.6. Then by calculation, O_2 content in air = 9.66% and nitrogen content = 36.34%. By difference inerting nitrogen is 70–46 = 24% by volume. Since 9.66% O_2 is greater than 6.4%, the mixture is explosive.

Point X Should not be explosive. From X drop vertically and read 21.5% acetylene as before. Move horizontally left and read 19% air on YY. Then by calculation find O_2 in air = 3.99% and N_2 in air = 15.01%, leaving 59.5% inerting nitrogen by volume. Since $O_2 = 3.99\%$ and is less than critical value of 6.4%, mixture is *not* explosive.

Point 2 Should be explosive. Acetylene = 30%, air = 70%. $O_2 = 14.7\%$ and nitrogen = 53.3%. Zero inerting nitrogen. Now since O_2 is greater than 6.4%, mixture is explosive.

X A line and UEL line intersect Acetylene = 19%, air = 29%, O_2 = 6.09%, 52% inserting nitrogen. This is a borderline case and safely assume nitrogen is explosive. Dilute with acetylene of nitrogen to render mixture non-explosive.

XB On dilution of mixture X with nitrogen, new mixture will fall along XB and remain non-explosive. In this process, per cent O_2 will continue to drop below 6.4%. Dilution with acetylene would effect the same results.

When shutting down Add N_2 until acetylene reaches 25% of experimentally determined lower limit. Thus, 0.25 × 4.8 = 1.2%.

When starting up Add N_2 until O_2 reaches 0.25 × 6.4 = 1.6%. When purging with any gas allow from *6* to *10* volume space changes before testing for concentrations. The Design Institute for Emergency Relief Systems (DIERS) Users Group, which is an affiliate of the American Institute of Chemical Engineers, has developed some methodology to design emergency relief systems.[8] The DIERS study was very extensive and complicated. It involved significant developments and applications of complex theories and experiments. Some aspects were reaction kinetics under runaway conditions and multiphase critical flashing flow for viscous and nonviscous systems. A number of DIERS users have attempted to simplify the DIERS technology.[9,10,11]

PSYCHOLOGICAL ASPECTS OF MAN'S ENVIRONMENT

Man's interaction with his environment is an integral part of the science of psychology. Psychology has been defined as the study of human and animal behavior. Behavior does not take place in a vacuum. It is conditioned by the environment in which it occurs.

The relationship between man and his environment is interactive. Man is not only influenced by his environment; his behavior may also profoundly affect his environment. Where psychology can predict behavior for various environments, it will permit calculation of the impact of behavior on the environment. To the extent that it has developed procedures for controlling such behavior, it can alter the impact of human and animal behavior on the environment by changing that behavior.

Viewed from this perspective, psychology might be expected to have far reaching impact on any area of environmental concern; indeed, for any area of human concern.

It is not surprising then, to find that much work in psychology is relevant to problems of concern to environmental scientists and engineers. Problems in almost any area of environmental study may have roots in psychology. Many substances whose physiological effects are of concern to environmentalists first make their effects on organisms apparent through behavioral indices and tasks studied by psychologists. Many standards problems have psychological aspects. Potable water must be acceptable to the palate, as well as meeting biological and chemical standards based on health considerations. It has been shown that existing ventilation standards for inhabited buildings originated in part from considerations of odor control. The impact of a field depends upon its achievements, as well as its domain of concern, however. One of the aims of this paper will be to consider the extent to which psychology can accomplish its aims in areas of environmental interest.

This paper will concern itself first with psychological studies relevant to man's physical environment. It will then go on to consider his psychological and social environment. These categories are to some extent artificial. The relevant environment for an organism consists of those aspects of the physical environment to which it is sensitive. This environment is not necessarily the same as the physical environment as measured by physicists or engineers. A colorblind organism will not respond to variations in the wavelength of light in the same way as one with color vision, though the physical stimulus is the same in both cases. Psychophysics is the branch of psychology concerned with the relationship between man's sensory processes and his physical environment and over one hundred years of psychophysical research has shown that the relationship is both subtle and complex. Nevertheless, such division conforms to some natural boundaries within the fields of psychology, and of environmental studies, and so it will be adopted here.

THE PHYSICAL ENVIRONMENT

The earliest studies in psychology were concerned with the relationship between measurements of the physical environment and perceptual processes. Since one cannot determine the nature of a percept directly, what was actually measured were certain observable responses, which were taken to be indices of these percepts. Although the concept of behaviorism was not originally enunciated in connection with psychophysics, but came later in connection with studies of learning, it is well to note that problems in all areas of psychology can be formulated in behavioral terms. In the author's opinion, this should always be done. It avoids innumerable arguments over concepts and processes if one recognizes that only the behavior is measurable, and that other concepts, such as motives, feelings, images, etc., are, from this point of view, theories developed to facilitate description of the relationships between the environment and behavior, however real these constructs may seem in other contexts.

Psychological Methods for Environmental Study

Psychological procedures relevant to environmental questions can be conveniently divided into the following categories: studies of sensory thresholds and simple perceptual and psychomotor tasks; behavior in simple learning situations; more complex-learning and decision tasks; methods for studying opinion; and evaluation of such complex processes as emotion and personality changes in response to environmental factors.

Psychophysical Procedures The study of sensory thresholds is one of the oldest areas of psychology, going back to the work of Weber and Fechner towards the end of the nineteenth century. Classically, two types of thresholds have been determined; absolute thresholds and difference thresholds. The absolute limen, or threshold (AL) is the minimum amount of stimulus energy required to elicit a response; the difference limen (DL) or threshold, is the minimum energy change required to perceive a change in the stimulus. Because the amount of energy related to that required for a perceived change is often related to the absolute value of the stimulus, the different limen is often given as a fraction of the absolute value.

Since the range of intensity for most of the senses is very large, it is customary to use a logarithmic scale in expression of the stimulus values. In audition, the decibel is a common unit. Intensity (I) is given in decibels (dB) by

$$I = 10 \log P_1/P_r \mathrm{dB},$$

where P_1 is the stimulus power, and P_r the reference level. Measurement in decibel units is less common for the other senses, but some type of logarithmic scale is frequently used.

The measurement of thresholds presents certain technical problems, due to variability in the response, and the possibility of response bias. Two major methods were devised to deal with the problem: the method of limits and the method of average error. In the method of limits, series of stimuli of varying intensity are presented and the subject is asked to make a response, according to whether the subject does or does not perceive the stimulus, or stimulus change. Since threshold values obtained typically depend on whether the approach to the threshold is up (from unperceived to perceived) or down (from perceived to unperceived), several series of trials in both directions may be averaged. The method of average error is an adjustment method. The subject is asked to adjust a variable to match a standard, and the variability of the response is used as a measure of the limen. It is most suitable to difference limen measurements.

Recently, the concept of a sensory threshold has been questioned, and the most popular view at present is to view the internal process as continuous, with a criterion applied to produce a dichotomous response. The view derives from the signal detection theory of sensory processes. The extent to which this model of the threshold differs from older ones is arguable; the arbitrary nature of the threshold concept has always been recognized. However, it has led to a more systematic treatment of the problems of noise and bias in threshold measurements. Procedurally it stresses the measurement of thresholds by yes/no judgments in which the probability of a false alarm is explicitly estimated, and by forced choice techniques. Receiver operating characteristic (ROC) curves are used to analyze the data. The resulting measure of sensitivity is usually referred to as *d*. From the point of view of reliability, either the classic methods or new signal detection procedures will usually lead to satisfactory results.

The sensory dimensions have been divided into two types: intensive dimensions and qualitative dimensions. Examples of intensive dimensions are the intensity of light and sound. Examples of qualitative dimensions are color and pitch, which often have recurrences in them, such as the scale relation in pitch, which complicate analysis. Sensory intensity normally increases logarithmically with increases in the physical stimulus. Qualitative dimensions may have more complex relationships with their physical correlates. The measurement of sensory thresholds may be extended to animals by means of conditioning procedures to be described in the next section.

Several thresholds other than the absolute and differential limens are important for environmental studies. Often, concern will lie in thresholds for discomfort, and for tolerance. It may also be desired to obtain information on the degree of discomfort produced by different environmental conditions. Direct judgments of discomfort or tolerance tend to be highly variable; individual tolerances, or at least statements about these tolerances, differ from individual to individual. One technique which is sometimes used is to obtain comparison judgments about the relative discomfort caused by different stimuli. One method of measuring pain thresholds is based on this principle; the discomfort caused by various stimuli is compared with the pain caused by a known exposure to infrared light on the forehead.

A fixed standard need not be used; cross comparison of the set of stimuli of interest is possible. Techniques have been developed for taking such paired judgments, and using them to scale the stimuli along the dimension of judgment. Variations of this technique can be applied to ranked data: ranking is less time consuming than a full set of paired comparison judgments, but it requires more assumptions to generate a scale. Multidimensional scaling techniques are usefully applied to preference or similarity judgments, however obtained. They are especially useful where the relevant dimensions of eth stimulus set are not clear, since they can be analyzed to obtain dimensions of judgment. It is also possible to analyze such judgments for clusterings among the subjects.

Classical and Operant Conditioning Classical conditioning is a type of learning pioneered by I. Pavlov, and still extensively studied by psychologists. In its simplest form, the procedure consists of presenting some stimulus which consistently elicits a response, known as the unconditioned stimulus (UCS) in combination with some other stimulus which does not normally evoke the response, known as the conditioned stimulus (CS). After a number of trials, the CS will be found to elicit the response in the absence of the UCS. Such a response is known as a conditioned response (CR).

Various complexities can be introduced into this paradigm and it has been the subject of extensive study and theoretical discussion. Its primary importance for the environmental field lies in the fact that the technique can be used to determine sensitivity to various stimuli. This can occur in two ways.

1) The effect of various physiologically active stimuli on the course of acquisition and extinction of a known CR can be studied. Changes in the course of learning and extinction are evidence of the effect of the stimulus.
2) The procedure can be used to determine threshold sensitivity to a stimulus. If a CR can be established to a given concentration or intensity of a stimulus, it is evidence that the organism is sensitive to the stimulus, though the reverse is not necessarily

> true. Thus, classical conditioning techniques can be used to measure sensory thresholds in animals.

A second major type of conditioning is known as operant conditioning. In operant conditioning, there is nothing equivalent to the UCS; a response which occurs is followed by some subsequent event, such as the occurrence of food, which will modify the frequency of the response. The desired response may have a low probability of occurrence and procedures such as shaping and the creation of special environments may be necessary. Shaping consists of reinforcing successively closer approximations to the desired response. A common example of a special environment is the Skinner box, a small enclosure whose most prominent feature is the response mechanism, usually a bar or button. The rat or pigeon in a Skinner box, pushing a bar or pecking or at a lever to obtain food or avoid electric shock are example of operant conditioning situations.

Operant conditioning procedures can be used for the same purposes as classical conditioning methods, but they have some advantages. Classical conditioning is relatively difficult to establish, is easily disturbed by any change in the environment and the CR ceases to occur (undergoes extinction) rapidly once the UCS is removed. Operant conditioning, on the contrary, is relatively easy to establish. One reinforcement often makes a marked difference in response rates. It is less sensitive to extraneous environmental interference and it can be maintained for long periods of time with a very low reinforcement rate. Records of cumulative responses to various reinforcement schedules show definite regularities. Changes in these patterns provide a sensitive measure of the effect of various chemicals on behavior and have been extensively used for this purpose in drug research. Threshold measurements in operant conditioning require a slightly more complex situation than in classical conditioning if the substance to be studied does not act as a reinforcer of behavior. However, by using it as a cue to indicate when some positive reinforcement is to be given, the thresholds of such substances can be studied by operant techniques. Both operant and classical conditioning techniques are applicable to humans as well as other organisms.

Other Simple Learning Situations Other types of learning situations which have been studied sufficiently to provide a basis for the study of behavioral effects of environmental factors are maze learning, discrimination learning, and a variety of simple verbal learning tasks. The former tasks may be used with either humans or animals. The verbal tasks are limited to humans. The complexity of the stimulus situation is generally greater in these tasks. Specifying the relevant dimensions of even simple mazes for learning situations is complicated, and an enormous and continuing effort has been devoted to the study of the features of verbal stimuli which affect simple learning tasks such as paired associate learning (where people are presented with pairs of words and then asked to recall one of the words when shown the other) and serial learning (where subjects are asked to learn lists of words). They are therefore less easy to quantify and compare across experiments than are conditioning responses and thus introduce additional problems for the study of environmental effects. However, with sufficient care, reliable measurements can be obtained.

These tasks come closer than simpler tasks to being of a complexity relevant to behavior in real life situations. It is quite possible that some stimulus will have no measurable effect on a simple process, but will effect more complex behaviors; the reverse is sometimes also the case; environmental conditions which will affect simple and monotonous tasks may not affect more intrinsically interesting tasks. For this reason, learning tasks other than simple conditioning are often studied when the effects of various environments are under investigation.

More Complex Tasks The number of human performances which have been studied by psychologists is very large; no satisfactory classification has been worked out for procedures going beyond the simplest. Various bases for categorization have been proposed; for example, sensory-motor to verbal, depending on the type of response; or in terms of complexity, from simple conditioning to complex problem solving. Probably the best ultimate solution will consist of a task analysis for more complex behaviors in terms of their dependence on more simple processes, but this has not been achieved in any general way at present. The particular type of task employed and the dimensions along which it is to be analyzed can be best considered at present in terms of the particular experimental situation. If an investigator is concerned with the effects of certain pollutants on complex judgments required by some task, he will do well to construct a task as much like the criterion task as possible and test the effects by means of a suitable design. If his concern is with performance in a vigilance situation, then a vigilance type task should be selected. Generalizations from effects on simple behaviors to more complex behaviors are hazardous at present.

Standardized Tests of Behavior Standardized tests have been developed for a wide variety of human abilities. IQ tests are the most famous, but many others exist. Such tests have as their primary purpose either selection in connection with personnel work, or evaluation for counseling for guidance, but they may be used in the same way as other tests for the evaluation of the effect of environments on performance.

Tests of this sort may be divided into tests of general ability, tests of specific ability, and tests of personality. Both of the former have been used in connection with environmental work. Occasionally, the latter have been also, though their suitability for the purpose of evaluating temporary shifts in emotional state is often dubious. Most standardized tests are designed to measure some relatively permanent characteristic. However, some of these characteristics, such as various types of manual dexterity, are sensitive to various environmental forces in a fairly straightforward way. The effects of depressant drugs on personality tests are considerably less clear. There is also a serious problem of validity with regard to some tests, especially personality tests. The objective tests, such as the Guilford-Zimmerman or the Minnesota Multiphasic Personality Index (MMPI), have been extensively validated against certain criteria, such as psychiatric diagnosis. However, the criteria themselves are open to argument in many cases. Also the criteria used for validation are seldom those of interest if a test is to measure temporary changes in emotional state due to changed environment. The tests often appear likely to be insensitive to the types of mood changes which may be of interest to environmentalists. Projective personality tests appear, on the surface, to be more sensitive for this purpose, for they permit much freer response than objective tests, and they have been used, for example, in studies of aggression. However, they are exceedingly difficult to validate, even against the type of criteria used for objective personality tests, and their predictive value for other types of behavior is almost entirely unknown.

Comments on Psychological Methods In evaluating these procedures for use in the environmental field, there are some general considerations to keep in mind. First, the psychophysical procedures are generally reliable, if carefully done, and generalization to other individuals from a small sample is good. This work is often done with two or three observers, and the results are repeatable. The extreme sensitivity of the sensory systems means that very precise control over the stimulus is needed, which is often expensive. Certain stimuli, especially odors, are difficult to handle; special equipment, such as odorometers, is necessary. Timing down into the millisecond range is typically needed in visual and auditory experiments.

Other types of behaviors tend to be more variable. Only in simple conditioning situations are such small numbers of experimental subjects likely to be found, and even here, for most purposes, more than three or four subjects are necessary. The requirements for stimulus control are somewhat less rigid, in most cases. In verbal learning studies, timing to .01 sec is usually adequate; less precision is often tolerable. However, the substantial variability of organisms presented with even relatively simple learning tasks, such as mazes or simple discrimination learning, makes a larger sample desirable. Individual experimental conditions may be tested on 10–12 subjects, or more; it is not uncommon to find verbal learning experiments which use several hundred subjects. Generalization to other populations is sometimes more of a problem and the equivalence of stimuli in different experiments is more difficult to establish. However, within these limitations, reliable results can be obtained in simple conditioning situations and most other simple learning tasks, including simple verbal learning tasks.

Both classical and operant conditioning procedures are very sensitive to the action of certain agents. Effects of levels of ionizing radiation have been reported as low as 5.0 r in conditioning experiments. Behavioral effects of several drugs of environmental importance, such as alcohol and amphetamines, can be found for relatively low dosages. While the information on the sensitivity of conditioning procedures to agents of interest such as SO_2 and NO_2 is sparse, there is no reason for believing that behavioral measures will not be equally applicable to many of these substances. Behavioral studies done in Russia emphasize the use of classical conditioning techniques in studying various environmental factors. In such research behavioral effects for low levels are frequent, though it is difficult to evaluate due to the obscurity of much of this literature by American standards of reporting.

Problems arise when it is desired to interpret behavioral measures in a more refined fashion than simply as indicators of some physiological activity of the substances. Temporary threshold shifts from noise exposure have been extensively investigated, but their implications for permanent damage is still being debated (see Noise). Similar problems exist for other measures. The problems which have faced psychopharmacologists in interpreting effects of drugs on animal behavior in terms of drug effects on humans have their counterpart in the environmental field; granted that a certain level of ionizing radiation can serve as an aversive stimulus in operant conditioning experiments on saccharin preference, for example, how are the results to be interpreted in terms of public health standards? How long lasting must such effect be in order to be indicators of possible physical damage? If no physical damage is to be expected, there is still the question of the costs of possible functional impairment. Does impairment of operant conditioning imply that the agent will also impair more complex functions in humans, with a possible increase in errors or accidents as the result? At present, answers are not available to these questions.

More complex tasks raise more serious problems of reliability. It is not uncommon in educational research for several experiments to yield contradictory results, for reasons which are often obscure. The complexity of the materials and other variations in subjects and procedures which are difficult to control or characterize are probably responsible. Thus, a single study done on the environmental effect of a substance on complex learning should be viewed with caution. Only when a series of experiments done under varying conditions converge on a result should the result be accepted.

Certain special problems which often arise are the effects of novelty (the so-called "Hawthorne" effect) and habituation effects. Individuals may perform well under a certain test procedure, which, when put into practice proves no better than the alternative. The problem is that subjects on whom new procedures are tried may make a special effort which is not sustained under routine conditions. A similar effect arises in regard to habituation. Individuals may respond badly to a new environment, but adjust to it over time without final decrement in performance. Since adaptation for some tasks can take months, adaptation effects are often inadequately tested.

Most research involving the possibility of exposure to physically hazardous conditions is done on animals. However, a good deal of research which involves physical discomfort or emotional stress is done on humans. Also, in some research, personal information of a private nature may be obtained. Concern over possible abuses of subjects has arisen in recent years, and several professional societies have or are developing codes of ethics to deal with these problems. There are also legal aspects to the use of human and animal subjects of which any potential research worker in these fields should make himself aware.

THE PHYSICAL ENVIRONMENT AND BEHAVIOR

Sensory Processes

Judged purely in terms of their adequacy as detectors, sensory systems are very efficient for many types of stimuli. The auditory system, for example, is capable of detecting sound near the level of Brownian motion under suitable test conditions. The number of photons required to obtain a visual response has been estimated as low as 5–14 photons under optimal conditions. The olfactory system is also exceedingly sensitive. As has been noted, the intensity of a sensation goes up approximately as a logarithmic function of increases in intensity of the physical stimulus (the Weber–Fechner law). It applies to such sensory domains as vision, audition, etc. In specific applications, of course, this information is inadequate for most purposes and more precise information is needed. The apparent loudness of a noise will depend on its frequency as well as its intensity, for example.

When qualitative factors are under consideration, it is more difficult to make any statements. The annoying properties of a noise are a complex function of specific combinations of frequency and intensity and it is still not well understood. See the article on noise in this volume for a more complete discussion of this problem.

There are, however, a few general statements about sensory systems which may be of use to environmentalists. First, of course, the primary channels of information to human beings are the visual and auditory systems. Senses such as touch, taste, smell, and so on are of far less importance than in the case of many animals. Of the major channels, vision has the larger channel capacity, in the information theoretic use of that term. However, this is not equivalent to an expression of their social importance. The auditory channel is the primary means of face-to-face communication between human beings, and studies indicate that loss of hearing may produce more profound personality changes than loss of vision. Early loss of hearing can produce a disastrous effect on language learning. For many purposes in adults, they may be equivalent for information transmission. When one is dealing with tasks which are purely informational, the visual channel may be more efficient, since in tasks like reading, humans can process more words than they can listen to in a given period of time.

Knowledge of visual and auditory parameters is important in the proper design of a number of environments. Consider the hazards associated with sources of glaring light along highways at night, for example. The visual system adapts relatively rapidly (usually within a minute) to large increases in light. The process of dark adaptation is much slower, however; it may take as long as half an hour to fully dark adapt the visual system. Rapid changes in the external light levels at night can therefore constitute a hazard, since they may keep the eyes of drivers in a state of adaptation to relatively high illumination levels even though the average level is relatively low.

Effects of Various Pollutants on Behavior

Ionizing radiation Perhaps the pollutant whose behavioral effects have been studied most extensively is ionizing radiation. Studies on both lethal and sublethal doses of both particulate and non-particulate radiation have been done. The conclusion has been that there is relatively little effect of either on the learning behaviors for most organisms. Insofar as tests are available, this seems to be true of man also. However, the activity levels of young rats have been reported to be affected when the mothers had been irradiated with one dose of 200 r. during pregnancy.

This does not mean, however, that organisms are not sensitive to radiation. Radiation has been used to condition avoidance to a saccharine solution (normally preferred by rats). It was found to produce an 80% decrease in response rate under some conditions. The amount of the decrement has been shown to be dose dependent. Russian research, using classical conditioning techniques, has reported a variety of behavioral effects, occasionally for doses as low as 5 r.

Air Pollutants The effects of carbon monoxide (CO) on behavior have received a good deal of study. Among other effects, 90 min of exposure to 50 ppm CO has been shown to impair ability to discriminate among relative lengths of short time intervals. The effect of CO on the electroencephalogram (EEG) patter in rats has been investigated. The results suggest a possible depressive effect of CO on central nervous system function. Significant reductions in tests of manual dexterity have been observed with blood carboxyhaemoglobin (COHb) levels in excess of 25%; such levels may be reached in garages and other enclosed areas containing motor vehicles. CO is known to elevate the visual threshold.

Since CO and some other pollutants have as one of their effects the reduction of the oxygen level in the blood supply, studies on the effects of hypoxia (oxygen deficiency) are relevant to the behavioral effects of gaseous pollutants. The visual threshold is very sensitive to hypoxia; significant impairment can occur at altitudes as low as 5000 ft, and at 15,000 ft twice as much light is required for minimum visibility as is required at sea level. Auditory and speech perception thresholds may also be affected slightly, especially for long exposures. Tasks requiring complex coordination, such as handwriting, deteriorate above 10,000 ft, and higher altitudes can affect simpler tasks and reaction times. Various cognitive tasks, such as card sorting, are affected, usually more than simple psychomotor tasks.

The physiological effects of a number of other pollutants such as NO_2 and SO_2 have been studied and information about their olfactory effects is also available. The olfactory system is very sensitive, and may give adequate warning for some pollutants. Sulfur dioxide, though extremely toxic is difficult to inhale at lethal concentrations without warning because of its intensely irritating properties. Habituating effects do occur with repeated exposure, however, and severe poisonings have occasionally been reported among workers who have adapted to high levels of this pollutants. It is important to note that the olfactory sense adapts very rapidly to most odors. This consideration is important when using odor tests, for chlorine in water, for example.

A number of other substances are not readily detectable by smell, however. Carbon monoxide is odorless, and nitrogen dioxide can cause fatal poisoning at concentrations which are not physically annoying.

Other Chemical Pollutants The behavioral effects of a number of other chemical substances which may be of environmental significance have been studied. These include alcohols, various psychoactive drugs, and various industrial chemicals. Ethyl alcohol has been found to increase reaction time by about 10% when the level of alcohol in the blood reaches 0.35%. Blood alcohol levels of 100 mg/100 ml have been reported to affect monitoring and tracking tasks, and lower levels have been reported to affect various complex tasks.

It has been possible to study the effects of a number of such chemicals in conditioning experiments. Several drugs have been shown to increase eating or drinking behavior in animals; these are usually drugs which act to reduce anxiety. Meprobamate and similar drugs usually increase eating; the barbiturates chiefly affect drinking. A number of such drugs have been shown to produce decrements in escape or avoidance conditioning, an effect usually attributed to their fear or anxiety reducing properties. Morphine addiction can be induced in animals, and the drug can serve as a positive reinforcer for behavior, permitting the study of various aspects of addiction, such as withdrawal, in animals, using conditioning concepts and procedures.

Depressant drugs, such as the barbiturates, have generally been found to impair memory in humans. Retrograde amnesia (failure to recall events just before administration of a drug or some traumatic incident, such as a blow to the head) has been reported for ether and for CO_2, administered post-trial. However, conflicting evidence exists. Post-trial administration of ether can also facilitate retention, and 30% nitrous oxide has also been reported to facilitate retention in humans when given after learning, though other studies have found impairment with nitrous oxide.

Facilitation effects on memory have been reported for a number of other drugs. Strychnine has been shown to improve maze learning for food rewards, discrimination learning, and other tasks. Various other substances have also been studied. However, the results are conflicting at present.

The various effects of chemicals on retention have been interpreted in various ways. It has been hypothesized that a certain period of time is necessary following learning for consolidation of the memory trace. Drugs or other events, such as a blow on the head, or the administration of electroconvulsive shock, may interfere with this process and prevent the retention of learned responses over time. Other possible explanations lie in facilitation or interference with nerve transmission or with protein synthesis. The inhibiting effects of puromycin and other antibiotics on some learned responses has been attributed to their interference with protein synthesis, though other explanations are possible. Explanations in terms of the drug effects on the animals' perception of the cues in the learning situation have also been suggested.

Environmental Stressors

Unusual conditions of temperature, noise, lighting, vibration, etc. may be encountered in some environments. Extreme values of such stimuli are often regarded as environmental stressors, and their physiological effects have been extensively studied. Concern has also been felt about their behavioral effects, and a number of studies have been done on this question.

Noise Excessive noise levels are known to be capable of damaging the auditory system. Noise can also be annoying, and its annoying properties are a complex function of its spectral composition (see Noise). It can also seriously interfere with tasks which depend on auditory communication. However, studies of effects on non-verbal tasks have reported mixed results, often negative. While interference through distraction may occur with sudden unpredictable sounds, in general, noise seems to have a minimal effect on most non-verbal tasks. It should be kept in mind, however, that adapting to noisy environments may impose additional stress on the organism. Noise can induce audiogenic seizures in susceptible strains of rats, and there have been reports of sound-induced seizures in epileptics.

Temperature A number of studies have shown decremental effects of elevated temperatures on a variety of tasks. Telegraph operators who had been acclimatized to a hot environment (Singapore) were studied at several temperatures above that of their usual environment. Errors were found that were related logarithmically to the temperature increase in the receipt of coded messages made up of assorted letter and number strings. Similar results have been reported by artificially acclimatized subjects in England. Subjects' judgments of comfort are not necessarily reliable guides to the temperature which gave best task performance. In general, the relationship between behavior decrement and heat stress is more straightforward for tasks involving physical effort than for other tasks, but effects on both have been reported.

Cold has also been studied, chiefly in relation to its effects on manual dexterity, which it decreases. Adaptation effects are also reported to cold.

Studies have been reported which show decrements in learning and retention with elevated temperatures, and improvements with cold environments. The latter have mostly been reported with invertebrates, and it is unclear whether the effect is directly temperature related, or due to restriction of activity with cold.

Vibration Excessive vibration has been shown to be physically damaging, especially to the circulatory system, in addition to causing symptoms such as seasickness in susceptible individuals. In terms of effects on other behaviors, the chief effect has been shown on visual acuity; most other studies have reported other behaviors to be unaffected. However, vibration has been reported to be unpleasant, if prolonged, even though the levels are below those believed to cause physiological damage, and secondary effects might be expected on monotonous tasks. The vibrations studied have varied from 0–60 Hz, these being the range of practical interest for most environmental purposes. Interactions with frequency are known to exist. Frequencies in the range of 10–24 Hz most severely impair visual acuity, while manual tracking is most seriously affected at frequencies of about 5 Hz. This frequency also produces the greatest subjective discomfort.

Inadequate Lighting Lighting may be inadequate either because it is too low, or because it causes glare. Excessive light intensities, such as those generated by lasers, can cause physical damage to the eye. While the eyes can adapt to a wide range of light conditions, the thresholds of the photopic receptors in the fovea of the eye are higher than in the periphery (scotopic vision). The density of receptors in the fovea is also higher, and the functioning of these receptors is important for tasks requiring good visual acuity. Therefore, if the light levels fall below the photopic threshold, such tasks will suffer. Visual acuity may be tested by means of Landolt rings (circles) with small breaks whose orientation the subject must detect) or by means of grids of varying fineness and orientation. Effects of light composition have also been shown on some tasks, even well above the photopic threshold. For most visual tasks, light levels well above the photopic threshold should be maintained.

Glare causes discomfort, and may interfere with various tasks. Two kinds of glare are distinguished; direct glare from a light source in the visual field; and specular glare due to light reflected from surfaces within the visual field. Both types of glare can be controlled by suitable adjustment of the environment. Direct lighting offers maximum light at the working surface when the source is directed downward, but it is likely to produce shadows, glare and undesirable brightness contrasts. Indirect lighting avoids these problems, and while it may lessen visual efficiency in reading over very prolonged periods, it has been shown superior to direct lighting in tests of 3 hr in length.

It should also be realized that color vision depends on the receptors in the fovea. Therefore, tasks requiring the use of colors must be performed with adequate lighting. The color of surfaces depends on the spectrum of the light which falls on them, so illuminants must be chosen to provide the proper colors for tasks involving color coding.

Special Environments

Changes in Sensory Input Early reports on the effect of isolated environments from polar expeditions and the like are in agreement with later experimental findings on the undesirable effects of restricted sensory inputs. Studies on extreme sensory restriction as carried out at McGill University, where subjects wore translucent goggles and stayed in low variability environments, have shown that such effects as loss of ability to concentrate and hallucinations may result. Polar expeditions have reported compensatory behavior in the form of the development of unusually structured groups, and special interests and hobbies on the part of individual members. Similar patterns sometimes develop in such isolation situations as solitary confinement.

Studies on early sensory restriction in animals have suggested that deficits of varying degrees of permanence may develop in subsequent behavior as a result. Extreme deprivation of sensory input and social contact is known to result in a variety of deficits in human infants, even though the physical needs of the infants have been met. The monotonous effects of long periods at tasks such as monitoring sonar screens for infrequent signals, and other vigilance tasks have shown deleterious effects in terms of missed targets.

The effects of excessive sensory input are less clear. Any situation which overloads the information processing capacities of an individual will be likely to result in decremental performance. However, apart from such short-term effects, it is not clear that there are long-term effects from an overly complex environment.

The reticular activating system in the brain stem, which has been shown to have an alerting effect, has been suggested as a possible locus for some of the effects of sensory isolation.

Other Special Environments Some other special environments that have received a good deal of study are submarines and simulated space capsules. The outstanding feature of the submarine environment is its limited space. Most studies have focused on physical problems associated with this environment, but a few have been concerned with the psychological effects. In general, adaptation to crowded conditions is seems to be good, though there are some losses of personnel attributed the confined conditions. One study reported a loss of 7% of 187 men over 6 months due to this factor. Complaints about lack of privacy have been reported also.

The problem of diurnal cycles arises in connection with such environments. The usual night–day shifts are lacking, of course, in extended undersea cruises, and time confusion has been reported: for example, inability to remember if it is 8.090 a.m. or p.m. It has been found desirable to introduce features, such as news reports and evening entertainments, into the daily routine which will avoid the sensation of being cut off from the rest of the world and which serve to mark diurnal cycles. It also appears that, although such cycles can be influenced by the environment to some extent, there are limits to the process. Alluisi reports evidence of diurnal cycling in performance under a variety of work–rest schedules, including some as extreme as 4 hr of work followed by four of rest.

Simulated space capsule environments have many of the features associated with sensory deprivation conditions, plus the added factor of fatigue. Prolonged exposure to such environments has been shown to produce decrements in a number of tasks, from vigilance tasks to complex decision making functions. Diurnal rhythms in efficiency have also been reported. However, it has also been found that trained pilots, who were familiar with the concept of diurnal rhythms, did not show such effects. Both motivational and adaptation processes may be at work here. It has been shown repeatedly that measures of "can" and "will" are often very different for special environments.

Diurnal cycles may be important in less exotic environments. Efficiency in a number of tasks has been shown to vary with the diurnal cycle. These variations appears to be related to the body temperature, which reaches its lowest point after several hours of sleep, and does not reach its maximum until the evening of the next day. These variations create problems for jobs with several shifts, since operator efficiency is constantly varying. While individual cycles show adaptation to changes in times spent awake and asleep, this adaptation takes time, so that several days may be required to adapt fully to a change in shift.

THE DESIGN OF ENVIRONMENTS

This section will be concerned with the design of physical environments for maximum human comfort. A later section will be concerned with psychology's role in the design of environments in a broader sense, as in urban planning.

A great many human engineering studies have been done on special environmental problems. Anthropometric measurements have been gathered to facilitate the design of objects used by humans, and a great deal of information is available on the integration of this information with special problems, such as designing handles for use with gloves. Information about the size and movement of various parts of the body are important to proper design of a wide variety of furnishings and equipment, from chairs to work areas.

The proper display of information is another important aspect of proper environmental design. Studies have shown that certain types of dials are read more easily than others. Airplane roll indicators which used a fixed artificial horizon with the position of the plane varying have been shown to be more easily interpreted than indicators which keep the plane steady and move the horizon, though the latter design had been commonly used. A good deal of information about desirable features of scales has been obtained, and some useful principles obtained. For example, operators should not have to transform information before using it. Jet aircraft tachometers, for example, may be calibrated in percentage rpm rather than actual rpm so that the pilot need not remember the maximum rpm for different engines in order to interpret the information.

Many other factors go into the proper display of information. For example, if color coding is used, it must be remembered that, while the visual system is able to discriminate a very large number of colors, in the sense of being able to say they are different if both are presented simultaneously, the number that can be correctly distinguished when only one is presented and memory must be used is far more limited. The exact number will depend on the colors, viewing conditions, and other factors such as training, but is unlikely to reliably exceed ten in many situations and may be much lower. Knowledge of these and many other aspects of visual and auditory perception are necessary for the safe and efficient design of many facets of our environment.

Another important problem is the proper integration of human operators into complex man–machine systems. Here again, knowledge of man's information processing capacities is important. Such questions as the speed with which an operator can respond, the probability of his detecting warning signals under various conditions of display and frequency, his tracking abilities with various displays and types of targets, are merely samples of the types of questions which arise and which have been extensively studied.

It should not be assumed, however, that such considerations are important only in military or industrial situations. Proper design considerations are important for the safety and comfort of the consumer as well. One study showed, for example, that different burner-control linkages on stoves resulted in different error rates even after a number of trails. Agreement among auto manufacturers on the arrangement of controls in cars with automatic transmissions is an example of the importance of establishing conventions for the design of widely used products. The list of consumer products with features whose design will affect either comfort or safety is very long indeed.

The information processing capacities of humans are important considerations in the design of any environment. The information processing capacities of any organism, including man, are limited. In such areas of environmental concern as urban planning, traffic control, etc., such considerations can be very important. Man is capable of remembering enormous amounts of information, and performing feats of processing which defy the most complex machines, but his capacity for short term information processing is distinctly limited. A large number of studies have been done on the problem of human attention and the effect of information over-loads on various performances. The results are quite consistent in showing very great limitations to man's short term information processing capacities. Exceeding these capacities will result in more or less serious performance decrements. For example, DAF (delayed auditory feedback) studies have shown that mismatches in input information can greatly degrade performance. Individuals have only a very limited capacity for responding to different information input simultaneously to the two ears.

Consideration of man's information processing capacities should be made in planning facilities for human beings. In particular, if new environments are being proposed, a very careful study should be made of their information processing demands. However, concern should not be limited to unusual environments. Badly planned highway signs, which require a driver to attend simultaneously to too much information and make too many decisions too rapidly are an obvious, and unfortunately all too common, example of failure to consider man's information processing capacities in designing the environment. The adequacy of instructions and cautions in connection with the use of equipment or potentially hazardous substances may also require consideration of certain of man's information processing capacities. Court cases have hinged on the adequacy of cautions regarding the use of equipment to inform potential users of hazards.

There are psychological aspects to the design of larger aspects of the environment. A classic study done on a student housing project at MIT showed that social groupings were significantly influenced by the physical arrangement of the apartments. Other aspects of modern building design may be important. For example, most large modern buildings are air-conditioned today. Air conditioning may affect the ionic balance of the air and some concern has been felt that it may produce symptoms such as depression, though the evidence to date is inconclusive.

MAN'S SOCIAL ENVIRONMENT

Decisions made regarding the physical environment have implications for social aspects of behavior, as we have seen in the previous section. In addition, some areas of environmental concern, such as urban planning, must consider man's psychological and social environment more or less explicitly. Population growth, for example, is greatly affected by social attitudes, as the dramatic change in the birth rate in Japan after World War II shows.

The social sciences, including psychology, have roles as information sources and in providing techniques for implementing decisions about the social environment, especially where these involve inducing changes in human behavior patterns. A vast amount of research has gone into the study of social factors which influence human behavior, and much of this information may be relevant in certain areas of environmental planning. Psychological techniques can be used to gain information about people's needs and preferences. It is not easy to design questionnaires which will provide reliable answers and many problems arise in obtaining representative samples of the target population. Psychologists and sociologists have studied these problems extensively. A great deal is known today about proper sampling techniques for such studies. General answers to designing questionnaires are more difficult to come by, but extensive experience has provided some useful practical advice. It appears likely that many difficulties which have arisen in the past in connection with such matters as public housing in urban areas, have been due in part to a failure to accurately assess the feelings and concerns of those affected by such projects. More extensive use of survey techniques might eliminate some of these problems.

Certain reservations about research on man's social environment should be mentioned, however. Large scale experimentation is obviously very difficult to do, and so reliance must often be placed on field studies. Direct measurement of behavior may be difficult, so recourse may be made to rating scales and other indirect measures whose relation to actual behavior is often uncertain. Smaller scale experiments often introduce varying degrees of unreality into a situation which may make generalization to the real world situation difficult. While all of these comments apply in some degree to all psychological research, they are especially apt to apply in areas relevant to man's social environment.

Any discussion of man's social environment must also consider areas in which psychological techniques can be employed to alter behavior. Consider, for example, the impact of problems such as crime, drug addiction, and so forth. on urban planning. Informational aspects of these problems certainly exist. For example, what is the evidence for a relationship between juvenile delinquency and housing conditions? Such questions have been extensively studied, and while the answers are still being debated, a great deal of information is available on observed correlations.

However, in addition to such informational aspects, the question of the role of psychologists in dealing with such questions must be considered. Plans must be made for dealing with such problems, and this means that resources must be allocated to them. Obviously, the proper allocations must depend in part on available options and their effectiveness. It is therefore reasonable to ask what techniques psychologists have available for modifying behavior and to inquire into their effectiveness.

A number of techniques, generally classified as psychotherapies, have been developed to deal with neurotic behaviors. It is difficult to characterize these procedures in any simple way, since they have diverse theoretical roots and practical implementation, but in general they depend on verbal interactions between therapist and patient to effect change.

A number of variations on the classic one-to-one patient–therapist relationship have developed in recent years. Various forms of group therapy have developed. In addition, sensitivity training procedures have been developed. These are usually aimed at changing the behavior of those not considered to be suffering from any personality disturbance, and they are likely to involve varying degrees of role playing and direct confrontation.

The effectiveness of psychotherapies has long been a matter of debate and the question has not yet been resolved. Difficulties in evaluating them in regard to neurotic behaviors stem from the high spontaneous remission rates, the difficulties of diagnosis, and the problems of defining what is meant by a cure and determining when one has occurred. The record with regard to disorders such as psychopathic personality, drug addiction, etc., is even less optimistic. Very little evidence of effectiveness is available, and many reports are discouraging.

The situation is similar for sensitivity training procedures and group therapy. While enthusiastic reports can be found, so can negative reports. Especially disturbing are reports of undesirable reactions to some kinds of sensitivity training, which can be rather aversive.

To those familiar with other health areas, these problems of evaluation may seem surprising. Clinical research has a long history in medicine, after all, and while problems such as placebo effects exist, methods have been developed to overcome them. However, in addition to the usual problems associated with any clinical research, much of the research on psychotherapies suffer from severe underlying problems associated with the entire concept of mental illness. Szasz has gone so far as to deny the utility of the concept, and has developed some interesting analogies between the concept of mental illness and the concept of witchcraft during the Middle Ages. While his views are hardly universally accepted, it is clear that the problems go beyond the merely procedural.

Behavior therapies, derived from conditioning techniques fare somewhat better. Classical conditioning techniques have had some success with alcoholics, though problems exist. Operant condition techniques have been applied extensively in the treatment of retardates, and have been used as the basis of token economies in mental institutions and homes for delinquents. It is usually somewhat easier to evaluate the behavior therapies, in part because the specification of the procedures in terms of reinforcement contingencies provides information about details of the process often lacking for other methods, and also because they focus on changing behavior. Such changes in behavior can usually be measured directly, whereas changes in personality or emotional state must be measured indirectly, and the appropriate tests are often uncertain. Behavior therapies are not invariably successful, of course, and a current weakness of the procedures is that it is difficult to establish systematic criteria for use. Another problem which has been reported are unpredicted effects on behaviors which were not under explicit control by reinforcement. These changes are not necessarily negative, but since they were not under intentional stimulus control, they may create problems. Finally, these procedures are relatively new, and the history of psychology is replete with procedures whose early promise has not been fulfilled.

Although the major use of explicit control of behavior by reinforcement contingencies has been in dealing with abnormal behaviors, the principles are not limited to such applications. An interesting example of an application in a different context is the use of reinforcement techniques to reduce littering behavior in theatres and campgrounds.

In addition to the techniques described above, psychologists and sociologists have been concerned with the effectiveness of communication in changing behavior. Much research has gone into such questions as the effect of the status of a speaker on his persuasiveness, and the role of various social pressures in changing opinion. In a sense, much educational research can be looked upon as the study of a special kind of behavior control where the concern is with inducing behaviors which result in learning in an educational setting. Rothkopf has done some interesting experiments on methods of inducing students to adopt appropriate behaviors to facilitate learning, which he refers to as mathemagenic behaviors.

In evaluating the usefulness of such techniques in the design of the social environment, it is important to take cost-effectiveness criteria into consideration. Judged by such criteria, the more traditional psychotherapies do not come off well. They require highly trained manpower, in a relatively large supply, and effectiveness is questionable, especially in situations where the cooperation of the target population is in doubt. Modifications such as group therapy may dilute the manpower requirements somewhat, but the other problems remain. The behavior therapies show up somewhat better in such an analysis. At least, it is possible to monitor behavior change to determine whether they are effective, and once a program has been established, it can often be carried out by personnel with little formal training.

In evaluating psychology as an information source for social planning, the need for sound information from the behavioral sciences cannot be overstressed, and every effort should be made to obtain more of such information. At the same time, the many obvious limitations of our present data suggest that they be used with due caution.

In particular, with the increasing use of psychological consultants in various aspects of environmental planning, the bases for various expert opinions should be scrutinized with great care. The judgment of experts in the social sciences, when it is not based on carefully controlled research, can be very misleading. The nature of the subject matter and the conditions of observation are such that it is very easy to find apparent support for a wide variety of hypotheses, many of which may be proved incorrect with more careful observation. It is always desirable to ascertain the factual basis for any recommendation, and to obtain the views of as many professionals from different backgrounds as possible.

FUTURE DEVELOPMENTS

The future cannot, of course, be predicted, but certain trends seem likely to continue. First, techniques for controlling behavior derived from operant conditioning procedures appear likely to come into increasing use. Environmental design will be likely to take into account more explicitly such facts in its design procedures. Human engineering procedures will also have an increasing impact on aspects of design for the environment. Certain fundamental questions about human behavior in complex situations will become better understood, and will provide the informational basis for superior design of learning environments and other special purpose environments. However, the 1984 or Brave New World fears seem unjustified at present. The more extensive attempts to control human behavior are more notable for their weaknesses than their power. Even predictive power is inversely associated with the behavioral complexity of the response. Skinnerian techniques seem to offer the best road at present to more powerful approaches. However even here caution should be noted. Most of the basic research on current contributions has been done on animals in very restricted environments. It has also been done on animals in more or less severe states of need; pigeon experiments using a food reinforcement typically maintain the birds at some percentage of *ad lib* body weight, such as 85%. Such animals are very well motivated, and the powerful effects of positive reinforcements found in these studies should be interpreted in this light. It is possible that most humans remain in a similar state of need with regard to the kinds of social reinforcers most likely to be manipulated in planning of larger environments, but the point has yet to be established. The limited environment is another factor which may lead to extensive modification of conditioning principles in larger situations, where a much wider choice of response alternative exist. However, the positive value for effective use of environmental resources which can result from a better understanding of human needs and response to various environments is very great, and it is in this area that the greatest impact of psychology should be anticipated.

RADIATION ECOLOGY

Radiation Ecology or Radioecology is a term that came into common usage in 1956 to denote that area of the broad field of ecology concerned with the assessment of radioactivity in the environment. More specifically, radiation ecology has come to be recognized as that area of ecology concerned with radioactive substances, radiation and the environment. The development and subsequent expansion of nuclear energy for military and peaceful purposes has been accompanied by environmental problems, some of which are typical of other facets of industrialization and some unique to atomic energy. The unique problems primarily concern the fate and ecological effects of radionuclides released into the environment.

The major environmental problems introduced by the Atomic Age may be grouped into several areas of scientific and public concern. Underlying each of these is the worry about the effects of ionizing radiation—on man, his domesticated plants and animals, and on the environment and its living components, Fallout from weapons testing, reactor radioactive waste effluents, radioactive waste disposal, nuclear war, and use of nuclear explosives for major engineering and related technological projects of large scale comprise the activities which have concerned society and which, because of potential impact on the environment and man, have stimulated the development of radiation ecology. Understanding the manner in which our ecological systems (ecosystems) distribute, assimilate, and affect the environmental behavior of radioactive substances, and the effects of radiations emitted from those substances, are the concern of the radioecologist.

RADIONUCLIDES OF ECOLOGICAL IMPORTANCE

Radionuclides which are of interest to the ecologist are listed in Table 1. These radioactive elements represent the major naturally-occurring and man-made sources of radiation in the environment. Principal sources of exposure from background (natural) radiation are represented by the uranium, thorium and actinium decay series. Internal exposure to man results primarily from ^{40}K, ^{14}C, ^{226}Ra, and ^{228}Ra and their daughter products that are deposited in the body. Radionuclides such as ^{222}Rn and ^{220}Rn and their daughter products represents sources of internal radiation exposure to man from inhalation.

Radionuclides produced by the fissioning of uranium (fission products) are of the greatest current concern. These man-made isotopes are not essential to organisms, but they constitute the major sources of radiation in the environment whether it be from fallout or waste disposal from reactor operations. All of these radionuclides may enter ecosystems where they become part of the flux of systems that are being circulated within and between systems.

Some of the fission products which are chemically similar to biologically essential elements are of special interest. They vary greatly in their physical half-life and in the extent to which they participate in metabolic processes of living organisms. The most important radionuclides affecting plants and animals on land are strontium-90, cesium-137, and iodine-131.

Strontium-90 remains in the environment for a long time. Its half-life is 28 years. Strontium is chemically similar to calcium, and it can enter living organisms as a replacement for calcium. In weapons fallout strontium-90 is usually deposited in the root systems of plants. the amount of ^{90}Sr that a plant absorbs from soils depends on several factors, particularly on the quantity of calcium in the soil, the relative quantities of calcium and strontium at the depth where the roots are located, and the ability of the plant to discriminate between the two elements. The plant is the base for ^{90}Sr to enter the human food chain. This chain is a short and simple one consisting of plants, cows, and man, with cow's milk being the chief source of entry into man. There is considerable discrimination against the transfer of strontium at each step in this food chain, but the small amount that is transported to man tends to concentrate in bone tissue. It remains there, undergoing radioactive decay and emitting its radiation. Its danger is related to the fact that bone contains blood forming (erythropoetic) tissue. In sufficient quantities the radiation can cause leukaemia and bone cancer.

TABLE 1
Radionuclides of ecological importance

Category	Major radionuclides	Ecological importance
Naturally occurring radionuclides	Uranium Thorium Actinium series elements Potassium-40 Carbon-14	Major contributors to background radiation (long half-lives)
Fission products	Strontium-89, 90, 91 Yttrium-90, 91 Zirconium-95 Niobium-95 Ruthenium-103, 106 Rhodium-106 Iodine-131 Cesium-137 Barium-137, 140 Lanthanum-140 Cerium-141, 144 Praeseodymium-143, 144 Neodymium-147 Promethium-147	Enter ecological systems through fallout or waste disposal (half-lives ranging from a few hours to 30 yrs)
Radioisotopes of elements essential to organisms	Hydrogen-3 Cobalt-60 Carbon-14 Sodium-22, 24 Phosphorus-32 Sulfur-35 Potassium-42 Calcium-45 Manganese-54 Iron-59 Copper-64 Zinc-65	Used as tracers in both radionuclide cycling and radiation effects studies on organisms and ecological systems

Strontium-90 accumulation normally is greater in children than in adults, because growing children are building bone at a greater rate and use a larger amount of calcium. A study of species in the deer family (cervidae) graphically demonstrated the effects of ^{90}Sr fallout. The levels of ^{90}Sr in the antlers of deer rose continually from 1947 through 1955, then remained constant for 2 yrs, and rose again in 1958. The concentration of ^{90}Sr was more than 8 × as high in 1958 as it was in 1947. With the cessation of major weapons tests in the 1960's, the levels began to drop off.

Cesium-137 is another major fission product that is found in fallout and untreated radioactive waste effluents. Cesium behaves chemically very much like potassium and follows the same metabolic route in plants and animals as potassium does. It enters plants directly through the leaves after being deposited by rain, and so it appears in plant tissues more quickly than does ^{90}Sr.

From there on the route of ^{137}Cs is much the same as ^{90}Sr; it appears in the milk and muscles of cattle that eat contaminated plants, and it enters the human body in food. Once in the human body, it becomes part of muscle tissue and so has an almost uniform distribution throughout the body. It stays there for only about 4 months. Since its half-life, like that of ^{90}Sr, is about 28 yrs, little of the ^{137}Cs undergoes radioactive decay while in the body.

The transfer of ^{137}Cs and ^{90}Sr from plants to animals also has been observed in species that are not important as food sources for man. The coconut crab, a land animal that lives on a diet of fruit and nuts on islands in the Pacific, was found to have accumulated radioactive materials as a result of the Pacific test explosions. Strontium-90 was found in the skeleton, and ^{137}Cs was found in the soft body parts—direct results of eating contaminated vegetation.

The third radionuclide or fission product of importance in fallout is radio-iodine (^{131}I). The chemistry of radioactive ^{131}I is exactly like that of natural ^{127}I, which is not radioactive. Therefore, its concentration in the body depends only on the concentration in the source material. Iodine becomes concentrated in the thyroid glands of vertebrate animals, where it can cause cancer of the thyroid and damage to other tissues. Like ^{90}Sr and ^{137}Cs, it enters plants as a result of radioactive fallout and then enters humans either by way of the plants themselves, or by way of contaminated milk from cows that eat the plants. The radioactivity of thyroid glands removed from certain animals can serve as a sensitive indicator of ^{131}I in the environment, because the concentration of ^{131}I in the thyroid can be as much as 10,000 × higher than the concentration in nature. The black-tailed jack-rabbit is a useful animal for such measurements. It has a large thyroid gland that is easy to remove and weigh. The level of radioactivity in each gram of its thyroid tissues varies directly with the fallout on vegetation.

Finally there are man-made radionuclides (activation products) which are important because they are the isotopes of elements which may be essential to plants and animals. Some of these also may enter the environment as activation products resulting from reactor operations or nuclear explosives. Examples of activation radionuclides are cobalt-60 and zinc-65. In aquatic or marine environments these radionuclides have been found to accumulate in food organisms especially shellfish and mollusks. Generally ^{60}Co can be anticipated to be accumulated by organisms or to be retained in organically enriched materials such as forest floor humus and organic sediment. Zinc-65 is of particular concern in marine environments where it is likely to be accumulated in clams and oysters. However, being an activation rather than a fission product its presence depends more on appropriate stable elements present which in turn are exposed to fast neutrons than on fissionable material.

RADIOSENSITIVITY OF ECOLOGICAL SYSTEMS

Although there is much current concern about the possible effect of low level, chronic radiation on ecological systems, there is relatively little comprehensive scientific data on

TABLE 2
Comparative radiosensitivity of groups of organisms

Group	Lethal dose range[a] (rads)
Bacteria	100,000–1,000,000
Insects	5,000–100,000
Fish	1,000–300
Mammals	300–1,200
Herbaceous plants	5,000–70,000
Coniferous trees	800–3,000
Deciduous trees	4,000–10,000

[a] Estimated acute whole body gamma radiation doses required to kill 50% or more of the adult organisms.

this problem. Much more is known about the radiosensitivity of organisms exposed to radiation doses which are much higher than we expect to contend with in the normal environment. In general, higher animals are far more sensitive to radiation than are lower animals, and the very young and the aged are more sensitive than mature, healthy animals. For example Table 2 gives estimated acute doses of gamma of X-radiation necessary to kill 50% or more of the adult members of several groups of organisms. These data should be considered only as an indication of relative radiosensitivity as they represent generalized ranges. Half the humans exposed to a single dose of 500 R will die. For other mammals the lethal dose ranges from less than 300–1200 R. Frogs and newts can survive higher radiation levels, depending on their body temperatures at the time of exposure. Insects can survive doses of up to 100,000 R in a few instances; most have lethal doses in the 10,000–20,000 R range. These kinds of data do not reflect the more complex responses of organisms subjected to ionizing radiation under natural conditions. For example, most organisms go through several stages of development from egg to adult. These stages may take place in different parts of the ecosystem. Likewise, the radiosensitivity of these organisms may differ in different stages of the life cycle. In radioresistance groups such as insects, 10% or less of the lethal dose to adults may be effective at juvenile or egg stages. For example, in the bagworm a dose of 450 R is sufficient to kill 50% of 1-day old eggs, whereas a dose of approximately 10,000 R was required to produce the same effect in the larvae.

Effects other than lethality also may be produced by radiation, especially in ecosystems where all organisms are linked through various interactive processes. Aside from genetic or reproductive effects, changes in number, growth, disease resistance, life span or response to physical environmental factors are of interest to the ecologist. Radiation-induced changes can affect the role of organisms or populations within the ecosystem. Predator–prey relationships, food chain transfers, and other ecological processes which depend on the continuing interaction between different organisms may be altered by the impact of ionizing radiation.

The effect of ionizing radiation on plants has been studied both outdoors and in greenhouses. One indoor test field consists of 10 acres of land with a ^{60}Co source located at the center. It is installed in a vertical tube, which can be raised to different heights for irradiation and then lowered by remote control into a lead case when not in use. Various species of plants grow in the soil in concentric circles around the source. Each species is arranged in a wedge-shaped area so that the plants are located at various distances from the source and receive various intensities of radiation. Plants are exposed to radiation for 20 hr a day.

Radiation effects on plants are complex and depend on a number of factors, including the plant species, the maturity of a plant, its physical condition, the parts of the plant exposed to radiation, the kind and amount of radiation, and the rate at which the radiation dose is applied. Woody plants generally are more sensitive to radiation than are herbaceous plants (Table 2). Gymnosperms are more sensitive to radiation than angiosperms. A pine tree shows severe growth inhibition at a level of about 10 R/day, while the same degree of inhibition in a gladiolus plant requires about 5000 R/day. Some ecologists have speculated that radiation from a nuclear attack would destroy all pine trees and other gymnosperms in irradiated areas, leaving other plants relatively unharmed.

It is possible to predict some radiation effects in plants. The meristematic or growth regions in plants are the most radiosensitive tissues. It is the absorption of radiation energy in these regions that alters plant growth and development. Ecologists and botanists have shown that the response of plants to ionizing radiation is directly proportional to the interphase chromosome volumes in meristematic tissues. That is, plant species with large chromosomes are more sensitive; those with small chromosomes are more resistant to radiation. In general, this is an extremely useful concept, and it has been applied to predict and assess probable radiation effects on vegetation (natural and agricultural) from military uses of nuclear devices.

Seeds are far less sensitive to radiation than are growing plants. A stand of pine trees exposed to a total of 12,000 R of gamma radiation was 90% destroyed, yet 95% of the seeds taken from cones on the same trees were viable. The high resistance of seeds to radiation damage is probably associated with their low water and oxygen content. The sensitivity of dry seeds varied widely among species, however. Lily seeds show practically no ability to sprout after receiving a dose of 2000 R. Yet the seeds of other plants seem to be stimulated to sprout more vigorously than normal under the same amount of radiation or more. Such differences favor the growth of certain species over others in areas where radiation is a factor in the environment.

EFFECTS OF RADIATION ON ECOSYSTEMS

The effects that large scale ionizing radiation such as from a nuclear attack would have on plants and animals living together in an ecosystem have concerned radioecologists ever since the first use of atomic bombs. Several studies have been conducted involving small ecosystems in an attempt to determine what would happen on a large scale. In one study, 10,000 acres of land surrounding a nuclear reactor where exposed to radiation ranging from lethal levels to levels no higher than the natural background radiation. The ecosystem on this land consisted mainly of an oak-hickory-pine climax forest. The forest was exposed to a mixture of gamma radiation and neutrons, with an intensity similar to that expected from fallout after a nuclear attack. The radiation reached about 37,00 trees, plus many more herbaceous species and many more shrubs. Ecologists examined thousands of plants in order to differentiate between the effects of ionizing radiation and the effects of frost, disease, insect damage, drought, and other natural factors. In still another study, a community of spring and summer annuals was exposed to gamma radiation for nearly 4 months during one growing season and then was observed over the next 3 yrs. In still another study, gamma radiation was applied daily throughout one winter and spring to a forest and to an open field with a well-established cover of annual plants.

On the basis of these and other studies, radioecologists have formulated a scenario depicting how ionizing radiation would affect the plants and animals of our forests and fields if a nuclear attack occurred during the summer growing season. People emerging from shelters several weeks after the attack would find little change in their surroundings, except in areas of extremely high radiation. All plants and animals, both large and small, would have been killed in these high radiation areas, and as the plants died they would subject the surrounding areas to further danger from fire. However, most fields and woodlands would appear unchanged by radiation when viewed from a distance. Closer inspection would reveal more clearly the extent of the damage. The ground would be littered with the bodies of birds and animals killed by the radiation. Inspection of lakes, streams, ponds and marshes would show that the lower animals had fared better. Fish, frogs, toads and salamanders would be alive and healthy. The sound of insects would be heard as before. Among the plants the damage would be least serious to those that appear early in a natural succession pattern. Mosses and lichens would be undamaged, annuals would be somewhat affected, shrubs more so, and trees most of all. The damage to pine trees would be most apparent. Pines nearest the radiation zone would have turned a brilliant red brown within a few days after the attack. Other plants in the forest and fields would undergo little change during the remainder of the summer.

In the autumn the oaks, hickories and other hardwood trees would lose their leaves earlier than usual—perhaps as much as 7 weeks earlier in areas nearest the high-radiation zone. The following spring these areas would remain in their state of winter dormancy 7 or 8 weeks longer than usual. Examination of the hardwoods (oaks, hickories, etc.) at this time would reveal severe damage to the buds, resulting in the development of fewer leaves and of abnormal leaves. Near the high-radiation zones, the trees might be leafless. The distribution of annuals in the open fields and on the forest floor would also be changed from previous years. Certain species would grow in greater numbers, partly as a result of the stimulation of their seeds by radiation and partly as a result of the radiation in seed germination among other competing species. The delay in development of leaves on the trees would give these annuals an extra long growing season. In the abundance of sunshine, weeds would grow on the forest to heights of 8 ft or more. The absence of a leafy canopy would also cause changes in the forest soil. With greater wind flow through the bare trees and higher temperatures from direct sunlight, the soil would become drier and harder during sunny weather. In rain storms the harder impact of rain drops would wash away topsoil in areas not covered by weeds or shrubs. Throughout the first summer following the attack, birds and animals from outside the irradiated areas would move in to replace those that were killed.

RADIOACTIVE TRACERS

With the threat of nuclear war receding, and nuclear reactors being equipped with ever more elaborate safe-guards to reduce radioactive releases to the environment, the thrust of radioecology is changing. Activation products in controlled quantities are now being used as radioactive tracers to follow the pathways of chemical elements in the bodies of organisms and in the complex interactions of ecosystems. The radioactive materials have the advantage of being easily detected and quantitatively measured in biological materials without elaborate chemical separation of the elements otherwise necessary.

For example, the radioisotope ^{137}Cs was added to the upward flow of water in trunks of yellow poplar trees in Tennessee about 18 years ago. In the ensuing years radioecologists have followed the movement of this relatively inert tracer into leaves of the trees, into leaf-eating insects, into the insect eating birds, into the forest litter as the dead leaves fell, into soil insects, and so forth. Periodic sampling has confirmed the recycling of natural materials in this forest ecosystem. The radioecologists, in concert with systems analysts, are currently developing computer simulation models to mimic the ecological cycles revealed by this cesium tagging experiment. Comparable information on the exchange of materials from one component of the ecosystem to another could never have been obtained without the knowledgeable use of radioactive materials by these trained radioecologists.

Other activation products such as calcium-45 or phosphorus-32 find use in studies of metabolic processes in organisms, populations or communities. Such studies lead to an understanding of regulatory processes and structural characteristics of living systems. Other examples of experimental use of radioactive tracers may range ecologically, from studying the uptake of ^{45}Ca tagged fertilizer by corn, to following the pathways of ^{32}P in a stream, including its distribution in the non-living as well as the living components.

Radiation ecology is now an area of ecological research and teaching that encompasses far more of the impacts of man on his environment than the atom bomb and nuclear reactors. Understanding of nearly all pollutant chemicals in the environment is being enhanced by use of techniques and principles of ecological cycling developed by radioecologists.

CURRENT DEVELOPMENTS IN RADIATION ECOLOGY

The last several years have witnessed a major decrease of interest in, and hence support of, research in radiation ecology. In the United States the research programs and projects initiated primarily under the Atomic Energy Commission (AEC) have been mostly dismantled. The rationale behind these policy shifts is difficult to comprehend; however, it seems to have been associated with a perception that most of the scientific challenges associated with the ecological aspects of radiation are either sufficiently understood or can contribute little to those practical issues related to radiation protection that are still of concern. Despite this rationale, there has been little change in the long-standing public fear of ionizing radiation and its potential consequences. In addition, the recent major accident at the Russian nuclear power station at Chernobyl (1986), in which 50–100 Mci was released into the environment, not only raised or exacerbated fears in those public sectors already concerned about radiation problems associated with nuclear power but also served to galvanize resistance in large groups (e.g., the Soviet public and other East European populations) that hitherto had either accepted nuclear power or manifested little if any public resistance.

The Chernobyl accident underscored both the ineffectuality of political boundaries against environmental contamination and the role of food chains, both natural and agricultural, in exposing humans and other organisms to potentially harmful levels of radionuclides. Likewise, Chernobyl focused interest on the direct consequences of radiation on ecosystems in the zones of high contamination (within a radius of 18 km of the reactor site). The release of large quantities of ^{134}Cs and ^{137}Cs resulted in the contamination of lakes, streams, and forests in the path of the plume. The need to understand the rates of transfer and patterns of bioaccumulation of these radionuclides in different ecological pathways became manifest in many European countries located thousands of kilometers away from the reactor. In Sweden, for example, high concentrations of ^{137}Cs were found in reindeer and moose (1,000 to 10,000 Bq/kg) and in several species of freshwater fish. The relatively rapid buildup of radionuclides in these organisms was the result of processes which can affect both the rate and extent of bioaccumulation in food chains. Thus the Chernobyl accident has emphasized an increased need for additional research in radiation ecology.

Food chains are the ecological pathways by which many substances are moved in terrestrial and freshwater environments. In the case of radionuclides, these pathways are important in the assessment of radiation exposure to critical population subgroups and human populations. Until recently the uptake and transfer coefficients used in regulatory models were mainly generic default values intended for use in lieu of site-specific information. The Chernobyl accident demonstrated the importance of and need for geographic-specific data on individual radionuclide behavior in terrestrial and fresh-water pathways.

Unlike the United States, most other countries are involved in extensive radioecological research. This research is aimed at obtaining data for predicting exposure resulting from transport of radionuclides in agricultural food chains. The processes of interest in terrestrial environments are those involving atmospheric deposition onto soils and vegetation; resuspension and leaching from these surfaces; uptake from soils by the edible portions of vegetation; and transfer into meat, milk, and other animal products utilized by humans. In the aquatic environment the key processes involve the bioaccumulation of radionuclides from sediments, water, and algae into the edible components of aquatic biota.

The assessment of the environmental and health impacts resulting from radiation exposure is dependent on the use of mathematical models, which, like all other models, are prone to uncertainty. The best method for evaluating uncertainties in the predictions of dose-assessment models is to test predictions against data obtained under real-world conditions. The large extent of contamination following the Chernobyl accident has provided exactly this type of opportunity. Currently an international cooperative effort known as BIOMOVS (BIOspheric MOdel Validation Study) is under way to test models designed for the calculation of environmental transfer and bioaccumulation of radionuclides and other trace substances. More than 20 assessment models are now being tested against data collected from numerous sites throughout the Northern Hemisphere. Upon completion of the initial model testing effort of the BIOMOVS project, additional long-term testing is being planned and organized by the International Atomic Energy Agency (IAEA).

Another issue of concern that has not received research attention recently in the United States in the direct effect of ionizing radiation on populations and communities of organisms. This issue invariably arises whenever there is a nuclear-related incident. In the case of the Chernobyl accident, radiation exposures in the immediate vicinity of the reactor resulted in 28 human fatalities, with a larger number or persons (209) suffering varying degrees of radiation sickness. Pine forests within several kilometers of the reactor site received sufficient contamination to result in an accumulated dose of more than 1000 rads. According to Soviet reports, pronounced morphological damage to pine foliage was visible within 5 months after the accident in the zones where the doses ranged from 300 to 1000 rads. Lethal effects in the 1000 rad zone were also manifest by this time, and by winter (7 months postaccident) 400 ha of forest was destroyed. An ecological preserve has been established in one of the natural areas subjected to high levels of radionuclide contamination. The Soviet government has announced its intention to carry out long-term radioecological observations and studies in this preserve to assess the long-term impacts, if any, on the resident flora and fauna.

To the Soviets' credit, they have recognized both the need and the opportunity to obtain data on the long-term effects of ionizing radiation on plant and animal populations as manifested through genetic mechanisms. To this end, they have established experimental facilities at the accident site to carry out this research. Radioecologists have long recognized the need for hard data on the long-term consequences of exposure to chronic radiation to populations of organisms. Little is known about the interaction of ionizing radiation and environmental stress on populations that are subject to competitive pressures, predation, and other factors that affect survival. We need to be concerned with the effects that a buildup of radionuclides in the environment would have on the eventual fate of the organisms inhabiting such an environment.

Thus, despite the current lack of attention given to research issues in radiation ecology in the United States, much can be learned by collaborating with scientists in Europe and Asia who are now engaged in investigating the fates and effects of radioactive substances deposited from the Chernobyl accident.

RADIOACTIVE WASTE MANAGEMENT: see MANAGEMENT OF RADIOACTIVE WASTE

RADON

Following the discovery of very high levels of indoor radon associated with homes in northeastern Pennsylvania in December of 1984, the New Jersey Department of Environmental Protection was designated as the lead state agency to address the potential for radon problems in New Jersey. The Department was charged with characterizing the problem as it might exist in New Jersey and developing a coordinated state response to the problem.

Due to the potentially serious public health implications of exposure to high levels of radon, the characterization of New Jersey's radon problem proceeded simultaneously with the development of a program to educate the public regarding radon and respond to residents' needs for reliable radon testing and radon remediation services.

The current data indicates that New Jersey's indoor radon levels are among the highest known and that as many as 1. 6 million homes in New Jersey may be at risk for radon problems. Approximately one-third of homes studied thus far test at or above the 4 picocuries per liter guidance level recommended by the United States Environmental Protection Agency as a feasible goal for remediation of high concentrations of indoor radon. New Jersey's response to this problem is characterized by an integrated multi-agency approach and the growth of firms providing reliable, regulated radon testing and remediation services in the private sector.

BACKGROUND

Radon-222 is the single gaseous isotope among the fourteen principal decay products composing the 4n + 2 natural decay series beginning with uranium-238 and terminating in lead-206. The principal decay products of this series, their half lives and principal associated emissions are given in Table 1.[1]

The atmospheric concentration of radon varies with location, but is typically on the order of 0.1 picocuries per liter (0.1 pCi/1) over land masses.[2] The average radon concentration indoors in the United States in not well known, but has been estimated[3] to be in the range of 1 to 2 pCi/1.

In December of 1984, previously unheard of levels of radon were found in the home of an engineer, Stanley Watras who worked at the Limerick Nuclear Generating Station and lived in the Boyertown, Pennsylvania area.[4] The engineer had been tripping portal monitor radiation alarms indicating radioactive material on his clothing when leaving work. Investigations conducted by the utility and the Pennsylvania Department of Environmental Resources demonstrated that the radioactive material on the engineer's clothing consisted of the short lived decay products of radon-222 (Po-218 through Po-214 in Table 1) which had originated in his home. The concentrations of radon in the home ranged as high as 2,600 pCi/1. Subsequent investigations of the area around the discovery home demonstrated that elevated levels of indoor radon were common to the area and that the probable source of the radon was the underlying gramitec rock formation known as the Reading Prong.[5]

In May of 1985, an article[6] by Phillip Shabecoff appeared in the New York Times reporting the Watras incident and noting that the Reading Prong ran in a northeasterly direction out of Pennsylvania, through northern New Jersey and into New York. The article also identified an increased risk of lung cancer as a possible outcome of exposure to elevated levels of radon and its decay products. Immediately, state agencies in New jersey, particularly the Department of Environmental Protection, were deluged by telephone and written requests for information on radon and assistance in obtaining radon testing services.

Numerous studies have demonstrated the link between exposure to radon and its decay products in mining situations and an increased risk of lung cancer.[7] Research efforts directed at establishing a link between residential exposure to radon and its decay products have been far more limited in scope than the mining studies and the data derived from them are, at best, equivocal.[8] Studies underway now in Sweden, New Jersey, Pennsylvania and New England may have sufficient power to elucidate the residential exposure risks.

Based primarily on the results of the mining studies he United States Environmental Protection Agency (EPA) has estimated that from 5,000 to 20,000 of the 130,000 lung cancer deaths annually in the United States are attributable to radon.[9] EPA has further estimated that 1 to 5 persons in 100 exposed in their homes to radon at 4 pCi/1 over a 70 year lifetime, with 75% occupancy, will develop lung cancer.[10] As this risk is assumed to be linear, the risk at 200 pCi/1 under similar conditions of exposure is estimated to be from 44 to 77 in 100. These risks are two or more orders of magnitude greater than other environmental health risk levels which traditionally trigger actions to reduce them.

It is important to note that radon itself is not believed to be the major contributor to the possible development of lung cancer.[11] As radon is an inert gas there is not preference for deposition with the body. When radon decays in ambient

air, however, the decay products formed are metals which initially associated with aggregates of water molecules in the air. These aggregates in turn adhere to airborne dust particles. When inhaled, the dust particles, if of appropriate size, will preferentially deposit in the tracheobronchial region of the lung. Radioactive decay of the short lived alpha emitting progeny of radon will result in intense local irradiation of the tissue underlying the deposited dust. It has been calculated that the vast majority of the total radiation dose to the lung tissue is due to the alpha decay of Po-218 and Po-214.[12] It is this localized irradiation which is believed to trigger the development of lung cancer.

In order to have a radon problem in a home, three conditions are necessary. First, the immediate parent of radon-222, radium-226, must be present in the underlying soil or rock to yield a radon source term. Second, the home must have penetrations in the basement or the ongrade slab which provide entry points for the gas. Third, the pressure inside the home must be less than the surroundings so as to provide a pressure differential to facilitate the entry of radon into the home. The first condition is geologic in origin and is met in many locations in the United States. The second condition is a typical consequence of standard construction techniques, particularly in homes where a peripheral channel in the basement slab and an associated sump pump are used to control wet basement problems. Other points of entry for radon in a home include unsealed openings around piping, at or below grade, cracks in the walls and floor, and porous concrete. The third condition is met by a combination of factors which include the normal stack effect associated with the house, combusting fuels for heating, and the use of appliances such as dryers which are vented to the outside. These conditions are met in homes in much of the northern portion of New Jersey, and to a lesser extent, in specific locations in southern New Jersey.

THE NEW JERSEY RADON PROGRAM

Shortly after the Watras incident, Pennsylvania Department of Environmental Resources personnel contacted their counterparts in the New Jersey Department of Environmental Protection (DEP) to advise them of the problem. In the beginning months of 1985, DEP staff working with the New Jersey Department of Health began to assess New Jersey's potential for a radon problem and develop a response to it.

A review of available data demonstrated that New Jersey had significant potential for a random problem and that it was likely that the problem would not be confined solely to New Jersey's section of the Reading Prong. The National Uranium Resource Evaluation data[13] indicated that significantly elevated levels of uranium, and hence radon, could exist both north and south of the Reading Prong. Outside the Reading Prong elevated levels of uranium were associated with limestone, shales and clays. Additionally, a literature survey[14] previously conducted by the New Jersey Geological Survey had found reports of more than 100 locations of radioactive minerals in New Jersey, many well outside the Reading Prong.

Early State planning activities focused on the need to educate the public with regard to radon and develop legislation providing specific programmatic mandates and associated funding.

In January of 1986, Governor Kean signed a bill providing $3.2 million to begin New Jersey's radon program. A second bill, signed into law in August of 1986, provided an additional $1 million, mandated the development of certification for testing and remediation firms and also guaranteed the confidentiality of random test results. The major components of the radon program developed using this funding include:

Radon Information Program

By December 1, 1987 the DEP's toll free information line had received and responded to more than 52,000 telephone inquiries. As a result of these inquiries more than 20,000 informational packages have been mailed out to New Jersey residents. As the knowledge of radon has grown among New Jersey residents so has the sophistication and complexity of the telephone inquires. Currently, a great deal of staff time is spent providing telephone consultation to residents who wish to discuss the interpretation of their radon test results or who wish an in depth discussion of the relative effectiveness of alternative remediation methods. The Department of Health also provides telephone consultation on specific health issues related to radon. The Department of Environmental Protection and the Department of Health provide speakers for groups interested in learning about radon. By December 1, 1987, more than 250 presentations have been made to interested groups. Also, a slide presentation on radon was developed for use with general audiences throughout the state. This slide presentation is currently being expanded and re-packaged in a video tape format for distribution to local libraries.

Statewide Study of Radon

In 1986 the DEP contracted with the environmental engineering firm of Camp, Dresser and McKee, Inc. (CDM) to perform a $1.3 million statewide study of radon. The specific tasks within this study are to:

a. Map areas of potential radon problems using all available geographic, geologic, radiometric and demographic data.
b. Develop a model to predict indoor radon exposure statewide.
c. Test the model developed in Task b using a sampling program including approximately 6,000 structures statewide.
d. Perform a risk assessment for New Jersey residents of the dangers posed by exposure to radon gas.
e. Develop a computerized database for data collected in the study.
f. Propose and prioritize further research suggested by the statewide study.
g. Provide a summary report containing the most salient findings of the study for presentation to the legislature and the public.

Epidemiologic Study

The New Jersey Department of Health is conducting a case-control study of female lung cancer victims and controls in New Jersey. The primary aim of this study is to determine whether or not the lung cancer risk estimates derived from studies of uranium and other miners are applicable to individuals exposed to radon in their homes. The DEP has supported this effort by performing radon tests in more than 800 homes of cases and controls.

Confirmatory Monitoring

As the radon program was being planned the spring of 1985, it was recognized that as many as 1.6 million New Jersey homes might be at risk for elevated levels of indoor radon. It was clearly outside the resources of state government to offer free testing to each potentially affected household. Preliminary cost analyses of no-charge testing for 1.6 million homes indicated a cost ranging from $40 million to $200 million. A conscious decision was therefore made to allow, and even assist in, the development of a radon testing industry in the private sector. It was also recognized however, that the unregulated growth of such a new industry carried with it a significant potential for error and for consumer fraud. Therefore, to protect New Jersey citizens, it was decided to offer confirmatory testing to those residents who had commercial radon tests performed in their homes and obtained radon concentrations equal to or greater than the 4 pCi/1 guidance level at which the EPA recommends consideration of remedial action.

Certification of Radon Testing and Mitigation Firms

The DEP is in the process of promulgating regulations for the mandatory certification of radon testing and mitigation firms. In the interim, a voluntary certification program has been implemented. This program currently enrolls 58 radon testing firms and 24 radon mitigation firms. Respectively, these total represent about one-half the number of firms applying for enrollment in the two programs. The firms are required to document specific expertise, refrain from scare-tactic advertising, participate in the EPA Radon Proficiency

Measurement Program[15] and meet other quality assurance objectives.

Follow-Up Testing

As residents tested for radon and remediated their radon problems, they requested access to reliable, unbiased radon testing which would enable them to determine whether or not the remediation methods employed were effective. In response to these requests, DEP began a program of testing remediated homes at no charge to the owner. As of December 1, 1987, a total of 774 homeowners had availed themselves of this service. In general, these follow up tests document the effectiveness of the remedial actions employed. When they do not, DEP staff advise both the homeowner and the contractor and then assist in working out a mutually acceptable solution.

Radon Cluster Identification

In March of 1986, through the Confirmatory Monitoring program, the DEP became aware of several homes in Clinton, New Jersey which had unusually high concentrations of indoor radon. The DEP and Department of Health worked closely with municipal and county officials to identify other homes in the area which also had very high radon levels. In one neighborhood in Clinton, 105 homes were found to be above 4 pCi/1. Forty of the 105 homes were found to be above 200 pCi/1 and five of the forty homes were found to be above 1000 pCi/1.

Through the cooperation of government at all levels, what could have been a disaster for the community became a solvable problem. The DEP, the Department of Health and local officials provided information on radon and access to testing for those judged to be at significant risk. The municipal government participated fully in all the decision making with regard to the State activities in Clinton and offered access to random testing at reduced cost to all residents. The EPA was invited to extend their radon remediation research program begun in Boyertown, Pennsylvania into New Jersey. EPA remediated ten of the highest radon level homes at no cost to the occupants and provided detailed specifications for the remediation of twenty more homes. The successful remedial techniques developed in Clinton have been adapted to hundreds of other homes in northern New Jersey.

Due to the experience of finding a clustering of high radon level homes in Clinton, the DEP and Department of Health

TABLE 3
Summary of initial results for radon testing in non-residential buildings

Province	Type of building	Number of buildings	Average radon concentration (PCI/L)	Range (PCI/L)
Valley & Ridge	School	8	1.5	1.4–2.9

* Becomes 2.4 if the single 192 pCi/1 value is excluded.

** Becomes 2.3 if the single 192 pCi/1 value is excluded.

developed a program of responding to reports of high radon level homes (i.e., homes which are confirmed to have radon concentrations at or above 200 pCi/1). A report of such a home triggers the Radon Cluster Identification Protocol under which the local governing body is advised of the confirmation of such a home in their community and their cooperation in sponsoring a public information meeting solicited. Following the public meeting, DEP staff test for radon in homes in the area around the "discovery" home. If this survey yields one or more additional homes with radon concentrations at or above 200 pCi/1, the survey is repeated in the area around these homes. This process is repeated until all homes in the area with radon levels at or above 200 pCi/1 have been identified. The specific concern with homes having this level of exposure to radon is that the lung cancer risk associated with a lifetime of such exposure at 75% occupancy is estimated by EPA to be in the range of 44 to 77 in 100. EPA has recommended that individuals finding such levels in their homes remediate them within several weeks or temporarily relocate until such remediation can be accomplished.[16]

Radon Remediation Research

In addition to supporting EPA's remediation research in Clinton, DEP is also cooperating with the EPA on its House Evaluation Program under which fifteen New Jersey homes, predominantly in the Piedmont region, are undergoing in-depth evaluation of their radon problems at no charge to the homeowner. This program is expected to yield important information on how specific house characteristics and weather patterns influence the radon levels in homes. Additionally, the DEP has contributed $185,000 in funding to a radon remediation research program being undertaken cooperatively by EPA, DEP, Lawrence Berkeley Laboratory of the University of California, Oak Ridge Associated Universities and Princeton University. The primary aim of this research is to fine tune existing remediation methods so as to make them easier to implement and more cost effective.

Radon Database Development

Radon testing firms participating in the voluntary certification program submit radon testing data they have collected summarized by municipality name and zip code. This data is entered into a computerized database by DEP and used as an aid to decision making.

Radon in Non-Residential Structures

The DEP issued interim guidance for the testing of non-residential structures such as schools, hospitals, government buildings and businesses in 1986. The Department of Health issued health related guidance for such structures in November of 1987.

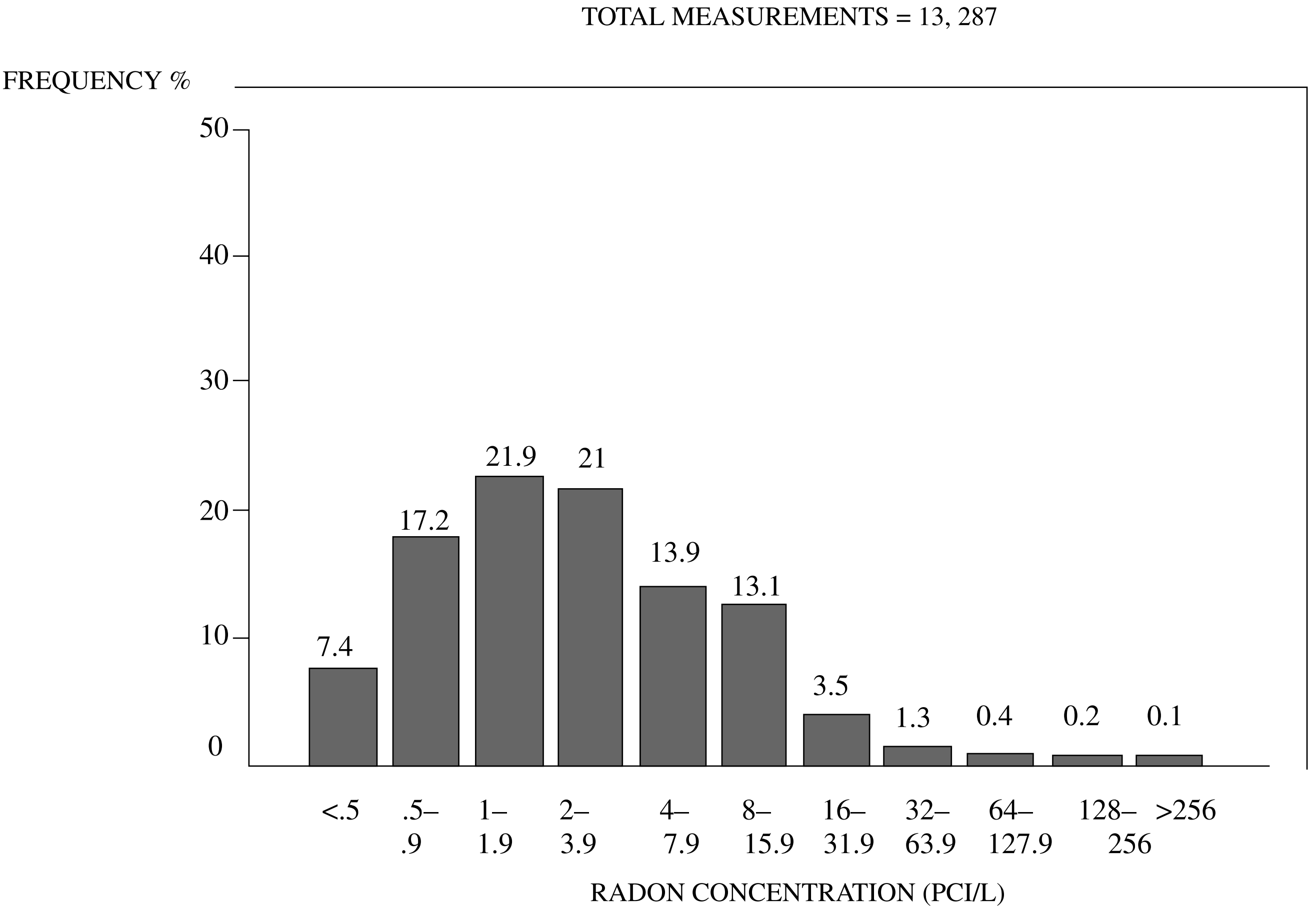

FIGURE 2 Commercial firm radon test data distribution, basement measurements.

Radon Registry

In order to maintain an open channel of communication with individuals who have already been exposed to elevated levels of radon, the Department of Health developed a Radon Registry for New Jersey residents. Participants in the survey are advised of the most current information regarding radon and lung cancer via a newsletter. Over 200 New Jersey residents are participating in the registry.

Low Interest Loans

In comparison to the equity value of most New Jersey homes, the cost of remediating a significant radon problem (i.e., initial test results in excess of 20 pCi/1) is relatively small, currently averaging about $1,200. There are, however, some New Jersey resident would find a single expenditure of this amount quite burdensome. In response to this potential problem, the New Jersey Housing and Mortgage Finance Agency developed a low interest loan program for affected residents. There are no income requirements associated with the program and the rate is at or below the best available loan rates, currently 7.875%. For residents with severe radon problems (e.g., radon levels at or above 200 pCi/1) an expedited loan application processing procedure is available within three working days.

Additional Research

External to the funding provided in the radon legislation, the DEP's office of Science and Research and the New Jersey Geological Survey are conducting research to determine radon in water levels in selected northern New Jersey aquifers.

ASSESSMENT

The various state radon efforts provide a significant body of data from which an assessment of New Jersey's radon problem can be drawn.

Preliminary radon concentration data from homes tested as part of the statewide study are listed by country in Table 2. The same data is organized by physiographic province in Figure 1. These data are almost exclusively for single family homes.

Data on the testing on non-residential structures obtained as part of the statewide study is summarized in Table 3.

All the radon test data presented here were obtained using charcoal canisters[17] exposed for a period of four days under the EPA recommended protocols.[18] All testing was conducted during the period from November 15, 1986 through March 15, 1987 when closed house conditions

generally prevail in New Jersey homes. In accordance with the EPA protocols, the canisters were placed in the level of the home closed to the underlying soil. Unless individuals live at the same level as the tests were made, this testing method tends to overestimate the average concentrations actually breathed by residents by a factor of about two. Most participants in the study lived one floor in the home above the testing level. An exception to the two fold reduction in radon concentration with a one floor increase in distance from the underlying soil occurs in homes with forced air heat. Openings in duct work in the basement make possible the circulation of basement air throughout the home.

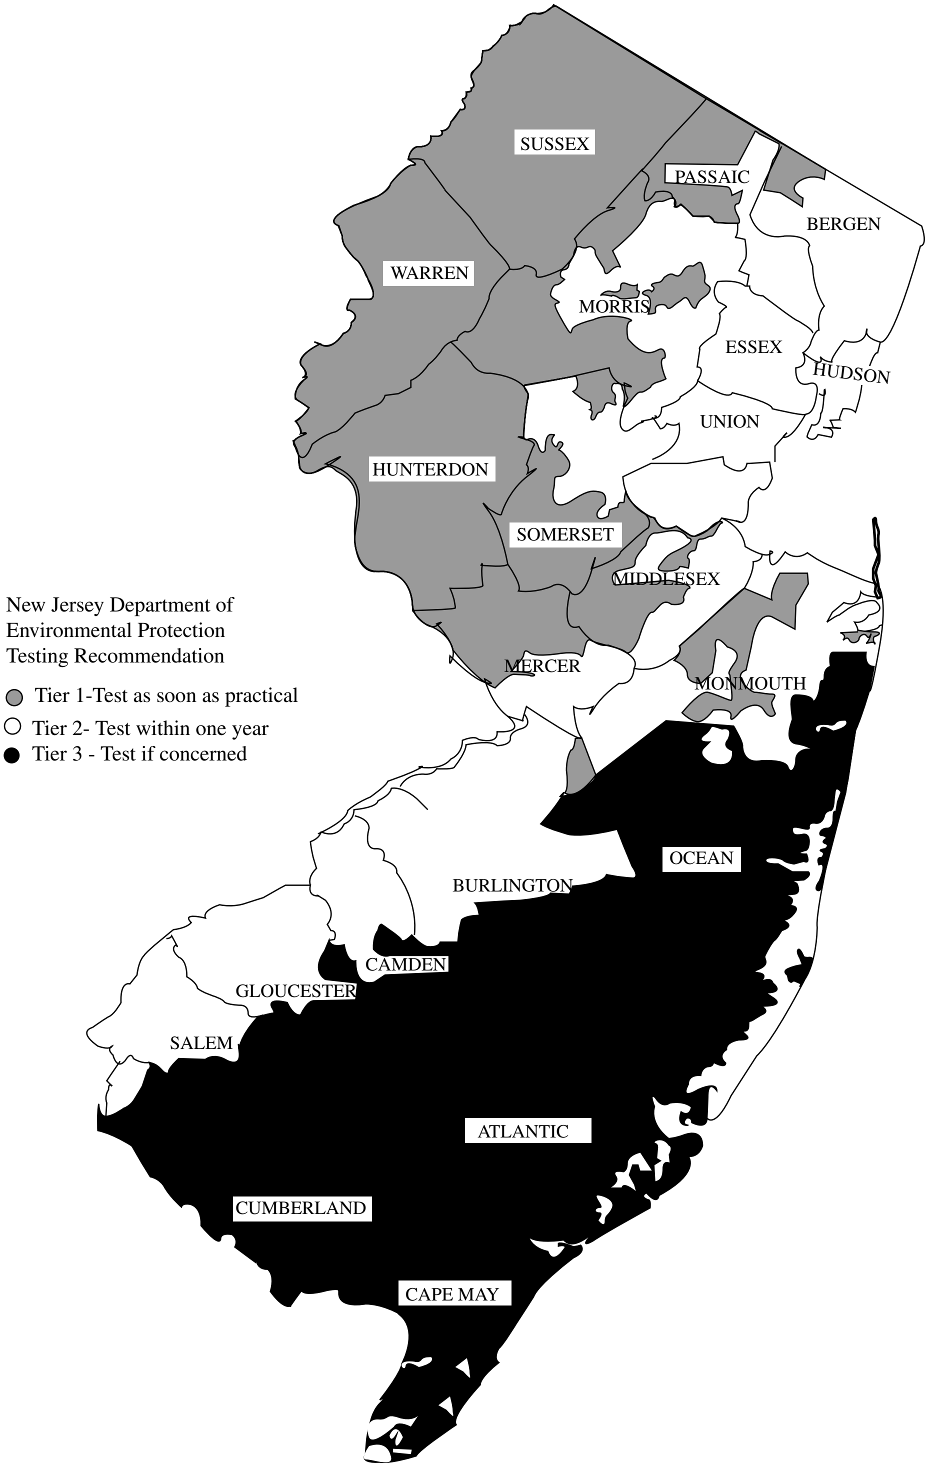

FIGURE 6 New Jersey Department for Environmental Protection, preliminary recommendations for radon testing.

Under these conditions, radon levels on upper floors have been observed to equal or, in a few cases, even surpass basement level radon concentrations.

It should be noted that the statewide study was designed to locate areas of potential radon problems and hence the area sampling density was varied depending on anticipated results. Approximately 20% of the total number of samples were set aside for use later in the sampling period to better define potential problem areas identified in the initial sampling. Hence, the sampling is somewhat biased in terms of problem prone areas, and the values somewhat overestimate the true population based averages.

A total of 35.0% of the homes in the study were found to have radon levels at or above the EPA's 4pCi/1 guidance level. This is in very good agreement with the 32.5% of the homes tested by commercial firms participating in the voluntary certification program. This data, which is approximately log-normally distributed, is shown in Figure 2. Data obtained by commercial firms using primarily charcoal canisters in ground levels of homes are shown in Figure 3. Approximately 11.7% of these results are equal to or exceed 4 pCi/1.

Data collected as part of the confirmatory monitoring program are shown in Figures 4 and 5. Figure 4 shows that, in 86.4% of the homes tested, the DEP measurements corroborated the commercial testing result to the extent that both indicated a radon concentration at 4 pCi/1 or greater. In the 13.6% of the homes where this corroboration did not occur, the difference between the two results is believed to be attributable to natural variations in the radon level, variation in the testing method, and the fact that many residents take action to reduce radon levels immediately upon receiving the initial result.

Residents participating in the confirmatory monitoring program who obtain their water from private wells also have their well water tested for them as part of the program. This data is shown in Figure 5.

The EPA has estimated that a radon in water concentration of 10,000 pCi/1 produces an increase in the radon concentration in the ambient air of approximately 1 pCi/1 in the home where that water is used. Approximately 100 to 1,800 of the 5,000 to 20,000 lung cancer deaths attributed by EPA to radon annually in the United States are believed to arise from exposure to radon entering the home via the domestic ground water supply. Inhalation is the only source of risk as drinking water containing radon is not considered a health threat.[19]

Through the Radon Cluster Identification Program, a number of high level radon homes have been identified. The data derived from the program is presented in Table 4. As indicated, approximately 85% of the homes tested as part of this program have radon levels at or above 4 pCi/1 Approximately 15% of the homes tested had a radon concentration of 200 pCi/1 or greater. Thus, identification of a high level home and subsequent sampling of surrounding homes is a means of identifying radon problem prone areas.

Based on the available data, the DEP made recommendations to residents regarding radon testing in September of 1987. These recommendations are summarized in Figure 6. The three tiers given in the figure reflect the probability for finding an indoor radon problem in a given area of the state based on available testing and geologic evidence.

CONCLUSIONS

Data obtained from the statewide study of radon, through the voluntary certification program for radon testing firms, and from the radon cluster identification program clearly demonstrate that New Jersey has a significant radon problem. Residents do, however, have ready access to testing and remediation services from State certified vendors in the private sector. Further, State programs exist to provide information, confirm test results, identify problem prone areas and support research specific to New Jersey needs.

RECYCLING WASTE MATERIALS

Reclamation of waste materials for the purpose of reuse is a commonly accepted definition of recycling. Although water is the substance reused in greatest volume, it will not be covered here. (See Biological Treatment of Wastewater; Municipal Wastewater; Physical and Chemical Treatment of Wastewater; Water Reuse; Water Treatment). Impurities in the air are considered only after removal. Baghouses are an example.

Recycling, or reuse, is based on economics. A used material will be discarded if reclamation costs exceed the cost of new (virgin) material. Disposal costs, however, have increased greatly in the last decade and it is no longer as easy to "throw away" many things. Acceptable disposal sites increasingly are in short supply and transportation costs have become a much more significant part of the expenses of disposal. A typical municipal solid waste can be expected to be somewhat close to the following, by weight:

Paper	35%
Yard wastes	16%
Food wastes	15%
Metals	10%
Glass	10%
Plastics, rubber and leather	7%
Textiles	2%
Miscellaneous	5%

These percentages will vary with the season.

More acute public awareness of environmental pollution has added to the pressure for recycling. Resources are not limitless and many non-renewable materials will be seriously depleted in the not-too-distant future. Raw materials for plastics are petroleum based. Oil has not had a very stable price since the early 1970's.

Landfills have served as repositories for municipal and industrial solid wastes since before the turn of the century. Waste was placed in a dump without regard to separation or segregation of materials. Odors and rodents were common problems. Little planning went into site selection of solid waste disposal areas. As urban areas grew, many dumps at the edge of town were bypassed and were then within the city limits. In many cases, these sites were covered and homes and buildings constructed. These structures all too frequently settled unevenly on the poorly compacted material. At present there is interest in use of decomposition gases from old landfills. Removal of these gases, primarily methane, gives a saleable product and also aids in compaction. Results have been mixed, at best.

Kitchen wastes, organic in nature, appear in unsegregated garbage and trash. Some authorities view these kitchen wastes as suitable for incineration. Older incinerators give rather poor performance, due to high water content in the garbage lowering process temperatures. Problems were common. Improved technology promises higher temperatures and cleaner stack effluents. Ideally, such installations will burn wastes, produce steam and generate electrical energy. The stream and electricity can then be sold and generate sufficient income to pay for the whole operation. It has been proposed that suitably prepared sewage sludge might be added to the combustible mixture. However, the NIMBY (Not in my backyard!) Syndrome complicates the situation. Every group wants to dispose of waste from an upstream vantage point. In the 1990's everyone is downstream from someone else. It is obvious that properly designed and implemented recycling programs can aid in alleviating both technical problems and public perception difficulties.

Ease of separation is fundamental in conversion of waste to a profitable product. Industrial wastes are more easily separated than are municipal solid wastes. Industrial wastes can be collected unmixed and in bulk quantities. Municipal solid waste requires separation techniques, increasing costs to a degree depending on the number of steps.

Reducing the volume of the waste stream reduces ultimate disposal costs by making recyclable materials more readily available and lessening the volume necessary to contain the wastes. About 2000 communities in the US are practicing curbside pick up of recyclables or plan to do so in the near future. The most important consideration in planning such a program is selection of the materials to be included. Decisions must be made as to which materials will be collected, both at startup and later in the program. If all materials are included at the planning stage, the equipment will be adequate, even if lesser numbers are initially processed. Trucks will be of sufficient size and will have enough compartments. Processing equipment will be in place and able to handle all the materials. Recyclable materials are usually segregated by the householder or industrial generator. It is necessary to make economic projections for the waste. Glass requires separation as to color.

In the 1960's plastic (polymeric) containers began to replace glass containers in many uses. Milk and soft drinks had been sold in glass bottles and deposits helped ensure that these containers were returned to the place of purchase. Imposition of deposits effectively kept much of the glass from the waste stream. The plastics have, however, added significantly to the volume of waste and have made waste management more difficult.

A controversial subject is “Beverage container deposit legislation” (BCDL), commonly called bottle bills. It has been found that such bills are effective in controlling litter.

The US Environmental Protection Agency estimates that the weight percentage of plastics in municipal solid waste is about 7–9% but this material occupies 25–30% of the total waste volume.

Many plastic containers today are stamped with symbols as an aid to recycling. These are shown in Figure 1 and are described in Table 1. Only PET and HDPE are commonly collected for recycling.

In 1989 plastics were a part of 800 state and local waste management related bills. This was indicative of the “greening” of consumer buying patterns and more stringent waste disposal regulations. Many major industrial users of plastics are now looking closely at further uses of plastics as a part of “design for disassembly” for ease of separation and reuse. Public attitudes seem to have changed. Once recycled materials in products were regarded as shoddy. Now recyclability is seen as a good selling point. Prices for recycled plastics are now close to those for virgin materials. It is expected that recycled plastics prices will stabilize at 80–90% of those for virgin materials. Major plastics manufacturers have become involved in plastics recycling efforts. In Europe, petrochemical producers have joined to form recycling research units. It is felt that industry must become actively involved in recycling. If it does not, legislation curbing applications and seriously affecting producers may be introduced. In Japan, which incinerates much of its municipal solid waste, industrial plastics producers have also become deeply involved in plastics recycling research. Much work is being done on conversion of plastics to fuel oil.

A major problem in plastics recycling is the low weight-to-volume ratio. It is unprofitable to transport uncrushed containers over long distances. As mentioned earlier, separation at the end user level is most important. Also, different types of plastics are mixed in the waste stream and their similar characteristics make them difficult to separate. Material recovery facilities (MRF), sometimes called municipal recycling facilities, have been established to address the latter problem.

Plastics for reuse are ground or chopped, washed and dried prior to use in extruding machines. Ground plastics may be remelted. This allow additional purification and assists in obtaining a more uniform color. Plastic pellets as the end product can be molded or extruded the same as virgin material. Plastic chips are separated by density differential in liquid flotation processes. Water is commonly used but hydrocarbon liquids have been tried. PET and HDPE are the plastics most commonly collected for recycling from municipal solid waste and inclusion of polyvinyl (PVC) bottles is not desirable. PVC melts and decomposes at reprocessing temperatures. Methods for automatic detection and separation are under development. One company, requiring consistent container color, has sandwiched recycled polyethylene between layers of virgin material. It is generally recognized that supply and regulatory problems must be solved in order to make plastics recycling a viable industry. At present the overall recovery rate for plastics is about 1–2%.

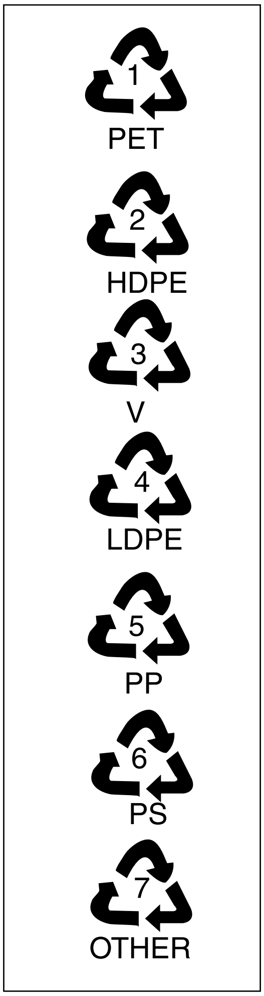

FIGURE 1

The majority of the paper recycling market is newsprint and corrugated paper. However, more valuable grades of paper are found among the 70 commercial grades of wastepaper. Many of these are now incinerated or landfilled.

By the end of the 1990’s about one quarter of the pulp supply in the US came from recycled sources. It is expected that capacity for “secondary” fiber (including recycled and byproduct material) will grow at a rate twice as great as that for virgin (primary) fiber. Chemicals used in making paper products are being reformulated or used differently in order to assist recycling efforts.

The European Economic Community (EEC) averages a recycle rate of about 35% for paper, about the same as that of

TABLE 1

1-PET	Polyethylene Terephthalate. Beverage bottles, frozen food boil-in-the-bag pouches, microwave food trays. About 7% of the plastic waste stream.
2-HDPE	High Density Polyethylene. Milk jugs, trash bags, detergent bottles, bleach bottles, aspirin bottles. About 31% of the waste stream.
3-V	Vinyl. Cooking oil bottles, meat packaging. About 5% of the stream.
4-LDPE	Low Density Polyethylene. Grocery store produce bags, bread bags, food wraps, squeeze bottles. About 33% of the total stream.
5-PP	Polypropylene. Yoghurt containers, shampoo bottles, straws, syrup bottles, margarine tubs. About 9% of the total stream.
6-PS	Polystyrene (Styrofoam^{TM}). Hot beverage cups, fast food clamshell containers, egg cartons, meat trays. About 11% of the total stream.
7-Other	All other plastic resins or mixes of 1–6 in the same product. About 4% of the stream.

Source: Council for Solid Waste Solutions.

the U.S. Japan recycles about 50% of its paper and expects to reach 55% by 1995.

The US EPA estimates that as much as 40% of the municipal solid waste stream is composed of paper and related fiber products. Fluctuations in supply and demand are serious obstacles to paper recycling. This is particularly true in areas which are near pulp producing regions. Once newsprint brought $20 per ton. Now many municipalities must pay for disposal and frequently it is hauled to landfills.

Proposed legislation will mandate that recycled paper make up a portion of the product mix. If enacted, demand will more closely correspond to supply. The U.S., at the beginning of the 90's, is the world's largest exporter of wastepaper.

There is a growing demand for better grades of recycled paper. Washing techniques for ink removal from paper are quite water use intensive and remove only ink particles larger than 30 micrometers. Flotation, on the other hand, removes about 85% of particles smaller than 30 micrometers and uses only half the water. Surfactants added to the bath aid in producing a cleaner pulp. Flotation produces a cleaner end product and reduces the amount of resulting waste sludge for disposal. There is a move towards surfactant producers to formulate products for a recycler's specific needs.

Magazines, in the past, were difficult to recycle. Coated paper in magazines had much more calcium carbonate or clay filler and less wood pulp than did newsprint or other paper grades. It has been found that filler makes it easier to separate ink from fiber in a flotation process. Some recyclers find it advantageous to add "old mixed grade" (OMG) to the new material entering a pulping system. It is estimated that, on the basis of 30% OMG and 70% newsprint, the recoverable supply of OMG could be exceeded by the end of the 90's. One new process shows promise of elimination of the deinking step by application of 400 psi steam at 400°F to newsprint.

Metals have been reclaimed on a regular basis from industrial sources. Now a significant source of scrap metal is municipal solid waste. The recovery rate for aluminum is about 60%. Typically, recycled metal is remelted, along with virgin ore, in furnaces similar to those used in metal production. The focus in metal recycling is on separation techniques and not on new smelting technology.

The Resource Conservation and Recovery Act (RCRA) will be reauthorized in 1991 and the final form of this Act will determine which wastes will be acceptable for reprocessing. One difficult question to be addressed is, "what is true recycling and what is disposal disguised as recycling?" There is no doubt that recycling reduces both the industrial and municipal solid waste streams. However, many Superfund sites were formerly recycling facilities. Of these, some were "sham" recyclers and some were legitimate. The knowledge of future effects of the wastes handled was not adequate when these facilities were put into operation. Some operators did not care.

The reader is directed to *Recycling, Fuel and Resource Recovery; Economic and Environmental Factors* for specific information on various industries.

The future of recycling is bright. Public acceptance of the need for recycling is probably the most important single development of the past two decades. This acceptance has given rise to legislative recognition of the importance of the subject.

REMOTE SENSING

Remote sensing is the act of acquiring information about an object from a distance. Environmental applications of remote sensing typically involve the collection of photographic or electronic images of the Earth's surface or atmosphere from airborne or spaceborne platforms. Visual interpretation or computer processing can then be used to analyze these images.

The history of remote sensing dates back to the 19th century, when the first aerial photographs were taken from balloons and kites. The invention of the airplane provided a better platform and aerial photography advanced rapidly after World War I. With the dawn of the Space Age in 1957, the field of photographic remote sensing expanded to include pictures taken from satellites and other space platforms, as demonstrated by pictures taken with a variety of camera types during the *Apollo* missions.

At the same time, non-photographic remote sensing systems such as electronic multispectral scanners (MSS) were developed for use on airborne platforms as well as on meteorological satellites, Earth resources satellites, and other spaceborne platforms. The 1990s have seen a further expansion of the field of remote sensing, with the appearance of new imaging radar satellites, imaging spectrometers, and high-resolution MSS systems, and with the improvement of methods for computer processing of remotely-sensed data.

TYPES OF REMOTE SENSING SYSTEMS

Several types of remote sensing systems can be differentiated based on the principles employed for measuring electromagnetic radiation. The most common types fall into four broad categories: photographic systems, videographic systems, multispectral scanners, and imaging radar systems. Within these categories, particular instruments are designed to operate in specific portions of the electromagnetic spectrum. The Earth's atmosphere scatters and absorbs many wavelengths of electromagnetic radiation, limiting the portion of the spectrum that can be used for remote sensing.

Photographic Systems

Many types of cameras have been used to acquire photographs of the Earth's surface from airplanes and from space. Common formats include 35-mm, 70-mm, and 9 × 9-inch film sizes, although specialized cameras that employ other film sizes are also used. Film types include black and white panchromatic, black and white infrared, color, and color infrared, covering the visible and near-infrared portions of the electromagnetic spectrum from approximately 0.4 to 0.9 μm. (Photography in the ultraviolet range, from 0.3 to 0.4 μm, is also possible but is rarely done due to atmospheric absorption and the need for quartz lenses.) Once the film has been processed, photographs can be electronically scanned at a variety of resolutions for use in a digital environment. Photographic systems provide relatively high-resolution images, with the nominal scale of a vertical aerial photograph being dependent on the focal length of the camera and the flying height of the sensor.[1]

Videographic Systems

Video cameras can be used to record images in analog form on videotape. Video systems have been designed to operate in the visible, near-infrared, and mid-infrared portions of the electromagnetic spectrum. The advantages of video systems include low cost, near-real-time image availability, and the ability to collect and store many image frames in sequence. The primary disadvantage of video is its low spatial resolution, with approximately 240 lines per image for standard video cameras.[2,3]

Multispectral Scanners

MSS systems use electronic detectors to measure electromagnetic radiation in selected bands of the spectrum from approximately 0.3 to 14 μm, including the visible and near-, mid-, and thermal-infrared regions. These individual bands may be fairly wide (greater than 0.2 μm in width) or quite narrow (less than 0.01 μm in width). The designs used for MSS systems fall into two categories. Across-track scanners employ a rotating or oscillating mirror to scan back and forth across the line of flight. Along-track ("push-broom") scanners use a linear array of charge-coupled devices (CCDs) to scan in parallel along the direction of flight. Distinct subcategories of MSS systems include thermal scanners, which measure emitted radiation in the thermal infrared portion of the spectrum, and imaging spectrometers, or "hyperspectral scanners," which generally collect data in over 100 continuous, narrow spectral bands, producing a complete reflectance spectrum for every pixel in the image.[1,4]

Airborne and satellite MSS systems have become widely used in many environmental science and resource management applications. Examples of different types of MSS system include the following:

- The U.S. Landsat satellite series includes two MSS systems. The original Landsat MSS (on board systems launched between 1972 and 1978) includes four spectral bands in the visible and near-infrared portions of the spectrum, with a spatial resolution of 80 m. The Landsat Thematic Mapper (TM) instrument (since 1982) includes six bands in the visible, near-, and mid-infrared regions, with a spatial resolution of 30 m (and a thermal infrared band with a resolution of 120 m). Both instruments operate in an across-track configuration with a swath width of 185 km, and a current orbital repeat cycle of 16 days.
- The HRV instrument on the French SPOT satellite series can collect data in either a single wide "panchromatic" band, with 10m resolution, or in three narrower bands in the visible (green and red) and near-infrared, with 20 m resolution. The orbital repeat cycle is 26 days, but the sensor's ability to be rotated (via ground command) up to 27°— left or right allows more frequent imaging of a given location on the Earth's surface. The HRV is an along-track scanner, with a swath width of 60 to 80 km depending on the viewing angle. Two identical HRVs are included on each SPOT satellite.

Imaging Radar Systems

Whereas the previous types of remote sensing systems operate in the visible and infrared portions of the electromagnetic spectrum, imaging radar systems operate in the microwave portion of the spectrum, with wavelengths from approximately 1 cm to 1 m. At these wavelengths, radar is unaffected by clouds or haze (shorter wavelength systems are used for meteorological remote sensing). In addition, radar systems are active sensors, transmitting their own radiation rather than passively measuring reflected solar or emitted radiation; thus, they can be operated at any time of day or night. Imaging radar systems are sensitive to the geometric structure and dielectric properties of objects, with the primary determinant of an object's dielectric properties being its liquid water content. Current satellite radar systems include the European ERS-series and the Canadian Radarsat, which each have a single 5-cm wavelength band, and the Japanese JERS-1 system with a 23-cm band. Several airborne radar systems have been developed, such as the NASA/JPL AIRSAR, which operates at multiple wavelengths.[5,6,7]

Photographic cameras, video cameras, and multispectral scanners can be operated in a vertical configuration to minimize the geometric distortion of the image, or at an oblique angle to provide a side view of the landscape. Imaging radar systems are not operated vertically, but in a side-looking configuration with a broad range of possible look angles.

ENVIRONMENTAL APPLICATIONS OF REMOTE SENSING

Remote sensing has been used for a wide variety of applications in the environmental sciences. Among the earliest uses of remote sensing was geologic mapping, including the discrimination of rock and mineral types, lineament mapping, and identifying landforms and geologic structures. Today, many types of remotely-sensed data are used for geological applications at a variety of spatial scales, ranging from high-resolution aerial photography, to thermal-scanner images, to lower-resolution Landsat images covering large areas.

Agricultural applications of remote sensing are also common. Aerial photography and other remotely-sensed data are widely used as a base for soil mapping, while multispectral and thermal images are used for soil moisture mapping. Imaging radar systems, with their sensitivity to moisture-related dielectric surface properties, can also be used to measure soil moisture. Multispectral visible and infrared data are used for crop classification and assessment, including monitoring the health and productivity of crops, with the goal of predicting yields and identifying areas of crop damage.

In forestry, aerial photographs are used to delineate timber stands and to estimate tree heights, stocking densities, crown diameters, and other variables relating to timber volume. Color infrared photography and multispectral imagery can be used to map forest types and to identify areas of stress due to pest infestations, air pollution, and other causes. Aerial and satellite imagery can be used to map the effects of wildfires, windthrow, and other phenomena in forested regions. Wildlife habitat can be assessed using remote sensing at a variety of scales. High-resolution aerial photography can also be used to assist in wildlife censuses in non-forested areas such as rangeland.

Many aquatic and hydrological applications make use of remote sensing. Water pollution can be monitored using aerial photography or MSS systems, and imaging radar can be used to detect oil slicks. Thermal imagery is used to study currents and circulation patterns in lakes and oceans. Both optical and radar data are used to monitor flooding, including flooding beneath a forest canopy in the case of radar. Wetlands delineation and characterization can both be assisted by remote sensing. Radar systems are used to measure ocean waves, and both radar and optical images have been used to detect sea and lake ice.

Remote sensing is often used to assist in site selection and infrastructure location, urban and regional planning, and civil engineering applications. Aerial photographs are often acquired with a significant overlap between adjacent photos, allowing heights to be measured using the stereoscopic effect. This process is extensively used for topographic mapping and for creation of geometrically-correct orthorectified photographs to serve as base maps for other applications. Radar interferometry is also being used on an experimental basis for topographic mapping.

IMAGE INTERPRETATION AND ANALYSIS

Many environmental applications of remote sensing rely solely on visual image interpretation. In many cases, visual analysis is improved by stereo viewing of overlapping pairs of images. Increasingly, however, some degree of digital image processing is used to enhance and analyze remote sensing data. Simple image enhancement techniques include data stretches, arithmetic operations such as ratioing and differencing, statistical transformations such as principal components analysis, and image convolution, filtering, and edge detection. More complex image processing techniques include automated land use/land cover classification of images using spectral signatures representing different land cover types.[8]

Most remote sensing applications require the collection of some form of reference data or "ground truth," which is then related to features or patterns in the imagery. For example, pixels in a remotely-sensed hyperspectral image might be compared to a series of mineral spectra acquired from ground samples. Ground measurements of soil moisture, crop productivity, or forest leaf-area index (LAI) could be related to observed reflectance in a satellite image using linear regression. Often, ground truth locations are established using the Global Positioning System (GPS) to facilitate the relation to a georeferenced image.

One significant advantage of digital remotely-sensed imagery, whether collected electronically or as scanned photographs, is the ability to use digital data in a geographic information system (GIS). Once a digital image has been georeferenced, it can be combined with a variety of other types of spatial data. This combination of image and non-image data can be used for a wide range of purposes from simple map updates to complex spatial analysis.[9,10,11,12]

Remote sensing is a rapidly changing field, with more than twenty new satellite systems scheduled for launching in the next decade. Major sources of new data will be high-resolution (approximately 1 m) commercial systems and the various sensors comprising the Earth Observing System (EOS).

SEDIMENT TRANSPORT AND EROSION

INTRODUCTION

The literature on the subject of erosion and sediment transport is vast and is treated in the publication of such disciplines as civil engineering, soil science, agriculture, geography and geology. This article provides a brief introduction to the subjects of soil erosion, transport of detritus by streams and the response of a stream channel to changes in its sediment characteristics.

The agriculturalist is concerned with the loss of fertile land through erosion. Sheet, gully and other erosion mechanisms result in the annual movement of about five billion tons of sediment in the United States.[1] By this process, plant nutrients and humus are washed away and conveyed to the streams, reservoirs, and lakes.

The sediment characteristics of a stream also affect its aquatic life. Changes in the character of the sediment load will normally tend to change the balance of aquatic life. Fine sediment, derived from sheet erosion, causes turbidity in the waterways. This turbidity may interfere with photosynthesis and with the feeding habits of certain fish, thus favoring the less susceptible (often less desirable) varieties of fish. The resulting mud deposits may have similar selective results on spawning. The plant nutrients (phosphates and nitrates) that accompany erosion from farmlands may contribute to the eutrophocation of the receiving waters.

Turbidity also makes waters less desirable for municipal and industrial use. Mud deposits may ruin sand beaches for recreational use.

From the engineer's point of view an understanding of sediment transport processes is essential for proper design of most hydraulic works. For example, the construction of dam on a stream is almost always accompanied by, a reservoir siltation or aggradation problem and a degradation problem. A reasonable prediction of the rate of reservoir siltation is necessary in order to establish the probable useful life and thus the economics of a proposed reservoir. The degradation or erosion of the downstream channel and the consequent lowering of the river level may, unless properly accounted for, endanger the dam and other downstream structures (due to under-cutting). After construction of the Hoover Dam the bed of the Colorado River downstream from the dam started to degrade. In 12 years the bed level dropped about 14 feet (Brown[1]).

In addition the downstream channel may change its regime (i.e. its dominant stable geometry). For example, a wide braided channel or delta area may become a much narrower and deeper meandering channel thus affecting the prior uses of the stream. This appears to have happened as a result of the Bennett Dam on the Peace River in British Columbia.[2]

CLASSIFICATION OF STREAMBORNE SEDIMENTS

Terminology

The materials transported by a stream may be grouped under the following type of load:

1) dissolved load,
2) bed load,
3) suspended load.

The dissolved load, although a significant portion of total stream load, is generally not considered in sediment transport processes. According to Leopold, Wolman and Miller,[3] the dissolved load in US streams increases with increasing annual runoff, reaching a maximum of about 125 tons/sq.mile/year for runoffs of 10 inches/year or more.

Bed load consists of granular particles, derived from the stream bed, which are transported by rolling, skipping or sliding near the stream bed. Einstein[4,5] defines the bed load as the sediment discharge within the bed layer which he assumes to have an extent of two sediment grain diameters from the bed.

Suspended sediment load is that part of the sediment load which is transported within the main body flow, i.e. above the bed layer in Einstein's terminology. Turbulent diffusion is the primary mechanisms of maintaining the sediment particles in suspension. The suspended load may be subdivided into:

1) Wash load which consists of fine sediments mainly derived from overland erosion and not found in

significant quantities in alluvial beds; often wash load is arbitrarily taken to be sediments finer than 0.062 mm, i.e. silts and clays.

2) Suspended bed material load which is the portion of the suspended load derived primarily from the channel bed; generally the bed material is assumed to be the sediment coarser than 0.062 mm, i.e. sands and gravels.

Table 1 indicates the terminology used by the American Geophysical Union in describing various sizes of sediment.

Properties of Sediments

An excellent review of the properties of sediments is presented by Brown.[1] He discussed the determination and significance of the following:

a) properties of the individual particle,
b) particle size distribution and
c) bulk properties of sediments.

Properties of the Particle Neglecting interaction effects, the behavior of an individual particle in a stream depends on its size, specific weight, shape, and the hydraulics of the stream.

Two commonly used methods of determining particle size are: (1) mechanical sieve analysis and (2) the fall velocity method. The sieve analysis method differentiates particle size on the basis of whether or not the particle will pass through a certain standard square opening in a sieve or mesh. This method is applicable for sands or coarser particles. Except in the case of spheres, “sieve size” will only be an approximation to the true equivalent diameter of the particle since the results depend to some extent on the particle shape.

The fall velocity method of determining the effective sediment size is gaining popularity in sediment transport research. On the basis of the particle’s terminal velocity, in a specified fluid (water) at a specified temperature, the particle is assigned a fall or sedimentation diameter equal to the diameter of the quartz sphere which has the same terminal velocity in the same fluid at the same temperature.[1] This particle size integrates the effects of grain size, specific weight and shape into a single meaningful parameter for sediment transport studies. Researchers at Colorado State University have developed a Visual Accumulation Tube to aid in the determination of the fall diameter distributions for sediment samples.

Particle Size Distribution On the basis of a sieve analysis of fall diameter analysis, of a sediment sample, a cumulative frequency curve for the particle size can be drawn. Figure 1 shows typical particle size frequency curves for a sample taken from a sandy stream bed and for a sample of suspended load over the same bed.[6] The frequency curves are usually plotted on logarithmic-probability paper.

TABLE 1
Sediment grade scale

Group	Particle size range, mm
Boulders	4096–256
Cobbles	256–64
Gravel	64–2
Sand	2–0.062
Silt	0.62–0.004
Clay	0.004–0.00024

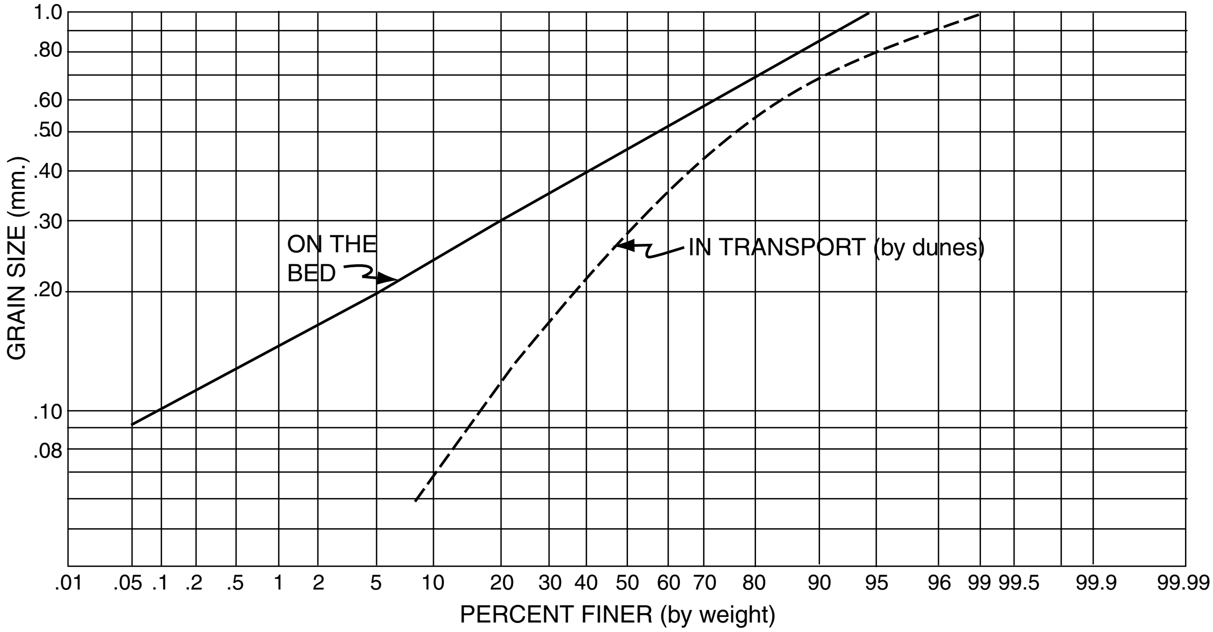

FIGURE 1 Typical particle size frequencies curves for stream sediments (after Bishop *et al.*).

Some important descriptors of the frequency distribution are: (1) the median size or d_{50}, that is, the size for which 50% by weight of the sample has smaller particles; (2) the scatter of particle size as indicated, for example, by the standard deviation or perhaps the geometric deviation; (3) the characteristic grain roughness which has been associated with the d_{65};[5,7,8] (4) the d_{35} has also been used as characteristic sediment size.[9]

Bulk Properties The determination of bulk, in place specific weights of sediments is discussed under *Reservoir Sedimentation.*

EROSION

Most of the sediment in streams is produced by the following processes:[1]

1) Sheet erosion,
2) Gully erosion,
3) Stream channel erosion,
4) Mass movements of soil (e.g. landslides and soil creep),
5) Erosion to construction works,
6) Solids wastes from municipal, industrial, agricultural and mining activities.

Morisawa,[10] using a system diagram, similar to Figure 2, summarizes the inter-relation of climatic and geologic factors that influence soil erosion and runoff. Figure 2 also shows man's influence on the system.

Langbein and Schumm[3,17] proposed the correlation shown in Figure 3 between annual sediment yield and effective annual precipitation for the United States. The effective precipitation is the adjusted precipitation which would have produced the observed runoff for an annual mean temperature of 50°F.

A recent paper by Saxton *et al.*[11] relates total runoff, surface runoff and land use practices to the sediment yield from loessial watersheds in Iowa. This paper compares erosion and surface runoff from contoured-corn watersheds and from pastured-grass and level-terraced areas. In a 6-year study the contoured-corn areas yielded, annually, about 19,000 tons/sq. mile of sheet erosion plus 3000 tons/sq. mile of gully erosion while the level terraced and grassed watersheds yielded about 600 tons/sq. mile. Similarly the surface runoff from the contoured-corn areas was approximately 5 inches compared with 1.5 inches for the level-terraced and grassed areas. The experimental watersheds were of the order of 100 square miles.

Other land use factors are discussed in a paper by Dawdy[12] who presents sediment yields for the state of Maryland. The annual sediment yield from heavily wooded areas is about 15 tons/sq. mile compared with 200 to 900 for crop land. The annual sediment yields from urban development areas (usually only a few acres) varied from about 1000 to 140,000 tons/sq. mile.

Curtis[13] obtained annual sediment yields of 390 and 290 for two watersheds (264 and 651 square miles) in the Miami Conservancy District, Ohio.

A number of empirical formulae have been developed[1,14,15] to permit estimation of rates of overland erosion. The US Department of Agriculture developed the universal soil-loss equation (for upland areas),

$$E = RKLSCP, \tag{1}$$

where E = soil loss/unit area; R = rainfall runoff factor; K = soil erodibility factor; L = slope length factor; S = slope steepness factor; C_1 = crop management factor; and P_1 = erosion control practice factor. Details for estimating the above factors are given by Meyer.[15]

MEASUREMENT OF SEDIMENT DISCHARGE

Samplers have been developed to measure both suspended and bed load in streams. However bed-load samplers are not

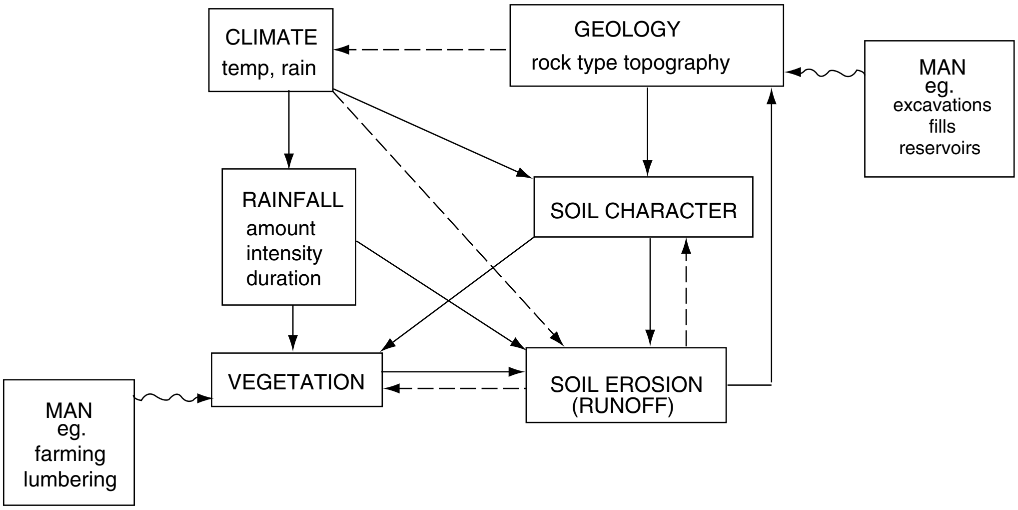

FIGURE 2 The relationship of climate and geology to soil erosion (adapted from Morisawa).

widely used because of their doubtful accuracy. Generally, only suspended load samples are collected in samplers of the type shown schematically in Figure 4. This sampler is designed so that the intake velocity is nearly the same as the local stream velocity. The extent of the suspended sampled zone is limited by the size of the sampler. Methods or extrapolating these measurements and estimating bed load are discussed in the next section.

For more details of sediment measurement techniques and equipment, the reader is referred to Nordin and Richardson,[15]

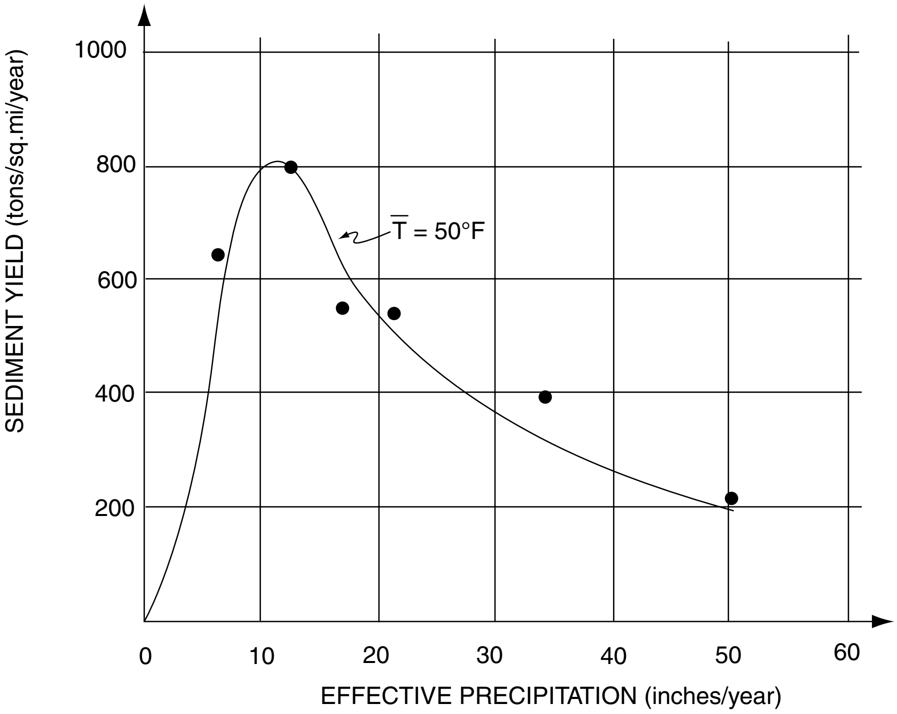

FIGURE 3 Sediment yield in the United States (after Langbein and Schumm).

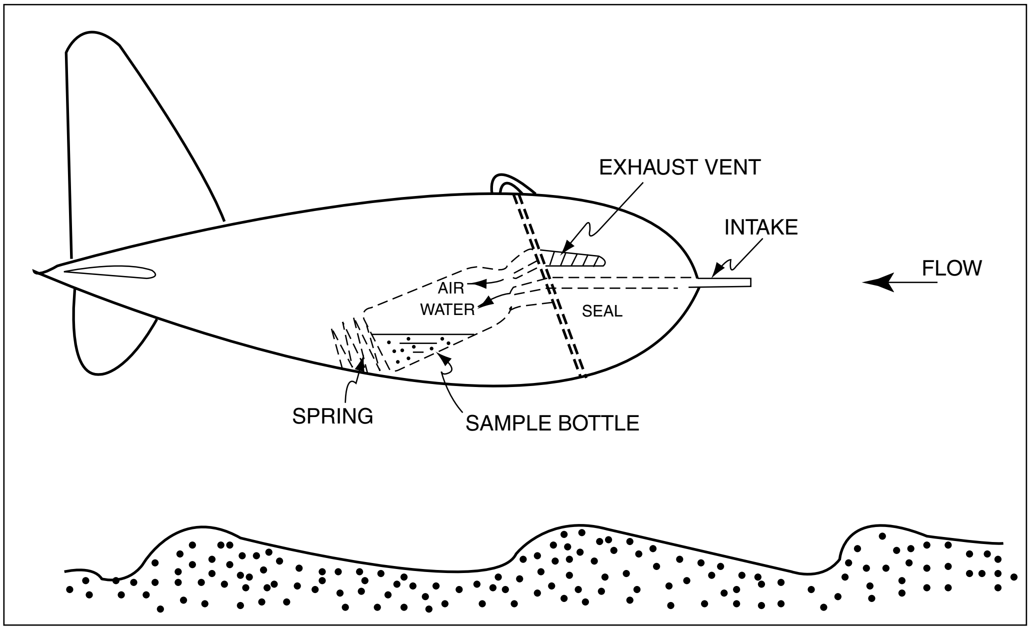

FIGURE 4 Sketch of a suspended load sampler.

Shen,[15] Karaki,[15] Graf,[16] Brown,[1] Simons, and Senturk and the ASCE Sedimentation Engineering Manual.

In some instances[15] turbulence flumes (a concrete lined reach with baffles to create severe turbulence) have been constructed across a stream channel in order to suspend the bed load and thus to sample it by suspended load techniques.

THE MECHANICS OF SEDIMENT TRANSPORT IN A STREAM

General

The nature of sediment transport in a stream depends on the shear intensity of the flow and the type of bed material. The diagram in Figure 5 shows the sequence of bed forms (waves) associated with increasing levels of shear on a fine granular bed material.[3] This figure also shows, schematically, the typical changes in the Darcy friction factor and the sediment concentration with increasing flow velocity. The primary mode of transport of particles, in the case of ripples,[17] is discrete steps along the bed; however with increasing shear more of the bed material becomes suspended until the particle motion is nearly continuous for anti-dunes.

Dunes and ripples are triangular in shape with relative flat upstream slopes and sleep downstream slopes. The water surface waves are out of phase with the dune formation while ripple formations appear to be independent of the free surface.

Dune wave lengths, λ_d, are related to the depth of flow and in general,

$$\lambda_d > 3 \text{ feet} \tag{2}$$

whereas ripple wave lengths λ_r are shorter,

$$2'' \lesssim \lambda_r \lesssim 18'' \tag{3}$$

Dune heights, H_d, are related to the depth of flow, with the limiting height approaching the average flow depth. The ratio of dune length to height is given by[17]

$$8 \lesssim \frac{\lambda}{H_d} \lesssim 15. \tag{4}$$

The maximum ripple height is about 0.1 feet.

Both ripples and dunes progress downstream. The transition from dunes to anti-dunes occurs at a Froude number close to 1.0.

Anti-dunes, as indicated by Figure 5, are in phase with the surface wave. The may be stationary or move upstream. The maximum height of an anti-dune is approximately equal to the flow depth at the trough of the surface wave.

Simons,[17,18] on the basis of experimental data, developed the relationship shown in Figure 6 between stream power and bedform for varying fall diameters. Simons and Richardson[19] also studied the variation of Chézy's C with bed form. Their results are summarized in Table 2.

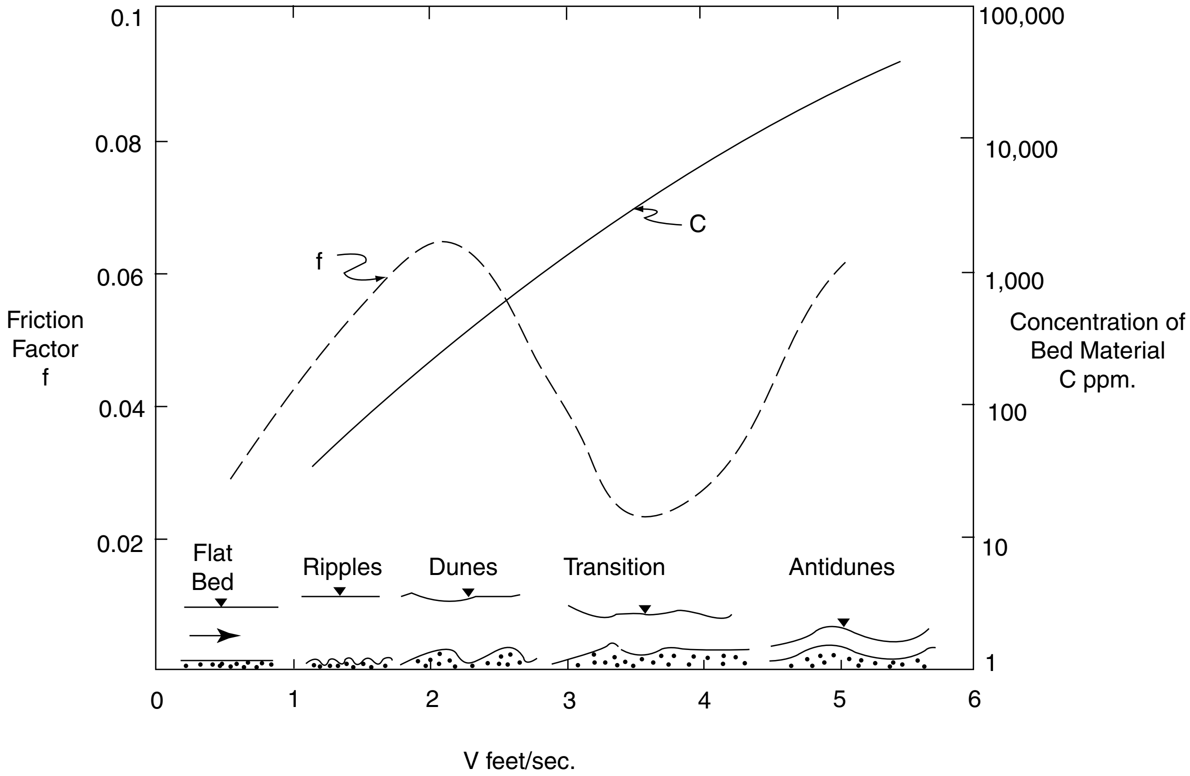

FIGURE 5 The behavior of a mobile stream bed (adapted from Leopold, Wolman, and Miller).

Initial Motion

White, in 1940,[20,21] using an analytical approach, showed that, for sufficiently turbulent flow over a granular bed, the critical shear or shear to initiate grain movement is

$$\tau_c = \kappa_c \gamma_f (S_s – 1)d, \tag{5}$$

in which κ_c ; 0.06; γ_f = fluid specific weight; S_s = specific gravity of sediment grain; d = grain diameter.

Shields,[21] using an experimental approach, obtained the more general equation

$$\tau_c = \gamma_f (S_s – 1)\, d f(R_*), \tag{6}$$

in which $R_* = U_* d/\nu$; U_* = friction velocity; ν = kinematic viscosity; and $f(R_*)$ is defined in Figure 7.

Permissible or allowable tractive stresses for use in channel designs with granular or cohesive boundaries are given by Chow.[7]

Bed Load Formulae

When the bed shear, τ_o, due to the flowing stream exceeds the critical shear, τ_c, a part of the bed material starts to move in a layer of the stream near the bed, i.e. the bed layer. Experimental studies[3] indicate that this sediment discharge, known as the bed load, q_B, is a function of the excess of τ_o above τ_c or

$$q_B \propto fcn\,(\tau_o—\tau_c). \tag{7}$$

Figure 8 illustrates a typical experimental relationship between q_B and $(\tau_o—\tau_c)$.

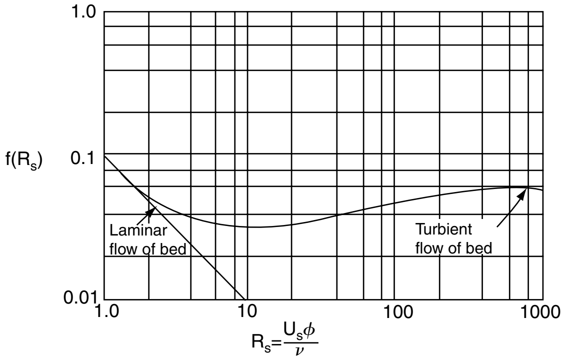

FIGURE 7 Shields' critical shear function (adapted from Henderson).

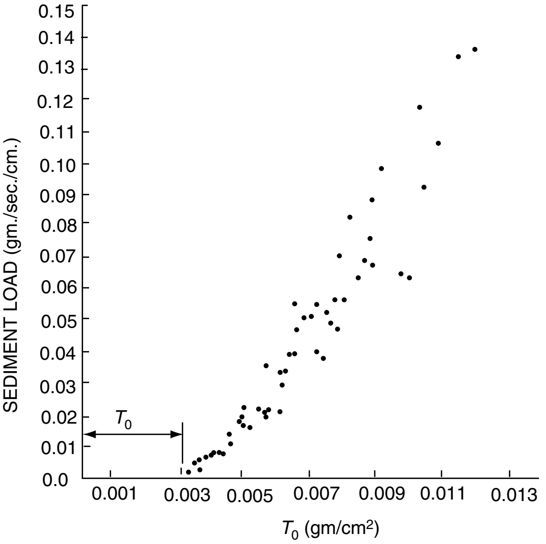

FIGURE 8 Typical relation of shear and sediment load (adapted from Leopold, Wolman and Miller).

DuBoys in 1879[22] treated the bed material, involved in the bed load, as it if consisted of sliding layers which respond to and distribute the applied stress τ_o. He proposed the relation

$$q_B = C_s\tau_o\,(\tau_o–\tau_c) \tag{8}$$

Both C_s and τ_c depend on particle size as indicated in Table 3.

Chang,[1] Schoklitsch,[1,16] MacDougall,[1] and Shields[1] have presented bed load formulae similar to Eq. (8).

The theoretical bed load model developed by Einstein[4,5,8,24] has formed the basis for a number of researches in sediment transport.[6,15,24,36] Einstein utilized: (1) the statistical nature of turbulent flow; (2) the fact that in steady uniform flow there is an equilibrium between the processes of erosion and deposition, that is, (probability of erosion) = (the probability of deposition); (3) the fact that grains near the bed are more in quick "steps" interrupted by "rest" periods; (4) a separate hydraulic radius, R', associated with grain roughness and another hydraulic radius, R'', associated with the bed form.

Einstein obtained the erosion probability function by assuming that the lift force, on a grain, consists of an average component [related to $(U_*)^2$] and a normally distributed random component. Einstein thus obtained the "bed load" equation

$$\frac{A_*\Phi_*}{1+A_*\Phi_*} = \frac{1}{\sqrt{\pi}}\int_{-B_*\psi_*-(1/\eta_o)}^{B_*\psi_*-(1/\eta_o)} \mathrm{d}t \tag{9}$$

in which

$$\Phi_* = \frac{i_B q_B}{i_b\gamma_s\sqrt{gd^3(S_s-1)}} \tag{10}$$

is Einstein's bed transport function; $A_* = 43.5$; $B_* = 0.143$; $\eta_o = 1/2$;

$$\psi_* = \xi Y\left\{\frac{\log\,10.6}{\log\dfrac{10.6X}{\Delta}}\right\}^2 (S_s-1)\frac{d}{S-R'} \tag{11}$$

in the Einstein flow intensity function; i_B = fraction of q_B in the size range associated with d; d = geometric mean of particle

TABLE 3
Typical values of C_s and τ_c (after Straub[22,23])

d mm	$\frac{1}{8}$	$\frac{1}{4}$	$\frac{1}{2}$	1	2	4
$\frac{C_s\text{ft}^6}{16^2-\text{sec}}$	0.81	0.48	0.29	0.17	0.10	0.06
$\tau_c\,\frac{\text{lb}}{\text{ft}^2}$	0.016	0.017	0.022	0.032	0.051	0.09

size range being considered; S_e = energy slope; i_b = fraction of bed sediment in specified range; ξ = hiding factor; Y = lift correction factor; $\Delta = d_{65}/X$; X = correction factor for hydraulically smooth flow; $\delta' = 11.6\, \nu/U_*$;

$$U'_* = \sqrt{gR'S_e} \tag{12}$$

$X = 0.770$ if $\Delta/\delta > 1.80$; $X = 1.39\,\delta$ if $\Delta/\delta < 1.80$.

Schen[15] gives an up-to-date review of the modern stochastic approaches to the bed material transport problem.

The Suspended Load

Equations of Motion of the Fluid The flow in natural streams is almost always turbulent and may be assumed to be incompressible; consequently the applicable equations of motion for the fluid are the Reynolds[25] equations

$$\rho\left[\frac{\partial \overline{U}_i}{\partial t} + \overline{U}_j \frac{\partial \overline{U}_i}{\partial x_j}\right] = \frac{\partial}{\partial x_j}(\sigma_{ji}) + \overline{F}_i, \tag{13}$$

in which $\bar{U}_i$ = ensemble mean point velocity in the direction i; σ_{ij} = stress tensor $=\{-\overline{P}\delta_{ji} + \mu\overline{D}_{ji} - \rho u_i u_j\}$ = average pressure; δ_{ji} = Kronecker delta; μ = dynamic viscosity; $\bar{D}_{ji}$ = deformation tensor; $-\rho u_i u_\xi$ = turbulence or Reynolds Stresses; ρ = fluid density ; u_i = random component of velocity in the i direction; $\overline{F}$ = body force in the i direction. The first term in the stress tensor represents the normal stresses due to the average pressure at a point; the second term represents the viscous shear forces; the last term or Reynolds stress has both normal and tangential components. A common method of simplifying equations involves the introduction of an eddy viscosity, ε_m such that

$$\rho\varepsilon_m \overline{D}_{ji} = -\rho\overline{u_i u}_{j(j\neq i)}. \tag{14}$$

The requirement that $(i \neq j)$ in Eq. (14) eliminates the normal stresses due to turbulence; in order to account for these normal stresses an average turbulence pressure $\overline{P}_i$ is added to $\overline{P}$ thus yielding the simplified stress tensor

$$\sigma_{ji} = -(\overline{P} + \overline{P}_t)\delta_{ji} + (\mu + \rho\varepsilon_m)_i D_{ji}. \tag{15}$$

The fluid continuity equation is

$$\frac{\partial \overline{U}_i}{\partial x_i} = 0. \tag{16}$$

Equations (13), (15), and (16) may be solved in a few cases by methods developed to solve the Navier-Stokes equations.

Transport of a Scalar Quantity in Turbulent Flow In an incompressible turbulent fluid the conservation of a scalar quantity requires that the rate of change of a scalar (say $\overline{c}$ plus the rate of generation of $\overline{c}$ at the point or

$$\frac{D\overline{c}}{Dt} = \frac{\partial}{\partial x_i}\left(h\frac{\partial \overline{c}}{\partial x_i} - \overline{u_i c'}\right) + \overline{F}_c \tag{17}$$

in which $c = \overline{c} + c'$; $\overline{c}$ = ensemble average of c; c' = random component of c; D/Dt = substantial derivative; $\overline{F}_c$ is the generation term; h = molecular diffusion coefficient. It is usual to introduce, into Eq. (17), an "eddy" transport coefficient ε_j, such that

$$-\overline{u_i c'} = \varepsilon_c \frac{\partial \overline{c}}{\partial x_i}. \tag{18}$$

Since in most practical problems $\varepsilon_c >> h$, then Eq. (17) can be reduced to

$$\frac{D\overline{c}}{dt} = \frac{\partial}{\partial x_i}\left(\varepsilon_c \frac{\partial \overline{c}}{\partial x_i}\right) + \overline{F}_c. \tag{19}$$

Equations (3) and (19) are valid for low sediment concentrations. A review paper by Vasiliev[26] discusses the governing equation which account for various levels of sediment concentrations. For example a first order correction to the Reynolds equations is

$$\rho\frac{D\overline{U}_i}{Dt} = \frac{\partial}{\partial x_i}(\sigma_{ji}) + (1 + r\overline{c})F_t. \tag{20}$$

The volume continuity equation is the same as Eq. (16) while the mass continuity equation becomes

$$\frac{D\overline{c}}{Dt} = -\frac{\partial}{\partial x_i}(\overline{\overline{cu_i}}) + \left\{v_s \frac{\partial \overline{c}}{\partial x_3}\right\} \tag{21}$$

in which $r = (S_s—1)$; $\overline{c}$ = average ensemble concentration at a point (mass/mass); ν_s = settling viscosity; x_3 = vertical coordinate (opposite to the direction of ν_s).

The Vertical Concentration Profile There is no general solution for Eqs. (3), (16), and (19) or (18), (20), and (21); however a few special cases, of practical interest, have been solved.

Using the simplifications which result for steady, uniform flow in two dimensions (as shown in Figures 9 and 10), it is possible to obtain a solution for the vertical velocity, and concentration profiles. The following assumptions are typical of those required to solve Eqs. (13), (14), and (21):

a) $\overline{c} >> 1$;

b) $\varepsilon_c = \beta\varepsilon_m$ where β ; 1;

c) $\overline{F}_x$; $g\rho s_0$;

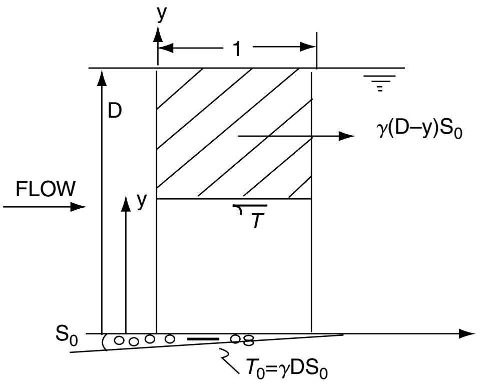

FIGURE 9 Defining sketch for uniform flow.

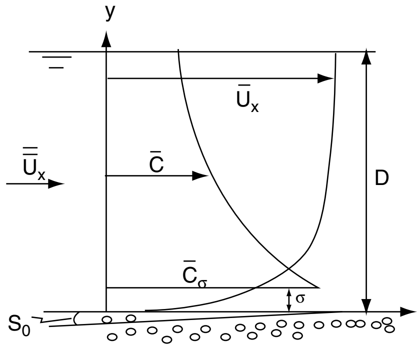

FIGURE 10 Defining sketch for velocity and concentration profiles.

d) $\dfrac{\partial(\bar{P}+\bar{P}_t)}{\partial x}=0;$

e) $\tau o = \rho g S o D$ and $\tau = \rho g S o (D-y)$;

Chang *et al.*, used the above assumptions to obtain: (a) the vertical velocity profile,

$$\bar{U}_x=\frac{2U_*}{\kappa}\left\{\sqrt{1-\varepsilon}-1\mathrm{n}\left(\frac{\varepsilon^{1/2}}{1-\sqrt{1-\varepsilon}}\right)+\frac{1}{3}\right\}+\bar{\bar{U}}_x \tag{22}$$

and (b) the vertical concentration profile

$$\bar{c}(y)=\bar{c}_a\left\{\left(\frac{y}{a}\right)^{1/2}\frac{\left(\sqrt{D}-\sqrt{D-a}\right)}{\left(\sqrt{D}-\sqrt{D-y}\right)}\right\}^{2z}, \tag{23}$$

in which U_* = friction velocity $=\sqrt{gDs_0}$; $\kappa = fcn\ (U_*d/v) \div 0.4$; $\varepsilon = y/D$; $\acute{U}$ = average velocity in vertical; a = reference height; $Z = v_s/(\beta U_*\kappa)$. Using the Keulegan velocity distributions

$$\bar{U}_x=5.75\log_{10}\left(\frac{9.05yU_*}{v}\right)\ \text{(for smooth boundaries)} \tag{24a}$$

$$\bar{U}_x=5.75\log_{10}\left(\frac{30.2y}{d_{65}}\right)\ \text{(for smooth boundaries)} \tag{24b}$$

Einstein and others[5,1] have obtained a slightly different equation for $c(y)$, i.e.

$$\bar{c}(y)=\bar{c}_a\left[\frac{a(D-y)}{y(D-a)}\right]^z. \tag{25}$$

The Suspended Sediment Load The suspended sediment discharge q_s (weight/unit time/unit width) above a reference level $y = a$ is given by

$$q_s=\gamma\int_a^D\bar{U}_x\bar{c}dy, \tag{26}$$

where $\bar{U}$ and $\bar{c}$ are given by Eqs. (22) and (23) or (24) and (25).

Longitudinal Dispersion Another problem which has received some attention is that of longitudinal diffusion and dispersion in natural streams and estuaries. Several researchers[16,33,34,35] have sought analytical and numerical solutions for the longitudinal variation in the mean concentration in the vertical, $\bar{c}$.

Considering two dimensional longitudinal dispersion, Eq. (17) can be approximated by[16]

$$\frac{\partial\hat{c}}{\partial t}+\bar{\bar{U}}_x\frac{\partial\hat{c}}{\partial t}=E_L\frac{\partial^2\hat{c}}{\partial x^2} \tag{27}$$

in which E_L ; coefficient of longitudinal diffusion. A typical[16] value for E_L is

$$E_L=5.9\bar{U}_*D.$$

The solution of Eq. (27) for an initial step change, M_o, in concentration, is

$$\hat{c}(x,t)=\frac{M_o}{\sqrt{4\pi E_L t}}e^{-(x-\bar{U}_x t)^2/4E_L t}. \tag{29}$$

Other treatments of the dispersion problem may be found in the works of Holley[28] Householder *et al.*,[29] Chiu *et al.*,[30] Conover *et al.*,[31] Sooky,[32] Fischer,[33] Harleman *et al.*,[34] and Sayre.[35]

The Total Sediment Load

Einstein[5] developed a unified total bed material formulae by converting his computed bed load, q_B to a reference concentration at $y = a = 2d$. Inserting into Eqs. (25) and (26) he obtained an estimate of q_{sB} the suspended bed material load. Hence the total bed material load per unit width, q_{TB} is

$$\begin{aligned} q_{TB} &= q_B + q_{sB} \\ &= \sum_{\substack{\text{all size}\\ \text{ranges}}} i_B q_B\,(1 + P_e I_1 + I_2) \end{aligned} \tag{30}$$

in which $I_1 = K\int_A^1 (1/y-1)^z\,\mathrm{d}y$; $I_2 = K\int_A^1 (1/y-1)\ln y\,\mathrm{d}y$; $K = 0.216\,A_e^{Z'-1}/(1-A_e)^{Z'}$; $A_\mathrm{e} = 2\mathrm{d}/D$; $P_\mathrm{e} = 2.3\log 30.2\chi d/d_{65}$; $Z' = v_\mathrm{s}/(\beta U_*\kappa)$; ($X$ *see Bed Load Formulae*).

The total sediment load per unit width in a stream q_T is

$$q_\mathrm{T} = q_\mathrm{TB} + q_\mathrm{w}, \tag{31}$$

where q_w = wash load (fines) which must be obtained independently, e.g. by direct measurement. The Einstein method requires a knowledge of: grain size distribution in the bed; the grain density; the energy slope, S_e; and the water temperature, in order to compute both bed material load and water discharge for a given depth and width of flow.

Colby and Hembree[9,36] modified Einstein's method in order to compute total sediment load (q_T). Their procedure utilizes: the sampled suspended load Q_s; measured discharge; measured depths and sampler depths, the extent of the sampled zone; and all the data used by the Einstein procedure except S_e. Their main modifications are:

1) The finer portion of the total suspended load, Q_s, is based on extrapolation of the actual sampled load Q'_s (using Eqs. (25) and (26)).
2) The coarser part of the total load (including the bed load) is computed from a simplified Einstein procedure (using a modification of Eq. (30)).
3) Einstein's grain shear velocity U'_* is replaced by an equivalent shear velocity U_m based on the Keulegan equations and the measured discharge.
4) Einstein's flow intensity function ψ_*, is replaced by the larger of

$$\Psi_\mathrm{m} = 1.65 g d_{35}/(U_\mathrm{m})^2 \text{ or } \Psi_\mathrm{m} = 0.66 g d/(U_\mathrm{m})^2 \tag{32}$$

5) The modified term Φ_m is used to enter Einstein's Eq. (9) to obtain a bed transport function ψ_*; the modified bed transport function is

$$\Phi_* = \Phi_*/2. \tag{33}$$

The value of Φ_m is used to compute the bed load associated with a size range *d*, i.e.

$$i_\mathrm{B} q_\mathrm{B}\ ;\ 1200 d^{3/2} i_\mathrm{B} \Phi_m \,\mathrm{lb/sec/ft}. \tag{34}$$

6) Using the computed bed load for a certain size range, $i_\mathrm{B}Q_\mathrm{B}$, the measured suspended load in the same size range, $I_s Q'_s$, and Einstein's Eq. (30) one can obtain a value for Z' in Eq. (25) which should be better than a Z' based on an estimated v_s.

Bishop, Simons, and Richardson[6] simplified the Einstein procedure for determining total bed material load. They introduced a single sediment transport function ΦT which includes both suspended bed material and bed load. Their flow intensity term is

$$v_T = (S_s - 1)\frac{d_{35}}{R' S_e}. \tag{35}$$

The experimental relationship shown in Figure 11 were established for actual river sediments of various median sizes. Using ΦT from Figure 11 the total bed material load per unit width, is

$$q_{TB} = \Phi_{T\rho s}(gd)^{3/2}(S_s - 1)^{1/2}. \tag{36}$$

The wash load must be added to q_TB to obtain the total sediment load.

Colby[37] analysed extension laboratory and field data to establish the empirical relationship, shown in Figure 12, for the determination of sand discharge. Figure 12 is valid for a water temperature of 60°F and a flow to moderate wash load ($\hat{c} < 10{,}000$ ppm). Colby provides adjustment coefficients for water temperature and wash load. For example, at a flow depth of 10 feet a ±20°F change in temperature would result in about +25% change in the sand discharge and an increase in the concentration of fines from 0 to 100,000 ppm could cause up to 10 fold increase in the sand load.

The reader is referred to Graf,[16] Shen,[15] and Chang *et al.*,[27] for other contributions to the determination of total bed material load.

The Annual Sediment Transport

In general it is not practical to continuously sample the sediment in a stream; instead, representative samples are taken for various flow conditions and a sediment load versus water discharge or sediment rating curve is established. A typical sediment rating curve is shown in Figure 13. A number of factors contribute to the scatter of data points in Figure 13. The sediment load is out of phase with the discharge hydrograph as illustrated by Figure 14. The sediment load depends on the season of the year.

Using the available stream flows and the sediment rating curve an average annual sediment transport can be estimated.

Often the bed load is not included in the sediment rating curve; if this is the case, the bed load may be computed as discussed under *Bed Load Formulae* and added to the annual sediment transport.

THE RESPONSE OF A CHANNEL TO CHANGES IN ITS SEDIMENT CHARACTERISTICS

Lane's Model

Lane[39] proposed the relationship

(sediment load) × (sediment size) ∞ (stream slope) × (stream flow)

or

$$(Q_\mathrm{s} \times d) \infty (S \times Q) \tag{37}$$

to describe qualitatively to behavior of a stream carrying sediment.

Lane used the following terms in referring to streams: (1) "grade ≡ equilibrium or regime slope; (2) "aggrading" ≡ rising of the stream bed due to deposition; (3) "degrading" ≡ losing of the stream bed due to scouring

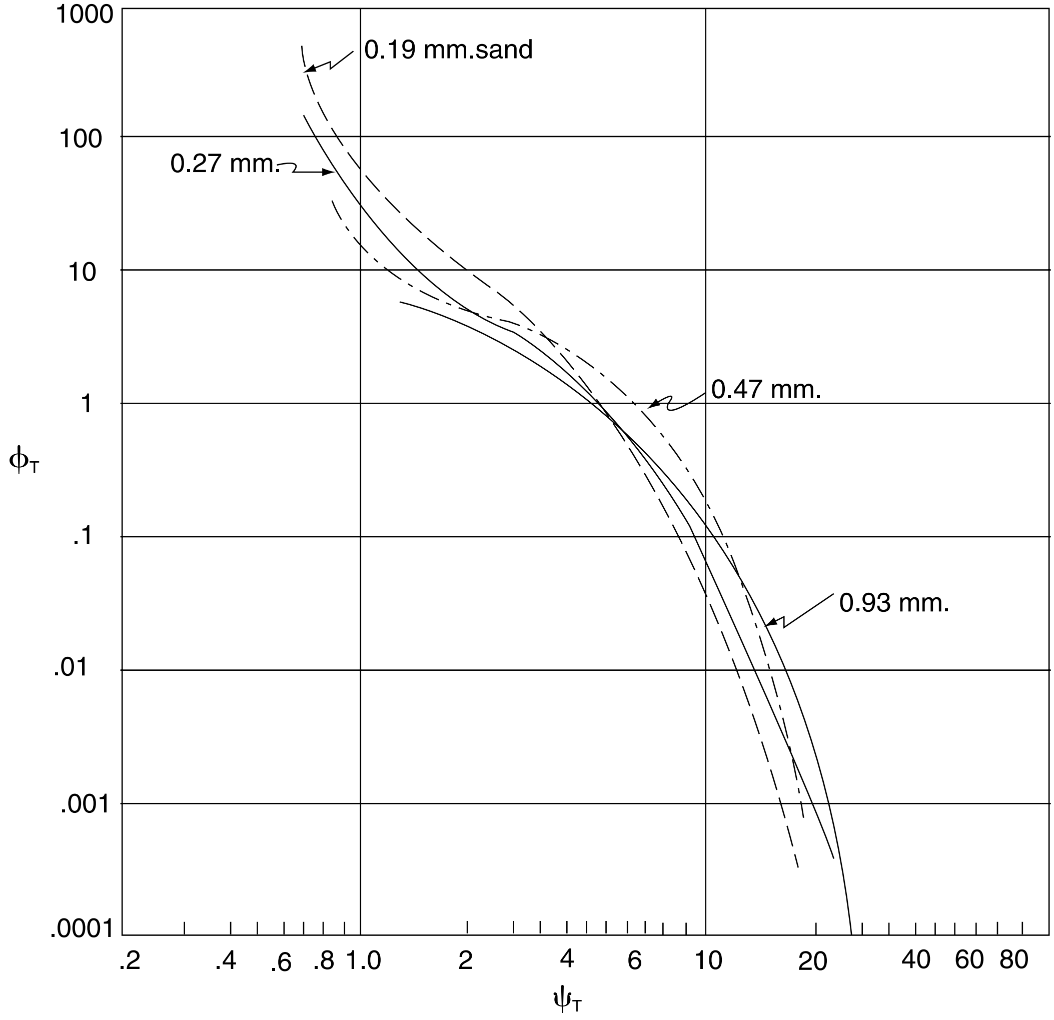

FIGURE 11 Bed material transport function (after Bishop *et al.*).

(4) "base level" ≡ the local level to which a stream tends to cut its bed.

Lane contended that there is a natural tendency for a balance between the products in Eq. (38). For example, if one of the factors, Q_s, is decreased then, in order to balance the equation, the stream slope might also tend to decrease, i.e. degradation. On the other hand an increase in Q_s could lead to an increase in S, i.e. aggradation.

The Regime Approach

"The dimensions (width, depth, and slope) of a channel to carry a given discharge, with a given silt load, are fixed by nature, i.e. uniquely determined." A channel whose dimensions are so established is said to be in regime.

In the geological sense[3,10] a river system is never really in equilibrium. According to W.M. Davis, who postulated a geomorphological cycle,[3,10] the agents of uplift and gravity (represented mainly by steam erosion) are always opposing each other. However, from the engineering point of view, a stream can be considered to be in "equilibrium" over a period of a few decades if its average behavior or average dimensions remain unchanged. There are always fluctuations, of the channel geometry, about this average; thus the steam is sometimes said to be in "dynamic equilibrium."

Of course, a stream may be aggrading or degrading (on the average in Engineering time) and thus it is not in equilibrium. The regime theory could be used to predict the ultimate dimensions of a stream that is not in regime.

Kennedy[40] and Lindley[41] collected data from canals in India (Pakistan) and proposed an equation for the non-filtering, non-scouring velocity, v,

$$v = C_1 y^n, \tag{38}$$

where $C_1 = 0.84$; $n = 0.64$; and y = depth of flow.

Kennedy was followed by Lacey, Inglis, and Blench who developed equations for channel slope and width.

Lacey[42,21] introduced the equations

$$v = 1.17\sqrt{fR} \tag{39}$$

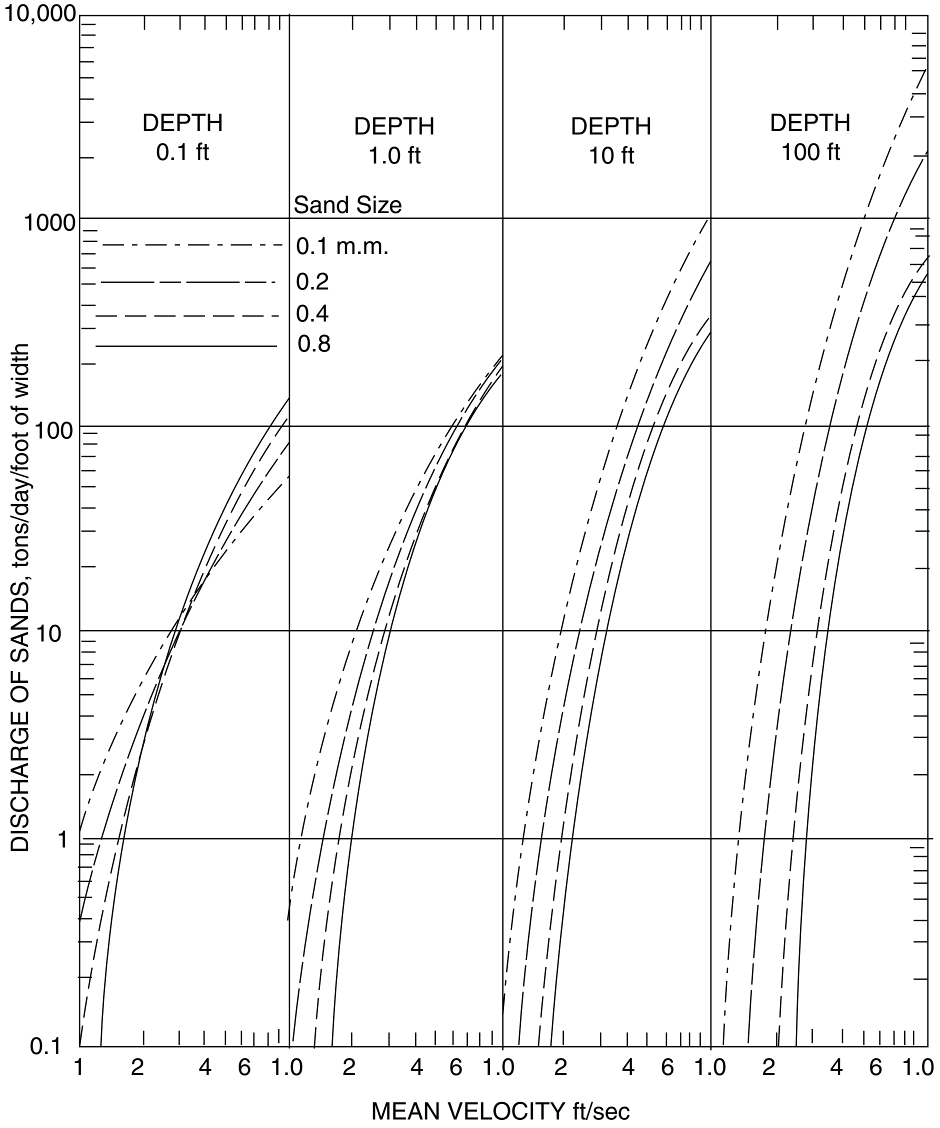

FIGURE 12 Sand discharge (after Colby).

$$f = 8\sqrt{d} \tag{40}$$

$$v = 16R^{2/3}S^{1/3} \tag{41}$$

$$P = 2.67\sqrt{Q} \tag{42}$$

in which R = hydraulic radius (ft.); d = medium grain diameter (inches); P = wetted perimeter (ft.) Q = dominant discharge = υPR(cfs.).

The dominant discharge in the case of canal flow is the design flow. In the case of a natural stream it is the channel forming flow which is often taken to be the bankfull discharge[3] which has an approximate return period of, between 1.25 and 2.33, years.

Blench[43] advanced the work of Lacey and introduced bed and side factors to better describe the depth and width of a channel in regime. His equations are:

$$f_b = v^2/y = \text{bed factor} \tag{43}$$

$$f_s = v^3/b = \text{side factor} \tag{44}$$

and

$$S = \frac{(f_b)^{5/6}(f_s)^{1/12}1^{1/4}}{3.63gQ^{1/6}(1+c/2330)}, \tag{45}$$

in which c is the concentration in ppm; b = mean width (ft—sec. units). The recommended f_b is

$$f_b = 9.6\sqrt{d(\text{in})}(1+0.012c) \tag{46}$$

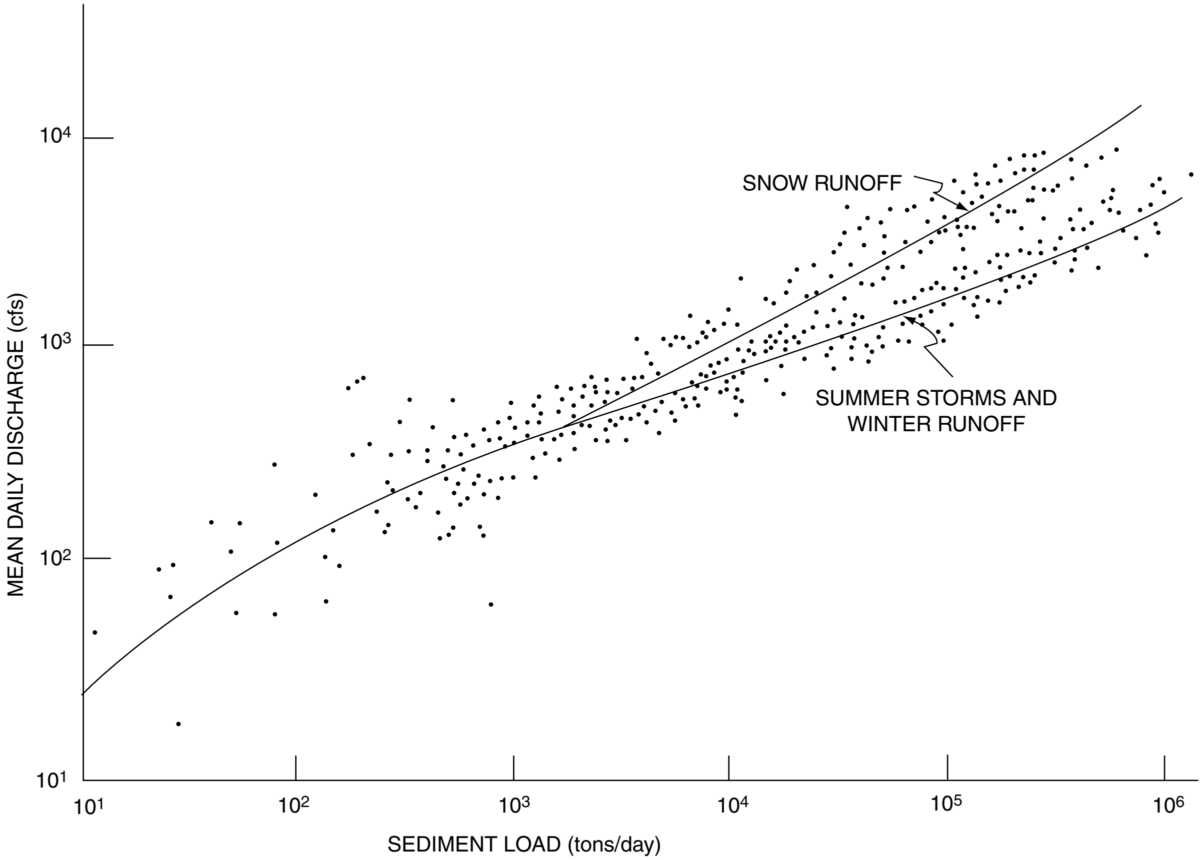

FIGURE 13 Typical sediment rating curve (adapted from Ref. 38).

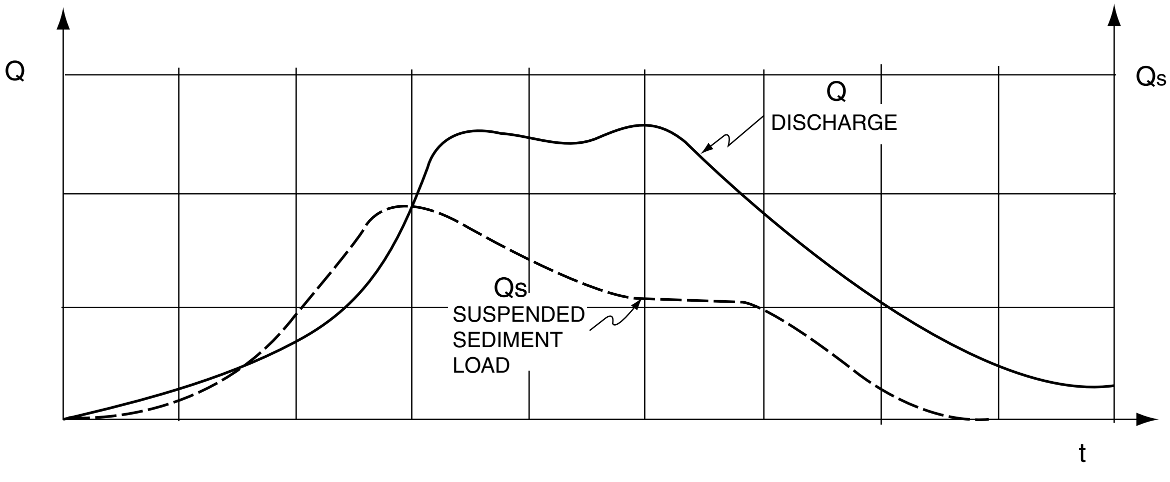

FIGURE 14 Variation of sediment load with time (adapted from Graf).

and f_s depends on the cohesiveness of the material in the channel banks. For example, f_s is approximately 0.1, 0.2, and 0.3 for low, medium, and high cohesiveness respectively.

The data of Lacey and Blench were mainly from canals, with moderate to low sediment loads ($c < 500$ ppm) and with sand beds and slightly cohesive banks.[17]

Simons and Albertson[44,21] have extended the regime equations to make them applicable to the five channel classifications shown in Table 4.

They proposed the following general equations:

$$P = K_1 Q^{1/2} \tag{47}$$

TABLE 4
Canal classification[21,44]

1) Sand bed and banks.
2) Sand bed and cohesive banks.
3) Cohesive bed and banks.
4) Coarse noncohesive material.
5) Same as for 2, but with heavy sediment loads, 2000–8000 ppm.

$$b = 0.9\,P \tag{48}$$

$$b = 0.92B–2.0 \tag{49}$$

$$R = K_2Q_{0.36} \tag{50}$$

$$y = 1.21\,R \text{ for } R < 7 \text{ ft.} \tag{51}$$

$$y = 2 + 0.93\,R \text{ for } R > 7 \text{ ft.} \tag{52}$$

$$v = K_3(R^2S)_m \tag{53}$$

$$\frac{C^2}{g} = \frac{v^2}{gyS} = K_4\left(\frac{vb}{v}\right)^{0.37} \tag{54}$$

in which C = Chézy coefficient; B = surface width; the values of the K's and m are defined in Table 5.

Schumm[17,45] studied the Great Plains rivers in the US and similar rivers in Australia; he correlated stream geometry with discharge (mean annual flood Q_{ma}) and the percent silt-clay, M, in the channel boundary. Some of his correlations are:

$$\text{Full Bank width} = W = \frac{2.3Q_{ma}^{0.58}}{(M)^{0.37}} \tag{55}$$

$$\text{Width: depth ratio} = \frac{W}{D} = \frac{21Q_{ma}^{0.18}}{(M)^{0.74}} \tag{56}$$

$$\text{Sinuosity} = 0.94M^{0.25}, \tag{57}$$

The high correlation of stream geometry and M led Schumm to classify channels (see Table 6) using M as an index to the ratio of coarse load to total load.

Schumm[45,17] associated meandering channels with high values of M and low bed load and braided channels (a relatively straight, steep main channel consisting of a maze of sub-channels sometimes separated by bars or islands) with low values of M and high bed load.

RESERVOIR SEDIMENTATION

A common objective of many sediment transport studies is the prediction of reservoir "siltation" rates. Reservoir siltation depends on: (1) the average annual sediment load entering the reservoir; (2) the grain size distribution of the sediment load; (3) the reservoir trap efficiency; (4) the bulk dry specific weight of the deposited sediments in the reservoir.

TABLE 5

Stream type	Bed load	Mixed load	Suspended load
M	Braided		Meandering
	> 5%	5–20%	> 20%
Coarse load Total total	> 11%	3–11%	< 3%

The determination of annual sediment yields was discussed in Sections *Erosion* and *The Mechanics of Sediment Transport in a Stream.* It is important to predict the possible effects of land development and/or sediment control measures on future sediment yields.[46]

An estimate of the percentage sand, silt, and clay for the incoming sediment can be obtained on the basis of grain size analyses of the existing load.

Brune in 1953[47,8] presented the trap efficiency curve shown in Figure 15, which applies to reservoirs which normally ponded. Detention type reservoirs would have lower trap efficiencies.

Since annual sediment yield is usually determined in terms of weight it is necessary to know the bulk dry specific weight, and the trapped sediments, in order to estimate the volumetric decrease in reservoir storage. To accomplish this Lane and Koelzer[48,8] developed an equation to describe the change in bulk dry specific weight, $\gamma*$, of reservoir deposits with time, i.e.

$$\begin{aligned}\gamma_* = (\gamma^*_{\text{sand}(1)} + K_{\text{sand}} \log_{10} T)X_{\text{sand}} \\ + (\gamma^*_{\text{silt}(1)} + K_{\text{silt}} \log_{10} T)X_{\text{silt}} \\ + (\gamma^*_{\text{clay}(1)} + K_{\text{clay}} \log_{10} T)X_{\text{clay}}\end{aligned} \tag{58}$$

in which T = time in years; X_{sand} = fraction of sand in deposit; $\gamma^*_{\text{sand}(1)}$ etc. are the respective bulk dry specific weights at $T \leqslant 1$ year (see Table 7); K_{sand} etc. are constants (see Table 7).

After a period of N years a reservoir will contain deposits varying in age from less than one year to N years with the consequence that the true bulk dry specific weight, γ^*, for the entire deposit should be found by averaging Eq. (58)

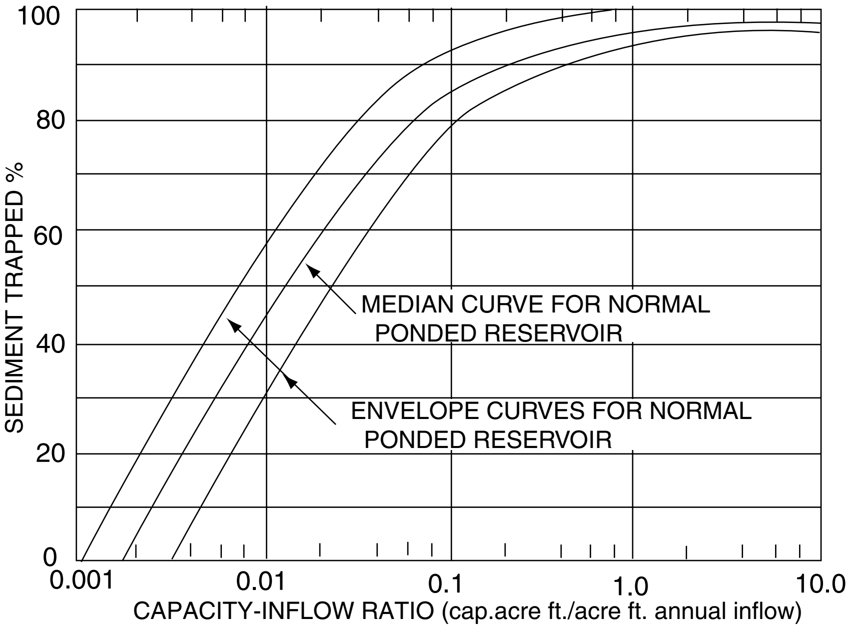

FIGURE 15 Trap efficiency curve (after Brune).

	γ^*	K	γ^*	K	γ^*	K
Normally submerged	93	0	65	5.7	30	16.0
Moderate reservoir drawdown	93	0	74	2.7	46	10.7
Considerable reservoir drawdown	93	0	79	1.0	60	6.0
Reservoir normally empty	93	0	82	0.0	78	0.0

over the N year period. Some typical[8] averaged values of $\bar{\gamma}^*$ for various time periods are:

$N = 10$ years, $\bar{\gamma}_{*10} = \gamma_{*T=1} + 0.675K$

$N = 50$ years, $\bar{\gamma}_{*50} = \gamma_{*T=1} + 1.298K$

$N = 100$ years, $\bar{\gamma}_{*100} = \gamma_{*T=1} + 1.588K$.

The decrease in storage (in acre-ft) during an N year period is given by:

$$\Delta v = \left(\frac{\overline{TE}}{100}\right)\frac{(SY)(DA)\times N}{\bar{\gamma}_{*N}}\times\left(\frac{2000}{43{,}560}\right) \tag{59}$$

in which

$\overline{TE}$ = average trap efficiency in percent;
$\overline{SY}$ = average annual sediment yields in tons/sq. mile;
(DA) = drainage area in sq. miles;
$\bar{\gamma}_{*N}$ = average bulk specific weight for the N-year computation period in lbs/ft^3.

A typical distribution of reservoir sediments is shown in Figure 16. The coarse sediments (sands and gravels) form a delta at the upstream section of the pond. Finer sediments are deposited downstream from the delta. Very fine sediment (clay particles) may pass through the reservoir or be deposited in the downstream portion of the pond.

THE DEGRADATION PROBLEM

The response of a stream to changes in its sediment load was described qualitatively in Section 6. The problem of computing the probable rate and extent of degradation downstream from a proposed reservoir has recently received the attention of a number of researchers.[15,49,50]

Numerical estimates of the degrading channel profiles may be obtained by solving, simultaneously, the following equations (see Gessler, Ref. 15):

1) the equation of sediment continuity—

$$\frac{\partial z}{\partial t} + \frac{1}{b(1-m)}\frac{\partial (q_{TB} b)}{\partial x} = 0 \tag{60}$$

2) the bed material transport equation which may have the form—

$$q_{TB} = C'\,(\tau_o - \tau_c)P \tag{61}$$

3) the bed shear equation—

$$\tau_o = \gamma R S_e \tag{62}$$

4) a friction equation, e.g. the Chézy equation—

$$v = C(RS_e)^{1/2}, \tag{63}$$

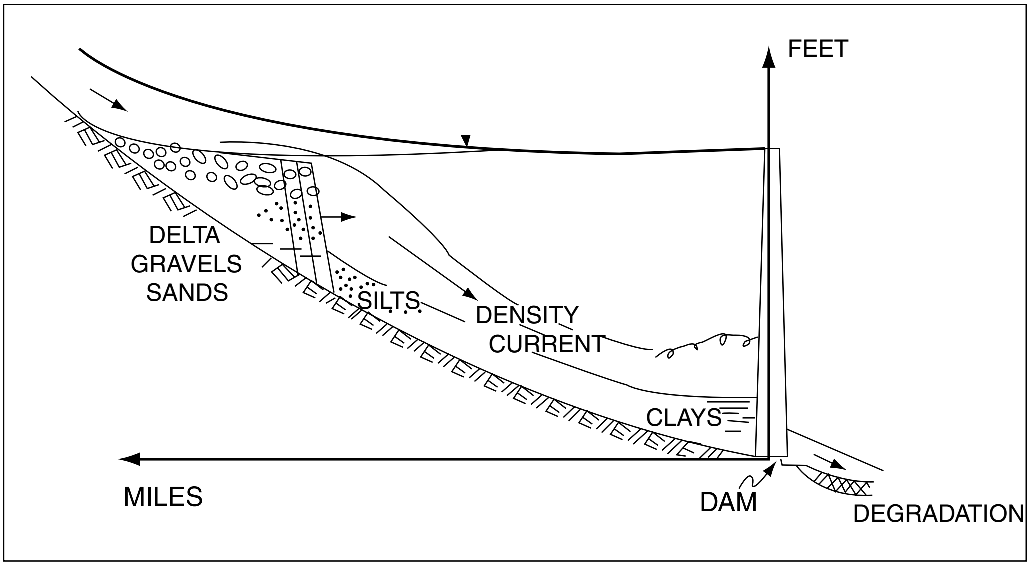

FIGURE 16 Distribution of deposits in a reservoir.

in which z = bed elevation; qTB = volumetric bed material load; m = bed porosity; C' and p are constants for a given bed material and bed form.

As the bed is soured, an armouring process occurs due to the fact that the finer bed material is more readily removed than the coarser particles in the bed (See Figure 1). This may be accounted for by adjusting τ_c in Eq. (62).

SEDIMENT CONTROL

The adverse effects of excessive sediment loads in reservoirs, navigation channels, harbors, and aquatic life may be alleviated by a sediment control program which may include measures such as prevention of over-hand erosion or containment of eroded soil near its source. On the other hand the removal of an established sediment load from a stream may also lead to undesirable consequences such as channel degradation or changes in the established aquatic life.[2]

The ASCE Sedimentation Tank Committee[46] has classified sediment control measures under: (1) land treatment, (2) structural.

Land treatment measures are used to reduce wash load (fines) resulting mainly from sheet erosion. Structural measures are most effective for reducing sediment load derived from stream-channel erosion, gully erosion, and sediment associated with mining and construction work.

The main *land treatment* measures are summarized below:[46]

1) *Vegetative treatment* includes changes in the existing land use towards more: use of cover crops and crop rotation, maintenance of effective vegetative cover in critical areas, leaving of straw and stubble in the field, use of long-term hay stands, mulching, pasture planting, and re-forestation.
2) *Protecting existing vegetative cover* involves protection of existing forest sands from excessive fire losses and the protection of all vegetated areas from over grazing.
3) *Mechanical field practices* are used in conjunction with (1) and (2) and include contour farming, contour furrowing of range land, contour strip-cropping, use of gradient and level terraces, use of diversions to divert runoff away from critical areas, use of grassed waterways and ditch and canal linings, and the use of grade stabilization structures in areas subject to possible gully erosion.

The ASCE Task Committee[46] outlined three commonly used *structure* measures:

1) *Reservoirs,* either detention or multi-purpose, decrease flood stages and consequently may decrease downstream damages due to deposition of flood borne sediments; however it should be remembered that reservoirs themselves create sediment problems which may be just as serious as the problem being solved.
2) *Stream channel improvement and stabilization*—these measures may include straightening, cleaning, deepening, and widening of existing channels in order to decrease local flood stages and related sediment damages; again, complications, such as increased channel erosion, can be expected. Other channel improvement methods are: lining the channel on bends and other erodible areas, and providing spur dykes to deflect the flow away from erodible banks.
3) *Debris and sedimentation basins* are usually relatively small reservoirs designed to trap debris and sediment near its source. This method is particularly useful in controlling sediment yields from construction sites or mining operations.

LIST OF SYMBOLS

a = $2d$ = reference distance from the stream bed;
A = flow area;
A_e = a/D;
b = average channel width;
B = top width of channel;
c = point concentration;
$\bar{c}$ = average concentration at a point;
c' = random component of concentration at a point;
$\hat{c}$ = average concentration in the vertical;
C = Chézy coefficient;
C_s = Du Boys' coefficient;
C = constant;
D = flow depth;
$\bar{D}_{ij}$ = deformation tensor;
E_L = coefficient of longitudinal dispersion;
E = erosion rate;
f = friction factor;
$fcn()$ = function of ();
$f()$ = function of ();
f = silt factor (Lacey);
f_b = bed factor (Blench);
f_s = side factor (Blench);
F_c = generation term:
F_t = body force;
g = acceleration due to gravity;
h = coefficient of molecular diffusion;
H = height;
i = index in tensor notation;
i_B = portion of material in the bed within a specified size range;
i_B = portion of the bed load in specified size range;
i_s = portion of the suspended load in specified size range;
j = index in tensor notation;
k = constant;
K = constant;
m = porosity;
m = exponent (Simons and Albertson);
M = percent silt-clay;
M_o = initial concentration;
n = exponent;
N = time period;
p = exponent;
P = wetted perimeter;
$\bar{P}$ = average pressure;
P_t = turbulence pressure;
q_B = bed load/unit width;
q_s = suspended load/unit width;
qTB = total bed material load/unit width;
qT = total sediment load/unit width;
qw = wash load/unit width;
Qs = total suspended load;
QT = total sediment load;
Q = water discharge;
R = hydraulic radius;
R' = hydraulic radius associated with grain roughness;
R'' = hydraulic radius associated with bed form;
r = (S_s-1);
S_s = specific weight of sediment grains;
S_o = bed slope;
S_e = energy slope;
SY = average annual sediment yield;
t = time;
T = time period;
u_i = random component of the velocity U;
U_i = instantaneous velocity in direction i;
$\bar{U}_i$ = average velocity in direction i;
U_* = friction velocity;
$\bar{U}_x$ = average point velocity in the x-direction;
U_x = average velocity in the vertical;
v = stream velocity;
v_S = terminal settling velocity of sediment particles;
w = wash load;
W = channel width;
x = coordinate;
y = coordinate;
z = coordinate;
Z = $\frac{v_s}{\beta U_* \kappa}$;
β = $\varepsilon_m/\varepsilon_c$;
γ = specific weight of water;
γs = specific weight of sediment grains;
γ^* = bulk dry specific weight of a deposit;
δ = laminar sub-layer thickness;
δ_{ij} = Kronecker delta;
ε_m = kinematic eddy viscosity;
ε_c = kinematic eddy transport coefficient;
κ = von Karman constant; 0.4;
λ = wave length;
μ = dynamic viscosity;
v = kinematic viscosity;
ρ = density;
σ_{ji} = stress tensor;
τ_o = bed shear stress;
τ_c = critical shear stress;
Φ = sediment transport function;
ψ = flow intensity function.

SMALL FLOW WASTEWATER TREATMENT TECHNOLOGY FOR DOMESTIC AND SPECIAL APPLICATIONS

Recent concern regarding water pollution and general worldwide public awareness of the problem associated with pollution has resulted in increased pressures on all waste dischargers to provide effective treatment and disposal of their waste streams. Small subdivisions, motels, resorts, mobile homes, watercraft, railroads, and the like, have not escaped these pressures, although in many respects their total waste contribution to the environment may be small. However, as a result of the public awareness of pollution and increasing regulatory pressures, there has been a rapid commercial growth in recent years in plants designed and built specifically for such applications. In this article the state of the art of small flow wastewater treatment systems developed for such special applications is presented.

INDIVIDUAL HOMES

The 1990 census figures indicate that there are more than 25 million onsite residential wastewater treatment systems in the United States, often because wastewater collection sewers are not available.[1] These systems include a variety of components and configurations. Among the most common systems are the anaerobic and aerobic biological treatment. In recent years constructed wetlands have also been investigated for home application. However, no treatment systems as yet has been entirely satisfactory either to homeowners or to health officials.[2,3]

Anaerobic System

Septic Tank Septic tank is the most commonly used individual waste disposal system. The US Environmental Protection Agency estimates that there are approximately 18 million housing units in the US that use on-site wastewater and disposal systems. This is about 25% of all housing units. Additionally, about one-half million new systems are being installed each year.[2,3]

A septic tank consists of a tank in which wastes are accumulated and digested under anaerobic conditions. The effluent from septic tanks is malodorous, and the bacterial count is often quite high. Subsurface absorption field is necessary to absorb the effluent from the septic tank. Capacity, hydraulic design and soil conditions are most important factors influencing the septic tank performance. A detailed discussion on septic tank design, performance, and economics is available in several publications.[1–7]

A conventional septic tank removes about 40–50 percent TSS. In recent years many improvements have been made in the design of septic tank, gravel filter, and soil absorption trenches that enhance their performance significantly. An important variation in conventional septic tank design is currently being manufactured. The *Ruck* system requires wash waters be separated from sanitary and kitchen wastes. The sanitary and kitchen wastes are thus held in an upper compartment for a longer period of anaerobic digestion, providing more concentrated treatment to the sanitary wastes.[3,8] The wash water is treated in a lower compartment for shorter periods where effluent from the upper chamber is mixed. The system is sold as a package unit in a fiberglass housing. A soil absorption system is also included in this package which is designed to make the system independent of the natural soil characteristics. Andreadakis reviewed the performance of an on-site treatment and disposal system using a septic tank, gravel filter, and soil absorption trenches.[9] BOD_5 and TSS removal efficiencies averaged over 92 and 93 percent respectively, and up to 70 percent nitrogen was removed due to nitrification followed by denitrification.[9,10] Many researchers believe that the reduction in hydraulic loading by water conserving devices will improve the performance of on-site treatment and disposal systems.[11]

Intermittent Sand Filters The main purpose of the intermittent sand filters is to reduce the BOD_5 and TSS prior to soil infiltration. Currently, many intermittent sand filters are used throughout the United States to treat wastewater from individual homes. The process is highly efficient, and requires a minimum of operation and maintenance. Intermittent sand filters are beds of granular material underlain by graded gravel and collecting tiles.[2] Uniform distribution is normally obtained by dosing or flooding the entire surface of the bed. Recirculation has also been used. The filters may be buried or may have some free access.

Disposal Methods Under favorable conditions the effluent from treatment devices are safely disposed of by (a) subsurface absorption, (b) evaporation, and (c) discharge into surface waters. The subsurface soil absorption is usually the best method of wastewater disposal from homes because of its simplicity, stability and low cost. Partially treated wastewater is discharged below ground surface where it is absorbed and treated by the soil as it percolates into the ground. Nearly one-third of the homes in the United States dispose of their wastewater in this way.[9]

Evaporation systems utilize techniques to evaporate the effluent without infiltration. The system utilize evaporation and evapotranspiration beds. Direct discharge of onsite treatment system effluent is also a disposal option if an appropriate receiving water is available and if the regulatory agencies permit such discharges. Various onsite disposal methods are listed below. Detailed discussion may be found in Ref. 2. Typical design of septic tank and intermittent filter are shown in Figure 1. Typical trench, seepage pit and mound systems are shown in Figure 2.

  - outfall in stream
  - outfall in lake

Aerobic System

Several types of household treatment systems are available which utilize aerobic stabilization of organic wastes. Most systems are designed for continuous flow.

The raw wastewater enters an anaerobic tank where solids are settled and partially digested. The liquid enters an aerobic compartment. Air is supplied either by mechanical aerators or by diffusers. The bacterial action thus produced is similar to that in an activated sludge plant. The solids in the aerated liquid are settled into a separate tank. This tank most commonly has a sloping bottom to return the settled sludge into the aeration tank by gravity. System components of such units are schematically shown in Figure 3.

Some of the manufacturers' variations in the aerobic system include (1) absence of anaerobic digestion tank, (2) different methods of aeration, (3) packed bed media, (4) trickling filter, (5) rotating biological contactor, and (6) use of tube settlers for increasing the sedimentation rate.[2,12] Many of these variations are shown in Figure 4.

The effluent from an aerobic system is generally better than that from a septic tank. Manufacturers claim BOD and suspended solids removal of about 90%. The effluent from aerobic systems has lower clogging effect on soil absorption system. If the system operates properly, the effluent is suitable for surface drainage. The disadvantages of the aerobic system are higher operating costs, susceptibility to shock loading, and variation in effluent quality. The design criteria, operational characteristics and cost data on aerobic systems are extensively available in the literature.[2,3,13,14]

Constructed Wetlands

Constructed and natural wetland rely solely on natural process to treat wastewater and are most often used for secondary treatment. In a single-residence system, for example, a septic tank generally provides partial treatment. The effluent flows to the wetlands where it is distributed into the system. Organic matter is stabilized by microorganisms attached to the plant roots. Aquatic plants deliver oxygen, provide shade, metabolic nutrients and surface area for microbiological growth.

Constructed wetlands are designed either as a "discharge" system or as an "non-discharge" system.[1] Two basic design approaches exit for constructed wetlands. These are developed by (1) Tennessee Valley Authority (TVA) for systems less than 75,700 L/d, and (2) EPA for larger municipal wastewater treatment plants. The design equations are based on hydraulic loading, organic loading, and Darcy's equation. The design procedure for constructed wetland can be found in Refs. 1, 15–17. The suggested residential wetland design details are: length = 12.7 m, width = 4.3m, depth = 0.3 m, detention time = 3d, and hydraulic loading criteria = 1.3 $m^2/L \cdot d$.

The aquatic plants are generally chosen from indigenous species of *Typhaceae* (cattail family), *Cyperaceae* (sedge family), *Gramineae* (grass family), *Scirpus validus* (softstem bulrush), or *Phragmites australis* (giant reed). Care should be taken to avoid plants that "choke out" each other, or those eaten by animals. The choice of vegetation is dependent upon wastewater characteristics, solar radiation, temperature, aesthetics, wildlife desired, indigenous species, and the depth of constructed wetlands. Vegetation harvesting may be necessary when it becomes too dense, cause obstruction to the natural flow and create anaerobic conditions.[1]

SMALL ESTABLISHMENTS

Small establishments generally include motels, restaurants, stores theatres, clubs, camps, rest areas, institutions, apartment houses, small factories, subdivisions, small communities, etc. Disposal of wastewaters from these establishments in suburban areas certainly poses serious problems. Construction of public sewer systems may not be economically feasible to convey the wastewaters to an existing treatment plant. Since the flows are relatively large, often septic tanks and subsurface absorption fields may not provide safe disposal, causing a very serious public health hazard or pollution of ground or surface waters.

Package treatment plants were first introduced about thirty-five years ago to treat wastes from small establishments. During this time, there has been a rapid commercial growth in package plant industry. The package plants are prefabricated in the factory and, in most cases, completely assembled prior to delivery to the plant site. Most of the plants are made of steel but many concrete plants are also

---

[*] Electro-osmosis is a technique used to drain and stabilize slowly permeable soils during excavation. A direct current is passed through the soil which draws the free water in the soil pores to the cathode.

available. During earlier years of package plant usage, the plant size was usually limited to the maximum size that could be shipped by truck. This was about 190–228 m^3/d (50,000 to 60,000 gallons per day (gpd)) maximum plant size. Currently the manufacturers fabricate the plants in the field. Thus package plants with capacities over 3800 m^3/d (one million gallons a day (mgd)) can be obtained.

The earlier package plants were designed as extended aeration plants. Currently available package plants utilize many treatment processes. Some of these processes are listed below.

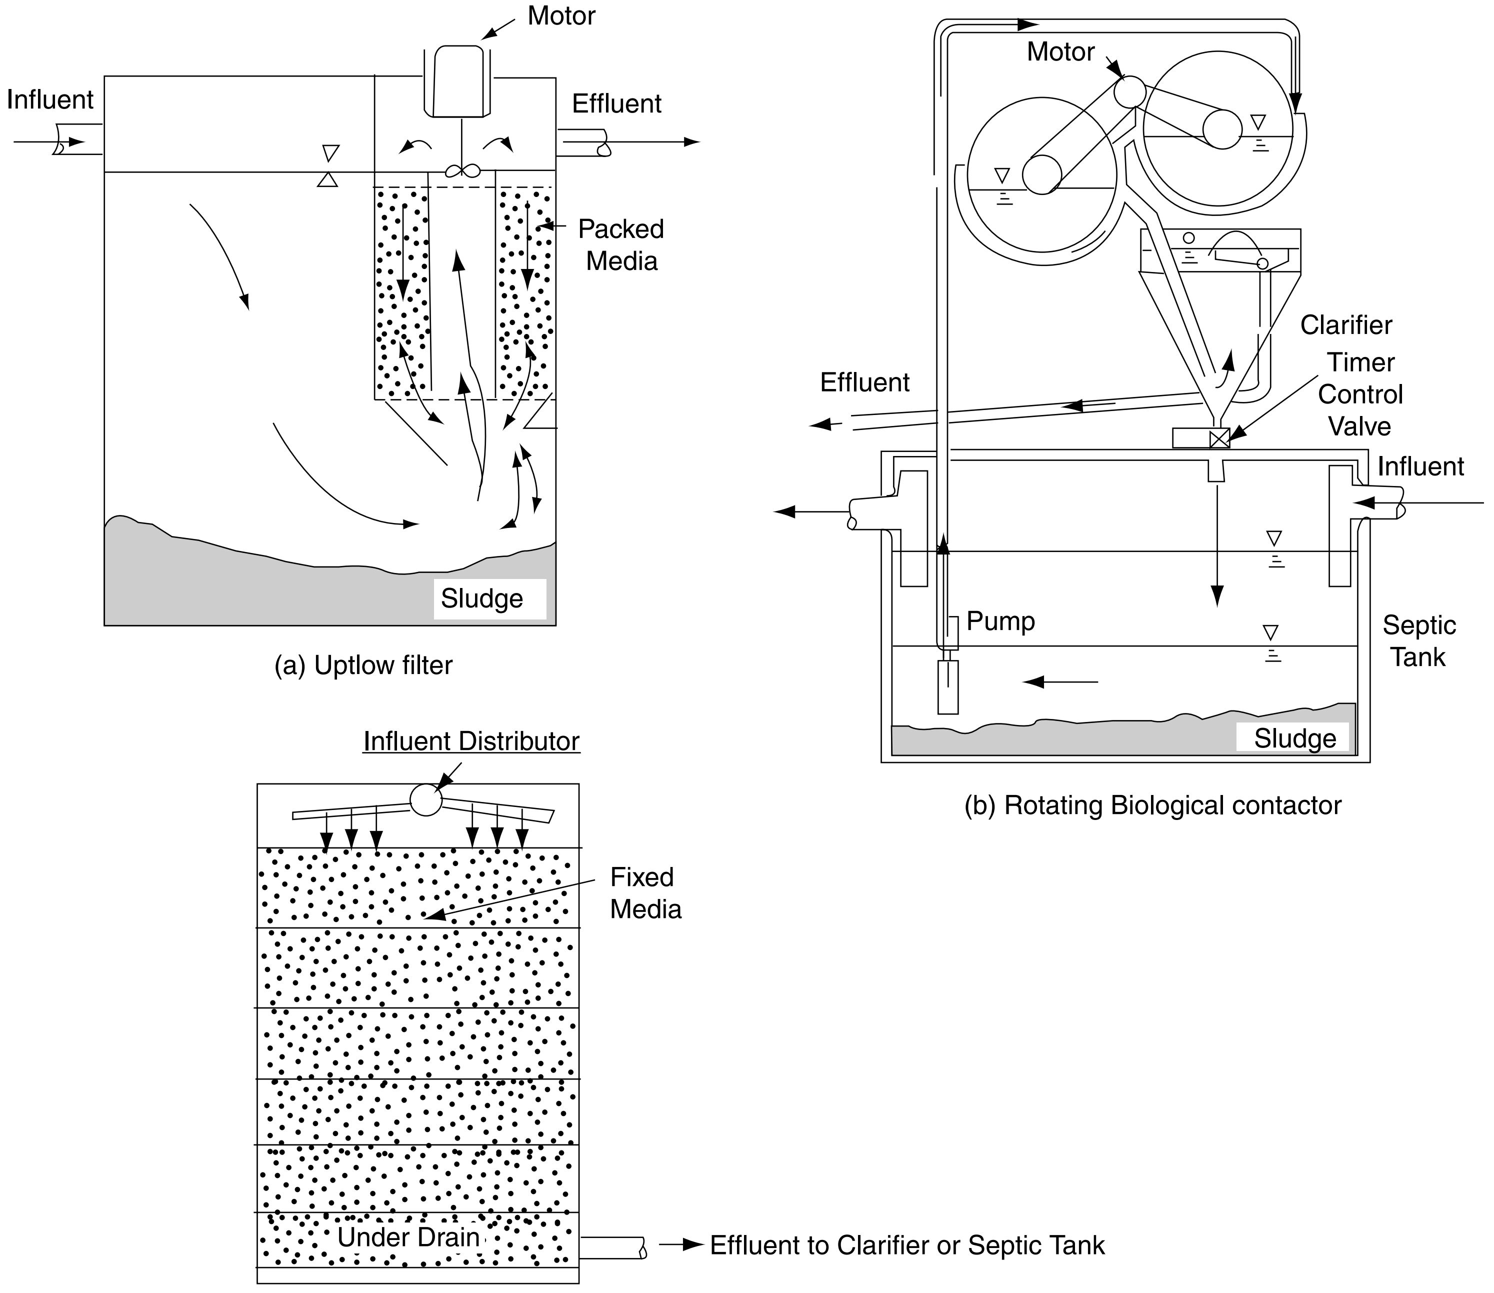
Biological

Extended aeration
Contact stabilization
Completely mixed
Step aeration
Trickling filter
Rotating biological contractor
Sequencing batch reactor (SBR)

Chemical

Chemical precipitation
Electrochemical flotation
Ultrafiltration

Detailed discussions on package plants including manufacturers, process alternatives, size, weight, design criteria, and cost is extensively available in the literature.[18–22] These plants have been successfully applied in the treatment of wastewaters in the suburban areas. The range of these plants has expanded from small establishments to large municipal and industrial applications. Manufacturers broadly group the models or design series into flow capacity, BOD loading, dimensions, air supply, motor horse power, etc., which has simplified the job of unit selection.



(a) Uptlow filter

(b) Rotating Biological contactor

(c) Tricking filter

FIGURE 4 System components of aerobic attached growth biological treatment process. (Adapted from Ref. 2.)

In recent years natural systems are also used for wastewater treatment from small establishments and sub-divisions. Among these are land treatment, and natural and constructed wetland. Information on natural system may be found in Refs. 1, 4, 15–17, 23 and 24.

POLAR REGIONS

Waste handling in polar regions is a complex problem. Conventional wastewater collection and treatment systems have severe limitations due to cold weather. Sewers constructed through snow, ice or permafrost[2] must be insulated to transport the wastes without freezing. Waste treatment by chemical or biological methods may not be possible due to retarded reaction rates.

The predominant sanitary facility used in small Alaskan villages is manual collection of human fecal waste and their disposal to ground, snow or ice. In many cases, pit privies, vaults, bored holes, straddle trenches, box and can, and crude chemical toilets are also used. Problems with these systems are: inconvenient to use especially in cold climates, unaesthetic features such as odor and unsightly conditions, and health hazards.[25,26]

Perhaps the most comprehensive analysis of waste problems in arctic areas was conducted by the Federal Housing Administration about 50 years ago.[27,28] Subsequently, a number of research programs were conducted by the US Public Health Service, National Research Council, US Navy, US Air Force, and US Army in developing suitable systems for use in Greenland, Alaska and most recently in the Antarctic.[29] Prime requirements for a system suitable for installation in these areas were: (1) minimum water use as year-round water supply in these areas may be lacking, (2) non-electric operation, (3) freeze-free, (4) minimum final disposal problems, (5) odor-free, and (6) minimum of maintenance. Systems investigated in these research programs included: (1) incinerating toilets, (2) chemical toilets, and (3) chemical and biological toilets with recirculation.

Incinerating Toilets

Incinerating toilets have been designed to destroy human body wastes. The thermal energy required may be obtained from electricity, fuel, oil, or liquified petroleum gas (LPG). Several designs of incinerating toilets are now commercially available. Although these toilets provide complete prevention of pollution from human wastes, they are relatively inefficient in terms of fuel consumption and often fail to provide complete burning which may result in a noxious odors or excessive smoke.[28] Two incinerating toilets *Incinolet* and *Stornburn* are manufactured for application in Alaska.[26]

Chemical and Composting Toilets

Chemical toilets require addition of chemicals into the waste storage tank. These chemicals liquify the fecal wastes, produce bactericidal effect and suppress fecal odors. Most commonly used chemicals are:[3] (1) halogens and their compounds, (2) coal-tar distillate (phenols and cresols), (3) heavy metals and their salts (zinc, copper and silver salts), (4) quaternary ammonium compounds, and (5) alkaline substances such as sodium and potassium hydroxide and lime. Various chemicals are sold in the market under different trade names.

One mechanical-flush chemical toilet was developed by Naval Engineering Laboratory, Port Huneme, California (US Patent No. 3,460,165) for use at remote Antarctic stations. This toilet was extensively tested by the military personnel and found satisfactory for polar applications.

A variety of composting toilets are on the market for application in cold region. These toilets use no water, and eventually produce compost that can be used on home garden. Three composting toilets named in the literature are *AlasCan,* the *Phoenix,* and the *Sun-Mar.*[26,29,30]

Chemical and Biological Toilets with Recirculation

A special application of waste treatment unit for polar use is a unit where treated effluent could be recirculated as a flush fluid. Such concepts with both chemical and biological treatment systems were investigated. Walters developed a recirculating chlorinator toilet which used standard toilet fittings.[31] The heavily chlorinated effluent from the storage tank was reused for flushing the toilet bowl. The system was tested in Alaskan single homes and results were found esthetically acceptable.

Another study evaluated three extended aeration plants in which the effluent was recirculated for toilet flushing.[32] The findings of this investigation showed that the flushing fluid turned brown during the first week and remained that color for the entire test period of several months. However, no odors were detected.

Both the chemical and biological treatment system with effluent recirculation have great promise in developing toilets for use in polar regions. These toilets have unique features such as: no water requirement, non-electrical (with hand pump), non-freezing, no odor, conventional toilet design, and a minimum of maintenance.

A number of innovative wastewater collection, treatment, reuse and disposal system have also been applied for community and individual home applications in polar region. Among these are pressurized and vacuum collection systems, low flush, ultra-low flush, micro-flush toilets, and mineral oil flush systems.[26,33–38]

WATERCRAFT

Use of the waterways for pleasure boating has increased enormously in this country. Because of a substantial increase in the number of recreational vessels, the public has become aware of the potential seriousness of the waterborne pollution resulting from this source. Many recreational watercraft and commercial and government vessels discharge wastes into the water.[34] Recreational watercraft are highly mobile, and may reach beaches, commercial fisheries, shell-fish growing areas and may seriously contaminate the waters, thereby rendering them dangerous for public water supplies and water contact sports. Contamination may also seriously affect the commercial fisheries and the shellfish industry.

The discharge in territorial waters of the United States is regulated by the Clean Water Act.[40] This Act also specifies allowable types of marine sanitation devices (MSD), and mandates, that the US Coast Guard test the various types of MSD and certify them for use aboard water craft. These tests are found in 33CFR 159, page 492, 500 and 501.[41,42] Type I MSD utilize macerator and disinfection. Both commercial disinfectants and onsite electrochemical devices are included. Type II MSD include biological treatment or fiber filtration (microscreening). Type III MSD consists of storage tank.

Sewage equipment for use aboard watercraft is already available in the form of (1) maceration-disinfection devices, (2) holding tanks and recirculating toilets, (3) incinerator devices, and (4) chemical and biological treatment facilities. A brief discussion of these systems is given below. For details on manufacturers, cost and unit variations, readers are referred to several sources in the literature.[43–49]

Maceration-Disinfection Devices

Maceration-disinfection devices utilize a mechanical macerator to grind the human fecal wastes, mix a disinfecting chemical (usually hypochlorite) and retain the disinfected sewage mixture for a brief period before discharging it into the water. A number of companies manufacture such units for installation aboard virtually every type of watercraft. Such units are small, lightweight, and relatively easy to install. However, their performance in terms of BOD and suspended solids reduction, and degree of disinfection achieved may be questionable.

Holding Tanks and Recirculating Toilet

A holding tank is a closed container for retaining sewage onboard a watercraft until it can be properly emptied, usually into an onshore sewage receiving facility. Holding tanks include chemical toilets, recirculating flush toilets, classic holding tanks, and any variation which simply retains the sewage for later disposal at an appropriate site.

One potentially useful variation of the holding tank is the recirculating flush toilet. This device requires a small amount of precharge of chemically treated water in the retention tank integrated into the toilet design. Waste deposited in this toilet accumulates in the retention tank. For subsequent flushing, an internal separation mechanism recovers a fraction of this precharge/waste mixture for continued reuse as flushing fluid. The tank retains sewage from 80 to 100 toilet usages before it must be emptied. It uses minimum space and requires no water for flushing.

Although holding tanks completely prevent the discharge of sewage from watercraft, they require extensive shore support facilities for emptying and cleaning. Low flush and vacuum flush toilets are desirable because they minimize storage and treatment requirement.[34]

Incinerator Devices

As described earlier, several types of incinerating toilets have been developed to reduce human waste to a small amount of ash. The most common problems encountered with incinerator devices with watercraft include the difficulty of supplying electrical power as most small craft do not have the generating equipment required. If gas or oil burner type incinerators are used, space is also required. Such burners also provide fire hazards if improperly designed. Regardless of the type of fuel used, however, burning of human wastes may result in emission of odor from the venting stack.

Chemical and Biological Treatment Plants

Wastewater treatment plants similar to those frequently used for land-base sewage treatment have been adopted for vessel use. The mot successful of the biological treatment systems are the extended aeration activated sludge process.[48] Attempts have been made also to adapt thermally heated aeration systems for increased biological activity. Trickling filter-type biological treatment systems with forced air aeration have also been adopted to shipboard applications.[18] These systems, which provide treatment to all waste streams generated aboard the watercraft, are relatively large and heavy, and easily upset due to change in salinity of flush water.

Among the chemical systems, an electrochemical floatation plant for shipboard waste treatment was designed and built.[49,50] This system utilized chlorine gas for disinfection, and partial oxidation and flotation of organic matter. Another chemical process oriented system utilized a comprehensive approach to the management of wastewater on board ship and is concerned not only with an improved treatment but also with an innovation and improved collection system. The system employs two main elements: (1) a recirculating chemical toilet, and (2) an evaporation system for solid/liquid separation.[31,51–53] Condensed liquid is discharged overboard after chlorination. Concentrated sludge is stored for subsequent disposal to shore facility or into unrestricted waters.

COMMERCIAL AIRCRAFT

Until about 1940, waste management problems aboard aircraft were considered minor; human wastes were simply discharged overboard. In January of 1943, the US Public Health Service published the "Sanitation Manual for Land and Air Conveyance Operating in Interstate Traffic," which formulated policy regarding "Discharge of Wastes from Conveyance En Route."[54] Following this publication, the International Sanitary Convention for Aerial Navigation issued a publication in February, 1945, forbidding aircraft to throw or let fall matter capable of producing an outbreak of infectious diseases.[55] Federal laws and regulations now prohibit air-planes indiscriminately discharging untreated human wastes.[56]

Early waste management practices for aircraft included carry-out pail methods of waste collection within aircraft and hand-carrying them to the ground servicing facilities.

Subsequently, this system was replaced by built-in retention tanks. These retention tanks utilized wash and galley water for toilet flushing purposes. The system posed several operational problems, including the fact that the flushing water taxed the capacity of the retention tanks on longer flights, and was later replaced by recirculating chemical toilets.

Recirculating chemical toilets currently being used aboard commercial aircraft have highly improved features to fulfill the requirements of the modern planes. Reinforced fiberglass retention tanks for lightness, teflon coated toilet bowls for cleanliness, timer assemblies to control the flush cycle, improved reversible-motor-operated pumps, and a number of filter and filter-cleaning devices have all been developed to provide trouble-free operation and an aesthetic facility.

The recirculating chemical toilets provide efficient operation but, depending on the capacity of the water tank, the system requires frequent ground servicing. Furthermore, the amount of space and weight available for waste storage in aircraft is quite limited. Therefore, a system to concentrate the wastes during the flight is considered highly desirable. To achieve this, several waste-volume-reduction techniques have been investigated for use aboard commercial aircraft. These include:

1) Evaporation of the liquid to yield dry or highly concentrated solids to reduce the waste-storage space in the aircraft and eliminate the frequent ground servicing need.
2) Incineration devices which utilize electrical and fuel energy for waste incineration. Several improved incineration systems for aircraft application have been built and evaluated.[57–59]
3) Evapo-combustion system to burn the macerated waste into a combustion chamber of the jet engine. Vacuum toilets have also been successively installed on large commercial aircraft. These toilets reduce the waste accumulation.[34, 60–64.]

RAILROAD TRAINS

Historically, wastes from railroad trains have been discharged into the environment without benefit of any treatment. This primitive practice poses a threat to the public health. Although passenger traffic on trains in the US has declined in recent years, large numbers of persons, including railroad employees still use toilet facilities on trains. According to Food and Drug Administration (FDA), about 23 million pounds of human excrement or 16 million gallons of wastewater are discharged annually from locomotives and cabooses, and about 9.5 million gallons of "untreated human wastes" were discharged in 1968 from intercity and commuter passenger train cars.[56] A history of some of waste disposal practices of Amtrak was presented in a hearing before Congress in 1988.[65]

Federal laws and regulations now prohibit buses (42 CFR 72.156) from discharging untreated human waste.[56,57] As a result, the passenger buses are equipped with suitable types of chemical or recirculating toilets.

Currently, several types of waste treatment and disposal systems are being marketed which are designed and built for railroad trains. These include incinerating toilets, retention tanks, and recirculating toilets.

Incinerating toilets built for railroad cars operate on natural gas, propane, diesel fuel, or electricity. These toilets operate without the use of water or chemicals and require no holding tanks or plumbing fixtures.

Recirculating toilets of various types are also available for railroad use. One system built for locomotives, cabooses and crew cars uses a vacuum system. In this system air, rather than water, is used to carry waste from the toilets to a centrally located tank.[56,61] This system enables locating the holding tank elsewhere in the railroad car and two or more toilets can be connected to this tank.

PICKUP CAMPERS, TRAVEL-TRAILERS, TENT CAMPING

Various types of portable recirculating toilets are currently manufactured. These units have suitcase-style handles molded into their cases for easy carrying; can be used in tents or in camper.[66] A small family can get a few day's use before the facility must be emptied and recharged.

A unique system for reducing the volume of wastes from recirculating toilets was developed. In this system, the fecal wastes were liquefied by adding chemicals. The liquid mixture is pumped to a sanitizer which is a short, stainless steel tank connected to the exhaust pipe of the vehicle. The sanitizer operates at about 500°F. At this operating temperature, the waste is concentrated and the microorganisms are destroyed.[66] The operating temperature of the sanitizer is reached at a vehicle speed of about 35 mph.

ENVIRONMENTAL CONTROL AND LIFE SUPPORT SYSTEMS (ECLSS) FOR SPACE STATION

NASA has sponsored programs to develop efficient, compact equipment to handle the various aspect of environmental life support for spacecraft and for the planned space station. The tasks include CO_2 removal, O_2 regeneration, temperature and humidity control, the purification of water recovered from the dehumidifier condensate, hygiene uses, and in the future, from urine. Also the removal of trace contaminants from the air, the maintenance of the air composition and pressure, and the storage of solid wastes pending their return to earth are included. A wide variety of techniques have been evaluated depending upon their prospects for meeting the desired performance specifications.[67–73] Table 1 provides a list of ECLSS technologies used or evaluated.

The space systems have grown in complexity and comprehensiveness as both the duration of the missions and the size of the crew have increased. With the possibility of long duration space missions to other planets, and also the establishment of bases on the moon, NASA is in the early stages of testing technologies for solid waste treatment and recycling, and the intensive agricultural technique necessary to grow and process food in very confined spaces under low or zero gravity.

Some of the technologies developed for the space program have possible application on earth. Many of the applications will only be relevant to submarines and hyperbaric chambers. In some cases there may be more widespread uses, such as the recovery and reuse of dehumidification and hygiene water in arid areas or in very cold climates, removing CO_2 and regenerating O_2, and controlling temperature and humidity in deep mines or while drilling long tunnels. Certain technologies may be applicable to the treatment of industrial emissions and/or effluents. It is likely that the basic technological knowledge will be applied to terrestrial problems, rather than the actual hardware developed for the space program.[74–77] Possible terrestrial application of space craft environmental systems are presented in Table 2.

TABLE 1
ECLSS technologies used or evaluated

ECLSS subsystem category	Used/Evaluated	Technology
Atmosphere revitalisation	Used	LiOH
	Used	Molecular sieve
	Used	Sabatier reactor
	Used	Static feed water electrolysis
	Evaluated	Solid amine fixed bed
	Evaluated	Liquid sorbent closed loop
	Evaluated	Bosch system
	Evaluated	Algal bioreactor
	Evaluated	Growing green plants
Trace contaminant removal	Used	Activated charcoal
	Used	Catalytic oxidiser
	Used	Particulate filters
Water recovery and management	Used	Vapor compression distillation
	Used	Chlorine
	Used	Sodium hypochlorite injection
	Used	Iodine injection
	Used	Heat sterilisation
	Used	Fuel cell byproduct water
	Evaluated	Unibed filter
	Evaluated	TIMES membrane filter
	Evaluated	Reverse osmosis
	Evaluated	Electrodialysis
	Evaluated	Electrooxidation
	Evaluated	Supercritical water oxidation
	Evaluated	Electrodeionisation
	Evaluated	Air evaporation
	Evaluated	Vapor phase catalytic ammonia removal
	Evaluated	Immobilised cell or enzyme bioreactors
	Evaluated	Plant transpiration and water recovery
Temperature and humidity control	Used	Condensing heat exchangers
	Used	Water cooled suits
Atmosphere control and supply	Used	Compressed gas storage
	Used	Cryogenic gas storage
Waste management	Used	Urine stored in bags
	Used	Feces stored in bags
	Used	Urine vented
	Used	Feces stored in bags and vacuum dried
	Used	Urine stored in tank and vented
	Used	Feces stored in bags and compacted

TABLE 2
Possible terrestrial applications of spacecraft environmental systems

ECLS systems	Possible earthbound uses
Water reclamation	Submarines, arid area operations, supply of filtered and sterile water for medical, experimental uses. Cleaning industrial effluent.
Oxygen generation	Submarines, medical use in oxygen enriched atmosphere, hyperbaric chambers, under water habitats and deep undergroundwork locations.
CO_2 removal	Submarines, rescue and scuba equipment, under water habitats, hyperbaric chambers. Cleaning industrial emmissions. Revitalising atmosphere in deep underground work locations.
Trace contaminant removal	Submarines, under water habitats, hyperbaric chambers.
Temperature, humidity control	Passive systems developed for the control of the space station temperature gain and loss from and to space itself may have some terrestrial applications. Active systems used in controlling temperature in locations where there are localised sources of heat may be useful for cooling dense electronics, in satellites, possibly in aircraft, and perhaps in advanced super computers.

A joint NASA and NSF life support system utilizing some of the water recovery, waste treatment, plant growth, and energy efficiency technologies is to be installed at the US research station at the South Pole. This will provide a real world opportunity to use the planned technologies on a realistic scale.[78]

STACK SAMPLING

INTRODUCTION

It is frequently necessary to determine the amount, concentration, or rate of emission of various pollutants in the exhaust streams from industrial or commercial processes. Because this generally involves the sampling and eventual analysis of the gas flowing through a stack into the outside air, it is usually called “stack emission sampling”, or more simply, “stack sampling”.

In most cases, it is not possible or practical to collect all of the gases emitted to the outside air over any reasonable time period. Therefore, it is necessary to collect only a fraction of the overall gas stream. A representative side stream is isolated from the main flow (usually by removing it from the stack altogether) and processed in some way. The gas stream may be filtered, condensed, bubbled, adsorbed, bottled, or pumped through an automatic analyzer. The equipment used for this purpose is called the sampling train. The end result of this step is usually an assessment of the contents of the stream. Meanwhile, an assessment is made about the other characteristics of the stack gas itself, such as temperature and flow rate. The information from these two assessments is then combined to produce a measure of the emissions from the stack in the desired units, such as pounds per hour, grains/dry standard cubic foot, kg/kg of fuel burned, and so on. Generally, the units are chosen to conform with applicable regulations.

Of course, the testing must include all of the pollutants that are of interest, under all of the process conditions that are needed. This must also include a wide range of checks and balances, often termed Quality Control (QC) and Quality Assurance (QA) to ensure and measure the reliability of the results. Most importantly, it all must be based on a well reasoned plan, called a Stack Test Protocol or Quality Assurance Project Plan (QAPP) that is written ahead of time and approved by all interested parties. Finally, these results must be reported in a way that fairly represents what was done, to allow regulators and/or the sources to make informed decisions.

A prime criterion for method selection is that the method must produce data useful for the purpose intended. For example, is the detection limit of the method low enough to prove compliance with the emission standard, or is the method able to measure and/or account for cyclonic flow in the stack, or is it able to differentiate between similar chemical species, or is that necessary? These sorts of questions fall into a general category called QA. They can be restated as six data quality parameters:

P	Precision	Repeatability
A	Accuracy	Bias, closeness to “correct”
R	Representativeness	Typical of actual stack gas
C	Comparability	Similar to other data
C	Completeness	Enough information
S	Sensitivity	Low enough detection levels

These so-called PARCCS Parameters are simply ways to ensure that the results of a sampling project will yield useful results. When methods published by EPA are used, the PARCCS parameters have already been determined and are built into the methods. For novel methods, the PARCCS parameters must be determined, at least qualitatively. This is well beyond the scope of this chapter but must be borne in mind should new methodology need to be developed to fit a specific circumstance.

This leads to the most important warning concerning stack testing. In all but the most dire emergencies, stack testing projects should be planned and carried out by trained, experienced stack testing teams. No one should believe that even a close reading of this chapter would provide sufficient background to plan or perform stack tests.

There are four recent advances in the stack testing field that rate special mention. The first is the increasing reliance on external quality assurance, as embodied in audit samples and devices. Several agencies and organizations, particularly the Emissions, Monitoring and Analysis Division in USEPA’s North Carolina facility, are now producing reliable Performance Evaluation (PE) audit samples that can be obtained for the purpose of checking analytical accuracy at the time of sample analyses. They are available for many parameters, as listed in the specific Test Methods.

The second major recent advance in stack testing is the development and proliferation of reliable continuous emission monitoring systems (CEMS). CEMS are generally electronic analyzers that determine and record instantaneous concentrations of given parameters continuously.

For example, a CEMS for stack gas opacity, termed a transmissometer, shines a light beam through the stack gas and measures the fraction of light transmitted, taking a reading every few seconds. A CEMS for SO_2 extracts a small sample of stack gas and sends it to a monitor outside the stack for analysis and recording. The CEMS records present an excellent picture of the continuing status of compliance of the stack gas, reveal any inconsistencies, failures of control devices, or process upsets, and allow plant operators to act immediately when any anomaly appears. It is likely that more and more CEMS will be required as they become available. CEMS are becoming more available for mercury, particulate matter and ammonia.

While detailed discussion of CEMS technology, procedures, and operation cannot be presented here, the Performance Specifications for the CEMs currently required by USEPA may be found in Appendix B to 40 CFR Part 60, immediately following the Test Methods.

A third major advance in stack testing is the introduction of the 300 series methods found in 40 CFR Part 63 Appendix A. In an effort to measure the hazardous air pollutants to demonstrate emission reductions pursuant to MACT requirements, EPA has introduced a number of 300 series methods. Some of these methods are specific for pollutants from specific sources. Method 301, which is undergoing revision in 2005, is a field validation procedure that will enable source owners to validate their own test methods in the absence of a recognized EPA method.

The fourth is the rewrite of the manual methods into a standard format. The instrumental methods are being rewritten in 2005, along with some major changes.

The following sections of this chapter will deal with the selection of sampling and analytical methods, followed by some general information on protocol and final report preparation.

Selection of a Sampling Method

The choice of stack sampling methodology is most strongly dependent on the pollutants to be measured. In many cases, similar pollutants can be measured with the same or slightly modified methods, while dissimilar pollutants may require totally different methods.

The most obvious categorization of pollutants is based on their physical state: gaseous, liquid, or solid. Gaseous pollutants are generally easier to sample and can be collected using one of a few simple train configurations. Liquid and solid pollutants, usually lumped into a single category called particulates, require a totally different collection concept.

The following sections will describe the generalized methods employed for collecting particulate and gaseous stack samples. These are followed by more detailed descriptions of methods to be used for specific compounds, or groups of compounds. When the U.S. Environmental Protection Agency (EPA) has designated a method as a Test Method, it is required by EPA and by most states for compliance determinations. For convenience, the appropriate EPA designations are indicated. When a Test Method is used in establishing an emission limit and is specified by a regulation that method is called the Reference Method.

Particulate Sampling

When the pollutant of interest is or is attached to solid particles or liquid droplets at stack conditions, it is necessary to select a method that physically traps the particles. But the first step must be the selection of a side stream that is truly representative of the stack exhaust gases.

A representative sample of the stack exhaust gas will look and behave like a small-scale version of the actual exhaust gas. It will contain the same fraction of particulates as the main stream (including the same ratios of large and small particles) and will contain a fair share of material from each part of the stack cross section. (This is necessary because gases flow faster near the center of a stack and slower near the walls due to friction).

In addition a representative sample must be taken at a location that is free of unusual flow patterns, such as cyclonic flow (in which a significant component of the flow is not along the axis of the stack) or stratified flow (in which the particulates are bunched along one side of the stack). This is because it is very difficult to figure out the actual average flow rate and particulate rate when the measurements are all skewed by the flow anomalies. In most cases, flow abnormalities are caused by recognizable disturbances, such as bends, fans, expansions, contractions, or shape changes in the duct. These disturbances, whether upstream or downstream from the sampling location, have the potential for making useful testing very difficult, or even impossible. For that reason, the first criterion for good particulate testing is to find a location that is sufficiently far from flow disturbances. Extensive testing has shown that a sampling location 8 stack diameters downstream from any disturbance and 2 diameters upstream from any disturbance is sufficiently far. In this measurement, the term stack diameter is used literally for circular stacks. For rectangular stacks, an equivalent stack diameter is calculated.

In some cases, it is impossible to find a location in the stack or in any straight duct leading to the stack that satisfies these criteria. It is possible to use a location closer to disturbances. However, other provisions must be taken to account for the possible inaccuracies introduced by the disturbed flow. All of this is described in detail in Test Method 1.

Once a sampling location is selected, it is necessary to collect samples of the gas stream that are representative of the gas flowing by that location. This is achieved by sampling for a short time at each of several points across the stack cross-section.

In practice, two or more holes, or ports, are cut in the stack wall and a sampling probe inserted. The probe is essentially a hollow tube shaped like a shepherd's crook with the short end, or nozzle, facing into the gas stream. The gas stream is then pumped by suction from the main stream through the nozzle and probe into the collection part of the sampling train located outside the stack. The probe is held in one spot, aligned into the main stream, for a specified time. It is then moved to another point and held for the same time. This process is repeated along the line between the port and the opposite wall. The process of moving the probe along this line is called a traverse, and the individual sampling points termed traverse points. The configuration of the ports and the traverse points is generally chosen according to Test Method 1.

Three additional considerations must be addressed in order for the sample to be considered representative. First, the particulate-laden gas stream entering the nozzle must be typical of the stream flowing by it. Second, the makeup of the gas stream leaving the probe and entering the rest of the sampling train must be substantially the same as it was when it entered the nozzle. Third, sampling must be conducted at a time and for sufficient duration to cover any inconsistencies in the pollution emission rate.

The first of these conditions may sound like overkill. However, the previous work was to ensure the representativeness of the location. This part concerns the representativeness of the gas collected there. This is ensured by careful design of the nozzle and control o the side stream flow rate. The opening of the nozzle is designed with sharply tapered edges. The nozzle itself is shaped to minimize deposition of particulates on the inside walls as the stream turns 90°.

The sampling stream flow rate is extremely important because of the difference in aerodynamics and inertial effects of particles. Very small particles tend to behave like gas molecules and tend to follow gas flow stream lines. For these particles, sample flow rates are not critical. Large particles, however, do not necessarily follow the gas flow streamlines. Instead, their flow is controlled more by their inertia. In other words, they tend to keep going in straight lines. Thus, if the flow rate into the sampling nozzles is different than the local gas flow rate, the gas itself and the fine particles will be skewed, either into or out of the nozzle, depending on the relative rates. The large particles, however, will continue along their straight paths. Those, and only those, in direct line with the nozzle face will enter. This can have a significant effect on the measured particulate concentrations, depending on the degrees of error in the nozzle flow rate and on the fraction of particulate mass attributable to the large particles.

Sampling at exactly the right flow rate is termed isokinetic sampling. Sampling at too great a velocity is called superisokinetic, while sampling at too low a velocity is called subisokinetic. Generally, superisokinetic sampling results in an underestimation of the actual particulate concentration (termed a low bias), while subisokinetic sampling results in an overestimation (high bias). Test Method 5 contains instructions for choosing the appropriate nozzle size and sampling flow rate to ensure isokinetic sampling. Sample flow rate and nozzle size are based on the volume of sample gas that needs to be collected and on the flow rate in the stack gas. The needed sample volume is based on the amount of particulate needed for the physical or chemical analyses to be conducted, and will be discussed in the analysis section. The stack gas flow rate is determined according to procedures described in Test Method 2. The procedure involves the measurement of linear flow rate by means of the relationship between the static and dynamic pressure in the gas stream. The static pressure is the pressure of the gas stream, as measured by a pressure tap perpendicular to the flow. The dynamic pressure is the pressure exerted by the flowing stream and is indicative of the flow velocity. It is measured by a pressure tap facing directly into the flow stream. In practice, a device called an “S-type pitot tube” is used to measure static and dynamic pressure at a single location. Standard calculations are then used to compute the flow rate. By moving the pitot tube across a stack cross section, the flow rate at each point can be determined. All of this is described in detail in Test Method 2.

Next, it is necessary to assure that the sample gas stream does not change substantially between the time it enters the nozzle and leaves the probe for the collection part of the sampling train. This is accomplished by ensuring that the construction and operation of the probe do not interfere physically or chemically with the flowing sample stream. The nozzle and probe must be made of materials, such as stainless steel, glass, or teflon, that are smooth and do not react with the stream. In addition, the probe may be heated to ensure that vapors in the stream do not condense on the walls of the probe. A stainless steel nozzle and a glass-lined probe heated to 120 ± 14°C (248 ± 25°F) will suffice for most situations. However, special construction materials and/or probe temperature settings may be required for sampling exhaust streams from certain source types of containing certain contaminants. The appropriate sections of this chapter should be consulted in detail before any decisions are made.

The third and final consideration for ensuring representative particulate sampling is that the sampling is conducted at a time and over a sufficient time period to account for variabilities in the exhaust steam. In general, it is desirable to measure the maximum possible emissions, so as to determine compliance under so-called worst case conditions. This is accomplished by first determining the stage or stages in the plant process mot likely to produce the greatest emission rate. This might require preliminary testing, or it may be specified in the applicable regulations.

Once the time for testing is selected, it is necessary to decide the duration of each sample run and the number of runs to be performed. Generally, this is specified in the applicable regulation or in the Test Methods. However, in some cases, it may be necessary to select different sampling periods. The basic reason for sampling for any given time is to account for temporal variability in the emissions. Very few processes produce emission streams that are truly constant over more than a few minutes at a time. In most cases, though, an hour or two-hour sampling period will be sufficient to smooth out any inherent variation in the exhaust stream. In practical terms, this is accomplished by pumping the sample stream through the filter, solutions, or sorbents for the full sampling period. This effectively averages the collected sample over the entire time period. Of course, it is possible that variations in the emission rate with time could mean that higher concentrations are measured at one point in a traverse, such as near one stack wall, etc. However, in most cases, these variations are not significant.

The individual regulations or Test methods usually state the required sampling duration. There are two reasons that the sampling duration might be changed. First, if the source is known to vary over a longer or shorter cycle, such that a different sampling period would be likely to yield more meaningful results. Second, with some state operating permits establishing very low emission limits, sampling times are increased to provide adequate quantification limits.

At this point, the sample gas stream should be as representative as can be collected using these methods. However, there is still the inherent variability of the methods themselves. To account for this, most testing programs include a series of three or more test runs in a single test. Depending on the underlying regulations, the results of the test runs can be used independently or averaged to reach a final emission measurement.

Once an appropriate sample gas stream has been extracted from an exhaust stream, it must be collected in some way for subsequent analysis. Most particulate sampling trains separate the particulate matter from the rest of the gas stream, saving the particulates and exhausting the particulate-free gas sample stream. This separation can be accomplished physically, chemically, or both. Examples of physical separation are filtration, inertial separation (using a "cyclone"), or condensation. Examples of chemical separation include dissolving into solution, adsorption, or chemical reaction into a solution.

One or more of these separation techniques may be appropriate for a given particulate material or under given process and/or stack conditions. The specific technique to be used and the limiting conditions may be found under the specific Test Methods described later in this Section. The essence of each is to ensure that all of the particulate matter flowing through the nozzle and probe is actually collected for subsequent analysis.

The following is a brief list of these particulate sampling principles, rearranged in an order that might be followed for an actual test.

1) Select a sampling location far from disturbances.
2) Determine traverse point locations.
3) Select appropriate nozzle, probe, heater, and so on.
4) Determine appropriate time for testing (worst case, etc.)
5) Determine isokinetic sampling rates.
6) Select sample train configuration.
7) Perform test runs.

Gaseous Sampling

When the pollutant of interest is a gas at ambient pressure, sampling is much easier and more straightforward than for particulate samples. This is because gas streams are almost always well mixed across the stack and are not subject to the internal considerations at the nozzle or in the probe. As a result, there is usually no need to worry about the sample location, traversing the stack cross-section, or isokinetic sampling. An exception is the measurement of nitrogen oxides from gas turbines using method 20. This method requires a stratification study.

The only real concern is that the probe be constructed of materials that will not react with or adsorb contaminants from the sample stream.

Sampling is usually performed by inserting a probe at a convenient location and sampling at the centroid of the cross-section. As with particulate sampling, it is important to measure the gas flow rate in the stack to allow calculations of emission rate. This is done in the same way as for particulate sampling using Test Method 2.

Protocol and Final Report Preparation

A stack sampling project, like most other investigative work, is not likely to succeed unless it is well planned and documented. The Stack Test Protocol, or Quality Assurance Project Plan, is the means used to document the planning of the project. The more detail that can be included in the protocol, the better the likelihood that the test will succeed the first time. Most EPA Regions and State Agencies have specific protocol formats and require specific types of information. Therefore, the project manager should contact the Agency well before the projected test date to obtain the format and to discuss any special conditions that need to be included, such as audit samples.

The final Stack Test Report is just as important as the Protocol. It is the means by which the testing team documents what they did and their results. If the Report does not fairly report what actually happened on the stack, in the laboratory and in the calculations, the entire test might well be wasted. Again, it is advisable for the project manager to contact the regulatory agency well before the test to obtain information of acceptable report formats and special information that might be needed. It is likely, though, that the Agency will require copies of all field data sheets, lab data sheets and print-outs, calculation procedures, examples, and results, diagrams, etc. A fourth advance has been made in the dissemination of stack testing information through EPA's electronic bulletin board. The Emission Measurement Technical Information Center (EMTIC) bulletin board is available as part of the Technology Transfer Network Bulletin Board Service (TTNBBS). The EMTIC bulletin board includes promulgated methods, proposed methods, some state test methods, papers on stack analysis, a data base on validated methods for various compounds, etc. It can be used to get answers to specific questions. Access to the TTNBBS is available through the Internet at "http://www.epa.gov//ttn"

Stack Test Guidance is available at http://www.epa.gov/Compliance/assistance/air/index.html

This his document does not address test methods. However, it does provide a good discussion of regulatory requirements for stack testing, including notifications, time frames, observation by regulatory agencies, and reporting.

TEST METHOD DESCRIPTIONS

The main body of this chapter includes brief descriptions of selected current U.S. EPA Test Methods. These are the methods approved by U.S. EPA for testing emissions from sources subject to the New Source Performance Standards (NSPS), found in 40 CFR Part 60, and the National Emissions Standards for Hazardous Air Pollutants (NESHAPS), found at 40 CFR Parts 61 and 63. The methods themselves can be found in the appendices to those regulations.

The U.S. EPA Test Methods may, of course, be used for purposes other than NSPS or NESHAPS. However, their applicability and validity may be unsure. The same is true for methods developed by the states or by others. Many methods are completely appropriate for a given circumstance for which they have been extensively verified (as have the EPA methods for NSPS and NESHAPS). However, their validity under other circumstances should always be questioned until and unless their performance can be confirmed.

The descriptions presented here are valuable for developing general understanding of the equipment and procedures. However, the methods should never be attempted without a thorough reading and understanding of the methods themselves. Stack Testing is still a very complex process that requires experience if useful results are to be obtained.

To assist in the selection of a Test Method, Table 1 lists the parameters that can be measured, along with the appropriate methods.

Test Method 1

Test Method 1 is used to determine representative traverse points for measuring solid or liquid pollutants and/or determine total volumetric flow rate from a stationary source. The procedures described in this method are used to determine the minimum number of points, the location of these points, and whether the chosen points are free from cyclonic flow. The Method contains a rote procedure for choosing point locations that are at the centroids or equal area portions of the stack cross section. This ensures equal weighting of all flows into the average flow rate determination.

The minimum number of sampling points is determined from Figure 1. This figure is applicable to both round and rectangular ducts based on the distance from the nearest disturbance, bend, exit o other obstruction which might disrupt the flow of gas through the duct. The ducts must be at least

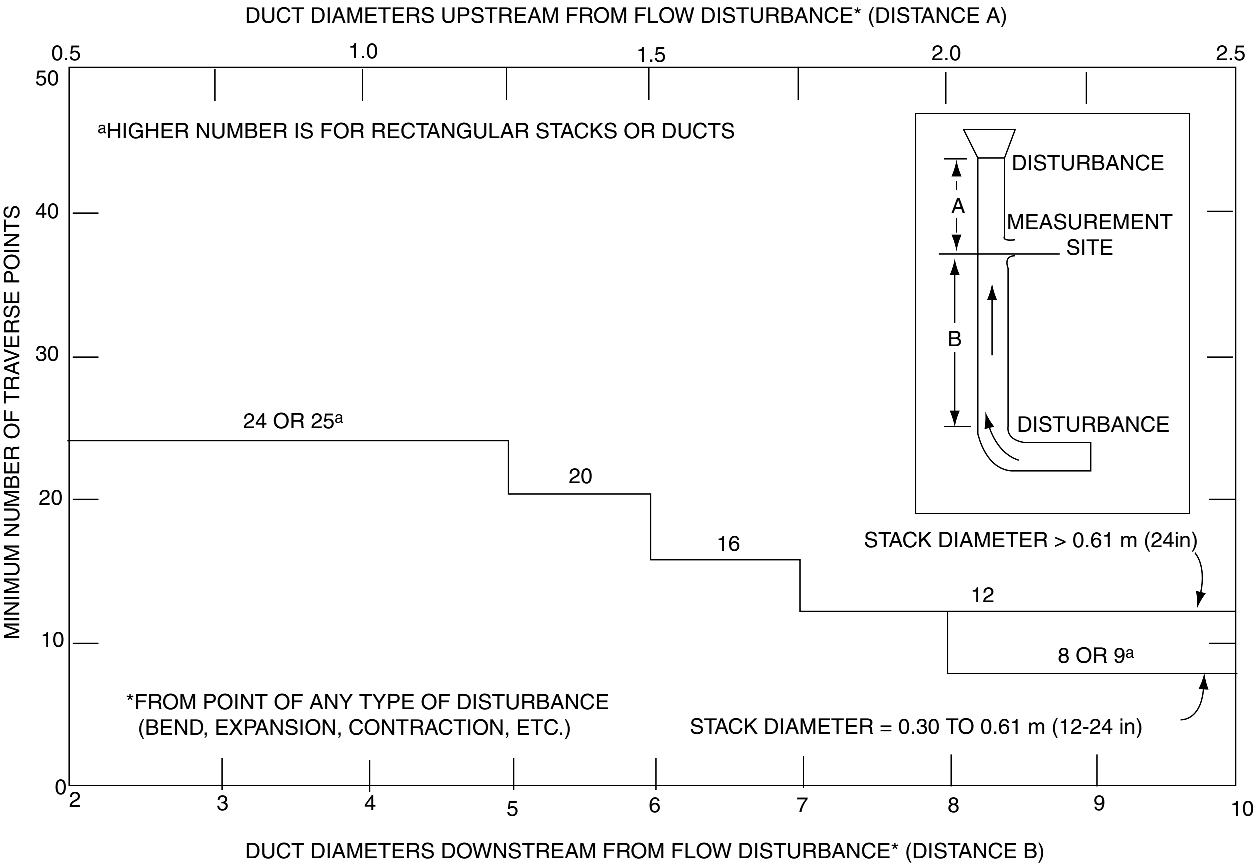

FIGURE 1 Minimum number of traverse points for particulate traverses.

12 inches (0.3 m) in diameter or 113 in^2 (0.071 m^2) cross-sectional area. Sampling ports must not be within 2 duct diameters downstream or half a diameter upstream from any flow disturbance. Sampling points are then determined by dividing the stack into equal area sections as shown in Figures 2 and 3. A table is provided in the Method which gives the percentage of the stack diameter from the inside wall to each traverse point. For stacks greater than 24 inches in diameter, no point should be closer than 1 inch from the wall; for smaller stacks, no closer than 0.5 inch.

Once these criteria are met measurement of the direction of flow is made to insure absence of significant cyclonic flow. The angle of the flow is determined by rotating a Type S pitot tube until a null or zero differential pressure is observed on the manometer. The angle of the pitot tube with the stack is then measured. This procedure is repeated for each sampling point and the average of the absolute values of the angles calculated. If the average angle is greater than 20º, the sampling site is not acceptable and a new site must be chosen, the stack extended, or straightening veins installed.

A few unusual cases have been accounted for by the method. If the duct diameter or size is smaller than that required by Method 1, Method 1A can be used. For cases where 2 equivalent stack diameters downstream or a half diameter upstream are not available, a directional velocity probe can be used to determine the absence of cyclonic flow, as described in Method 1. If the average angle is less than 20º, then the sampling site is satisfactory; however a greater number of points must be used.

Test Method 2

Test Method 2 is used to determine the average velocity in a duct by measuring the differential pressure across a Type S (Stausscheibe) pitot tube. The Type S pitot tube is preferable to the standard pitot tube when there are particles that could cause plugging of the small holes in the standard pitot tube. Measurement sites for velocity determination are chosen as described in Method 1, that is, required number of sites and absence of cyclonic or swirling flow.

The type S and standard pitot tubes are shown in Figure 4. When the Type S pitot tube has been correctly manufactured and installed on a probe as shown in Figure 5, there is no interference and calibration is not necessary. A pitot tube constant of 0.84 is assumed. If the criteria for interferences are not met, the method discusses the necessary calibration procedures.

TRAVERSE POINT	DISTANCE, % of diameter
1	4.4
2	14.6
3	29.6
4	70.4
5	85.4
6	95.6

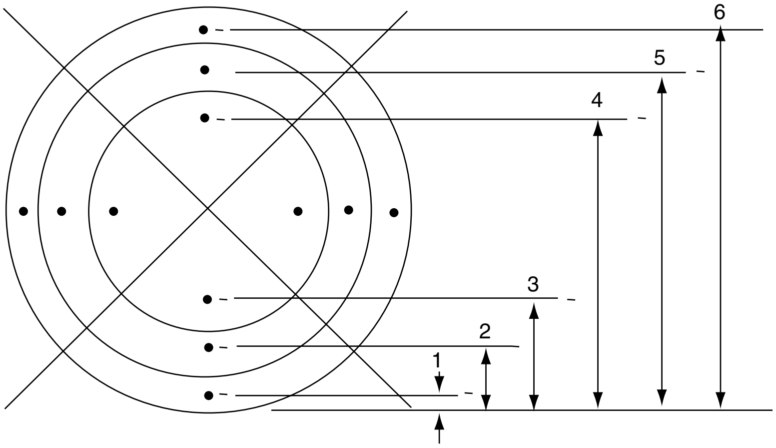

FIGURE 2 Example showing circular stack cross section divided into 12 equal areas, with location of traverse points indicated.

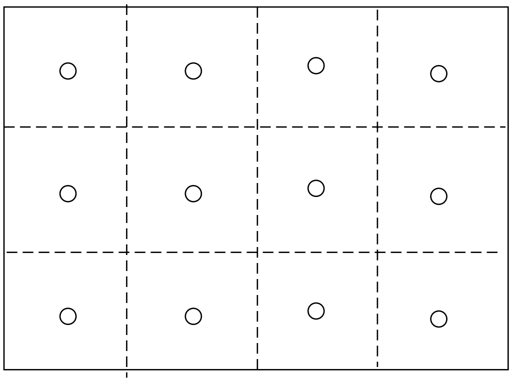

FIGURE 3 Example showing rectangular stack cross section divided into 12 equal areas, with a traverse point at centroid of each area.

Velocity, as measured with a pitot tube, is proportional to the square root of the differential pressure across the two sides of the pitot tube and the density of the stack gas. Most sampling trains use a combination inclined–vertical manometer to measure the velocity head, or Δp. These manometers usually have 0.01 inch of water subdivisions from 0–1 inch of water. The vertical section has 0.1 inch divisions from 1–10 inches of water. This type of gauge provides sufficient accuracy down to 0.05 inches; below that a more sensitive gauge should be used.

The temperature of the gases is usually measured using a type K (Chromel-Alumel) thermocouple mounted on the probe. The absolute pressure is calculated by adding the static pressure in the stack to the barometric pressure. The molecular weight of the stack gases is determined using Methods 3 and 4.

Velocity is calculated by the equation below:

$$V_s = K_p C_p (\Delta p^{0.5})_{avg} \{T_{s(avg)}/(P_s M_s)\}^{0.5}$$

where:
K_p = Velocity equation constant

$$K_p = 34.97 \frac{m}{sec} \left[\frac{(g/g\text{ - mole})(mmHg)}{(\ K)(mmH_2O)} \right]^{0.5} \text{ metric}$$

$$K_p = 85.49 \frac{ft}{sec} \left[\frac{(lb/lb\text{ - mole})(in.Hg)}{(\ R)(in.H_2O)} \right]^{0.5} \text{ English}$$

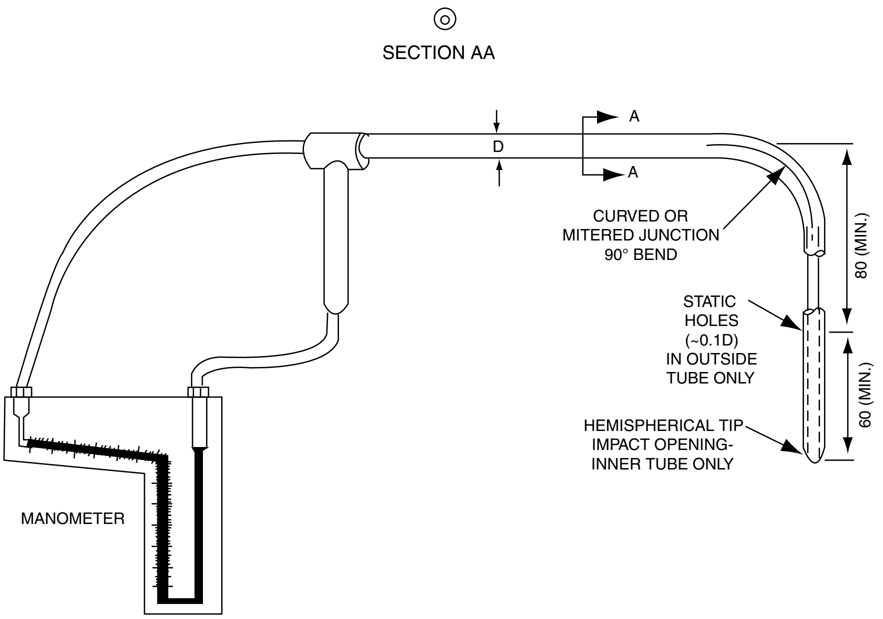
C_p = Pitot tube Coefficient (0.84 for S Type without interferences)
Δp = pressure difference across the two sides of the pitot tube (velocity head of the stack gas)
P_s = Absolute pressure of the stack, mm Hg or in. Hg
M_s = Molecular weight of the wet stack gases, g/g mole or lb/lb mole
T_s = Absolute stack temperature, ºK (273 + ºC) or ºR (460 + ºF)

The average dry volumetric stack flow is:

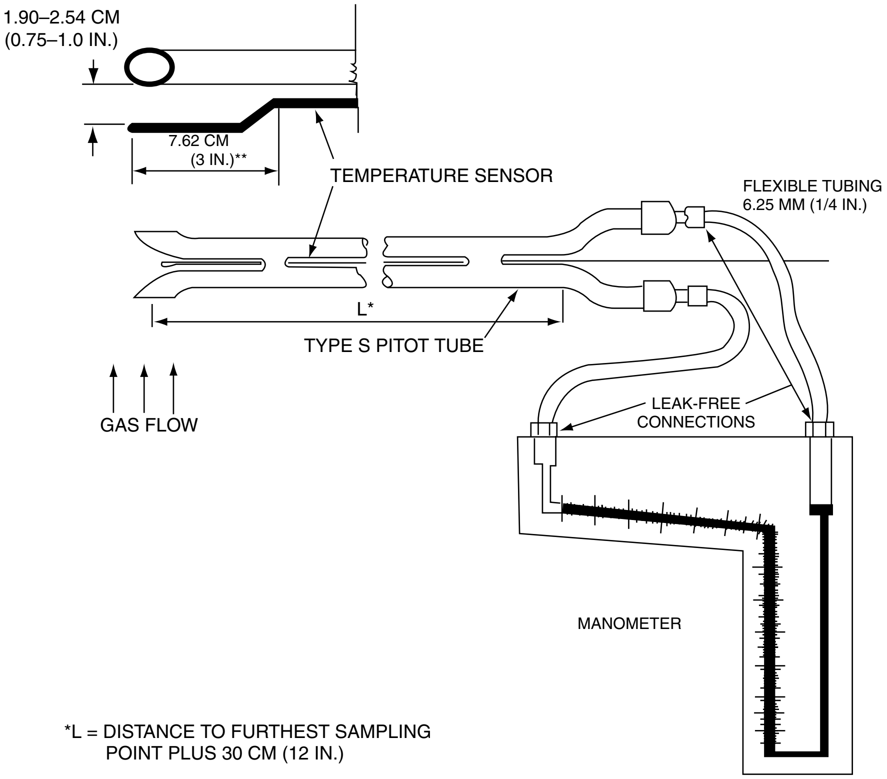
$$Q_{sd} = 3{,}600(1 - B_{ws})V_s A(T_{std}/T_{s(avg)})(P_s/P_{std})$$

where:

Q_{sd} = Average stack gas dry volumetric flow rate
B_{ws} = Water vapor in the gas stream from Method 4 or 5
V_s = Average stack gas velocity
A = Cross-sectional area of the stack
T_{std} = Standard absolute temperature 293ºK or 528ºF
P_{std} = Standard absolute pressure 760 mm Hg or 29.92 in. Hg



Standard pitot tube design specifications.



*L = DISTANCE TO FURTHEST SAMPLING POINT PLUS 30 CM (12 IN.)

Other methods 2A through 2H are used for specific conditions.

Test Method 3

Test Method 3 is used to determine the oxygen (O_2) and carbon dioxide (CO_2) concentration from combustion gas streams for the determination of molecular weight.

The method can also be used for other processes where compounds other than CO_2, O_2, CO or N_2 are not present in concentrations that will affect the results significantly. The O_2 and CO_2 can then be used to calculate excess air, molecular weight of the gas, or to correct emission rates as specified by various subparts of 40 CFR Part 60. Method 3 can also be used to determine carbon monoxide when concentrations are in the percent range.

Two types of analyzers can be used depending on the use intended for the data. Both analyzers depend on the absorption of components in the combustion gases by specific chemicals. The Orsat Analyzer sequentially absorbs CO_2, O_2, and CO. The change in sample volume is measured with a gas burette after each absorption step. Potassium hydroxide solution is used to absorb CO_2, forming potassium carbonate. When no further change in volume is noted, the difference from the starting volume is the amount of CO_2 present. Since the starting volume in the burette is usually 100 ml, the difference in ml is also the concentration of CO_2 in percent. The absorbent solution for O_2 is a solution of alkaline pyrogallic acid or chromous chloride. The CO absorbent is usually cuprous chloride or sulfate solution. The Fyrite type analyzers are available for either CO_2 or O_2, however they do not provide the accuracy of the Orsat Analyzer, **using Method B.**

Test Method 3A

Test Method 3A is an instrumental method for determining O_2 and CO_2.

From stationary sources when specified in the applicable regulations. Calibration procedures are similar to those discussed in Method 6C.

Test Method 3B

The Orsat analyzer is required for emission rate corrections and excess air determinations. Concentration values from 3 consecutive analyses must differ by no more than

0.3 percentage points when used for above purposes. When only the molecular weight determination is desired, the analysis is repeated until the dry molecular weights from any three analyses differ by less than 0.32 g/g-mole (lb/lb-mole). The Fyrite analyzer can be used only for determination of molecular weight.

Sampling is done in one of three methods: grab, integrated, or multi-point integrated. Grab samples are used when the source is spacially uniform and concentration as a function of time is required, or the source is considered uniform over time. Integrated samples are the most commonly used. A leak-free 30 liter plastic bag is filled using a pump and flow meter to insure that the sample is representative of the same period of time as the emission test. Bags must be analyzed within 8 hours for determination of molecular weight, or 4 hours when samples were collected for emission rate correction. For a multi-point integrated sample, the stack is traversed as described in Method 1. Samples are uniformly collected in suitable sampling bags.

Leak-checks of the analyzer and bags are required. The leak-check should also insure that the valve does not leak in the open position. To assure the data quality when both O_2 and CO_2 are measured, a fuel factor, F_0, should be calculated using the equation:

$$F_0 = \frac{20.9 - \%O_2}{\%CO_2}$$

The value of F_0 should be compared with the values given in the Test Method for the fuel used. If F_0 is not within the specified range, the source of error must be investigated.

The EPA Test Method 3 write-up contains detailed instructions, along with a list of references. It should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by trained and experienced personnel using equipment and materials designed for this purpose.

Test Method 3C

Test Method 3C is a gas chromatographic method used to measure CO_2, CH_4, N_2 and O_2 from landfill gases.

Test Method 4

Test Method 4 is used to determine moisture content in stack gases. In this method a sample is extracted at a constant rate from the stack; the moisture is removed and determined either gravimetrically or volumetrically. Often this measurement is made as part of particulate emission measurements.

When saturated conditions are present in the stack gases, (i.e. water droplets are present), the test method may yield questionable results. Moisture content for saturated stack gases should be based on stack temperature measurements and either phschrometric charts or vapor pressure tables. Molecular weight determinations and velocity calculations should be based on the lower of the two water concentration determinations.

The procedure described next for Method 5 is appropriate for Method 4. If particulate measurements are not required, the method can be simplified as follows:

1) The filter required in Method 5 can be replaced with a glass wool plug.
2) The probe need be heated only enough to prevent condensation.
3) The sampling rate does not have to be isokinetic, instead the source can be sampled at a constant rate within ± 10%.

The EPA Test Method 4 write-up contains detailed instructions, along with a list of references. It should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by trained and experienced personnel using equipment and materials designed for this purpose. A table for determination of vapor pressure of water at saturation is located in section 3.3.6 page 7 of the *Quality Assurance Handbook of Air Pollution Measuring Systems: Volume III.*

Test Method 5

Test Method 5 is used to measure particulate emissions from stationary sources. Stack gases containing particulate matter are drawn isokinetically through a glass fiber filter. The volume of gas after removal of all water is measured with a dry gas meter. The particulates are measured gravimetrically.

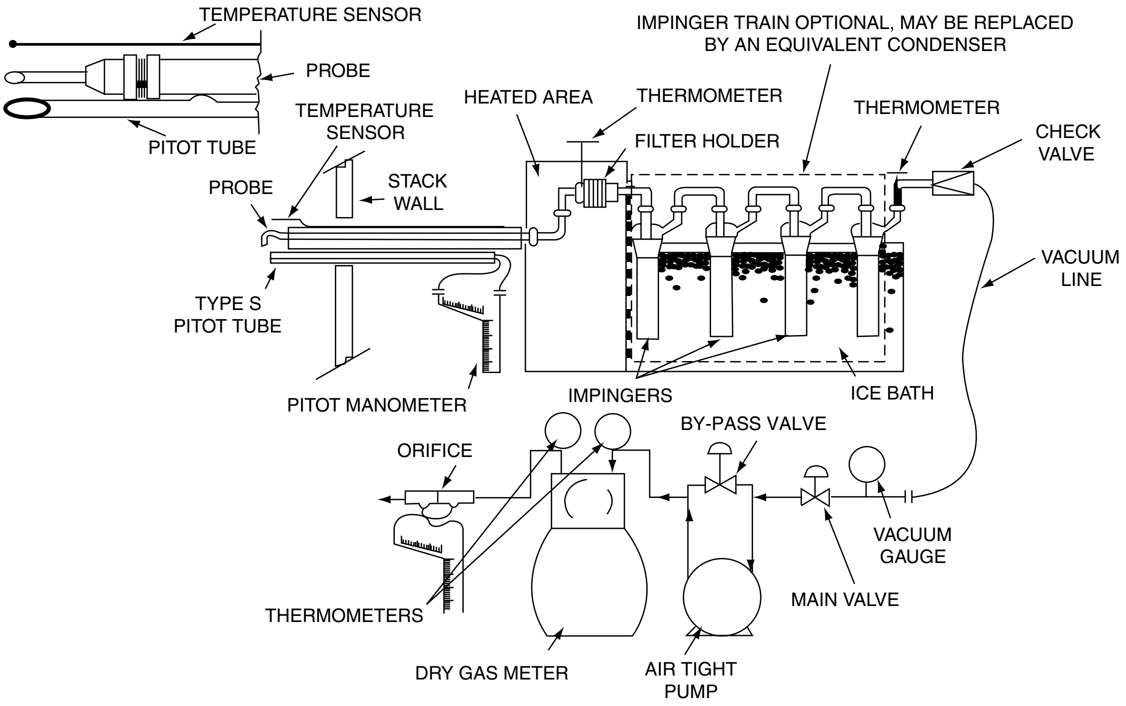
The equipment used in Method 5 forms the basis for many other emission measurements, therefore, the components of the Method 5 Train, Figure 6, will be described in some detail.

Probe Nozzle

The probe nozzles are usually stainless steel tubing in the shape of a Shepherd's Crook with a sharp tapered opening. Nozzles are available in a variety of sizes from 1/8" to 3/4" in diameter. They are calibrated by measuring the diameter in three different directions. The difference between the high and low value must be less than 0.004". The nozzle tips should be inspected before each use to ensure that the nozzle has not been damaged. During the sample recovery phase, all external particulate matter is wiped off and the opening capped with aluminum foil. When the probe has cooled sufficiently, the nozzle is removed. The nozzle is then cleaned by rinsing with reagent grade acetone and brushing with a Nylon bristle brush until further rinses with acetone are free of particulates. The acetone is saved in a bottle labeled Container 2 for later analysis.

Probe

Probe liners are usually constructed of borosilicate glass, or, if stack temperatures are expected to exceed 480ºC, quartz. Metal liners can be used subject to EPA approval. The probe liner is wrapped wit heater tape to maintain temperatures adequate to prevent condensation. The temperature of



Schematic of Method 5 sampling train.

FIGURE 6 Schematic of Method 5 sampling train.

the probe liner is regulated with a variable voltage controller. The controller is calibrated by introducing air at various temperatures in the range of the stack temperature and determining the controller setting necessary to maintain the probe temperature required by the Method (120 ± 14°C) or the specific regulation, such as a subpart of 40 CFR Part 60. The probe liner, with the heating element, is inserted in a stainless steel tube.

The probe liner is cleaned in much the same way as the nozzle. Once it has cooled it is removed from the train and the ends wiped free of silicone grease and covered. During cleaning, the probe is loosely held on an incline with utility clamps. The probe is then rinsed with acetone while slowly rotating the probe. A nylon brush, extended with teflon tubing, is used to scrub the inside of the probe liner. The acetone is saved in the bottle labeled Container 2 for later analysis.

Pitot Tube

A type S pitot tube is secured to the outside of the probe. The pitot tube was discussed in the Method 2 description. The special relationship to the nozzle is critical, in terms of both the location and the alignment. The pitot tube should be inspected before and after each run to insure that it has not been damaged. The pitot tube and the tubing connecting it to the manometer should be leak checked before and after each run. This can easily be done by slipping rubber tubing over the end of one side of the pitot, blowing gently on the rubber tubing producing at least 3 inches water pressure, then clamping the rubber tubing with a pinch clamp. No change in pressure should be observed in 15 seconds.

Filter

The filter holder is made of borosilicate glass with a glass frit filter support and silicone rubber gasket. Clamps of varying designs are used to seal the filter between the two halves of the holder.

The filter is a glass fiber filter capable of capturing at least 99.95% of 0.3 micron particles. Filters, desiccated at room temperature and ambient pressure, are weighted every six hours until the change is less than 0.5 mg. This process is called desiccating to constant weight. Alternatively the filters can be dried in an oven to constant weight. They are allowed to cool to room temperature in a desiccator before each weighing.

After the test, the filters are inspected for signs of gases passing around the edges of the filter and for water stains on the filter. Either would seriously compromise the results. The filter is carefully transferred to a petri dish. Any pieces of filter sticking to the housing are removed with forceps or a sharp instrument. The front half of the filter holder is rinsed with acetone and the acetone saved in the bottle labeled Container 2 for later analysis.

The filter holder must be maintained at 120 ± 14°C, **or as specified in the applicable regulation.**

Any heating system capable of providing this temperature around the filter holder during the run is acceptable.

Condenser

The condensation of the water vapor serves two purposes: first, it prevents condensation in the dry gas meter and the vacuum pump. Second, the collected condensate is used to determine the water vapor content in the stack gases. This collection is considered quantitative if the exit gases are maintained below 20ºC (68ºF). Four Greenburg-Smith impingers are connected in series and placed in an ice bath. The first, third, and fourth impingers are modified by removing the tip and replacing it with a straight piece of glass. One hundred ml of water is placed in the first and second impingers. The third is left empty and the fourth is filled with 200 to 300 grams of silica gel, at least some of which is the indicating type that turns from blue to pink when it is spent. The silica gel is usually put into a preweighed bottle before the start of testing. After use, it is returned to the same bottle and the weight difference is recorded.

After the sampling is complete the total water collected is determined by measuring the liquid in the first three impingers and subtracting the starting 200 ml. Any oil film or color of the water should be noted. Added to the liquid water collected is the weight gain of the silica gel. The color of the silica gel should be noted after sampling; if it all has changed to pink, all of the water passing through the train water may not have been collected.

Meter System

The metering system is used to withdraw isokinetically a measured quantity of gas from the stack. A vacuum pump is used to withdraw the sample. There is a vacuum gauge located before the vacuum pump. A dry gas meter capable of 2% accuracy is used to measure the gas sample volume. Two thermometers, one at the meter inlet and one at the outlet, are used to measure the gas temperature. To maintain isokinetic sampling rates, it is important to know the gas flow rate. This is done by measuring the pressure difference across an orifice in the exit from the dry gas meter.

The meter must be calibrated before initial use against a wet test meter. Then after each field use the calibration is checked at one point with either a wet test meter or critical orifice. The calibration check can not deviate from the initial reading by more than 5%. The metering system should be leak checked from the pump to the orifice meter prior to initial use and after each shipment.

Nomograph

The sampling rate necessary to maintain isokinetic conditions is dependent on the conditions in the stack (i.e. water content, average molecular weight of the gas, temperature, velocity, and pressure) and at the meter (i.e. temperature and pressure). The correct sampling rate is determined from the above parameters. The sampling rate is controlled by selecting the nozzle size and regulating vacuum. They serve as the course and fine adjustment of sampling rate. An initial velocity traverse is done to determine the stack conditions. A nomograph, special slide rule, or computer program is used to select an appropriate nozzle size to allow the fine adjustments of the vacuum pump to cover the expected range. This is necessary because the vacuum pump has a limited range. Because the stack velocity can change during the run, the operator must be able to rapidly recalculate the desired flow rate through the meter. The slide rule and computer can also be used to correct rapidly for changes in temperatures and pressures.

Sampling

The first step in determining particulate emissions is the selection of the sampling site and number of traverse points by Method 1. The following are the steps to perform particulate sampling:

1) Set up the equipment as shown in Figure 5.
2) Do initial traverse to determine appropriate nozzle.
3) Install nozzle.
4) Leak check from nozzle to vacuum pump.
5) Insert probe into stack and heat probe and filter.
6) Start traverse maintaining isokinetic sampling.
7) After traverse, leak check equipment.
8) After cooling, clean probe, nozzle and front of filter housing. Transfer filter to a petri dish.
9) Determine the amount of water collected.
10) Calculate the isokinetic variation. It must be within 10%.
11) Evaporate acetone from probe and nozzle washes and weigh.
12) Desiccate or oven dry the filter to constant weight.
13) Calculate the particulate emissions in the required units.

The EPA Test Method 5 write-up contains detailed instructions, along with a list of references. It should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by trained and experienced personnel using equipment and materials designed for this purpose.

Test Method 5A

Test Method 5A is used to determine particulate emissions from the Asphalt Processing and Asphalt Roofing Industry. This method differs from Method 5 in only two aspects:

1 The glass fiber filter is maintained at 42º ± 10ºC (108º ± 18ºF).
2 Trichloroethane is used to wash the probe and front half of the filter housing instead of acetone. This may be evaporated at 38ºC.

Test Method 5B

Test Method 5B is used to determine the non-sulfuric acid particulate matter from stationary sources. This method is very similar to Method 5 except that the filter housing is kept at 160º ± 14ºC (320º ± 25ºF) during the sample collection and dried at the same temperature for six hours. This volatilizes the sulfuric acid mist that collected on the filter. Once the acetone from the probe wash has been evaporated, the residue is also dried at high temperature to remove the sulfuric acid.

Test Method 5D

The purpose of this method is to select appropriate alternate locations and procedures for sampling emissions from positive pressure fabric filters. Many times these air pollution control devices were not designed with emission sampling in mind. This method should be consulted if a source using fabric filters does not met the criteria specified in Method 1.

Test Method 5E

Test Method 5E is used for the determination of particulate emissions from the wool fiberglass insulation industry. Method 5 has been modified to include the measurement of condensable hydrocarbons in this method. A 0.1N NaOH solution is used in place of distilled water in the impingers. The particulates condensed in this solution are analyzed with a Total Organic Carbon (TOC) analyzer. The sum of the filtered particulates and the condensed particulates is reported as the total particulate mass.

Test Method 6

Test method 6 is used for **determining the sulfur** dioxide (SO_2) emissions from stationary sources. The sulfuric acid mist and the sulfur trioxide are separated from the SO_2, and the SO_2 quantified using the barium-thorium titration method.

In this method, the use of midget impingers is recommended. However, the standard size impingers as used in Method 5 or 8 can be used if the modifications required by Method 6 are implemented. SO_2 can be determined simultaneously with moisture and particulates by making the required modifications.

The train for Method 6 is similar to Method 5 except for the size of the impingers and the use of a glass wool plug in the probe tip, replacing the particulate filter. The first impinger or bubbler (fritted glass tip) contains 15 ml of 80% isopropanol and a glass wool plug at the exit. The first impinger will collect SO_3 in the isopropanol solution and the glass wool will prevent the carry-over of sulfuric acid mist. The isopropanol should be checked for the presence of peroxides with potassium iodide. Peroxides would prematurely oxidize the SO_2 and capture it along with the SO_3. The next two midget impingers each contain 15 ml of 3% hydrogen peroxide. This will oxidize the SO_2 to sulfuric acid for analysis. The hydrogen peroxide should be prepared daily from 30% hydrogen peroxide. A drying tube containing silica gel is used to protect the vacuum pump and dry gas meter. The dry gas meter must be capable of 2% accuracy for a 20 liter sample. The vacuum pump should be a leak-free diaphragm pump. A surge tank should be used to eliminate pulsations.

Sampling for SO_2 is not done isokinetically since the gas is assumed to be uniformly dispersed in the stack. Sampling is done at one point and at a constant rate (+ 10%). Crushed ice should be added as necessary to maintain 68ºF at the last impinger.

After sampling, the train is leak checked, then the ice drained and the train purged with clean air for 15 minutes at the sampling rate. This will remove any SO_2 dissolved n the isopropanol and carry it over to the peroxide solution for oxidation and analysis. The isopropanol solution is then discarded. The peroxide solution containing the oxidized SO_2 is transferred to a graduated cylinder and diluted to 100 ml with distilled water. A 20 ml aliquot with four drops of thorium indicator is titrated with barium perchlorate. The solutions should be standardized as described in the method. The end point for this titration can be difficult to catch. It is possible, however, to get replicate titrations within 1% or 0.2 ml as required by the method. Audit samples are available through the EPA's Emissions, Monitoring and Analysis Division.

The EPA Test Method 6 write-up contains detailed instructions, along with a list of references. It should be read in detail before the Method is attempted. Testing should be performed only by personnel trained and experienced with the equipment and titrations specified in this method.

Test Method 6A

Test Method 6A is used for the simultaneous determination of SO_2 and CO_2 from fossil fuel combustion source. Moisture may also be determined by this method. The train for Method 6A is very similar to Method 6 with the following exceptions:

1) The probe is heated to prevent moisture condensation.
2) The fourth impinger contains 25 grams of anhydrous calcium sulfate to remove the water. This is weighed after sampling to determine the moisture content.
3) In place of the drying tube in Method 6, there is a CO_2 absorber tube containing Ascarite II. This is weighed to determine the CO_2 concentration.

As with Method 6, the EPA Test Method 6A write-up contains detailed instructions, along with a list of references. It should be read in detail before the Method is attempted. Testing should be performed only by personnel trained and experienced with the equipment and titrations specified in this method. The Method 6 audit samples are also appropriate for this method.

Test Method 6B

Test Method 6B is used for the simultaneous determination of SO_2 and CO_2 daily average emissions from fossil fuel combustion sources.

The train for Method 6B is very similar to Method 6A with the following exceptions:

1) The probe is heated to 20ºC above the source but not greater than 120ºC.

2) The isopropanol bubbler or impinger is eliminated. An empty bubbler is used for the collection of liquid droplets.
3) The stack gases are extracted from the sampling point intermittently over the specified period, usually 24 hours. An industrial timer is used to cycle the pump on for at least 12 periods of at least two minutes each. Between 25 and 60 liters of gas must be collected.

The EPA Test Method 6B write-up contains detailed instructions, along with a list of references. It should be read in detail before the Method is attempted. Testing should be performed only by personnel trained and experienced with the equipment and titrations specified in this method. The Method 6 audit samples are also appropriate for this method.

Test Method 6C

Test Method 6C is an instrumental method for the determination of sulfur dioxide from stationary sources. No specific instrument is required by this method. Ultraviolet, nondispersive infrared, or fluorescence instruments can be used providing they meet the performance specifications and the test procedures are followed.

The following Measurement System Performance Specification must be passed by the instrument before actual environmental samples are analyzed:

1) Analyzer Calibration Error must be less than ± 2% of the span for the zero, mid-range, and high-range calibration gases.
2) Sampling System Bias must be less than ± 5% of the span for the zero, mid-range, and high-range calibration gases.
3) Zero Drift must be less than ± 3% of the span over the period of each run.
4) Calibration Drift must be less than ± 3% of the span over the period of each run.

The analytical range must be selected such that the SO_2 emission limit required of the source is not less than 30% of the instrument span. Any run in which the SO_2 concentration in the stack gas goes off-scale must be repeated.

The EPA Test Method 6C write-up contains detailed descriptions of the calibration gases required, calibration procedures, sampling procedures in addition to a list of references. It should be read in detail before the Method is attempted. The manufacturer's instructions will provide instrument specific instructions. Testing should be performed only by personnel trained and experienced with the equipment being used.

Test Method 7

Test Method 7 is used for the determination of nitrogen oxide (NO_x) emissions from stationary sources. In this method the NO_x concentration of a grab sample, collected in an evacuated two liter flask, is measured colorimetrically using the phenoldisulfonic acid procedure.

The apparatus for sample collection consists of probe, squeeze bulb, vacuum pump, manometer, and a two liter flask. The probe is heated if necessary to prevent condensation. A one way squeeze bulb is used to purge the probe before sampling. The vacuum pump is used to evacuate the flask. A manometer is used to measure the flask pressure. The two liter flask contains 25 ml of a H_2SO_4/H_2O_2 solution. This solution will absorb the NO_2. Oxygen from the source is required for the oxidation of the NO. If less than 1.5% oxygen is present in the stack gases, the steps described in the method to introduce additional oxygen must be used. Once the flask is evacuated 75 mmHg, valves are rotated to isolate the flask from the pump, and a sample is introduced into the flask. It should take less than 15 seconds for the flask to reach ambient pressure. If a longer time is required, check the probe for plugging.

After sampling, the flask should sit for at least 16 hours for the NO to oxidize. The flask is then shaken for two minutes before checking the pressure of the flask. The liquid is then transferred to a container, and the flask rinsed with distilled water. The pH of the liquid is adjusted to between 9 and 12 with 1 normal NaOH. Just prior to analysis the liquid is transferred to a 50 ml volumetric flask and diluted to 50 ml. A 25 ml aliquot is transferred to an evaporating dish and evaporated to dryness. Two ml of the phenoldisulfonic acid solution is added to the evaporating dish along with 1 ml of distilled water and four drops of concentrated sulfuric acid. The solution is again heated for three minutes followed by the addition of 20 ml of water. The solution is then adjusted to pH 10 with ammonium hydroxide. The solution is filtered if necessary and transferred to a 100 ml volumetric flask and diluted to 100ml. The absorbance is measured at the optimum wave length and compared against standards for quantification. Audit samples are available through the EPA's Emissions, Monitoring and Analysis Division.

The EPA Test Method 7 write-up contains detailed instructions, along with a list of references. It should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by personnel trained and experienced with the equipment and the spectrophotometer used in this method.

Test Method 7A

Test Method 7A is man alternative to Method 7 for the determination of nitrogen oxide (NO_x) emissions from stationary sources. The sample is collected with the same sampling train used in Method 7. However, instead of using the colorimetric phenoldisulfonic acid procedure, ion chromatography is used for quantification. Audit samples, available through the EPA's Quality Assurance Division, are required for this method.

The EPA Test Method 7A write-up contains detailed instructions, along with a list of references. It should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by personnel trained and experienced with the sampling train and the ion chromatograph used for this method.

Test Method 7B

Test Method 7B is used for the determination of nitrogen oxide (NO_x) emissions from nitric acid plants. This method is very similar to Method 7 except that in this method the NO_x concentration of the grab sample is measured using an ultraviolet spectrophotometer. Audit samples, available through EPA's Quality Assurance Division, are required for each set of compliance samples.

The EPA Test Method 7B write-up contains detailed instructions, along with a list of references. It should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by personnel trained and experienced with the equipment and spectrophotometer used for this method.

Test Method 7C

Test Method 7C is used to determine NO_x from fossil-fuel fired steam generators, electric utility plants, nitric acid plants, or other sources as specified in the regulations. In this method, an integrated sample is collected in alkaline-permanganate solution. The NO and NO_2 in the stack gas are oxidized to NO_2 and NO_3 by the permanganate. The NO_3 is then reduced by cadmium to NO_2, then the NO_2 from both starting chemicals is measured colorimetrically.

The train used for Method 7C is similar to the one used for Method 6 except that the three impingers are larger and have restricted orifices at the tips. 200 ml of $KMnO_4$/NaOH solution is placed into each of the three impingers. The probe is heated as necessary to prevent condensation. A sampling rate of 400–500 cc/minute should be used since greater rates will give low results. The sample run must be a minimum of 1 hour. Carbon dioxide should be measured during the run with either an Orsat or Fyrite analyzer.

The EPA Test Method 7C write-up contains detailed instructions for sample preparation, analysis and calibrations, along with a list of references. It should be read in detail before the Method is attempted. Testing should be performed only by personnel trained and experienced with the equipment and titrations specified in this method. The Method 7 audit samples are appropriate for this method as well.

Test Method 7D

Test Method 7D is used to determine NO_x from stationary sources. In this method, an integrated sample is collected in alkaline-permanganate solution. The NO and NO_2 in the stack gas are oxidized to NO_3 by the permanganate. The NO_3 is analyzed by ion chromatography.

The train and sample recovery procedure used for Method 7D is identical to the one used for Method 7C. The Method describes the calibration and recommended chromatographic conditions for the analysis by ion chromatography.

The EPA Test Method 7D write-up contains detailed instructions for sample preparation, analysis and calibration along with a list of references. It should be read in detail before the Method is attempted. Testing should be performed only by personnel trained and experienced with the equipment and ion chromatography used in this method. The Method 7 audit samples are appropriate for this method.

Test Method 7E

Test Method 7E is an instrumental method for the determination of NO_x from stationary sources. In this method, a gas sample is continuously extracted from a stack and conveyed to a chemiluminescence analyzed for determination of NO_x.

The performance specifications and test procedures in Method 6C are incorporated by reference to ensure data reliability.

The chemiluminescence analyzer is based on the reaction of NO with ozone to produce NO_2 and a photon of light. This light is measured with a photomultiplier. If total NO^x is required, the NO_2 is thermally converted to NO before analysis. When the converter is used NOx is measured.

The EPA Test Method 7E write-up contains instructions for calibrations, along with a list of references. The manufacturer's instructions should be followed for set up of the instrument. Testing should be performed only by trained personnel.

Test Method 8

Test Method 8 will provide data on both the sulfur dioxide and sulfuric acid mist from stationary sources. This method is similar to Method 6 except that the sulfuric acid in the isopropanol solution is also measured by the barium–thorin titration method.

Instead of using the midget impingers as used in Method 6, the full size impingers, as in Method 5, are used. A filter is installed between the isopropanol impinger and the first hydrogen peroxide impinger to catch any sulfuric acid carry over.

The EPA Test Method 8 write-up contains detailed instructions, along with a list of references. It should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by trained and experienced personnel using equipment and materials designed for this purpose.

Test Method 9

Test Method 9 is used for visually determining the opacity of emissions from stacks or ducts. The specified procedures are to be followed by human observers trained and certified by procedures also contained in the method.

The training and certification portion of the method is based on teaching observers to identify smoke of given opacity between zero and 100% in increments of 5%. This is accomplished using a smoke generator machine capable of producing white and black smoke separately and identifying the opacity with a transmissometer, or smoke meter calibrated accurately to within ±2%. Once the observers have "calibrated their eyes" to identify emissions of different opacities, they are given a test consisting of 25 black smoke readings and 25 white smoke readings. An observer first takes a classroom training session then passes the two sets of smoke observations and is thus certified to "read smoke." To pass, the average error for each color smoke must be no greater than 7.5% and no individual reading more than 15% from the correct value. Observers must be recertified every six months, needing to pass the test but not take the classroom training.

The remainder of the method describes the procedure to be followed by the observer in observing actual smoke emissions and for recording them. The basic idea for performing visible emission (VE) observations is to try and minimize the influence of those factors that might bias the results of the observations or might cause them to be unreliable. The four major variables that can be controlled by the observer all relate to position. They are: distance from the emission point, the viewing angle relative to the direction of the emission, the angle relative to the sun, and the angle relative to the wind. The goal is to keep the sun to your back, the wind to your side, the emission at about eye level, and at a sufficient distance to allow comfortable viewing.

VE observations are momentary glances at the densest part of the plume every 15 seconds. They are recorded in 5% increments on an observational record sheet that also contains a diagram of the observer/source/conditions and other relevant information. Normally, 24 consecutive readings constitute a minimum data set, representing the average emissions over that 6-minute period. However, more or fewer observations may be required or allowed by a specific regulation.

More detailed instructions for operating a certification program and for making VE observations is included in the method. However, in almost all cases, a certification course would be offered by an experienced organization. In the case of this method, the admonition about experienced personnel does not apply. Anyone who can pass the test can perform VE observations.

Test Method 9, Alt 1

Alternative 1 to Test Method 9 allows for the remote observation of emission plume opacity by a mobile lidar system, rather than by human observers, as specified in Method 9. Lidar is a type of laser radar (Light Detection and Ranging) that operates by measuring the backscatter of its pulsed laser light source from the plume. It operates equally well in daylight or at night.

The lidar unit shall be calibrated at least once a year and shall be subjected to one of two routine verification procedures every four hours during observations. The calibration shall be performed either on the emissions from a Method 9 smoke generator or using screen material of known opacity. The system is considered to be in calibration if the lidar's average reading is within ± 5% for the smoke generator, or within ±3% for the screens. The routine verification procedures require either the use of neutral density filers or an optical generator. In either case, average readings within ±3% are required.

The actual operation of the lidar system is conceptually straightforward but technically complex. The unit is positioned with an unobstructed view of a single emission, the backscatter recorded, and the plume opacity calculated. However, the actual procedures for accomplishing this must be performed only by personnel experienced at operating lidar units and interpreting their results. Detailed criterion are provided in the method for both.

Test Method 10

Test Method 10 is used for the determination of carbon monoxide (CO) emissions from stationary sources employing a nondispersive infrared analyzer (NDIR). Either an integrated or continuous sample can be extracted from the source for analysis by this method.

The analyzer compares the infrared energy transmitted through a reference cell to the same length cell containing a sample of the stack gases. A filter cell is used to minimize the effects of CO_2 and hydrocarbons. The use of ascarite traps further reduces the interference of carbon dioxide. Silica gel is used to remove water which would also interfere with the measurement of CO. Both the ascarite and silica gel traps are placed in an ice bath.

The EPA Test Method 10 write-up contains detailed instructions for calibrations, leak check procedure, and sampling, along with a list of references. It should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by trained and experienced personnel using equipment and analyzer designed for this purpose.

Test Method 11

Test Method 11 is used to determine the hydrogen sulfide (H_2 S) content of fuel gas streams in petroleum refineries. The H_2S is absorbed by cadmium sulfate solution to form cadmium sulfide.

The sampling train is similar to the one used for Method 6. Five midget impingers are used. The first contains hydrogen peroxide to absorb SO_2, which would interfere with the analysis. The second impinger is empty to prevent carry-over of the peroxide into the cadmium sulfate absorbing solution in the last three impingers. If the gas to be sampled is pressurized, a needle valve is used to regulate the flow. If the pressure is not sufficient, a diaphragm pump is used to draw the sample through the train. A sampling rate of 1 (±10%) liter per minute is maintained for at least 10 minutes. As with Method 6, the train is purged after sampling is complete.

After sampling, the peroxide solution, containing the SO_2 trapped as H_2SO_4, is discarded. The contents of the third, fourth, and fifth impingers are quantitatively transferred to a 500 ml flask. Excess acidic iodine solution is added to the flask. After allowing 30 minutes for the sulfide to react with the iodine, the amount of excess iodine is determined by titration with either 0.01 N sodium thiosulfate or phenylarsine oxide.

The EPA Test Method 11 write-up contains detailed instructions for calibrations, leak check procedure, sampling, and calculations, along with a list of references. It should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by trained and experienced personnel using equipment and the titrations required by this method.

Test Method 12

Test Method 12 is used for the determination of inorganic lead (Pb) emissions from stationary sources. Both particulate and gaseous forms of lead are measured by this method.

The sampling train is identical to the Method 5 train. The water in the first two impingers is replaced by dilute nitric acid to collect any gaseous lead emissions, converting them to the nitrate. The filter is not weighed. Instead it is treated with acid to dissolve the lead compounds, which are then analyzed using atomic absorption spectroscopy. The impinger liquid is evaporated to 15 ml and digested according to the instructions in the method. Once the sample from the impingers is prepared, it is also analyzed by atomic absorption spectroscopy.

The EPA Test Method 12 write-up contains detailed instructions for calibration, leak check procedure, sampling, and analysis, along with a list of references. It should be read in detail before the Method is attempted. Analysis of audit samples, prepared and distributed by EPA's Emissions, Monitoring and Analysis Division, is required. As with all of these methods, testing should be performed only by trained and experienced personnel using the equipment and atomic absorption spectrometer required for this analysis.

Test Method 13A

Test Method 13A is used for the determination of inorganic fluoride from stationary sources as specified in the regulations. It does not measure organic fluorine compounds such as the chlorofluorocarbons (freons).

The sampling train for Method 13A is similar to the Method 5 train, except that the filter can be located either in the standard position or placed behind the third and fourth impingers. If the filter is placed before the impingers, it should be either paper or organic membrane such that it will withstand temperatures up to 135ºC and retain at least 95% of 0.3 μm particles. Distilled water is used in clean-up instead of the acetone used in Method 5.

The total fluoride concentration of the combined filter, probe wash, and impinger contents is determined using the SPADNS Zirconium Lake Colorimetric Method. The sample preparation procedure includes breaking up of the filter, evaporating of the water and fusing with NAOH at 600ºC. The remaining ash is acidified with H_2SO_4, then distilled at 175ºC. SPADNS reagent is added to a suitable aliquot of the distillate and the absorbance at 570 nm compared with standard solution.

The EPA Test Method 13A write-up contains detailed instructions for sample preparation, calibrations, sample analysis, blanks analysis, and calculations, along with a list of references. It should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by personnel trained and experienced with the equipment, chemicals, and the analytical procedures required by this method.

Test Method 13B

Test Method 13B is used for the determination of fluoride emissions from stationary sources. It uses the same sampling and sample preparation procedures as Method 13A. Analysis is with specific ion electrode method instead of the spectrophotometric method used there.

The EPA Test Method 13B write-up contains instructions for calibration along with a list of references. The manual for the specific ion electrode and the meter should be consulted before using this equipment. As with all of these methods, testing should be performed only by personnel trained and experienced with the equipment, chemicals, and the analytical procedures required by this method.

Test Method 14

Test method 14 provides guidance for setting up a sampling system for fluoride emissions from potroom roofs at primary aluminum plants. Gaseous and particulate emissions are drawn into a permanent sampling manifold through several large nozzles. The sample is then transported from the sampling manifold to ground level where it is sampled and analyzed by either Method 13A or 13B.

Anemometers are required for velocity measurements in the roof monitors (the large roof vents at such places). These anemometers are required to meet the specifications in the method for construction material, accuracy, etc. One anemometer is required for every 85 meters of roof monitor length. For roof monitors less than 130 meters, two anemometers are required.

An industrial exhaust fan is attached to the sample duct. The fan capacity must be adjustable and have sufficient capacity to permit isokinetic sampling. The fan is adjusted to draw a volumetric flow rate such that the entrance velocity into each manifold nozzle approximates the average effluent velocity in the roof monitor. A standard pitot tube is used for the velocity measurement of the air entering the nozzles because the standard pitot obstructs less of the cross section than a Type S pitot tube.

The EPA Test Method 14 write-up contains detailed instructions for the set-up, calibration, and use of permanent manifolds for sampling emissions from potroom roof monitors at aluminum plants. It should be read in detail before considering the installation of this type of system.

Test Method 15

Test Method 15 uses gas chromatography for the determination of hydrogen sulfide (H_2S), carbonyl sulfide (COS), and carbon disulfide (CS_2) emissions from stationary sources, such as tail gas control units for sulfur recovery plants. Any gas chromatographic system with a flame photometric detector (FDP) shown to be capable of resolving the compounds of interest and meeting the specifications in the method is acceptable.

A stainless steel or glass probe equipped with a particulate filter is used to extract stack gas continually. Condensed water, carbon dioxide, carbon monoxide, and elemental sulfur can interfere with the analysis. The analyst must show that these substances will not affect the determination. A dilution system is usually employed to reduce the effects of the CO and CO_2. The water condensation problem is minimized by heating the sampling lines by the dilution system. Heating the sampling lines will help to prevent buildup of sulfur in the lines. However, the probe and sampling lines should be inspected after each run and cleaned if necessary. If the probe is observed to be clogged during a run, the run must be repeated. The performance tests for calibration precision and calibration drift must fall within the stated limits. Calibration procedures and leak checks in the method must be followed. Aliquots of the diluted, heated sample stream are withdrawn periodically and injected directly into the GC-FPD for analysis. A sample run consists of a minimum of 16 injections over a period of not less than three hours or more than six hours.

The EPA Test Method 15 write-up contains performance specifications, instructions for sampling and calibration along with a list of references. The manual for the gas chromatograph should be consulted before using this equipment. As with all of these methods, testing should be performed only by personnel trained and experienced with the sampling procedure and gas chromatography required by this method.

Test Method 15A

Test Method 15A is used to determine total reduced sulfur emissions from sulfur recovery plants in petroleum refineries.

An integrated gas sample is extracted from the stack. A measured amount of air is added to the stack gas during sampling. This oxygen enriched mixture is passed through an electrically heated quartz tube at 1100 ± 50°C, and the sulfur compounds are oxidized to sulfur dioxide (SO_2). The remainder of the train is identical to that used for Method 6. The SO_2 collected in the hydrogen peroxide solution is analyzed using the barium-thorin titration technique.

The EPA Test Method 15A write-up contains detailed instructions, along with a list of references. It should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by trained and experienced personnel using equipment and materials designed for this purpose.

Test Method 16

Test Method 16 is a semi-continuous method for the determination of total reduced sulfur (TRS) emissions from stationary sources such as recovery furnaces, lime kilns, and smelt dissolving tanks at kraft pulp mills. Total reduced sulfur includes hydrogen sulfide (H_2S), methyl mercaptan (MeSH), dimethyl sulfide (DMS), and dimethyl disulfide (DMDS). These compounds are separated by gas chromatography and measured with a flame photometric detector.

The interferences, performance specifications, sampling and analysis procedures are very similar to those of Test Method 15.

The EPA Test Method 16 write-up contains instructions, along with a list of references. It should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by trained and experienced personnel using equipment and materials designed for this purpose.

Test Method 16A

This method is applicable to the determination of total reduced sulfur (TRS) emissions including hydrogen sulfide (H_2S), carbonyl sulfide (COS), dimethyl sulfide (DMS), and dimethyl disulfide (DMDS).

The sampling train for Method 16A is similar to the Method 15A train except that there is a citric acid scrubber before the oxidation tube to remove sulfur dioxide. Because the sources that would use this method have sufficient oxygen in their exhausts, additional air is not added before the oxidation step. The oxidized sulfur compounds are collected and analyzed as in Method 6. Sampling runs are either three hours, or three samples collected for one hour each. This provides data that are comparable with Method 16, which requires runs to be from three to six hours.

A system performance check is done to validate the sampling train components and procedure before the test and to validate the results after the test. Audit samples for Method 6 are used with this method.

The EPA Test Method 16A write-up contains instructions, along with a list of references. It should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by trained and experienced personnel using equipment and materials designed for this purpose.

Test Method 16B

This method is applicable to the determination of total reduced sulfur (TRS) emissions, i.e., hydrogen sulfide (H_2S), carbonyl sulfide (COS), dimethyl sulfide (DMS), and dimethyl disulfide (DMDS).

The sampling and analytical equipment and procedures train for Test Method 16B is similar to those used in Method 16A, except that gas chromatography is used to determine the SO_2 formed by the oxidation of the TRS, instead of the Method 6 procedure. There must be at least 1% oxygen in the stack gas for the oxidation procedure to work properly. As with Method 16, 16 injections are required per run over a period of not less than three hours nor more than six.

A system performance check is done to validate the sampling train components and procedure before the test and to validate the results after the test.

The EPA Test Method 16B and the other methods incorporated by reference contain instructions, along with a list of references. These should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by trained and experienced personnel using equipment and materials designed for this purpose.

Test Method 17

Test Method 17 is used for the measurement of particulate emissions from stationary source using an in-stack filter. In this method, unlike Method 5 in which the filter housing is maintained at 250 ± 25°F, there is no control of the filter temperature. This is important since particulate matter is not an absolute quantity, but dependent on the temperature at which it is measured. For example, some hydrocarbons are solids at the Method 5 standard temperature, but would not be solid at a stack temperature of 400°F. However, controlling the temperature of the filter can be difficult. Therefore, when particular matter is known to be independent of temperature, it is desirable to eliminate the glass probe liner and heated filter system necessary for Method 5 and to sample at the stack temperature using an in-stack filter. This method is intended to be used only when specified by the applicable regulation and only within the applicable temperature range. Except for the filter, this method is very similar to Method 5.

The EPA Test Method 17 and 5 write-ups contain detailed instructions, along with a list of references. They should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by trained and experienced personnel using equipment and materials designed for this purpose.

Test Method 18

Test Method 18 uses gas chromatography (GC) to determine the identity and concentration of organic compounds emitted from stationary sources. This method is based on the ability of a material in a GC column to separate a mixture of gaseous phase organic mixtures into its component compounds. An appropriate detector must be chosen to provide a response when a compound of interest passes through it. A chart recorder provides a plot of detector response versus time. When a compound separated by the column passes through the detector, the signal increases from the baseline to a maximum then returns to the baseline; this is called a peak. The time from when the mixed sample was injected to the time of maximum peak height is the retention time. The compounds are tentatively identified by comparison of the retention time with that of known compounds. The components are then quantified by comparison of the peak height with that of known concentrations of the identified compound.

There are many variables in gas chromatography, making the GC a very versatile tool. However, these parameters require careful selection to provide the necessary separation and quantification. They include: column material, column temperature, column packing material, carrier gas glow rate, injection port temperature, detector type, detector temperature, etc.

A presurvey is necessary before the actual sampling to determine the VOCs present and their approximate concentration. A presurvey sample is collected in an evacuated glass flask, purged through a glass flask, or collected in a tedlar bag. The sample containers are then heated to duct temperature to vaporize any condensed compounds. The optimum chromatographic conditions for separation are determined. If any peaks are not identified by comparison with known samples, other techniques such as GC/mass spectroscopy can be used for identification.

Based on the presurvey analysis, calibration standards are prepared. There should be at least three standard concentrations bracketing the expected concentration for each compound found during the presurvey. A calibration standard may contain more than one compound.

The final sampling can take four forms: integrated bag sample, direct injection, diluted interface sampling, and the adsorption tube procedure. For the integrated bag sample, a tedlar bag is placed in a rigid container then filled by evacuating the container. This sucks sample gas into the bag, eliminating the possibility of contamination or absorption by a sampling pump. The bag should be heated to the source temperature before analysis. The contents of the bag are flushed through a heated gas sample loop on the GC. An automated valve injects the contents of the loop onto the chromatographic column. The resulting peaks are identified by retention time comparison and quantified against the prepared standards. Bags should be analyzed within two hours of collection.

The direct injection technique does not permit integrated sampling, however it does eliminate the possibility of adsorption or contamination by the bags. All sampling lines must be maintained at stack temperatures to prevent condensation. The sample is sucked directly through the gas sample loop. Analysis is the same as for bag samples.

The dilution interface sampling and analysis procedure is appropriate when the source concentration is too high for direct injection. The stack gases are diluted by a factor of 100:1 or 10:1 by the addition of nitrogen or clean dry air.

Adsorption tubes can be used to collect organic compounds from stack gases. The selection of the adsorben is based on the chemicals present in the stack gas. Once a known volume of gas has been drawn through the tube the tube can be taken back to the laboratory for analysis. Tubes can generally be stored up to a week by refrigerating a sample. Once back at the laboratory, the adsorbent is extracted with suitable solvent and the solvent analyzed by GC. There are many variables that affect the efficiency of the tube for collecting representative samples. The quantitative recovery percentage of each organic compound from the adsorbent material must be known. When the adsorbent capacity of the tube is exceeded, material will break through the tube and not be collected. This is dependent on the sample matrix, i.e. the amount of moisture and the effect of other compounds competing for the adsorbent.

The EPA Test Method 18 write-up and the QA Handbook Section 3.16 contain detailed instructions for sampling, analysis and calibrations, along with a list of references for many organic compounds of interest. Both should be read in detail before the Method is attempted. Testing should be performed only by personnel trained and experienced with source sampling and gas chromatography. Audit samples are available for many compounds through EPA's Emissions, Monitoring and Analysis Division.

Test Method 19

Test Method 19 is not a stack test method. Instead, it contains procedures for measuring the sulfur content of fossil fuels. It also contains extensive procedures for calculating emission rates for particulates, nitrogen oxides (NO_x) and sulfur dioxide (SO_2) and for calculating SO_2 removal efficiency, all for electric utility steam generators. These calculations are based on sulfur in fuel measured by this method, on stack gas concentrations measured by the appropriate methods, and by ultimate fuel analyses (determination of the major elemental constituents in samples).

The sulfur content in fuel, either before or after pretreatment, is determined using ASTM procedures specified in this method. The primary consideration is the representativeness of the sampling procedure. The SO_2 removal efficiency of the pretreatment is calculated by the standard (in-out)(in) procedure, in which the 5% values are corrected for the gross caloric value of the fuel to compensate for changes in mass related to the S removal. SO_2 removal attributed to the flue gas desulfurization unit is calculated in the same way, but without need for correction. Overall percent removal is calculated from them.

Many regulations prefer particulate, SO_2, and NO_x emission rates to the heat input to the boiler, as "pounds/million Btu." In order to calculate these values, the emission rates must be corrected by so-called F factors to account for the different heat content of the fuel and the excess combustion air. This method includes detailed procedures or calculating F factors from ultimate analyses and average F factors for various fuels. It also includes procedures for correcting for moisture and for combining various results together.

Finally, Method 19 describes procedures for combining the SO_2 emission rates calculated before and after a control device for determining removal efficiency.

Test Method 20

Test Method 20 is used for determining the nitrogen oxide (NO_x) emission rate from stationary gas turbines. Since measurement of oxygen (O_2) or carbon dioxide (CO_2) is needed in order to calculate NO_x emissions, this method also includes procedures for their determination. Finally, the method includes provisions for calculating sulfur dioxide (SO_2) emissions based on Method 6 measurements of SO_2 and diluent measurements from this method.

The basic principles of this method is that a gas sample is extracted from eight or more traverse points, filtered, stripped of moisture, and fed to automatic NO_x and diluent analyzers. The results of the instrument readings are then used to calculate the NO_x and/or SO_2 emission rates.

The sampling train begins with a heated probe, a calibration valve (where calibration gases can be added instead of stack gas), a moisture trap, a heated pump, an automatic analyzer for either O_2 or CO_2 (to indicate the amount of excess air in the exhaust stream), a NO_2 to NO converter (to ensure the inclusion of all NO_x molecules in the analysis), and a NO_x analyzer.

The method includes detailed specifications for the calibration gases and for the analyzers. All of the calibration gases must be either traceable to National Institute of Standards and Technology Standard Reference Materials (NIST SRMs) or must be certified in a manner specified in the method. The analyzers must be able to pass a calibration check and must be subjected to a response time determination. The NO_x monitor must pass an interference response check (to ensure that high levels of CO, CO_2, O_2, and/or SO_2 will not interfere in its performance). In addition, the NO_2 to NO converter must be checked with calibration gases to ensure that the conversion will be stable at peak loading.

Before conducting the actual NO_x and diluent measurements, a sampling rate and site must be selected and a preliminary diluent traverse performed. Site selection is both important and difficult. The method presents some factors to be considered, such as turbine geometry and baffling, but leaves to the testing team the selection of a representative location. The guidance provided in section 6.1.1. of the method should be read carefully before a site is selected. The preliminary traverse is then performed, sampling for a period of one minute plus the instrument response time at each of at least eight points (The number of points, between eight and 49, is determined by a calculation procedure included in the method) for the purpose of selecting the eight sampling points exhibiting the lowest O_2 concentration or the highest CO_2 concentration. Those are the points expected to show the highest NO_x concentrations and are the eight to be sampled for both NO_x and diluent.

Three test runs constitute a test at each load condition specified in the regulation. A run consists of sampling at each designated traverse point for at least one minute plus the instrument response time.

The measured CO_2 and NO_x values are then averaged algebraically and corrected to dry conditions using data from a Method 4 traverse. The CO_2 concentration is corrected to account for fuel heat input by using an F factor obtained from Method 19 (either from the Table there or by calculation based on ultimate analysis). Both NO_x and diluent concentrations are then corrected to 15% O_2 (to ensure consistent comparison with regulatory standards). Finally, the emission rates are calculated using the corrected concentrations. The most sensitive portion of Method 20 is the calibration and operation of the diluent analyzer, as the diluent concentration strongly affects the NO_x corrections. All of the procedures should be attempted only by trained personnel using appropriate equipment.

Test Method 21

Test Method 21 is used for determining Volatile Organic Compound (VOC) leaks from process equipment. The method actually presents three different ways for determining leaks. The first and most common way is to place the nozzle of a portable instrument right against the potential leak source. If the instrument reads above an arbitrarily defined value, a leak is found. The second way is for screening prior for conducting a survey with the portable instrument. This screening is performed by spreading a soap solution on the flange, for example, and looking for bubbles. The third way to look for leaks is to look for the absence of leaks. This is performed by measuring background concentration in the vicinity of the process equipment with the portable instrument and then determining whether the concentration at the equipment is significantly higher than background. The choice of procedure is dictated entirely by the prevailing regulation.

The second factor dictated by the applicable regulation is the definition of a leak. Method 21 defines all characteristics of a leak but one. As stated above, Method 21 procedures determine that a piece of equipment is leaking when the instrument is placed against it and reads above an arbitrarily defined value. The regulation must supply the value. Typical levels are 10,000 ppmv or 25,000 ppmv. The definition of no detectable emission is then defined as a reading less than 5% of the leak value above background. Thus, if background is 500 ppmv and the leak definition is 25000 ppmv, no detectable emission is reported at less than $0.05 \times 25000 + 500 = 1750$ ppmv.

Method 21 contains detailed specifications for the selection calibration, and operation of the instrument, without specifying the detector. Flame ionization detectors and photoionization detectors are the most common, but others, such as infrared absorption, have also worked successfully for this purpose. One of the most important criteria for selecting an instrument is its ability to detect the compounds of interest at the necessary concentration levels.

In order to allow consistent instrument selection and calibration, a single compound is generally specified in the regulation as the reference compound. All calibrations and instrument checks are then performed using calibration gases that are mixtures of that compound in air. A two point calibration is performed, using zero air, at one end, and a concentration close to the leak definition at the other.

Method 21 also contains detailed instructions for conducting leak detection surveys, describing acceptable procedures for measuring leaks at various types of equipment. These surveys may be conducted by personnel who have been trained to do so but who may not know the details of instrument troubleshooting, etc. However, someone at each facility performing the survey should be qualified to work on the instruments.

Test Method 22

Test Method 22 is used for determining fugitive emissions and smoke emissions from flares. Like Method 9, it is a visual method performed by trained observers. However, this method is not a quantitative method. This method involves only the timing of the observed emission and the calculation of the fraction of time that the emission is observed.

Fugitive emissions include all emissions that are not emitted directly from a stack or duct. They include emissions from doors, windows, cracks or holes as well as emissions from piles or directly from process equipment or operations.

In order to perform valid readings, the observer finds a suitable location more than 15 feet from the source, starts a stopwatch to record elapsed observation time, and begins observing the source. The observer continuously observes the source, starting a second stopwatch when emissions are noted, stopping it when they stop. This process continues until either the regulatory requirement has been met or 15 to 20 minutes have elapsed. At that point, the observer must take a 5 to 10 minute break. The clock time of all observations and the time and duration of emission observation should be recorded on an appropriate form, along with a suitable description and drawing of the observation position, etc.

Observers need not pass the certification exam of Method 9 but must have training equivalent to the classroom part of Method 9 certification.

Test Method 24

Test Method 24 is not a stack test method. Instead, it is used to determine the amount of volatile organic solvent used to determine the amount of volatile organic solvent water content, density, volume of solids, and weight of solids of surface coatings. This method applies to paints varnish, lacquer, and other related coatings. American Society of Testing Methods (ASTM) procedures have been incorporated by reference into this test method.

Test Method 24A

Test Method 24A is not a stack test method. Instead, it is used to determine the volatile organic content (VOC) and density of printing inks and related coatings.

The amount of VOC is determined by measuring the weight loss of a one to three gram sample heated to 120 ± 2°C at an absolute pressure of 510 ± 51 mm Hg for 4 hours or heated in a forced draft oven at atmospheric pressure for 24 hours. The coating density and solvent density are determined using ASTM D 1475–60, which is incorporated to this method by reference.

The EPA Test Method 24A write-up and the ASTM method contain detailed instructions for sample preparation and analysis. These should be read before attempting this method.

Test Method 25

This method is used to determine the emissions of total gaseous non-methane organics (TGNMOs) as carbon. It is used mainly for testing sources such as combustion sources for which the organic constituents of the emission are unknown and/or complex. The collected sample is injected onto a gas chromatographic column where the TGNMOs are separated from CO_2 and methane. Using an unusual backflush procedure, the TGNMOs are then oxidized to CO_2, catalytically reduced to methane, and analyzed using a flame ionization detector. By measuring the organics in this way, the difference in flame ionization response factors for various organic compounds that may be present is eliminated.

There are some limitations of this method, which the analyst should be familiar with.

1) Organic particulate matter will interfere with the analysis, giving higher values than actual. This can be eliminated by using a heated filter.
2) The minimum detection limit is 50 ppm as carbon.
3) When both water and CO_2 are present in the stack gas there can be a high bias in the concentration of the sample. This is due to the inability of the chromatographic column to separate the carbon dioxide from the hydrocarbons when large amounts of CO_2 and water are present in the sample gas. When the product of the percent water times the percent CO_2 is greater than 100, this bias is considered to be significant. In such cases, other methods should be used.

An emission sample is drawn at a constant rate through a heated filter and then through a condensate trap cooled with dry ice into an evacuated sample tank. The probe is heated to maintain an exit gas temperature of at least 129ºC (266ºF). The filter is heated in a chamber capable of maintaining a gas temperature of 121 ± 3ºC (250 ± 5ºF). The sample tank must be leak checked and cleaned by the procedures described in the method. The pressure of the sample tank is measured before and after sampling, and this information is used to determine the amount of sample collected. After sampling the sample tank valve is closed and the condensate trap is capped.

The condensate trap will contain water, CO_2, and condensed organic compounds. The CO2 will interfere with the analysis of the organics in the trap. CO2 is removed by purging the trap with clean air into the original sampling tank. The method describes this procedure in more detail and includes a figure showing the recommended equipment. After the purge is complete, the sample tank is pressurized to 1060 mm Hg absolute. The condensate tube is then connected to an oxidation catalyst and heated while purging with air or oxygen. The water collected with the sample and that produced by the oxidation of the hydrocarbons is removed with a cold trap. The CO_2 produced from the oxidation of the condensed organic compounds is collected in an intermediate collection vessel.

The analysis of the gas in the sample collection tank and the intermediate collection vessel both use gas chromatographic separation. The gas chromatograph column and operating conditions are chosen to separate CO, CH_4, and CO_2. These compounds are first oxidized then reduced to methane that is quantified by the flame ionization detector. The non-methane organics are retained on the column. A valve then reverses the flow of carrier gas through the column, back flushing the organics off the column through the oxidation then reduction catalyst before going to the detector. The TGNMO concentration is the sum of the non-methane organics and CO_2 from the intermediate sampling vessel.

The Method requires extensive quality assurance and quality control measures to insure that valid data are produced. The analysis of two audits gases provided by the Emissions, Monitoring and Analysis Division at Research Triangle Park, NC is required in the Method. This method should be performed only by personnel familiar with the sampling method and the gas chromatography necessary for the analysis. There have been recent changes in this Method; therefore it should be read carefully by all persons involved in its use.

Test Method 25A

Test Method 25A uses a Flame Ionization Analyzer (FIA) that has a flame ionization detector to directly measure that total gaseous organic compounds from a stationary source. A gas sample is extracted from the center of the stack. The sample is filtered if necessary to remove particulates which could give high readings or clog the detector. The concentration is expressed in terms of propane or the concentration as carbon is calculated.

This method is much simpler to perform than Method 25. However, there are two major limitations that must be understood.

1) The FIA will not separate or identify the organic compounds present.
2) The response of the detector is different for each compound.

Method 25A is the method of choice for the following situations.

1) When only one compound is present.
2) When the organic compounds present consist of only hydrogen and carbon, in which case the response factor will be about the same for all.
3) When the relative percentages of the compounds are known, in which case proper calibration standards can be prepared.
4) When a consistent mixture of compounds is present before and after an emission control device, and only the relative efficiency is to be determined.
5) When the FIA can be calibrated against mass standards of the compounds emitted.

This method will not distinguish between methane and nonmethane hydrocarbons. If this is required, Method 25 should be used or methane should be determined using Method 18 and subtracted.

The following Measurement System Performance Specification must be passed by the instrument before actual environmental samples are analyzed:

1) Analyzer Calibration Error must be less than ± 5% of the span for the zero, mid-range, and high-range calibration gases.
2) Zero Drift must be less than ± 3% of the span over the period of each run.
3) Calibration Drift must be less than ± 5 of the span over the period of each run.

The analytical range must be selected based on the applicable regulation and is usually 1.5 to 2.5 times the emission limit. The EPA Test Method 25A write-up contains detailed descriptions of the calibration gases required, calibration procedures, sampling procedures in addition to a list of references. It should be read in detail before the Method is attempted. The manufacturer's instructions will provide instrument specific instructions. Testing should be performed only by personnel trained and experienced with the equipment being used.

Test Method 27

Test Method 27 is used for determining leaks from gasoline delivery tank trucks or rail cars. It does not involve actual measurements of gasoline emissions. Instead, it involves the pressurization and/or evacuation of the tank and the subsequent measurement of the pressure and/or evacuation of the tank and the subsequent measurement of the pressure and/or vacuum after a given number of minutes. The pressure, time span, and allowable pressure change are all specified in the applicable regulation. Typically, the initial pressure is 450 mm water, with an allowable pressure loss of 75 mm water after five minutes.

Prior to conducting this test the tank must be emptied of both gasoline liquid and gasoline vapor and must be thermally stabilized. This is best accomplished by flushing the tank with a non-volatile liquid such as heating oil. In addition, care must be exercised to protect against fire by ensuring proper electrical grounding of the tank.

A suitable pump is attached to the tank and pressure or vacuum applied until the specified level is reached, as indicated on a liquid manometer or other instrument capable of reading up to 500 mm water gauge pressure, with ± 2.5 mm precision. The valve is then shut and the reading taken again after the specified period.

This test method should be performed only by people experienced in dealing with gasoline delivery equipment and operation.

Test Method 101

Test Method 101 is used to determine the emissions of gaseous and particulate mercury (Hg) when the gas stream is predominantly air. It is used mainly at chloralkali facilities that produce chlorine gas from salt in mercury-based galvanic cells. The gas stream is extracted from the stack isokinetically using a sampling train like the standard Method 5 train.

The main differences are that the impingers contain an iodine monochlorine solution (ICI), and no filter is employed. The probe must be lined with borosilicate or quartz glass tubing to prevent reactions with the mercury.

The method relies on the reaction of both particulate and gaseous mercury with the ICI to form $HgCl_2$, which remains in the impinger solutions. During subsequent analysis, the $HgCl_2$ is reduced to elemental mercury with a solution of HCI and $SnCl_2$, forming H_2SnCl_6. The mercury is then aerated into an optical cell where it is measured by atomic absorption spectrophotometry (AA).

Sample train preparation is about the same as for Method 5, with a few exceptions. First, care must be taken in selecting the nozzle size to allow the use of a single nozzle for each entire test run. Second, the 0.1 M ICI solution must be prepared, used to clean the impingers, and added to them. Third, it may be necessary to break a 2 hour sampling run into two or more subruns if high Hg or SO_2 concentrations lead to liberation of free iodine (evidenced by reddening of the first impinger solution). Finally, an empty impinger may be used as a knock-out chamber prior to the silica gel to remove excess moisture.

Calibration of the sampling train and actual sampling proceed exactly as with Method 5, as do calculations of percent isokinetic conditions. Sample recovery is essentially the same as for method 5 except that 0.1 M ICI solution is used as the rinse solution, to ensure capture of all mercury from the probe walls, etc.

The analytical system of this Method is designed to free the Hg from solution and to allow the Hg vapor to flow into an optical cell connected to an AA spectrophotometer that records the absorption at 253.7 nm light, the characteristic wavelength of Hg. This is accomplished by mixing a stannous chloride solution with aliquots of the recovered sample in a closed container then aerating with nitrogen. The nitrogen carrier-gas and the Hg then flow through the optical cell.

The flow rate through the aeration cell is calibrated with a bubble flowmeter or a wet test meter. The heating system for the optical cell, needed to prevent condensation on the cell windows, is calibrated with a variable transformer. The spectrophotometer itself is calibrated by using six different aliquots of a 200 ng/ml working solution of mercury, repeating each analysis until consecutive pairs agree to within ±3% of their average. Either peak area or peak height may be used. The aliquots are added to the aeration cell and N_2 bubbled through as during cell calibration, except without the flowmeter. A straight line is then fitted through the five points; it must pass within ±2 percent of full scale of the origin.

Analysis follows the same procedures as calibration except that aliquots of diluted sample are substituted for the working standard. Again, the aerated sample from each aliquot is analyzed until consecutive pairs agree to within 3%. The average is then compared to the calibration line and used in the succeeding calculations for determining the mass of mercury in the original sample solution. This value is then combined with the stack and flow volume factors in the same way as for Method 5 to arrive at the total mercury emission rate, in grams/day. Isokinetic variation and test acceptability are also determined according to Method 5 criteria.

The EPA Method 101 write-up contains detailed instruction for each of these steps, along with estimates of range, sensitivity, accuracy, precision, possible interferences and a list of references. It should be read in detail before the Method is attempted. Also, as with all of these methods, testing should be performed only by trained and experienced personnel using equipment and materials designed for this purpose.

Test Method 101A

Test Method 101A is used to determine total particulate and gaseous mercury (Hg) emissions from sewage sludge incinerators. It is almost identical to Method 101. The gas stream is sampled isokinetically using, essentially, a Method 5 sampling train and bubbled through an acidic potassium permanganate ($KMnO_4$) solution where the mercury is collected and held in solution. During subsequent analysis, the mercury is reduced to elemental form, and aerated into an optical cell where it is analyzed by an atomic absorption spectrophotometer.

The main differences from Method 101 are as follows:

- There are two main differences in the sampling train. First, the impingers are filled with an acidic solution of 4 percent $KMnO_4$ solution instead of ICl. Second, a filter may be used prior to the impingers if the exhaust gas stream is expected to contain high concentrations of particulate matter.
- Analysis, including calibration, is also essentially the same as for Method 101 except for modifications related to the change from ICl to $KMnO_4$ as the oxidizing agent. In this case, the reducing solution is an acidic solution of $SnCl_2$, as in Method 101 plus sodium chloride hydroxylamine. The rest of the procedure is generally the same.

As for Method 101, the EPA Method 101A write-up should be read in detail, and the method should be attempted only by experienced personnel.

Test Method 102

The Method 102 is used to determine the emissions of particulate and gaseous mercury (Hg) when the gas stream is predominantly hydrogen. Such streams are common at chlor-alkali facilities that produce chlorine gas from salt in mercury-based galvanic cells. The equipment, procedures, and calculations are identical to those employed in Method 101 except for special safety precautions related to the flammability and explosiveness of hydrogen streams or related to hydrogen's low molecular weight.

For example, probe heaters, fans, and timers are used. Also, venting provisions are more elaborate. Finally, meter box calibrations must be performed with hydrogen or other special gases.

As with all other procedures, the EPA Method should be read in detail and attempted only by trained personnel using proper equipment. This is even more important than normal because of the serious risk of explosion.

Test Method 103

Test Method 103 is used as a screening method for determining approximate emissions of beryllium (Be). The Method has not been extensively verified and is generally used to produce order to magnitude estimates. If the results of a Method 103 test show the Be emissions to be within a factor of 10 or so of the level of interest (such as a regulatory emission standard), the test would normally be repeated using Method 104, which is much more reliable, if more expensive.

Method 103 uses a rough isokinetic sampling procedure, in which a sample probe is placed at only three locations along a stack diameter. The sample train consists of a nozzle and probe connected to a filter and a meter-pump system. No impingers are used.

Sample site location and train operation are the same as for Method 5 except, of course, for the reduction in the number of points and the absence of impingers. Points are chosen at 25, 50, and 75 percent of the stack diameter at the selected location. Sample recovery with acetone is also essentially the same.

Test Method 104

Test Method 104 is used to measure beryllium (Be) emissions at Be extraction plants, machine shops, ceramic plants, etc. The gas stream is extracted from the stack isokinetically using a Method 5 sampling train and Method 5 calibration and sampling procedures with a few minor exceptions. The sample is also recovered according the Test Method 5. The sample is then digested in acid and analyzed for Be by atomic adsorption spectrophotometry (AA). Once the sample has been collected and recovered, the solution is digested by addition of concentrated HNO_3, heating until light brown fumes indicate destruction of all organic matter, cooling, and subsequent addition of concentrated H_2SO_4 and concentrated $HClO_4$. The resulting solution is evaporated to dryness and redissolved in HCl. During this process, extreme care must be taken to avoid emanation of dangerous perchlorates. Therefore, all work should be done under an appropriate hood.

Analysis is then performed using a nitrous oxide/acetylene flame AA at 234.8 nm. If aluminum, silicon or certain other materials may be present, interferences may exist. They can be eliminated by following procedures cited in the Test Method. Calibration follows the AA manufacturer's specifications with specific provisions for dealing with cases in which the concentration of the sample is outside the normal calibration range.

The EPA Test Method 104 write-up contains detailed instructions, along with a lists of references. It should be read in detail before the Method is attempted. As with all of these methods, testing should be performed only by trained and experienced personnel using equipment and materials designed for this purpose. This is especially true for this Method, considering the hazard associated with Be exposure, as well as the perchlorate danger.

Test Method 105

Test Method 105 is not a stack testing method. Instead, it is the method used by EPA for estimating the maximum possible emissions of mercury from sewage sludge treatment plants. This is accomplished by measuring the mercury content of the feed sludge, multiplying this by the maximum feed rate to calculate the maximum emissions if all of the mercury in the sludge were to go up the stack. Method 105 thus serves as an inexpensive screening method for use at plants that expect their emissions to be well below the emission standard.

The Method requires the collection of about one liter of sludge each half hour for 8 hours. The samples are then combined into one, weighed, digested in potassium permanganate, and analyzed as in Method 101A, using atomic spectrophotometry.

Details, including the range, limitations, reagents, and equipment, may be found in the method write-up. Even though the field portion of this test is relatively straightforward, it should be performed only by trained personnel.

Test Method 106

Test Method 106 is used to measure the emissions of vinyl chloride monomer (VCM) in stack gas. It does not measure VCM in particulate matter. Stack gas is withdrawn from the centroid of the stack into a tedlar bag using the bag-in-a-box technique that isolates the sample from the pump. The sample is then analyzed directly using a gas chromatograph-flame ionization detector (GC-FID).

The sampling probe for this method is a standard stainless steel probe. The rest of the sampling train is unusual, however, because most of it is actually never seen by the sample. The probe is connected directly by new teflon tubing to an empty tedlar bag (usually between 50 and 100 liters capacity). The bag is sealed in a large box that is, in turn, connected to a needle valve, pump, carbon tube, and rotameter for measuring the flow. As the pump evacuates the air in the box, the bag sucks gas from the stack. Through the use of this indirect pumping procedure, there is no need for concern for contamination from the pump, or loss of VCM in the pump. While elaborate box configurations are available, a 55 gallon drum with two fittings and a sealable top works fine.

Prior to sampling, the bags and the box should be leak checked. Just before sampling, the bag should be partially filled with stack gas to condition the bag and purge the sample lines. It is then emptied by switching the pump to the bag fitting. Sampling then proceeds at a fixed rate proportional to the stack flow rate.

The GC-FID is calibrated by injection of 3 VCM standard gases prepared from a single certified 99.9% cylinder of VCM gas or cylinder standards appropriately certified by the manufacturer. During calibration and subsequent sample analysis, the VCM peaks must be of sufficient size and must not overlap with interfering peaks (such as acetadehyde). Procedures for calculating overlap are provided in Appendix C to 40 CFR Part 61 (right after the NESHAPS Test Methods). Procedures for minimizing overlap and interference are mentioned in the Method but are not specified. This is why an experienced GC operator is required for this analysis.

Immediately before analyzing samples, the analyst must analyse 2 audit gas cylinders supplied by EPA or another independent party. These audit cylinders contain concentration of VCM in nitrogen in 2 ranges to ensure the accuracy of the analytical procedures.

The sample is then injected directly into the GC-FID. The ratio of the peak height to peak area for the VCM peak is compared to the ratio for the nearest peak standard peak. If they differ by more than 10%, interference is probably present and an alternate GC column is needed. It is strongly recommended that the laboratory be given actual samples of stack gas for analysis at least a day before on official test is to take place. This will allow time to select appropriate levels for the standard gas concentrations and to determine whether alternate GC columns are required.

The concentration of VCM in the bag is then calculated using the GC calibration curve and the temperature, pressure, and humidity in the stack. This process is usually repeated for three test runs.

After the sample is extracted from the bag, the bag must be leak checked by filling it with air and connecting it to a water manometer. Any displacement of the manometer after 10 minutes indicates a leak. The box must also be checked for leaks. This is accomplished by placing the bag in the box-and evacuating the bag with a rotameter in line before the pump. Any displacement of the rotameter after the bag appears empty indicates a leak.

During the entire sampling and analytical procedure, extreme can must be taken to avoid exposure to the VCM gas, which is carcinogenic. The carbon tube included in the sampling train is for the purpose of absorbing VCM. Nevertheless, the tubing existing the pump should be aimed well away from the sampling team. Similarly, all laboratory work should be performed in appropriate vented or hooded areas. This is one more reason why this test for VCM should be performed only by experienced personnel who are extremely familiar with their equipment and with the procedure.

Test Method 107

Test Method 107 is not a stack testing method. It is used for determining the Vinyl Chloride Monometer (VCM) content of water or slurry samples associated with the manufacture of polyvinyl chloride (PCV) from VCM. Such sampling is often required as part of a comprehensive program for measuring the total VCM emitted from a PCV facility, to ensure that VCM removed from exhaust gas streams is not simply transferred to a water stream and discharged into the environment.

The method involves the collection of a sample of the wastewater stream or a stream of slurry containing PCV resin in a 60 ml vial, quickly capping the vial without trapping any air, and refrigerating. The vial is then conditioned at 90ºC for an hour. During that time the VCM dissolved in the water or remaining in the resin (termed Residual VCM, or RVCM) will reach equilibrium with the material that vaporizes, forming the so-called headspace in the vial.

The headspace is subsequently sampled by syringe and injected into a Gas Chromatograph-Flame Ionization Detector (GC-FID). The GC-FID is calibrated using vials filled with standard gas mixtures bracketing the expected range. The VCM concentration in the samples is calculated from the GC-FID response factor.

As with the other VCM Test Methods, this procedure should be performed only by trained individuals taking special precautions to avoid exposure to the carcinogenic VCM vapors.

Test Method 107A

Test Method 107A is not a stack testing method. It is a method used for determining the Vinyl Chloride Monomer (VCM) content in solvent solutions or in polyvinyl Chloride (PCV) resin slurry samples. This procedure supplements stack testing at PCV manufacturing facilities for determining the overall emissions of VCM from exhaust gas streams as well waste water and fugitive sources.

The method involves the collection of liquid or slurry samples in tightly capped 20ml glass vials. A small amount of the sample material is subsequently withdrawn by syringe and injected into a Gas Chromatograph (GC), where the sample vaporizes and is analyzed for VCM content. The GC is calibrated using standard solutions of VCM in an appropriate solvent. VCM content in the sample is calculated based on the response factor of the GC.

As with other VCM Test Methods, this method should be attempted only by trained personnel who should take special precautions to avoid exposure to the carcinogenic VCM vapors.

Test Method 108

Test Method 108 is used to determine stack gas emissions of particulate and gaseous forms of inorganic arsenic (As) from stationary sources. The principle is that a side stream is withdrawn isokinetically and both the particulate and gaseous forms are collected on a filter and in water solution. The arsenic is then concentrated, combined into one sample, and analyzed by flame atomic absorption (AA) spectrophotometry.

Sample train construction and operation are almost exactly ad described in Method 5 to ensure isokinetic sampling. Two of the impingers need to be modified slightly, the filter box is heated, and the sample flow rate is reduced.

The filter sample is recovered by digestion. Each portion of the sample (the impinger and filter catches) is then prepared for analysis by combining with nitric acid and boiling to dryness.

If sample concentrations are sufficiently low, special procedures must be followed to the detection limit of the AA. Either a Vapor Generator Procedure or a Graphite Furnace Procedure may be employed, following steps detailed in the Method and in the manufacturer's instructions.

Calibration standard solutions are prepared from stock arsenic solutions. The stock solutions are prepared by dissolving As_2O_3 in NaOH, adding nitric acid, heating to dryness and reconstituting with water. The calibration standards are then prepared by diluting aliquots of the stock solution with nitric acid. The sampling train is calibrated in much the same way as for Method 5.

Standard absorbances are then determined against blank levels. Samples are then run in the same way, with concentrations determined form the resulting calibration curve.

Concurrent with analysis of samples, special Quality Assurance Audit Samples must be analyzed. These samples are prepared and supplied through EPA's Emissions, Monitoring and Analysis Division in North Carolina. To be effective in evaluating the analyst's technique and the standards preparation, the Audit Samples must be analyzed by the same people and using the same equipment that will be used throughout the test program. EPA or the State agency must be notified at least 30 days in advance to ensure timely delivery of the Audit Samples.

The As concentration in the original stack gas is then computed with reference to the gas flow rate, moisture content, and measured As content.

As with all of these Test Methods, Method 108 should only be attempted by properly trained personnel using appropriate equipment.

Test Method 108A

Test Method 108A is not a stack sampling method. Instead, it is a procedure for measuring the Arsenic (As) content of As ore samples, particularly form nonferrous foundries. It is used primarily for determining the As feed rate, often needed to calculate As emission rate relative to feed rate.

In this method, the ore sample is finely pulverized, digested in hot acid, and filtered. Depending on the concentration of the sample, it is then analyzed either by flame atomic absorption spectrophotometry or by the graphite furnace procedure. In either case, the manufacturer's instructions are followed.

There are also two mandatory Quality Assurance checks associated with this procedure. First, there is a check for matrix effects, identical to the one described in Test Method 12. Second, it is required that all laboratories analyzing samples according to this method first acquire audit samples prepared and distributed by the Emissions, Monitoring and Analysis Division of US EPA, as with Method 12. These are to be analyzed along with the actual samples. The address for obtaining these samples is included in the Method.

As with all of these Test Methods, they should only be attempted by properly trained individuals, using appropriate equipment.

Test Method 111

Test Method 111 is used for measuring the emissions of Polonium (Po)-210 in stack gases. The sampling is exactly as in Method 5. In the analysis, the particulate Po-210 is dissolved in solution and deposited on a silver disc. The radioactive disintegration rate is measured using an alpha spectrometry system.

After sampling using the Method 5 train and techniques, the filter containing the sample is prepared for analysis. Care must be taken to complete analysis within 30 days of sampling to ensure that the results are not biased high as the result of decay of lead 210.

Sample preparation consists of repeated dissolution of the sample filter in concentrated hydrofluoric acid and heating to dryness until the filter is gone. The sample is then dissolved in a mixed acid solution and prepared for screening. The screening is designed to determine the approximate radioactivity of the sample, allowing the selection of an appropriate sample concentration to protect the detector. Once the aliquot size is chosen, an amount of Pb-209 is added in approximately equal activity. This will be used to assess Po recovery in the spectrometry system.

A specially prepared 3.8 cm silver disc, with one side painted to prevent deposition, is suspended in the heated sample solution for 3 hours. After rinsing in distilled water, the disc is placed in the alpha spectrometry system and its emissions counted for 1000 minutes. The picocuries of Po-210 per filter are then calculated from the counts in the Po-210 region, the counts of Po-209, and the Po recovery, based on the Po-209 counts.

The emission rate of Po-210 is then calculated based on the stack flow rate, as measured by Method 2. In most cases, the emission rate desired would be for rock processing plants, such as for phosphate rock. In that case, the processing rate is placed in the denominator or the rate equation. Detailed procedures for all typical calculations are included in the Method.

Several quality assurance steps are required by this method. First, the Alpha Spectrometry System must be standardized. This is accomplished by filtering a standardized solution of a different alpha-emitting actinide element and exposing the detector to the dried filter. Second a standardized Po-209 solution must be filtered and exposed to the detector in the same way. Next, each sample is analyzed in duplicate, with the difference between pairs required to be below stated limits. Finally, an independent analyst, under the direction of the Quality Assurance Officer for the testing project, should prepare a performance evaluation sample of Po, unknown to the analyst, for every 10 samples analyzed.

As with all of the Test Methods, Method III should not be attempted by anyone not trained to perform stack sampling. In particular, the analysis should only be performed by individuals experienced in dealing with radioactive sample analyses and hydrofluoric acid digestion.

Method 0010 (Modified Method 5)

Modified Method 5, or MM5, as it is usually called is used for Resource Conservation and Recovery Act (RCRA) trial burns to determine semi-volatile organic emissions from hazardous waste incinerators. This method, under the designation method 0010, can be found in SW-846.

In many ways, the equipment and operation of this train are similar to Test Method 5. A sample is extracted isokinetically from the stack and filtered to collect particulate material. In addition, the gases are cooled in a condenser and then trapped with Amberlite XAD-2 resin. A methylene chloride/methanol mixture is used for the probe wash instead of acetone.

The semi-volatile compounds on the filter and XAD-2 resin are extracted using an appropriate continuous extractor, and are concentrated for analysis. The condensate in the first impinger and, if required, the contents of the other impinger, are extracted using a separatory funnel and concentrated for analysis. The solvent rinses from the train are concentrated for analysis.

Analysis of these samples is done using Method 8270 which is also found in SW-846. The discussion of this method is beyond the scope of the next.

Modified Method 5 contains detailed descriptions of the quality control, calibration procedures, and sampling procedures in addition to a list of references. It should be read in detail before the Method is attempted. Testing should be performed only by personnel trained and experienced with the equipment being used.

Test Method 0030 Volatile Organic Sampling Train (VOST)

The Volatile Organic Sampling Train (VOST) is used to collect volatile organic compounds during resource Conservation and Recovery Act (RCRA) trial burns. This method can be found in SW-846 as Method 0030. It provides for the collection of gas samples in a pair of sorbent traps with subsequent desorption, concentration, and analysis of the contents of each tube. This method has been validated for many organic compounds boiling between 30°C and 100°C. This method should not be used for low boiling chlorofluorocarbons. Compounds which are water soluble may not be purged from the condensate completely and therefore should not be analyzed by this method. This method has been successfully used for some compounds boiling higher than 100°C.

In this method, a 20 liter gas sample is extracted from the stack with a glass lined probe at the rate of either 1 liter/minute or 0.5 liter/minute. Samples are collected from the center of the stack, not isokinetically. The sample gas is cooled with a condenser that has ice water pumped through it. The objective is to cool the gas to below 20ºC before the organic components are adsorbed onto a pair of sorbent resin traps in series. Any condensate present is collected between the two resin traps. The first trap contains approximately 1.6 grams of 2,6-diphenylene oxide polymer (Tenax). The backup trap contains approximately 1 gram each of Tenax and carbon. Both traps are cleaned by purging with a nitrogen while heating the traps to 190ºC. The method provides detailed instruction for the preparation of the sorbent tubes. The gases are dried before they are pumped by a vacuum pump through a dry gas meter.

Because of the relatively short time that each pair of tubes may collect samples, and the need to sample over at least an hour, a total of three pairs of tubes must be analyzed for each run. To account for the possibility of tube breakage during transport and analysis, between 4 and 6 pairs are actually collected. Each tube is analyzed by first heating the trap to desorb the compounds that are then collected on a smaller analytical trap. This tube is heated quickly and the compounds separated by gas chromatography and quantified with a suitable detector. The back-up traps are analyzed separately. When the traps are desorbed, the second, or back-up, trap should contain less than 30% of each organic compound. If this is not the case, there is a possibility of significant breakthrough of that compound through the traps. The condensate should be analyzed to show that there are no organic compounds present. To increase the detection limit, all three of each type of tube can be analyzed together.

This method requires extensive quality assurance and quality control measures to insure that valid data is produced. The majority of problems with this technique are usually from contamination of the sorbent traps in the field or laboratory. The analysis of audit gas provided by the Quality Assurance Division at Research Triangle Park, NC is required in the Method. This method should be performed only by personnel familiar with the sampling method and the gas chromatography necessary for the analysis.

Test Methods 204 et al.

EPA has published a number of Test Methods, Protocols, Procedures, and Regulations all aimed at determining the effectiveness of a control device to capture potential emissions of volatile organic compounds (VOCs). As a prelude to testing, most of the Procedures require the source to construct and verify a total enclosure, either permanent or temporary. Method 204 and Methods 204 A through F (published in Appendix M of 40 CFR Part 51) are to be used for measuring the VOC content in various process and emission streams, and for verifying the total enclosure. Then, additional Procedures from Part 52 are used to determine the actual Capture Efficiency.

STATISTICAL METHODS FOR ENVIRONMENTAL SCIENCE

All measurement involves error. Any field which uses empirical methods must therefore be concerned about variability in its data. Sometimes this concern may be limited to errors of direct measurement. The physicist who wishes to determine the speed of light is looking for the best approximation to a constant which is assumed to have a single, fixed true value.

Far more often, however, the investigator views his data as samples from a larger population, to which he wishes to apply his results. The scientist who analyzes water samples from a lake is concerned with more than the accuracy of the tests he makes upon his samples. Equally crucial is the extent to which these samples are representative of the lake from which they were drawn. Problems of inference from sampled data to some more general population are omnipresent in the environmental field.

A vast body of statistical theory and procedure has been developed to deal with such problems. This paper will concentrate on the basic concepts which underlie the use of these procedures.

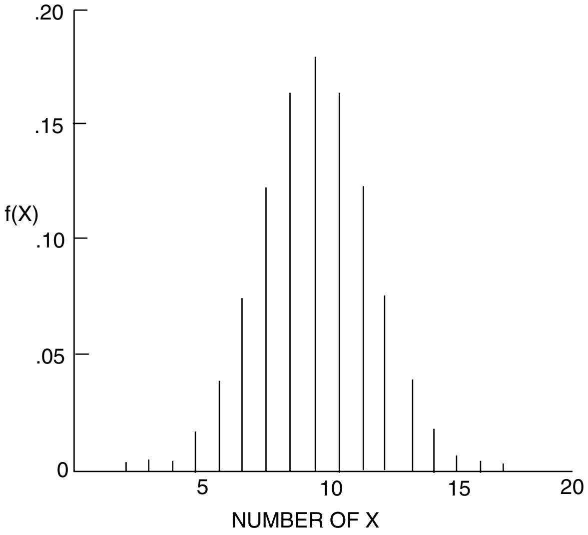

FIGURE 1

DISTRIBUTIONS

Discrete Distributions

A fundamental concept in statistical analysis is the probability of an event. For any actual observation situation (or experiment) there are several possible observations or outcomes. The set of all possible outcomes is the sample space. Some outcomes may occur more often than others. The relative frequency of a given outcome is its probability; a suitable set of probabilities associated with the points in a sample space yield a probability measure. A function *x,* defined over a sample space with a probability measure, is called a random variable, and its distribution will be described by the probability measure.

Many discrete probability distributions have been studied. Perhaps the more familiar of these is the binomial distribution. In this case there are only two possible events; for example, heads and tails in coin flipping. The probability of obtaining x of one of the events in a series of n trials is described for the binomial distribution by where θ is the probability of obtaining the selected event on a given trial. The binomial probability distribution is shown graphically in Figure 1 for $\theta = 0.5$, $n = 20$.

$$f(x;\theta,n) = \binom{n}{x}\theta^{x}(1-\theta)^{n-x}, \qquad (1)$$

It often happens that we are less concerned with the probability of an event than in the probability of an event *and* all less probable events. In this case, a useful function is the cumulative distribution which, as its name implies gives for any value of the random variable, the probability for that and all lesser values of the random variable. The cumulative distribution for the binomial distribution is

$$F(x;\theta,n) = \sum_{i=0}^{x} f(x;\theta,n). \qquad (2)$$

It is shown graphically in Figure 2 for $\theta = 0.5$, $n = 20$.

An important concept associated with the distribution is that of the moment. The moments of a distribution are defined as

$$\mu_k = \sum_{i=1}^{n} x_i^k f(x_i) \qquad (3)$$

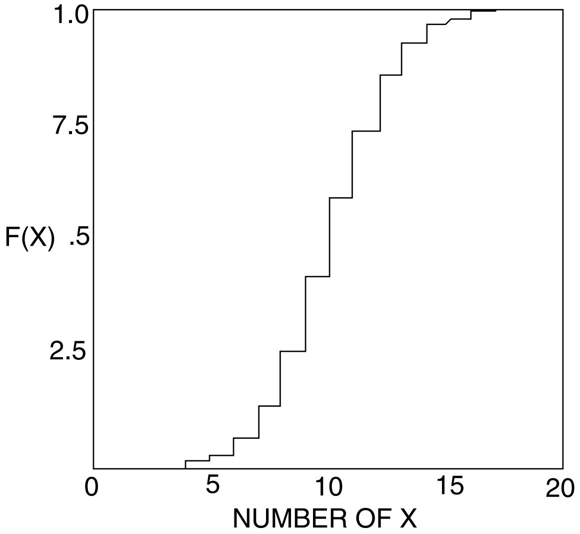

FIGURE 2

for the first, second, third, etc. moment, where $f(x_i)$ is the probability function of the variable x. Moments need not be taken around the mean of the distribution.

However, this is the most important practical case. The first and second moments of a distribution are especially important. The mean itself is the first moment and is the most commonly used measure of central tendency for a distribution. The second moment about the mean is known as the variance. Its positive square root, the standard deviation, is a common measure of dispersion for most distributions. For the binomial distribution the first moment is given by

$$\mu = n\theta \tag{4}$$

and the second moment is given by

$$\sigma^2 = n\theta(1-\theta). \tag{5}$$

The assumptions underlying the binomial distribution are that the value of θ is constant over trials, and that the trials are independent; the outcome of one trial is not affected by the outcome of another trial. Such trials are called Bernoulli trials. The binomial distribution applies in the case of sampling with replacement. Where sampling is without replacement, the hypergeometric distribution is appropriate. A generalization of the binomial, the multinomial, applies when more than two outcomes are possible for a single trial.

The Poisson distribution can be regarded as the limiting case of the binomial where n is very large and θ is very small, such that $n\theta$ is constant. The Poisson distribution is important in environmental work. Its probability function is given by

$$f(x;\lambda) = \frac{\lambda^x e^{-\lambda}}{x!}, \tag{6}$$

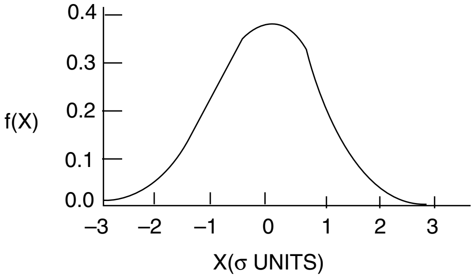

FIGURE 3

where $\lambda = n\theta$ remains constant.
Its first and second moments are

$$\mu = \lambda \tag{7}$$

$$\sigma^2 = \lambda. \tag{8}$$

The Poisson distribution describes events such as the probability of cyclones in a given area for given periods of time, or the distribution of traffic accidents for fixed periods of time. In general, it is appropriate for infrequent events, with a fixed but small probability of occurrence in a given period. Discussions of discrete probability distributions can be found in Freund among others. For a more extensive discussion, see Feller.

Continuous Distributions

The distributions mentioned in the previous section are all discrete distributions; that is, they describe the distribution of random variables which can be taken on only discrete values.

Not all variables of interest take on discrete values; very commonly, such variables are continuous. The analogous function to the probability function of a discrete distribution is the probability density function. The probability density function for the standard normal distribution is given by

$$f(x) = \frac{1}{\sqrt{2\pi}} e^{-x^2/2}. \tag{9}$$

It is shown in Figure 3. Its first and second moments are given by

$$\mu = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} x e^{-x^2/2} \mathrm{d}x = 0 \tag{10}$$

and

$$\sigma^2 = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} x^2 e^{-x^2/2} \mathrm{d}x = 1. \tag{11}$$

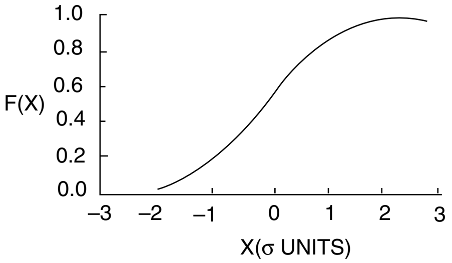

FIGURE 4

The distribution function for the normal distribution is given by

$$F(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} e^{-t^2/2}\,dt. \tag{12}$$

It is shown in Figure 4.

The normal distribution is of great importance for any field which uses statistics. For one thing, it applies where the distribution is assumed to be the result of a very large number of independent variable, summed together. This is a common assumption for errors of measurement, and it is often made for any variables affected by a large number of random factors, a common situation in the environmental field.

There are also practical considerations involved in the use of normal statistics. Normal statistics have been the most extensively developed for continuous random variables; analyses involving nonnormal assumptions are apt to be cumbersome. This fact is also a motivating factor in the search for transformations to reduce variables which are described by nonnormal distributions to forms to which the normal distribution can be applied. Caution is advisable, however. The normal distribution should not be assumed as a matter of convenience, or by default, in case of ignorance. The use of statistics assuming normality in the case of variables which are not normally distributed can result in serious errors of interpretation. In particular, it will often result in the finding of apparent significant differences in hypothesis testing when in fact no true differences exists.

The equation which describes the density function of the normal distribution is often found to arise in environmental work in situations other than those explicitly concerned with the use of statistical tests. This is especially likely to occur in connection with the description of the relationship between variables when the value of one or more of the variables may be affected by a variety of other factors which cannot be explicitly incorporated into the functional relationship. For example, the concentration of emissions from a smokestack under conditions where the vertical distribution has become uniform is given by Panofsky as

$$C = \frac{Q}{\sqrt{2\pi V D \sigma_y}} e^{-y^2/2\sigma y^2}, \tag{13}$$

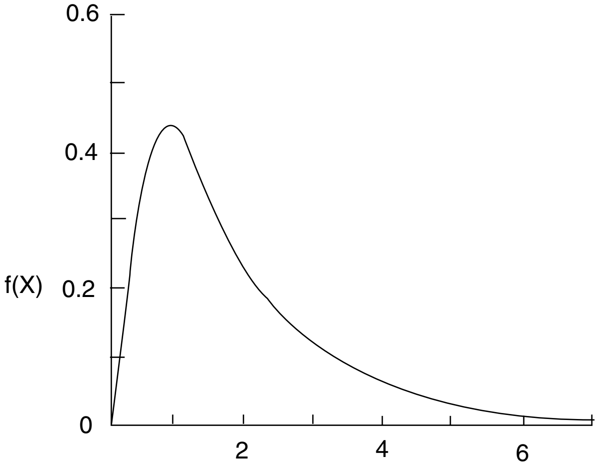

FIGURE 5

where y is the distance from the stack, Q is the emission rate from the stack, D is the height of the inversion layer, and V is the average wind velocity. The classical diffusion equation was found to be unsatisfactory to describe this process because of the large number of factors which can affect it.

The lognormal distribution is an important non-normal continuous distribution. It can be arrived at by considering a theory of elementary errors combined by a multiplicative process, just as the normal distribution arises out of a theory of errors combined additively. The probability density function for the lognormal is given by

$$\begin{aligned} f(x) &= 0 \text{ for } x \le 0 \\ f(x) &= \frac{1}{\sqrt{2\pi\sigma x}} e^{-(1nx-\mu)^2/2\sigma^2} \text{ for } x > 0. \end{aligned} \tag{14}$$

The shape of the lognormal distribution depends on the values of μ and σ^2. Its density function is shown graphically in Figure 5 for $\mu = 0$, $\sigma = 0.5$. The positive skew shown is characteristic of the lognormal distribution.

The lognormal distribution is likely to arise in situations in which there is a lower limit on the value which the random variable can assume, but no upper limit. Time measurements, which may extend from zero to infinity, are often described by the lognormal distribution. It has been applied to the distribution of income sizes, to the relative abundance of different species of animals, and has been assumed as the underlying distribution for various discrete counts in biology. As its name implies, it can be normalized by transforming the variable by the use of logarithms. See Aitchison and Brown (1957) for a further discussion of the lognormal distribution.

Many other continuous distributions have been studied. Some of these, such as the uniform distribution, are of minor importance in environmental work. Others are encountered occasionally, such as the exponential distribution, which has been used to compute probabilities in connection with the expected failure rate of equipment. The distribution of times between occurrences of events in Poisson processes are described by the exponential distribution and it is important in the theory of such stochastic processes (Parzen, 1962). Further discussion of continuous distributions may be found in Freund (1962) or most other standard statistical texts.

A special distribution problem often encountered in environmental work is concerned with the occurrence of extreme values of variables described by any one of several distributions. For example, in forecasting floods in connection with planning of construction, or droughts in connection with such problems as stream pollution, concern is with the most extreme values to be expected. To deal with such problems, the asymptotic theory of extreme values of a statistical variable has been developed. Special tables have been developed for estimating the expected extreme values for several distributions which are unlimited in the range of values which can be taken on by their extremes. Some information is also available for distributions with restricted ranges. An interesting application of this theory to prediction of the occurrence of unusually high tides may be found in Pfafflin (1970) and the Delta Commission Report (1960) Further discussion may be found in Gumbel.

HYPOTHESIS TESTING

Sampling Considerations

A basic consideration in the application of statistical procedures is the selection of the data. In parameter estimation and hypothesis testing sample data are used to make inferences to some larger population. The data are assumed to be a random sample from this population. By random we mean that the sample has been selected in such a way that the probability of obtaining any particular sample value is the same as its probability in the sampled population. When the data are taken care must be used to insure that the data are a random sample from the population of interest, and make sure that there must be no biases in the selective process which would make the samples unrepresentative. Otherwise, valid inferences cannot be made from the sample to the sampled population.

The procedures necessary to insure that these conditions are met will depend in part upon the particular problem being studied. A basic principle, however, which applies in all experimental work is that of randomization. Randomization means that the sample is taken in such a way that any uncontrolled variables which might affect the results have an equal chance of affecting any of the samples. For example, in agricultural studies when plots of land are being selected, the assignment of different experimental conditions to the plots of land should be done randomly, by the use of a table of random numbers or some other randomizing process. Thus, any differences which arise between the sample values as a result of differences in soil conditions will have an equal chance of affecting each of the samples.

Randomization avoids error due to bias, but it does nothing about uncontrolled variability. Variability can be reduced by holding constant other parameters which may affect the experimental results. In a study comparing the smog-producing effects of natural and artificial light, other variables, such as temperature, chamber dilution, and so on, were held constant (Laity, 1971) Note, however, that such control also restricts generalization of the results to the conditions used in the test.

Special sampling techniques may be used in some cases to reduce variability. For example, suppose that in an agricultural experiment, plots of land must be chosen from three different fields. These fields may then be incorporated explicitly into the design of the experiment and used as control variables. Comparisons of interest would be arranged so that they can be made within each field, if possible. It should be noted that the use of control variables is not a departure from randomization. Randomization should still be used in assigning conditions within levels of a control variable. Randomization is necessary to prevent bias from variables which are not explicitly controlled in the design of the experiment.

Considerations of random sampling and the selection of appropriate control variables to increase precision of the experiment and insure a more accurate sample selection can arise in connection with all areas using statistical methods. They are particularly important in certain environmental areas, however. In human population studies great care must be taken in the sampling procedures to insure representativeness of the samples. Simple random sampling techniques are seldom adequate and more complex procedures, have been developed. For further discussion of this kind of sampling, see Kish (1965) and Yates (1965). Sampling problems arise in connection with inferences from cloud seeding experiments which may affect the generality of the results (Bernier, 1967). Since most environmental experiments involve variables which are affected by a wise variety of other variables, sampling problems, especially the question of generalization from experimental results, is a very common problem. The specific randomization procedures, control variables and limitations on generalization of results will depend upon the particular field in question, but any experiment in this area should be designed with these problems in mind.

Parameter Estimation

A common problem encountered in environmental work is the estimation of population parameters from sample values. Examples of such estimation questions are: What is the "best" estimate of the mean of a population: Within what range of values can the mean safely be assumed to lie?

In order to answer such questions, we must decide what is meant by a "best" estimate. Probably the most widely used method of estimation is that of maximum likelihood, developed by Fisher (1958). A maximum likelihood estimate is one which selects that parameter value for a distribution describing a population which maximizes the probability of obtaining the observed set of sample values, assuming random sampling. It has the advantages of yielding estimates which fully utilize the information in the sample, if such estimates exist, and which are less variable under certain conditions for large samples than other estimates.

The method consists of taking the equation for the probability, or probability density function, finding its maximum value, either directly or by maximizing the natural logarithm of the function, which has a maximum for the same parameter values, and solving for these parameter values. The sample mean, $\hat{\mu} = (\Sigma_{n}^{i=1} x_i)/N\theta$, is a maximum likelihood estimate of the true mean of the distribution for a number of distributions. The variance, $\hat{\sigma}^2$, calculated from the sample by $\hat{\sigma}^2 = (\Sigma_{i=1}^{n} (x_i - \hat{\mu})^2$, is a maximum likelihood estimate of the population σ^2 for the normal distribution.

Note that such estimates may not be the best in some other sense. In particular, they may not be unbiased. An unbiased estimate is one whose value will, on the average, equal that of the parameter for which it is an estimate, for repeated sampling. In other words, the expected value of an unbiased estimate is equal to the value of the parameter being estimated. The variance is, in fact, biased. To obtain an unbiased estimate of the population variance it is necessary to multiply σ^2 by $n/(n-1)$, to yield s^2, the sample variance, and $s, (+\sqrt{s^2})$ the sample standard deviation.

There are other situations in which the maximum likelihood estimate may not be "best" for the purposes of the investigator. If a distribution is badly skewed, use of the mean as a measure of central tendency may be quite misleading. It is common in this case to use the median, which may be defined as the value of the variable which divides the distribution into two equal parts. Income statistics, which are strongly skewed positively, commonly use the median rather than the mean for this reason.

If a distribution is very irregular, any measure of central tendency which attempts to base itself on the entire range of scores may be misleading. In this case, it may be more useful to examine the maximum points of $f(x)$; these are known as modes. A distribution may have 1, 2 or more modes; it will then be referred to as unimodal, bimodal, or multimodal, respectively.

Other measures of dispersion may be used besides the standard deviation. The probable error, p.e., has often been used in engineering practice. It is a number such that

$$\int_{\mu-p.e.}^{\mu+p.e.} f(x)dx = 0.5. \tag{15}$$

The p.e. is seldom used today, having been largely replaced by σ^2.

The interquartile range may sometimes be used for a set of observations whose true distribution is unknown. It consists of the limits of the range of values which include the middle half of sample values. The interquartile range is less sensitive than the standard deviation to the presence of a few very deviant data values.

The sample mean and standard deviation may be used to describe the most likely true value of these parameters, and to place confidence limits on that value. The standard error of the mean is given by $s/\sqrt{n}$ (n = sample-size). The standard error of the mean can be used to make a statement about the probability that a range of values will include the true mean. For example, assuming normality, the range of values defined by the observed mean $1.96s/\sqrt{n}$ will be expected to include the value of the true mean in 95% of all samples.

A more general approach to estimation problems can be found in Bayseian decision theory (Pratt *et al.*, 1965). It is possible to appeal to decision theory to work out specific answers to the "best estimate" problem for a variety of decision criteria in specific situations. This approach is well described in Weiss (1961). Although the method is not often applied in routine statistical applications, it has received attention in systems analysis problems and has been applied to such environmentally relevant problems as resource allocation.

Frequency Data

The analysis of frequency data is a problem which often arises in environmental work. Frequency data for a hypothetical experiment in genetics are shown in Table 1. In this example, the expected frequencies are assumed to be known independently of the observed frequencies. The chi-square statistic, χ^2, is defined as

$$\chi^2 = \sum \frac{(E-O)^2}{E^2} \tag{16}$$

where E is the expected frequency and O is the observed frequency. It can be applied to frequency tables, such as that shown in Table 1. Note that an important assumption of the chi-square test is that the observations be independent. The same samples or individuals must not appear in more than one cell.

In the example given above, the expected frequencies were assumed to be known. In practice this is very often not the case; the experimenter will have several sets

TABLE 1

Hypothetical data on the frequency of plants producing red, pink and white flowers in the first generation of an experiment in which red and white parent plants were crossed, assuming single gene inheritance, neither gene dominant of observed frequencies, and will wish to determine whether or not they represent samples from one population, but will not know the expected frequency for samples from that population.

		Flower color		
		Red	Pink	White
Number of plants	expected	25	50	25
	observed	28	48	24

In situations where a two-way categorization of the data exists, the expected values may be estimated from the marginals. For example, the formula for chi-square for the fourfold contingency table shown below is

	Classification II	
Classification I	A	B
	C	D

$$\chi^2 = \frac{N\left(|AD - BC| - \frac{N}{2}\right)^2}{A\cdot B\cdot C\cdot D}. \tag{17}$$

Observe that instead of having independent expected values, we are now estimating these parameters from the marginal distributions of the data. The result is a loss in the degrees of freedom for the estimate. A chi-square with four independently obtained expected values would have four degrees of freedom; the fourfold table above has only one. The concept of degrees of freedom is a very general one in statistical analysis. It is related to the number of observations which can vary independently of each other. When expected values for chi-square are computed from the marginals, not all of the $O - E$ differences in a row or column are independent, for their discrepancies must sum to zero. Calculation of means from sample data imposes a similar restriction; since the deviations from the mean must sum to zero, not all of the observations in the sample can be regarded as freely varying. It is important to have the correct number of degrees of freedom for an estimate in order to determine the proper level of significance; many statistical tables require this information explicitly, and it is implicit in any comparison. Calculation of the proper degrees of freedom for a comparison can become complicated in specific cases, especially that of analysis of variance. The basic principle to remember, however, is that any linear independent constraints placed on the data will reduce the degrees of freedom. Tables for value of the χ^2 distribution for various degrees of freedom are readily available. For a further discussion of the use of chi-square, see Snedecor.

Difference between Two Samples

Another common situation arises when two samples are taken, and the experimenter wishes to know whether or not they are samples from populations with the same parameter values. If the populations can be presumed to be normal, then the significance of the differences of the two means can be tested by

$$t = \frac{\hat{\mu}_1 - \hat{\mu}_2}{\sqrt{\frac{s_1^2}{N_1} + \frac{s_2^2}{N_2}}} \tag{18}$$

where $\hat{\mu}_1$ and $\hat{\mu}_2$ are the sample means, s_1^2 and s_1^2 are the sample variances, N_1 and N_2 are the sample sizes. and the population variances are assumed to be equal. This is the **t**-test, for two samples. The **t**-test can also be used to test the significance of the difference between one sample mean and a theoretical value. Tables for the significance of the **t**-test may be found in most statistical texts.

The theory underlying the **t**-test is that the measures of dispersion estimated from the observations within a sample provide estimates of the expected variability. If the means are close together, relative to that variability, then it is unlikely that the populations differ in their true values. However, if the means vary widely, then it is unlikely that the samples come from distributions with the same underlying distributions. This situation is diagrammed in Figure 6. The **t**-test permits an exact statement of how unlikely the null hypothesis (assumption of no difference) is. If it is sufficiently unlikely, it can be rejected. It is common to assume the null hypothesis unless it can be rejected in at least 95% of the cases, though more stringent criteria (99% or more) may be adopted if more certainty is needed.

The more stringent the criterion, of course, the more likely it is that the null hypothesis will be accepted when, in fact, it is false. The probability of falsely rejecting the null hypothesis is known as a type I error. Accepting the null hypothesis when it should be rejected is known as a type II error. For a given type I error, the probability of correctly rejecting the null hypothesis for a given true difference is known as the power of the test for detecting the difference. The function of these probabilities for various true differences in the parameter under test is known as the power function of the test. Statistical tests differ in their power and power functions are useful in the comparison of different tests.

Note that type I and type II errors are necessarily related; for an experiment of a given level of precision, decreasing the probability of a type I error raises the probability of a type II error, and vice versa. Thus, increasing the stringency of one's criterion does not decrease the overall probability of an erroneous conclusion; it merely changes the type of error which is most likely to be made. To decrease the overall error, the experiment must be made more precise, either by increasing the number of observations, or by reducing the error in the individual observations.

Many other tests of mean difference exist besides the **t**-test. The appropriate choice of a test will depend on the assumptions made about the distribution underlying the observations. In theory, the **t**-test applies only for variables which are continuous, range from ± infinity in value, and

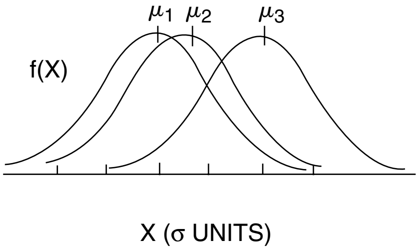

FIGURE 6

are normally distributed with equal variance assumed for the underlying population. In practice, it is often applied to variables of a more restricted range, and in some cases where the observed values of a variable are inherently discontinuous. However, when the assumptions of the test are violated, or distribution information is unavailable, it may be safer to use nonparametric tests, which do not depend on assumptions about the shape of the underlying distribution. While nonparametric tests are less powerful than parametric tests such as the **t**-test, when the assumptions of the parametric tests are met, and therefore will be less likely to reject the null hypothesis, in practice they yield results close to the **t**-test unless the assumptions of the **t**-test are seriously violated. Nonparametric tests have been used in meteorological studies because of nonnormality in the distribution of rainfall samples. (Decker and Schickedanz, 1967). For further discussions of hypothesis testing, see Hoel (1962) and Lehmann (1959). Discussions of nonparametric tests may be found in Pierce (1970) and Siegel (1956).

Analysis of Variance (ANOVA)

The **t**-test applies to the comparison of two means. The concepts underlying the **t**-test may be generalized to the testing of more than two means. The result is known as the analysis of variance. Suppose that one has several samples. A number of variances may be estimated. The variance of each sample can be computed around the mean for the sample. The variance of the sample means around the grand mean of all the scores gives another variance. Finally, one can ignore the grouping of the data and complete the variance for all scores around the grand mean. It can be shown that this “total” variance can be regarded as made up of two independent parts, the variance of the scores about their sample means, and the variance of these means about the grand mean. If all these samples are indeed from the same population, then estimates of the population variance obtained from within the individual groups will be approximately the same as that estimated from the variance of sample means around the grand mean. If, however, they come from populations which are normally distributed and have the same standard deviations, but different means, then the variance estimated from the sample means will exceed the variance are estimated from the within sample estimates.

The formal test of the hypothesis is known as the F-test. It is made by forming the F-ratio.

$$F = \frac{\text{MSE}_{(1)}}{\text{MSE}_{(2)}} \tag{19}$$

Mean square estimates (MSE) are obtained from variance estimates by division by the appropriate degrees of freedom. The mean square estimate in the numerator is that for the hypothesis to be tested. The mean square estimate in the denominator is the error estimate; it derives from some source which is presumed to be affected by all sources of variance which affect the numerator, except those arising from the hypothesis under test. The two estimates must also be independent of each other. In the example above, the within group MSE is used as the error estimate; however, this is often not the case for more complex experimental designs. The appropriate error estimate must be determined from examination of the particular experimental design, and from considerations about the nature of the independent variables whose effect is being tested; independent variables whose values are fixed may require different error estimates than in the case of independent variables whose values are to be regarded as samples from a larger set. Determination of degrees of freedom for analysis of variance goes beyond the scope of this paper, but the basic principle is the same as previously discussed; each parameter estimated from the data (usually means, for (ANOVA) in computing an estimator will reduce the degrees of freedom for that estimate.

The linear model for such an experiment is given by

$$X_{ij} = \mu + G_i + e_{ij,} \tag{20}$$

Where X_{ij} is a particular observation, μ is the mean, G_i is the effect the Gth experimental condition and e_{ij} is the error uniquely associated with that observation. The e_{ij} are assumed to be independent random samples from normal distributions with zero mean and the same variances. The analysis of variance thus tests whether various components making up a score are significantly different from zero.

More complicated components may be presumed. For example, in the case of a two-way table, the assumed model might be

$$X_{ijk} = \mu + R_{\mathrm{i}} + C_j + R_{cij} + \mathrm{e}_{ijk} \tag{21}$$

In addition to having another condition, or main effect, there is a term RC_{ij} which is associated with that particular combination of levels of the main effects. Such effects are known as interaction effects.

Basic assumptions of the analysis of variance are normality and homogeneity of variance. The **F**-test however, has been shown to be relatively “robust” as far as deviations from the strict assumption of normality go. Violations of the assumption of homogeneity of variance may be more serious. Tests have been developed which can be applied where violations of this assumption are suspected. See Scheffé (1959; ch.10) for further discussion of this problem.

Innumerable variations on the basic models are possible. For a more detailed discussion, see Cochran and Cox (1957) or Scheffé (1959). It should be noted, especially, that a significant F-ratio does not assure that all the conditions which entered into the comparison differ significantly from each other. To determine which mean differences are significantly different, additional tests must be made. The problem of multiple comparisons among several means has been approached in three main ways; Scheffé’s method for post-hoc comparisons; Tukey’s gap test; and Duncan’s multiple range test. For further discussion of such testing, see Kirk (1968).

Computational formulas for ANOVA can be found in standard texts covering this topic. However, hand calculation becomes cumbersome for problems of any complexity, and a number of computer programs are available for analyzing various designs. The Biomedical Statistical Programs (Ed. by Dixon 1967) are frequently used for this purpose. A method recently developed by Fowlkes (1969) permits a particularly simple specification of the design problem and has the flexibility to handle a wide variety of experimental designs.

SPECIAL ESTIMATION PROBLEMS

The estimation problems we have considered so far have involved single experiments, or sets of data. In environmental work, the problem of arriving at an estimate by combining the results of a series of tests often arises. Consider, for example, the problem of estimating the coliform bacteria population size in a specimen of water from a series of dilution tests. Samples from the water specimen are diluted by known amounts. At some point, the dilution becomes so great that the lactose broth brilliant green bile test for the presence of coliform bacteria becomes negative (Fair and Geyer, 1954). From the amount of dilution necessary to obtain a negative test, plus the assumption that one organism is enough to yield a positive response, it is possible to estimate the original population size in the water specimen.

In making such an estimate, it is unsatisfactory simply to use the first negative test to estimate the population size. Since the diluted samples may differ from one another, it is possible to get a negative test followed by one or more positive tests. It is desirable, rather, to estimate the population from the entire series of tests. This can be done by setting up a combined hypothesis based on the joint probabilities of all the obtained results, and using likelihood estimation procedures to arrive at the most likely value for the population parameter, which is known as the Most Probable Number (MPN) (Fair and Geyer, 1954). Tables have been prepared for estimating the MPN for such tests on this principle, and similar procedures can be used to arrive at the results of a set of tests in other situations.

Sequential testing is a problem that sometimes arises in environmental work. So far, we have assumed that a constant amount of data is available. However, very often, the experimenter is making a series of tests, and wishes to know whether he has enough data to make a decision at a given level of reliability, or whether he should consider taking additional data. Such estimation problems are common in quality control, for example, and may arise in connection with monitoring the effluent from various industrial processes. Statistical procedures have been developed to deal with such questions. They are discussed in Wald.

CORRELATION AND RELATED TOPICS

So far we have discussed situations involving a single variable. However, it is common to have more than one type of measure available on the experimental units. The simplest case arises where values for two variables have been obtained, and the experimenter wishes to know how these variables relate to one another.

Curve Fitting

One problem which frequently arises in environmental work is the fitting of various functions to bivariate data. The simplest situation involves fitting a linear function to the data when all of the variability is assumed to be in the *Y* variable. The most commonly used criterion for fitting such a function is the minimization of the squared deviations from the line, referred to as the least squares criterion. The application of this criterion yields the following simultaneous equations:

$$\sum_{i=1}^{n} Y_i = nA + \sum_{i=1}^{n} X_i \tag{22}$$

and

$$\sum_{i=1}^{n} X_i Y_i = A\sum_{i=1}^{n} X_i + B\sum_{i=1}^{n} X_i^2 . \tag{22}$$

These equations can be solved for *A* and *B,* the intercept and slope of the best fit line. More complicated functions may also be fitted, using the least squares criterion, and it may be generalized to the case of more than two variables. Discussion of these procedures may be found in Daniel and Wood.

Correlation and Regression

Another method of analysis often applied to such data is that of correlation. Suppose that our two variables are both normally distributed. In addition to investigating their individual distributions, we may wish to consider their joint occurrence. In this situation, we may choose to compute the Pearson product moment correlation between the two variables, which is given by

$$r_{xy} = \frac{\operatorname{cov}(x_i y_i)}{\sigma_x \sigma_y} \tag{23}$$

where $\operatorname{cov}(x_i\, y_i)$ the covariance of *x* and *y,* is defined as

$$\sum_{i=1}^{n} \frac{(x_i - \mu_x)(y_i - \mu_y)}{n}. \tag{24}$$

It is the most common measure of correlation. The square of *r* gives the proportion of the variance associated with one of the variables which can be predicted from knowledge of the other variables. This correlation coefficient is appropriate whenever the assumption of a normal distribution can be made for both variables.

Another way of looking at correlation is by considering the regression of one variable on another. Figure 7 shows the relation between two variables, for two sets of bivariate data, one with a 0.0 correlation, the other with a correlation of 0.75. Obviously, estimates of type value of one variable based on values of the other are better in the case of the higher correlation. The formula for the regression of *y* on *x* is given by

$$\frac{y-\hat{\mu}_y}{\hat{\sigma}_y}=\frac{r_{xy}(x-\hat{\mu}_x)}{(\hat{\sigma}_x)}. \qquad (25)$$

A similar equation exists for the regression of *x* on *y.*

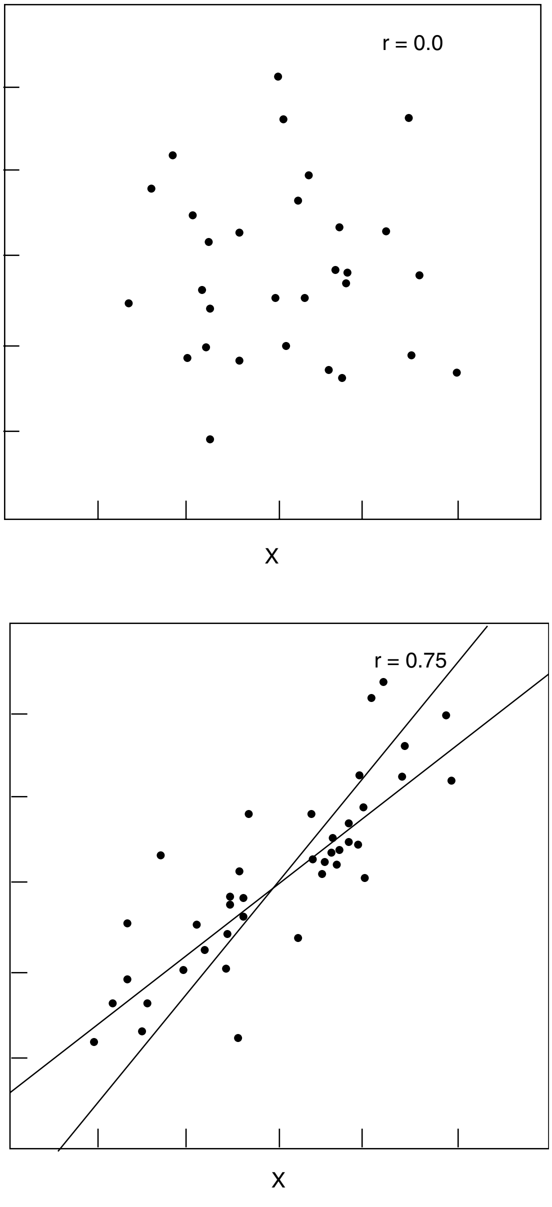

FIGURE 7

A number of other correlation measures are available. For ranked data, the Spearman correlation coefficient, or Kendall's tau, are often used. Measures of correlation appropriate for frequency data also exist. See Siegel.

MULTIVARIATE ANALYSIS

Measurements may be available on more than two variables for each experiment. The environmental field is one which offers great potential for multivariate measurement. In areas of environmental concern such as water quality, population studies, or the study of the effects of pollutants on organisms, to name only a few, there are often several variables which are of interest. The prediction of phenomena of environmental interest, or such as rainfall, or floods, typically involves the consideration of many variables. This section will be concerned with some problems in the analysis of multivariate data.

Multivariate Distributions

In considering multivariate distributions, it is useful to define the *n*-dimensional random variable *X* as the vector

$$X'=[X_1,X_2,\mathrm{K},X_n]. \qquad (26)$$

The elements of this vector will be assumed to be continuous unidimensional random variables, with density functions $f_1(x_1)$,F$f_2(x_2)$K,$f_n(x_n)$ and distribution functions $F_1(x_1)$,$F_2(x_2)$K,$F_n(x_n)$ Such a vector also has a joint distribution function.

$$F(x_1,x_2,\mathrm{K},x_n)=P(X_1\le x_1,\mathrm{K},X_n\le x_n) \qquad (27)$$

where *P* refers to the probability of all the stated conditions occurring simultaneously.

The concepts considered previously in regard to univariate distribution may be generalized to multivariate distributions. Thus, the expected value of the random vector, *X,* analogous to the mean of the univariate distribution, is

$$E(X')=[E(X_1),E(X_2),\mathrm{K}E(X_n)], \qquad (28)$$

where the $E(X_i)$ are the expected values, or means, for the univariate distributions.

Generalization of the concept of variance is more complicated. Let us start by considering the covariance between two variables,

$$\sigma_{ij}=E[X_i-E(X_i)][X_j-E(X_j)]. \qquad (29)$$

The covariances between each of the elements of the vector *X* can be computed; the covariances of the *i*th and *j*th elements will be designed as σ_{ij} If $i = j$ the covariance is the variance of X_i, and will be designed as σ_{ij} The generalization of the concept of variance to a multidimensional variable then becomes the matrix of variances and covariances. This matrix will be called the covariance matrix. The covariance matrix for the population is given as

$$\Sigma = \begin{bmatrix} \sigma_{11}\sigma_{12}\mathrm{K}\sigma_{1n} \\ \sigma_{21}\sigma_{22}\mathrm{K}\sigma_{2n} \\ \mathrm{K\ K\ K\ K\ K} \\ \sigma_{n1}\sigma_{2n2}\ldots\sigma_{nn} \end{bmatrix}. \tag{30}$$

A second useful matrix is the matrix of correlations

$$\begin{bmatrix} r_{11}\Lambda\, r_{1n} \\ r_{21}\Lambda\, r_{2n} \\ \Lambda\ \Lambda\ \Lambda \\ r_{n1}\ldots r_{nn} \end{bmatrix} \tag{31}$$

If the assumption is made that each of the individual variables is described by a normal distribution, then the distribution of X may be described by the multivariate normal distribution. This assumption will be made in subsequent discussion, except where noted to the contrary.

Tests on Means

Suppose that measures have been obtained on several variables for a sample, and it is desired to determine whether that sample came from some known population. Or there may be two samples; for example, suppose data have been gathered on physiological effects of two concentrations of SO_2 for several measures of physiological functioning and the investigator wishes to know if they should be regarded as samples from the same population. In such situations, instead of using **t**-tests to determine the significance of each individual difference separately, it would be desirable to be able to perform one test, analogous to the **t**-test, on the vectors of the means.

A test, known as Hotelling's $\mathbf{T}^2$ test, has been developed for this purpose. The test does not require that the population covariance matrix be known. It does, however, require that samples to be compared come from populations with the same covariance matrix, an assumption analogous to the constant variance requirement of the **t**-test.

To understand the nature of $\mathbf{T}^2$ in the single sample case, consider a single random variable made up of any linear combination of the n variables in the vector X (all of the variables must enter into the combination, that is, none of the coefficients may be zero). This variable will have a normal distribution, since it is a sum of normal variables, and it can be compared with a linear combination of elements from the vector for the population with the same coefficients, by means of a **t**-test. We then adopt the decision rule that the null hypothesis will be accepted only if it is true for all possible linear combinations of the variables. This is equivalent to saying that it is true for the largest value of **t** as a function of the linear combinations. By maximizing $\mathbf{t}^2$ as a function of the linear combinations, it is possible to derive $\mathbf{T}^2$. Similar arguments can be used to derive $\mathbf{T}^2$ for two samples.

A related function of the mean is known as the linear discriminant function. The linear discriminant function is defined as the linear compound which generates the largest $\mathbf{T}^2$ value. The coefficients used in this compound provide the best weighting of the variables of a multivariate observation for the purpose of deciding which population gave rise to an observation. A limitation on the use of the linear discriminant function, often ignored in practice, is that it requires that the parameters of the population be known, or at least be estimated from large samples. This statistic has been used in analysis of data from monitoring stations to determine whether pollution concentrations exceed certain criterion values.

Other statistical procedures employing mean vectors are useful in certain circumstances. See Morrison for a further discussion of this question.

Multivariate Analysis of Variance (MANOVA)

Just as the concepts underlying the **t**-test could be generalized to the comparison of more than two means, the concepts underlying the comparison of two mean vectors can be generalized to the comparison of several vectors of means.

The nature of this generalization can be understood in terms of the linear model, considered previously in connection with analysis of variance. In the multivariate situation, however, instead of having a single observation which is hypothesized to be made up of several components combined additively, the observations are replaced by vectors of observations, and the components by vectors of components. The motivation behind this generalization is similar to that for Hotelling's $\mathbf{T}^2$ test: it permits a test of the null hypothesis for all of the variables considered simultaneously.

Unlike the case of Hotelling's $\mathbf{T}^2$, however, various methods of test construction do not converge on one test statistic, comparable to the F test for analysis of variance. At least three test statistics have been developed for MANOVA, and the powers of the various tests in relation to each other are very incompletely known.

Other problems associated with MANOVA are similar in principle to those associated with ANOVA, though computationally they are more complex. For example, the problem of multiple comparison of means has its analogous problem in MANOVA, that of determining which combinations of mean vectors are responsible for significant test statistics. The number and type of possible linear models can also ramify considerably, just as in the case of ANOVA. For further discussion of MANOVA, see Morrison (1967) or Seal.

Extensions of Correlation Analysis

In a number of situations, where multivariate measurements are taken, the concern of the investigator centers on the prediction of one of the variables. When rainfall measurements are taken in conjunction with a number of other variables, such as temperature, pressure, and so on, for example, the purpose is usually to predict the rainfall as a function of the other variables. Thus, it is possible to view one variable as the dependent variable for *a prior* reasons, even though the data do not require such a view.

In these situations, the investigator very often has one of two aims. He may wish to predict one of the variables from all of the other variables. Or he may wish to consider one variable as a function of another variable with the effect of all the other variables partialled out. The first situation calls for the use of multiple correlation. In the second, the appropriate statistic is the partial correlation coefficient.

Multiple correlation coefficients are used in an effort to improve prediction by combining a number of variables to predict the variable of interest. The formula for three variables is

$$r_{1.23} = \sqrt{\frac{r_{12}^2 + r_{13}^2 - 2r_{12}r_{13}r_{23}}{1 - r_{23}^2}}. \tag{32}$$

Generalizations are available for larger numbers of variables. If the variables are relatively independent of each other, multiple correlation may improve prediction. However, it should be obvious that this process reaches an upper limit since additional variables, if they are to be of any value, must show a reasonable correlation with the variable of interest, and the total amount of variance to be predicted is fixed. Each additional variable can therefore only have a limited effect.

Partial correlation is used to partial out the effect of one of more variables on the correlation between two other variables. For example, suppose it is desired to study the relationship between body weight and running speed, independent of the effect of height. Since height and weight are correlated, simply doing a standard correlation between running speed and weight will not solve the problem. However, computing a partial correlation, with the contribution of height partialled out, will do so. The partial correlation formula for three variables is

$$r_{12.3} = \frac{r_{12} - r_{13}r_{23}}{\sqrt{1 - r_{13}^2}\sqrt{1 - r_{23}^2}}, \tag{33}$$

where $r_{12.3}$ gives the correlation of variables 1 and 2, with the contribution of variable 3 held constant. This formula may also be extended to partial out the effect of additional variables.

Let us return for a moment to a consideration of the population correlation matrix, *p*. It may be that the investigator has same *a priori* reason for believing that certain relationships exist among the correlations in this matrix. Suppose, for example there is a reason to believe that several variables are heavily dependent on wind velocity and that another set of variables are dependent on temperature. Such a pattern of underlying relations would result in systematic patterns of high and low correlations in the population matrix, which should be reflected in the observed correlation matrix. If the obtained correlation matrix is partitioned into sets in accordance with the *a priori* hypothesis, test for the independence of the sets will indicate whether or not the hypothesis should be rejected. Procedures have been developed to deal with this situation, and also to obtain coefficients reflecting the correlation between sets of correlations. The latter procedure is known as canonical correlation. Further information about these procedures may be found in Morrison.

Other Analyses of Covariance and Correlation Matrices

In the analyses discussed so far, there have been *a priori* considerations guiding the direction of the analysis. The situation may arise, however, in which the investigator wishes to study the patterns in an obtained correlation or covariance matrix without any appeal to *a priori* considerations. Let us suppose, for example, that a large number of measurements relevant to weather prediction have been taken, and the investigator wishes to look for patterns among the variables. Or suppose that a large number of demographic variables have been measured on a human population. Again, it is reasonable to ask if certain of these variables show a tendency to be more closely related than others, in the absence of any knowledge about their actual relations. Such analyses may be useful in situations where large numbers of variables are known to be related to a single problem, but the relationships among the variables are not well understood. An investigation of the correlation patterns may reveal consistencies in the data which will serve as clues to the underlying process.

The classic case for the application of such techniques has been the study of the human intellect. In this case, correlations among performances on a very large number of tasks have been obtained and analyzed, and many theories about the underlying skills necessary for intellectual function have been derived from such studies. The usefulness of the techniques are by no means limited to psychology, however. Increasingly, they are being applied in other fields, as diverse as biology (Fisher and Yates, 1964) and archaeology (Chenhall, 1968). Principal component analysis, a closely related technique, has been used in hydrology.

One of the more extensively developed techniques for the analysis of correlation matrices is that of factor analysis. To introduce the concepts underlying factor analysis, imagine a correlation matrix in which the first x variables and the last $n - x$ variables are all highly correlated with each other, but the correlation between any of the first x and any of the second $n - x$ variables is very low. One might suspect that there is some underlying factor which influences the first set of variables, and another which influences the second set of variables, and that these two factors are relatively independent statistically, since the variables which they influence are not highly correlated. The conceptual simplification is obvious; instead of worrying about the relationships among n variables as reflected in their $n(n - 1)/2$ correlations, the investigator can attempt to identify and measure the factors directly.

Factor analysis uses techniques from matrix algebra to accomplish mathematically the process we have outlined intuitively above. It attempts to determine the number of factors, and also the extent to which each of these factors influences the measured variables. Since unique solutions to this problem do not exist, the technique has been the subject of considerable debate, especially on the question of how to determine the best set of factors. Nevertheless, it can be useful in any situation where the relationships among a large set of variables is not well understood.

ADDITIONAL PROCEDURES

Multidimensional Scaling and Clustering

There are a group of techniques whose use is motivated by considerations similar to those underlying the analysis of correlation matrices, but which are applied directly to matrices of the distances, or similarities, between various stimuli. Suppose, for example, that people have been asked to judge the similarity of various countries. These judgments may be scaled by multidimensional techniques to discover how many dimensions underlie the judgments. Do people make such judgments along a single dimension? Or are several dimensions involved? An interesting example of this sort was recently analyzed by Wish (1972). Sophisticated techniques have been worked out for such procedures.

Multidimensional scaling has been most extensively used in psychology, where the structure underlying similarity or distance measurements may not be at all obvious without such procedures. Some of these applications are of potential importance in the environmental field, especially in areas such as urban planning, where decisions must take into account human reactions. They are not limited to such situations however, and some intriguing applications have been made in other fields.

A technique related in some ways to multidimensional analysis is that of cluster analysis. Clustering techniques can be applied to the same sort of data as multidimensional scaling procedures. However, the aim is somewhat different. Instead of looking for dimensions assumed to underlie the data, clustering techniques try to define related clusters of stimuli. Larger clusters may then be identified, until a hierarchical structure is defined. If the data are sufficiently structured, a “Tree” may be derived.

A wide variety of clustering techniques have been explored, and interest seems on the increase (Johnson, 1967). The procedures used depend upon the principles used to define the clusters. Clustering techniques have been applied in a number of different fields. Biologists have used them to study the relationships among various animals; for example, a kind of numerical taxonomy.

The requirements which the data must meet for multidimensional scaling and clustering procedures to apply are usually somewhat less stringent than in the case of the multivariate procedures discussed previously. Multidimensional scaling in psychology is often done on data for which an interval scale of measurement cannot be assumed. Distance measures for clustering may be obtained from the clustering judgments of a number of individuals which lack an ordinal scale. This relative freedom is also useful in many applications where the order of items is known, but the equivalence of the distances between items measured at different points is questionable.

Stochastic Processes

A stochastic or random process is any process which includes a random element in its description. The term stochastic process is frequently also used to describe the mathematical description of any actual stochastic process. Stochastic models have been developed in a number of areas of environmental concern.

Many stochastic processes involve space or time as a primary variable. Bartlett (1960) in his discussion of ecological frequency distributions begins with the application of the Poisson distribution to animal populations whose density is assumed to be homogeneous over space, and then goes on to develop the consequences of assuming heterogeneous distributions, which are shown to lead to other distributions, such as the negative binomial. The Sutton equation for the diffusion of gases applied to stack effluents, a simplification of which was given earlier for a single dimension (Strom, 1968) is another example of a situation in which statistical considerations about the physical process lead to a spatial model, in this case, one involving two dimensions.

Time is an important variable in many stochastic models. A number of techniques have been developed for the analysis of time series. Many of the concepts we have already considered, such as the mean and variance, can be generalized to time series. The autocorrelation function, which consists of the correlation of a function with itself for various time lags, is often applied to time series data. This function is useful in revealing periodicities in the data, which show up as peaks in the function. Various modifications of this concept have been developed to deal with data which are distributed in discrete steps over time. Time series data, especially discrete time series data, often arise in such areas as hydrology, and the study of air pollution, where sampling is done over time. Such sampling is often combined with spatial sampling, as when meterological measurements are made at a number of stations.

An important consideration in connection with time series is whether the series is stationary or non-stationary. Stationarity of a time series implies that the behavior of the random variables involved does not depend on the time at which observation of the series is begun. The assumption of stationarity simplifies the statistical treatment of time series. Unfortunately, it is often difficult to justify for environmental measurements, especially those taken over long time periods. Examination of time series for evidence of non-stationarity can be a useful procedure, however; for example, it may be useful in determining whether long term climatic changes are occurring (Quick, 1992). For further discussion of time series analysis, see Anderson.

Stochastic models of environmental interest are often multivariate. Mathematical models applied to air pollution may deal with the concentrations of a number of pollutants, as well as such variables as temperature, pressure, precipitation, and wind direction. Special problems arise in the evaluation of such models because of the large numbers of variables involved, the large amounts of data which must be processed for each variable, and the fact that the distributions of the variables are often nonnormal, or not well known. Instead of using analytic methods to obtain solutions, it may be necessary to seek approximate solutions; for example, by extensive tabulation of data for selected sets of conditions, as has been one in connection with models for urban air pollution.

The development of computer technology to deal with the very large amounts of data processing often required has made such approaches feasible today. Nevertheless, caution with regard to many stochastic models should be observed. It is common to find articles describing such models which state that a number of simplifying assumptions were necessary in order to arrive at a model for which computation was feasible, and which then go on to add that even with these assumptions the computational limits of available facilities were nearly exceeded, a combination which raises the possibility that excessive simplification may have been introduced. In these circumstances, less ambitious treatment of the data might prove more satisfactory. Despite these comments, however, it is clear that the environmental field presents many problems to which the techniques of stochastic modelling can be usefully applied.

ADDITIONAL CONSIDERATIONS

The methods outlined in the previous sections represent a brief introduction to the statistics used in environmental studies. It appears that the importance of some of these statistical methods, particularly analysis of variance, multivariate procedures and the use of stochastic modelling will increase. The impact of computer techniques has been great on statistical computations in environmental fields. Large amounts of data may be collected and processed by computer methods.

T

THE TERRESTRIAL SYSTEM

Space-vehicle Earth was so superbly well designed, equipped and supplied as to have been able to sustain human life aboard it for at least two million years—despite humanity's comprehensive ignorance which permitted a fearfully opinionated assumption of an infinitely extensive planar *World.* Humanity also spontaneously misassumed that its local pollution could be dispelled by the world's infinite extensiveness. Humanity also misassumed that an infinite succession of new and pleasing varieties of abundant, vital resources would be disclosed progressively as man exhausted first one and bespoiled another of the as yet known valuable, because vital, resources. Man must learn in a spontaneously self-enlightening manner to discard many, if not most, of yesterday's false premises, and axioms only believingly accepted; and he must, on his own, discard false premises and learn that only the non-sense Universe is reliable and that a lunatic is not a crazy man but one so sane, well informed, well coordinated, self-disciplined cooperative and fearless as to be the first Earthian human to have been ferried to a physical landing upon the Moon and thereafter to have been returned safely to reboard his mother space vehicle "Earth".

Long, long ago—little bands of humans seeking fish and fruits, or following animals, frequently became permanently lost and separated from one another. Endowed with the procreative urge, those of the few males and females surviving in company inbred for generations in their respective remotenesses utterly unaware of one another's tribes and separate tribal evolution—and thus evolved a plurality of superficial differences in appearance through special chromosomic concentration brought about by the special characteristics of the survival adaptation process. Thus have developed hundreds of only superficially different types, some very numerous and powerful, some successfully monopolizing specific land areas and others as yet wandering. In their ignorance, all of humanity's national governments assume, misinformedly, that there is not and never will be enough of the vital resources to support all or even a large number of humans, *ergo,* that they must automatically fight one another to the death to discover which government might survive. Often to encourage their respective peoples, political leaders evolve partly expedient and partly idealistic ideologies suitable to their viewpoints, but all the ideologies misassume an only-you-or-me—not both—survival premise as having no axiomatic alternative. Because of the invisibility of 99.9% of the source information that contradicts the assumption of a fundamental inadequacy of resources, the probability is that if man is left exclusively to political contriving he will become embroiled in approximately total self-destruction. While the top speed of the intercontinental ballistic rocket is many times that of a bullet, its 20,000 mph is as nothing beside radar-sight's speed of 70,000,000 mph. The speed of information is now so swift that for the first time in history the lethal missile is no longer faster than man's ability to apprehend both its coming and its specific course—twenty minutes before it can reach him. But the ability to see it coming does not confer the capability to dodge it. Now every one of the opposed political systems' swiftest rocketry attacks can be detected so far in advance that each and every side can dispatch, retaliatorily, not only its full arsenal of atomic warheads but also all its rocket-borne chemical and biological warfare missiles. All opposed sides can and will retaliate automatically *in toto,* thus bringing about approximately total human destruction of vast millions immediately, with the balance to be destroyed soon thereafter by the radiational, biological and chemical contamination.

As in our industrio-social age we now design everything *except* the astro-vehicle paraphernalia, all the metals that have ever been mined and put to use have an average quarter century recycling, invention-to-obsolescence periodicity which includes the scrap, melt, redesign and re-use cycling time. All the metals ever mined and so put to use are now invested in structures and machines that, if operated at full capacity, could take care of only 44% of humanity. The rate at which we have been finding and mining new metals is far slower than the rate of increase of human population. This means that if we freeze the world's design standards at their present levels, which are far below the standards of the astro-vehicle technology, 56% of humanity, which means humanity's political majority, is doomed to premature demise, and to want and suffering en route to that early death. There is nothing that politics, per se, can do to alter that condition;

only a design revolution—such as that which is already "made to order" in the potentially thousand-fold performance per pounds, minutes and kilowatts advancement to be realized by the astro-vehicle industry—can change those fundamental conditions of humanity overnight from failure to comprehensive world-around, human success.

Between 1900 and 1969 our space-vehicle Earth's passengers have experienced an increase of from less than 1% of its total population to 41% of total world population now enjoying a standard of living superior to that either experienced or dreamed of by any monarch before 1900. During that time the material resources per each world man were continually decreasing so that the advancement was not accomplished by exploiting more resources. This historical forty-folding of the percentage of humanity's "haves" can only be explained as the fallout of ever higher performance per pound technology as developed for the ships of the world's water and air oceans. That an over-night advancement from 40 to 100% is possible can be understood when we realize that the technological fall-out into our domestic economy of ships of extraterrestrial astrogation have not had time to have important effect on the standard of living because their technological fallout has not yet had time to occur.

It seems eminently clear that we not only must put our space programs on highest priority of attention and resource investment but that all humanity must be accredited and financed to enter into a new re-educational system that is geared to develop our most prominent awareness, that we indeed *are in space* and that all of our concern is with the fact that our space-vehicle Earth and its life-energy-giving Sun, and the tide-pumping Moon can provide ample sustenance and power for all humanity's needs to be derived from our direct energy income without further robbing our fossil fuels energy savings account. In reality, the Sun, the Earth and the Moon are nothing else than a most fantastically welldesigned and space-programmed team of vehicles. All of us *are,* always have been, and so long as we exist, *always will be—nothing else but—astronauts.* Let's pull our heads out of the brain benumbing, mind frustrating misinformedly conditioned reflexes. If it is going to be "All ashore who's going ashore," once more intent to return to nonspace DOWN HERE ON EARTH, humanity is doomed.

But there is hope in sight. The young! While the university students are intuitively skeptical of the validity of any and all evolution-blocking establishments, *ergo,* negatives, the high school age youth thinks spontaneously and positively in astro and electromagnetic technology and their realistic uses. The young of all age levels abhor hypocrisy. They are bored with obsolete UP and DOWN dancing, with bureaucratic inertia, bias of any kind or fear-built security. They disdain white, gray, black and blue lies. The students and school children around the world have idealistic compassion for all humanity. There is a good possibility that they may take over and successfully operate SPACESHIP EARTH. How may we use our intellectual capability to higher advantage? Our muscle is very meager as compared to the muscles of many animals. Our integral muscles are as nothing compared to the power of a tornado or the atom bomb which society contrived—in fear—out of the intellect's fearless discoveries of generalized principles governing the fundamental energy behaviors of physical universe.

In organizing our grand strategy we must first discover where we are now; that is, what our present navigational position in the universal scheme of evolution is. To begin our position-fixing aboard our Spaceship Earth we must first acknowledge that the abundance of immediately consumable, obviously desirable or utterly essential resources have been sufficient until now to allow us to carry on despite our ignorance. Being eventually exhaustible and spoilable, they have been adequate only up to this critical moment. This cushion-for-error of humanity's survival and growth up to now was apparently provided just as a bird inside of the egg is provided with liquid nutriment to develop it to a certain point. But then by design the nutriment is exhausted at just the time when the chick is large enough to be able to locomote on its own legs. And so as the chick pecks at the shell seeking more nutriment it inadvertently breaks open the shell. Stepping forth from its initial sanctuary, the young bird must now forage on its own legs and wings to discover the next phase of its regenerative sustenance.

My own picture of humanity today finds us just about to step out from amongst the pieces of our just one-second-ago broken eggshell. Our innocent, trial-and-error-sustaining nutriment is exhausted. We are faced with an entirely new relationship to the universe. We are going to have to spread our wings of intellect and fly or perish; that is, we must dare immediately to fly by the generalized principles governing universe and not by the ground rules of yesterday's superstitious and erroneously conditioned reflexes. And as we attempt competent thinking we immediately begin to reemploy our innate drive for comprehensive understanding.

The architects and planners, particularly the planners, though rated as specialists, have a little wider focus than do the other professions. Also as human beings they battle the narrow views of specialists—in particular, their patrons—the politicians, and the financial and other legal, but no longer comprehensively effective, heirs to the great pirates'—now only ghostly—prerogatives. At least the planners are allowed to look at *all* of Philadelphia, and not just to peek through a hole at one house or through one door at one room in that house. So I think it's appropriate that we assume the role of planners and begin to do the largest scale comprehensive thinking of which we are capable.

We begin by eschewing the role of specialists who deal only in parts. Becoming deliberately expansive instead of contractive, we ask, "*How* do we think in terms of *wholes*?" if it is true that the bigger the thinking becomes the more lastingly effective it is, we must ask, "How big can we think?"

One of the modern tools of high intellectual advantage is the development of what is called general systems theory. Employing it we begin to think of the largest and most comprehensive systems, and try to do so scientifically. We start by inventorying all the important, known variables that are operative in the problem. But if we don't really know how big "big" is, we may not start big enough, and are thus likely to leave unknown, but critical, variables outside the system which will continue to plague us. Interaction of the unknown variables inside and outside the arbitrarily chosen limits of the system are probably going to generate misleading or outrightly wrong answers. If we are to be effective, we are going to have to think in both the biggest and most minutely-incisive ways permitted by intellect and by the information thus far won through experience.

Can we think of, and state adequately and incisively, what we mean by universe? For universe is, inferentially, the biggest system. If we could start with universe, we would automatically avoid leaving out any strategically critical variables. We find no record as yet of man having successfully defined the universe—scientifically and comprehensively—to include the nonsimultaneous and only partially overlapping, micro-macro, always and everywhere transforming, physical and metaphysical, omni-complementary but nonidentical events.

Man has failed thus far, as a specialist, to define the microcosmic limits of divisibility of the nucleus of the atom, but, epochally, as accomplished by Einstein, has been able to define successfully the physical universe but not the metaphysical universe; nor has he, as yet, defined total universe itself as combining both the physical and metaphysical. The scientist was able to define physical universe by virtue of the experimentally-verified discovery that energy can neither be created nor lost and, therefore, that energy is conserved and is therefore finite. That means it is equatable. Einstein successfully equated the physical universe as $E = Mc^2$. His definition was only a hypothetical venture until fission proved it to be true. The physical universe of associative and dissociative energy was found to be a closed, but nonsimultaneously occurring, system—its separately occurring events being mathematically measurable; i.e., weighable and equatable. But the finite physical universe did not include the metaphysical weightless experiences of universe. All the unweighables, such as any and all our thoughts and all the abstract mathematics, are weightless. The metaphysical aspects of universe have been thought by the physical scientists to defy "closed system's" analysis. I have found, however, as we shall soon witness, the total universe including both its physical and metaphysical behaviors and aspects are scientifically definable.

Einstein and others have spoken exclusively about the physical department of universe in words which may be integrated and digested as *the aggregate of nonsimultaneous and only partially overlapping, nonidentical, but always complementary, omni-transforming, and weighable energy events.* Eddington defines science as "the earnest attempt to set in order the facts of experience." Einstein and many other first-rank scientists noted that science is concerned exclusively with "facts of experience."

Holding to the scientists' experiences as all important, I define universe, including both the physical and metaphysical, as follows: *The universe is the aggregate of all of humanity's consciously-apprehended and communicated experience with the nonsimultaneous, nonidentical, and only partially overlapping, always complementary, weighable and unweighable, ever omni-transforming, event sequences.*

Each experience begins and ends—ergo, is finite. Because our apprehending is packaged, both physically and metaphysically into time increments of alternate awakeness and asleepness as well as into separate finite conceptions such as the discrete energy quanta and the atomic nucleus components of the fundamental physical discontinuity, all experiences are finite. Physical experiments have found no solids, no continuous surfaces or lines—only discontinuous constellations of individual events. An aggregate of finites in finite. *Therefore, universe as experimentally defined, including both the physical and metaphysical, is finite.*

It is therefore possible to initiate our general systems formulation at the all inclusive level of universe whereby no strategic variables will be omitted. Thee is an operational grand strategy of General Systems Analysis that proceeds from here. It is played somewhat like the game of "Twenty Questions," but GSA is more efficient—that is, is more economical—in reaching its answers. It is the same procedural strategy that is used by the computer to weed out all the wrong answers until only the right answer is left.

Having adequately defined the whole system we may proceed to subdivide, progressively. This is accomplished through progressive division into two parts—one of which, by definition could not contain the answer—and discarding of the sterile part. Each progressively retained life part is called a "bit" because of its being produced by the progressive binary "yes" or "no" bi-section of the previously residual live part. The magnitude of such weeding operations is determined by the number of successive bits necessary to isolate the answer.

How many "bi-secting bits" does it take to get rid of all the irrelevancies and leave in lucid isolation that specific information you are seeking? We find that the first subdividing of the concept of universe—bit one—is into what we call a system. *A system subdivides universe into all the universe outside the system (macrocosm) and all the rest of the universe which is inside the system (microcosm) with the exception of the minor fraction of universe which constitutes the system itself.* The system divides universe not only into macrocosm and microcosm but also coincidentally into typical conceptual and nonconceptual aspects of universe—that is, an overlappingly-associable consideration, on the one hand, and, on the other hand, all the nonassociable, nonoverlappingly-considerable, nonsimultaneously-transforming events of nonsynchronizable disparate wave frequency rate ranges.

A thought is a system, and is inherently conceptual—though often only dimply and confusedly conceptual at the moment of first awareness of the as yet only vaguely describable thinking activity. Because total universe is nonsimultaneous it is not conceptual. Conceptuality is produced by isolation, such as in the instance of one single, static picture held out from a moving-picture film's continuity, or scenario. Universe is an evolutionary-process scenario without beginning or end, because the shown part is continually transformed chemically into fresh film and re-exposed to the ever self-reorganizing process of latest thought realizations which must continually introduce new significance into the freshly written description of the ever-transforming events before splicing the film in again for its next projection phase.

Heisenberg's principle of "indeterminism" which recognized the experimental discovery that the act of measuring always alters that which was being measured turns experience into a continuous and never-repeatable evolutionary scenario. One picture of the scenario about the caterpillar phase does not communicate its transformation into the butterfly phase, etc. The question, "I wonder what is outside the outside-of-universe?" is a request for a single picture description of a scenario of transformations and is an inherently invalid question. It is the same as looking at a dictionary and saying, "Which word is the dictionary?" It is a meaningless question.

It is characteristic of "all" thinking—of all system's conceptioning—that all the lines of thought interrelationships must return cyclically upon themselves in a plurality of directions, as do various great circles around spheres. Thus may we interrelatedly comprehend the constellation—or system—of experiences under consideration. Thus may we comprehend how the special-case economy demonstrated by the particular system considered also discloses the generalized law of energy conservation of physical universe.

To hit a duck in flight a hunter does not fire his gun at the bird where the gunner sees him but ahead of the bird, so that the bird and the bullet will meet each other at a point not in line between the gunner and the bird at time of firing. Gravity and wind also pull the bullet in two different directions which altogether impart a mild corkscrew trajectory to the bullet. Two airplanes in nighttime dogfights of World War II firing at each other with tracer bullets and photographed by a third plane show clearly the corkscrew trajectories as one hits the other. Einstein and Reiman, the Hindu mathematician, gave the name *geodesic lines* to these curvilinear and *most economical lines of interrelationship between two independently moving "events"*—the events in this case being the two airplanes.

A great circle is a line formed on a sphere's surface by a plane going through the sphere's center. Lesser circles are formed on the surfaces of spheres by planes cutting through spheres but not passing through the sphere's center. When a lesser circle is superimposed on a great circle it cuts across the latter at two points, *A* and *B*. It is a shorter distance between *A* and *B* on the great circle's shortest are than it is on the lesser circle's shortest arc. Great circles are geodesic lines because they provide the most economical (energy, effort) distances between any two points on a spherical system's surface; therefore, nature, which always employs only the most economical realizations must use those great circles which, unlike spiral lines, return upon themselves in the most economical manner. All the system's paths must be topologically and circularly interrelated for conceptually definitive, locally transformable, polyhedronal understanding to be attained in our spontaneous—ergo, most economical—geodesicly structured thoughts.

Thinking itself consists of self-disciplined dismissal of both the macrocosmic and microcosmic irrelevancies which leaves only the lucidly-relevant considerations. The macrocosmic irrelevancies are all the events too large and too infrequent to be synchronizably tuneable in any possible way without consideration (a beautiful word meaning putting stars together). The microcosmic irrelevancies are all the events which are obviously too small and too frequent to be differentially resolved in any way or to be synchronizably-tuneable within the lucidly-relevant wave-frequency limits of the system we are considering.

How many stages of dismissal of irrelevancies does it take—that is, proceeding from "universe" as I defined it, how many bits does it take—lucidly to isolate all the geodesic interrelations of all the "star" identities in the constellation under consideration? The answer is the formula $(N^2 - N)/2$ where N is the number of stars in the thought-discerned constellation of focal point entities comprising the problem.

"Comprehension" means identifying all the most uniquely economical inter-relationships of the focal point entities involved. We may say then that:

$$\text{Comprehension} = \frac{N^2 - N}{2}.$$

This is the way in which thought processes operate with mathematical logic. The mathematics involved consist of topology, combined with vectorial geometry, which combination I call "synergetics"—which word I will define while clarifying its use. By questioning many audiences, I have discovered that only about one in three hundred are familiar with synergy. The word is obviously not a popular word. Synergy is the only word in our language that means *behavior of whole systems unpredicted by the separately observed behaviors of any of the system's separate parts of any subassembly of the system's parts.* There is nothing in the chemistry of a toenail that predicts the existence of a human being.

I once asked an audience of the National Honors Society in chemistry, "How many of you are familiar with the word, synergy?" and all hands went up. Synergy is the essence of chemistry. The tensile strength of chrome-nickel, steel, which is approximately 350,000 pounds per square inch, is 100,000 PSI greater than the sum of the tensile strengths of all of each of its alloyed together, component, metallic elements. Here is a "chain" that is 50% stronger than the sum of the strengths of all links. We think popularly only in the terms of a chain being no stronger than its weakest link, which concept fails to consider, for instance, the case of an endlessly interlinked chain of atomically self-renewing links of omni-equal strength or of an omni-directionally interlinked chain matrix of ever renewed atomic links in which one broken link would be, only momentarily, a local cavern within the whole mass having no weakening effect on the whole, for every link within the matrix is a high frequency, recurring, break-and-make restructuring of the system.

Since synergy is the only word in our language meaning behavior of wholes unpredicted by behavior of their parts, it is clear that society does not think there are behaviors of whole systems unpredicted by their separate parts. This means that society's formally-accredited thoughts and ways of accrediting others are grossly inadequate in comprehending the nonconceptual qualities of the scenario "universal evolution."

There is nothing about an electron alone that forecasts the proton, nor is there anything about the Earth or the Moon that forecasts the coexistence of the sun. The solar system is synergetic—unpredicted by its separate parts. But the interplay of Sun as supply ship of Earth and the Moon's gravitationally produced tidal pulsations on Earth all interact to produce the biosphere's chemical conditions which permit but do not cause the regeneration of life on Spaceship Earth. This is all synergetic. There is nothing about the gases given off respiratorily by Earth's green vegetation that predicts that those gases will be essential to the life support of all mammals aboard Spaceship Earth, and nothing about the mammals that predicts that the gases which they give off respiratorily are essential to the support of the vegetation aboard our Spaceship Earth. Universe is synergetic. Life is synergetic.

Summarizing synergetically I may conclude that since my experimental interrogation of more than one hundred audiences all around the world has shown that less than one in three hundred university students has ever heard of the word synergy, and since it is the only word that has that meaning it is obvious that the world has not thought there are any behaviors of whole systems unpredictable by their parts. This is partially the consequence of overspecialization and of leaving the business of the whole to the old pirates to be visibly conducted by their stooges, the feudal kings or local politicians.

There is a corollary of synergy which says that the known behavior of the whole and the known behavior of a minimum of known parts often makes possible the discovery of the values of the remaining parts as does the known sum of the angles of a triangle plus the known behavior of three of its six parts make possible evaluating the others. Topology provides the synergetic means of ascertaining the values of any system of experiences.

Topology is the science of fundamental pattern and structural relationships of even constellations. It was discovered and developed by the mathematician Euler. He discovered that all patterns can be reduced to three prime conceptual characteristics: to *lines; points* where two lines cross or the same line crosses itself; and *areas,* bound by lines. He found that there is a constant relative abundance of these three fundamentally unique and no further reducible aspects of all patterning

$$P + A = L + 2.$$

This reads: the number of points plus the number of areas always equals the number of lines plus the number constant two. There are times when one area happens to coincide with others. When the faces of polyhedra coincide illusionarily the congruently hidden faces must be accounted arithmetically in formula.

Thus man has developed an externalized metabolic regeneration organism involving the whole of Spaceship Earth and all its resources. Any human being can physically employ that organism, whereas only one human can employ the organically integral craft tool. All 91 of the 92 chemical elements thus far found aboard our spaceship are completely involved in the world-around industrial network. The full family of chemical elements is unevenly distributed, and therefore our total planet is at all times involved in the industrial integration of the unique physical behaviors of each of all the elements. Paradoxically, at the present moment our Spaceship Earth is in the perilous condition of having the Russians sitting at one set of the co-pilot's flying controls while the Americans sit at the other. France controls the starboard engines, and the Chinese control the port engines, while the United Nations controls the passenger operation. The result is an increasing number of UFO hallucinations of sovereign states darting backwards and forwards and around in circles, getting nowhere, at an incredibly accelerating rate of speed.

All of humanity's tool extensions are divisible into two main groups: the craft and the industrial tools. I define the craft tools as all those tools which could be invented by one man starting all alone, naked in the wilderness, using only his own experience and his own integral facilities. Under these isolated conditions he could and did invent spears, slings, bows, and arrows, etc. By industrial tools I mean all the tools that cannot be produced by one man, as for instance the SS *Queen Mary.* With this definition, we find that the spoken word, which took a minimum of two humans to develop, was the first industrial tool. It brought about the progressive integration of all individual generation-to-generation experiences and thoughts of all humanity everywhere and everywhen. The Bible says, "In the beginning was the word"; I say to you, "In the beginning of industrialization was the spoken word." With the graphic writing of the words and ideas we have the beginning of the computer, for the computer *stores* and retrieves information. The written word, dictionary and the book were the first information storing and retrieving systems.

The craft tools are used initially by man to make the first industrial tools. Man is using his hands today most informatively and expertly only to press the buttons that set in action the further action of the tools which reproduce other tools which may be used informatively to make other tools. In the craft economies craftsman artists make only end or consumer-products. In the industrial economy the craftsman artists make the tools and the tools make the end or consumer-products. In this industrial development the mechanical advantages of men are pyramided rapidly and synergetically into invisible magnitudes of ever more incisive and inclusive tooling which produces ever more with ever less resource investment per each unit of end-product, or service, performance.

As we study industrialization, we see that we cannot have mass production unless we have mass consumption. This was effected evolutionarily by the great social struggles of labor to increase wages and spread the benefits and prevent reduction of the numbers of workers employed. The labor movement made possible mass purchasing; ergo, mass production ergo, low prices on vastly improved products and services, which have altogether established entirely new and higher standards of humanity's living.

Our labor world and all salaried workers, including school teachers and college professors, are now, at least subconsciously if not consciously, afraid that automation will take away their jobs. They are afraid they won't be able to do what is called "earning a living," which is short for earning the right to live. This term implies that normally we are supposed to die prematurely and that it is abnormal to be able to earn a living. It is paradoxical that only the abnormal or exceptional are entitled to prosper. Yesterday the term even inferred that success was so very abnormal that only divinely ordained kings and nobles were entitled to eat fairly regularly.

It is easy to demonstrate to those who will take the time and the trouble to unbias their thoughts that automation swiftly can multiply the physical energy part of wealth much more rapidly and profusely than can man's muscle and brain-reflexed—manually-controlled production. On the other hand humans alone can foresee, integrate, and anticipate the new tasks to be done by the progressively automated wealth-producing machinery. To take advantage of the fabulous magnitudes of real wealth waiting to be employed intelligently by humans and unblock automation's postponement by organized labor we must give each human who is or becomes unemployed a life fellowship in research and development or in just simple thinking. Man must be able to dare to think truthfully and to act accordingly without fear of losing his franchise to live. The use of mind fellowships will permit humans comprehensively to expand and accelerate scientific exploration and experimental prototype development. For every 100,000 employed in research and development, or just plain thinking, one probably will make a breakthrough that will more than pay for the other 99,999 fellowships. Thus, production will no longer be impeded by humans trying to do what machines can do better. Contrariwise, omni-automated and inanimately powered production will unleash humanity's unique capability—its metaphysical capability. Historically speaking, these steps will be taken within the next decade. There is no doubt about it. But not without much social crisis and consequent educational experience and discovery concerning the nature of our unlimited wealth. Through the universal research and development fellowships, we're going to start emancipating humanity from being muscle and reflex machines. We're going to give everybody a chance to develop their most powerful mental and intuitive faculties. Given their research and development fellowship, many who have been frustrated during their younger years may feel like going fishing. Fishing provides an excellent opportunity to think clearly; to review one's life; to recall one's earlier frustrated and abandoned longings and curiosities. What we want everybody to do is to *think* clearly.

We soon will begin to generate wealth so rapidly that we can do very great things. I would like you to think what this may do realistically for living without spoiling the landscape, or the antiquities or the trails of humanity throughout the ages, or despoiling the integrity of romance, vision, and harmonic creativity. All the great office buildings will be emptied of earned living workers, and the automated office-processing of information will be centralized in the basements of a few buildings. This will permit all the modernly mechanized office buildings to be used as dwelling facilities.

When we approach our problems on a universal, general systems basis and progressively eliminate the irrelevancies, somewhat as we peel petals from an artichoke, at each move we leave in full visibility the next most important layer of factors with which we must deal. We gradually uncover *you* and *me* in the heart of now. But evolution requires that we comprehend each layer in order to unpeel it. We have now updated our definitions of universe by conforming them with the most recent and erudite scientific findings such as those of Einstein and Planck. Earlier in our thinking we discovered man's function in universe to be that of the most effective metaphysical capability experimentally evidenced thus far within our locally observable phases and time zones of universe. We have also discovered that it is humanity's task to comprehend and set in order the special case facts of human experience and to win therefrom knowledge of the *a priori* existence of a complex of generalized, abstract principles which apparently altogether govern all physically evolving phenomena of universe.

We have learned that only and exclusively through use of his mind can man inventively employ the generalized principles further to conserve the locally available physical energy of the only universally unlimited supply. Only thus can man put to orderly advantage the various, local, and otherwise disorderly behaviors of the entropic, physical universe. Man can and may metaphysically comprehend, anticipate, shunt, and meteringly introduce the evolutionarily organized environment events in the magnitudes and frequencies that best synchronize with the patterns of his successful and metaphysical metabolic regeneration while ever increasing the degrees of humanity's space and time freedoms from yesterday's ignorance sustaining survival procedure chores and their personal time capital wasting.

Now we have comprehended and peeled off the layers of petals which disclosed not only that physical energy is conserved but also that it is ever increasingly deposited as a fossil-fuel savings account aboard our Spaceship Earth through photosynthesis and progressive, complex, topsoil fossilization buried ever deeper within Earth's crust by frost, wind, flood, volcanoes, and earthquake upheavals. We have thus discovered also that we can make all of humanity successful through science's worldengulfing industrial evolution provided that we are not so foolish as to continue to exhaust in a split second of astronomical history the orderly energy savings of billions of years' energy conservation aboard our Spaceship Earth. These energy savings have been put into our Spaceship's life-regeneration-guaranteeing bank account for use only in self-starter functions.

The fossil fuel deposits of our Spaceship Earth correspond to our automobile's storage battery which must be conserved to turn over our main engine's self-starter. Thereafter, our "main engine," the life regenerating processes, must operate exclusively on our vast daily energy income from the powers of wind, tide, water, and the direct Sun radiation energy. The fossil-fuel savings account has been put aboard Spaceship Earth for the exclusive function of getting the new machinery built with which to support life and humanity at ever more effective standards of vital physical energy and reinspiring metaphysical sustenance to be sustained exclusively on our Sun radiation's and Moon pull gravity's tidal, wind, and rainfall generated pulsating and therefore harnessable energies. The daily income energies are excessively adequate for the operation of our main industrial engines and their automated productions. The energy expended in one minute of a tropical hurricane equals the combined energy of all the USA and USSR nuclear weapons. Only by understanding this scheme may we continue for all time ahead to enjoy and explore universe as we progressively harness evermore of the celestially generated tidal and storm generated wind, water, and electrical power concentrations. We cannot afford to expend our fossil fuels faster than we are "recharging our battery," which means precisely the rate at which the fossil fuels are being continually deposited within Earth's spherical crust.

We have discovered that it is highly feasible for all the human passengers aboard Spaceship Earth to enjoy the whole ship without any individual interfering with another and without any individual being advantaged at the expense of another, provided that we are not so foolish as to burn up our ship and its operating equipment by powering our prime operations exclusively on atomic reactor generated energy. The too-shortsighted and debilitating exploitation of fossil fuels and atomic energy are similar to running out automobiles only on the self-starters and batteries and as the latter become exhausted replenishing the batteries only by starting the chain reaction consumption of the atoms with which the automobiles are constituted.

We have discovered also why we were given our intellectual faculties and physical extension facilities. We have discovered that we have the inherent capability and inferentially the responsibility of making humanity comprehensively and sustainably successful. We have learned the difference between brain and mind capabilities. We have learned of the superstitions and inferiority complexes built into all humanity through all of history's yesterdays of slavish survival under conditions of abysmal illiteracy and ignorance wherein only the most ruthless, shrewd, and eventually brutish could sustain existence, and then for no more than a third of its known potential life span.

This all brings us to a realization of the enormous educational task which must be successfully accomplished right now in a hurry in order to convert man's spin-dive towards oblivion into an intellectually mastered power pullout into safe and level flight of physical and metaphysical success, whereafter he may turn his Spaceship Earth's occupancy into a universe exploring advantage. If it comprehends and reacts effectively, humanity will open an entirely new chapter of the experiences and the thoughts and drives thereby stimulated.

Most importantly we have learned that from here on it is success for all or for none, for it is experimentally proven by physics that "unity is plural and at minimum two"—the complementary but not mirror-imaged proton and neutron. You and I are inherently different and complementary. Together we average as zero—that is, as eternity. Now having attained that cosmic degree of orbital conceptioning we will use our retro-rocket controls to negotiate our reentry of our Spaceship Earth's atmosphere and return to our omnibefuddled present. Here we find ourselves maintaining the fiction that our cross-breeding World Man consists fundamentally of innately different nations and races which are the antithesis of that cross-breeding. Nations are products of many generations of local inbreeding in a myriad of remote human enclaves. With grandfather chiefs often marrying incestuously the gene concentrations brought about hybrid nationally-unique physiological characteristics which in the extreme northern hibernations bleached out the human skin and in the equatorial casting off of all clothing inbred darkly tanned pigmentation. All are the consequence only of unique local environment conditions and super inbreeding.

The crossbreeding world people on the North American continent consists of two separate *input* sets. The first era input set consists of those who came with the prevailing winds and ocean currents eastward to the North, South, and Central Americas by raft and by boat from across the Pacific, primarily during an age which started at least thirty thousand years ago, possibly millions of years ago, and terminated 300 years ago. The eastbound trans-Pacific migration peopled the west coast of both South and North America and migrated inland towards the two continents' middle ground in Central America and Mexico. In Mexico today will be found every type of human characteristic and every known physiognomy, each of which occur in such a variety of skin shades from black to white that they do not permit the ignorance-invented "race" distinctions predicted only superficially on extreme limits of skin color. The second or west-bound input era set of crossbreeding world man now peopling the Americas consists of the gradual and slower migration around the world from the Pacific Ocean westward into the wind, "following the sun," and travelling both by sea through Malaysia, across the Indian Ocean up the Persian Gulf into Mesopotamia and overland into the Mediterranean, up the Nile from East Africa into the South and North Atlantic to America—or over the Chinese, Mongolian, Siberian, and European hinterlands to the Atlantic and to the Americas.

Now both east and westbound era sets are crossbreeding with one another in ever-accelerating degree on America's continental middleground. This omni reintegration of world man from all the diverse hybrids is producing a crossbred people on the Pacific Coast of North America. Here with its aerospace and oceans penetrating capabilities, a world type of humanity is taking the springboard into all of the hitherto hostile environments of universe into the ocean depths and into the sky and all around the earth. Returning you again to our omni-befuddled present, we realize that reorganization of humanity's economic accounting system and its implementation of the total commonwealth capability by total world society, aided by the computer's vast memory and high speed recall comes first of all of the first-things-first that we must attend to make our space vehicle Earth a successful man operation. We may now raise our sights, in fact must raise our sights, to take the initiative in planning the world-around industrial retooling revolution. We must undertake to increase the performance per pound of the world's resources until they provide all of humanity a high standard of living. We can no longer wait to see whose biased political system should prevail over the world.

You may not feel very confident about how you are going to earn your right to live under such world-around patronless conditions. But I say to you the sooner you do the better chance we have of pulling out of humanity's otherwise fatal nose dive into oblivion. As the world political economic emergencies increase, remember that we have discovered a way to make the total world work. It must be initiated and in strong momentum before we pass the point of no return. You may gain great confidence from that fact that your fellow men, some of them your great labor leaders, are already aware and eager to educate their own rank and file on the fallacy of opposition to automation.

I have visited more than 300 universities and colleges around the world as an invited and appointed professor and have found an increasing number of students who understand all that we have been reviewing. They are comprehending increasingly that elimination of war can only be realized through a design and invention revolution. When it is realized by society that wealth is as much everybody's as is the air and sunlight, it no longer will be rated as a personal handout for anyone to accept a high standard of living in the form of an annual research and development fellowship.

I have owned successively, since boyhood, fifty-four automobiles. I will never own another. I have now given up driving. I began to leave my cars at airports—never or only infrequently getting back to them. My new pattern requires renting new cars at the airports as needed. I am progressively ceasing to own things, not on a political-schism basis, as for instance Henry George's ideology, but simply on a practical basis. Possession is becoming progressively burdensome and wasteful and therefore obsolete. Why accumulate mementos of far away places when you are much more frequently in those places than at your yesterday's home, state, city and street identified residences, as required for passport, taxing, and voting functions? Why not completely restore the great cities and buildings of antiquity and send back to them all their fragmented treasures now deployed in the world's museums? Thus, may whole eras be reinhabited and experienced by an ever increasingly interested, well-informed, and inspired humanity. Thus, may all the world regain or retain its regenerative metaphysical mysteries.

I travel between Southern and Northern Hemispheres and around the world so frequently that I no longer have any so-called normal winter and summer, nor normal night and day, for I fly in and out of the shaded or sunflooded areas of the spinning, orbiting Earth with ever-increased frequency. I wear three watches to tell me what time it is at my "home" office, so that I can call them by long distance telephone. One is set for the time of day in the place to which I am next going, and one is set temporarily for the locality in which I happen to be. I now see the Earth realistically as a sphere and think of it as a spaceship. It is big, but it is comprehensible. I no longer think in terms of "weeks" except as I stumble over their antiquated stop-and-go habits. Nature has no "weeks." Quite clearly the peak traffic patterns exploited by businessmen who are eager to make the most profit in order to prove their right to live causes everybody to go in and out of the airport during two short moments in the twenty-four hours with all the main facilities shut down two-thirds of the time. All our beds around the world are empty for two-thirds of the time. Our living rooms are empty seven-eighths of the time.

The population explosion is a myth. As we industrialize, down goes the annual birth rate. We observed[4] that, by 1997, the whole world became industrialized, and, as with the United States, and as with all Europe and China and Japan today, the birth rate is dwindling, and the bulge in population will be recognized as accounted for exclusively by those who are living longer.[4]

When world realization of its unlimited wealth has been established there as yet will be room for the whole of humanity to stand indoors in greater New York City, with more room for each human than at an average cocktail party.

We will oscillate progressively between social concentrations in cultural centers and in multideployment in greater areas of our Spaceship Earth's as yet very ample accommodations. The same humans will increasingly converge for metaphysical intercourse and deploy for physical experiences.

Each of our four billion humans' shares of the Spaceship Earth's resources as yet today amount to two-hundred billion tons.

It is also to be remembered that despite the fact that you are accustomed to thinking only in dots and lines and a little bit in areas does not defeat the fact that we live in omnidirectional space-time and that a four dimensional universe provides ample individual freedoms for any contingencies.

So, planners, architects, and engineers, take the initiative. Go to work, and above all co-operate and don't hold back on one another or try to gain at the expense of another. Any success in such lopsidedness will be increasingly short-lived. These are the synergetic rules that evolution is employing and trying to make clear to us. They are not man-made laws. They are the infinitely accommodative laws of the intellectual integrity governing universe.[2]

The preceding material has been excerpted from the work of Dr. R. Buckminster Fuller[1,2] with permission of the author.

As a fitting postscript to this article by the late Professor Fuller, the reader is referred to the declaration on climate change adopted at the 1989 Ministerial Conference held in the Netherlands[3] which is presented in Appendices (Table 11 of this Encyclopedia).

This was an important landmark in an ongoing series of international meetings in the field of climate change policy at the political level.

Consultations and discussions prior to, and during, the Conference culminated in the adoption of a Declaration, by consensus of all parties present (This included 67 countries). The Noordwijk Declaration's unique new concepts and targets are addressed as follows:

- CO_2-emission stabilization and future reductions;
- a global forest stock balance and future net forest growth;
- funding mechanisms for both existing and additional funds;
- elements of a climate change convention;
- the principle of shared responsibility and the particular responsibilities of both developed and developing countries.

Also, there is an agreement to strengthen the amendments of the Montreal Protocol to phase out chlorofluorocarbons in a more timely fashion (i.e. by the year 2000).

The Kyoto accord,[6] negotiated in 1997 in Kyoto, Japan, requires industrial nations—with varying targets—to reduce their emissions of greenhouse gases which trap heat and result in global warming below their 1990 levels, in the five years from 2008 to 2012. As of Feb. 16, 2005, the date the agreement took effect, 35 nations planned to cut their emissions of carbon dioxide and other greenhouse gases.

However, in the United States, which generates a fifth of the world's greenhouse gases and which formally rejected the Kyoto pact in 2001, a growing number of companies regard mandatory reductions as inevitable. In keeping with the spirit of Kyoto, Michael G. Morris, chief executive of American Electric Power, the largest electricity generator in the United States and a top emitter of CO_2, has pledged a 10% reduction in those emissions from its plants by 2006, rather than resisting the agreement's philosophy. Nations with rapidly growing economies, like China and India, which approved the agreement, are not required to reduce greenhouse gas emissions in Kyoto Phase One—even though together, they already account for 14 percent of the world's total. "For the European Union, the target is an 8 percent reduction below emissions levels in 1990. But the Germans went beyond that and agreed to a more ambitious target of 21 percent because they expected windfall gains by shutting down polluting, coal-fired power plants in the former East Germany. (It now seems likely to fall somewhat short of that.)"[5] The Kyoto Protocol encourages trading carbon dioxide emissions credits, some of which may be earned from reforestation projects which absorb CO_2 from the atmosphere and others from the use of cleaner technologies.[5]

TEACHING OF ENVIRONMENTAL STUDIES: see ENVIRONMENTAL EDUCATION

THERMAL EFFECTS ON FISH ECOLOGY

Of all environmental factors that influence aquatic organisms, temperature is the most all-pervasive. There is always an environmental temperature while other factors may or may not be present to exert their effects. Fish are, for all practical purposes, thermal conformers, or obligate poikilotherms. That is, they are able to exert little significant influence on maintaining a certain body temperature by specialized metabolic or behavioral means. Their body temperature thus fluctuates nearly in concert with the temperature of their aquatic medium (although particularly large, actively-moving fish such as tuna have deep muscle temperatures slightly higher than the water). Intimate contact at the gills of body fluids with the outside water and the high specific heat of water provide a very efficient heat exchanger that insures this near identity of internal and external temperatures.

Every response of fish, from incubation of the egg to feeding activity, digestive and metabolic processes, reproduction, geographic distribution, and even survival, proceeds within a thermal range dictated by the immediate environment. As human activities change this thermal environment, such as through deforestation, damming or thermal discharges from power stations, the activities of indigenous fish species must also change. Depending upon the magnitude and rates of the thermal changes, there may be minor readjustments of the rates of metabolism and growth, or major changes in the distribution of species and of the functioning of the affected aquatic ecosystems.

In our recent environmental awareness, we have coined the phrase “thermal pollution” for extensive thermal changes to natural aquatic environments that are believed to be detrimental to desired fish populations. The key to controlling “thermal pollution” is a firm understanding of how temperature affects fish, and of the circumstances that truly constitute pollution.

The subject of thermal effects on fishes has been given critical scientific review periodically especially over the years (e.g. Fry, 1947; Bullock, 1955; Brett, 1956; Fry, 1964; Fry, 1967 and Brett, 1970). Scientific knowledge as a basis for controlling pollution is clearly more advanced in this area than for almost any other environmental factor. This knowledge has been applied to the context of thermal modifications by electricity generating stations in two symposium volumes (Parker and Krenkel, 1969; Krenkel and Parker, 1969) and by Cairns (1968), Clark (1969), Parker and Krenkel (1969) and Countant (1970 and 1972). The voluminous scientific literature on temperature effects on fishes may be easily searched for specific information in bibliographies by Kennedy and Mihursky (1967), Raney and Menzel (1969) and annual literature reviews by Coutant (1968, 1969, 1970, 1971) and Coutant and Goodyear (1972). Readers seeking more than a general review are advised to read these materials. (*See also* Alabaster 1986).

While fish must conform to water temperature, they have evolved mechanisms other than body temperature regulation to deal with vicissitudes of temperature fluctuations that occur geographically, seasonally and daily. That such mechanisms exist became apparent when fish physiologists realized that at any one temperature a fish may survive or die, be hyperactive or be numbed into activity, be stimulated to migrate or be passive, be sexually mature or immature, all depending upon the state of previous temperature exposures. Temperature affects organisms not only by absolute level (as in physics and chemistry) but also by change. Like light, temperature can exert effects through daily or seasonal patterns that exhibit a special quality beyond that of absolute level[†].

The functional properties of temperature acting on fish can be summarized as follows: Temperature can act as a lethal agent that kills the fish directly, as a stressing agent that destroys the fish indirectly, as a controlling factor that sets the pace of metabolism and development, as a limiting factor that restricts activity and distribution, as a limiting factor that restricts activity and distribution, as a masking factor that interacts with other environmental factors by blocking or altering their potential expression, and as a directing agent in gradients that stimulate sensory perception and orient activity. Each of these properties can be visualized as acting on two levels—on the individual fish and on the population of any one fish species.

TEMPERATURE AS A LETHAL AGENT

Mass mortalities of fish in nature have often been reported, but usually the causes are obscure. Fish rarely die in places and at times when proper field instrumentation is operating or when trained observers are at hand. Many deaths probably go unnoticed, for scavengers may act quickly or water

---

[†] Clear distinction must be made between *heat* which is a quantitative measure of energy of molecular motion that is dependent upon the mass of an object or body of water and *temperature* which is a measure (unrelated to mass) of energy intensity. Organisms respond to temperature, not to heat.

currents disperse carcasses (particularly of small fishes). The most common reports are of cold kills brought about by particularly severe winters or rapid drops in temperature (e.g. summaries by Brett, 1970). It is well known among fishery biologists that the abundance of a species reproduced in any one year varies tremendously, a fact that many scientists have attributed in part to deaths from unfavorable temperatures at early life stages where the fish are too small to be recognized as constituting a "fish kill".

Studies of temperature tolerance in fishes began in the last century. The early method of determining the lethal end-point (generally the cessation of opercular movements) by slow heating or cooling was generally supplanted in the 1940s by a more precise method of direct transfer to a series of preset temperatures in which the rates of dying of individual fish and the statistical variation among many individuals could be obtained. These experiments demonstrated the importance of recent past history of the fish, both the controlled holding temperature imposed in the laboratory prior to testing acclimation and the seasonal environmental temperature when fish were tested directly from field collections (acclimatization).

These experiments also showed that each species of fish (and often each distinct life stage of one species) has a characteristic range of temperature that it will tolerate that is established by internal biochemical adjustments made while at the previous holding temperature (Figure 1). Ordinarily (for purposes of comparison) the upper and lower ends of this range are defined by survival of 50% of a sample of individuals similar in size, health and other factors, for a specified length of time, often one week. The tolerance range is shifted upward by long-term holding (acclimation) in warmer water, and downward by acclimation to cooler water. This accommodation is limited, however, at the lower end by freezing point of water (for species in temperate latitudes) and at the upper end by an ultimate lethal threshold. The graphic representation (Figure 1) is a geometric figure for which an area can be computed. The areas (as degrees squared) provide convenient measures of the relative overall sensitivity of tolerance among different species and life stages (a small area or zone on the graph signified high thermal sensitivity).

It is not surprising that rough species such as carp and goldfish were found to have large thermal tolerance zones.

Outside the thermal tolerance zone, premature death is inevitable and its onset is a function of both temperature and time of exposure (thermal resistance). Death occurs more rapidly the farther the temperature is from the threshold (Figure 2), an attribute common to the action of toxicants, pharmaceuticals, and radiation. The duration of survival of half of a test population of fish at extreme temperature can be expressed as an equation based on experimental data for each acclimation temperature:

$$\log \text{survival time}_{(\text{min})} = a + b\,(\text{Temp}_{(^\circ\text{C})}),$$

in which a and b are intercept and slope of the linear regression lines in Figure 2. In some cases the time-temperature relationship is more complex than this semi-logarithmic model, but this expression is the most generally applicable and is the one most generally accepted by the scientific community. The equation defines the average rate of dying at any extreme temperature.

The thermal resistance equations allow prediction of fish survival (or death) in zones where human activity induces

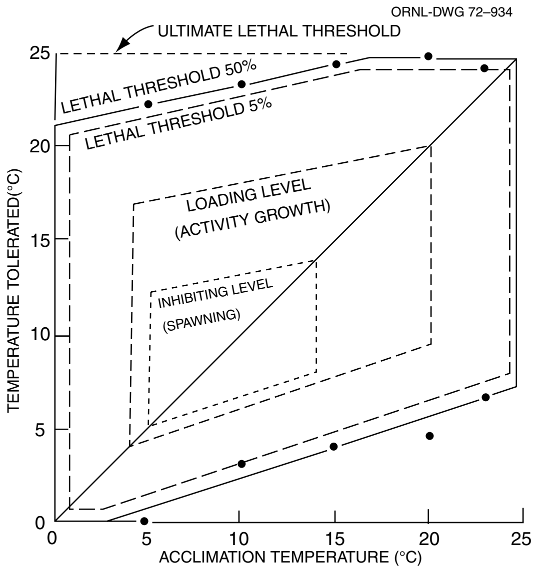

FIGURE 1 Upper and lower lethal temperatures for young sockeye salmon with various acclimation temperatures, plotted to show the ranges of tolerance, and within these ranges more restrictive requirements for activity, growth or spawning. (Reproduced by permission from Coutant, 1972.)

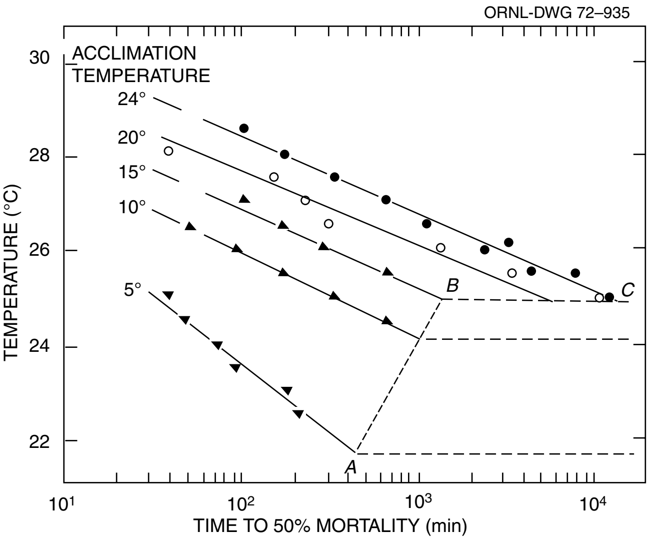

FIGURE 2 Median resistance times to high temperatures among young chinook salmon acclimated to the temperatures indicated. Line A-B denotes rising lethal threshold levels with increasing acclimation temperature. This rise ceases at higher acclimation temperatures. (Reproduced by permission from Coutant, 1972.)

extreme high temperatures. For example, juvenile salmon and trout were found to pass through warm mixing zones of thermal discharges to the Columbia River during their seaward migration (Becker *et al.,* 1971). The thermal exposure was a complex pattern of rapid temperature rise (often to temperatures beyond the tolerance zone) followed by a slow decline as the heated effluent mixed with the cooler river. By using the equation-expressed rates of dying at each of the temperatures briefly experienced, and the length of time the fish were exposed to each incremental temperature, the ability of the fish to survive the exposure was estimated and compared with actual field exposures. Similar predictions can be made for proposed thermal discharges, and corrective engineering can be selected before the project is constructed. Similar predictions can be made for circumstances where fish may become acclimated to warm water (e.g. in a discharge canal) and then be cooled rapidly and face a potential cold kill. This predictive methodology is further described by Coutant (1972).

TEMPERATURE AS A STRESSING FACTOR

Death need not come to fish directly from temperature or its change. In natural ecological systems death often comes as the result of a secondary agent acting upon a fish weakened by some stress such as temperature. This secondary agent is often disease or predator. A potentially lethal high temperature will, for example, induce loss of equilibrium before the physiological death point is reached, and equilibrium loss (going "belly-up") in a natural environment is an open invitation to predators. In fact, ongoing research indicates that stress from relatively small temperature changes (both up and down) will induce selective predation on the stressed fish. The effect appears to follow a time-temperature pattern similar to that for death, with stress appearing after shorter exposures and lower temperatures than required for death directly. The predictability developed for lethal responses can be applied to these stressing conditions as well, if we wish to prevent "ecological death."

TEMPERATURE AS A CONTROLLING FACTOR

Metabolism

Within the zone of thermal tolerance of any species (Figure 1), the most important contributor to survival and success in nature is the dynamic cycle of energy intake, conversion and utilization for activity, development (the differentiation of cells) and growth (multiplication of cells and storage of energy reserves). Since the time that Fry (1947) observed that environmental temperature controls energy metabolism, there has been extensive research in this area of fish physiology and biochemistry. This research has yielded important generalizations about the temperature responses of fish, and the physiological and biochemical "reasons" for these responses.

Metabolic processes are basically chemical in character. Among the most significant vital chemical reactions are the actions of the living catalysts (enzymes) which control the oxidation of organic food materials. Most enzymes show an optimum temperature at which they reach a maximum rate of catalytic activity. This is sometimes higher than the upper lethal threshold for the whole fish. The aggregate of many metabolic reactions also exhibits a temperature optimum, or point of maximum rate, which is often remarkably similar for various functions involved, for example digestion, development and locomotion (Figure 3). Through genetic selection, the optimum has become different for any two species. Below the optimum, the maximum rate possible is controlled by water temperature. These rates can be quite different for various functions. It should be noted that the optimum temperature

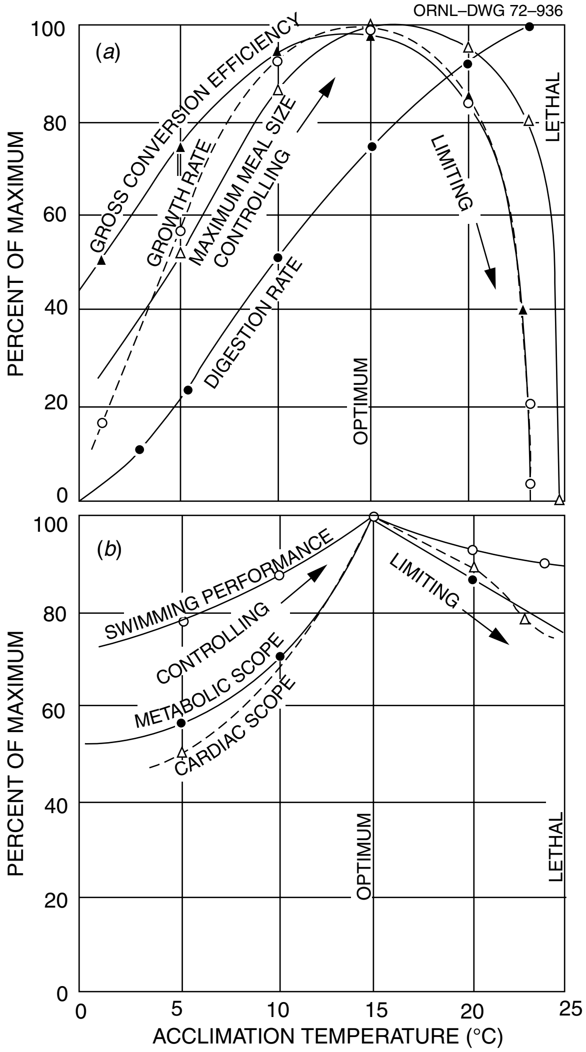

FIGURE 3 Performance of sockeye salmon in relation to acclimation temperature. There are three characteristic type responses; two have coinciding optima. (Reproduced by permission from Coutant, 1972.)

and the maximum metabolic rates at any given temperature may be quite different during embryonic development and during the lifetime of the fully-developed fish.

Of the various methods that have been used to measure metabolic rates (see Brett, 1971), the most often measured has been the rate of oxygen consumption. This provides an instantaneous measure of enzyme activity so long as no oxygen debt, or delayed oxidation of certain chemical compounds, is accumulated. Three levels of metabolic rates have been commonly recognized for fish: (1) *Standard metabolic rate,* representing that fraction which is just necessary to maintain vital functions of a resting fish, (2) *routine metabolic rate,* which also includes the energy demands of routine, spontaneous activity, and (3) *active metabolic rate,* which represents the maximum level of oxygen consumed by a working (swimming) fish. The amount of energy available for active work (or growth) is termed the *metabolic scope* for activity, and it is the difference between active and standard metabolic rates. Each of these is related to temperature in a different way. The most important measure for a fish's ability to cope with the overall environmental demands is the metabolic scope, which has an optimum temperature (Figure 3).

Activity

As temperature controls the metabolic rate which provides energy for activity, that activity, then, is also controlled. The literature contains many references to increases in fish activity with temperature rise, particularly swimming performance. This increase in activity ceases at an optimum temperature that appears to coincide with the temperature of maximum metabolic scope (Figure 3).

Growth

Temperature is one of the principal environmental factors controlling growth of fishes, others being light and salinity. There recently has been a considerable amount of laboratory experimentation to separate these often-correlated influences on growth.

Whenever there is abundant food, increasing temperature enhances growth rate up to an optimum (Figure 3) above which there is a decline. Low temperatures generally retard growth, although organisms residing habitually in cold areas such as the arctic have evolved metabolic compensations that allow good growth even at low extremes. Optimum growth appears to occur at about the same temperature as maximum metabolic scope. Restriction of food generally forces the optimum growth temperature toward cooler levels and restricts the maximum amount of growth attainable (Brett *et al.,* 1969).

TEMPERATURE AS A LIMITING FACTOR

As the previous discussion implied, there comes a point (the optimum) on a rising temperature scale at which increased temperature no longer speeds processes but begins to limit them. In contrast to the gradual increase in performance with temperature rise exhibited at suboptimum temperatures, the responses at levels above optimum often show a precipitous decline (Figure 3). Performance is often reduced to zero several degrees below temperatures which would be directly lethal in the relatively short period of one week. One of the most significant of thermal limitations from the standpoint of a fish's overall success in this environment is upon set growth rate for the population. If a majority of individuals of the species cannot sustain positive growth, then the population is likely to succumb. While it is probably unnecessary for populations to grow at maximum rates, there must be a thermal maximum for prolonged exposures of any fish species that is less than the established lethal levels at which growth limitation becomes critical for continued population survival. The requirement for sustained growth may be one of the most important mechanisms of geographic limitations of species. Intensive research in this area is needed to establish rational upper temperature standards for water bodies.

TEMPERATURE AS A MASKING FACTOR

All other environmental factors, such as light, current, or chemical toxins, act upon fish simultaneously within a temperature regime. With so much of a fish's metabolic activity dependent upon temperature, both immediate and previous, it is little wonder that responses to other environmental factors change with differing temperature. The interactions are seemingly infinite, and the general impression that one obtains is that temperature is masking a clear-cut definition of the response pattern to any other environmental parameter.

This pessimism overstates the case, however. Two-factor experimentation is routine today, and interactions of temperature and a variety of pollutants are now becoming clear. For instance, research in Britain has shown that the effect of increased temperature on the toxicity of poisons to fish is generally to reduce their time of survival in relatively high lethal concentrations, but median *threshold* concentrations for death may not be markedly changed, or may even be increased (Ministry of Technology, 1968). An increase in temperature of 8°C reduced the 48 hr LC_{50} (median lethal concentration) to rainbow trout by a factor of 1.8 for zinc (i.e. increased toxicity) but increased it (i.e. reduced toxicity by about 1.2 for phenol, by 2.0 for undissociated ammonia, and by 2.5 for cyanide. The effect of temperature on ammonia toxicity is further expressed by changing the dissociation of ammonia in water and thus the percentage of actively toxic ammonia available. For estuarine and marine fishes temperature-salinity interactions are of special importance, and are receiving increased research attention.

TEMPERATURE AS A DIRECTING AGENT

Gradient responses

Numerous observations of fish in horizontal and vertical thermal gradients both in the laboratory and under field conditions have demonstrated preferred or selected temperatures. There are wide differences among species, and some differences among life stages of any one species. The preferred temperature is dependent upon recent prior thermal history, but continuous exposure to a gradient (in which metabolic acclimation gradually takes place) results in a "final preferendum". Preferred ranges have been shown to coincide with the species-specific optimum temperature for maximum metabolic scope for activity, and thus the directive mechanism would appear to have survival value.

Many fish have a delicate sense for temperature discrimination. The threshold for teleosts (bony fish) appears to be on the order of ±0.05°C, although elasmobranches (sharks, rays) have a threshold quite a bit higher (about ±0.8°C). Orientation responses have generally been elicited by differences of about 0.5°C (Brett, 1971). Many fish are very capable of detecting undesirable temperatures and of avoiding water masses that are potentially detrimental to them.

Directive cues

A mechanistic response to temperature gradients is often overridden by seasonal influences and special behavior patterns involving temperature-oriented activities such as migration. The seasonal response to a specific temperature has been shown to have great importance for reproductive activity of a large number of fishes.

The sequence of events relating to gonad maturation, spawning migration, courting behavior, release of gametes, and subsequent development of egg and embryo represents one of the most complex phenomena in nature. While temperature cues appear critical in many cases, the interactions with other factors such as seasonal light intensity are still not clearly understood. Advance or retardation of reproduction has been closely related to temperature of the months preceding spawning in such fish as the cod *Gadus morhua.* The difference in the effect of temperature governing a rate phenomenon (controlling or limiting) and temperature acting as a releasing factor is clearly shown in cases where falling temperatures induce spawning, as in the Pacific salmon.

Temperature appears to confine spawning to a narrower range than most other functions. The average range for spawning of marine fish is one-quarter to one-third that of the lethal range (Brett, 1971).

SUMMARY

From this brief introduction, we can see that temperature is probably the preeminent master factor in the lives of fish. No study of fish in relation to their environment ("fish ecology") would be meaningful without consideration of thermal relationships. This review can direct the curious to more comprehensive treatises. From a different perspective, there are few environmental modifications that man could make to aquatic systems that would be so assured to causing some ecological change as temperature. Within limits, fish possess effective mechanisms for adapting to thermal changes, for such changes are a normal part of their existence. Man must be careful not to exceed these limits, however, if he wishes to preserve a productive commercial and recreational fishery.

TOXIC EFFECTS: see AIR POLLUTANT EFFECTS; EFFECTS OF CHEMICALS

TOXICOLOGY

The terms *toxicology, toxicity,* or *toxic substance* (*toxicant*) are used daily in the scientific and general literature. Review of almost any daily newspaper will reveal one or more articles on the toxic effects of a substance, most of which when released into the environment are called *pollutants.* Today there are scientific journals devoted to the subject of toxicity, illustrating the importance of this topic. However, many do not understand the term *toxicology* or have an understanding of its concepts. So what is a good definition of toxicity? It can be best defined as the science of poisons. Of course, this brings us to the question of what a poison is: any substance that can result in a detrimental effect when the concentration is increased. An increased response as compared to increasing concentration has been called a "dose-response curve," which will be discussed later.

When using the definition of toxicity provided above, most will consider poisoning of animals and humans; however, this definition can be extended to all life forms, including microbes (Thomulka et al., 1996) and plants (Haarmann and Lange, 2000). In the broadest term, toxic insult can be evaluated from an ecological viewpoint and can encompass effects to an ecosystem. This is what is commonly considered when looking at poisoning in an industrial environment. However, in today's changing environment, the viewpoint from an industrial perspective is changing to include the entire environment. The scope of toxicology is ever-increasing, and from the point of view of an engineer, especially an environmental engineer, should not be limited. Depending on the focus, toxicity can also be viewed from global impact (e.g., mercury release from burning fossil fuels) to that which affects single-celled organisms in a local pond.

Public awareness has raised the term *toxicity* to an everyday usage, although most do not understand how to properly apply this term. Most consider that when something is listed as toxic it means an effect from an exposure has occurred. Certainly in the most general sense this is true. Forgotten for the term *toxicity* is that every substance is toxic, at least in the right dose. So what can be added to the concept of a poison is that the dose makes the poison.

For engineers, often the terms *hazardous substance* or *waste* are used as substitutes for *toxicity.* This in the strict definition is not correct, in that a hazardous waste may not act as a poison, but rather result in a physical effect (e.g., a burn). However, even a substance capable of causing a burn will do so in proportion to the concentration applied. Thus, even for these types of substances, there is a dose-response effect. If any effect from a substance is considered a toxic response, then *hazardous waste* is another name for *toxicity.* In most cases a hazardous waste is a mixture of substances and/or chemicals at a site, and its release was uncontrolled or unregulated. Regardless, this mixture will have its own dose-response, while the individual chemicals or substances will exhibit separate responses (a differing dose-response curve).

What is of importance to many engineers when examining toxicity is the use of standard references. Table 1 lists number of textbooks and governmental sources that contain various numerical values for toxicity and basic information on chemicals. These sources are a very good staring point to obtain basic information about a chemical, its regulatory limits, and general information on the hazards associated with the substance.

AREAS OF TOXICOLOGY

Toxicology can be divided into a variety of subareas. These areas can be categorized by organ systems, chemicals (substances), or discipline. Examples of categorization are shown in Table 2, along with a brief description. For the most part, engineers will work in the general areas of environmental and occupational toxicology, although some will venture into others as well. In special cases, engineers will venture into areas such as forensic toxicology. What needs to be kept in mind is that toxicology is an area that borrows from other basic fields of science, such as chemistry, physics, biology, and mathematics.

ENDPOINTS OF TOXICITY

Historically, toxicology was associated with the response of animals when exposed to an agent or agents. Mostly this has been performed using small rodents such as mice and rats. However, for engineers, animal toxicity data are only one part, especially for work that relates to the environmental areas. For example, evaluation of a hazardous-waste site can involve the toxic effects to plants, invertebrates, microbes, and aquatic organisms. Commonly, toxicity of a substance or toxicant is often referred to a single organism. In the environmental area, as well as in others, there may be many different types of organisms affected, along with different effects among these organisms. Use of a single value will not likely represent toxicity to entire groups or a system. Thus, representation of toxicity as a single value may be misleading. Toxicity endpoints for a chemical can vary by logarithmic orders, even for the same organism. This is illustrated by the chemical copper for *Strongylocentrotus purpuratus* using the endpoint EC_{50}, which is the median effective concentration (where 50% of the organisms are affected at a given period of time). ED_{50} is the median exposure dose, which is the concentration in air or water. The other commonly used endpoint of measure for industrial (occupational) toxicology is the median lethal dose (LD_{50}; again, this is a value where 50% of the organisms die at the given concentration, assuming that the mean and median values are equal, as in a normal curve, although used in more studies to refer to the median concentration). Obviously the LD_{50} is not useful in setting occupational-exposure limits, but provides a relative comparison for different chemicals. Similar in nature to the LD_{50} is the EC_{50}. Here the concentration has to be in some unit of air or liquid (water) for the endpoint to be measured. The variability for a chemical as related to effective endpoints (dose) can be illustrated using copper in aquatic organisms (Table 3). The LD_{50} of copper for the various organisms listed have a large variation (log order). This variation is commonly observed when evaluating a chemical among different organisms and even the same organism between laboratories.

A toxic response can be reported as any endpoint measurement that is reproducible. This can include death, as represented by an LD_{50} or another, such as a behavior endpoint measurement, which could be an EC_{50}. When evaluating

TABLE 2

Some areas of toxicology

Environmental	Concerned with effects on the environment, which can be considered pollution. This can be further divided into air, soil, and water systems. There can also be a measurement on a species as well.
Forensic	The occurrence of toxic effects on people and possibly other organisms, such as livestock, that is in relation to a crime.
Occupational	Effects of chemicals or substances on those in the working environment and industry.
Regulatory	Effects of chemicals (may also be drugs) in regard to the risk associated with the purposes or in some cases prevention of that chemical's use. This is often associated with some regulation or law, like the U.S. Clean Air Act (CAA).
Mechanistic	Evaluates a chemical's mechanism of action and how this action causes a toxic effect on the organism.

TABLE 3

Aquatic toxicology values of various organisms for copper

Organism	LD_{50}	Reference
Mesocyclops peheiensis	75 μg/l	Wong and Pak, 2004
Tilapia zillii	6.1 mg/l	Zyadah and Abdel-Baky, 2000
Mysis sp. (from Nile River)	2.89 mg/1	Zyadah and Abdel-Baky, 2000
Mugil cephalus	5.3 mg/1	Zyadah and Abdel-Baky, 2000
Photobacterium phosphoreum	>100 mg/1	Thomulka et al., 1993
Strongylocentrotus purpuratus	15.3 μg/1$^+$	Phillips et al., 2003
Penaes merguiensis	0.38 mg/1	Ahsanullah and Ying, 1995

$^+$ An EC_{50}.

data, the endpoint must be identified, especially when looking at nonlethal measurements such as EC_{50}'s.

There are three general routes of exposure: inhalation, dermal (skin), and ingestion (oral). A fourth route, which is more related to medical situations, is injection. Depending on the chemical and the activity employed, one or more of these will have a great deal of importance in the toxic outcome. Occupationally, the most important route is inhalation, since it generally results in the most severe health consequences. Dermal effects are the most numerous, but in most cases are of minor importance. Most dermal effects are related to irritation of the skin and related allergic reactions. As a general rule in occupational toxicology, skin problems are the most common, although effects such as cancer of various organs can also be of concern (Lange, 2003). Using cement as an example, epidemiological studies have reported this agent to cause cancer in a variety of organs. The organs or systems of carcinogenic concern include the skin, bladder, stomach, and lungs (Smailyte et al., 2004), although the most common problem reported in occupations using this building material is dermatological (skin) (Winder and Carmondy, 2002; Lange, 2003), which is a noncarcinogenic occupational hazard. This illustrates that a chemical can have multiple toxic endpoints for different organs.

Most toxicologists divide the exposure to humans and organisms into four categories: acute, subacute, subchronic, and chronic. *Acute* is commonly defined as a single or repeated exposure that occurs over a 24-hour period that results in a measurable effect. Although this definition is not perfect, it tells us that acute cases are generally of short duration and high concentration. *Subacute,* on the other hand, is exposure that occurs over about a 1-month time period and in this case is generally lower in concentration, and the effect requires a longer period of time to occur in comparison to a true acute exposure. It is not uncommon to report acute effects as case studies. In the case report by Dote et al. (2003), an industrial worker accidentally exposed (sprayed) himself with the agent hydrogen fluoride (HF), or hydrofluoric acid. HF is a highly corrosive agent that can result in serous chemical burns, and in this case the burns occurred on the face of the industrial worker. As a result of this exposure, the worker died within a half hour as a result of acute respiratory failure. In the case of HF, this substance would be considered a hazard to both the respiratory and dermal systems, in this case inhalation being the main route of exposure that resulted in death. To put HF exposure in perspective, Hathaway et al. (1991) reported that the LD_{50} for a 5-minute exposure is between 500 and 800 parts per million (ppm).

Chronic toxicology is defined as an effect resulting from an exposure that occurs over a long period of time, like years. Certainly the time period of measurement also depends on the length of an organism's life history as well. *Subchronic,* as compared to chronic, is of shorter duration with a higher concentration and can be considered to occur within a time period of 1 to 3 months for people. Although these terms are discussed for an occupational setting, the terms are also applied to environmental toxicology. Historically, acute exposure was a key factor in exposure prevention. As industrial exposures are becoming better controlled, there has been a change in focus to chronic conditions, at least in the developed countries.

Since inhalation is the most important route of exposure in the occupational (industrial) environment, most reported limits of acceptable exposure are for this route. However, in other systems, such as aquatic or terrestrial, dermal contact or ingestion may be the most important routes of exposure.

OCCUPATIONAL EXPOSURE LIMIT VALUES

For occupational exposure, established upper limits have been published by governmental and private agencies or groups. These values are: permissible exposure limit (PEL), threshold limit value (TLV), and recommended exposure limit (REL). PELs are established by the U.S. Occupational Safety and Health Administration (OSHA) and are the legal standard for the maximum exposure level. OSHA PELs are published in the Code of Federal Regulations (CFR) at 29 CFR 1910.1000. It should be noted that these exposure concentrations are mostly for inhalation, as previously mentioned, and the levels represented are somewhat out of date, since they have to go through a regulatory process for updating. TLVs are established by the American Conference of Governmental Industrial Hygienists (ACGIH), which is considered a consensus organization. Many consider these values to be the most up-to-date, although they are, like most decision-making processes, subject to industry pressure and other political factors when being established. Generally, TLVs are lower in concentration than PELs, although there are exceptions to this statement. It can be considered that the PELs, as they change, are also subject to industry and political considerations as well. Both the PELs and TLVs are established for an 8-hour time-weighted average (TWA). This average is an arithmetic mean of all the exposures collected in that workday. The formula for making a TWA is shown below.

$$\text{TWA} = (C_1 \times T_1) + (C_2 \times T_2) + \ldots + (C_n \times T_n)/ \\ (T_1) + (T_2) + \ldots + (T_n)$$

C—concentration
T—time

The maximum and ideal time of sample (exposure) collection is 8 hours, although this is not usually feasible. Most consider that to obtain a TWA the sample should be collected for at least 6.5 hours of the 8-hour work shift. The remaining 1.5 hours would be included as a 0 exposure level. The REL is a 10-hour TWA exposure limit and is set by the National Institute of Occupational Safety and Health (NIOSH) as a value to be considered by OSHA in the rule-making process. For all the values (PEL, TLV, and REL), they are established for a 40-hour workweek.

When evaluating exposure limits, exceedance can be considered for a single measurement or summation of measurements (Letters to the Editor, 1998). There has been considerable discussion of the correct evaluation for exposure. For those chemicals that are considered to be chronic in nature, disease appears to follow the arithmetic mean of exposure, suggesting that summation exposure values best represent potential health effects (Lange, 2002).

A short-term exposure limit (STEL) has also been established for many chemicals. STELs are for 15-minute periods with at least 2 hours of exposure below the PEL, as an example, with no more than four exposure periods (STELs) occurring per day. When applying STELs, the PEL should not be exceeded when these values are included in the TWA. If there is an exceedance of the PEL, appropriate personal protective equipment is then required.

Exposure limit values (TLV-TWA) are established using three general criteria. First, in order of importance, are epidemiological data. Occupational and in some cases environmental epidemiology studies provide the most important information on the hazards from a chemical. Since there are different types of epidemiological studies, those of the greatest strength, in order, are: cohort, case-control, cross-sectional, and ecological. Next is animal experimentation in identifying hazards, and last are case studies or reports. The ACGIH publishes documentation summarizing the basis for establishing and setting TLVs and is often useful as a general reference. Another good reference that provides summary information on chemicals is Hathaway et al. (1991).

Exposure levels are given in units of mg/m^3, ppm, and fibers per cubic centimeter (f/cc). In most cases these values are for inhalation, but there are some listed for skin (e.g., decaborane).

Another value that is of importance to toxicologists in the industrial environment is IDLH (immediately dangerous to life and health). The problem with IDLH is that it has two different definitions (NIOSH/OSHA/USCG/EPA, 1985). The Mine Safety and Health Administration (MSHA) (30 CFR 11.3[t]) defines IDLH as the concentration that will cause immediate death of permanent injury. However, NIOSH, in the *Pocket Guide* (1994; see Table 1), defines this as the maximum concentration where one can escape within 30 minutes without irreversible health effects. So care must be taken when using IDLH values, as each source has completely different criteria.

DOSE-RESPONSE

In toxicity there exists an increased response to a chemical with the chemical's increasing concentration. This is known as the "dose-response effect" and is fundamental to toxicology. In general, it can be said that every chemical has a dose-response effect. The response is any repeatable indicator or measurement that is used to evaluate the response of an organism to the chemical. At some point the concentration becomes high enough that the response is 100%. Figure 1 shows time of exposure to various concentrations of the chemical sodium bisulfate (Haarmann and Lange, 2000). As the concentration of each chemical varies there is a reduction in root length after a given period of time. In many cases the curve would appear reversed, where there would be no inhibition at the lower concentrations and inhibition at the higher levels. However, here, for the root length, which was for radish-seed elongation, the highest length is at the lower concentration of chemical. The shape of the dose-response curve can provide information on the effect of a chemical, and data extracted from this relationship is often used in risk-assessment analysis. LD_{50} and related values are extracted from dose-response curves. Different formulas can be used to obtain this information as well (Thomulka et al., 1996).

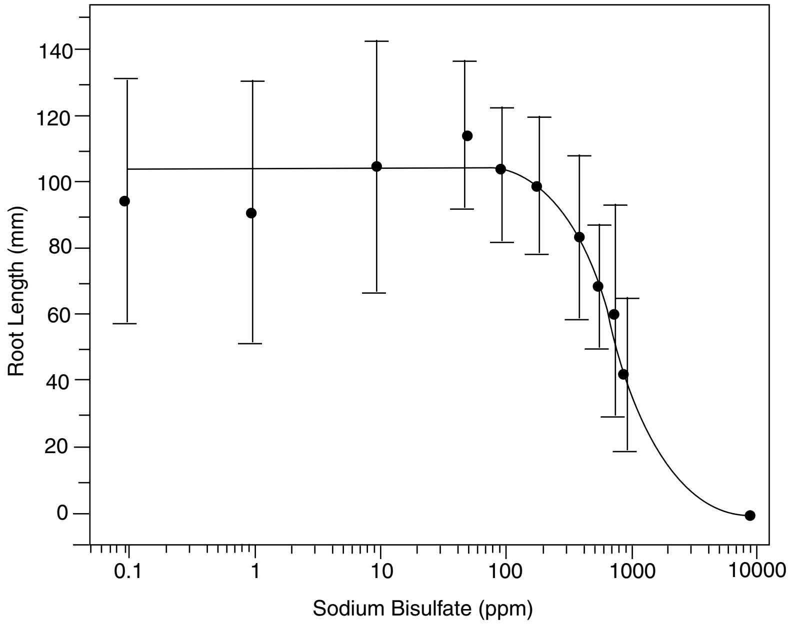

FIGURE 1 Dose-response curve for sodium bisulfate in Lake Erie water (from Haarmann and Lange, 2000; with permission from Parlar Scientific Publications).

Dose-response curves are often used to provide information on a chemical as well as comparison to other chemicals. Potency is one factor that can be derived from the dose-response. This term refers to the concentrations that result in an increasing response to the chemical. Two chemicals can have the same slope on a dose-response curve, but have different potencies. Thus, various information can be extracted from dose-response curves.

EXPOSURE

Exposure can be considered to be at the heart of toxicology. Just because you are exposed does not mean that there will be an effect or even that the chemical will be taken up by the organism. There are a number of factors that influence the cause and effect, including absorption, distribution, excretion, and biotransformation. To understand exposure, a brief discussion of each will be presented.

A toxicant is often called a *xenobiotic,* which means a foreign substance, and these terms are often used interchangeably in texts. In some cases, a xenobiotic may not be foreign to the organism (e.g., selenium), but exist in a higher or lower concentration that results in a disease state. Of importance to environmental and occupational toxicology is that a lower concentration may also result in disease or an undesired event, which for the purposes of this chapter will be considered a toxic action. In some unusual cases increased occupational exposure has been reported to result in beneficial effects. This has been illustrated by the exposure of organic dust that appears to reduce lung cancer (Lange, 2000; Lange et al., 2003). However, it needs to be noted that exposure to organic dust (like cotton dust, in the textile industry) also results in severe respiratory diseases (e.g., bysinosis), which outweigh any benefits of reduced lung cancer, as in this case.

Absorption

Absorption is the process where a xenobiotic crosses a membrane or barrier (skin) and enters the organism, most commonly into the blood. As previously mentioned, the major routes of absorption are ingestion (the gastrointestinal [GI] system), inhalation (lungs), and dermal (skin). Oral intake is not a common route of occupational exposure, but one of major importance environmentally. Transport across barriers occur as passive transport, active transport, facilitated diffusion, or specialized transport. Transport can occur in the uptake and excretion of chemicals. Passive transport, which is simple diffusion, follows Frick's Law and does not require energy. Here a concentration gradient exists, and molecules move from the higher to the lower concentration. As a rule, for biological systems, the more nonionized the form of a molecule, the better it is transported across lipid membranes. The membranes of cells are composed of a lipid bilayer, thus favoring nonionized compounds. Active transport involves the movement of a chemical against a gradient and requires the use of energy. This requires a transporter molecule to facilitate the movement and would be subject to saturation of the system. Facilitated transport is similar to active transport, except it does not work against a gradient and does not require energy. There are other specialized forms of transport, such as phagocytosis by macrophages. These various transport mechanisms are also used to bring essential substances and xenobiotics into the organisms.

Absorption in the GI tract can occur anywhere from the mouth to the rectum, although there are some generalizations that can be made. If the chemical is an organic acid or base, it will most likely be absorbed in locations where it exists in its most lipid-soluble form. The Henderson-Hasselbalch equation can be used to determine at what pH a chemical exists as lipid-soluble (nonionized) as compared to ionized. As a general rule, ionized forms of a chemical are not easily absorbed across biological membranes.

For the lungs, gases, vapors, and particles can be absorbed. In the lungs, ionization of a chemical is not as important as it is for the GI tract. This is due to the rapid absorption of chemicals and the thinness of the separation of alveolar cells (air in the lungs and blood system) with the body fluids (blood). Ionized molecules are also generally nonvolatile and are therefore usually not in high concentration in the air. Particles are separated as they travel the pulmonary system. The larger ones (say, greater than 10 μm in size) are removed early in the pulmonary system, like in the nasal area, whereas the smaller ones (say, 1 μm) enter the alveolar region. As a general rule, it can be said that particles around 5 to 10 μm are deposited in the nasopharyngeal area, those 2 to 5 μm in the tracheobronchial area, and those less than 1 to 2 μm in the alveolar region. The alveolar region is where air is exchanged with the blood system, oxygen is taken up, and waste gases (carbon dioxide) are returned to the atmosphere. Particles that are deposited into the alveolar region have been termed "respirable dust" (Reist, 1993). Distribution of particles described is not exact, but provides a generalization of particle distribution for lungs. Some chemicals, like those that are highly water-soluble (e.g., formaldehyde), can be scrubbed out at various locations of the respiratory tract. Here, formaldehyde is removed by the nose, and in general this is a site of its toxic action, irritation, and nasal cancer (Hansen and Olsen, 1995).

Skin is generally not highly penetrable and is a good overall protective barrier. This protection is a result of the multiple layers of tissue associated with the skin. However, the primary layer of protection is the stratum corneum. This is the top layer of cells on the skin; it is dead and can vary in thickness. On the hands and feet this cell layer can be 400 to 600 μm thick, while on the legs it can be 8 to 15 μm. Some chemicals can disrupt the skin's protection and allow chemicals to pass more easily. An example of this is dimethyl sulfoxide (DMSO), which can de-fat the skin and allow better penetration of chemicals.

Distribution

After a chemical enters the organism, it is usually distributed rapidly. This distribution is commonly achieved by the blood system. Many chemicals have locations in the organism where

TABLE 4
Locations or organs of toxic action by classes of chemical compound

Class of Chemical/Substance	Location or Organ (Example)
Metals	Kidney, bone, immune
Solvents	Liver
Pesticides	Nervous
Radiation	Blood

they concentrate (e.g., lead in bone). It is often important to know where a chemical is concentrated or its organ of toxicity. Some generalities, although not complete, can be made for different classes of compounds (Table 4). However, when evaluating toxicity it is necessary to obtain specific information on the compound because there are many exceptions to general rules of site of toxic action. It is not uncommon that one chemical will have multiple organs or locations of toxicity. A good example of this is the metal arsenic. Arsenic can be both an environmental and occupational poison. Ingestion of arsenic in drinking water, at elevated concentrations, has been shown to result in skin cancer (which has been referred to as Blackfoot disease) as well as other forms of cancer (e.g., lung; Bhamra and Costa, 1992) and noncancer diseases (e.g., dermatological; Lange, 2004a). Environmental problems associated with arsenic exposure (via water) can be most acute and are well illustrated in a well-water problem for Bangladesh (Murshed et al., 2004). Here water wells were established to provide safe drinking-water sources (free of microbial contaminates). However, at the time these wells were placed it was not known that the soil contained high levels of arsenic. This resulted in drinking-water sources being contaminated with this metal. Subsequently, there has been a high rate of arsenic-related diseases (e.g., bladder, liver, and lung cancer; Chen and Ahsan, 2004) as a direct result of using these water sources. Arsenic does not only result in cancer, it also causes many environmentally related noncancer diseases (Milton et al., 2003). As mentioned, there are also occupational diseases from this metal (Bhamra and Costa, 1992; Lange, 2004a). For example, workers in smelting plants that use arsenic have been shown to exhibit elevated levels of lung cancer, and from these types of studies arsenic has been identified as a lung carcinogen. Although arsenic has been reported to cause detrimental effects, it should be noted that it is also an essential trace element. Deficiency in arsenic has been reported to result in various health problems as well as increased mortality (Bhamra and Costa, 1992). Thus, many chemicals can have a dual role in causing and preventing disease. It has even been suggested that some chemicals and substances can have a protective effect in the occupational environmental (Lange, 2000; Lange et al., 2003).

Chemicals can also be identified individually with a site or organ system being affected. Examples of chemicals and their general site of action are shown in Table 5. Certainly this list is not comprehensive, but provides the range of organ systems a single chemical can influence in the disease process. Effects can be both acute and chronic along with many having both carcinogenic and noncarcinogenic properties (e.g., benzene).

TABLE 5
Specific chemicals and some of their general organs or sites of action

Chemical	Location or Organ (Example)
Aluminum	Endrocrine, kidney, lung
Arsenic	Bladder, skin, heart, liver, lung, nervous
Benzene	Blood, liver
Cadmium	Kidney, reproductive
Carbon monoxide	Blood
Coke oven gases	Lung
Cotton dust	Lung
Ethanol	Liver
Formaldehyde	Lung (respiratory)
Fungus (*Fusarium moniliforme*)	Liver
Lead	Bone, blood, heart, kidney, nervous
Mercury	Kidney, nervous, heart
Methyl ethyl ketone	Heart
Paraquat	G1, heart, lung
Phenol	Liver, skin
Polyaromatic hydrocarbons	Immune, liver, reproductive
Polychlorinated biphenys	Immune
Rotenone	Endrocrine, eye, lung, skin
Tetrachloroethylene	Kidney
Thallium	Eye

"Heart" includes the vascular system as a general group.

Excretion

Toxicants that are taken up by an organism must be eliminated in some way. There are three major routes of excretion (urine, feces, and air [exhalation]) and several minor routes (hair, nails, saliva, skin, milk, and sweat). Many compounds are biotransformed before being excreted. This biotransformation results in xenobiotics being more water-soluble. As will be mentioned later, biotransformation involves a two-step process known as Phase I and Phase II biotransformation. Generally, substances with the greatest toxicity are those that do not completely undergo the biotransformation process.

Urinary excretion involves elimination through the kidney and is commonly considered the most important route of excretion. The kidney receives about 25% of the cardiac output. Toxic agents are generally excreted by being filtered out through the glomeruli or tubules in the kidney.

Fecal excretion can involve both the GI tract and liver/gallbladder. Some toxicants pass through the alimentary system (GI tract) unabsorbed or modified by bacteria or other processes in this system. Biliary excretion involves removal of toxicants from the blood by the liver and their subsequent elimination through a fecal route. Here a xenobiotic is biotransformed by the lever and transported to the gallbladder, which then excretes the chemical into the GI tract for elimination. There are some cases where a chemical eliminated by this route is then reabsorbed by the intestine into the body, resulting in a long half-life for this substance. This process is known as the "enterohepatic cycle." Ideally chemicals are metabolized into a polar form, making these poorly reabsorbable. However, microbes in the intestine can transform these compounds into a more lipid-soluble compound, which favors reabsorption.

Exhalation

Substances that exists in a gas phase are mostly eliminated through the lungs. These chemicals are mostly eliminated through simple diffusion, with elimination generally related to the inverse proportion of their rate of absorption. Thus, chemicals with low blood-solubility are rapidly eliminated, while others with high solubility are eliminated slowly.

Other Routes

Several other routes of excretion have been mentioned. Overall, these other routes are of minor importance in elimination of toxicants. However, they can be used to test the existence and concentration of various toxicants in the organism. This is commonly known as "biological monitoring." For example, hair can be used to test where a person has suffered from previous exposure to and possible toxicity of heavy metals, like arsenic. Thus, these minor excretion routes can be important for specific areas of toxicology (e.g., forensic). It should be noted that the major routes can also be used for biological monitoring, with urine and blood being the most important, particularly clinically and occupationally.

Biological Monitoring

Biological monitoring has become a common method for evaluating absorption of chemicals and drugs. It has been used for such activities as drug and alcohol testing. Methods have been established to determine the absorbed dose of a chemical, which are therefore important in many areas of toxicology, including clinical, forensic, and occupational toxicology. The ACGIH has established BEI values for some chemicals as one measure of monitoring risk to industrial populations. This allows evaluation of exposure from all routes, including occupational and nonoccupational. In many cases, only one route of exposure is evaluated, airborne levels, while exposure from other routes (e.g., dermal) contributes to the absorbed and toxic dose. Biological monitoring can be used for both major and minor routes of excretion. As noted, hair and nails can be used to evaluate exposure to heavy metals. An example of biological monitoring in the occupational environment is for methyl ketone (MEK), which has been suggested to be measured at the end of a work shift using urine as the biological fluid. The ACGIH BEI for MEK is 2 mg/l.

Biological monitoring is also used as part of medical evaluations and in environmental toxicology as well. A good example of its use in medical evaluations is for lead-abatement workers. Blood lead levels (BLL) for workers in this industry or exposure category have been established by OSHA. Here workers having a BLL over 40 μg/dl (deciliter of whole blood—100 ml of blood) are required to undergo an annual medical examination. Workers over 50 μg/dl are required to be removed from the work area (removal from exposure) until the BLL (two connective readings) is below 40 μg/dl. This illustrates the use of biological monitoring in prevention of occupational disease and its incorporation in regulatory toxicology.

Environmentally, lead is often monitored in children since it can cause harm in a number of organ systems and with effects that are characterized with a developing organism. The Centers for Disease Control and Prevention (CDC) suggest that children below the age of 6 not have a BLL that exceeds 10 μg/dl. This is the lowest level that has been suggested to have biological effects for humans. Biological concentrations of chemicals have also been used to evaluate exposure and toxic effects in organisms other than man.

Monitoring of biological fluids and tissue in environmental toxicology is a common practice (Pip and Mesa, 2002). Both plants (Pip and Mesa, 2002) and animals (Madenjian and O'Connor, 2004) are used for evaluating the distribution and uptake of toxicants from polluted environments. Monitoring can also be extended to abiotic conditions that influence toxicity to organisms (Mendez et al., 2004). The use of biological systems for monitoring can include effects on metabolism and other systems as well (Lange and Thomulka, 1996). Thus, biological monitoring is commonly used in both environmental and occupational settings as well as other areas of toxicology. Monitoring of this nature has even been extended to ecosystems as a methodology for evaluating health.

Biotransformation

Xenobiotic substances that are taken up by an organism must eventually be eliminated. To eliminate many of these chemicals, they must be transformed into a water-soluble product. This transformation is called "biotransformation." In many vertebrates, this transformation occurs in the liver, although other tissues and organs (e.g., the kidney) are also involved. Generally, chemicals are absorbed as lipid compounds and excreted as water-soluble (hydrophilic) compounds. Hydrophilic compounds can be easily passed along with the urine and feces. In the lungs, volatile compounds are favored for excretion in the exhaled gas, while those that are nonvolatile are generally retained. If chemicals were not biotransformed, their rate of excretion as lipid-soluble compounds would be very long, and this would result in buildup of xenobiotics. The rate at which a chemical is metabolized or excreted is called its half-life ($t_{1/2}$). Half-lives can be very short (as in minutes) or long (as in years).

Biotransformation and *metabolism* are often used as synonymous terms. In general they can be used interchangeably, although here *biotransformation* is used in describing the metabolism of xenobiotics that are not part of normal metabolism or at concentrations related to pollutant or toxicant exposure.

Some chemicals are able to actually increase or stimulate the biotransformation of other compounds. This is known as "induction." Induction can occur for a variety of compounds.

As previously mentioned, biotransformation is generally divided into two categories, Phase I and Phase II. Phase I reactions involve oxidation, reduction, and hydrolysis, which prepare the compound to undergo a Phase II reaction. Phase II involves conjugation. Commonly the most toxic products of a chemical are those from Phase I. If the system becomes saturated, Phase I compounds will seek alternative routes of metabolism, and this may result in more toxic intermediates. If this occurs, it is said that the metabolic system has become saturated.

MIXTURE TOXICITY

Most toxicology studies involve the use of a single compound; however, rarely in the real world does exposure occur to only a single substance. Although single-exposure events do occur, they generally result in acute toxicity, while multiple exposures are more frequently associated with chronic events. Certainly there are numerous exceptions to this rule, like asbestos and mesothelioma, but even with asbestos there are mixtures associated with this substance. One of the best illustrations for a mixture is asbestos and smoking in the case of lung cancer. Here smoking magnifies the potential effect of inhaled asbestos, resulting in a higher-than-expected rate of lung cancer than would occur for either alone. Most exposures in the industrial environmental focus on a single predominant toxicant associated with that activity, or at the most the top two or three chemicals, and generally concerns are identified with acute events. Both PEL and TLV are established with nonexposure time periods between exposures and often have an emphasis on acute occurrences. In environmental toxicology this is not always the case, since most regulatory standards have been established to protect against chronic events, considering most organisms spend their entire life in a single media. This is also true for humans as related to air and water pollution.

Mixture toxicity or interaction studies can be generally categorized by several terms (Table 6). *Additivity* is when two chemicals together exhibit equal toxicity with each having the same additive response. So if chemicals A and B were mixed and have an effect of ten, by adding five units of each, than adding ten units of A alone or B alone would have the effect of ten as well. *Synergism* is where the combination of the two chemicals magnify the outcome, as in asbestos and smoking. Asbestos may cause 1 cancer in 1000 and smoking 200 cases in 1000, but when together this may rise to 700 cases out of 1000. *Antagonism* is when one chemical reduces the effect caused when combined with another. *Potentiation* is when one chemical allows another to have its full toxic potential. This can be illustrated when the barrier of the skin is disrupted, as with DMSO, and a chemical that would not previously pass through the skin now enters easily. Generally, most chemical combinations exhibit additivity.

TABLE 6
Terms used for identifying mixture interactions

Term	Example by Numerical Value
Additivity	$5 + 5 = 10$
Synergism	$5 + 5 = 40$
Antagonism	$5 + 5 = 7$
Potentiation	$1 + 5 = 12$

Unfortunately, little information exists on chemical combinations (Lange and Thomulka, 1997). The lack of information is often due to the complexity and costs associated with these studies. However, recent advances in using bacterial systems (Lange and Thomulka, 1997) for evaluating mixtures does provide a more cost-effective and convenient way of testing more than one chemical.

There have been a number of methods published, excluding statistical comparisons, for evaluating two chemicals in combination. One of the early methods was a graphic representation of the two chemicals together, called an "isobole plot" (Lange and Thomulka, 1997). Here chemical combinations at some set value (like each chemical's LD_{50}) are plotted. Usually combinations of 100% of A, 80(A)/20(B)%, 60/40%, 20/80%, and 100% of B are used in making the plot. When this graph is represented in proportions, it is called an isobologram (Lange et al., 1997).

Another method that employs a formula is called the additive index (AI) (Lange and Thomulka, 1997). Here two chemicals using the same endpoint value (like LD_{50}) are evaluated, and these results are incorporated into the formula to obtain the AI. The AI is shown below:

$$S = \mathrm{A}m/\mathrm{A}i + \mathrm{B}m/\mathrm{B}i$$

S is sum of activity
A and B are chemicals
i is individual chemical and m is mixture of toxicities (LD_{50})

for S 1.0, the AI $= 1/S - 1.0$
for S 1.0, the AI $= S(-1) + 1$

For the AI, a negative number (sum of activity, S) suggests that the chemicals are less than additive (antagonistic), with zero being additive and a positive value synergistic. Certainly in these calculations the numbers are not exact, so confidence intervals (CIs) are often incorporated to reflect the range of these mixture interactions. In using CI values, at 95%, the upper and lower CIs are used to determine the range. If the CI range includes zero, then this mixture is considered to be additive.

Mixture toxicity is a commonly discussed topic, but as mentioned, it is not well understood. One basis for synergism is related to inhibition of detoxification pathways; however, as noted, most chemical mixtures are additive, which is probably due to few chemicals, at least in mixtures, using exactly the same metabolic pathways. Other methods exist for evaluating mixtures (e.g., the mixture-toxicity index; Lange et al., 1997). Determination of interactions for more than one chemical can in many ways be identified as an art (Marking, 1985). However, as science develops, better methods are being developed to evaluate combinations.

CARCINOGENICITY

The existence of cancer-causing chemicals has been known for thousands of years. However, it was not until recently that a direct relationship between environment or occupation and cancer was established. One of the early examples of an occupational relationship was provided by the English physician Percival Pott around 1775. Pott observed a high number of cases of scrotum cancer in chimney sweeps. He concluded that this cancer was a result of soot exposure in this occupational group. Later Japanese investigators (Yamagawa and Ichikawa, 1915) determined that coal tar (a common component of which is polyaromatic hydrocarbons), a component in soot, exhibited carcinogenic effects on animals, providing a basic animal model to support the occupational observations of Pott.

Cancer in its simplest term is the unregulated or uncontrolled growth of cells in an organism. Cancer, or neoplasm, can be either benign or malignant. Those that are benign generally occupy a given space and do not spread to other parts of the body. If the cancer is said to be malignant, it is then metastatic and can spread and form secondary sites at various other locations within the body.

Probably the best-known cancer-causing agent is cigarette smoke. Studies have shown that direct and indirect use of this product can result in cancer. Doll and Hill (1954) demonstrated that cigarette smoking was a major cause of lung cancer. Although this was an epidemiological study, these types of investigations opened up a new era of investigation into cancer-causing agents.

A cancer-causing agent generally has two processes in the causation of a tumor: initiation and promotion. This has resulted in chemicals being identified as either initiators or promoters, although there are some, known as "complete carcinogens," that exhibit both properties. This concept was developed by painting chemicals on the skin of mice at different time periods and observing whether tumor formation occurred. It was discovered that for some chemical combinations, the initiator had to be applied before the promoter. When the promoter was applied first, a time period waited, and then the initiator applied, no tumor formation occurred. Cancer can also be caused by other nonchemical factors such as heredity and viruses.

There has been considerable debate as to the amount of cancer caused by environmental pollutants and exposures in the occupational environment. However, it is known that there are a large number of agents capable of causing cancer in both the environmental and occupational settings. A list of a few occupationally associated carcinogens is shown in Table 7.

TABLE 7
Some carcinogenic chemicals (substances) and the cancers they cause

Substance	Cancer Caused
Aniline	Bladder
Arsenic	Skin, lung
Benzene	Leukemia
Cadmium oxide	Prostate, lung
Carbon tetrachloride	Liver
Cement dust (Portland cement)	Lung, stomach
Coke oven gases	Lung, kidney
Ethylene oxide	Leukemia
Lead arsenate	Lung, skin
Mustard gas	Larynx, lung
Nickel	Lung, nasal
Styrene oxide	Stomach
Toxaphene	Liver

This list is not complete but demonstrates the large variety and locations of cancers. Most environmental engineers look at the agents capable of or identified as causing cancer when evaluating a situation; however, this is usually done for simplicity, in that cancer is an endpoint of clarity—it exists or it does not exist. It must be kept in mind that there are other endpoints of interest as well that are noncarcinogenic (e.g., kidney toxicity).

To classify carcinogens, several agencies list chemicals or substances according to their degree of carcinogenicity. One of the most frequently cited agencies is the International Agency for Research on Cancer (IARC). The IARC is located in Lyon, France, and is part of the World Health Organization. As part of this agency's charter, it publishes monographs for various substances and is considered by many an excellent reference on information on carcinogens. This agency classifies cancer-causing agents into five different groups (Table 8). These grouping are based on data from epidemiological and animal studies. Many consider the IARC to be the best source of information and classification for carcinogens.

Group 1 indicates that there is sufficient epidemiological data that the substance is a human carcinogen. This is the highest level of classification, and as noted in Table 8, an example is arsenic. Group 2 has two classifications, A and B. Group 2A represents limited epidemiological evidence but sufficient animal evidence that the substance is a carcinogen, while with group 2B there is sufficient animal evidence, but epidemiological data are lacking or of poor quality. With Group 3 there is inadequate evidence for classifying a chemical or substance as a carcinogen. Group 4 evidence supports that it is not a carcinogen.

The IARC is not the only agency that classifies carcinogens. The National Toxicity Program (NTP) provides a classification scheme. Here carcinogens are listed as known human carcinogens or as reasonably anticipated to be a human carcinogen.

TABLE 8
IARC classification groups for carcinogenic substances

Group 1: Carcinogenic to humans (common called "known") carcinogen (examples: asbestos, arsenic) (evidence supports the chemical or substance as a human carcinogen)

Group 2A: Probably carcinogenic to humans (examples: diethyl sulfate, vinyl bromide) (limited evidence in humans and sufficient evidence in experimental animals)

Group 2B: Possibly carcinogenic to humans (examples: bracken fern, chlordane) (limited evidence in humans and less than sufficient evidence in experimental animals)

Group 3: Unclassified or not classified as carcinogenic to humans (examples: aldrin, aniline) (inadequate evidence in humans and inadequate or limited evidence in animals)

Group 4: Probably not carcinogenic to humans (example: caprolactam) (evidence suggesting lack of carcinogenicity in humans and animals)

For a chemical to be classified as a known human carcinogen there must be sufficient evidence to support a causal relationship between its exposure and the occurrence of human cancer. For substances to be listed as an anticipated human carcinogen there must exist sufficient evidence that it is a carcinogen, but alternative explanations exist or there is insufficient evidence supporting classification, experimentally and epidemiologically, as a carcinogen.

Regardless of the classification used, evidence of carcinogenicity for a substance requires epidemiological and experimental evidence. Epidemiological information is considered to be the strongest in establishing a substance as a carcinogen.

REGULATORY TOXICOLOGY

Regulatory toxicology is the area that interrelates toxicology with regulatory standards. The purpose of this area is to establish standards to provide protection against a specific chemical or group of chemicals. In many cases, standards are established before the full knowledge of a chemical is complete. Some identify this type of decision making to be part of risk assessment. In the United States, regulations related to toxicology can be generally divided into the major agencies that promulgate criteria for chemicals. These are the Food and Drug Administration (FDA), the Environmental Protection Agency (EPA), OSHA, MSHA, and the Consumer Product Safety Commission (CPSC). There are other agencies (e.g., the Department of Transportation), but for the purposes of this section they are considered minor. The agencies that are important for environmental engineers are the EPA and OSHA. However, those with the mining industry will also consider MSHA of great importance. The EPA, in general, establishes standards for environmental protection, and OSHA for protection related to those in the occupational environment. For consumer substances and products, the CPSC regulates toxicity.

OSHA came into existence with the passage of the Occupational Safety and Health Act on December 29, 1970 (effective April 28, 1971). OSHA as well as MSHA are part of the U.S. Department of Labor. OSHA has five major parts, with each regulating different industrial groups (Table 9).

TABLE 9
Sections of the CFR related to OSHA standards

29 CFR 126—Construction

TABLE 10
Some environmental acts of importance

Clean Air Act
Clean Water Act
Toxic Substance Control Act
Resource Conservation and Recovery Act
National Environmental Policy Act
Comprehensive Environmental Response, Compensation, and Liability Act Emergency Planning and Right to Know Act

The OSHA act sets out two primary duties for employers, which are for them to maintain a workplace free of recognized hazards and to comply with OSHA regulations. The act also requires that employees comply with the act, although clarification of this requirement is often lacking. Requirements of the employer are called the General Duty Clause. States can have their own OSHA plan and enforce OSHA as a state provision if they meet certain requirements. Currently, there are 23 state plans.

Commonly, environmental engineers will be required to interact with OSHA inspectors. OSHA often conducts inspections as a random process, or more frequently does so as a result of complaint. When an inspection occurs, the inspector will present identification to the management of the facility. If a labor union exists, the inspector must also notify the labor-union representative. Usually there is then an examination of the OSHA records, usually materials safety data sheets (MSDS) and the OSHA 200 form. Lack of MSDS, which is part of the Hazard Communication Plan, is one of the most frequently cited violations. A walkthrough is then conducted, which may include the collection of samples. At the end of this process there is a closing conference. At this time alleged violations are discussed. If citations are issued they can consist of one of three types: imminent danger, serious violations, and willful violations.

Employers can contest citations. This is usually initiated through an informal hearing. If the employer then decides to contest the citation, there is a specific process that must be undertaken. OSHA has an independent review commission as part of the Department of Labor to hear contested citations. To contest the citation, the employer must file notice within 15 working days by certified mail. There is no formal application, but the notice must clearly indicate that the citation is being contested. The employer must also post notice of this contestation. The notice is sent to the area director of OSHA.

The EPA was not created, as OSHA was, through legislative action, but rather by presidential order. This agency establishes regulations for environmental protection. There are a number of environmental acts and provisions (Table 10).

Some of the regulations established by the EPA overlap OSHA and other agencies. There is often confusion about the interpretation of the various regulations when they cross regulatory boundaries. Since most environmental regulations involve control of toxicants, toxicology is an important aspect of EPA regulations.

URBAN AIR POLLUTION MODELING

INTRODUCTION

Urban air pollution models permit the quantitative estimation of air pollutant concentrations by relating changes in the rate of emission of pollutants from different sources and meteorological conditions to observed concentrations of these pollutants. Many models are used to evaluate the attainment and maintenance of air quality standards, urban planning, impact analysis of existing or new sources, and forecasting of air pollution episodes in urban areas.

A mathematical air pollution model may serve to gain insight into the relation between meteorological elements and air pollution. It may be likened to a transfer function where the input consists of both the combination of weather conditions and the total emission from sources of pollution, and the output is the level of pollutant concentration observed in time and space. The mathematical model takes into consideration not only the nature of the source (whether distributed or point sources) and concentrations at the receptors, but also the atmospheric processes that take place in transforming the concentrations at the source of emission into those observed at the receptor or monitoring station. Among such processes are: photochemical action, adsorption both on aerosols and ground objects, and of course, eddy diffusion.

There are a number of areas in which a valid and practical model may be of considerable value. For example, the operators of an industrial plant that will emit sulfur dioxide want to locate it in a particular community. Knowing the emission rate as a function of time; the distribution of wind speeds, wind direction, and atmospheric stability; the location of SO_2-sensitive industrial plants; and the spatial distribution of residential areas, it is possible to calculate the effect the new plant will have on the community.

In large cities, such as Chicago, Los Angeles, or New York, during strong anticyclonic conditions with light winds and low dispersion rates, pollution levels may rise to a point where health becomes affected; hospital admissions for respiratory ailments increase, and in some cases even deaths occur. To minimize the effects of air pollution episodes, advisories or warnings are issued by government officials. Tools for determining, even only a few hours in advance, that unusually severe air pollution conditions will arise are invaluable. The availability of a workable urban air pollution model plus a forecast of the wind and stability conditions could provide the necessary information.

In long-range planning for an expanding community it may be desirable to zone some areas for industrial activity and others for residential use in order to minimize the effects of air pollution. Not only the average-sized community, but also the larger megalopolis could profitably utilize the ability to compute concentrations resulting from given emissions using a model and suitable weather data. In addition, the establishment of an air pollution climatology for a city or state, which can be used in the application of a model, would represent a step forward in assuring clean air.

For all these reasons, a number of groups have been devoting their attention to the development of mathematical models for determining how the atmosphere disperses materials. This chapter focuses on the efforts made, the necessary tools and parameters, and the models used to improve living conditions in urban areas.

COMPONENTS OF AN URBAN AIR POLLUTION MODEL

A mathematical urban air pollution model comprises four essential components. The first is the source inventory. One must know the materials, their quantities, and from what location and at what rate they are being injected into the atmosphere, as well as the amounts being brought into a community across the boundaries. The second involves the measurement of contaminant concentration at representative parts of the city, sampled properly in time as well as space. The third is the meteorological network, and the fourth is the meteorological algorithm or mathematical formula that describes how the source input is transformed into observed values of concentration at the receptors (see Figure 1). The difference between what is actually happening in the atmosphere and what we think happens, based on our measured

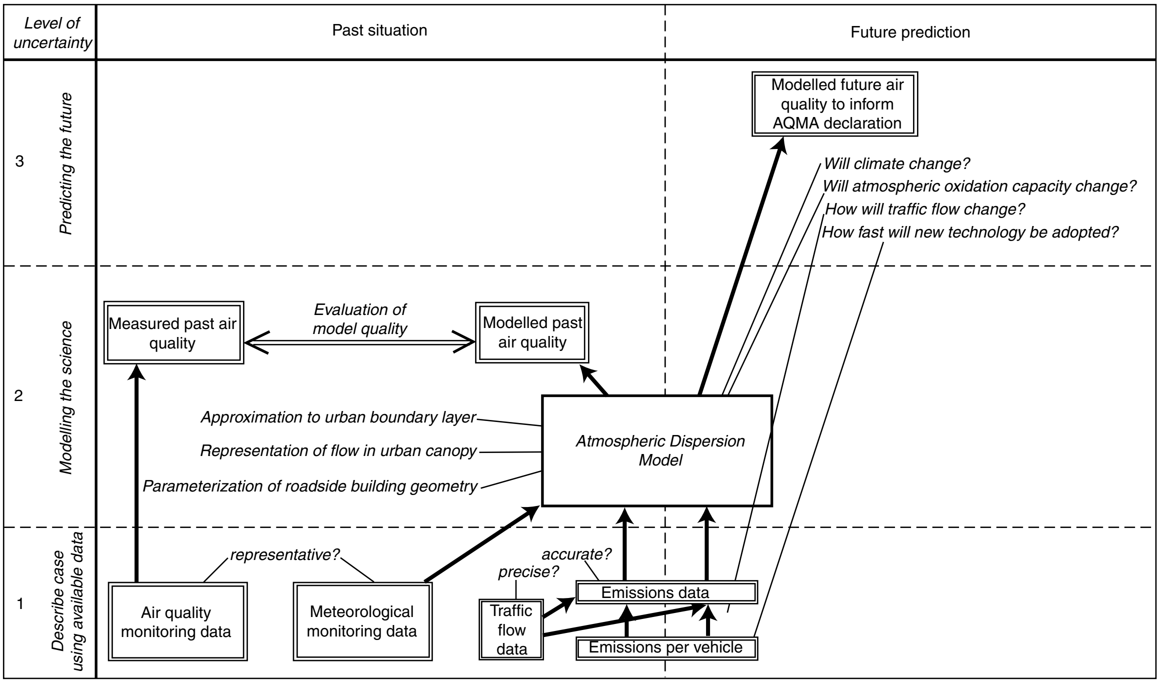

FIGURE 1 Schematic diagram showing flow of data into and out of the atmospheric dispersion model, and three categories of uncertainty that can be introduced (From Colvile et al., 2002, with permission from Elsevier).

sources and imperfect mathematical formulations as well as our imperfect sampling of air pollution levels, causes discrepancies between the observed and calculated values. This makes the verification procedure a very important step in the development of an urban air pollution model. The remainder of this chapter is devoted to these four components, the verification procedures, and recent research in urban air pollution modeling.

Accounts may be found in the literature of a number of investigations that do not have the four components of the mathematical urban air pollution model mentioned above, namely the source inventory, the mathematical algorithm, the meteorological network, and the monitoring network. Some of these have one or more of the components missing. An example of this kind is the theoretical investigation, such as that of Lucas (1958), who developed a mathematical technique for determining the pollution levels of sulfur dioxide produced by the thousands of domestic fires in a large city. No measurements are presented to support this study. Another is that of Slade (1967), which discusses a megalopolis model. Smith (1961) also presented a theoretical model, which is essentially an urban box model. Another is that of Bouman and Schmidt (1961) on the growth of pollutant concentrations in the cities during stable conditions. Three case studies, each based on data from a different city, are presented to support these theoretical results. Studies relevant to the urban air pollution problem are the pollution surveys such as the London survey (Commins and Waller, 1967), the Japanese survey (Canno et al., 1959), and that of the capital region in Connecticut (Yocum et al., 1967). In these studies, analyses are made of pollution measurements, and in some cases meteorological as well as source inventory information are available, but in most cases, the mathematical algorithm for predicting pollution is absent. Another study of this type is one on suspended particulate and iron concentrations in Windsor, Canada, by Munn et al. (1969). Early work on forecasting urban pollution is described in two papers: one by Scott (1954) for Cleveland, Ohio, and the other by Kauper et al. (1961) for Los Angeles, California. A comparison of urban models has been made by Wanta (1967) in his refreshing article that discusses the relation between meteorology and air pollution.

THE SOURCE INVENTORY

In the development of an urban air pollution model two types of sources are considered: (1) individual point sources, and (2) distributed sources. The individual point sources are often large power-generating station stacks or the stacks of large buildings. Any chimney stack may serve as a point source, but some investigators have placed lower limits on the emission rate of a stack to be considered a point source in the model. Fortak (1966), for example, considers a source an individual point source if it emits 1 kg of SO_2 per hour, while Koogler et al. (1967) use a 10-kg-per-hour criterion. In addition, when ground concentrations are calculated from the emission of an elevated point source, the effective stack height must be determined, i.e., the actual stack height plus the additional height due to plume rise.

Information concerning emission rates, emission schedules, or pollutant concentrations is customarily obtained by means of a source-inventory questionnaire. A municipality with licensing power, however, has the advantage of being able to force disclosure of information provided by a source-inventory questionnaire, since the license may be withheld until the desired information is furnished. Merely the awareness of this capability is sufficient to result in gratifying cooperation. The city of Chicago has received a very high percentage of returns from those to whom a source-inventory questionnaire was submitted.

Information on distributed sources may be obtained in part from questionnaires and in part from an estimate of the population density. Population-density data may be derived from census figures or from an area survey employing aerial photography.

In addition to knowing where the sources are, one must have information on the rate of emission as a function of time. Information on the emission for each hour would be ideal, but nearly always one must settle for much cruder data. Usually one has available for use in the calculations only annual or monthly emission rates. Corrections for diurnal patterns may be applied—i.e., more fuel is burned in the morning when people arise than during the latter part of the evening when most retire. Roberts et al. (1970) have referred to the relationship describing fuel consumption (for domestic or commercial heating) as a function of time—e.g., the hourly variation of coal use—as the "janitor function." Consideration of changes in hourly emission patterns with season is, of course, also essential.

In addition to the classification involving point sources and distributed sources, the source-inventory information is often stratified according to broad general categories to serve as a basis for estimating source strengths. The nature of the pollutants—e.g., whether sulfur dioxide or lead—influences the grouping. Frenkiel (1956) described his sources as those due to: (1) automobiles, (2) oil and gas heating, (3) incinerators, and (4) industry; Turner (1964) used these categories: (1) residential, (2) commercial, and (3) industrial; the Connecticut model (Hilst et al., 1967) considers these classes: (1) automobiles, (2) home heating, (3) public services, (4) industrial, and (5) electric power generally. (Actually, the Connecticut model had a number of subgroups within these categories.) In general, each investigator used a classification tailored to his needs and one that facilitated estimating the magnitude of the distributed sources. Although source-inventory information could be difficult to acquire to the necessary level of accuracy, it forms an important component of the urban air pollution model.

MATHEMATICAL EQUATIONS

The mathematical equations of urban air pollution models describe the processes by which pollutants released to the atmosphere are dispersed. The mathematical algorithm, the backbone of any air pollution model, can be conveniently divided into three major components: (1) the source-emissions subroutine, (2) the chemical-kinetics subroutine, and (3) the diffusion subroutine, which includes meteorological parameters or models. Although each of these components may be treated as an independent entity for the analysis of an existing model, their inferred relations must be considered when the model is constructed. For example, an exceedingly rich and complex chemical-kinetic subroutine when combined with a similarly complex diffusion program may lead to a system of nonlinear differential equations so large as to preclude a numerical solution on even the largest of computer systems. Consequently, in the development of the model, one must "size" the various components and general subroutines of compatible complexity and precision.

In the most general case, the system to be solved consists of equations of continuity and a mass balance for each specific chemical species to be considered in the model. For a concise description of such a system and a cogent development of the general solution, see Lamb and Neiburger (1971).

The mathematical formulation used to describe the atmospheric diffusion process that enjoys the widest use is a form of the Gaussian equation, also referred to as the modified Sutton equation. In its simplest form for a continuous ground-level point source, it may be expressed as

$$\frac{\chi}{Q} = \frac{1}{\pi u \sigma_y \sigma_z} \exp\left(-\frac{y^2}{2\sigma_y^2} - \frac{z^2}{2\sigma_z^2} \right) \tag{1}$$

where

χ: concentration (g/m^3)

Q: source strength (g/sec)

u: wind speed at the emission point (m/sec)

σ_y: perpendicular distance in meters from the centerline of the plume in the horizontal direction to the point where the concentration falls to 0.61 times the centerline value

σ_z: perpendicular distance in meters from the centerline of the plume in the vertical direction to the point where the concentration falls to 0.61 times the centerline value

x, y, z: spatial coordinates downwind, cross-origin at the point source

Any consistent system of units may be used.

From an examination of the variables it is readily seen that several kinds of meteorological measurements are necessary. The wind speed, u, appears explicitly in the equation; the wind direction is necessary for determining the direction of pollutant transport from source to receptor.

Further, the values of σ_y and σ_z depend upon atmospheric stability, which in turn depends upon the variation of temperature with height, another meteorological parameter. At the present time, data on atmospheric stability over large urban areas are uncommon. Several authors have proposed diagrams or equations to determine these values.

The temperature variation with height may be obtained by means of thermal elements mounted on radio or television towers. Tethered or free balloons carrying suitable sensors may also be used. Helicopter soundings of temperature have been used for this purpose in New York City; Cincinnati, Ohio; and elsewhere. There is little doubt that as additional effort is devoted to the development of urban air pollution models, adequate stability measurements will become available. In a complete study, measurements of precipitation, solar radiation, and net radiation flux may be used to advantage. Another meteorological variable of importance is the hourly temperature for hour-to-hour predictions, or the average daily temperature for 24-hour calculations. The source strength, Q, when applied to an area source consisting of residential units burning coal for space heating, is a direct function of the number of degree-hours or degree-days. The number of degree-days is defined as the difference between the average temperature for the day and 65°. If the average temperature exceeds 65°, the degree-day value is considered zero. An analogous definition applies for the degree-hour. Turner (1968) points out that in St. Louis the degree-day or degree-hour values explain nearly all the variance of the output of gas as well as of steam produced by public utilities.

THE USE OF GRIDS

In the development of a mathematical urban air pollution model, two different grids may be used: one based on existing pollution sources and the other on the location of the instruments that form the monitoring network.

The Pollution-Source Grid

In the United States, grid squares 1 mile on a side are frequently used, such as was done by Davidson, Koogler, and Turner. Fortak, of West Germany, used a square 100 × 100 m. The Connecticut model is based on a 5000-ft grid, and Clarke's Cincinnati model on sectors of a circle. Sources of pollution may be either point sources, such as the stacks of a public utility, or distributed sources, such as the sources representing the emission of many small homes in a residential area.

The Monitoring Grid

In testing the model, one resorts to measurements obtained by instruments at monitoring stations. Such monitoring stations may also be located on a grid. Furthermore, this grid may be used in the computation of concentrations by means of the mathematical equation—e.g., concentrations are calculated for the midpoints of the grid squares. The emission grid and monitoring grid may be identical or they may be different. For example, Turner used a source grid of 17 × 16 miles, but a measurement grid of 9 × 11 miles. In the Connecticut model, the source grid covers the entire state, and calculations based on the model also cover the entire state. Fortak used 480 × 800-m rectangles.

TYPES OF URBAN AIR POLLUTION MODELS

Source-Oriented Models

In applying the mathematical algorithm, one may proceed by determining the source strength for a given point source and then calculating the isopleths of concentration downwind arising from this source. The calculation is repeated for each area source and point source. Contributions made by each of the sources at a selected point downwind are then summed to determine the calculated value of the concentration. Isopleths of concentration may then be drawn to provide a computed distribution of the pollutants.

In the source-oriented model, detailed information is needed both on the strength and on the time variations of the source emissions. The Turner model (1964) is a good example of a source-oriented model.

It must be emphasized that each urban area must be "calibrated" to account for the peculiar characteristics of the terrain, buildings, forestation, and the like. Further, local phenomena such as lake or sea breezes and mountain-valley effects may markedly influence the resulting concentrations; for example, Knipping and Abdub (2003) included sea-salt aerosol in their model to predict urban ozone formation. Specifically, one would have to determine such relations as the variations of σ_y and σ_z with distance or the magnitude of the effective stack heights. A network of pollution-monitoring stations is necessary for this purpose. The use of an algorithm without such a calibration is likely to lead to disappointing results.

Receptor-Oriented Models

Several types of receptor-oriented models have been developed. Among these are: the Clarke model, the regression model, the Argonne tabulation prediction scheme, and the Martin model.

The Clarke Model

In the Clarke model (Clarke, 1964), one of the most well known, the receptor or monitoring station is located at the center of concentric circles having radii of 1, 4, 10, and 20 km respectively. These circles are divided into 16 equal sectors of 22 1/2°. A source inventory is obtained for each of the 64 (16 × 4) annular sectors. Also, for the 1-km-radius circle and for each of the annular rings, a chart is prepared relating x/Q (the concentration per unit source strength) and wind speed for various stability classes and for various mixing heights. In refining his model, Clarke (1967) considers separately the contributions to the concentration levels made by transportation, industry and commerce, space heating, and strong-point sources such as utility stacks. The following equations are then used to calculate the pollutant concentration.

$$\chi_T = \sum_{i=1}^{4} (\chi/Q)_{Ti} Q_{Ti}$$

$$\chi_I = \sum_{i=1}^{4} (\chi/Q)_{Ii} Q_{Ii}$$

$$\chi_S = \sum_{i=1}^{4} (\chi/Q)_{Si} Q_{Si}$$

$$\chi_{\text{Total}} = a\chi_T + b\chi_I + c\chi_S + \sum_{i=1}^{4} k_i \chi_p$$

where

χ: concentration (g/m^3)
Q: source strength (g/sec)
T: subscript to denote transportation sources
I: subscript to denote industrial and commercial sources
S: subscript to denote space-heating sources
p: subscript to denote point sources
i: refers to the annular sectors

The above equations with some modification are taken from Clarke's report (1967). Values of the constants *a, b,* and *c* can be determined from information concerning the diurnal variation of transportation, industrial and commercial, and space-heating sources. The coefficient k_i represents a calibration factor applied to the point sources.

The Linear Regression-Type Model

A second example of the receptor-oriented model is one developed by Roberts and Croke (Roberts et al., 1970) using regression techniques. Here,

$$\chi = C_0 + C_1Q_1 + C_2Q_2 + \sum_{i=1}^{n} k_iQ_i$$

In applying this equation, it is necessary first to stratify the data by wind direction, wind speed, and time of day. C_0 represents the background level of the pollutant; Q_1 represents one type of source, such as commercial and industrial emissions; and Q_2 may represent contributions due to large individual point sources. It is assumed that there are *n* point sources. The coefficients C_1 and C_2 and k_i represent the $1/\sigma_y\sigma_z$ term as well as the contribution of the exponential factor of the Gaussian-type diffusion equation (see Equation 1).

Multiple discriminant analysis techniques for individual monitoring stations may be used to determine the probability that pollutant concentrations fall within a given range or that they exceed a given critical value. Meteorological variables, such as temperature, wind speed, and stability, are used as the independent variable in the discriminant function.

The Martin Model

A diffusion model specifically suited to the estimation of long-term average values of air quality was developed by Martin (1971). The basic equation of the model is the Gaussian diffusion equation for a continuous point source. It is modified to allow for a multiplicity of point sources and a variety of meteorological conditions.

The model is receptor-oriented. The equations for the ground-level concentration within a given 22 1/2° sector at the receptor for a given set of meteorological conditions (i.e., wind speed and atmospheric stability) and a specified source are listed in his work. The assumption is made that all wind directions within a 22 1/2° sector corresponding to a 16-point compass occur with equal probability.

In order to estimate long-term air quality, the single-point-source equations cited above are evaluated to determine the contribution from a given source at the receptor for each possible combination of wind speed and atmospheric stability. Then, using Martin's notation, the long-term average is given by

$$\chi = \sum_{N}\sum_{L}\sum_{S} F(D_n, L, S)\chi(\rho_n, L, S)$$

where D_n indicates the wind-direction sector in which transport from a particular source (n) to the receptor occurs; ρ_n is the distance from a particular source to the receptor; $F(D_n, L, S)$ denotes the relative frequency of winds blowing into the given wind-direction sector (D_n) for a given wind-speed class (S) and atmospheric stability class (L); and N is the total number of sources. The joint frequency distribution $F(D_n, L, S)$ is determined by the use of hourly meteorological data.

A system of modified average mixing heights based on tabulated climatological values is developed for the model. In addition, adjustments are made in the values of some mixing heights to take into account the urban influence. Martin has also incorporated the exponential time decay of pollutant concentrations, since he compared his calculations with measured sulfur-dioxide concentrations for St. Louis, Missouri.

The Tabulation Prediction Scheme

This method, developed at the Argonne National Laboratory, consists of developing an ordered set of combinations of relevant meteorological variables and presenting the percentile distribution of SO$_2$ concentrations for each element in the set. In this table, the independent variables are wind direction, hour of day, wind speed, temperature, and stability. The 10, 50, 75, 90, 98, and 99 percentile values are presented as well as the minimum and the maximum values. Also presented are the interquartile range and the 75 to 95 percentile ranges to provide measures of dispersion and skewness, respectively. Since the meteorological variables are ordered, it is possible to look up any combination of meteorological variables just as one would look up a name in a telephone book or a word in a dictionary. This method, of course, can be applied only as long as the source distribution and terrain have not changed appreciably. For continued use of this method, one must be cognizant of changes in the sources as well as changes in the terrain due to new construction.

In preparing the tabulation, the data are first stratified by season and also by the presence or absence of precipitation. Further, appropriate group intervals must be selected for the meteorological variables to assure that within each grouping the pollution values are not sensitive to changes in that variable. For example, of the spatial distribution of the sources, one finds that the pollution concentration at a station varies markedly with changes in wind direction. If one plots percentile isopleths for concentration versus wind direction, one may choose sectors in which the SO_2 concentrations are relatively insensitive to direction change. With the exception of wind direction and hour of day, the meteorological variables of the table vary monotonically with SO_2 concentration. The tabulation prediction method has advantages over other receptor-oriented technique in that (1) it is easier to use, (2) it provides predictions of pollution concentrations more rapidly, (3) it provides the entire percentile distribution of pollutant concentration to allow a forecaster to fine-tune his prediction based on synoptic conditions, and (4) it takes into account nonlinearities in the relationships of the meteorological variables and SO_2 concentrations. In a sense, one may consider the tabulation as representing a nonlinear regression hypersurface passing through the data that represents points plotted in n-dimensional space. The analytic form of the hypersurface need not be determined in the use of this method.

The disadvantages of this method are that (1) at least 2 years of meteorological data are necessary, (2) changes in the emission sources degrade the method, and (3) the model could not predict the effect of adding, removing, or modifying important pollution sources; however, it can be designed to do so.

Where a network of stations is available such as exists in New York City, Los Angeles, or Chicago, then the receptor-oriented technique may be applied to each of the stations to obtain isopleths or concentration similar to that obtained in the source-oriented model. It would be ideal to have a source-oriented model that could be applied to any city, given the source inventory. Unfortunately, the nature of the terrain, general inaccuracies in source-strength information, and the influence of factors such as synoptic effect or the peculiar geometries of the buildings produce substantial errors. Similarly, a receptor-oriented model, such as the Clarke model or one based on regression techniques, must be tailored to the location. Every urban area must therefore be calibrated, whether one desires to apply a source-oriented model or a tabulation prediction scheme. The tabulation prediction scheme, however, does not require detailed information on the distribution and strength of emission sources.

Perhaps the optimum system would be one that would make use of the advantages of both the source-oriented model, with its prediction capability concerning the effects of changes in the sources, and the tabulation prediction scheme, which could provide the probability distributions of pollutant concentrations. It appears possible to develop a hybrid system by developing means for appropriately modifying the percentile entries when sources are modified, added, or removed. The techniques for constructing such a system would, of course, have general applicability.

The Fixed-Volume Trajectory Model

In the trajectory model, the path of a parcel of air is predicted as it is acted upon by the wind. The parcel is usually considered as a fixed-volume chemical reactor with pollutant inputs only from sources along its path; in addition, various mathematical constraints placed on mass transport into and out of the cell make the problem tractable. Examples of this technique are discussed by Worley (1971). In this model, derived pollution concentrations are known only along the path of the parcel considered. Consequently, its use is limited to the "strategy planning" problem. Also, initial concentrations at the origin of the trajectory and meteorological variables along it must be well known, since input errors along the path are not averageable but, in fact, are propagated.

The Basic Approach

Attempts have been made to solve the entire system of three-dimensional time-dependent continuity equations. The ever-increasing capability of computer systems to handle such complex problems easily has generally renewed interest in this approach. One very ambitious treatment is that of Lamb and Neiburger (1971), who have applied their model to carbon-monoxide concentrations in the Los Angeles basin. However, chemical reactions, although allowed for in their general formulation, are not considered because of the relative inertness of CO. Nevertheless, the validity of the diffusion and emission subroutines is still tested by this procedure.

The model of Friedlander and Seinfeld (1969) also considers the general equation of diffusion and chemical reaction. These authors extend the Lagrangian similarity hypothesis to reacting species and develop, as a result, a set of ordinary differential equations describing a variable-volume chemical reactor. By limiting their chemical system to a single irreversible bimolecular reaction of the form $A + B + C$, they obtain analytical solutions for the ground-level concentration of the product as a function of the mean position of the pollution cloud above ground level. These solutions are also functions of the appropriate meteorological variables, namely solar radiation, temperature, wind conditions, and atmospheric stability.

ADAPTATION OF THE BASIC EQUATION TO URBAN AIR POLLUTION MODELS

The basic equation, (1), is the continuous point-source equation with the source located at the ground. It is obvious that the sources of an urban complex are for the most part located above the ground. The basic equation must, therefore, be modified to represent the actual conditions. Various authors have proposed mathematical algorithms that include appropriate modifications of Equation (1). In addition, a source-oriented model developed by Roberts et al. (1970) to allow for time-varying sources of emission is discussed below; see the section "Time-Dependent Emissions (the Roberts Model)."

Chemical Kinetics: Removal or Transformation of Pollutants

In the chemical-kinetics portion of the model, many different approaches, ranging in order from the extremely simple to the very complex, have been tried. Obviously the simplest approach is to assume no chemical reactions are occurring at all. Although this assumption may seem contradictory to our intent and an oversimplification, it applies to any pollutant that has a long residence time in the atmosphere. For example, the reaction of carbon monoxide with other constituents of the urban atmosphere is so small that it can be considered inert over the time scale of the dispersion process, for which the model is valid (at most a few hours).

Considerable simplification of the general problem can be effected if chemical reactions are not included and all variables and parameters are assumed to be time-independent (steady-state solution). In this instance, a solution is obtained that forms the basis for most diffusion models: the use of the normal bivariate or Gaussian distribution for the downwind diffusion of effluents from a continuous point source. Its use allows steady-state concentrations to be calculated both at the ground and at any altitude. Many modifications to the basic equation to account for plume rise, elevated sources, area sources, inversion layers, and variations in chimney heights have been proposed and used. Further discussion of these topics is deferred to the following four sections.

The second level of pseudo-kinetic complexity assumes first-order or pseudo-first-order reactions are responsible for the removal of a particular pollutant; as a result, its concentration decays exponentially with time. In this case, a characteristic residence time or half-life describes the temporal behavior of the pollutant. Often, the removal of pollutants by chemical reaction is included in the Gaussian diffusion model by simply multiplying the appropriate diffusion equation by an exponential term of the form $\exp(-t/T)$, where T represents the half-life of the pollutant under consideration. Equations employing this procedure are developed below. The interaction of sulfur dioxide with other atmospheric constituents has been treated in this way by many investigators; for examples, see Roberts et al. (1970) and Martin (1971). Chemical reactions are not the only removal mechanism for pollutant. Some other processes contributing to their disappearance may be absorption by plants, soil-bacteria action, impact or adsorption on surfaces, and washout (for example, see Figure 2). To the extent that these processes are simulated by or can be fitted to an exponential decay, the above approximation proves useful and valid.

These three reactions appear in almost every chemical-kinetic model. On the other hand, many different sets of equations describing the subsequent reactions have been proposed. For example, Hecht and Seinfeld (1972) recently studied the propylene-NO-air system and list some 81 reactions that can occur. Any attempt to find an analytical solution for a model utilizing all these reactions and even a simple diffusion submodel will almost certainly fail. Consequently, the number of equations in the chemical-kinetic subroutine is often reduced by resorting to a "lumped parameter" stratagem. Here, three general types of chemical processes are identified: (1) a chain-initiating process involving the inorganic reactions shown above as well as subsequent interactions of product oxidants with source and product hydrocarbons, to yield (2) chain-propagating reactions in which free radicals are produced; these free radicals in turn react with the hydrocarbon mix to produce other free radicals and organic compounds to oxide NO to NO_2, and to participate in (3) chain-terminating reactions; here, nonreactive end products (for example, peroxyacetylnitrate) and aerosol production serve to terminate the chain. In the lumped-parameter representation, reaction-rate equations typical of these three categories (and usually selected from the rate-determining reactions of each category) are employed, with adjusted rate constants determined from appropriate smog-chamber data. An attempt is usually made to minimize the number of equations needed to fit well a large sample of smog-chamber data. See, for examples, the studies of Friedlander and Seinfeld (1969) and Hecht and Seinfeld (1972). Lumped parameter subroutines are primarily designed to simulate atmospheric conditions with a simplified chemical-kinetic scheme in order to reduce computing time when used with an atmospheric diffusion model.

Elevated Sources and Plume Rise

When hot gases leave a stack, the plume rises to a certain height dependent upon its exit velocity, temperature, wind speed at the stack height, and atmospheric stability. There are several equations used to determine the total or virtual height at which the model considers the pollutants to be emitted. The most commonly used is Holland's equation:

$$\Delta H = \frac{v_s}{u}\left[1.5 + \left(2.68 \times 10^{-2}(P)\left(\frac{T_s - T_a}{T_a}\right)d\right)\right]$$

where

ΔH: plume rise
v_s: stack velocity (m/sec)
d: stack diameter (m)
u: wind speed (m/sec)
P: pressure (kPa)
T_s: gas exit temperature (K)
T_a: air temperature (K)

The virtual or effective stack height is

$$H = h + \Delta H$$

where

H: effective stack height
h: physical stack height

With the origin of the coordinate system at the ground, but the source at a height *H,* Equation (2) becomes

$$\frac{\chi}{Q} = \frac{1}{\pi u \sigma_y \sigma_z} \exp\left(-\frac{y^2}{2\sigma_y^2} - \frac{(z-H)^2}{2\sigma_z^2} \right) \exp\left(-\frac{0.693t}{T_{1/2}} \right) \quad (3)$$

Mixing of Pollutants under an Inversion Lid

When the lapse rate in the lowermost layer, i.e., from the ground to about 200 m, is near adiabatic, but a pronounced inversion exists above this layer, the inversion is believed to act as a lid preventing the upward diffusion of pollutants. The pollutants below the lid are assumed to be uniformly mixed. By integrating Equation (3) with respect to z and distributing the pollutants uniformly over a height *H,* one obtains

$$\frac{\chi}{Q} = \frac{1}{\pi u \sigma_y H} \exp\left(-\frac{y^2}{2\sigma_y^2} \right) \exp\left(-\frac{0.693t}{T_{1/2}} \right)$$

Those few measurements of concentration with height that do exist do not support the assumption that the concentration is uniform in the lowermost layer. One is tempted to say that the mixing-layer thickness, *H,* may be determined by the height of the inversion; however, during transitional conditions, i.e., at dawn and dusk, the thickness of the layer containing high concentrations of pollutants may differ from that of the layer from the ground to the inversion base.

The thermal structure of the lower layer as well as pollutant concentration as a function of height may be determined by helicopter or balloon soundings.

The Area Source

When pollution arises from many small point sources such as small dwellings, one may consider the region as an area source. Preliminary work on the Chicago model indicates that contribution to observed SO_2 levels in the lowest tens of feet is substantially from dwellings and exceeds that emanating from tall stacks, such as power-generating stacks. For a rigorous treatment, one should consider the emission Q as the emission in units per unit area per second, and then integrate Q along x and along y for the length of the square. Downwind, beyond the area-source square, the plume may be treated as originating from a point source. This point source is considered to be at a virtual origin upwind of the area-source square. As pointed out by Turner, the approximate equation for an area source can be calculated as

$$\frac{\chi}{Q} = \frac{\exp\left(-\frac{y^2}{2\left[\sigma_y^2\left(x_{y0}+x\right)\right]^2} - \frac{(z-h)^2}{2\sigma_z^2} \right) \exp\left(-\frac{0.693t}{T_{1/2}} \right)}{\pi u \left[\sigma_y\left(x_{y0}+x\right)\right]\sigma_z}$$

where $\sigma_y(x_{y0} + x)$ represents the standard deviation of the horizontal crosswind concentration as a function of the distance $x_{y0} + x$ from the virtual origin. Since the plume is considered to extend to the point where the concentration falls to 0.1 that of the centerline concentration, $\sigma_y(x_{y0}) = S/403$ where $\sigma_y(x_{y0})$ is the standard deviation of the concentration at the downwind side of the square of side length S. The distance x_{y0} from the virtual origin to the downwind side of the grid square may be determined, and is that distance for which $\sigma_y(x_{y0}) = S/403$. The distance x is measured from the downwind side of the grid square. Other symbols have been previously defined.

Correction for Variation in Chimney Heights for Area Sources

In any given area, chimneys are likely to vary in height above ground, and the plume rises vary as well. The variation of effective stack height may be taken into account in a manner similar to the handling of the area source. To illustrate, visualize the points representing the effective stack height projected onto a plane perpendicular to the ground and parallel both to two opposite sides of the given grid square and to the horizontal component of the wind vector. The distribution of the points on this projection plane would be similar to the distribution of the sources on a horizontal plane.

Based on Turner's discussion (1967), the equation for an area source and for a source having a Gaussian distribution of effective chimney heights may be written as

$$\frac{\chi}{Q} = \frac{\exp\left(-\frac{y^2}{2\left[\sigma_y\left(x_{y0}+x\right)\right]^2} - \frac{(z-h)^2}{2\left[\sigma_z\left(x_{z0}+x\right)\right]^2} \right) \exp\left(-\frac{0.693t}{T_{1/2}} \right)}{\pi u \left[\sigma_y\left(x_{y0}+x\right)\right]\left[\sigma_z\left(x_{z0}+x\right)\right]}$$

where $\sigma_z(x_{z0} + x)$ represents the standard deviation of the vertical crosswind concentration as a function of the distance $x_{z0} + x$ from the virtual origin. The value of $\sigma_z(x_{z0})$ is arbitrarily chosen after examining the distribution of effective chimney heights, and the distance x_{z0} represents the distance from the virtual origin to the downwind side of the grid square. The value x_{z0} may be determined and represents the distance corresponding to the value for $\sigma_z(x_{z0})$. The value of x_{y0} usually differs from that of x_{z0}. The other symbols retain their previous definition.

In determining the values of $\sigma_y(x_{y0} + x)$ and $\sigma_z(x_{z0} + x)$, one must know the distance from the source to the point in question or the receptor. If the wind direction changes within the averaging interval, or if there is a change of wind direction due to local terrain effects, the trajectories are curved. There are several ways of handling curved trajectories. In the Connecticut model, for example, analytic forms for the trajectories were developed. The selection of appropriate trajectory or streamline equations (steady state was assumed) was based on the wind and stability conditions. In the St. Louis model, Turner developed a computer program using the available winds to provide pollutant trajectories. Distances obtained from the trajectories are then used in the Pasquill diagrams or equations to determine the values of $\sigma_y(x_{y0} + x)$ and $\sigma_z(x_{z0} + x)$.

Time-Dependent Emissions (The Roberts Model)

The integrated puff transport algorithm of Roberts et al. (1970), a source-oriented model, uses a three-dimensional Gaussian puff kernel as a basis. It is designed to simulate the time-dependent or transient emissions from a single source. Concentrations are calculated by assuming that dispersion occurs from Gaussian diffusion of a puff whose centroid moves with the mean wind. Time-varying source emissions as well as variable wind speeds and directions are approximated by a time series of piecewise continuous emission and meteorological parameters. In addition, chemical reactions are modeled by the inclusion of a removal process described by an exponential decay with time.

The usual approximation for inversion lids of constant height, namely uniform mixing arising from the superposition of an infinite number of multiple source reflections, is made. Additionally, treatments for lids that are steadily rising or steadily falling and the fumigation phenomenon are incorporated.

The output consists of calculated concentrations for a given source for each hour of a 24-hour period. The concentrations can be obtained for a given receptor or for a uniform horizontal or vertical grid up to 1000 points.

The preceding model also forms the basis for two other models, one whose specific aim is the design of optimal control strategies, and a second that repetitively applies the single-source algorithm to each point and area source in the model region.

METEOROLOGICAL MEASUREMENTS

Wind speed and direction data measured by weather bureaus are used by most investigators, even though some have a number of stations and towers of their own. Pollutants are measured for periods of 1 hour, 2 hours, 12 hours, or 24 hours. 12- and 24-hour samples of pollutants such as SO_2 leave much to be desired, since many features of their variations with time are obscured. Furthermore, one often has difficulty in determining a representative wind direction or even a representative wind speed for such a long period.

The total amount of data available varies considerably in the reviewed studies. Frenkiel's study (1956) was based on data for 1 month only. A comparatively large amount of data was gathered by Davidson (1967), but even these in truth represent a small sample. One of the most extensive studies is the one carried out by the Argonne National Laboratory and the city of Chicago in which 15-minute readings of SO_2 for 8 stations and wind speed and direction for at least 13 stations are available for a 3-year period.

In the application of the mathematical equations, one is required to make numerous arbitrary decisions: for example, one must choose the way to handle the vertical variation of wind with height when a high stack, about 500 ft, is used as a point source; or how to test changes in wind direction or stability when a change occurs halfway through the 1-hour or 2-hour measuring period. In the case of an elevated point source, Turner in his St. Louis model treated the plume as one originating from the point source up to the time of a change in wind direction and as a combination of an instantaneous line puff and a continuous point source thereafter. The occurrence of precipitation presents serious problems, since adequate diffusion measurements under these conditions are lacking. Furthermore, the chemical and physical effects of precipitation on pollutants are only poorly understood. In carrying forward a pollutant from a source, one must decide on how long to apply the calculations. For example, if a 2-mph wind is present over the measuring grid and a source is 10 miles away, one must take account of the transport for a total of 5 hours.

Determining a representative wind speed and wind direction over an urban complex with its variety of buildings and other obstructions to the flow is frequently difficult, since the horizontal wind field is quite heterogeneous. This is so for light winds, especially during daytime when convective processes are taking place. With light-wind conditions, the wind direction may differ by 180° within a distance of 1 mile. Numerous land stations are necessary to depict the true wind field. With high winds, those on the order of 20 mph, the wind direction is quite uniform over a large area, so that fewer stations are necessary.

METHODS FOR EVALUATING URBAN AIR POLLUTION MODELS

To determine the effectiveness of a mathematical model, validation tests must be applied. These usually include a comparison of observed and calculated values. Validation tests are necessary not only for updating the model because of changes in the source configuration or modification in terrain characteristics due to new construction, but also for comparing the effectiveness of the model with any other that may be suggested. Of course, the primary objective is to see how good the model really is, both for incident control as well as for long-range planning.

Scatter Plots and Correlation Measures

Of the validation techniques appearing in the literature, the most common involves the preparation of a scatter diagram relating observed and calculated values (Y_{obs} vs. Y_{calc}). The degree of scatter about the $Y_{obs} = Y_{calc}$ line provides a measure of the effectiveness of the model. At times, one finds that a majority of the points lies either above the line or below the line, indicating systematic errors.

It is useful to determine whether the model is equally effective at all concentration levels. To test this, the calculated scale may be divided into uniform bandwidths and the mean square of the deviations abou t the $Y_{\text{obs}} = Y_{\text{calc}}$ line calculated for each bandwidth. Another test for systematic error as a function of bandwidth consists of an examination of the mean of the difference between calculated and observed values for $Y_{\text{calc}} < Y_{\text{obs}}$ and similarly for $Y_{\text{calc}} > Y_{\text{obs}}$.

The square of the linear correlation coefficient between calculated and observed values or the square of the correlation ratio for nonlinear relationships represent measures of the effectiveness of the mathematical equation. For a linear relationship between the dependent variable, e.g., pollutant concentration, and the independent variables,

$$R^2 = 1 - \frac{S_y^2}{\sigma_y^2} = 1 - \frac{\text{unexplained variance}}{\text{total variance}} = \frac{\sigma_y^2 - S_y^2}{\sigma_y^2}$$

$$= \frac{\text{explained variance}}{\text{total variance}}$$

where

R^2: square of the correlation coefficient between observed and calculated values

S_y^2: average of the square of the deviations about the regression line, plane, or hyperplane

σ_y^2: variance of the observed values

Statistical Analysis

Several statistical parameters can be calculated to evaluate the performance of a model. Among those commonly used for air pollution models are Kukkonen, Partanen, Karppinen, Walden, et al. (2003); Lanzani and Tamponi (1995):

The index of agreement

$$\text{IA} = 1 - \frac{\overline{(C_p - C_o)^2}}{[|C_p - \overline{C_o}| + |C_o - \overline{C_o}|]^2}$$

R

$$R = \overline{\left[\frac{(C_o - \overline{C_o})(C_p - \bar{C}_p)}{\sigma_o \sigma_p}\right]}$$

The bias

$$\text{Bias} = \frac{\bar{C}_p - \overline{C_o}}{\overline{C_o}}$$

The fractional bias

$$\text{FB} = \frac{\bar{C}_p - \overline{C_o}}{0.5(\bar{C}_p + \overline{C_o})}$$

The normalized mean of the square of the error

$$\text{NMSE} = \frac{\overline{(C_p - \overline{C_o})^2}}{\bar{C}_p \overline{C_o}}$$

where

C_p: predicted concentrations

C_o: predicted observed concentrations

σ_o: standard deviation of the observations

σ_p: standard deviation of the predictions

The overbar concentrations refer to the average overall values.

The parameters IA and R^2 are measures of the correlation of two time series of values, the bias is a measurement of the overall tendency of the model, the FB is a measure of the agreement of the mean values, and the NMSE is a normalized estimation of the deviation in absolute value.

The IA varies from 0.0 to 1.0 (perfect agreement between the observed and predicted values). A value of 0 for the bias, FB, or NMSE indicates perfect agreement between the model and the data.

Thus there are a number of ways of presenting the results of a comparison between observed and calculated values and of calculating measures of merit. In the last analysis the effectiveness of the model must be judged by how well it works to provide the needed information, whether it will be used for day-to-day control, incident alerts, or long-range planning.

RECENT RESEARCH IN URBAN AIR POLLUTION MODELING

With advances in computer technology and the advent of new mathematical tools for system modeling, the field of urban air pollution modeling is undergoing an ever-increasing level of complexity and accuracy. The main focus of recent research is on particles, ozone, hydrocarbons, and other substances rather than the classic sulfur and nitrogen compounds. This is due to the advances in technology for pollution reduction at the source. A lot of attention is being devoted to air pollution models for the purpose of urban planning and regulatory-standards implementation. Simply, a model can tell if a certain highway should be constructed without increasing pollution levels beyond the regulatory maxima or if a new regulatory value can be feasibly obtained in the time frame allowed. Figure 2 shows an example of the distribution of particulate matter (PM_{10}) in a city. As can be inferred, the presence of particulate matter of this size is obviously a traffic-related pollutant.

Also, some modern air pollution models include meteorological forecasting to overcome one of the main obstacles that simpler models have: the assumption of average wind speeds, direction, and temperatures.

At street level, the main characteristic of the flow is the creation of a vortex that increases concentration of pollutants on the canyon side opposite to the wind direction, as

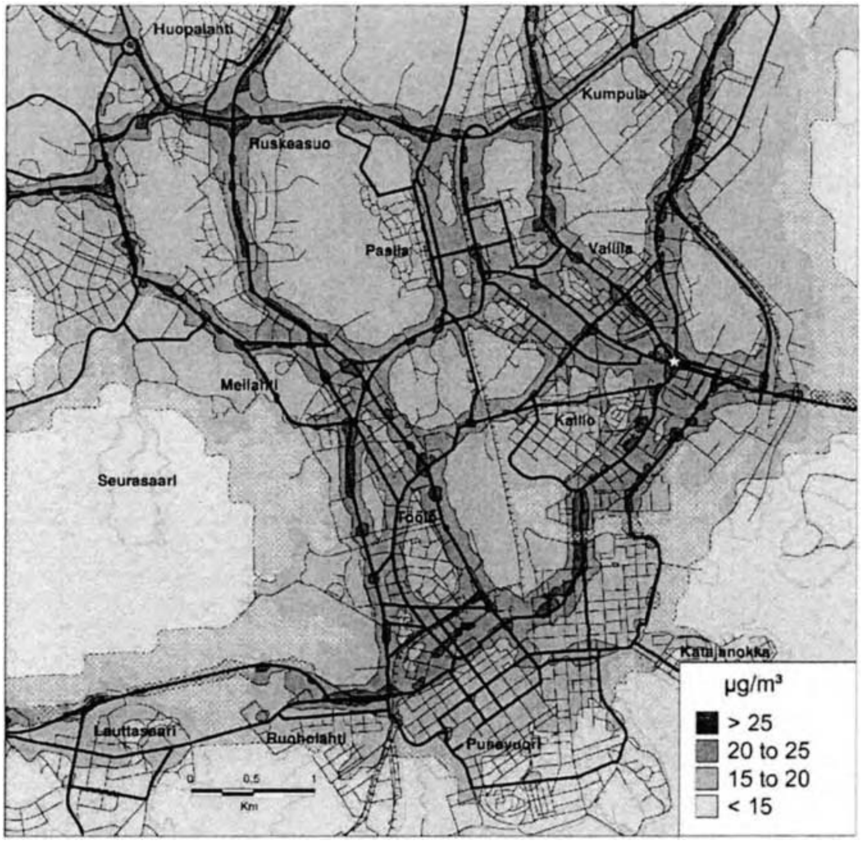

FIGURE 2 Predicted spatial distribution of the yearly means of PM_{10} in central Helsinki in 1998 (mg/m^3). The white star indicates the predicted maximum concentration in the area (40.4 mg/m^3) (From Kukkonen et al., 2001, with permission from Elsevier).

shown in Figure 3 (Berkowicz, 2000a). The Danish operational street pollution model (OSPM) has been used by several researchers to model dispersion of pollutants at street level. Several studies have assessed the validity of the model by using data for different cities in Europe.

New techniques such as Fuzzy Logic and Neural Networks have been used with great results (Kukkonen, Partanen, Karppinen, Ruuskanen, et al., 2003; Viotti et al., 2002, Pokrovskya et al., 2002; Pelliccioni and Poli, 2002). Schlink and Volta (2000) used grey box stochastic models and extended autoregressive moving average models to predict ozone formation. Other approaches have been time-series analysis, regression analysis, and statistical modeling, among others.

For additional information, the reader is referred to the references at the end of the chapter.

CONCLUDING REMARKS

Inadequacies and shortcomings exist in our assessment of each of the components of the mathematical urban air pollution model. In this section these difficulties are discussed.

The Source Inventory

For large metropolitan areas, one finds that the inventory obtained by the usual methods, such as questionnaires, is often out of date upon its completion. Continuous updating is necessary. However, in a receptor-oriented model, the requirement for a detailed source inventory is relaxed. Further, by developing a receptor-oriented "anomaly" model, one may further reduce the error resulting from inadequate source information. In the anomaly-type model, changes in the dependent variable over a given time period are calculated. This interval may be 1, 2, 4, or 6 hours.

Initial Mixing

According to Schroeder and Lane (1988), "Initial mixing refers to the physical processes that act on pollutants immediately after their release from an emission source. The nature and extent of the initial interaction between pollutants and the ambient air depend on the actual configuration of the source in terms of its area, its height above the surrounding terrain, and the initial buoyancy conditions."

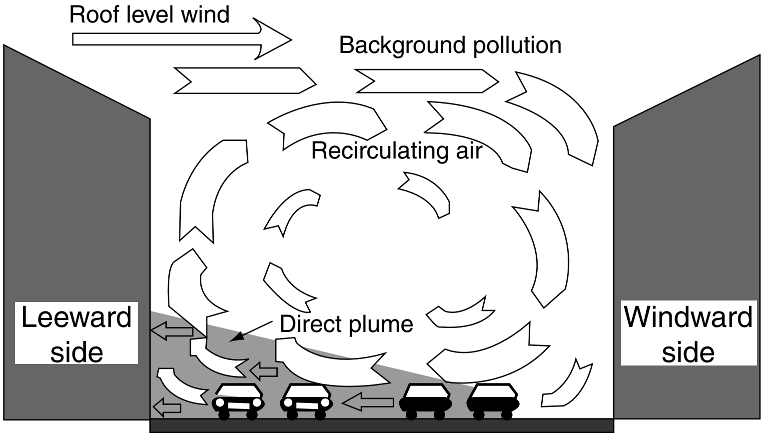

FIGURE 3 Schematic illustration of flow and dispersion of pollutants in street canyons (From Berkowicz, 2000a, with permission of Springer Science and Business media).

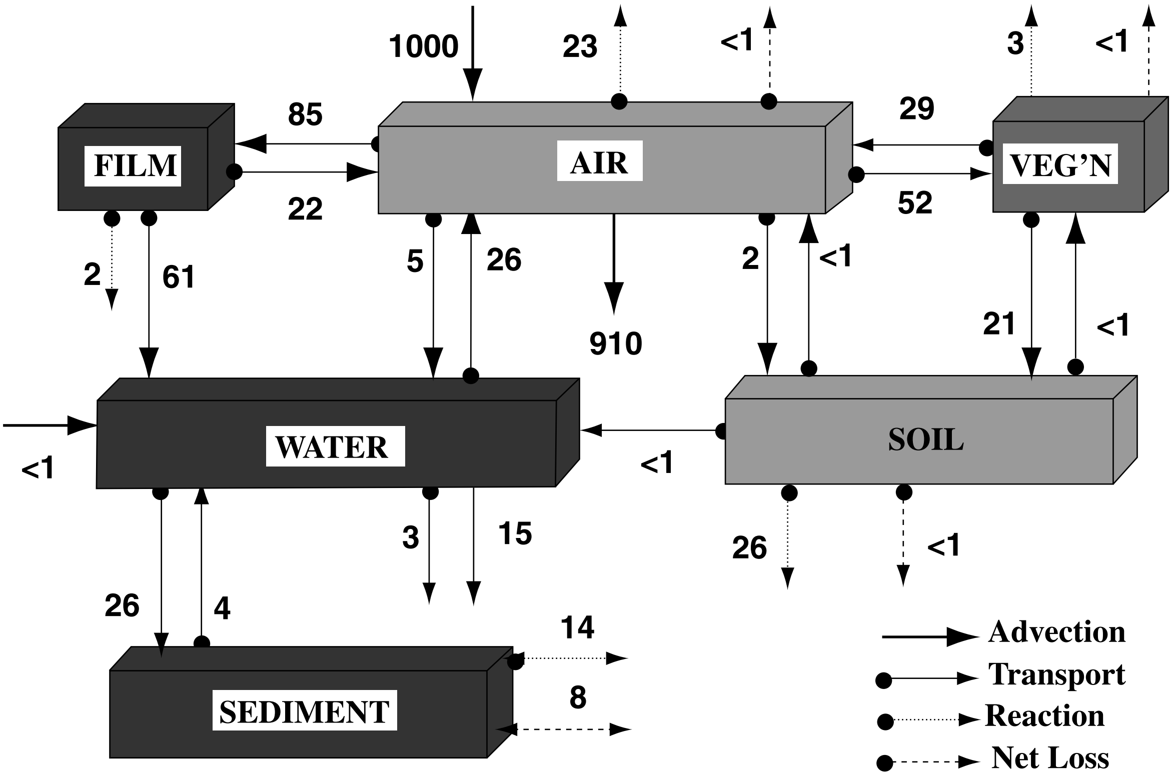

FIGURE 4 Estimated rates of chemical movement and transformation for 2,3,7,8-CL$_4$DD based on an emission of 1 mil/hour into air. Numbers shown are transport rate in mmol/hour (From Diamond et al., 2001, with permission from Elsevier).

The mixing layer is the lower region of the troposphere in which pollutants are relatively free to circulate and disperse vertically as well as horizontally because of the preponderance of small-scale turbulence. It may extend to a height as small as 50 m or as great as 5 km above the surface (Deardorff, 1975). More typically, it extends about 1 to 2 km during the day and a few hundred meters at night, although day-to-day variations can be quite large (Smith, 1982). This turbulence promotes intimate contact between vapor-phase and aerosol-associated pollutants.

Such direct contact is an important step in the chain of events that ultimately results in chemical transformations of pollutants near their source before extensive dilution has occurred and while their air concentrations are still relatively high. The consequences of limited vertical mixing may be exacerbated at northern latitudes, where air pollutants released close to the ground may disperse only to a very limited extent because of the extreme stability of air brought about by inversion layers characteristic of the Arctic, especially in winter. This situation can give rise to elevated ambient-air concentration of noxious contaminants in those regions.

Pollutant Measurements

It is necessary to remember that the distribution of any contaminants is a function of space and time. With a heterogeneous distribution of sources in space and the pronounced variation in source strength with time, one can hardly expect a few stations to describe adequately the distribution of the contaminant sources. Also, the averaging time is important. A 1-hour sample or even a 2-hour sample will bring out the diurnal effects quite well; however, 24-hour samples do not.

Photochemical Transformations

Schroeder and Lane (1988) have also discussed the reactions occurring in the atmosphere thus: "During transport and diffusion through the atmosphere, all but the most inert toxic pollutants are likely to participate in complex chemical or photochemical reactions. These processes can transform a pollutant from its primary state (the physical and chemical form in which it first enters the atmosphere) to another state that may have similar or very different characteristics."

Transformation products can differ from their precursors in chemical stabilities, toxic properties, and various other characteristics. For example, pyrene, a nontoxic, noncarcinogenic organic molecule, can react with NO_x and nitric acid in the air to form various nitropyrenes, which are highly potent, direct-acting mutagens. Secondary pollutants may be removed from the atmosphere in a manner different from that of their parent substances as a result of characteristic chemical and photochemical degradation or physical-removal mechanisms. It is difficult to formulate general statements regarding atmospheric transformations of Toxic Air Pollutants because the contributing chemical processes are numerous and complex.

The Earth's atmosphere is an efficient oxidizing medium even though most of its mass is composed of either relatively inert molecules or chemically reducing gases such as N_2, H_2, and CH_4. Nevertheless, the atmosphere acts as an oxidative system because of its overall composition and the relative chemical reactivity of natural atmospheric constituents or contaminants. Some of the more chemically reactive species known to be present in ambient air are atomic oxygen, ozone, hydroxyl and other free radicals (HO_2, CH_3O_2), peroxides (H_2O_2, CH_3O_2H), nitrogen oxides, sulfur oxides, and a wide variety of acidic and basic species. Consequently, contaminants of environmental interest, once emitted into ambient air, are converted at various rates into substances characterized by higher chemical oxidation states than their parent substances.

FUTURE CONSIDERATIONS

If mathematical modeling is to be effective, it is essential that information be available on the space-time distribution of both the pollutant and the necessary meteorological variables. By considering concentration changes with time and using the receptor-oriented approach, one may minimize the influence of the source inventory, but in the last analysis, source-inventory information is necessary for any model. In the validation procedure, one must consider the occurrence of systematic errors, i.e., readings consistently too high or too low compared to the calculated values. Similarly, large deviations between calculated and observed values should be carefully investigated. The selection of an appropriate sampling time is very important.

In conclusion, although the efforts made to date on the problem are commendable, the results can still be improved. Continued effort in the development of an urban air pollution model is necessary, and hopefully will provide the needed tools for handling urban air pollution problems.

URBAN RUNOFF

INTRODUCTION

This article is a survey of control and treatment of combined sewer overflows (CSOs). The discussions of control/treatment technologies that consist mostly of downstream treatment have been divided into seven sections:

1) Source Control: Street Sweeping
2) Collection System Control
3) Storage
4) Physical (with/without) Chemical Treatment
5) Biological Treatment
6) Advanced Treatment
7) Disinfection

Storage is the oldest documented abatement measure currently practiced, and it should be considered at all times in system planning because it allows for maximum use of existing dry-weather facilities. Physical (with/without) chemical treatment will generally be the minimum required to meet discharge or receiving-water-quality goals. If a higher degree of organics removal is needed, biological treatment should be examined. If maintaining a viable microorganism population is not feasible, but removal of dissolved and colloidal organics is desired, advanced treatment may be attractive. If disinfection is required, it would follow some level of physical treatment.

General discussions of CSO control/treatment can be found in several documents, including the following:

EPA-600/2-76-286, "Cost Estimating Manual-Combined Sewer Overflow Storage and Treatment." (NTIS PB 266 359).

EPA-600/8-77-014, "Urban Stormwater Management and Technology: Update and User's Guide." (NTIS PB 275 654).

1 SOURCE CONTROL: STREET SWEEPING

Street sweeping to remove accumulated dust, dirt, and litter, has been shown to be an effective but limited method of attacking the source of stormwater-related pollution problems. Street-cleaning effectiveness is a function of (1) pavement type and condition, (2) cleaning frequency, (3) number of passes, (4) equipment speed, (5) sweeper efficiency, and (6) equipment type. Pavement type and condition affect performance more than do differences in equipment: In general, smooth asphalt streets are easier to keep clean than those consisting of loosely bound aggregate in a thick, oily matrix; and of course, the poorer a pavement's condition, the more difficult to keep it clean. The most important measure of street-cleaning effectiveness is "pounds per curb-mile removed" for a specific program condition. This removal value, in conjunction with the curb-mile costs, allows the cost for removing a pound of pollutant for a specific street-cleaning program to be calculated.

In the San Jose, California, street-sweeping project (EPA-600/2-79-161), experimental design and sampling procedures were developed that can be used in different cities to obtain specific information about street-dirt characteristics and their effects on air and water quality. At the test site in San Jose, it was determined that frequent street cleaning on smooth asphalt streets (once or twice per day) can remove up to 50% of the total solids and heavy-metal mass yields of urban runoff, whereas typical street-cleaning programs (once or twice per month) remove less than 5% of the total solids and heavy metals in the runoff. It was also determined that removal-per-unit effort decreased with increasing numbers of passes per year. This is shown in Figure 1, which relates the annual total solids removed to the street-cleaning frequency, for different street-surface conditions in San Jose.

Street-sweeping results are highly variable. Therefore, a street-sweeping program for one city cannot be applied to other cities, unless the program is shown to be applicable through experimental testing. This may be seen when comparing street-sweeping test results from San Jose with those of Bellevue, Washington. In Bellevue, it was demonstrated that additional cleaning, after a certain level of effort, is not productive and that the additional street-cleaning effort would be better applied to other areas. For the study area in Bellevue, it is estimated that street cleaning operations of about two or three passes per week would remove up to

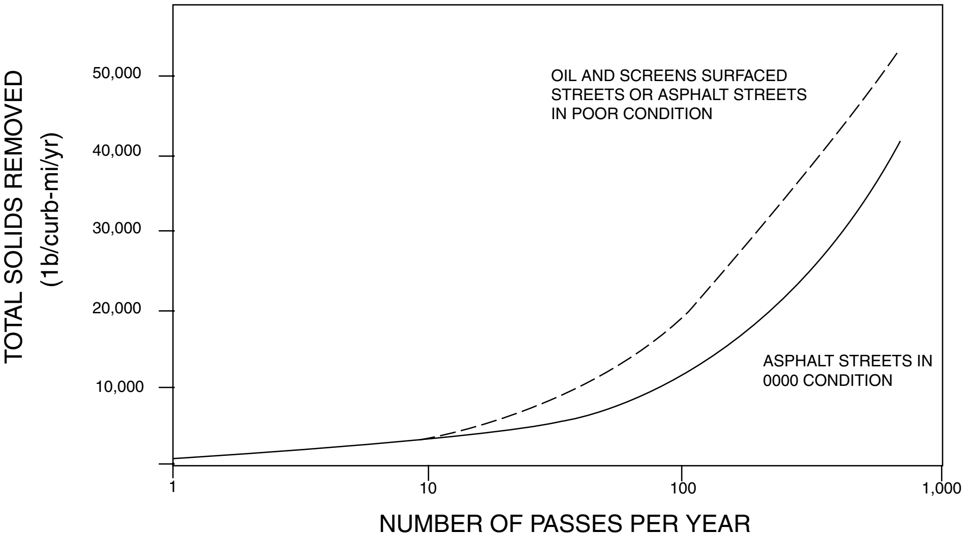

FIGURE 1 Street sweeping: annual amount removed as a function of the number of passes per year at San Jose test site.

68 kg (150 lb/curb-mi), or up to 25% of the initial street-surface load. Increased utilization of street-cleaning equipment would result in very little additional benefit. This is illustrated, for total solids and chemical oxygen demand (COD) removals, in Figures 2 and 3, respectively. Increased street-cleaning operations beyond two or three times per week are likely to increase the street-surface loadings due to erosion of the street surface. Increasing the cleaning frequency from once per week to two or more times per week will have only a very small additional benefit. Cleaning very infrequently (once every two months) may not be beneficial at all, except in cities where it may be possible to schedule street cleaning so that it is coordinated with rainfall events.

Street cleaning not only affects water quality but has multiple benefits, including the improvement of air quality, aesthetic conditions, and public health. Since street cleaning alone will probably not ensure that water-quality objectives are met, a street-cleaning program would have to be incorporated into a larger program of “best management practices” and/or downstream treatment. Costs of street cleaning have been reported to range from $4.92 to $19.03/curb-km ($7.92 to $30.61/curb-mi). The wide variation in these costs was attributed to differences in labor rates and equipment costs.

2 COLLECTION SYSTEM CONTROL

Catch Basins

A catch basin is defined as a chamber or well, usually built at the curbline or a street, for the admission of surface water to a sewer or subdrain, having at its base a sedimentation sump to retain grit and detritus below the point of overflow. It should be noted that a catch basin is designed to trap sediment, while an inlet is not. Historically, the role of catch basins has been to minimize sewer clogging by trapping coarse debris (from unpaved streets) and to reduce odor emanations from low-velocity sewers by providing a water seal.

In a project conducted in the West Roxbury section of Boston, three catch basins were cleaned, and subsequently four runoff events were monitored at each catch basin. Average pollutant removals per storm are shown in Table 1.

Catch basins must be cleaned often enough to prevent sediment and debris from accumulating to such a depth that the outlet to the sewer might become blocked. The sump must be kept clean to provide storage capacity for sediment and to prevent resuspension of sediment. Since the volume of stormwater detained in a catch basin will reduce the amount of overflow by that amount (it eventually leaks out or evaporates), it is also important to clean catch basins to provide liquid storage capacity. To maintain the effectiveness of catch basins for pollutant removal will require a cleaning frequency of at least twice per year, depending upon conditions. The increased cost of cleaning must be considered in assessing the practicality of catch basins for pollution control.

Typical cost data for catch basins are presented in Table 2. The reported costs will vary, depending on the size of the catch basin used by a particular city. Catch basin cost multiplication factors, as a function of sump storage capacity, are shown in Figure 4.

Estimated national average costs for three catch-basin cleaning methods are presented in Table 3.

Sewer Flushing

The deposition of sewage solids in combined sewer systems during dry weather has long been recognized as a major contributor to “first-flush” phenomena occurring during wet-weather runoff periods. The magnitude of these loadings during runoff periods has been estimated to range

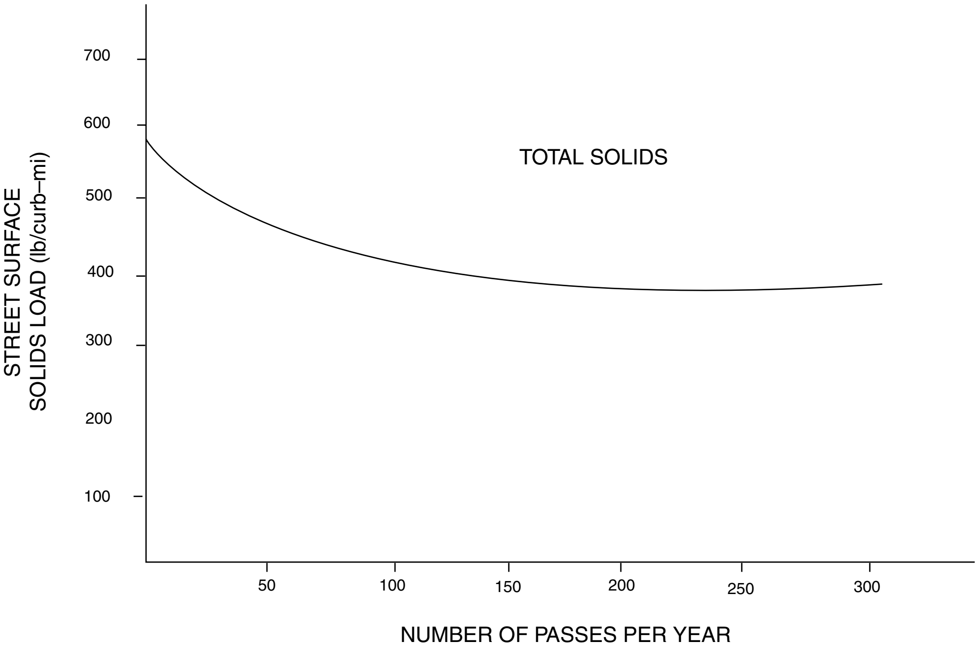

FIGURE 2 Street cleaner productivity in Bellevue, Washington.

up to 30% of the total annual dry-weather sewage loadings. Sewer flushing during dry weather is designed to periodically remove the material, as it accumulates, and hydraulically convey it to the treatment facilities, thus preventing resuspension and overflow of a portion of the solids during storm events and lessening the need for CSO treatment. Flushing is particularly beneficial for sewers with grades too flat to be self-cleansing and also helps ensure that sewers can carry their design flow capacities. Sewer flushing requires cooperation between the authorities with jurisdiction over collection system maintenance and wastewater treatment.

For developing sewer-flushing programs, it is necessary to be able to estimate deposition buildup. Predictive equations have been developed, based on field studies in Boston, to relate the total daily mass of pollutant deposition in a collection system to the system characteristics, such as per-capita waste-production rate, service area, total pipe length, average pipe slope, and average pipe diameter. A simple model is given by the equation

$$TS = 0.0076(L')^{1.063}(\bar{S})^{-0.4375}(q)^{-0.51} \quad (R^2 = 0.845)$$

where

TS = deposited solids loading, lb/d
$\bar{S}$ = mean pipe slope, ft/ft
L' = total length of sewer system, ft
q = per-capita waste rate (plus allowance for infiltration), gpcd

(EPA-600/2-79-133)

The total pipe length (L') of the system is generally assumed to be known. In cases where this information is not known, and where crude estimates will suffice, the total pipe length can be estimated from the total basin area, A (acres), using the expressions that follow.

For low population density (10–20 people/acre):

$$L' = 168.95(A)^{0.928} \quad (R^2 = 0.821).$$

For moderate-high population density (30–60 people/acre):

$$L' = 239.41(A)^{0.928} \quad (R^2 = 0.821).$$

If data on pipe slope are not available, the mean pipe slope can be estimated using the following equation:

$$\bar{S} = 0.348(\bar{S}_g) \quad (R^2 = 0.96)$$

where $\bar{S}_g$ = mean ground slope, ft/ft.

It has been found that cleansing efficiency of periodic flush waves is dependent upon flush volume, flush discharge rate, sewer slope, sewer length, sewer flowrate, sewer diameter, and population density. Maximum flushing rates at the downstream point are limited to the regulator/interceptor capacities prior to overflow. Internal automatic flushing devices have been developed for sewer systems. An inflatable bag is used to stop flow in upstream reaches until a volume capable of generating a flushing wave is accumulated. When the appropriate volume is reached, the bag is deflated with the assistance of a vacuum pump, releasing impounded sewage and resulting in the cleaning of the sewer segment. Field experience has indicated that sewer flushing by manual means (water-tank truck) is a simple, reliable method for CSO solids removal in smaller-diameter laterals and trunk sewers.

Pollutant removals as a function of length of pipe flushed (Dorchester, Massachusetts, EPA-600/2-79-133) are presented in Table 4. The relationship between cleaning efficiency and pipe length is important, since an aim of flushing is to wash the resuspended sediment to strategic locations, such as a point where sewage is flowing, to another point where flushing will be initiated, or to the sewage treatment plant.

Flushing is also an effective means for suspending and transporting heavy metals associated with light colloidal solids particles. Approximately 20–40% of heavy metals contained within sewage sediment—including cadmium, chromium, copper, lead, nickel, and zinc—have been found to be transported at least 305m (1,000 ft) by flush waves. Estimated costs of sewer-flushing methods are shown in Table 5.

TABLE 4

Pollutant removals by sewer flushing as a function of length of segment flushed (254–381 mm [10–15 in.] pipe)

	% Removals: organics and nutrients	% Removals: dry-weather grit/ inorganic material
Manhole-to-Manhole Segments	75–95	75

305 m (1,000 ft)	35–45	18–25

TABLE 5

Estimated costs of sewer-flushing methods based on daily flushing program (ENR = 5,000)

Number of segments: 46(254–457mm [10–18 in.] pipe) Automatic-flushing module operation (one module/segment)	
Capital cost	$21,640
Annual O&M cost	$199,084
Manual flushing mode	
Capital cost	$137,050
Annual O&M cost	$236,738

Regulator/Concentrators

The dual-functioning swirl regulator/concentrator can achieve both flow control and good removals (90–100%, laboratory determined) of inert settleable solids (effective diameter 0.3 mm, specific gravity 2.65) and organics (effective diameter 1.0 mm, s.g. 1.2). It should be noted that the laboratory test solids represent only the heavier fraction of solids found in CSO. Actual CSO contains a wider range of solids, so removals in field operations are closer to 40–50%.

Swirls have no moving parts. Flow is regulated by a central circular weir spillway, while simultaneously, solid–liquid separation occurs by way of flowpath-induced inertial separation and gravity settling. Dry-weather flows are diverted through the foul sewer outlet to the intercepting sewer for subsequent treatment at the municipal plant. During higher-flow storm conditions, 3–10% of the total flow—which includes sanitary sewage, storm runoff, and solids concentrated by swirl action—is diverted by way of the foul sewer outlet to the interceptor. The relatively clear, high-volume supernatant overflows the central circular weir and can be stored, further treated, or discharged to a stream. The swirl is capable of functioning efficiently over a wide range of CSO rates and has the ability to separate settleable solids and floatable solids at a small fraction of the detention time normally required for sedimentation. Suspended solids (SS) removals for the Syracuse, New York, prototype unit, as compared to hypothetical removals in a conventional regulator, are shown in Table 6. The BOD_5 removals for the Syracuse unit are shown in Table 7 (see EPA-600/2-79-134. *Disinfection/ Treatment of Combined Sewer Outflows*).

The *helical bend regulator/concentrator* is based on the concept of using the helical motion imparted to fluids at bends when a total angle of approximately 60 degrees and a radius of curvature equal to 16 times the inlet pipe diameter (*D*) are employed. Figure 5 illustrates the device. The basic structural features of the helical bend are: (1) the transition section from the inlet to the expanded straight section before the bend, (2) the overflow side weir and scum baffle, and (3) the foul outlet for removing concentrated solids and controlling the amount of underflow going to the treatment works. Dry-weather flow goes through the lower portion of the device and to the intercepting sewer. As the liquid level increases during wet weather, helical motion beings and the solids are drawn to the inner wall and drop to the lower level of the channel leading to the treatment plant. When the

(EPA-600/2-79-134; EPA-625/2-77-012).

storm subsides, the velocity of flow increases, due to the constricted channel. This helps prevent the settling of solids. As with the swirl, the proportion of concentrated discharge will depend on the particular design. The relatively clean CSO passes over a side weir and is discharged to the receiving water or to storage and/or treatment facilities. Floatables are prevented from overflowing by a scum baffle along the side weir and collect at the end of the chamber. They are conveyed to the treatment plant when the storm flow and liquid level subside.

Based on laboratory tests, pollutant removals in a helical bend unit are comparable to those in a swirl (a helical bend was demonstrated in Boston). Helicals and swirls are, in effect, upstream treatment devices for the removal of relatively heavy, coarse material, but they cannot be used to substitute for primary clarification. A comparison of construction costs for helical bend and swirl regulator/concentrators is presented in Table 8. It should be noted that these costs do not reflect the real cost-effectiveness of swirls and helicals, since these units actually serve dual functions (i.e., flow control and wastewater treatment). Even though the construction cost for the helical bend is higher than for the swirl, the helical may be more appropriate for a particular site, based on space availability and elevation difference between the interceptor and the incoming combined sewer (the helical requires a smaller elevation difference than the swirl). If there is not sufficient hydraulic head to allow dry-weather flow to pass through the facility, an economic evaluation would be necessary to determine the value of one of three alternatives: (1) pumping the foul sewer flow continuously, (2) pumping the foul flow during storm conditions, or (3) bypassing the facility during dry-weather conditions.

3 STORAGE

Because of the high volume and variability associated with CSO, storage is considered a necessary control alternative. Storage is also the best documented abatement measure currently practiced. Storage facilities are frequently used to attenuate peak flows associated with CSO. Storage must be considered at all times in system planning because it allows for maximum use of existing dry-weather treatment plant facilities and results in the lowest-cost system in terms of treatment. The CSO is stored until the treatment plant can accept the extra volume. At that time, the CSO is discharged. Storage facilities can provide the following advantages: (1) They respond without difficulty to intermittent and random storm behavior, and (2) they are not upset by water-quality changes.

TABLE 8
Comparison of constructor costs for helical bend and regulator/concentrators (ENR = 5,000)

Capacity	Swirl	Helical
1.42 m^3/s (50 cfs)	$459,360	$1,121,500
2.83 m^3/s (100 cfs)	744,910	2,102,300
4.67 m^3/s (165 cfs)	1,034,595	2,963,090

Note: Land costs not included.

Figure 6 shows that there is an increase in BOD_5 and SS percent removals, with an increase in tank volume per drainage area. Figure 7, however, demonstrates decreasing removal efficiencies per unit volume as tank size increases. Also, beyond an optimum tank volume, the rate of cost increase for retaining the extra flow increases; therefore, it is not economical to design storage facilities for the infrequent storm. During periods when the tank is filled to capacity, the excess that overflows to the receiving water will have had a degree of primary treatment by way of sedimentation.

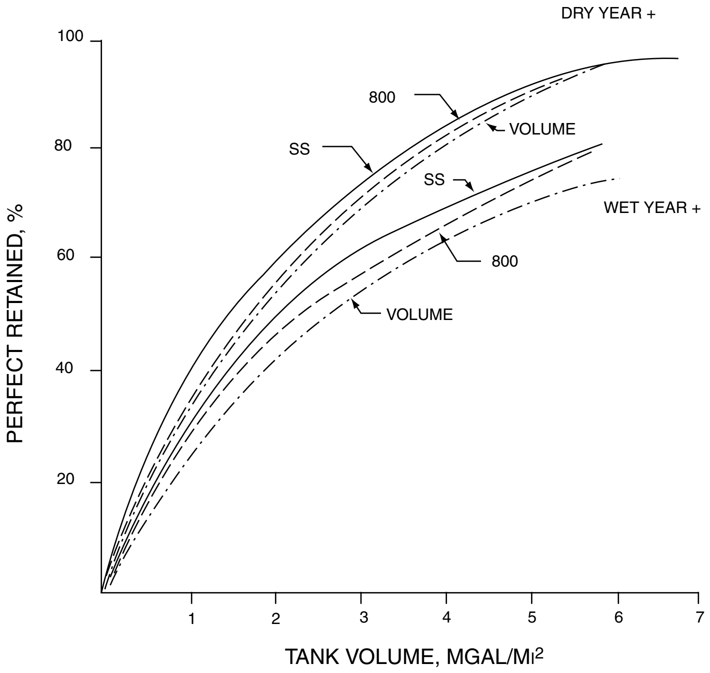
Storage facilities can be classified as either in-line or off-line. The basic difference between the two is that in-line storage has no pumping requirements. In-line storage can consist of either storage within the sewer pipes ("in-pipe") or storage in in-line basins. Off-line storage requires detention facilities (basins or tunnels) and facilities for pumping CSO to either storage or sewer system. Examination of storage options should begin with in-pipe storage. If this is not suitable, the use of in-line storage tanks should be considered; however, head allowances must be sufficient since no pumps will be used. Off-line storage should be considered last, since this will require power for pumping. Since the idea of storage is to lower the cost of the total treatment system, the storage capacity must be evaluated simultaneously with downstream treatment capacity so that the least cost combination for meeting water/CSO quality goals can be implemented.

If additional treatment capacity is needed, a parallel facility can be built at the existing plant, or a satellite facility can be built at the point of storage.

In-Pipe Storage

Because combined sewers are designed to carry maximum flows occurring, say, once in 5 years (50–100 times the average dry-weather flow), during most storms there will be considerable unused volume within the conduits. In-pipe storage is provided by damming, gating, or otherwise restricting flow passage causing sewage to back up in the upstream lines. The usual location to create the backup is at the regulator, or overflow point, but the restrictions can also be located upstream.

For utilization of this concept, some of all of the following may be desirable: sewers with flat grades in the vicinity of the interceptor, high interceptor capacity, and extensive control and monitoring networks. This includes installation of effective regulators, level sensors, tide gates, rain gauge networks, sewage and receiving water quality monitors, overflow detectors and flow-meters. Most of the systems are computerized, and to be safe, the restrictions must be easily and automatically removed from the flow stream when critical flow levels are approached or exceeded. Such systems have been successfully implemented in Seattle and Detroit. In-pipe storage was also demonstrated in Minneapolis–St. Paul. Costs associated with in-pipe storage systems are summarized in



*48.5 cm (19.1 in.) rainfall
+103.4 cm (40.7in.) rainfall
runoff coefficient (C) = 0.5

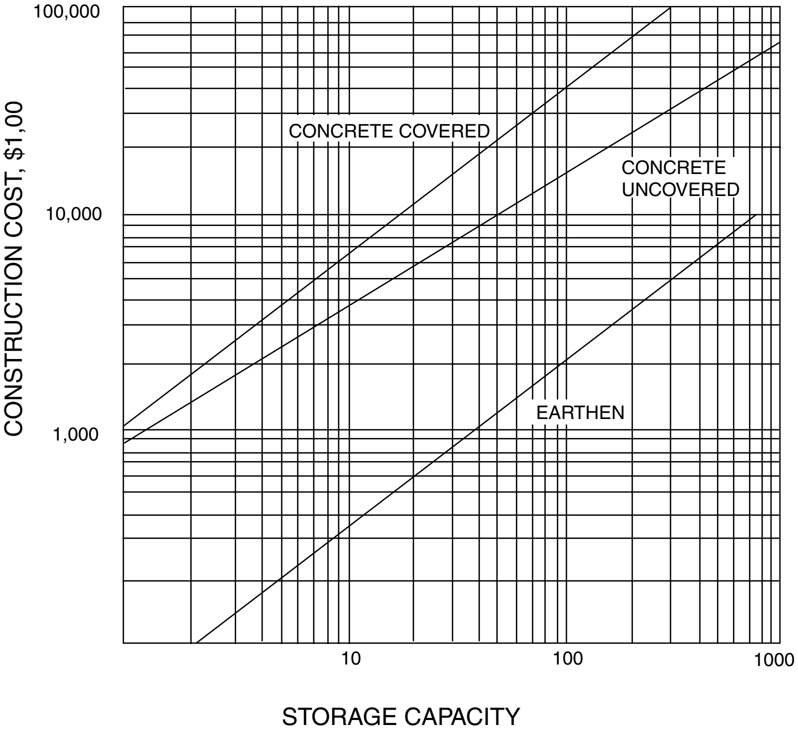

FIGURE 8 Storage basin construction costs: ENR = 5,000 (EPA-600/8-77-014).

Table 9. Costs include regulator stations, central monitoring and control systems, and miscellaneous hardware.

Off-Line Storage

Off-line storage facilities can be located at overflow points or near dry-weather treatment plants. Typical storage facilities include lagoons and covered or uncovered concrete tanks. Tunnels are also used where land is not available. Costs for basin storage facilities are presented in Table 10, and construction cost curves are shown in Figure 8. Note that these curves do not include pumping facilities, so these curves are applicable to in-line basins; the costs for earthen basins include liners.

Innovative Storage Technology

In-receiving Water Flow Balance System Karl Dunkers, an independent research engineer from Sweden, has developed, under the auspices of the Swedish EPA counterparts, an approach to lake protection against pollution from stormwater runoff. Instead of using conventional systems for equalization (i.e. concrete tanks or lined ponds), which are relatively expensive and require a lot of land area, the flow balanced method uses a wooden pontoon tank system in the lake, which performs in accordance with the plug-flow principle. The tank bottom is the lake bottom itself. The tank volume is always filled up, either with polluted stormwater runoff or with lake water. When it is raining, the stormwater runoff will "push" the lake water from one compartment to another. The compartment walls are of flexible PVC (polyvinyl chloride) fiberglass cloth. When not receiving runoff, the system reverses by automatically flowing back and the lake water fills up the system. Thus, the lake water is utilized as a flow balance medium. These units are sized to yield an effective in-water volume equal to the storage required for the storm size selected for design. Added benefits are the ease of construction and the flexibility to expand the volume if deemed necessary after initial installation; initial storage-volume estimates need not be as exact. Costs have been estimated to be one-fifth to one-tenth the cost of conventional land-side storage without real estate costs.

Sweden has invested in three of the installations so far. Two have been in operation for eight to nine years, and a third for seven years. The systems seem to withstand wave action up to 0.9 m (3 ft) as well as severe icing conditions. If a wall is punctured, patching is easily accomplished. Maintenance has been found to be inexpensive. The in-receiving water-flow balance system has been successfully demonstrated with urban runoff in freshwater lakes only. If used with CSO, consideration would have to be given to sludge handling and disposal. EPA's Storm and Combined Sewer Pollution Control Program is demonstrating this unique system with CSO in a much harsher marine/estuarine environment in New York City. Testing for seven storms indicates effectiveness as both a floatables trap and a temporary storage of CSO volumes. The estimated cost of this system is $1,641/lin m ($500/lin ft).

Self-cleaning Storage/Sedimentation Basin In Zurich, Switzerland, an in-line sedimentation storage tank was designed to prevent solids from shoaling after a storm and to provide for solids transport to the interceptor. The floor of the tank contains a continuous dry-weather channel (which is an extension of the tank's combined sewer inlet) that meanders from side to side (see Figure 9) through the tank. This channelized floor arrangement allows for complete sediment transport to the interceptor both during dry weather and upon drawdown after a storm event. The dry-weather flow comes through the meandering bottom channel. During wet-weather flows, the water level in the tank rises above the channel. If the storm intensity is low enough, there is complete capture, and if the storm intensity continues to rise, an overflow occurs through a weir at the tail end of the tank. A scum baffle prevents entrained solids from overflowing. This arrangement allows for sedimentation to take place during a tank overflow condition and, at the same time, for transport of solids that settle by way of the bottom channel.

4 PHYSICAL (WITH/WITHOUT) CHEMICAL TREATMENT

Physical-chemical processes are of particular importance in CSO treatment because of their adaptability to automatic operation (including almost instantaneous startup and shutdown), excellent resistance to shockloads, and ability to consistently produce a low SS effluent. In this discussion, physical-chemical systems will be limited to screening, filtration, chemical clarification, and dissolved air flotation.

TABLE 11
Description of screening devices used in CSO treatment

Type of screen	General description	Process application	Comments
Drum Screen	Horizontally mounted cylinder with screen fabric aperture in the range of 100–841 microns. Operates at 2–7 r/min.	Pretreatment	Solids are trapped on inside of drum and are back-washed to a collection trough.
Microstrainers	Horizontally mounted cylinder with screen fabric aperture in the range of 23–100 microns. Operates at 2–7 r/min.	Main treatment	Solids are trapped on inside of drum and are back-washed to a collection trough.
Rotostrainer	Horizontally mounted cylinder made of parallel bars perpendicular to axis of drum. Slot spacing in the range of 250–2,500 microns. Operates at 1–10 r/min.	Pretreatment	Solids are retained on surface of drum and are removed by a scraper blade.
Disk Strainer	Series of horizontally mounted woven wire discs mounted on a center shaft. Screen aperture in the range of 45–500 microns. Operates at 5–15 r/min.	Pretreatment, or posttreatment of concentrated effluents	Unit achieves a 12–15% solids cake
Rotary Screen	Vertically aligned drum with screen fabric aperture in the range of 74–167 microns. Operates at 30–65 r/min.	Main treatment	Splits flow into two distinct streams: unit effluent and concentrate flow, in the proportion of approximately 85:15.
Static Screen	Stationary inclined screening surface with slot spacing in the range of 250–1,600 microns.	Pretreatment	No moving parts. Used for removal of large suspended and settleable solids.

* A vertically mounted microstrainer is available, which operates totally submerged at approximately 65 r/min. Aperture range is 10–70 microns. Solids are moved from the screen by a sonic cleaning device.
(EPA-600/8–77/014).

Screening

Screens have been used to achieve various levels of SS removal contingent with three modes of screening process applications:

1) *Main treatment.* Screening is used as the primary treatment process.
2) *Pretreatment.* Screening is used to remove suspended and coarse solids prior to further treatment to enhance the treatment process or to protect downstream equipment.
3) *Dual use.* Screening provides either main treatment or pre-treatment of stormwater and is used as an effluent polisher during periods of dry weather.

Screens can be divided into four categories:

Screen Type	*Opening Size*
bar screen	>25.4 mm (>1 in.)
coarse screen	4.8–25.4 mm (3/16–1 in.)
fine screen	0.1–4.8 mm (1/250–3/16 in.)
microscreen	<0.1 mm (<1/250 in.)

TABLE 12

(EPA-600/8-77-014).

No special studies have been made to evaluate bar and coarse screens in relation to CSO, so the basis for design should be the same as for their uses in dry-weather treatment facilities. Because CSO contains a significant amount of coarse debris, which is aesthetically undesirable, providing coarse screening as the minimum CSO treatment may be useful. Fine screens and microscreens are discussed together because, in most cases, they operate in a similar manner.

Several distinct types of screening devices have been developed and used for SS removal from CSO, and are described in Table 11. Design parameters for static screens, microstrainers, drum screens, disc screens, and rotary screens are presented in Tables 12, 13, and 14. Removal efficiency of screening devices is adjustable by changing the aperture size of the screen placed on the unit, making these devices very versatile. Solids removal efficiencies are affected by two mechanisms: (1) straining by the screen, and (2) filtering of

smaller particles by the mat (schmutzdecke) deposited by the initial straining.

The efficiencies of screens treating a waste with a typical distribution of particle sizes will increase as the size of screen opening decreases.

The second-most important condition affecting removal efficiencies, especially for microstrainers, is the thickness of filtered material on the screen. Whenever the thickness of this filter mat is increased, the suspended matter removal will also increase because of the decrease in effective pore size and the filtering action of the filtered mat. This will also increase headloss across the screen. It was found, during experimental microstrainer operation in Philadelphia, that because of extreme variation in the influent SS concentration of CSO, removal efficiency would also vary, while effluent concentration remained relatively constant. For example, an effluent concentration of 10 mg/l SS would yield a reduction of 99% for an influent concentration of 1,000 mg/l (representative of "first-flush"), whereas the SS reduction would be only 50% if the influent concentration were 20 mg/l (representative of tail end of storm). This concentration-dependent phenomenon is apt to recur in other physical-chemical stormwater treatment operations (R. Field and E. Struzeski, JWPCF, Vol. 44, No. 7, July 1972).

Microstrainers and fine screens remove 25–90% of the SS, and 10–70% of the BOD_5, depending on the size of the screens used and the type of wastewater being treated. At Philadelphia, polyelectrolytes addition (0.25–1.5 mg/l) improved the operating efficiency of the microstrainer. Suspended solids removal increased from 70% to 78%, and the average effluent SS was reduced from 40 to 29 mg/l. The flux rate also increased from an average of 56.2 m³/m²/h (23 gal/ft²/min) to 95.4 m³/m²/h (39 gal/ft²/min). After an extensive laboratory coagulation study, moderately charged, high-molecular-weight cationic polyelectrolytes were found to be the most suitable for this application. Microstrainer, drum screen, static screen, and rotary screen performances as a function of influent SS concentration, for several experimental projects, are shown in Figures 10, 11, 12 and 13, respectively.

Costs of screening facilities are presented in Table 15.

Screening/Dual Media High-Rate Filtration

Dual media high-rate filtration (DMHRF) (>29 m³/m²/h [>8 gal/ft²/min]) removes small-sized particulates that remain after screening, and floc remaining after polyelectrolyte and/or coagulant addition. Principal advantages of the proposed system are: (1) high treatment efficiencies, (2) automated operation, and (3) limited space requirements. To be most effective, filtration through media that are graded from coarse to fine in the direction of filtration is desirable. A uniform sized, single specific-gravity medium filter cannot conform to this principle since backwashing of the bed automatically grades the bed from coarse to fine in the direction of washing; however, the concept can be approached by using a two-layer bed. A typical case is the use of coarse anthracite particles on top of less coarse sand. Since anthracite is less dense than sand, it can be coarse and still remain on top of the bed after the backwash operation. Another alternative would be an upflow filter, but these units have limitations in that they cannot accept high filtration rates.

The principal parameters to be evaluated in selecting a DMHRF system are media size, media depth, and filtration rate. Since much of the removal of solids from the water takes

place within filter media, their structure and composition is of major importance. Too fine a medium may produce a high-quality effluent, but also may cause excessive headlosses and extremely short filter runs. On the other hand, media that is too coarse may fail to produce the desired clarity of the effluent. Therefore, the selection of media for DMHRF should be made by pilot testing using various materials in different proportions and at different flow rates. Depth of media is limited by headloss and backwash considerations. The deeper the bed, the greater the headloss and the harder it is to clean. On the other hand, the media should be of sufficient depth so as to be able to retain the removed solids within the depth of the media for the duration of the filter run at the design flux rate without permitting breakthrough. The design filtration flux must be such that the effluent will be of a desired quality without causing excessive headloss through the filter, which in turn requires frequent backwashing. At high flux, shear forces seem to have significant effect on solids retention and removal.

Several DMHRF pilot-study installations have been demonstrated for control of CSO pollution. These facilities have used 15.2-, 30.5-, and 76.2-cm (6-, 12-, and 30-in.)-diameter filter columns with anthracite and sand media, together with various dosages of coagulants and/or polyelectrolytes. Descriptions of the DMHRF facilities are summarized in Table 16. Suspended solids removal by DMHRF was found to vary directly with influent SS concentrations and inversely with flux or hydraulic loading rate. Experimental results (from New York and Cleveland) have shown that SS removals from CSO increase appreciably with appropriate

chemical additions. The DMHRF treatment of CSO at New York's dual-use facility (40 $m^3/m^2/h$ [16 $gal/ft^2/min$] constant flux) provided overall average SS removals of 61% across the filter and 66% across the system, with an average influent SS concentration of 182 mg/l. Average SS removals for the three testing models(l) no chemicals, (2) polymer only, (3) polymer and alum—and test ranges are shown in Table 17.

A measure of the capability of a filter to remove SS, which is useful for predicting removals and filter-run cycle, is the *specific capture* or *mass capture.* This can be expressed as pounds of solids removed per filter surface, or pounds of solids removed per media volume. Table 18 presents average SS mass captures obtained across the filter (New York) during CSO tests of at least 3 hours duration, and the average for tests S-13, -14, and –16, which used more optimal chemical feeds and occurred during the storms of greatest intensity. It should be noted that these mass capture values are specific to the Newtown Creek filter and the test conditions.

BOD removals (New York) from CSO averaged 32% across the filter and 41% across the system with an average influent BOD_5 of 136 mg/l. The removals improved with chemical additions. Average BOD removals for the three testing modes and test ranges are shown in Table 19. It should be noted that the nature of the CSO tested (e.g., the presence of dissolved industrial organic contaminants) may account for variable BOD removals.

Limited tests were also run (New York) to determine heavy-metals reduction. These results, shown in Table 20, represent composite samples. Design parameters for DMHRF are shown in Table 21. Costs of CMHRF facilities are summarized in Table 22. These costs are based on facilities similarly designed to that of the Cleveland demonstration project. Comparison with alternate treatment systems show that DMHRF is cost-competitive with conventional sedimentation facilities for dual process (sanitary and CSO) or CSO treatment, yet DMHRF has only 5–7% the area requirements. For strict CSO treatment, DMHRF is competitive with dissolved air flotation and micro-straining processes.

Screening/Dissolved Air Flotation

Dissolved air flotation (DAF) is a unit operation used to separate solid particles or liquid droplets from a liquid phase. Separation is brought about by introducing fine air bubbles into the liquid phase. As the bubbles attach to the solid particles or liquid droplets, the buoyant force of the combined particle and air bubble is great enough to cause the particle to rise. Once the particles have floated to the surface, they are removed by skimming. The most common

process for forming the air bubbles is to dissolve air into the waste stream under pressure and then release the pressure to allow the air to come out of solution. The pressurized flow carrying the dissolved air to the flotation tank is either (1) the entire stormwater flow, (2) a portion of the stormwater flow (split flow pressurization), or (3) recycled DAF effluent.

High overflow rates 3.2–25 m^3/m^2/h (1.3–10.0 gal/ft^2/min) and shorter detention times (0.2–1.0 h) can be used for DAF than for conventional settling (0.5 m^3/m^2/h [0.2–0.7 gal/ft^2/min]; 1.0–3.0 h). This process has a definite advantage over gravity sedimentation when used on CSO, since particles with densities both higher and lower than the liquid can be removed on one skimming operation. Dissolved air flotation also aids in the removal of oil and grease, which are not as readily removed during sedimentation. The principal parameters that affect removal efficiencies are: (1) overflow rate, (2) amount of air dissolved in the flows, and (3) chemical addition. Chemical addition has been used to improve removals, and ferric chloride has been the chemical most commonly added. A treatment system consisting of screening followed by DAF has been found to be an effective method of reducing pollutants in CSO.

The basis of this system is that screening will remove particles that are too heavy for the air bubbles to carry. Average reported percent removals (Milwaukee pilot: 18,925 m^3/d [5 Mgal/d]), with and without chemical addition, are listed in Table 23. The chemical flocculant addition required to achieve the removals therein was 20 mg/l ferric chloride, and 48 mg/l cationic polyelectrolytes.

At Racine, Wisconsin, with full-scale prototype plants (54,126 m^3/d and 168,054 m^3/d [14.3 and 44.4 Mgal/d]), 40 mg/l ferric chloride and 2 mg/l cationic polyelectrolytes were used. The percent removals (concentration basis) are presented in Table 24. The results from Site II are better than from Site I because the hydraulic loading was usually lower at Site II than at Site I, resulting in lower overflow rates and longer tank detention times at Site II. Typical design parameters for DAF facilities are presented in Table 25.

(EPA-600/8-77-014).

For the two full-scale CSO test sites in Racine, capital costs (including land) were $1,064,000 and $2,132,000 for 54,100- and 168,000-m^3/d (14.3- and 44.4-Mgal/d) facilities, respectively (ENR = 5,000). Construction cost curves (ENR = 2,000) for DAF facilities, based on the experienced cost of the demonstration facilities, are presented in Figure 14. The operation and maintenance cost (ENR = 5,000) of the systems was $0.16/$m^3$ ($0.58/1,000 gal). It was thought that these costs could be reduced to $0.09/$m^3$ ($0.30/1,000 gal) by process and procedural modifications as described in EPA-600/2-79-106a. The major reason for the high O&M cost is the cost of labor for maintenance of the sites and cleanup of the sites after a system operation. These costs were $0.10/$m^3$ ($0.38/1,000 gal), or 65% of the total. Therefore, maintenance becomes the major cost item in

the full-scale application of screening/DAF for the treatment of CSO. Table 26 represents a tabulated summary of various physical treatment systems, including the swirl regulator/concentrator previously described.

5 BIOLOGICAL TREATMENT

Biological treatment is a means for stabilizing dissolved organic matter and removing nonsettleable colloidal solids. This can be accomplished either aerobically or anaerobically. Several biological processes have been applied to CSO treatment. These include contact stabilization, trickling filters, rotating biological contractors (RBC), and treatment lagoons. Descriptions of these processes and typical combined sewage treatment installations are provided in Tables 27 and 28. Biological treatment processes are generally classified as secondary treatment processes, capable of removing 70–95% of the BOD_5 and SS from waste flows at dry-weather design flowrates and loadings. When biological treatment processes are used for combined sewage treatment, removal efficiencies are lower (the percent organic matter is smaller for CSO solids than for dry-weather solids) and are controlled to a large degree by hydraulic and organic loading rates. Most biological systems are susceptible to overloading conditions and shock loads as compared to physical treatment processes. However, RBC have achieved high removals at flows 8–10 times dry-weather design flows.

Typical pollutant removals for contact stabilization, trickling filters, and RBCs (wet-weather loading conditions) are presented in Table 29. These processes include primary (except contact stabilization) and final clarification. Final clarification greatly influences the overall performance of the system by preventing the carry-over of biological solids produced by the processes. Pollutant removal efficiencies by treatment lagoons have varied from highs of 85–95% to negative values due to excessive algae production and carry-over. In addition to the type of lagoon and the number of cells in series (stages), several major factors that influence removal efficiencies include: (1) detention time, (2) source of oxygen supply, (3) mixing, (4) organic and hydraulic loading rates, and (5) algae removal mechanisms. A single-cell storage/oxidation lagoon in Springfield, Illinois averaged 27% BOD_5 removal and 20% SS removal; however, fish kills in the receiving water were greatly reduced as compared to that prior to the construction of the facility. Multiple-cell facilities with algae control systems constructed at Mount Cleimens, Michigan and Shelbyville, Illinois provide 75–90% SS and BOD_5 removal efficiencies during wet-weather conditions.

An operational problem common to all stormwater biological systems is that of maintaining a viable biomass to treat

TABLE 27
Description of biological processes used in CSO treatment

Biological process	Process description	Source of biomass	Requires additional treatment	Type of additional treatment
Contact Stabilization	Process is a modified activated sludge process in which the absorption phase, or contact, and the oxidation phase (stabilization) takes place in two separate tanks. Sludge is wasted from the stabilization tank to maintain constant biomass concentrations.	From conventional activated sludge treatment facility	Yes	Secondary clarification
Trickling Filters	Standard trickling filter process in which a biological growth is supported on a stationary medium and the stormwater distributed over the surface and allowed to flow through the media. Process can include standard rate or deep bed plastic media designs.	Must be continuously maintained with a source of food	Yes	Secondary qualification
Rotating Biological Contactors	Process operates on the same principle as trickling filters; however, the biological growth is supported on large diameter, closely-spaced disks that are partially submerged and rotate at slow speeds.	Must be continuously maintained with a source of food	Yes	Secondary clarification
Oxidation Ponds	Shallow aerobic ponds that rely on surface reaeration for oxygen supply to maintain biological uptake of organics. Sedimentation also occurs in oxidation ponds.	Allowed to generate for each storm	Optional	Final clarification, screening, or sand filtration
Aerated Lagoons	Similar to oxidation ponds except they are deeper and rely on artificial means of oxygen supply such as surface aerators or diffused air systems. System operates under aerobic conditions.	Allowed to generate for each storm	Optional	Final clarification, screening, or sand filtration
Facultative Lagoons	Facultative lagoons are the deepest of the lagoons and rely on surface reaeration. The lagoons have three distinct layers: (1) aerobic near the surface due to algae and aeration, (2) a transitions zone, and (3) an anaerobic zone near the bottom sludge deposits. The biological oxidation and anaerobic stabilization occur simultaneously.	Allowed to generate for each storm	Optional	Final clarification, screening, or sand filtration.

(EPA-600/8-77-014).

flows during wet-weather conditions. At New Providence, New Jersey trickling filters are operated in series during dry weather and in parallel during wet weather. This type of operation maintains a viable microorganism population during dry weather and also provides greater capacity for the wet-weather flows. For processes that borrow biomass from dry-facilities or allow the biomass to develop, a lag in process efficiency may be experienced as the biomass becomes acclimated to the changing waste strength and flowrate. Also, because of the limited ability of biological systems to handle fluctuating and high hydraulic shock loads, storage/detention facilities preceding the biological processes may be required. General maintenance problems experienced by wet-weather biological facilities are similar to those experienced at conventional biological installations. Winter operations of mechanical surface aerators have had some serious drawbacks, including icing, tipping, or sinking. Other methods of providing the required oxygen that show promise and have been demonstrated at many dry-weather facilities include diffused air systems and submerged tube aerators.

A comparison of construction and O&M costs for biological treatment systems and treatment lagoons is presented in Table 30. Costs of final clarification are included where control of solids and sludge produced by the biological treatment system are required. Costs also include pumping, disinfection, and algae control systems, where applicable. Engineering, administration, and land costs are not included in the estimates; however, land costs may be the controlling economic factor in the evaluation of lagoon treatment systems, and therefore must be evaluated for each specific location. Biological CSO treatment systems generally are integrated with or are a part of dry-weather treatment facilities. Cost estimates of the wet-weather portion of these facilities were separated from total costs of the total treatment systems. The cost of the in-line RBC at Milwaukee was used together with an estimated cost for a final clarifier to develop an estimated cost of a complete RBC treatment system. The final clarifier cost was based on one 19.8-m (65-ft) diameter clarifier with a surface loading rate of 2.04 $m^3/m^2/h$ (1,200 $gal/ft^2/d$). Costs of lagoon treatment systems vary widely and are a function of the type of lagoon (oxidation, aerated, or facultative), the number of cells and the miscellaneous equipment requirements (e.g., aeration equipment, disinfection equipment, instrumentation, pumping, and algae control provisions). Costs for many of these CSO facilities are based on only one installation of each biological treatment process. Therefore, these costs should be considered only coarse estimates and may be greatly influenced by the degree of integration with dry-weather treatment required to produce a viable system.

* Removal reflects low ranges from 30 to 10 times dry weather flow (EPA-600/8-77-014).

These costs can be used as a preliminary guide, but detailed analyses should be performed to compare and evaluate biological treatment alternatives with other methods of treatment and control. Initial capital investments of integrated dual-use facilities can be reduced by apportioning part of the costs to the dry-weather facility. The cost reduction is in proportion to the net benefit that the wet-weather facility provides to the overall treatment efficiency during dry-weather periods.

6 ADVANCED TREATMENT

High Gradient Magnetic Separation

High gradient magnetic separation (HGMS) is a new treatment technology applied to CSO management. In its simplest form, the high gradient magnetic separator consists of a canister packed with a fibrous ferromagnetic material that is magnetized by a strong external magnetic field (coils surround the canister). An iron frame increases the efficiency of the electromagnetic coils. The device operates in a sequence of feed and flush modes.

The magnetic particles are trapped on the edges of the magnetized fibers while the nonmagnetic particles and slurry pass through the canister. The matrix offers only a small hydraulic resistance to the feed flow, occupying less than 5% of the canister volume (95% void volume). When the matrix has become loaded with magnetic particles, the particles are easily washed from the matrix by reducing the magnetic field to zero and opening valves and backflushing. High gradient magnetic separation may also be used to remove nonmagnetic contaminants from water. This is accomplished by binding finely divided magnetic seed particles, such as magnetic iron oxide (magnetite), to the nonmagnetic contaminants, thus creating a "magnetic handle" ("indirect filtration" or "seeded water treatment"). Binding of the magnetic seed is accomplished in two general ways: (1) adsorption of the contaminant to magnetic seed and (2) chemical coagulation (alum). Particles ranging in size from soluble through settleable (0.001 μ) may be removed with this process. Design parameters for HGMS are presented in Table 31.

Magnetic separation can provide the rapid filtration of many pollutants from water, with a small expenditure of energy. Removal is much more efficient than with sedimentation because the magnetic forces on fine particles may be many times greater than gravitational forces. To date, only bench scale tests and a pilot-plant scale system of 1–4/min (0.26–1.06 gal/min) have been operated. Typical pollutant removals are shown in Tables 32, 33 and 34.

Costs of HGMS have been evaluated for a 94,625-m^3/d (25-Mgal/d) facility and are summarized in Table 35. Capital costs include pre-treatment, chemical addition, thickening and dewatering equipment, pumps, backflush system, instrumentation, and disinfection system. Operation and maintenance costs include chemicals, labor, electrical utilities, and maintenance.

Powdered Activated Carbon-Alum Coagulation

Several combined sewage treatment demonstration projects have evaluated the benefits of chemical aids to process operations, but only one pilot operation representing a complete physical–chemical treatment system has been implemented. It was demonstrated at a 379-m^3/d (100,000-gal/d) pilot unit in Albany, New York. In this project, raw municipal sewage and CSO were mixed with powdered activated carbon to remove dissolved organics. Alum was then added to aid in subsequent clarification. Addition of polyelectrolytes was followed by a short flocculation period. Solids were separated from the liquid stream by gravity settling, and the effluent

was then disinfected and discharged, or filtered (tri-media), then disinfected prior to discharge. Carbon regeneration in a fluidized bed furnace and alum recovery from the calcined sludge were also demonstrated, as was reuse of the reclaimed chemicals. Average carbon losses per regeneration cycle were 9.7%. Average removals in excess of 94% COD, 94% BOD, and 99% SS were consistently achieved (without filtration) in treating combined sewage. Representative capital and O&M costs for a physical-chemical treatment plant designed for raw stormwater treatment, projected from data developed during the Albany project, are summarized in Table 36.

DISINFECTION

Conventional municipal sewage disinfection generally involves the use of chlorine gas or sodium hypochlorite as the disinfectant. To be effective for disinfection purposes, a contact time of not less than 15 min at peak flowrate and a chlorine residual of 0.2–2.0 mg/l are commonly recommended. Disinfection of CSO is generally practiced at treatment facilities to control the discharge of pathogens and other microorganisms in receiving waters. However, an approach other than that used for the conventional municipal sewage is required, mainly because such flows have characteristics of intermittency, high flowrate, high SS content, wide temperature variation, and variable bacterial quality. Several other aspects of disinfection practices require consideration for CSO treatment applications:

1) A residual disinfecting capability may not be feasible for CSO (and all wastewater) discharges. Chlorine residuals and compounds discharged to natural waters may be harmful to aquatic life.
2) The coliform count is increased by surface runoff in quantities unrelated to pathogenic organism concentration. Total coliform or fecal coliform levels may not be the most useful indication of disinfection requirements and efficiencies.
3) Discharge points requiring disinfection are often at outlying points on the sewer system and require unmanned, automated installations.

The disinfectant used at a facility for treatment of CSO should be adaptable to intermittent use. Other considerations include the disinfection effectiveness and the safety and ease

(EPA-600/8–77–014).

of feeding. Table 37 shows disinfectants that might be used for storm disinfection. Chlorine and hypochlorite will react with ammonia to form chloramines and with phenols to form chlorophenols.

These are toxic to aquatic life and the latter also produce taste and odor in the water. Chlorine dioxide does not react with ammonia and completely oxidizes phenols. Ozone also is effective in oxidizing phenols. Other disinfectants that could be considered for future applications are bromine and ultraviolet light. However, certain factors limit their application at this time. While bromine can be shown to be a more effective disinfectant (Alleman, 1988), it may pose a greater toxicity concern to the aquatic system (White, 1986). Ultraviolet disinfection represents an appealing simplicity for remote locations (no disinfectant storage requirements and on-off control), but the high degree of solids removal and capital costs remain as impediments to its application to CSOs.

High-rate disinfection refers to achieving either a given percent or a given bacterial count reduction through the use of (1) decreased disinfectant contact time, (2) increased mixing intensity, (3) increased disinfectant concentration, (4) chemicals having higher oxidizing rates, or (5) various combinations of these. Where contact times are less than 10 min, (usually in the range of 1–5 min), adequate mixing is a critical parameter, providing complete dispersion of the disinfectant and forcing disinfectant contact with the maximum number of micro-organisms. The more physical collisions high-intensity mixing causes, the lower the contact time requirements.

Mixing can be accomplished by mechanical flash mixers at the point of disinfectant addition and at intermittent points,

Estimated capital and O&M costs for a physical-chemical treatment plant (ENR = 5,000)

Capital costs*				O&M costs[†] (cents/1,000 gal)			
1 Mgal/d	10 Mgal/d	25 Mgal/d	100 Mgal/d	1 Mgal/d	10 Mgal/d	25 Mgal/d	100 Mgal/d
448,000	447,800	9,110,000	26,675,000	48.0	47.1	39.0	29.3

* Capital costs include screens, grit chambers, overflow facilities, pipe reactor vessels, pumps, chemical storage, carbon slurry tanks, sludge storage, agitators, flocculators, tube settlers, filtration, chlorination, carbon regeneration/sludge incineration, fluidized bed furnace, chemical make-up system, 10% contingencies, and land.

[†] O&M costs include all materials, power, and labor. (Plant is designed for raw stormwater treatment.)

TABLE 37

Characteristics of principal stormwater disinfection agents.

Characteristics	Chlorine	Hypochlorite	Dioxide	Ozone
Stability	Stable	6-month half-life	Unstable	Unstable
Reacts with ammonia to form chloramines	Yes	Yes	No	No
Destroys phenols	At high concentrations	At high concentrations	Yes	Yes
Produces a residual	Yes	Yes	Short-lived*	No
Affected by PH	More effective	More effective	Slightly	No
Hazards	Toxic	Slight	Toxic; explosive	Toxic

* Chlorine dioxide dissociates rapidly.

(EPA-600/8-77-014)

or by specially designed plug flow contact chambers containing closely spaced, corrugated parallel baffles that create a meandering path for the wastewater.

High-rate disinfection was shown to be enhanced beyond the expected additive effect by sequential addition of Cl_2, followed by ClO_2 at intervals of 15–30s (EPA-670–2-75–021; EPA-600/2-76-244). A minimum effective combination of 8 mg/l of Cl_2 followed by 2 mg/l of ClO_2 was found as effective in reducing total and fecal coliforms, fecal streptococci, and viruses to acceptable target levels as adding 25 mg/l Cl_2 or 12 mg/l ClO_2 individually. It was surmised that the presence of free Cl_2 in solution with chlorite ions (ClO_2^- [the reduced state of ClO_2]) may cause the oxidation of ClO_2^- back to its original state. This process would prolong the existence of ClO_2, the more potent disinfectant.

Ozone has a more rapid disinfecting rate than chlorine and also has the further advantage of supplying additional oxygen to the wastewater. The increased disinfecting rate of ozone requires shorter contact times and results in a lower capital cost for a contactor, as compared to that for a chlorine contact tank. Ozone does not produce chlorinated hydrocarbons or a long-lasting residual as chlorine does, but it is unstable and must be generated on-site just prior to application. Thus, unlike chlorine, no storage is required. In tests on CSO in Philadelphia (see "microstraining and disinfection" reports listed in the references at the end of this section),

TABLE 38

Cost data on chlorine gas and hypochlorite disinfection (ENR = 5,000)

Location, agent, source	Capital cost ($)	Operating cost ($/yr)	Cost/lb available chlorine ($)
Akron, OH*			
Sodium hypochlorite Purchased	1,104,000	58,200	0.37–0.67
Cambridge and Somerville, MA			
Sodium hypochlorite Purchased	—	—	0.97
On-site generation	—	—	0.51
New Orleans, LA[†]			
Sodium hypochlorite			
On-site generation	1,448,000	724,000	0.30
Saginaw, MI[‡]			
Chlorine gas	406,000	5,800	0.87
Sodium hypochlorite			
Purchased	49,000	16,000–30,000	0.45–0.78
On-site generation	239,000–403,000	11,700–13,000	0.69–1.0
South Essex Sewage District, MA[§]			
Chlorine gas	1,667,000	582,000	0.09
Sodium hypochlorite			
Purchased	1,054,000	913,000	0.12
On site generation Seawater	4,200,000	406,000	0.09
Brine	4,200,000	758,000	0.13

* CSO disinfection.

[†] Storm sewer discharge disinfection.

[‡] CSO disinfection at use rate of 42,000 lb/yr of chlorine.

[§] Sewage treatment plant effluent disinfection at use rate of 24,000 lb/day of chlorine.

TABLE 39

Comparison of estimated capital costs for three different disinfection methods (ENR = 5,000)

Disinfection method	Capital cost ($/mgd)
2-min ozone contact (chamber with once-through oxygen-fed ozone generator)	32,530
2-min chlorine contact (chamber with hypochlorite feeder)	3,800
5–10-min conventional chlorine contact	4,230

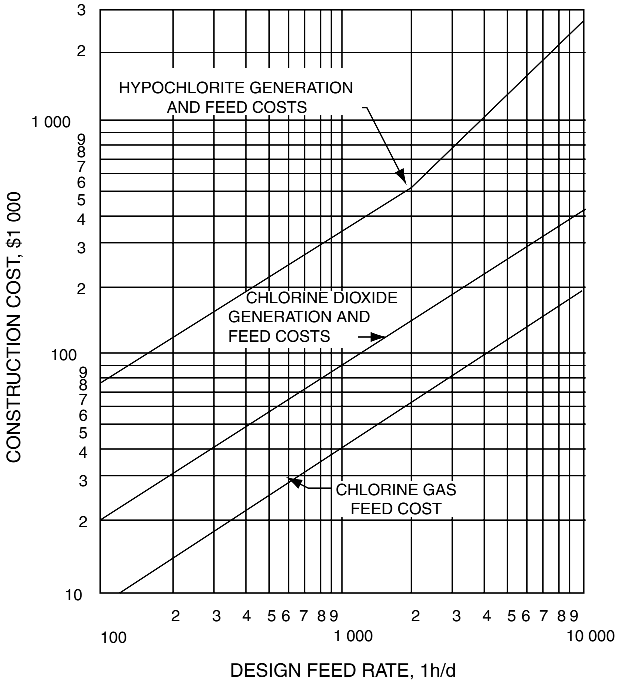

FIGURE 15 Chlorine disinfection feed facilities cost curves: ENR = 2,000.

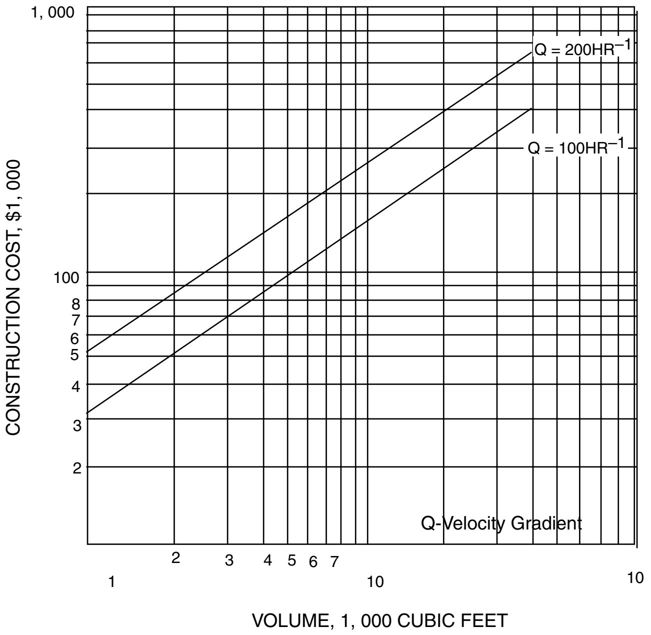

FIGURE 16 High-intensity mixing/chlorine contact basin cost: ENR = 5,000 (EPA-600/2–76–286).

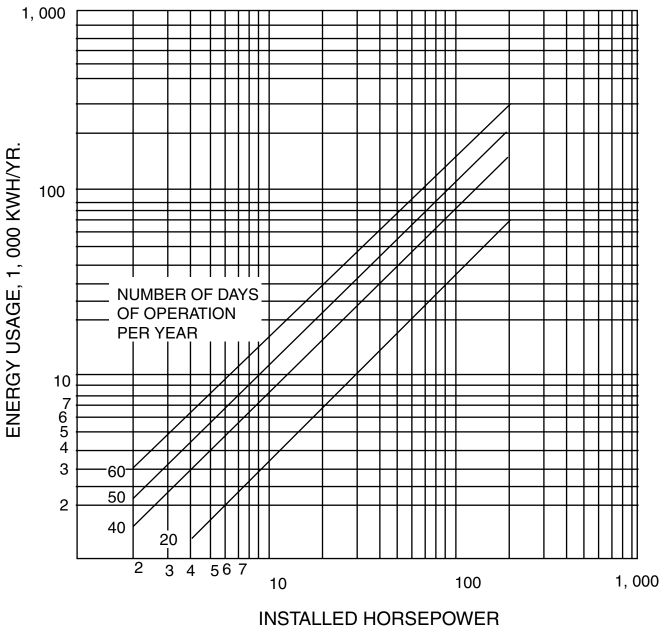

FIGURE 17 High-intensity mixing (chlorine contact) power requirements.

equivalent disinfection was obtained using either 3.8 mg/l of ozone or 5 mg/l of chlorine.

Because of the characteristic intermittent operation associated with treatment of CSO, reduction of construction cost with a potential increase in operating costs often results in overall minimum costs. In the case of chlorination facilities, as applied to treatment of CSO, the construction costs associated with contact basins having conventional contact time of 15–30 min are high and difficult to justify. Therefore, consideration should be given to higher mixing intensities, to make better usage of the chlorine and/or higher chlorine dosages and smaller, shorter detention-time contact basins to effect the same end results. Disinfectant costs for CSO treatment are higher than those for sewage treatment. This is the result of smaller total annual disinfectant volume requirements, increased disinfectant concentration requirements, and higher unit O&M costs for CSO treatment facilities. These costs could be reduced by using the facilities in conjunction with dry-weather flow treatment plants, whenever possible. Curves comparing generation and feed costs for chlorine gas, chlorine dioxide, and hypochlorite generation disinfection systems for CSO have been developed and are presented in Figure 15. These costs include manufactured equipment, labor, piping, housing, electrical and instrumentation, and miscellaneous items; no allowance for land was included. Capital and operating costs for several CSO and stormwater disinfection facilities are presented in Table 38.

As previously mentioned, conventionally long contact times may not be economical. Short-term contact times with more intense mixing, using a basin and mixer similar to those used in coagulant mixing, can effect the same disinfection results. Construction cost curves for high-intensity mixing/chlorine contact basins are presented in Figure 16. Power requirement curves, for high-intensity mixing, are presented in Figure 17.

The capital costs for different disinfection agents and methods resulting from the Philadelphia study are shown in Table 39. The capital costs for ozone generation are usually the highest of the most commonly used processes. Ozone operation costs are very dependent on the cost of electricity and the source of the ozone (air or pure oxygen).

V

VAPOR AND GASEOUS POLLUTANT FUNDAMENTALS

The toxic gases produced during combustion and other chemical processes may be removed by destructive disposal, dispersive dilution or as recoverable side products. The removal path chosen is at the present time motivated primarily by economics, but public pressure and awareness of environmental problems also influence the choice.

This section will concern itself with destructive disposal and/or various recovery processes, the subject of dispersion being ably handled in the sections on *Air Pollution Meteorology and Urban Air Pollution Modeling.* The main emphasis will be on principles of gaseous reaction and removal with the description of equipment for air pollution abatement covered by pollutant. Problems specifically concerned with the automobile can be found under *Mobile Source Pollution.* Although the control principles to be described below are general, it is usually necessary to design equipment for each installation because of variations in physical and chemical properties of effluents; also, in general, the cost of adding pollution devices to an existing unit (retrofit) will be higher than if they were placed in the original design, because of construction difficulty and downtime.

Although the majority of effluent material from combustion occurs in the gaseous state, it is important to characterize the total effluent stream for control purposes. For example, the effluent may be condensible at operating temperature (a vapour) or noncondensible (a gas), but it usually is a mixture of the two. Particulate matter (solids) and mists (liquids) are often suspended in the gaseous stream; if the particles do not separate upon settling they are called aerosols. The considerations in this section deal with gas or vapor removal only and not with liquid or solid particle removal.

SULFUR DIOXIDE, SO_2, AND TRIOXIDE, SO_3

Sulfur dioxide is generated during combustion of any sulfur-containing fuel and is emitted by industrial processes that use sulfuric acid or consume sulfur-containing raw material. The major industrial sources of SO_2 are sulfuric acid plants, smelting of metallic ores, paper mills, and refining of oil. Fuel combustion accounts for roughly 75% of the total SO_2 emitted. Associated with utility growth is the continued long term increase in utility coal consumption from some 650 million tons/year in 1975 to between 1400 and 1800 million tons/year in 1990. Also the utility industry is increasingly converting to coal. Under the current performance standards for power plants, national SO_2 emissions are projected to increase approximately 15 to 16% between 1975 and 1990 (Anon. 1978). The SO_2 emitted from power plants is usually at low concentration ($<0.5\%$ by volume). However, a 900 MW unit will emit over 13,000 pounds of SO_2 per hour for a 1% sulfur coal. The SO_2 emitted from industrial processes is at higher concentrations and lower flow rates. The emitted SO_2 combines readily with mists and aerosols, thus compounding the removal problem.

Information concerning emissions standards is essential to pollution control engineering design. The current US federal SO_2 emissions limits for a stack are 1.2 lb/10^6 BTU for new oil and gas fired plants. Also, uncontrolled SO_2 emissions from new plants firing solid, liquid, and gaseous fuels are required to be reduced by 85%. The percent reduction requirement does not apply if SO_2 emissions into the atmosphere are less than 0.2 lb/10^6 BTU.

Flue gas desulfurization (FGD) methods are categorized as nonregenerable and regenerable. Nonregenerable processes produce a sludge that consists of fly ash, water, calcium sulfate and calcium sulfite. In regenerable processes, SO_2 is recovered and converted into marketable by-products such as elemental sulfur, sulfuric acid or concentrated SO_2. The sorbent is regenerated and recycled. The US Environmental Protection Agency believes the following types of FGD systems are capable of achieving the emissions limit standards: lime, limestone, Wellman-Lord, magnesium oxide and double alkali. Due to the process economics, utility industry prefer the lime/limestone systems. Limestone processes constitute about 58% of the current calcium-based capacity in service and under construction, and 69% of that planned, which amounts to 63% of the total (De Vitt *et al.*, 1980). The following reactions take place in the limestone systems:

$$\begin{aligned}
&\mathrm{CaCO_3(s)} \rightleftharpoons \mathrm{CaCO_3(aq)}\\
&2\,\mathrm{CaCO_3(aq)} + 2\mathrm{H^+} \rightleftharpoons \mathrm{CaCHCO_3} + \mathrm{Ca^{+2}}\\
&\mathrm{SO_2(g)} \rightleftharpoons \mathrm{SO_2(aq)}\\
&\mathrm{SO_2(aq)} + \mathrm{H_2O} \rightarrow \mathrm{H_2SO_3} \rightleftharpoons \mathrm{HSO_3^-} + \mathrm{H^+}\\
&\mathrm{HSO_3^-} + \tfrac{1}{2}\mathrm{O_2(aq)} \rightarrow \mathrm{SO_4^{-2}} + \mathrm{H^+}\\
&\mathrm{Ca^{+2}} + \mathrm{SO_4^{-2}} \rightleftharpoons \mathrm{CaSO_4(aq)} \rightarrow \mathrm{CaSO_4(s)} \downarrow
\end{aligned}$$

Or

$$\begin{aligned}
&\mathrm{Ca^{+2}} + 2\mathrm{Cl^-} \rightleftharpoons \mathrm{CaCl_2(aq)} \rightarrow \mathrm{CaCl_2(s)} \downarrow\\
&2\mathrm{H^+} + \mathrm{SO_4^{-2}} \rightleftharpoons \mathrm{H_2SO_4}\\
&\mathrm{H^+} + \mathrm{Cl^-} \rightleftharpoons \mathrm{HCl}\\
&\mathrm{Ca(HCO_3)_2} + 2\mathrm{H^+} \rightleftharpoons \mathrm{Ca^{+2}} + 2\mathrm{H_2CO_3}\\
&\mathrm{H_2CO_3} \rightleftharpoons \mathrm{CO_2} + \mathrm{H_2O}
\end{aligned}$$

The dissolution rate of limestone depends on the pH values. The pH values encountered in practical operations of limestone systems is in most cases between 5.5 and 6.5. If the limestone systems operate at too low pH, SO_2 removal efficiency will decrease. At too high pH, the scale formation will be promoted. Other factors affecting the performance of limestone systems include solids content, liquid-gas ratio, and corrosion. A discussion can be found elsewhere (De Vitt *et al.*, 1980).

In selecting the FGD processes, the following should be considered:

1) process type: wet or dry, regenerable or non-regenerable.
2) chemical reagent used.
3) end-product produced: saleable product or disposable waste.

The reagent, end product, principle of operation, and SO_2 removal efficiency of major FGD processes are shown in Table 1 (Princiotta, 1978). For details of SO_2 removal refer to the *Stack gas cleaning* sections.

Sulfur dioxide reacts slowly with a large excess of oxygen in the presence of sunlight to form trioxide. Gerhard (1956) showed that the process occurs with O_2 at a rate of 0.1–0.2% per hour and Cadle (1956) with ozone, O_3, at <0.1% per day. Niepenburg (1966) illustrates the effects of oxygen in the waste gas during combustion of oil.

The conversion of SO_2 to SO_3 is believed to be possible at realistic rates because of the presence, on diverse surfaces, of Fe_2O_3 which acts as a catalyst. The SO_3 has a short lifetime since it readily combines with water vapor in the atmosphere to form sulfuric acid.

Oxides of Nitrogen, NO_x

NO_x is produced in all combustions which take place using air as an oxygen supply and in those chemical industries employing nitric acid. More than 55% of the total NO_x emissions of 20 million tons originate from stationary sources as shown in Figure 1, and 93% of all stationary source NO_x emissions are from combustion of fossil fuels for utilities. Direct industry-related emissions account for only 5% of the stationary source total. Approximately 30% of all stationary source NO_x is emitted by coal-fired utility boilers. Uncontrolled NO_x emissions from coal-fired sources have been measured in the range 0.53 to 2.04 lb/10^6 BTU at full load (Ziegler and Meyer, 1979). The NO_x formed in combustion is from fixation of atmospheric nitrogen and/or fuel nitrogen. Ermenc (1956) found that at high temperature nitrogen and oxygen combine to form both NO and NO_2. The yield of NO increases from 0.26% at 2800°F to 1.75% at 3800°F. If the temperature is reduced slowly the reverse reaction will take place, but if the products are quenched by rapid heat exchange, the reverse reaction rate becomes small and the oxides remain in the exhaust stream. The oxide NO can usually be oxidized to form NO_2 according to:

$$2\mathrm{NO} + \mathrm{O_2} \rightarrow 2\mathrm{NO_2}.$$

Because this is a tri-molecular gas phase reaction, the concentration of NO and NO_2 tremendously affects the rate at which the oxidation takes place. At low concentration, for example 1–5 ppm in air, the reaction is so slow that it would be negligible except for the photochemical reactions which take place in the presence of sunlight. The dioxide also reacts with oxygen to form ozone. The existence of nitrogen trioxide at low concentration in polluted atmospheres is postulated (Hanst, 1971) to form by the reaction with ozone.

$$\mathrm{NO_2} + \mathrm{O_3} \rightleftharpoons \mathrm{NO_3} + \mathrm{O_2}$$

and remain in equilibrium with N_2O_5

$$\mathrm{N_2O_5} \rightleftharpoons \mathrm{NO_2} + \mathrm{NO_3}.$$

The NO_3 formation reaction only takes place after NO is substantially depleted in the atmosphere and O_3 begins to appear. Without more stringent control of new sources, the NO_x emissions by 1995 are projected to be 66% higher than than in 1985. Even with application of the best control method to all new sources there is still a projected 24% increase over 10 year emissions (McCutchen, 1977). The typical NO_x emission from nitric acid plants is 1000–3000 ppm. The federal standard for new nitric acid plants is 3 lb NO_x/ton 100% HNO_3—that is, about 200 ppm (Ricci, 1977). The most widely used process for nitric acid plant tailgas cleanup is catalytic decomposition of NO_x to nitrogen and oxygen.

The current and projected values of the New Source Performance Standards (NSPS) for NO_x are discussed later in this article. During recent years N_2O formation rates have been the subject of controversy, especially in fuel NO_x mechanisms.

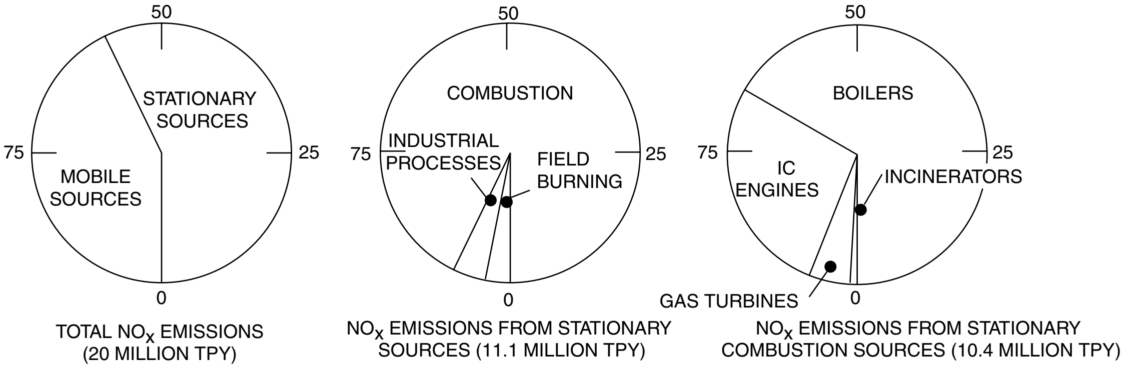

FIGURE 1 Sources of NO_x emissions.

TABLE 1
Status of Commercial FGD Processes (Adapted from Princiotta, 1978)

FGD Process	Reagent	End Product	Principle of Operation	SO_2 Removal Efficiency(%)
Limestone Scrubbing	Limestone (LS)	$CaSO_3/CaSO_4$ Sludge	LS slurry reacts in scrubber absorbing SO_2 and producing insoluble sludge.	80–90
Lime Scrubbing	Lime	$CaSO_3/CaSO_4$ Sludge	Lime slurry reacts in scrubber absorbing SO_2 and producing insoluble sludge.	85–95
Wellman Lord	Sodium carbonate (regenerated)	Sulfuric Acid Sulfur	Soluble sodium sulfite absorbs SO_2 in scrubber, the sodium bisulfite produced is thermally regenerated, yielding sodium sulfite and SO_2 for either acid or S production.	85–95
Double Alkali	Sodium carbonate (regenerated)	$CaSO_3/CaSO_4$ sludge	Soluble sodium sulfite absorb SO_2 in scrubber; the sodium bisulfite produced is reacted with lime precipitating $CaSO_3/CaSO_4$.	85–95
Magnesium Oxide	Magnesium oxide (regenerated)	Sulfuric Acid	Magnesium oxide slurry absorbs SO_2 in scrubber; the magnesium sulfite produced is thermally treated, yielding MgO and SO_2 for acid production.	85–95

Oxides of Carbon

The carbon dioxide, CO_2, concentration threshold for humans is 5% (5000 ppm) for an 8-hour exposure. This compares with a normal atmospheric CO_2 concentration of 0.03% (300 ppm). With a perfect stoichiometric combination of pure carbon in air, a CO_2 concentration of about 21% could be attained. Considering the usual dispersion of combustion gases it would take an unusual isolation to produce a CO_2 health hazard. A more detailed description of CO_2 consequences may be found in the Appendix.

Incomplete combustion of fuels is the more serious problem, since carbon monoxide, CO, will form. This rarely happens in stationary furnaces for which efficiencies of combustion are high and oxygen is available in excess of the theoretical requirements.

It has been estimated (Anon., 1970) that slightly more than 100 million tons of CO are emitted annually in the USA, of which the major sources are automobiles (59%), various open burnings (16%), chemical industry (10%) and other transportation means (5%). New York City, with its acute urban traffic problem, has established a first alert at 15 ppm of CO over

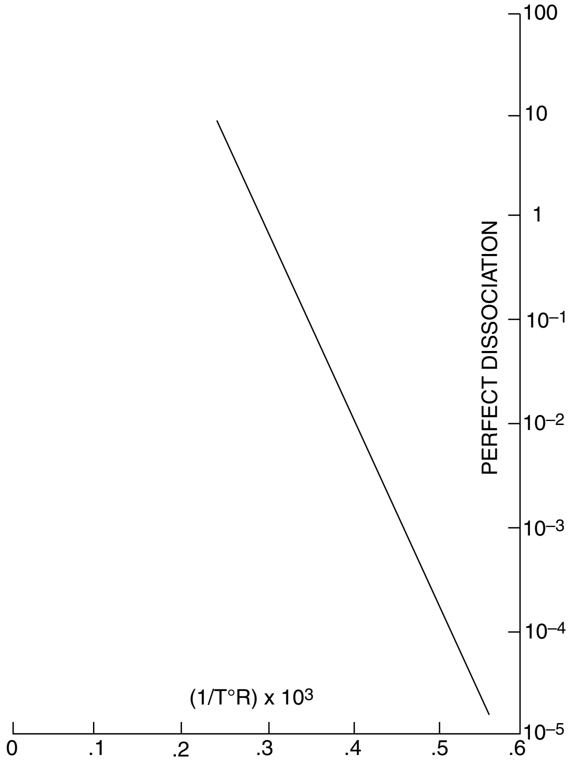

FIGURE 2

at 8-hour period. High temperatures favor the equilibrium dissociation of CO_2 to CO, with the latter being very stable at high temperatures. Thus is a CO_2–CO mixture is quenched from its high temperature zone the percentage CO may remain high, since at lower temperatures longer times are required to reach equilibrium. Rich fuel-air mixtures favor the formation of CO over CO_2. A complete description of CO control methods may be found in the section *Mobile Source Pollution.*

Miscellaneous Gases

Compounds of *fluorine* are known to have negative effects (Fluorisis) at concentrations as low as 5×10^{-3} ppm. They are generated as waste gases of fertilizer aluminum and ceramic processes, but are present to a lesser extent in most flue gases. A concentration of 0.1 ppm (vol.) of fluorine has been set as a maximum permissible value by the American Conference of Governmental Industrial Hygienists; USSR standards are roughly one tenth as stringent.

Ozone, O_3, is one of the strongest gaseous oxidants and is formed naturally from oxygen during electrical discharges in the atmosphere and at the high temperatures of combustion.

$$O_2 \rightarrow 2O$$
$$O_2 + O\cdot \rightarrow O_3$$

Taken as oxidants, New York City classified an ozone level above 0.03 ppm as unsatisfactory and above 0.07 ppm as unhealthy over a 6 hour period. Eye irritation commences at concentrations of about 0.1 ppm. Interestingly enough ozone in the lower stratosphere affords part of the protective shield against ultraviolet radiation from the sun, which could destroy land vegetation.

$$O_3 \rightarrow O_2 + O\cdot$$

Some scientists are concerned that nitric oxide formed by supersonic jets may deplete the ozone supply in the lower stratosphere, eroding the barrier to the destructive rays.

High temperature processes involving metal recovery from ores emit *mercury* vapor in addition to sulfur dioxide. Mercury is available at concentrations up to a few hundred ppm (Kangas *et al.,* 1971) during zinc sulfide ore processing for example. *Hydrochloric* and hydrofluoric acids also appear in the roaster gases of such processes. No danger levels for mercury vapor have been officially established in ambient air quality standards.

A few limits have been established for less common pollutants of the process industries in USSR standards given below.

The US ambient air quality standards call for *hydrocarbon* concentrations below 160 mg/m³ (0.24 ppm) between 6–9 am.

Aldehydes and other *oxygenated hydrocarbons* are formed by the action of ozone on unburned hydrocarbons in the presence of sunlight. For example,

$$O_3 + \text{1-3 Butadiene} \rightarrow \text{A crolein} + \text{Formaldehyde.}$$

In the above reaction both products have been linked to the severe eye irritation encountered in urban environments.

TRANSPORT OF POLLUTANTS

The feed and waste materials of any combustion or chemical process travel through ducts or pipes. Control devices may be placed at various stages of the process, depending on the separation technique to be employed. It will be valuable to review the flow and transport behavior for fluids and then the separation methods. The important process variables to be considered are the mass flow rate of the waste gas, its temperature, pressure and composition. The raw material feed rate variables may also be of significance, as in the desulfurization of fuel oil. Control devices may broadly be classified according to the physical separation process being used, adsorption: absorption: extraction: distillation: or to the chemical process, homogenous or heterogeneous catalytic reaction. In each instance, equations which account for the transport of material and energy must be developed.

In a sense almost any process may be considered as taking place in a pipeline. The simplest model of flow is called plug flow and assumes that no mixing takes place along the axis of the pipeline, but that lateral mixing is complete. Also, this assumes a flat velocity profile exists at each

TABLE 2
Properties of Selected Gaseous Pollutants

					Solubility, CC per 100 GMS		
Name	Formula	Molec WT	Sense Properties	Boiling Pt, °C	Cold H_2O	Warm H_2O	Other
Ammonia	NH_3	17.03	Colorless Pungent	−33.4	Very soluble	> 1000 (99°)	—
Carbon monoxide	CO	28.01	Colorless Odorless	−192	3.5 (0°)	2.32 (20°)	Alcohol, Cu_2Cl_2
Chlorine	Cl_2	70.91	Gn-yellow Pungent	−34.6	310 (10°)	177 (30°)	Aq. NaOH or KOH
Fluorine	F_2	38.00	Gn-yellow	−187	decomposes	—	—
Hydrochloric acid	HCl	36.47	Colorless	−85	very soluble	> 1000 (99°)	Alcohol, Ethylether
Hydrafluoric acid	HF	20.01	Colorless	19.4	very soluble	> 1000 (99°)	—
Hydrogen sulfide	H_2S	34.08	Colorless Decay odor	−59.6	437 (0°)	186 (40°)	Alcohol, CS_2
Mercury	Hg	200.61	—	356.9	—	—	—
Nitric oxide	NO	30.01	Colorless	−151	7.34 (0°)	0 (100°)	Alcohol, H_2SO_4
Nitrogen dioxide	NO_2	46.01	Red-brown	21.3	decomposes	—	HNO_3, H_2SO_4, CS_2
Ozone	O_3	48.00	Faint blue	−112	0.494 (0°)	0 (50°)	Oil turp., oil cinn.
Sulfur dioxide	SO_2	64.07	Colorless Choking	−10	8000 (9°)	1600 (50°)	H_2SO_4, alcohol, acetic acid
Sulfur trioxide	SO_3	80.66	Colorless	44.6	decomposes	—	H_2SO_4

longitudinal position, or that the average velocity is the same at each lateral position.

Continuity

If the density, κ, of the fluid at a distance along the pipe, *Z*, of cross section, *S*, changes, the velocity must also change as seen by an elemental mass balance across *d Z* distance, i.e. setting the mass accumulation rate equal to the sum of net input and generation rates (see Figure 3).

$$\frac{\partial \varrho}{\partial t} = \frac{1}{S}\frac{\partial(\varrho v S)}{\partial Z}. \tag{1}$$

For steady state results, $\varrho v S$ = const. = W_o and the mass flow rate becomes the same at all axial positions. If the fluid is incompressible, ϱ= const., as for most liquids, *vS*, the volumetric flow rate, does not vary with position even during transient conditions.

Motion

In a comparable manner an elemental momentum (force) balance may be made over length *dZ*, which for incompressible flow reduces to

$$\frac{\partial v}{\partial t} = \frac{1}{2}\frac{\partial v^2}{\partial Z} - \frac{g_c}{\varrho}\frac{\partial p}{\partial Z} - \frac{g_c(F+F_w)}{\varrho S_o} + g_z. \tag{2}$$

TABLE 3

	Daily		Instantaneous	
	mg/m³	ppm/wt	mg/m³	ppm/wt
Cl_2	0.03	(0.024)	0.10	(0.081)
H_2S	0.01	(0.0081)	0.03	(0.024)
CS_2	0.15	(0.122)	0.50	(0.406)
P_2O_5	0.05	(0.049)	0.15	(0.122)
Phenol	0.10	(0.081)	0.30	(0.24)

For both steady and incompressible flow

$$\frac{dp}{dZ} = \left[\frac{F}{S_o} - \frac{\varrho g_z}{g_c}\right] - const. \tag{3}$$

The equation describes the relation between velocity and pressure along the pipe. The quantities *F* and F_w are the magnitudes of skin frictional force and force doing work on external surfaces, respectively, both per unit length of pipe.

ENERGY

The First Law of Thermodynamics may be written for the differential element of length, *dz*, at steady state

$$\frac{dH}{dz} + \frac{g}{g_c} + \frac{v}{g_c}\frac{dv}{dz} = \delta Q - \delta W_s. \tag{4}$$

For unsteady behaviour where temperature gradients are desired the equation of thermal energy may be applied assuming a uniform temperature at any cross-section and no axial conduction.

$$\varrho c_v \frac{\partial T}{\partial t} = -T\left(\frac{\partial p}{\partial T}\right)_{\&}\left(\frac{\partial v}{\partial z}\right) + \delta q - \delta w_s - \frac{\partial(\varrho_v v T)}{\partial z} \tag{5}$$

in which *q* and w_s are the volumetric thermal energy input rate (produced for example by an electrical or chemical phenomenon) and the work output rate, respectively. For a constant density fluid equation (5), the left hand side represents the accumulation of internal energy, and the right hand terms represent the influence of pressure on the energy transport rate, the combined energy input rate per unit volume by generation and forces and the net energy input rate by flow (force convection), respectively.

Component Balance

The equations of continuity, motion and energy often may be applied to describe the situation in stacks of power plants, in the flow of fuels and effluents, and in the analysis of material, momentum and energy requirements of a

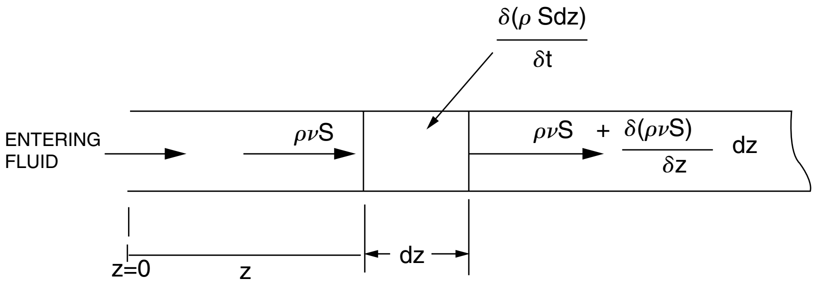

FIGURE 3

pollution producing process. To analyze the concentrations of pollutant it still remains to make component material balances of $n - 1$ species within the system (for which n components exist). For separation processes an additional phase equation is usually required for transfer of pollutants between the rich and lean phases.

The mass balance on a particular species may be found for component A by examining the imaginary stationary differential element of thickness dz. Assuming plug flow we may derive an expression for c_A:

$$\begin{array}{ccccc} \text{Accum.} & = & \text{Net Input} & + & \text{Generation} \\ \text{rate of } A & & \text{rate of } A & & \text{rate of } A \end{array} \tag{6}$$

c_A—*molar concentration*
F_a—*flux of* A at position Z, moles A flowing/(time) (cs. area) $= vc_A$
R_A—production rate of component A, by chemical or nuclear reaction, moles A formed/(time) (vol.)
v—average fluid velocity.

Also, r_A is usually some empirical function of c_A such as kc_A^n for an irreversible decomposition reaction of nth order.

Gas Adsorption

Adsorption is the process by which a solid surface attracts fluid phase molecules and forms a chemical or physical bond with them. The mechanism of adsorption includes:

1) diffusion of the pollutant from bulk gas to the external surface of the particles,
2) migration of the adsorbate molecules from the external surface of the absorbent to the surface of the pores within each particle,
3) adsorption of the pollutant to active sites on the pore.

The attraction for a specific gas phase component will depend on properties such as the concentration of the gas phase component, the total surface area of absorbent, the temperature, polarity of the component and adsorbent, and similar properties of competing gas molecules. Adsorption is used to concentrate (30–50 fold) or store pollutants until they can be recovered or destroyed in the most economical manner. Adsorption is an exothermic process. The heat of adsorption for chemical adsorption is higher than that for physical adsorption. In the former, if the amount of pollutants to be removed large, it is necessary to remove the heat of adsorption, since the concentration of adsorbed gas decreases with increasing temperature at a given equilibrium pressure. For chemical adsorption, properties which affect reaction kinetics will also come into play (see section on Gas Reaction).

Activated carbon, silicon, aluminum oxides, and molecular sieves make up the majority of commercially significant adsorbents. Activated carbon is the least affected by humidity and physically adsorbs nonpolar compounds since it has no great electrical charge itself. The adsorption rate of activated carbon can be increased with chemical impregnation. For instance, activated carbon impregnated with oxides of copper and chromium are found very useful to remove the hydrogen sulfide in gas streams where oxygen is not present (Lovett and Cunniff, 1974). Alumina and silica materials preferentially adsorb polar compounds. Molecular sieves have greater capture efficiencies than activated carbons but they often have a lower retention efficiency and are considerably more expensive.

The ease of adsorbent regeneration depends on the magnitude of the force holding the pollutants on the surface of adsorbent. The usual methods for the adsorbent regeneration include stripping (steam or hot inert gas), thermal desorption, vacuum desorption, thermal swing cycle, pressure swing cycle, purge gas stripping, and in situ oxidation.

In many respects the equilibrium adsorption characteristics of a gas or vapor upon a solid resemble the equilibrium solubility of a gas in a liquid. For simple systems, a single curve can be drawn of the solute concentration in the solid phase as a function of solute concentration or partial pressure in the fluid phase. Each such curve usually holds at only one specific temperature, and hence is known as an isotherm. Five types of commonly recognized isotherms are shown by the curves in Figure 4. There are three commonly used mathematical expressions to describe vapor or gas adsorption equilibrium: the Langmuir, the Brunauer-Emmett-Teller (BET), and the Freundlich isotherm. The Langmuir isotherm applies to adsorption on completely homogeneous surfaces, with negligible interaction between adsorbed molecules. It might be surmised that these limitations correspond to a constant heat of adsorption. The Freundlich isotherm can be derived by assuming a logarithmic decrease in heat of adsorption with fraction of coverage. Gas adsorption is an unsteady state process. The curve of effluent concentration as a function of time is commonly referred to as the break-through curve. It usually has an S shape. The break-through curve may be steep or relatively flat, depending on the rate of adsorption, the adsorption isotherm, the fluid velocity, the inlet concentration, and the column length. The time at which the break-through curve first begins to rise appreciably is called breakpoint.

The design of an adsorption column requires prediction of the breakthrough curve, and thus the length of the adsorption cycle between elutions of the beds, given a bed of certain length and equilibrium data. Because of the different forms of equilibrium relationship encountered, and the unsteady nature of the process, prediction of the solute break-through curve can be quite difficult. At present, detailed design of adsorption columns is still highly dependent on pilot scale evaluations of simulated or real systems.

Before discussing the method of predicting the breakthrough curves, one should consider the isotherm. For Langmuir isotherm (Langmuir, 1917), if it is assumed that A_I reacts with an unoccupied site X_0 to form adsorbed component X_1,

$$A_I + X_0 \underset{k-1}{\overset{k_1}{\rightleftharpoons}} X_1 \tag{7}$$

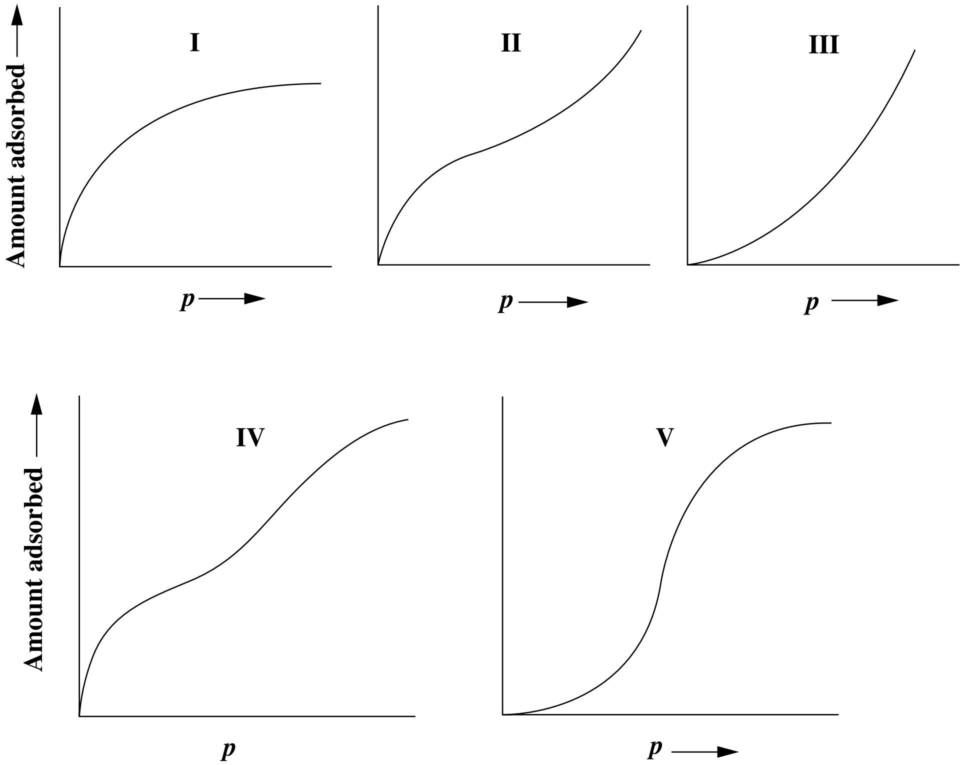

FIGURE 4 Types of adsorption isotherms.

the equilibrium adsorption concentration, C, is obtained in terms of the gas phase concentration C_1 and the total adsorption site concentration, C_0

$$\frac{C}{C_0} = \frac{K_1C_1}{1 + K_1C_1}. \tag{8}$$

Here, K_1 is the adsorption equilibrium constant which varies only if temperature varies.

Diatomic molecules such as chlorine might be expected to simultaneously adsorb and dissociate on adjacent sites. Such an adsorption might be described symbolically by

$$A_1 + 2X_0 \overset{k_1}{\underset{k-1}{\square}} 2X_1$$

in which case the equilibrium isotherm expression can readily be shown to be

$$\frac{C}{C_0} = \frac{(K_1C_1)^{1/2}}{1 + (K_1C_1)^{1/2}}. \tag{9}$$

If more than one pollutant is being adsorbed, each component, A_j, undergoes

$$A_j + X_0 \square \; X_j.$$

The equilibrium for single site adsorption of component A_j becomes

$$\frac{C}{C_0} = \frac{K_1C_1}{1 + \sum_{j=1}^{n} K_jC_j}. \tag{10}$$

The latter may be referred to as competitive adsorption. Figure 5 depicts the different dependence on gas phase concentration for the adsorption types described thus far.

Another isotherm finding wide use, particularly in multilayer adsorption, is that of Brunauer, Emmett and Teller (1938), the BET equation

$$\frac{C_s}{C_{\max}} = \frac{Q_2X}{(1 - X)[1 + (Q_2 - 1)X]} \tag{11}$$

in which:

C_s, $C_{\max}$—amount of gas absorbed per gm. of solid, and maximum amount, respectively

Q_2—term exponentially dependent on heat of adsorption

X—ratio of equilibrium gas phase concentration of saturation Value.

If neither the Langmuir or BET equations are satisfactory, a plynomial fit to adsorption data may be required.

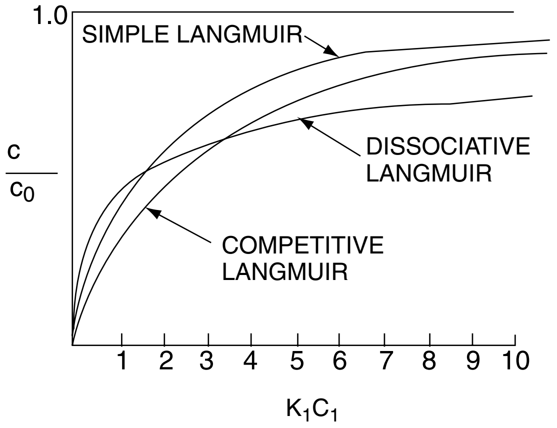

FIGURE 5

For adsorption the particles are usually dumped into a column as a packed bed (Figure 6). In commercial adsorption columns, equilibrium concentrations are not attained uniformly, but for convenience the rate of adsorption is assumed to be proportional to *C*. See below under Reaction.

The time t_3 in which breakthrough (C_{ig} at the exit equals the permissible set amount) occurs may be established by analyzing the differential component mass balance assuming that the transport of material again is governed by diffusion through a film

$$N_i = k_g(C_{ig} - C^*_{ig}) \tag{12}$$

in which C^*_{ig} is the gas phase concentration in equilibrium with the absorbed concentration C_{is} at the same elevation.

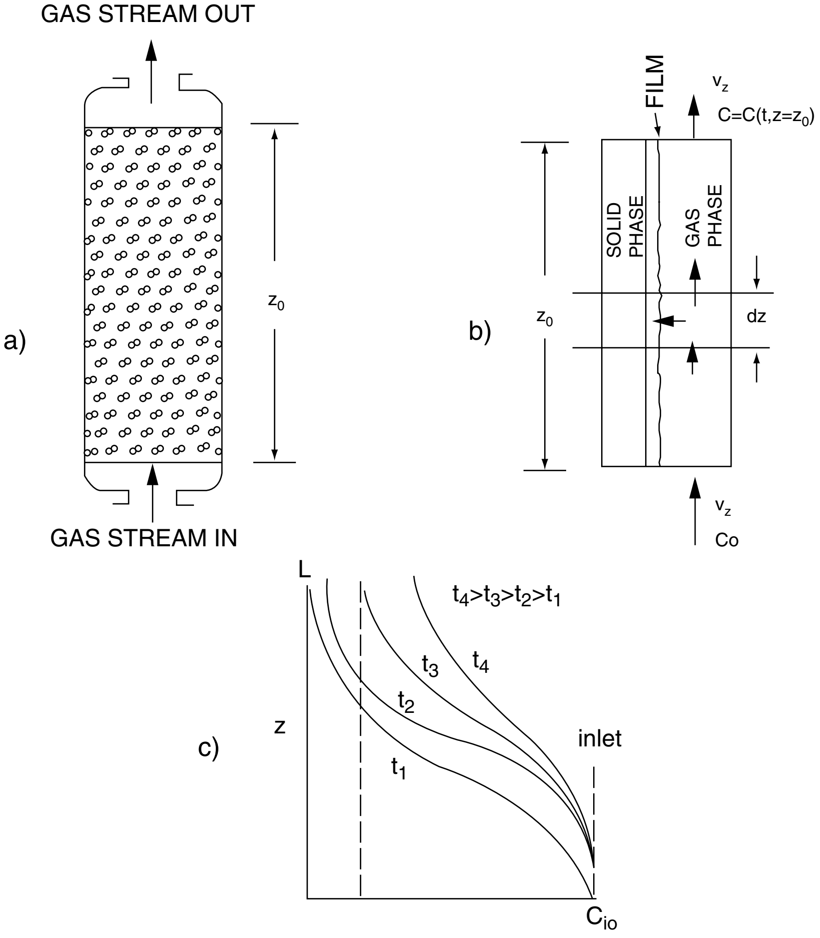

FIGURE 6 (a) Pictorial representation. (b) Schematic model showing a differential element over which a mass balance is made. (c) Pollutant concentration as a function of time at various heights.

The equilibrium concentrations have been determined for most commercially available adsorbents and typical pollutants and are presented as either Langmuir or BET isotherms. In general such equations take the form

$$C_{is} = f(C_{ig}^*) \tag{13}$$

The generation term is excluded, as it is assumed that chemical reaction is not taking place in the system. To develop an expression for the net rate of accumulation of the mass of A_i in the column, that is, the rate expression for the adsorption process, one also needs the function of the concentration of A_i in the fluid phase.

Considering a differential column segment and writing the continuity relationship for pollutant A_i in each phase for this differential section, one gets for the solid phase in this section.

$$\frac{1}{M_a} P_s(1-\varepsilon)\left(\frac{\partial C_{is}}{\partial t}\right) = k_g(C_i - C^*) \tag{14}$$

where:

k_g: is the gas phase mass transfer coefficient in units of (time – 1).

M_a: is the molecular weight of A_1.

P_s: is the averaged density of the solids.

ε: is the fractional voidage in the bed.

For the gas phase in this differential segment,

$$\varepsilon\frac{\partial C_{if}}{\partial t} = -V\frac{\partial C_{if}}{\partial z} - k_g(C_i - C_g^*) \tag{15}$$

where:

V_z: is the superficial velocity of the fluid.

These partial differential equations (13)–(15) may be solved simultaneously by numerical analysis using difference formulas to approximate the partial derivatives. In such a way the breakthrough curves of hazardous organic vapors may be predicted for a given adsorbent.

Smoothed computerized results were plotted on Figure 7 for five different compounds having Langmuir type behavior on activated carbon under the same hypothetical operating conditions. If one wishes to attain a 90% removal of certain organic vapor, one could easily see from Figure 7 that diethyl ether requires the shortest re-cycle time and methyl isobutyl ketone the longest among the five materials on the graph.

Properties of Adsorbents

Figures 8 and 9 are adsorption isotherms for activated carbon with nitrous oxide and carbon dioxide respectively. A more sophisticated correlation of adsorption data is presented in Figures 10–12 for pure CO, C_2H_4 and CO_2 gases. Here $(RT/V_s)\ln f_s/f_g$ is plotted versus N_s (in which:—gas constant, T—temperature, °K, V_s—molar volume of adsorbate, cc/mole, f_s and f_g—fugacites of adsorbate and gas and N—amount of gas adsorbed, g—moles/gm. adsorbent. Hydrocarbons and SO_3 adsorb readily on activated carbon. SO_2 has a maximum retention of 10 wt.% on carbon at 20°C, 760 torr. Ozone decomposes to oxygen on carbon (Ray and Box, 1950).

Figure 13 has comparable results plotted for CO_2 adsorption on silica gel. Activated carbon has significantly better equilibrium properties than does silica gel (vis Figure 9 vs. Figure 13).

Other results for activated carbon and zeolites may be found in the book by Strauss (1968). Basic facts about adsorption properties of activated charcoal, system types and components and applications are discussed by Lee (1970). He tabulated data on the air purification applications for inexpensive, nonregenerative, thin bed adsorbers and for regenerative systems, and discusses the design of a solvent vapor recovery system.

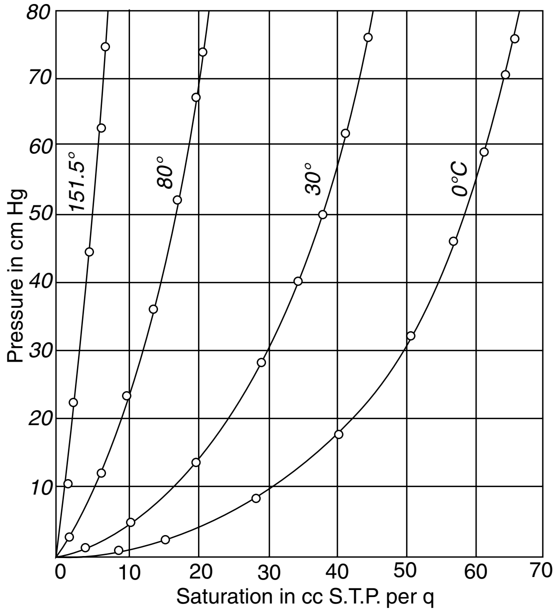

FIGURE 9 Absorption isotherms for the system CO_2-carbon (note that $t_c = 31°C$).

"Activated carbon filters were used to concentrate atmospheric mixtures of acrolein, methyl sulfide, and *n*-propyl mercaptan. Removal efficiency and carbon capacity for each of the odor compounds were investigated using two different carbones, Cliffchar (4–10 mesh) and Barnebey–Cheney (C-4). A closed system was devised to establish a known atmospheric odor concentration for each filter run. Solvent extraction techniques were employed to desorb and recover the odor compounds from the carbon filters. All quantitative analyses were conducted with gas liquid chromatography utilizing the hydrogen flame ionization detector. The removal studies conducted indicate that the efficiency of removal of a carbon filter is essentially 100% up to the point of filter breakthrough. This breakthrough point is governed by the filter's capacity for a particular compound. This study indicated that the filter capacity is dependent both on the type of carbon employed and the particular odor compound adsorbed. Solvent recovery of the odor compounds from the carbons varied from 0 to 4.5% for the mercaptan up to 96 to 98% for acrolein. Per cent recovery was found to vary for a given odor compound with different carbons and for a given carbon with different odor pollutants." (Brooman and Edgerley, 1966.)

Gas Absorption

Adsorption is a diffusional process that involves the transfer of molecules from the gas phase to the liquid phase because of the contaminant concentration gradient between the two phases. Adsorption of any species occurs either at the surface of the liquid film surrounding the packing or at the bubble surface when the gas is the dispersed phase. When a gas containing soluble components is brought into contact with a liquid phase an exchange of the soluble components will occur until equilibrium in a batch system or steady state in a flow system is attained. Adsorption may involve only a simple physical solubility step or may be followed by chemical reaction for more effective performance. The latter is usually used for flue gas desulfurization and denitrification. Rates of adsorption depend on the solubility of the gas. At equilibrium, for gaseous species of low or moderate solubility, the partial pressure of the component is related to its liquid mole fraction according to Henry's law,

$$p_i = HX_i$$

where H is Henry's constant. Both partial pressures and mole fraction may be related to concentration

$$p_i = C_{ig}RT \text{ and } X_i = C_{il}/C_l.$$

At constant temperature, $C_{ig} = H'C_{il}$, where $H' = H/C_tRT$. If the gas is highly soluble in the liquid, H will be small. The solubility of the gas is affected by the concentration of ions in the solution at the interface. Van Krevelen and Hoftijzer (1948) proposed an empirical equation to correct the effect of concentration of ions on Henry's constant.

The rate of mass transfer is proportional to both the interfacial area and the concentration driving force. The proportional constant is known as the mass transfer coefficient. Because material does not accumulate at the interface (Figure 14) the flux in each phase must be the same. Thus the rate of transfer per unit area is

$$N_i = j_g(C_{ig} - C_{igI}) = h_L(C_{iLI} - C_{iL}).$$

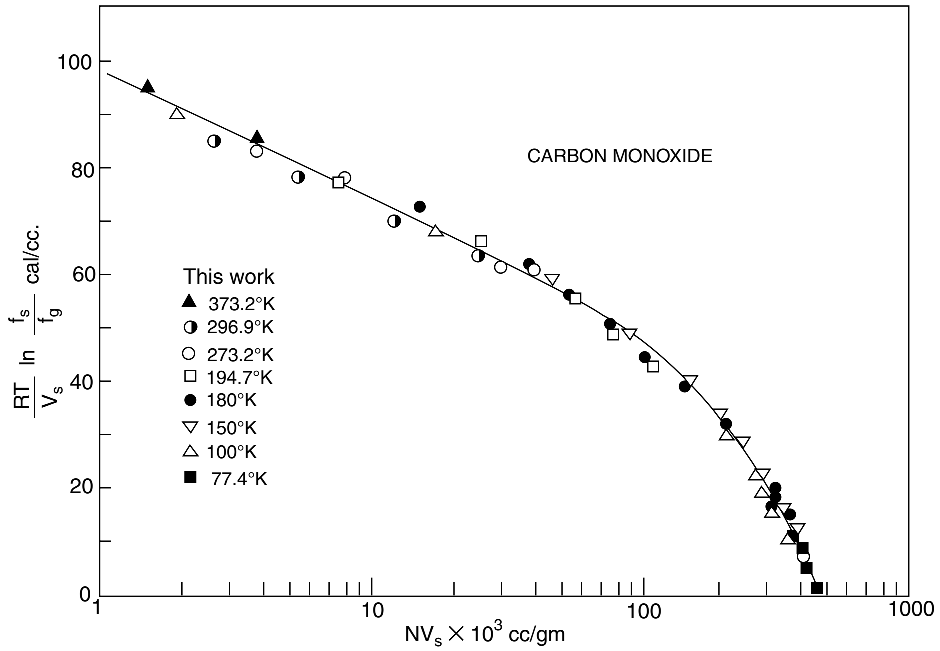

FIGURE 10

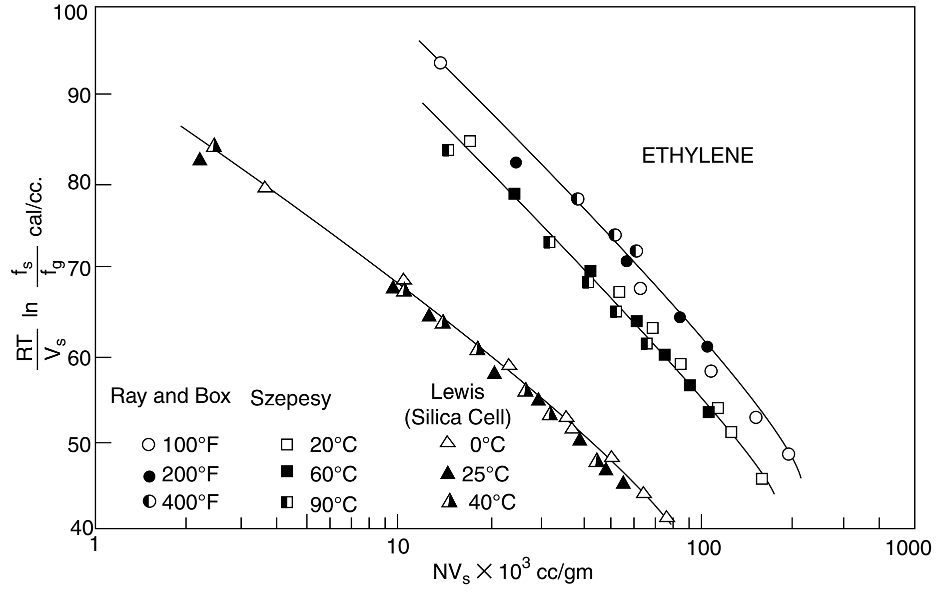

FIGURE 11

In most industrial adsorption processes, the gas is reacted with some substance to form a semistable compound in the liquid phase. This technique permits a great deal more gas to be adsorbed per gallon of liquid circulated, and, in most instances, will increase the mass transfer coefficient. In this situation,

$$\begin{aligned} N_i &= k_g(C_{ig} - C_{igI}) = k_1(C_{iLI} - C_{iL}) \\ &= k_{LE}(C_{iLI} - C_{iL}) \end{aligned}$$

where E = enhancement factor, k_L = mass transfer coefficient in absorption $E = 1$ for physical adsorption. The enhancement factor can be found elsewhere (Astarita, 1967; Danckwert, 1970; Sherwood *et al.*, 1975).

Consider a system whose equilibrium line is straight over the range of compositions which need be considered. The mass transfer rate may be described in forms of pseudo concentration values, thus,

$$N_i = K_g(C_{ig} - C_{ig}^*) = K_L(C_{iL}^* - C_{iL}),$$

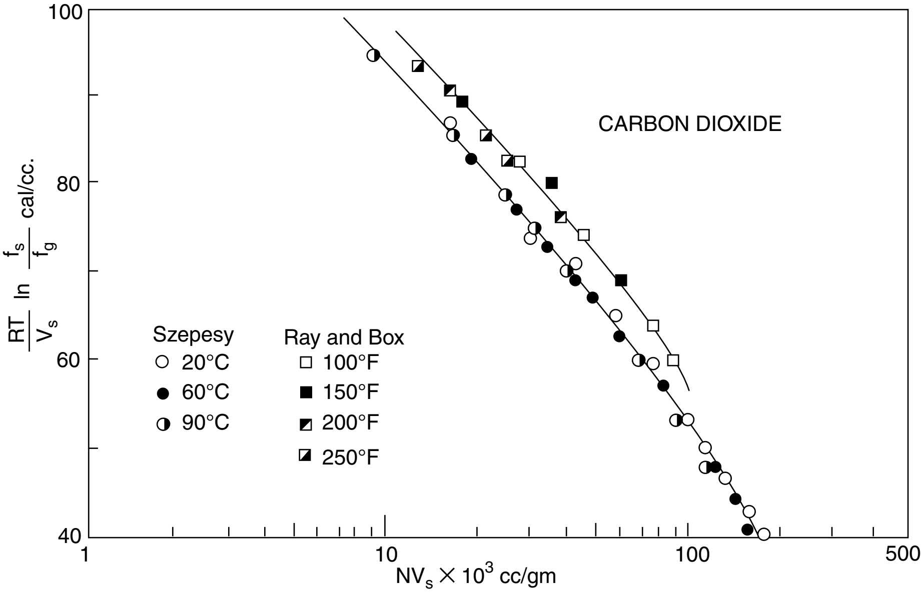

FIGURE 12

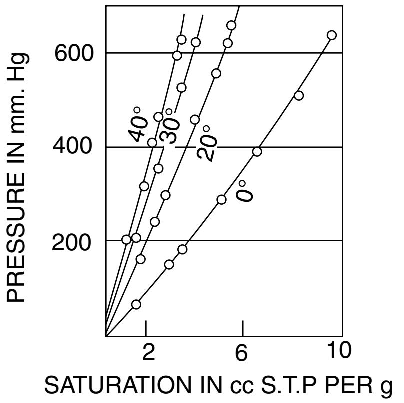

FIGURE 13 Adsorption isotherms for the system CO_2-silica gel (note that $t_c = 31$°C). Patrick, Preston and Owens: *J. Phys. Chem.* **29,** 421 (1925) (Fig. 1).

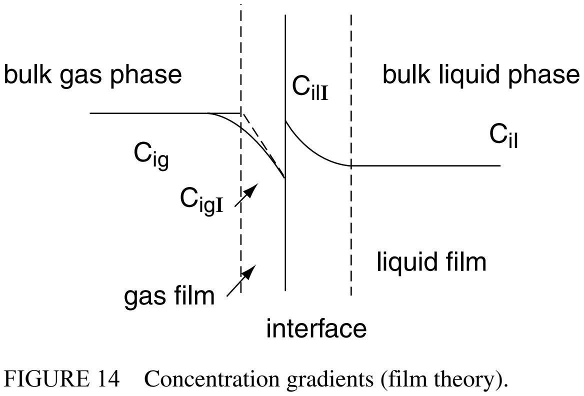

FIGURE 14 Concentration gradients (film theory).

where K_g and K_L are overall mass transfer coefficient in gas and liquid phase, respectively. If concentrations at equilibrium can be represented by Henry's law

$$C_{ig}^* = H'C_{iL},$$

then

$$\begin{aligned} N_i &= k_g(C_{ig} - C_{igI}) = k_L E(C_{iLI} - C_{iL}) \\ &= k_g(C_{ig} - C_{ig}^*) = K_L(C_{ig}^* - C_{iL}), \end{aligned}$$

whence

$$\frac{1}{K_g} = \frac{1}{k_g} + \frac{H'}{Ek_L} = \frac{H'}{K_L}.$$

If the gas is highly soluble in the liquid, H' will be small and $K_g = k_g$. Hence the mass transfer rate is

$$N_i = K_g(C_{ig} - C_{ig}^*)$$

and absorption is said to be gas phase controlled.

In cleaning an effluent stream of low pollutant species concentration physical absorption alone is often insufficient to produce the required removal and a reactant may be added to the absorbing solution to enhance the rate. For example potassium permanganate has been found to be an excellent absorbent for NO (see excellent review by C. Strombald (1988)).

The design of absorbers involves the estimation of column diameter, height, and pressure drop. The column diameter is fixed by the contaminated gas flow rate. The determination of the height of the two-phase contacting zone involves an estimation of the mass transfer coefficients, the alternating use of equilibrium concentration relationship, and the law of mass conservation. For nonisothermal or adiabatic operating conditions, the law of energy conservation needs to be considered. There are many types of equipment and configurations for absorbers or scrubbers. For example, McCarthy (1980) discussed the scrubber types and selection criteria.

For packed towers the interfacial area, *a,* differs from the packing surface area, a_T, because the packing is not always completely wetted. A fraction of the surface may not be active in mass transfer. Also, stagnant pockets will be less effective than flowing streams. The correlation of Onda *et al.* (1968) may be used to estimate the value of interfacial area.

$$\frac{a}{a_1} = 1 - \exp \left\{ -1.45 \left(\frac{\sigma_c}{\sigma} \right)^{.75} \left(\frac{L}{a_1 \mu_L} \right)^{.1} \left(\frac{L^2 a_t}{\rho_L^2 g} \right)^{-.5} \left(\frac{L^2}{\rho_L \sigma a_t} \right)^{-.2} \right\}$$

Where σ_c represents the critical surface tension above which the packing can't be wetted. The values of σ_c for various packing materials are shown in Table 4 (Onda *et al.*, 1967)

L : the superficial liquid mass flow rate

P_L, μ_L : density and viscosity of the liquid, respectively

σ : surface tension of the liquid, dynes/cm.

TABLE 4
Critical surface tension of packing materials

Material	σc dynes/cm
Carbon	56
Ceramic	61
Glass	73
Paraffin	20
Polyethylene	33
Polyvinylchloride	40
Steel	75

This equation correlates results with a maximum error of 20% except in the case of Pall rings where it is conservative. The reason is probably that the interfacial and wetted area are different for Pall rings whose shape forces a fraction of the liquid phase to be dispersed in small droplets that are not accounted for in the values of *a.* Values of a Pall rings are underestimated about 50% according to Charpentier (1976).

The liquid phase mass transfer coefficient can be estimated using Mohunta's equation (1969).

$$k_L a = 25 \times 10^{-4} \left(\frac{g \rho_L}{a_t \mu_L} \right)^{.66} \left(\frac{g^2 \rho_L}{\mu_L} \right)^{.111} \left(\frac{\mu_L \mathrm{L}^3 \mathrm{a}_t^3}{g^2 \rho_L^4} \right)^{.25} \times \left(\frac{\mu_L}{\rho_L D_L} \right)^{-.5}$$

within a range of ±20%.

The range of variables and physical properties of Mohunta's equation are:

Variables	*Range*
L	0.1–42 k_g/m^2 sec
G	0.015–1.22 k_g/m^2 sec
μ_L	0.7–1.5 CP
$\mu_L/\rho_L \mathrm{D}_L$	140–1030
d	0.6–5 cm
D (column)	6–50 cm

where G : superficial gas mass flow rate
D_L : liquid diffusivity
d : packing diameter.

For the gas phase mass transfer coefficient, Laurent and Charpentier (1974) derived the correlation

$$\frac{k_g P}{G} = \frac{C}{M} (a_t d)^{-1.7} \left(\frac{\mathrm{Gd}}{\mu_\mathrm{G}} \right)^{-.3} \left(\frac{\mu_G}{\rho_G D_G} \right)^{-.5}$$

where P : total pressure, atm
M : gas molecular weight
D_G : solute gas diffusively
C = 2.3 for d , < 1.5 cm
C = 5.23 for d > 1.5 cm.

Tray type towers have also been used successfully. Bubble cap plates correlations have been proposed by Andrew (1961)

$$k_g = 7u^{1/4} S^{-1/2} D_g^{1/2} \text{ cm/sec}$$

$$k_l = 11u^{1/4} S^{-1/2} D_l^{1/2} \text{ cm/sec}$$

$$a = 0.7u^{1/2} S^{5/6}$$

in which:

S = effective liquid area on plate, cm^2
u = superficial gas velocity, cm/sec
a = interfacial area/unit area of plate.

A conservative estimate for the liquid phase coefficient in a sieve plate may be obtained from the Equation of Claderbank and Moo–Young (1961)

$$k_l = 0.31(g v_1)^{1/3}(d_l/v_1)^{2/3} \text{ cm/sec}$$

where v_1 is the kinematic liquid viscosity. For CO_2 and water at ordinary temperature, $k_l \approx 0.01$ cm/sec. Typical sieve plate N_i values are about 10^{-4} g mole/cm^2-sec-atm.

"Each tray of Figure 15 has a series of drawn orifices fitted with a cage and cap. The orifice has a flared entrance. This reduces the dry pressure drop allowing a greater percentage of the work expended to be utilized for scrubbing. The floating cap maintains the scrubbing efficiency even with variations in gas flow as wide as 40–110% of capacity.

Gas enters the vessel flowing upward through the valve trays. Liquid is introduced on the top tray and flows across each tray over a weir and then to a sealed downcomer to the next lower tray. A level is maintained over each tray by the weir. The upward flowing gas is given a horizontal component by the cap causing atomization of the liquid on the tray. The froth formed consisting of a myriad of small droplets traps the particles and absorbs or reacts with acid or alkaline vapors. The liquid agitation on the tray surface prevents buildup. This has been demonstrated by the many successful applications in the Petrochemical Industry involving tarry solids and liquids.

Each tray has a 1½ W.G. pressure drop. A typical installation with four (4) trays would require less than 8″ W.G. pressure loss."

An excellent review of gas phase absorption may be found in the work of Danckwerts (1970). The molecular diffusivities in the vapor phase D_r, and in the liquid D_1, may be found from existing correlations, for example see Bird *et al.* (1960). Unlike the solid in adsorption the liquid solvent in absorption usually leaves the system where it can be regenerated. Hence a steady state plug flow analysis in either phase in terms of overall coefficients is possible

$$\begin{aligned} LdC_{il} = GdC_{ig} &= K_g a(C_{ig} - C^*_{ig})dz \\ &= K_1 a(C^*_{il} - C_{il})dz. \end{aligned}$$

The required tower height is then given by either of the following integral relationships:

$$Z = \frac{G}{K_g a}\int_{C_{go}}^{C_{ge}} \frac{dC_g}{C_g - C^*_g} = \frac{L}{K_1 a}\int_0^{C_{le}} \frac{dc_{il}}{C^*_{il} - C_{il}}$$

in which: a is the surface area of contact per unit volume of bed; L and G are per superficial mass velocities. Further discussion on the subject may be found in the work of Cooper and Alley (1994).

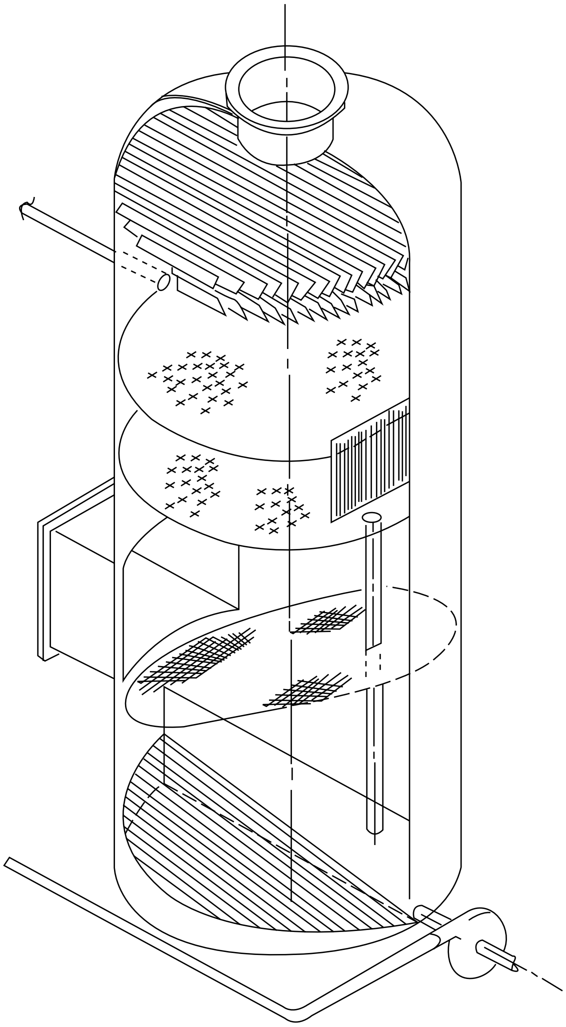

FIGURE 15 Flexitrary Scrubber (Courtesy of Koch Engineering).

PROPERTIES OF ABSORBENTS

Henry's law constants for CO, CO_2, NO and H_2S, are presented in Table 5. Lower values of H such as those for H_2S correspond to higher solubility values. Table 6 contains specific wt. fraction absorbed at equilibrium vs. gas partial pressure for both ammonia and SO_2 in water; Table 7 has similar material for HCl.

Highly soluble materials have absorption rates which are controlled by diffusion through the gas phase (see Table 8).

REACTION

Processes exist for catalytically removing gaseous pollutants by either forming harmless products or products more amenable to recovery. The behavior of most catalytic reactions requires a more substantial analysis than homogeneous systems because of the presence of at least two phases. One of the

TABLE 5

Henry's Law constant for slightly soluble pollutants, H $\times 10^{-4}$ atm/mole-fraction

T,°C	CO	CO_2	NO	H_2S	SO_2
0	3.52	0.0728	1.69	0.0268	0.0016
20	5.36	0.142	2.64	0.0483	0.0033
40	6.96	0.233	3.52	0.0745	0.0062
60	8.21	0.341	4.18	0.103	—
80	8.45	—	4.48	0.135	—
100	8.46	—	4.54	0.148	—

primary differences is that heterogeneous reactions require the adsorption of a fluid phase component on the catalyst surface. In addition to adsorption, diffusion rates may be significant for both main stream to surface gas transfer and for transport inside catalyst pores. The analysis is often simplified by lumping the parameters of the system and assuming plug flow.

Thus for a packed bed of catalyst as in Figure 16 the catalyst mass is lumped as a single substance and the gas phase as another, the latter in plug flow.

The mass of catalyst required to attain a given conversion may be calculated if the dependence of u and P_i on c_i is known.

$$M = \&_B V = S\int_{c_{io}}^{c_i} \frac{d(u\bar{c}_i)}{P_i}$$

where:

u = superficial velocity based on total cross-sectional area S

K_B = bulk density, mass of solids/unit volume

$P_i(\bar{C_i})$ = production rate, moles of A_l formed/(mass solids) (time).

The dependence of the production rate on concentration is usually determined assuming either a Langmuir-Hinshelwood or a Langmuir Rideal mechanism, if diffusion rate constants are large.

If we let X_i represent an adsorbed component A_i on an active site X_0, the *Langmuir-Rideal* sequence, which assumes that a fluid phase reactant combines with a surface adsorbed molecule, the sequence may be expressed as

$$A_1 + X_0 \overset{k_1}{\underset{k-1}{\&}} X_1 \qquad \text{Langmuir adsorption}$$

$$A_2 + X_1 \overset{k_2}{\underset{k-2}{\&}} X_3 + A_4 \qquad \text{Precursor — surface reaction}$$

$$X_3 \overset{k_3}{\underset{k-3}{\&}} A_3 + X_0 \qquad \text{Langmuir desorption.}$$

Usually, to simplify the analysis all the equations save one are assumed to be at equilibrium and the unsteady equation is said to control the rate. Thus for the Langmuir-Hinshelwood equation, the rate of product formation is if

Surface Reaction Controls

$$P = \frac{(k_s K_1 K_2 C_1 C_2 - k_{-s} K_3 K_4 C_3 C_4) C_0^2}{\left(1 + \sum_{j=1}^{4} k_j C_j\right)^2}.$$

The denominators indicate that each component competes for adsorption sites on the catalyst surface. The rate constants and equilibrium constants are denoted by k and K, respectively, with subscripts denoting surface reaction and j referring to adsorption of component A_j. The concentration of each component can be put in terms of C_3 by stoichiometry considerations.

CATALYST PROPERTIES

A typical conversion described by Langmuir adsorption followed by chemical reaction is that for SO_2 removal over vanadium oxide catalyst (Mars and Maessen, 1961)

$$SO_2 + \partial V^{5+} + O^{2-} \square \; SO_3 + \partial V^{4+}$$

95% Yield at 450°C

$$r = kp_{O_2} \frac{Kp_{SO_2}/P_{SO_3}}{[1 + (Kp_{SO_2}/P_{SO_3})^{1/2}]^2}$$

k = rate constant,

K = equilib. constant for above reaction,

p_i = partial pressure of ith species.

Similarly for the oxidation of ethylene

$$r = \frac{kp_{c_2H_2}^2 p_{O_3}}{[1 + K_1 C_{C_2H_4} + K_2 C_{CO_2}^2]^2}.$$

From Sherwood, T.H., Ind. Eng. Chem., 17 (1925), 745.

The simplifications in the above expressions come about because of differences in the order of magnitudes of various rate and equilibrium constants.

Dependence of gaseous diffusion coefficient on temperature: $D \propto T^{3/2}_{\text{absolute}}$. Values for many gases can be estimated from Reid, Sherwood and Prausnitz (1977).

One other place where reaction occurs frequently is in the *combustion* process. Oxygen in the air usually combines with a fuel containing carbon, hydrogen, sulfur, hydrogen sulfide, and hydrocarbons. In addition, the nitrogen in the air will also react with oxygen at the elevated temperatures of a combustion furnace. In Table 9 many

gaseous properties including the heat liberated during combustion are presented.

An excess of air is typically used over the theoretical amount of oxygen actually required for combustion; see Table 10.

In both instances safety considerations are important for preventing explosive mixtures. The detonation limits for various pure gases with air are presented in Table 12 below.

Talmage (1971) describes a flammability envelope diagram which must be considered for handling flammable vapors, Figure 18(a),(b). By appropriately adding inerts or other fuel, it is possible to operate outside of such an envelope. Another review focuses on the addition of nitrogen to combustion mixtures (Subramaniam, 1990).

REACTION RATE PARAMETERS

Table 13 is a compilation of bimolecular reaction rate constants involving typical pollutants.

The decomposition of ozone takes place with a rate constant (Laider, 1965)

$$k = 4.6 \times 10^{15}\, e^{-2400/RT} \text{ cc mole}^{-1} \text{ sec}^{-1}.$$

POLLUTANT CONTROL METHODS

Gases containing compounds of sulfur such as SO_2, SI_3, H_2S and mercaptans have received the widest attention for the purpose of control of all noxious gases. For this reason the

[†] From *Gaseous Fuels*, Ed. by L. Shnidman (New York: American Gas Association, 1954).

All gas volumes corrected to 60°F and 30 in. Hg dry. For gases saturated with water at 60°F, 1.73% of the Btu value must be deducted.

[a] Calculated from atomic weights, Am. Chem. Soc., February 1937.

[b] Densities calculated from values given in grams per liter at 0°C and 760 mm in the International Critical Tables allowing the known deviations from the gas laws. Where the coefficient of expansion was not available, the assumed value was taken as 0.0037 per°C. Compare the with 0.003662 which is the coefficient for a perfect gas. Where no densities were available the volume of the mol was taken as 22.4115 liters.

[c] Converted to mean Bru/lb (1/180 of the heat per pound of water from 32°F to 212°F) from data by Frederick D. Rossini, National Bureau of Standards, letter of April 10, 1937, except as noted.

subject has been treated separately in the overview article entitled *Sulfur Removal.* In this section we shall consider the removal of NO_x, ozone, HF, HCl, and mercury vapor. Additional information on NO_x, HC, and CO removal may be found in the section entitled *Automotive Pollution.*

NITROGEN OXIDE

Before discussing the NO_x removal techniques, one should consider the differences between the combustion flue gas and nitric acid plant tailgas. The differences are shown in Table 14. Also in coal fired units particulate matter is present in gas phase making elimination by certain techniques impractical.

NITRIC ACID PLANT TAILGAS

The amount of NO_x emitted from nitric acid plants in the US is approximately 27,000 metric tons per year. The systems for nitric acid plants tailgas cleanup involve

catalytic reduction, molecular sieve adsorption, extended water-absorption, tailgas scrubbing with nitric acid, and a there-stage absorber which combines gas chilling and urea scrubbing (Ricci, 1977).

There are two types of catalytic reduction: selective and nonselective catalytic reductions. Nonselective reduction uses natural gas (or H_2) as reductant to decompose the NO_x to nitrogen and oxygen. However, it has high capital and operating costs, and results in lower plant efficiency and higher CO emissions, nonselective catalytic reduction is not an attractive method. Selective catalytic reduction involves addition of a species, usually NH_3, which selectively reduces NO_x in an oxygen-containing environment to N_2 and N_2O. The selective catalytic reduction may be used to control the SO_2 and NO_x emissions simultaneously.

Removal of entrained water and acid mist by using a chilling method and mist eliminator is followed by gas drying with a desiccant. Then the gas stream passes through a molecular-sieve bed that catalytically converts NO to NO_2. Finally, the sieve selectively absorbs the NO_2. The absorbed NO_x is then released by heating and returned to the absorber. This method has high efficiency of NO_x removal. However, platinum catalyst may be lost and the method requires higher energy.

The extended water-absorption process involves routing tailgas from the existing absorber tower to a second unit for additional NO_x absorption. Counter-current washing with water produces a weak acid that is pumped to the first absorber. In order to increase the conversion of NO to NCO_2 which is relatively easy to scrub out, high pressure is required. For new plants, the pressure should surpass 150 psia.

There is no chemical consumption in the tailgas scrubbing with nitric acid process since nitric acid is recycled internally. Low energy consumption is the other advantage. However, its high liquid-gas ratio may lower tower capacity.

About 80% of the initial NO_x input is recovered as weak nitric acid in the three-stage absorber which combines gas chilling and the urea scrubbing process. The remainder is urea and ammonium nitrate. They can serve to prepare liquid fertilizers.

COMBUSTION FLUE GAS

There are two major categories of NO_x control for stationary combustion sources: combustion modification and flue gas denitrification. Combustion modification involves change of either operating or design conditions.

COMBUSTION MODIFICATION

Modification of Operating Conditions The production of thermal NO_x is very temperature sensitive. Reducing the flame temperature is effective in reducing thermal NO_x production. This can be achieved by using flue gas recirculation by reduced air preheat, and by steam or water injection. In flue gas recirculation, the recirculated gas must be returned to the combustion zone. The greatest reduction in flame temperature is achieved by mixing the gas directly with the combustion air. The above methods are not as effective for coal fired boilers since coal contains high fuel nitrogen. Both thermal and fuel NO_x can be reduced by staged combustion, low excess air, reduced heat release rate, and a combination of these methods. In staged combustion, fuel is mixed with sub-stoichiometric amounts of air and burned in the first stage. In the second stage fuel burn-out is completed by injecting secondary air into the stage. Formation of NO is thereby limited in the first stage because of the low air level. By using interstage cooling, temperatures can be held down in the second stage where the excess air is injected. Low excess air decreases the NO_x emissions by reducing oxygen availability. The effectiveness of low excess air combustion has been demonstrated for gas and oil combustion by Sensenbaugh and Jonakin (1960). Low excess air combustion for coal may result in furnace slagging, smoke, flame instability, and efficiency loss due to carbon carry over. This technique is always implemented concurrently with other combustion modifications. Reduced heat release reduces the flame temperature and thereby NO_x emissions. The fuel NO_x can be reduced by changing to a fuel with lower %N. On an equivalent heat generation basis, fuels in order of decreasing NO_x formation are coal, oil, gas. Duhl (1976) pointed out that NO_x found in the methanol flue gas was lower than that produced by natural gas, and even lower than that derived from oil combustion. Southern California Edison successfully tested methanol in a 26-MW gas turbine and got NO_x emissions of 45–50 ppm against 260 ppm for distillate fuel in an identical unit (Parkinson, 1981). The effects of the modification of operating conditions to reduce NO_x emissions by fossil fuel combustion are shown in Table 15 (Ricci, 1977).

MODIFICATION OF DESIGN CONDITIONS

Low NO_x Burner Low NO*x* burners are either the delayed or minimum mixing of fuel and air method to increase the locally fuel-rich zones and thereby decrease volatile nitrogen conversion. Also secondary air or tertiary air is added to ensure the carbon burn-out. For instance, the split-flame burners, Figure 19, of Babcock and Wilcox, reduce NO_x emissions by minimizing mixing between the coal and primary air. The secondary air stream is introduced from the outer annulus to complete the carbon burn-out. According to the manufacturer, the NO_x emission is 0.45lb/10^6 BTU without overfire air or flue gas recirculation (Parkinson, 1981).

TABLE 15
How current NO_x control methods fare with fossil fuels

	NO_x reduction		
Method	Gas (%)	Oil (%)	Coal (%)
Flue-gas circulation	60	20	Not effective
Reduced combustion-air preheat	50	40	Not competitive
Steam or water injection	60	40	Not competitive
Staged combustion	55	40	40
Low excess air	20	20	20
Reduced heat-release rate	20	20	20
Combined staging, low excess air, and reduced heat release	50	35	40
Change to fuel with lower percent N	Not effective	40	20

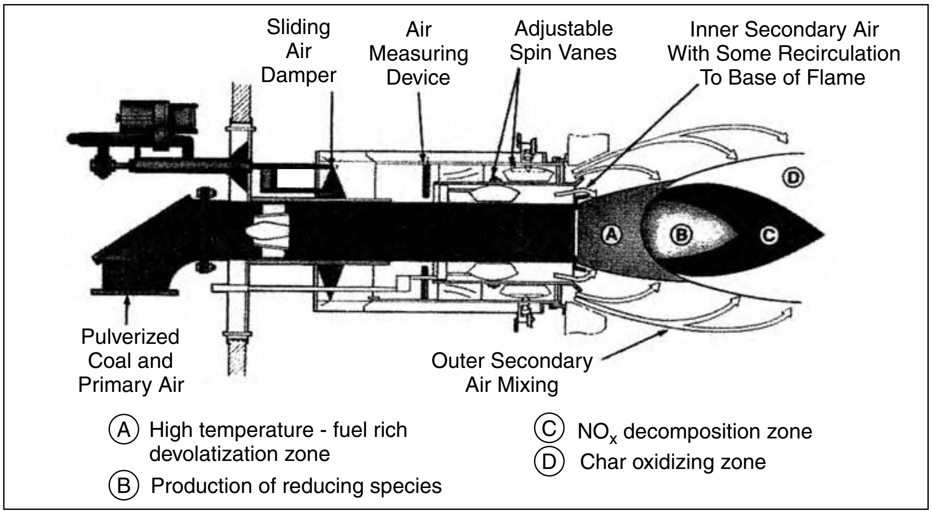

FIGURE 19 B & W dual register, low NO_x burner (1993). (See Color Plate III)).

Fluidized Bed Combustion (FBC) According to the operating pressure of the beds, there are two classifications of FBC—atmospheric pressure and pressurized. The former is appropriate for both utility and industrial heating applications. The latter is for electricity-generating plants. In FBC, crushed coal is fed to a bed of fine limestone or dolomite solvent particles which is fluidized by hot air. Water which is circulated through tubes immersed in the bed is converted into steam by the heat released during combustion. The bed temperature is in the range of 1500–1600°F. The raw limestone ($CaCO_3$) will calcine to lime (CaO) at the normal bed operating temperature. The lime will react with SO_2 released during coal combustion and form gypsum ($CaSO_4$) on the surface of the particles. The necessary sulfur capture is achieved by continuously feeding limestone and maintaining proper bed inventory.

A fluidized bed offers very high heat transfer rates with resulting low combustion temperatures. In addition, the limestone or dolomite absorbs much of the sulfur in the fuel. Thus, fluidized bed combustion promises lower SO_2 and NO_x emissions, coupled with high overall efficiency generating steam or electricity. Also it allows for the use of lower grade fuels. A comparison of EPA permissible limits with NO_x and SO_2 emissions from the 100,000 lb saturated steam/hr FBC unit at Georgetown University is shown in Table 16 (Gamble, 1980). FBC produces more particles in the offgas than conventional systems, since there is no slag to carry them off and an offgas dust collector of high efficiency is required.

FLUE GAS DENITRIFICATION

There are two major classifications of flue gas denitrification: dry and wet. (Dry techniques tests to date include selective catalytic reduction.)

Dry Processes (*SCR*) These include nonselective catalytic reduction, selective noncatalytic reduction, adsorption and electron-beam radiation. The selective catalytic reduction of NO_x to nitrogen and water by injection of ammonia in the presence of a catalyst has been developed and commercialized by a number of Japanese companies because of Japan's special need. In selective catalytic reduction of NO_x with ammonia as the reductant, the main reactions are

$$4NH_3 + 4NO + O_2 \rightarrow 4N_2 + 6H_2O$$
$$4NH_3 + 2NO_2 + O_2 \rightarrow 3N_2 + 6H_2O.$$

TABLE 16
Comparison of FBC stack emission with EPA limit (Gamble, 1980)

	EPA limit	FBC stack emission
SO_2lb/10^6 BTU	1.2	0.48
NO_xlb/10^6 BTU	0.7	0.3

The first reaction predominates when the NO concentration is about 90–95% of the NO_x in combustion flue gas. The application of SCR techniques to coal fired sources does not have long commercial experience, because of catalyst pore plugging problems in the presence of particulate fines. Two commercial units with a fixed bed "parallel passage reactor" to remove the NO_x with efficiency of 98–99% have been reported. Japan Gas Co. (JGC) claimed that this configuration allows NO_x reduction while minimizing dust plugging and pressure drop. Moving bed reactors have also been developed (Ricci, 1977).

Exxon's Thermal De NO_x system is a typical selective noncatelytic reduction process. The technique uses ammonia, but no catalyst and operates in a fairly narrow temperature range 1700–1800°F. The reaction temperature can be reduced to around 1300–1400°F by introducing hydrogen. Due to the narrow reaction temperature range, it is difficult to maintain optimum reaction temperature. However, Exxon's system claims low denitrification costs and no catalyst plugging problem. Mitsui Petrochemical Industries, Ltd. was the first one to commercially apply the process. The NO_x reduction at full load on a 120 tons/hr heavy fuel oil fired steam boiler is about 50%.

As previously described, the molecular sieves can be used to reduce the NO_x emissions from nitric acid plants. NO_x reduction using activated carbon adsorption is tested in pilot plant. The Activated carbon can (1) adsorb NO_2 to form nitric acid (2) promote the oxidation of NO to NO_2 (3) catalyze reduction NO to N_2. Chemical impregnations, such as those of copper and vanadium, enhance carbon's catalytic effect on NO_x/NH_3 reaction. NH_3 is injected into the column. The carbon in the columns adsorb SO_2, NO_x reacts with ammonia to form N_2 and water.

Wet Processes Wet processes fall into four categories, absorption-reduction, oxidation-absorption-reduction, absorption-oxidation, and oxidation-absorption. The classification system for wet NO_x removal processes is shown in Figure 20 (Fawcett *et al.*, 1977). Due to the high capital and operating costs, and the formation of NO_3 containing wastewater, the wet NO*x* removal processes haven't been able to match the commercial gains posted by selective catalytic reduction and other dry techniques. The details of dry and wet methods for NO*x* removal have been reviewed by Fawcett *et al.* (1977). Also, Siddiqi and Tenini (1981) reviewed the commercial flue gas treating applications. The flue gas treating applications in the US and Japan shown in Table 17.

FLUORIDES

Not all fluoride emissions are gases. The system employed must have the capability of handling particulates, dispersed in huge quantities of air. Phosphoric acid production is a typical fluoride producer.

The process begins with the grinding of rock phosphate (typically $Ca_{10}F_2(PO_4)_6$). This is naturally a source of particulates, as is the drying of the pulverized phosphate. Acidulation

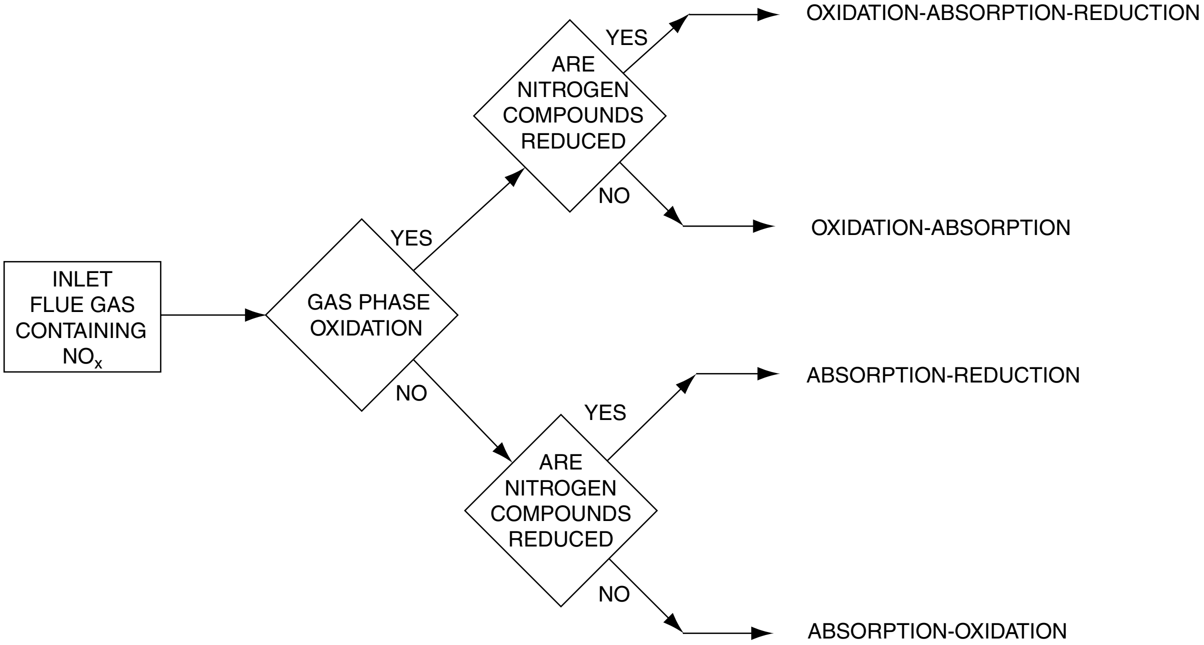

FIGURE 20 Classification system for wet NO_x removal processes (Fawcett *et al.*, 1977).

with sulphuric acid produces the gaseous pollutants associated with this process, most notably hydrogen fluoride, and silicon tetrafluoride. Both of these gases can be scrubbed in aqueous medium, but each one causes a severe handling problem, after scrubbing. The HF is highly corrosive, and the SiF_4 combines with water to form a gelatinous mass which can clog an improperly designed scrubber.

Another constraint is the extremely low effluent concentrations allowed by law, about 0.02 mg/ft^3. Since each unit in the process stream is a source, there are at least 250,000 ft^3/min which much be scrubbed down from 200–500 mg/ft^3. This is a reasonable requirement, considering the toxicity of the pollutants, but it is still a difficult objective to attain.

Teller claims to solve all these problems at once with a cross flow scrubber and a high water flow rate. The device is a baffled tank with wetted baffles so that any solids which do not immediately dissolve will just drop to the bottom after colliding and not clog the air ducts. The large water flow rate keeps the fluorine concentration low, so that the same efficiency (4.8 transfer units) typical of a countercurrent flow scrubber can be maintained.

Cost factors cause the designer to look very hard at the size of this system and its pumping costs. It is obvious that a scrubber which has a greater than necessary number of transfer units will be un-economical. Evan with a tight design on both size and pressure drop, the enormous volumes of gas can still make this system undesirable. A way must be found to decrease the volume.

The best way to do this is by taking advantage of the fact that not all the units produce pollutants at the same concentration level. Since the total flow is large enough that multiple scrubbers would probably be necessary anyway, the first scrubbers in the line take the dirtiest gas and clean it to the level of the next stream. The two are mixed and sent to the next scrubber, and so on. Only the last scrubber need be large enough to accommodate the entire flow. This should solve the air pollution problems to a sufficient degree.

There are two problems which deserve mention: these are water pollution from the dissolved fluorides and solid waste sludges which slough off the baffles. Both of these are highly contaminated and must ultimately lead to a disposal problem.

Teller suggests the water problem be solved by the use of a closed cycle holding pond. Byproduct recovery would appear to be a possible way to solve this problem, but the situation requires further study. There is mention of neutralization of HF, but this will give a CaF_2 precipitate, which would eventually fill even a large holding pond. Regardless of the method chosen, the water must be cleaned of excess fluoride before it can be recycled.

Efficiency of fume control in the aluminium smelting industry has been the subject of a thorough study (Cook *et al.*, 1971). They note that the recovery process may be divided into two categories: "interception of total particulate which includes both fluorine compounds and relatively innocuous aluminium oxide.

Hydrogen fluoride is by far the dominant gaseous fluorine compound in pot gas. Recovery of HF is a function of surface area of alumina, the HF concentration in pot gas delivered to the reactors, quantity of alumina through the system, and contacting efficiency between pot gas and alumina. Reaction between HF and alumina is rapid and with proper reactor design, contacting is no problem. With a sufficient feed rate of alumina to the reactor, reaction efficiency remains high even at very low bed levels. On the other hand, insufficient feed rate or total cessation of feed for a period of time can impair the efficient recovery of HF as the bed becomes saturated. Similarly high concentration of HF in pot gas due to poor operating conditions also can overload the sorptive capacity of available alumina. Provided an adequate alumina supply, the recovery of HG gas is invariably above 99% and frequently above 99.9%.

The interception of particulate fluoride compounds takes place primarily in the fluid bed of the reactor. Fluoride concentration in the bed is found to be about 3½% nearly twice the concentration of hydrogen fluoride sorbed in alumina.

The final interception of particulate, both alumina and fluoride, is a mechanical filtration step which depends upon bag condition. Old or worn bags or poor connection to the tube sheet cause particulate loss. Bag fabric quality, a highly variable factor in its own right, also weighs heavily on particulate loss. Bag fabric quality, a highly variable factor in its own right, also weighs heavily on particulate recovery performance.

Solids efficiency tends to be less than gas efficiency, although this is not always the case. The two are not related because of factors previously discussed. As we are more vulnerable to particulate losses than to gas phase fluoride losses, so are we more vulnerable to fluoride loss in particulate than to alumina loss. About 10% of total particulate loss is fluoride compounds.

The Alcoa 398 system, or any other treatment system, can only capture fluorides from pot fume collected and delivered to the system. Hooding and fume duct, therefore, become important parts of the control system. In newer potlines, hooding is designed to achieve 95% interception.

"The recovery of fluorine in a directly reusable form in the process results in reduced fluoride additions to smelting installations. In addition to the performance measurements taken from operating reactors and pot-room monitors, patterns of fluorine consumption by individual pots, potlines, and entire plants were examined. Observation of the cells served by the prototype installation or Alcoa 398 Process revealed a reduction in aluminium fluoride consumption from 101 lb/ton aluminium produced to 32lb/ton aluminium. Since AlF3 is added to bath neutralize Na_2O incoming with alumina as well as to compensate for loss of fluorides to potlining and atmosphere, the fluorine cycle in smelting cells is complex, and part of this reduction in aluminium fluoride consumption was compensated by additional cryolite requirements. A more general measure of fluoride recovery was derived by evaluation of calcium fluoride sludge collected in ponds serving wet scrubber installations. All of the HF and solids which end in a sludge pond, and a little more besides, are returned directly to the pots with this process. On a fluorine basis, 30 lb of fluorine are retrieved per ton of aluminium produced."

Packed towers have also been used successfully (Specht and Calaceto, 1967) particularly in phosphate fertilizer manufacture.

Use of the packed tower principle has been twofold:

1) To handle high SiF_4 gas loadings in a single, long vessel. When high SiF_4 gas loading are scrubbed, the plugging effects can be disastrous unless there are provisions for a spray chamber to reduce the concentration of SiF_4 and for the subsequent removal of silica. A working design includes a cross-flow packed section for optimum removal of SiF_4 and then a counterflow packed section.
2) To handle very weak SiF_4 concentration (less than 0.5mg as F/std. cu. ft.) in a simplified counterflow tower or to serve as a positive entrainment eliminator.

"Generally, the cyclonic scrubber or packed tower requires 7 to 10 gal for every 30mg of F reduction. Depending on the severity of service, liquid pressure at the cyclonic and spray chamber may be 50 to 1001lb/sq in. gauge, while the liquid pressure at the packing area, depending on the method of distribution, may be 5 to 20lb/sq in. gauge."

Mercury Vapor

Activated carbon, impregnated with elemental sulfur, has been found effective for removing mercury vapor from air or other gas streams (Lovett and Cunniff, 1974). Impregnating the sulfur on activated carbon can increase the reaction rate of mercury vapor and sulfur due to the enormous internal surface area. When the carbon is spent, mercury can be recovered by thermal oxidation in a retort.

Measurements of losses through roof vents help to determine overall fume control performance as summarized in the *Indoor Air Pollution* article. The emission factors for various sources are available from the US EPA's Air Chief software. These factors, referred to as AP-42 factors, are presented for uncontrolled facilities as well as for facilities having air pollution control equipment in place. Factors for which control technology is indicated, do not necessarily reflect the best available or state-of-the-art controls, but rather reflect the level of (typical) control for which data were available at the time the information was published.

The factors are strongly influenced by the type of fuel being combusted and a separate chapter is devoted to EXTERNAL COMBUSTION SOURCES. These include steam/electric generating plants, industrial boilers, and commercial and domestic combustion units. Coal, fuel oil, and natural gas are the major fossil fuels used by these sources. Liquefied petroleum fuels are also used in relatively small quantities. A number of other fuel types are reviewed. Power generation, process heating, and space heating are some of the largest fuel combustion sources of sulfur oxides, nitrogen oxides, and particulate emissions. The commercially available control technology for removing gaseous pollutants is discussed for each fuel. In addition to the external combustion sources, other categories covered are as follows:

(1) Solid Waste Disposal, (2) Stationary Internal Combustion Sources, (3) Evaporation Loss Sources, (4) Petroleum Industry, (5) Organic Chemical Process Industry, (6) Liquid Storage Tanks, (7) Inorganic Chemical Industry, (8) Food And Agricultural Industries, (9) Wood Product Industries, (10) Mineral Products Industry, (11) Metallurgical Industry, (12) Miscellaneous Sources, and (13) Greenhouse Gas Biogenic Sources.

Because emission factors essentially represent an average of a range of emission rates, approximately half of the subject sources will have emission rates greater than the emission factor and the other half will have emission rates less than the factor. As such, a permit limit using an AP-42 emission factor would result in half of the sources being in noncompliance. Also, for some sources, sources often are tested more frequently when they are new and when they are believed to be operating properly, and either situation may bias the results.

WATER AND WASTE MANAGEMENT SYSTEMS IN SPACE

INTRODUCTION

Environmental Control and Life Support System (ECLSS) is the NASA terminology for the systems which allow people to exist and work in confined spaces and in uninhabited locations and hostile environments. These systems supply air, water, temperature and humidity controls to enable personnel to survive and work under hostile conditions. The purpose of this paper is to review the various devices that have been developed for the recovery and reuse of liquid wastes in spacecraft and space stations, and their possible terrestrial applications.

A SHORT HISTORY OF U.S. SPACECRAFT ECLS SYSTEMS

The U.S. spacecraft ECLS systems have grown in capabilities and complexity as the spacecraft have grown and the duration of their missions has been extended. Initial systems were almost completely open loop, with only CO_2 removal in a closed loop. There was no recycling of water or wastes. On the Orbiter, water is not recycled, but is vented overboard. Air is recycled. Solid wastes are returned to the earth. This system will be changed as the Orbiter is reconfigured for longer duration missions. Due to the high cost of transporting fresh water and oxygen into orbit, the space station is designed to operate in an almost completely closed loop mode. Only solid body waste and trash will be returned to the earth. Air and liquid wastes will be recycled.

Regenerative systems have been evaluated by NASA for the different functions of the ECLSS (Figure 1).[1] A partial list of the various technologies is given in Table 1. The emphasis is on purification and recycling the air and wastewater streams for atmosphere revitalization and water recovery and management. The high cost of transporting mass into orbit, approximately \$22,000/kg, causes NASA to place a premium on low weight, low volume, high efficiency, and low maintenance requirements.[2]

DRINKING WATER QUALITY STANDARDS

NASA has very strict standards for water consumed on the shuttle, and even stricter standards for the proposed space station. This is logical, as the water on the space station will be continuously recycled, and hence the astronauts will be exposed to this water for an extended duration. Table 2 lists the present potable water standards for the shuttle and Space Station Freedom (SSF), and compares these to the existing EPA potable water standards. The SSF hygiene water standards are also shown in the table. These standards were established early in the program.[3]

In order that hardware designers should have constant reference solutions to use when testing their equipment, NASA found it necessary to determine the compositions of urine and wastewater that would be produced on the space station. Hence NASA analyzed average urine composition, and determined a chemical model for urine, which could be made up and used to test recycling equipment. Similarly, a chemical model formula for hygiene water, i.e., water used for personal washing, laundry, and food preparation, was derived. These model compositions for urine and wastewater were then used to test individual items of hardware and complete processing systems. However, the final evaluation tests must include the processing of urine and wastewater obtained from volunteers living in a closed test environment.

TECHNOLOGIES TESTED FOR USE IN THE ECLSS

Various technologies were tested and/or evaluated for the ECLSS systems, with the emphasis on the water and air revitalization systems. Less attention has been paid to the treatment of solid waste, as this will only be required for long space voyages and for long term inhabitation of stations on the moon and planets. A number of water recovery and waste management systems have been tested for application in the space station. These systems have been evaluated by comparing them to the baseline technology that was originally

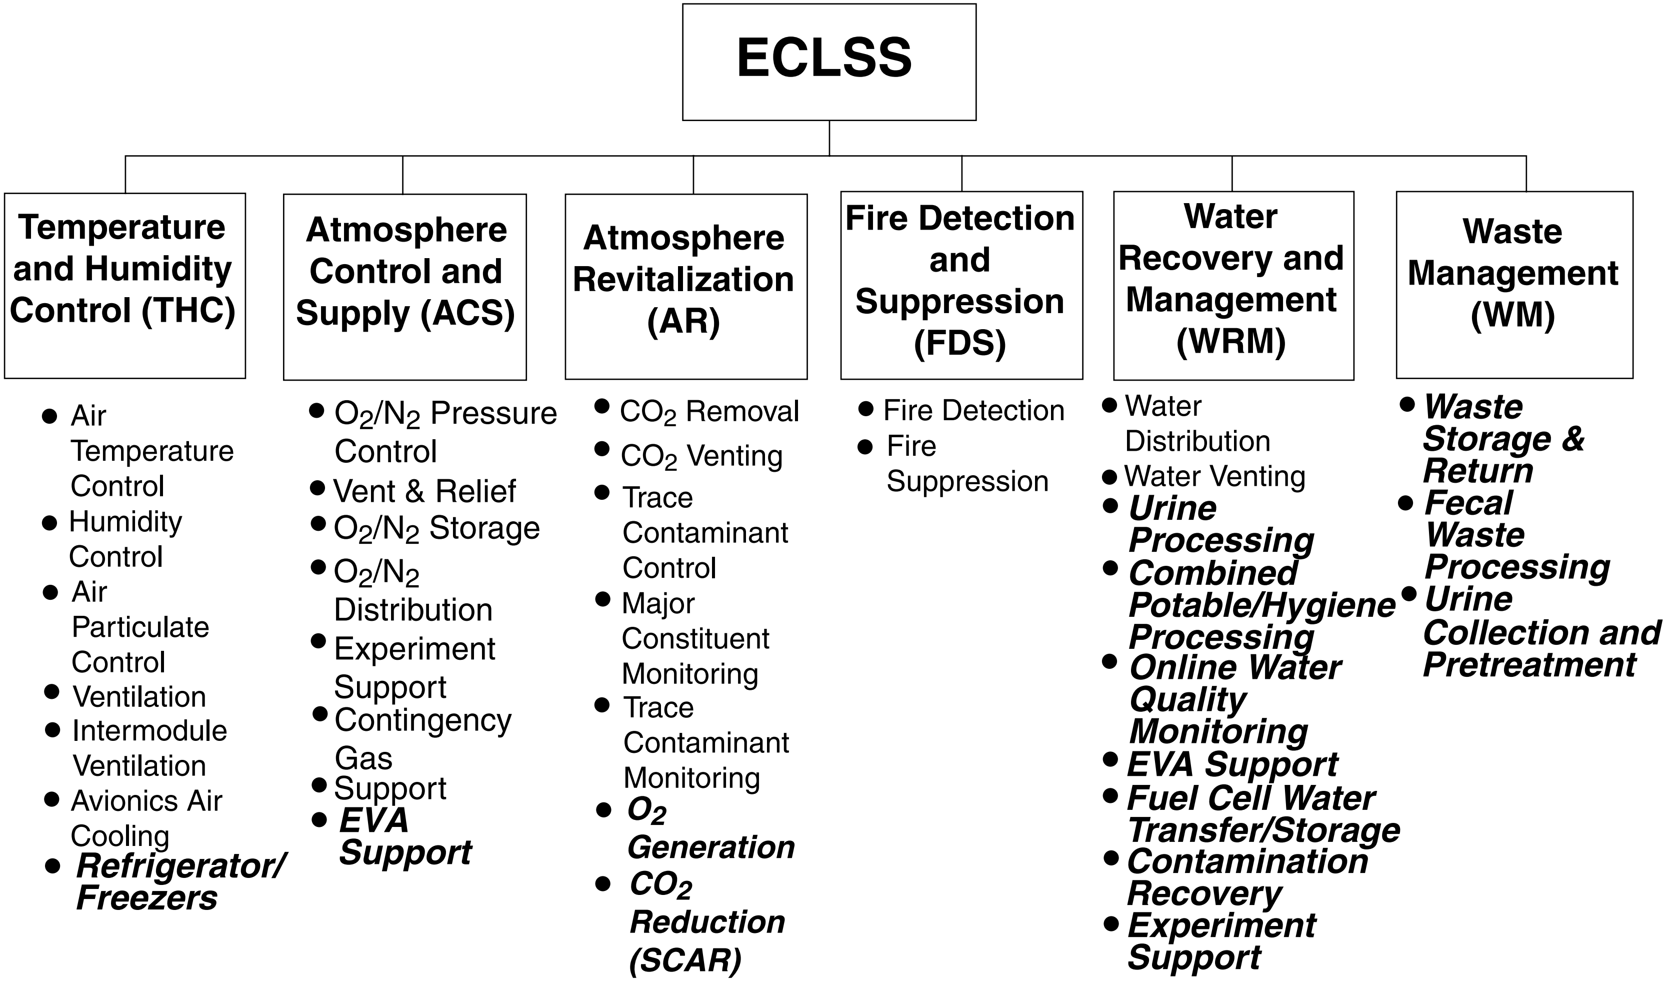

FIGURE 1 Space Station Alpha Environmental Control and Life Support System (ECLSS) Functions. *Source:* Ref. 4.

selected for the space station. The original baseline system was the Thermoelectric Integrated Membrane Evaporation Subsystem (TIMES). This was replaced by a new baseline subsystem which is a combination of multibed filtration (Unibed) and Vapor Compression Distillation (VCD). These baseline systems along with many other promising technologies are described below.

In all cases urine is pretreated immediately upon collection to minimize bacterial growth and possible damage to collection and handling equipment. In addition to inhibiting bacteria, the treatment is intended to control ammonia, stabilize dissolved solids to prevent precipitation, and allow the overall subsystem to function in a zero-gravity environment. Present pretreatment comprises the injection of either Oxone

TABLE 1
ECLSS Technologies Used or Evaluated

ECLSS Subsystem Category	Used/Evaluated	Technology
Atmosphere revitalisation	Used	LiOH
	Used	Molecular sieve
	Used	Sabatier reactor
	Used	Static feed water electrolysis
	Evaluated	Solid amine fixed bed
	Evaluated	Liquid sorbent closed loop
	Evaluated	Bosch system
	Evaluated	Algal bioreactor
	Evaluated	Growing green plants
Trace Contaminant Removal	Used	Activated charcoal
	Used	Catalytic oxidiser
	Used	Particulate filters
Water recovery and management	Used*	Vapor compression distillation
	Used	Chlorine
	Used	Sodium hypochlorite injection
	Used	Iodine injection
	Used	Heat sterilisation
	Used	Fuel cell by-product water
	Evaluated*	Unibed filter
	Evaluated*	TIMES membrane filter
	Evaluated*	Reverse osmosis
	Evaluated*	Electrodialysis
	Evaluated*	Electrooxidation
	Evaluation*	Supercritical water oxidation
	Evaluation*	Electrodeionisation
	Evaluation*	Air evaporation
	Evaluation*	Vapor phase catalytic ammonia removal
	Evaluation*	Immobilized cell or enzyme bioreactors
	Evaluation*	Plant transpiration and water recovery
Temperature and humidity control	Used	Condensing heat exchangers
	Used	Water cooled suits
Atmosphere control and supply	Used	Compressed gas storage
	Used	Cryogenic gas storage
Waste management	Used	Urine stored in bags
	Used	Feces stored in bags
	Used	Urine vented
	Used	Feces stored in bags and vacuum dried
	Used	Urine stored in tank and vented
	Used	Feces stored in bags and compacted

* Described in this paper.

(a potassium monopersulfate compound) combined with sulfuric acid, or hypochlorite (bleach) before distillation.

Thermoelectric Integrated Membrane Subsystem (TIMES)

This was the original baseline water recovery subsystem for the space station (Figure 2). Wastewater is heated to 66°C in a heat exchanger, and is then pumped through bundles of small diameter hollow Nafion fiber membranes in the evaporator module. The Nafion allows only water, gases, and small neutral molecules to pass through. The pressure on the exterior of the membrane is reduced to 17 kPa (2.5 psi) to assist in both transport through the membrane, and subsequent evaporation. The water vapor is then condensed, and the latent heat of condensation is conducted to the input heat exchanger. The TIMES system was found to produce poorer quality water than the VCD.[4,5]

Vapor Compression Distillation (VCD)

The VCD process involves spreading a thin film of the wastewater on the inside wall of a thin-walled rotating drum under low pressure, typically about 4.8 kPa (0.7 psi). The VCD is shown in Figure 3, and in-depth discussions may be found in Refs. 4, and 6–11. The system operates at 35°C which is slightly above ambient temperature. Heat is applied to the outside of the wall causing the thin film of water to boil. The vapor is extracted from the drum interior and compressed by a pump. The compressed vapor is then condensed on the exterior wall of the drum. The compressed vapor condenses at a higher temperature than that at which it had originally evaporated. The latent heat of condensation thus supplied the heat required to evaporate the original feed water in the inside of the drum. The unevaporated brine, heavily loaded with contaminants, is recycled back to the inflow stream, or passed to another subsystem.

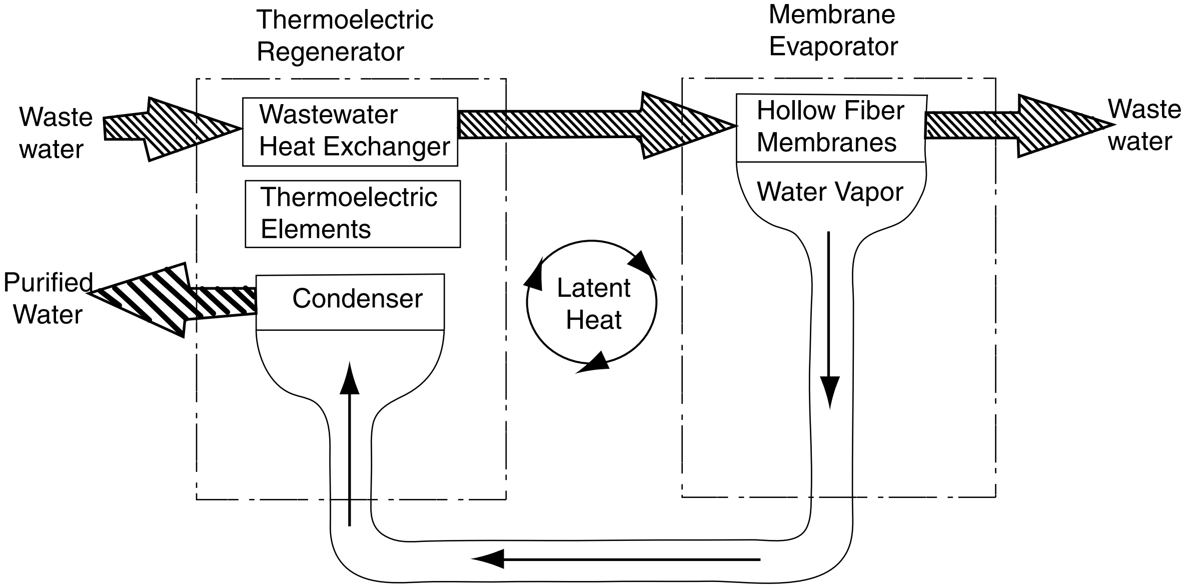

FIGURE 2 Schematic diagram of the TIMES (Thermoelectric Integrated Membrane Subsystem). *Source:* Ref. 4.

Reverse Osmosis (RO)

Reverse osmosis is a process in which pressure is applied to a concentrated solution which is on one side of a semipermeable membrane. The pressure forces the molecules of solvent through the membrane to the pure solvent or more dilute solution on the other side. Greater concentration differential between the two solutions on either side of the membrane require greater pressure. A test unit containing a bundle of tubes, capable of operating at up to 4140 kPa (600 psi), was evaluated. When wash water containing soap was processed a soap gel film formed on the membrane surfaces.[12] Reverse osmosis is a candidate for producing high quality water. A combination of several systems, including RO, produced water that met National Committee for Clinic Laboratory Standards.[13,14]

Multifiltration (Unibed)

The multifiltration system comprises a heat sterilization unit to kill microorganisms, followed by a series of progressively finer particulate filters down to 0.5 microns to avoid particulates clogging the sorbent beds.[15] The water then enters the Unibeds which remove the dissolved contaminants. The Unibed is a single replaceable unit which utilizes a set of beds of different sorptive materials arranged in a specified optimum sequence (Figure 4). The beds are designed to remove specified types and amounts of contaminants from a known waste stream in such a way that all the beds are exhausted at the same time. A sequence of Unibeds of identical design, each comprising three five-tube replaceable subunits, may be used. Unidentified compounds are generally removed by a mixture of several types of activated charcoal and nonionic sorbents near the outlet from the bed. Microbial control to avoid bacterial fouling of the various beds is achieved by iodinated resin beds at the inlet and outlet of each Unibed. Detailed discussions of the system may be found in Refs. 11, and 14–16.

Electrooxidation—Combined Electrolysis and Electrodialysis

Electrodialysis alone removes ions more efficiently than does reverse osmosis (RO); however, when combined with electrolysis the organic compounds are oxidized in the electrolysis and the inorganic salts are removed by the electrodialysis.[7] A combined electrolytic and electrodialytic cell is illustrated in Figure 5. No chemicals are used. Low voltages are used to avoid unwanted side effects such as the production of chlorine, or the formation of insoluble salts. Various types of electrode materials have been tested. Efficiency was increased considerably when the polarity across the electrodes was periodically reversed. This procedure is termed Periodic Reverse Pulsed Electrolysis (PRPE). The process has theoretical advantages over RO, as increasing the brine concentration improves the conductivity, and hence the efficiency of the process. Electrooxidation effectively kills bacteria in the feed.[17]

Supercritical Water Oxidation (SCWO)

Wastewater is heated to a temperature of 650°C under pressures of 250 atmospheres. When water is above its critical point, its properties as a solvent change. Organic compounds which are insoluble at normal temperature and pressure become soluble. The addition of sufficient oxygen then leads to the complete oxidation of these compounds. Most atmospheric gases and trace contaminant gases are also soluble in supercritical water, and will also be oxidized. The process also has the potential

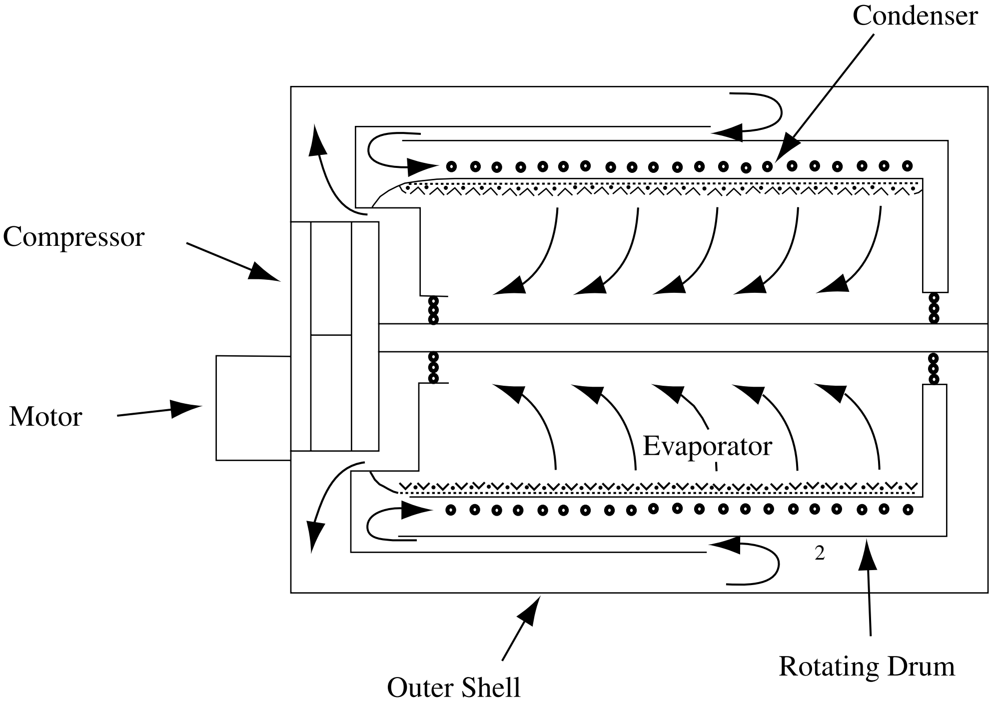

FIGURE 3 Cross section of a VCD (Vapor Compression Distillation) still. *Source:* Ref. 4.

for oxidizing much of the organic solid wastes produced on the space station.[18] Inorganic salts are produced when human metabolic wastes are subjected to supercritical water oxidation. These salts have very low solubility in supercritical water and precipitate out, and thus can be removed.[19] Metals are also precipitated out, with the exception of mercury, which carries over in the vapor phase, and has to be removed by ion adsorption.[20]

Electrodeionisation

Feed water moves through an ion exchange resin bed which selectively removes certain ions from the water. Simultaneously, the resin is regenerated by the action of an electric field imposed upon the resin bed.[21] A schematic process diagram may be found in Ref 21. Bacteria are not completely removed. It appears that this process works best to remove ionic contaminants. It is a candidate for the production of reagent grade water. Both benchtop and industrial capacity units are available.

Air Evaporation

A system with a heat pump and solar collectors for evaporative heat was tested. The system is capable of 100% water recovery from numerous types of contaminated sources. The wastewater is pretreated with a chemical solution to prevent decomposition and bacterial growth. It is then pumped through a wick filter to remove particles, in a series of pulses. The timing of the pulses is such that the liquid from one pulse is distributed along the wick by capillary action before the next pulse arrives. A heated air stream evaporates the water from the wick, leaving the solids behind. When the wick is full of solids, it is dried and replaced by a new wick. The air and vapor stream passes through a condensing heat exchanger and then through a water separator to extract the free water from the stream and test it for quality. It is then transferred to the post-treatment filter section and thence to the main water storage and distribution system. The wick system can be sterilized by heating it to 121°C while in a dry state.[22]

Vapor Phase Catalytic Ammonia Removal (VPCAR)

Neither pre-treatment nor post-treatment of the feed and product water are required. The high temperature employed also destroys microbes to a very great extent.[23] The present design utilizes the thin film evaporation technique of the VCD process in a rotating disk evaporator, combined with catalytic reactors for vapor phase chemical reactions. The ammonia and volatile hydrocarbons which are evaporated along with the water vapor are oxidized to innocuous gases by catalytic chemical reactions carried out in the vapor phase. The overall system schematic is shown in Figure 6.[10,11] The vapor from the VCD boiler passes over two catalytic beds. The first bed operates at a temperature of about 250°C, to oxidize organic volatiles to CO_2 and water, and ammonia to NO and water. The second bed operates at 450°C and reduces the NO to N_2 and O_2. The O_2 produced is more than sufficient for first bed usage. The vapor is recycled to maximize O_2 utilization. This high temperature vapor or steam supplies the

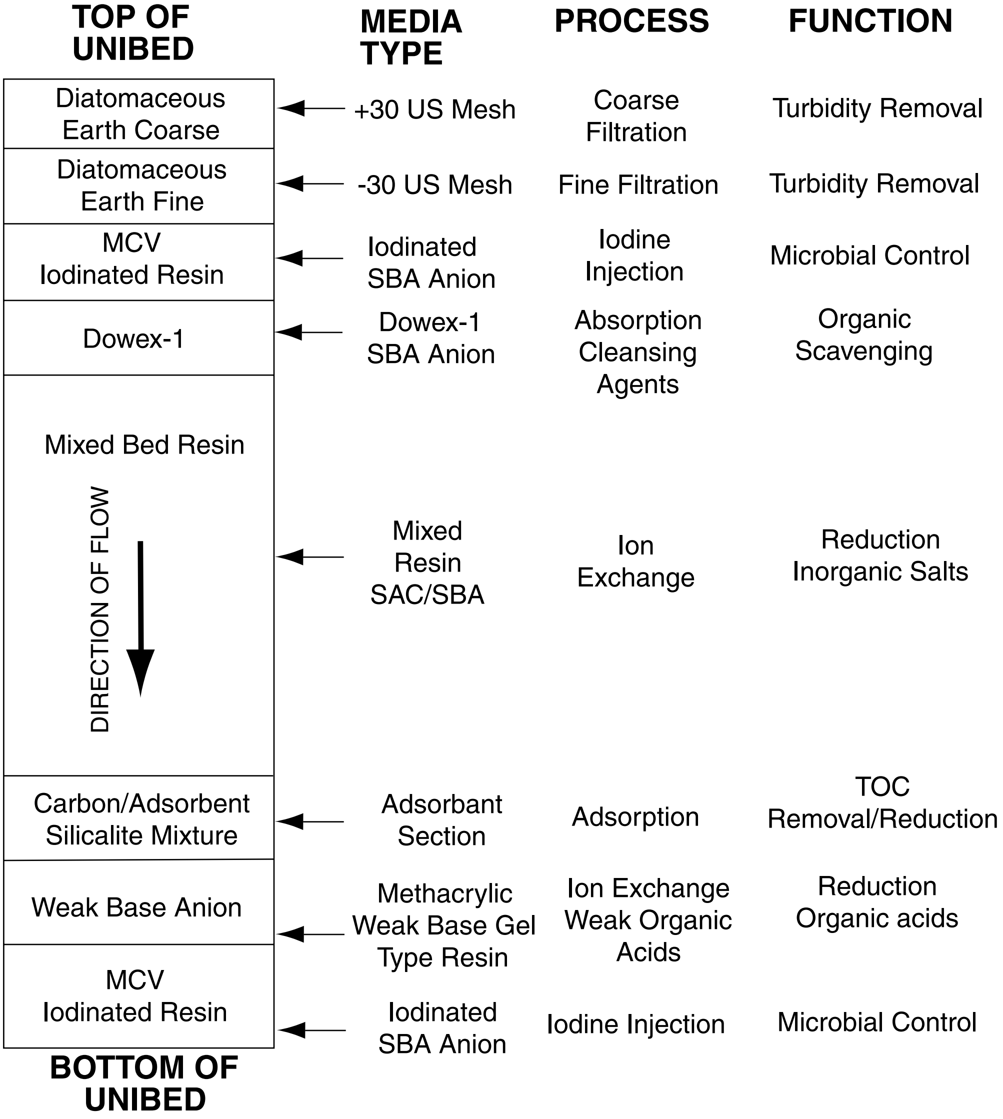

FIGURE 4 Multifiltration unibed schematic and process details. *Source:* Ref. 15.

heat to evaporate the feed, condensing to form the product water. The residual concentrated feed, or brine, is sent to a supercritical water oxidizer (SWCO) to remove the remaining contaminants. Bacterial growth is suppressed because bacteria do not thrive in the concentrated brine due to the buildup of both toxic compounds and of heavy metals in the brine. The vapor phase provides a barrier to non-airborne micro-organisms.[10]

Plant Transpiration and Water Recovery

The use of plants to produce clean water by transpiration is being examined by NASA. It is believed that plants can process wastewater, and transpire it with minimal contaminants. However, any volatile contaminants must be removed first, so that they cannot evaporate directly from the wastewater into the air. The type of pretreatment required will depend upon the waste steam being treated. Plant nutrients will have to be added to the water. Preliminary experiments using only a plant nutrient solution indicated that the amount of total organic carbon (TOC) in transpired water vapor from unstressed plants was very low, about 1.4 mg/L in the water that was collected in condensers outside the plant chamber. Water collected in the plant chamber had higher TOC values, averaging 2.5 mg/L. Stressed plants transpired water with TOC values of up to 7 mg/L. The average TOC level of tap water was 1.6 mg/L. Insect infestation stressed the plants, causing higher TOC levels in the transpired water. It was not clear if any of the increased TOC was derived from the insects themselves. There are many questions about the feasibility of using a compact growth facility to treat the wastewater. These questions need to be examined carefully.

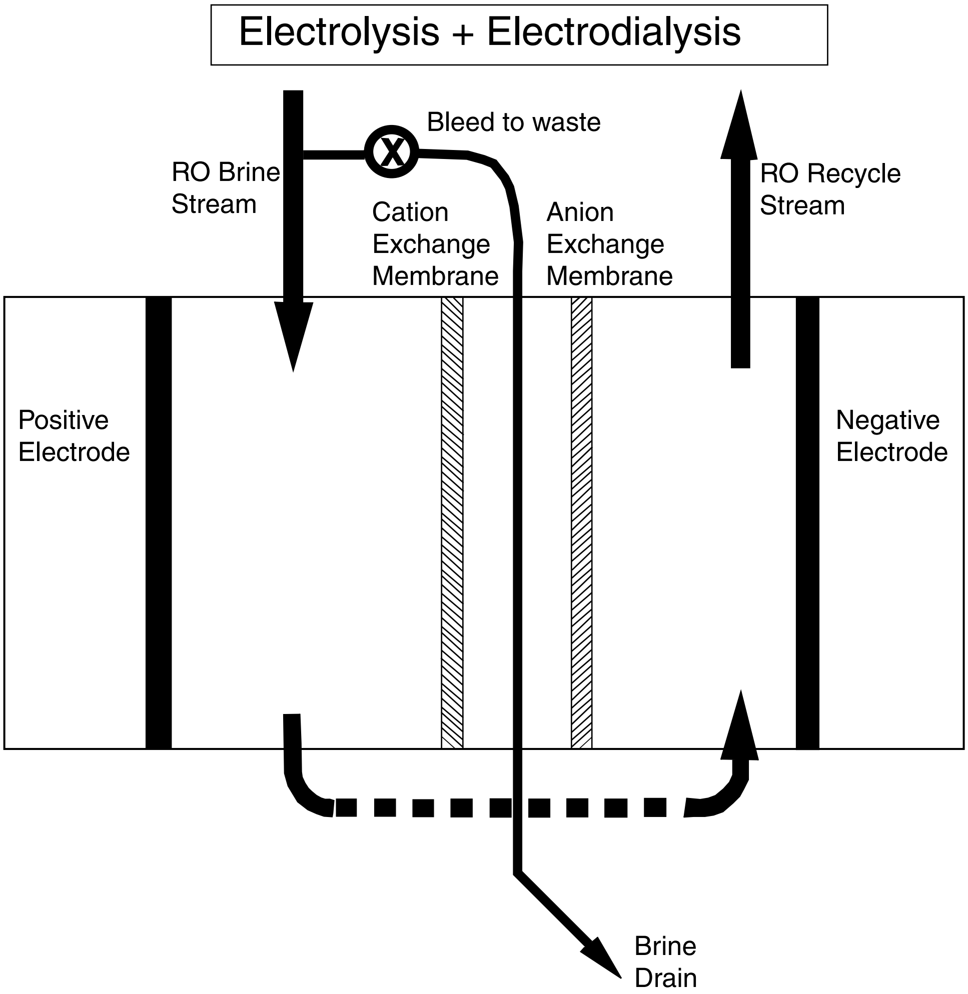

FIGURE 5 Electrooxidation—combined electrolytic and electrodialytic cell. *Source*: Ref. 7.

Discussions on these and related topics may be found in Refs. 24–27.

Immobilized Cell or Enzyme Bioreactors

Immobilized microorganisms convert contaminants into simpler molecules at near ambient temperatures. The immobilized cells can treat a wide variety of contaminants. This technology is under development, but it may have significant terrestrial uses.[28–30] These biological systems require little energy, and may leave little waste residue. Prototype reactors were tested using a packing of diatomaceous earth. When tested with feed containing 10 and 100 mg/L phenol in an oxygenated solution, they were able to produce an effluent with phenol content below the detection limit of 0.01 mg/L. The report did not say what organisms were used, nor how they were arranged for the test.[30] Immobilized microbial cell bioreactors have been used in industrial wastewater treatment applications. In a comparative test processing feed from a coal tar plant, a reactor using a porous polymeric biomass support achieved effluent phenol levels 100 times lower than those achieved by a commercial bioreactor utilizing a nonporous polyethylene support. Similar results were observed for minor contaminants, and the sludge output was about 20% of that from the nonporous system.

A bioreactor test using a consortium of enriched aerobic microorganisms immobilized in packed bed reactors was conducted, utilizing a simulated wastewater feed. A porous polymeric biomass support was used in the reactor. Influent concentrations were nominally 600 mg/L COD, and 1000 mg/L urea. COD reductions of 95% or more, and urea reductions of 95–99% were achieved when using hydraulic retention times of 24 or 48 hours. Effluent total suspended solids ranged from 1 to 3 mg/L.[28]

Tests have shown that low-molecular weight, polar, nonionic contaminants can be removed from solution by immobilized enzymes which catalyze the oxidation of various organic compounds, such as alcohols, aldehydes, and so on, to organic acids, for subsequent removal by ion exchange. Hence existing ion exchange technology (multifiltration Unibeds) can be

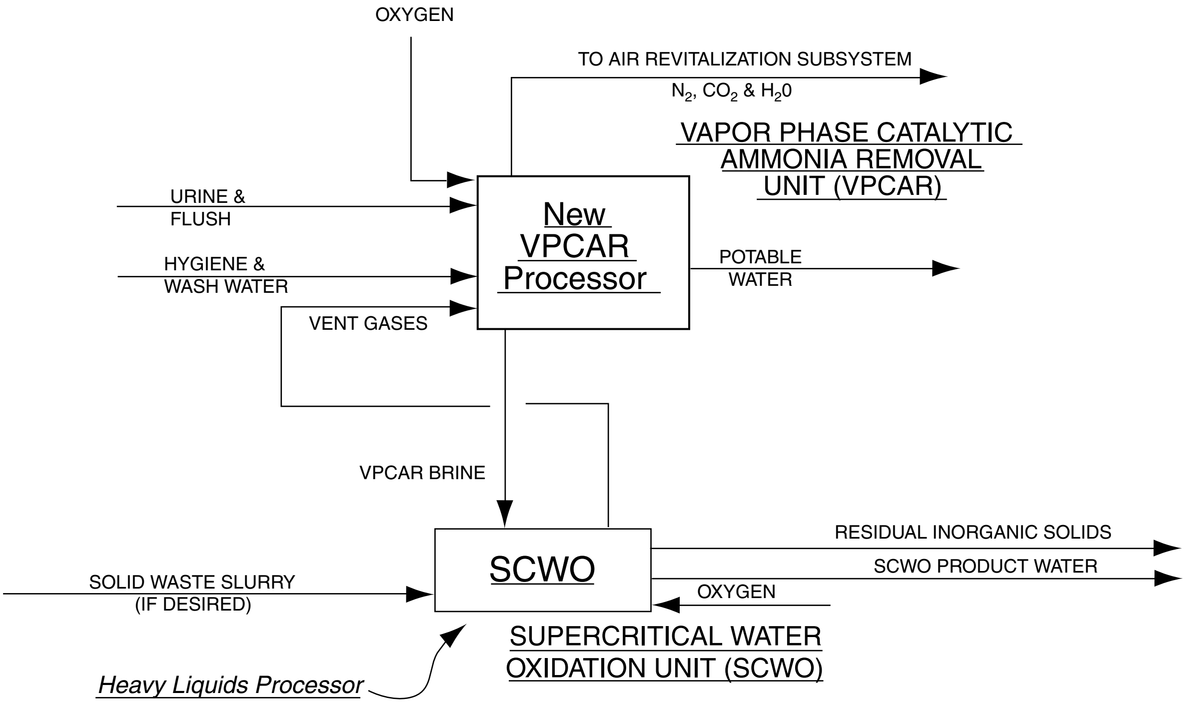

FIGURE 6 Schematic flow diagram of integrated water reclamation system utilizing a combination of VPCAR unit and SCWO unit. *Source:* Refs. 10 and 11.

made more effective. The enzymes are bound to support, usually, a silica-based material, which is in a form that makes it easy to utilize in a Unibed. Specific enzymes are used depending upon the compound or class of compound, to be removed. These Unibeds have to include iodine removers at the inlet, and iodinating resin beds at the outlets to maintain bacterial control in the water supply system of the spacecraft.[29]

Fuel Cell Product Water

When hydrogen and oxygen are combined in a fuel cell to produce electric power, pure water is also produced. This system was used in both the Apollo and Orbiter spacecraft.[5] Urine and wastewater can be electrolyzed to produce hydrogen and oxygen, thus providing a closed loop system (see Electrooxidation above).

COMPARATIVE PERFORMANCE OF TECHNOLOGIES

Many promising technologies for wastewater treatment and water recovery aboard the space station have been described briefly. Their performance levels vary depending upon the characteristics of the wastewater feed. The performance levels and the basic features of each system are compared in Table 3.

WATER QUALITY CONTROL

A major problem in these regenerative systems is bacterial contamination and biofilms forming on the internal surfaces of the water supply system. These biofilms are the result of colonies of bacteria forming on the surface. They occur even in nutrient-limited environments. Biofilms accelerate corrosion and are difficult to remove, or to prevent from forming.[31] Pathogenic bacteria have been shown to survive in sterile water and at elevated temperatures for many hours.[32] This bacterial contamination poses both health and long term mechanical problems in any recycling system. Adequate continuous sterilization procedures and equipment will be required in any recycling system. A high concentration of micro-organisms is found in shower water, reinforcing the necessity of ensuring the disinfection of the recycled potable water supply. A special soap is used for all washing on the Orbiter and is proposed for use on the space station, which reduces foaming and consequent problems in the recycling process.[33] Great care is taken to avoid the possibility of contamination due to cross connection of wastewater and processed water systems.

Pre- and Post-Treatment of Recycled Water

Pre- and post-treatment of water is generally necessary in order to obtain the desired water quality after the treatment of recycled water. NASA concentrated much of its research effort on distillation processes. The combination of distillation and ion exchange is quite successful in removing inorganic contaminants but is less successful in removing volatile organic contaminants. These volatiles must be removed to avoid their accumulation to toxic levels. Organic

TABLE 3
Summary of Described ECLSS Technologies for Water Recovery

Technology	Maximum Water Recovery Rate %	Comments	References
TIMES membrane filter	93	Max feed concentration 38%.	4,5
		Original baseline system. Volatile can be a problem.	
		Lower production rate than VCD.	
Vapor Compression Distillation (VCD)	95+	Max feed concentration 60%.	4,6–11
		Takes 50% power as TIMES, less susceptible to fouling, better quality of product water. Volatiles can be a problem.	
Reverse osmosis	95+	Poor removal of ionized gases.	12,13
		Poor rejection of urea, acids, and ammonia.	
Unibed filter	Nearly 100	Low power consumption, lightweight, simple.	11,14–16
		Filter bed units are expendable, must be replaced.	
		Wastestream must be of stable composition as filters are designed for a specific, stable, known wastestream composition.	
Electrooxidation—Combined Electrolysis and Electrodialysis	Nearly 100	Organic compounds are oxidised by electrolysis, and inorganic salts are removed by electrodialysis.	7,17
		High efficiency was achieved when polarity across the electrodes was periodically reversed.	
		Final TOC levels of 1 ppm is achieved when treating raw urine.	
		Solution has to be spiked with an expendable electrolyte.	
Supercritical Water Oxidation	Nearly 100	Organics, and most atmospheric and trace contaminant gases are completely oxidised.	18–20
		Process can also oxidise many solid wastes. Inorganic salts and metals produced have low solubility and precipitate out.	
		Mercury escapes into the vapor phase and must be removed by ion absorption.	
Electrodeionisation	Nearly 100	Bacteria not completely removed.	21
		Removes almost everything except silica.	
		Waste stream must be characterized for design of selective ion exchange resins.	
		Best for removal of known ionized contaminants.	
Air evaporation	Nearly 100	100% water recovery from urine and numerous other feeds.	22
		Consumables are required.	
		Use of solar collectors would reduce electrical power requirements significantly.	
Vapor Phase Catalytic Ammonia Removal	95	Energy efficient due to system integration.	10,23
		Bacterial growth in feed is suppressed, and vapor phase is a barrier to non-airborne organisms and contaminants. High temperatures destroy many micro-organisms.	
Plant transpiration and water recovery		Water vapor from unstressed plants had TOC of 1.4 ppm.	24–27
		No data on results using actual wastewater.	
Immobilised Cell or Enzyme Bioreactors	No water recovery	100 ppm phenol feeds were reduced to below detection limit of 10 ppb, i.e. 99 + % removal.	28–30
		COD reductions of 95 + %, and urea reductions of 95–99% are achieved.	
		Porous biomass support gives better results.	
Fuel cell product water	100	Pure water, byproduct of power generation.	5

contaminants may also encourage the growth of bacteria in the water storage and transport system. This is especially true when urine, with its heavy load of organic compounds, is treated and recycled. The specified maximum contaminant level for unidentified organic compounds is in the ppb range. Only about 70% of the organic content of urine distillate has been identified, hence it is difficult to design compound-specific removal techniques.

Oxidizers have been used to stabilize urine, but the use of such compounds produces many volatile organic compounds. Urine distillate obtained after such treatment was found to have a TOC content of 25–30 mg/L and a high ammonia concentration. When non-oxidizing compounds were used for pretreatment the TOC cotent was 8–10 mg/L and the ammonia concentration was lower. Certain of the processes described above are very effective in removing these organic compounds and ammonia, and hence require less pretreatment.

Post-treatment methods of polishing the product water are required after the main processes described above. Both multifiltration and UV assisted ozone oxidation reduced the TOC by over 90%. Reverse osmosis also achieved over 90% reduction of TOC and ammonia.[34] The post-treatment technique required depends upon the process used to perform the main water recovery.

Finished Water Quality Monitoring

In order to avoid contamination the processed water is continuously monitored for the levels of certain key parameters which are indicative of the water quality for the desired application. This is necessary to detect any loss of performance in the processing equipment, such as subsystem failure, or exhaustion of a consumable component in the system.

PLANNED TERRESTRIAL USE OF ECLSS

Attempts are being made to utilize ECLSS technology at the South Pole station. The proposed system is designed to recycle water and to grow plants, and later fish, for food at the South Pole. The Antarctic winter lasts some nine months, and the South Pole station is completely isolated during that time. Even emergency medical evacuations are very difficult and rare. A major supply problem is the need to transport some 240,000 gallons of diesel fuel to the station during the short 14 week summer flying season. The proposed ECLSS will reduce the amount of fuel needed. The system will be built in stages, and will ultimately include a waste processing facility. It will include some physical/chemical processing technology, particularly for the feed liquid to the plant growing facility. Experiments are being conducted to evaluate high yield varieties of edible crops. Experiments are planned to utilize wind power, solar obviously not being available during the Antarctic night.[35] This facility may prove more useful for evaluating possible terrestrial uses than many of the space studies, as the equipment is designed for normal gravity, with less emphasis on minimizing volume and weight, and maintenance requirements can be more relaxed than those for the space station.

SUMMARY

In summary, the systems described have high rates of water recovery, and remove or destroy a wide variety of contaminants. The technologies developed may have terrestrial applications. The emphasis on weight and volume saving that is such a major part of the NASA evaluation process may not apply to the same extent for terrestrial uses. Hence the production of reliable systems utilizing the principles tested by NASA should be relatively easy. It is not likely that the recycling of urine will be needed for many, if any, terrestrial uses, thus removing one of the most stringent NASA-imposed requirements for water recovery. Power efficiency, particularly in an integrated water recovery system, may be worth paying a high financial price for, in certain specialized needs. The present NASA system uses only 2 W per hour per kg of water recovered.[2] For some of the systems described it will be necessary to determine the composition of the contaminants in the waste stream as accurately as possible, in order to design and test the system. The requirements in possible terrestrial applications will vary tremendously according to the specific application. Recycling of urine is unlikely, but recycling of hygiene water is more likely. The make-up potable water may come from an original stored supply or low volume natural supply source. It may be possible to use metabolic wastes as input to a process for producing sterile fertilizer for plants, thus recovering water and reducing the volume and possibly the toxicity of the wastes generated. The water recovered from transpiration has potential for use as a potable water supply.

A major problem is that the conventional soap seriously affects some of the processes developed for space applications. They have all been designed to process wastewater which does not contain foaming cleansers. Hence any technology that is being considered must be tested with conventional cleaning products.

Other possible applications for ECLSS technologies may be to clean up well defined industrial waste streams. Several of the basic technologies can provide the capability to both concentrate and treat contaminants, and produce near-potable water as a bonus. As the basic technologies have been developed for space, it should be simple to produce mobile or package (skid-mounted) unites for industrial applications. It must be remembered that the hardware developed for the space program has been designed to handle the waste from a small number of people, and will probably have to be made much larger for most likely terrestrial applications.

WATER CHEMISTRY

AQUATIC CHEMICAL EQUILIBRIA

In this section a few example will be given that demonstrate how elementary principles of physical chemistry can aid in the recognition of interrelated variables that establish the composition of natural waters. Natural water systems usually consist of numerous mineral assemblages and often of a gas phase in addition to the aqueous phase; they nearly always include a portion of the biosphere. Hence, natural aquatic habitats are characterized by a complexity seldom encountered in the laboratory. In order to distill the pertinent variables out of a bewildering number of possible ones, it is advantageous to compare the real systems with their idealized counterparts.

Thermodynamic equilibrium concepts represent the most expedient means of identifying the variables relevant in determining the mineral relationships and in establishing chemical boundaries of aquatic environments. Since minimum free energy describes the thermodynamically stable state of a system, a comparison with the actual free energy can characterize the direction and extent of processes that are approaching equilibrium. Discrepancies between equilibrium calculations and the available data of real systems give valuable insight into those cases where chemical reactions are not understood sufficiently, where non-equilibrium conditions prevail, or where the analytical data are not sufficiently accurate or specific.

Alkalinity and Acidity for Aqueous Carbonate Systems

Alkalinity and acidity are defined, respectively, as the equivalent sum of the bases that are titratable with strong acid and the equivalent sum of the acids that are titratable with strong base; they are therefore capacity factors which represent, respectively, the acid and base neutralizing capacities of an aqueous system. Operationally, alkalinity and acidity are determined by acidimetric and alkalimetric titrations to appropriate pH end points. These ends points (equivalence points) occur at the infection points of titration curves as shown in Figure 1 for the carbonate system.

The atmosphere contains CO_2 at a partial pressure of 3×10^{-4} atmosphere, while CO_2, H_2CO_3, HCO_3^- and CO_3^{2-} are important solutes in the hydrosphere. Indeed, the carbonate system is responsible for much of the pH regulation in natural waters.

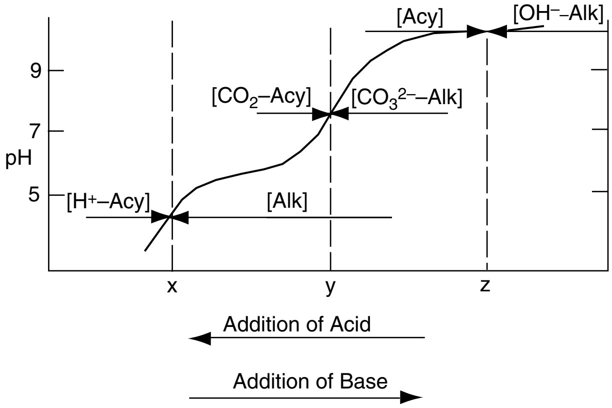

FIGURE 1 Alkalinity and acidity titration curve for the aqueous carbonate system. The conservative quantities alkalinity and acidity refer to the acid neutralizing and base neutralizing capacities of a given aqueous system. These parameters can be determined by titration to appropriate equivalence points with strong acid and strong base. The equations given below define the various capacity factors rigorously. Figure from Stumm, W. and J. Morgan, *Aquatic Chemistry,* Wiley-Interscience, New York, 1970, p. 130.

The following equations define for aqueous carbonate systems the three relevant capacity factors: Alkalinity (Alk), Acidity (Acy), and total dissolved carbonate species (C_T):[†]

$$[\mathrm{Alk}] = [\mathrm{HCO_3^-}] + 2[\mathrm{CO_3^{2-}}] + [\mathrm{OH^-}] - [\mathrm{H^+}] \qquad (1)$$

$$[\mathrm{Acy}] = 2[\mathrm{H_2CO_3}\,*] + [\mathrm{HCO_3^-}] + [\mathrm{H^+}] - [\mathrm{OH^-}] \qquad (2)$$

$$C^b = [\mathrm{H_2CO_3}\,*] + [\mathrm{HCO_3^-}] + [\mathrm{CO_3^{2-}}] \qquad (3)$$

where $[H_2CO_3^*] = [CO_2(aq)] + [H_2CO_3]$.

These equations are of analytical value because they represent rigorous conceptual definitions of the acid neutralizing and the base neutralizing capacities of carbonate systems. The definitions of alkalinity and acidity algebraically

---

[†] Brackets of the form [ ] refer to concentration, e.g., in moles per liter.

express the net proton deficiency and net proton excess of the systems with repect to specific proton reference levels (equivalance points). The definitions can be readily amplified to account for the presence of buffering components other than carbonates. For example, in the presence of borate and ammonia the definition for alkalinity becomes

$$\begin{aligned}[\mathrm{Alk}] = [\mathrm{HCO_3^-}] + 2[\mathrm{CO_3^{2-}}] + [\mathrm{B(OH)_4^-}] \\ + [\mathrm{NH_3}] + [\mathrm{OH^-}] - [\mathrm{H^+}]\end{aligned} \tag{4}$$

Although individual concentrations or activities, such as $[H_2CO_3^*]$ and pH, are dependent on pressure and temperature, [Alk], [Acy], and C_T are conservative properties that are pressure and temperature independent. (Alkalinity, acidity, and C_T must be expressed in terms of concentration, e.g., as molarity, molality, equivalents per liter or parts per million as $CaCO_3$). Note that 1meq/l 5 50 ppm as $CaCO_3$.

The use of these conservative parameters facilitates the calculation of the effects of the addition or removal of acids, bases, carbon dioxide, bicarbonates, and carbonates to aqueous systems. As shown in Figure 2, each of these conservative quantities remains constant for particular changes in the chemical composition. The case of the addition or removal of dissolved carbon dioxide is of special interest. Respiratory activities of aquatic biota contribute carbon dioxide to the water whereas photosynthetic activities decrease the concentration of this weak acid. An increase in carbon dioxide increases both the acidity of the system and C_T, the total concentration of dissolved carbonic species, and it decreases the pH, but it does not affect the alkalinity. Alternatively, acidity remains unaffected by the addition or removal of $CaCO_3(s)$ or $Na_2CO_3(s)$. C_T, on the other hand, remains unchanged in a closed system upon addition of strong acid or strong base. For practical purposes, systems may be considered closed if they are shielded from the atmosphere and lithosphere or exposed to them only for short enough periods to preclude significant dissolution of CO_2 or solid carbonates.

Dissolution of Carbon Dioxide

Though much of the CO_2 which dissolves in solution may ionize to form HCO_3^- CO_3^{2-}, depending upon the pH, only a small fraction (0.3% at 25°C) is hydrated as H_2CO_3. Hence, the concentration of the unhydrated dissolved carbon dioxide, $CO_2(aq)$, is nearly identical to the analytically determinable concentration of $H_2CO_3^*$ (= $[CO_2(aq)]$ + $[(H_2CO_3])$.

The equilibrium of a constituent between a gas phase and a solution phase can be characterized by a mass law relationship. Table 1 gives the various expressions and their interrelations for the characterization of the CO_2 dissolution equilibrium. A water that is in equilibrium with the atmosphere ($P\mathrm{CO}_2 = 10^{-3.5}$ atm) contains at 25°C approximately 0.44 milligram per liter (10^{-5} M) of CO_2; K_H (Henry's Law constant) at 25°C is $10^{-1.5}$ mole per liter-atm.

Dissolved Carbonate Equilibria

Two systems may be considered: (1) a system closed to the atmosphere and (2) one that is in equilibrium with the atmosphere.

Closed Systems In this case $H_2CO_3^*$ is considered a non-volatile acid. The species $H_2CO_3^*$, HCO_3, CO_3^{2-} and are interrelated by the equilibria:[†]

$$[\mathrm{H^+}][\mathrm{HCO_3^-}]/[\mathrm{H_2CO_3}^*] = K_1$$

$$[\mathrm{H+}][\mathrm{CO_3^{2-}}]/[\mathrm{HCO_3^-}] = K_2$$

where K_1 and K_2 represent the equilibrium constants (acidity constants).

The ionization fractions, whose sum equals unity (see Eq. (3)), can be defined as follows:

$$\alpha_0 = [\mathrm{H_2CO_3}^*]/C_T \tag{7}$$

$$\alpha_1 = [\mathrm{HCO_3^-}]C_T \tag{8}$$

$$\alpha_2 = [\mathrm{CO_3^{2-}}]/C_T \tag{9}$$

From Eqs. (3) to (9) the ionization fractions can be expressed in terms of $[H^+]$ and the equilibrium constants:

$$\alpha_0 = (1 + K_1/[\mathrm{H^+}] + K_1K_2/[\mathrm{H^+}]^2)^{-1} \tag{10}$$

$$\alpha_1 = ([\mathrm{H^+}]/K_1 + 1 + K_2/[\mathrm{H^+}])^{-1} \tag{11}$$

$$\alpha_2 = ([\mathrm{H^+}]^2/K_1K_2 + [\mathrm{H^+}]/K_2 + 1]^{-1} \tag{12}$$

Values for K_1 and K_2 are given in Tables 2A and 2B. Because HCO_3^- and CO_3^{2-} may form complexes with other ions in the systems (e.g., in sea water, $MgCO_3$, $NaCO_3^-$, $CaCO_3$ $MgHCO_3^+$, it is operationally convenient to define a total concentration of the species to include an unknown number of these complexes. For example,

$$\begin{aligned}[\mathrm{CO_{3T}^{2-}}] = [\mathrm{CO_{3T}^{2-}}] + [\mathrm{MgCO_3}] \\ + [\mathrm{CaCO_3}] + [\mathrm{NaCO_3^-}] + \Lambda\end{aligned} \tag{13}$$

The distribution of carbonate species in sea water as a function of pH is given in Figure 3.

Systems Open to the Atmosphere A very elementary model showing some of the characteristics of the carbonate system in natural waters is provided by equilibrating pure water with a gas phase (e.g., the atmosphere) containing CO_2 at a constant partial pressure. Such a solution will remain in

---

[†] To facilitate calculations the equilibria are written here in terms of concentration quotients. The activity corrections can be considered incorporated into the equilibrium "constants" which therefore vary with the particular solution. Such constants for given media of constant ionic strength, as well as the true thermodynamic constants, are listed in Tables 2A and 2B.

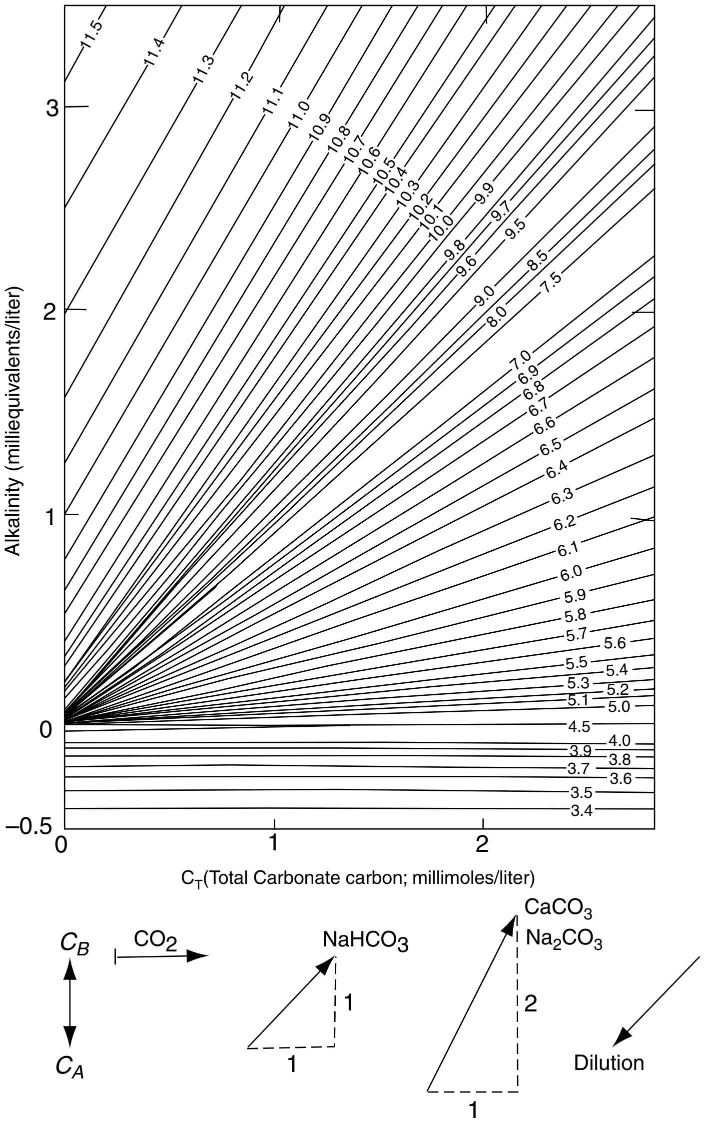

FIGURE 2 Closed system capacity diagram: pH contours for alkalinity versus C_T (total carbonate carbon). The point defining the solution composition moves as a vector in the diagram as a result of the addition (or removal) of CO_2, $NaHCO_3$, and $CaCO_3$ (Na_2CO_3) or C_B (strong base) and C (strong acid). (After K.S. Deffeyes, Limnol., *Oceanog.*, **10**, 412, 1965.) Figure from Stumm, W. and J. Morgan, *Aquatic Chemistry,* Wiley-Interscience, New York, 1970, p. 133.

equilibrium with p_{co}, despite any variation of pH by the addition of strong base or strong acid. This simple model has its counterpart in nature when CO_2 reacts with bases of rocks, for example with clays and silicates.

Figure 4 shows the distribution of the solute species of such a model. A partial pressure of CO_2 equivalent to that in the atmosphere and equilibrium constants valid at 25°C have been assumed. The equilibrium concentrations of the individual carbonate species can be expressed as a function of and $[H^+]_2$. From Henry's Law,

$$[H_2CO_3{}^*] = K_H p_{CO_2}, \tag{14}$$

and Eqs. (5) to (9), one obtains

$$C_T = \frac{1}{\alpha_0} K_H p_{CO_2} \tag{15}$$

$$[HCO_3^-] = \frac{\alpha_1}{\alpha_0} K_H p_{CO_2} = \frac{K_1}{[H^+]} K_H p_{CO_2} \tag{16}$$

TABLE 1
Solubility of gases

Example[a]: $CO_2(g)$ $CO_2(aq)$

Assumptions: Gas behaves ideally; $[CO_2(aq)] = [H2CO_3^*]$

I. Expressions for Solubility Equilibrium[b]

(1) Distribution (mass law) constant, K_D:

$K_D = [CO_2(aq)]/[CO_2(g)]$ (dimensionless) (1)

(2) Henry's law constant, K_H:

In (1), $[CO_2(g)]$ can be expressed by Dalton's law of partial pressure:

$[CO_2(g)] = p_{CO_2}/RT$ (2)

Combination of (1) and (2) gives

$[CO_2\ (aq)] = (K_D/RT)p_{CO_2} = K_H\ p_{CO_2}$, (3)

where $K_H = K_D/RT$ (mole liter^1 atm $^{-1}$)

(3) Bunsen absorption coefficient, α_B:

$[CO_2(aq)] = (\alpha_B/22.414)p_{CO_2}$ (4)

where $22.414 = RT/p$ (liter mole^{-1}) and

$\alpha_B = K_H \times 22.414$ (atm^{-1}) (5)

Partial Pressure and Gas Composition

$p_{CO_2} = x_{CO_2}\ (P_T - w)$ (6)

where X_{CO_2} = mole fraction or volume fraction in dry gas, P_T = total pressure and w = water vapor pressure

Values of Henry's Law Constants at 25°C

Gas		K_H(mole liter^{-1} atm^{-1})
Carbon Dioxide	CO_2	33.8×10^{-3}
Methane	CH_4	1.34×10^{-3}
Nitrogen	N_{2-}	0.642×10^{-3}
Oxygen	O_2	1.27×10^{-3}

[a] Same types of expressions apply to other gases.

[b] The equilibrium constants defined by (1)–(4) are actually constants only if the equilibrium expressions are formulated in terms of activities and fugacities.

Table from Stumm, W. and J. Morgan, *Aquatic Chemistry*, Wiley-Interscience, New York, 1970, p. 125.

and

$$[CO_3^{2-}] = \frac{\alpha_2}{\alpha_0} K_H P_{CO_2} = \frac{K_1 K_2}{[H^+]^2} K_H p_{CO_2}. \qquad (17)$$

It follows from these equations that in a logarithmic concentration—pH diagram (Figure 4) the lines of $H_2CO_3^*$, HCO_3^2, CO_3^{2-} have slopes of 0, +1, and +2, respectively.

If we equilibrate pure water with CO_2, the system is defined by two independent variables, for example, temperature and Pco_2, In other words, the equilibrium concentrations of all solute components can be calculated by means of Henry's Law, the acidity constants and the proton condition or charge balance if, in addition to temperature, one variable, such as Pco_2, $[H_2CO_3^*]$ or $[H^+]$, is known or measured. Use of the proton condition instead of the charge balance generally facilitates calculations because species irrelevant to the calculation need not be considered. The proton condition merely expressed the equality between the proton excess and the proton deficiency of the various species with respect to a convenient proton reference level. Figure 4 furnishes a graphic illustration of its use.

Solubility Equilibria

Minerals dissolve in or react with water. Under different physico-chemical conditions minerals are precipitated and accumulate on the ocean floor and in the sediments of rivers and lakes. Dissolution and precipitation reactions impart to the water and remove from it constituents which modify its chemical properties.

It is difficult to generalize about rates of precipitation and dissolution other than to recognize that they are usually slower than reactions between dissolved species. Data concerning most geochemically important solid-solution reactions are lacking, so that kinetic factors cannot be assessed easily. Frequently the solid phase initially formed is metastable with respect to a thermodynamically more stable solid phase. Relevant examples of such metastability are the formation of aragonite under certain conditions instead of calcite, the more stable form of calcium carbonate, and the over-saturation of quartz in most natural waters. This over-saturation persists due to the extremely slow establishment of equilibrium between silicic acid and quartz.

The solubilities of most inorganic salts increase with increasing temperature. However, a number of compounds of interest in natural waters (e.g. $CaCO_3$, $CaSO_4$) decrease in solubility with increasing temperature. The dependence of solubility on pressure is very slight but must be considered for the extreme pressures encountered at ocean depths. For example, the solubility product of $CaCO_3$ will increase by approximately 0.2 logarithmic units for a pressure of 200 atmospheres (ca. 2000 meters).

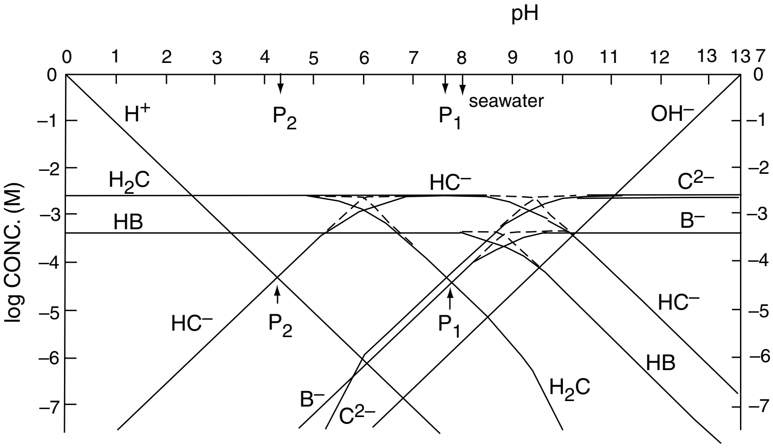

FIGURE 3 Logarithmic concentration—pH equilibrium diagram for seawater as a closed system. For seawater log $B_T = -3.37$, log $C_T = -2.62$ and the following pK values: 6.0 for $H_2CO_3^*$, 9.4 for and pK = 13.7. B_T = total borate boron and C_T = total carbonate carbon. Arrows gives [H^+] for seawater (pH = 8.0) and for two equivalence points (points of minimum buffer intensity): P_1, corresponding to a proton reference level of HB + HC^- + H_2O, and P_2, corresponding to a proton reference level of HB + H_2C + H_2O (From Dyrssen, D. and L.G. Sillén, *Tellus,* 19, 110, 1967).

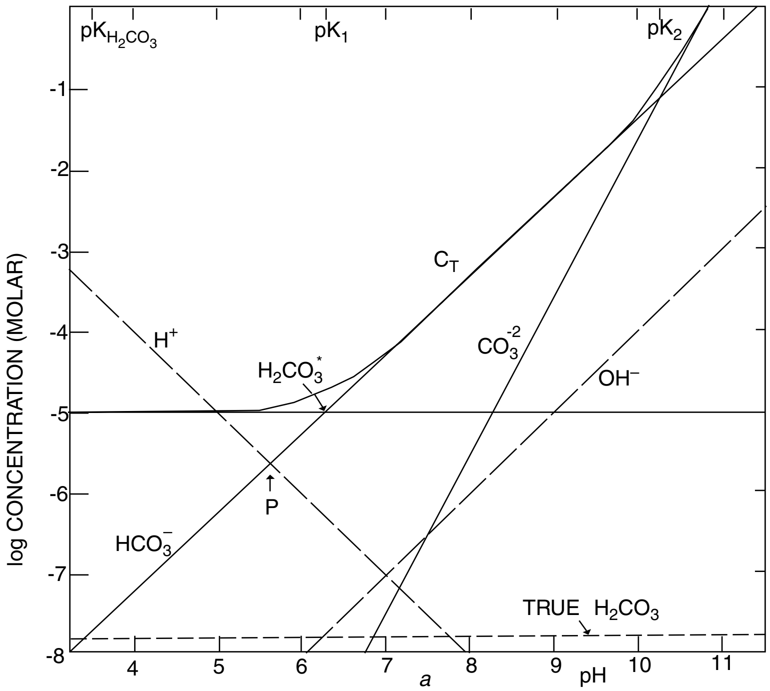

FIGURE 4 Logarithmic concentration—pH equilibrium diagram for the aqueous carbonate system open to the atmosphere. Water is equilibrated with the atmosphere ($pCO_2 = 10^{-3.5}$ atm) and the pH is adjusted with strong base or strong acid. Eqs. (14), (15), (16), (17) with the constants (25°C) $pK_H = 1.5$, $pK_1 = 6.3$, $pK_2 = 10.25$, pK(hydration of CO_2) $= -2.8$ have been used. The pure CO_2 solution is characterized by the proton condition $[H^+] = [HCO_3^-] + 2[CO_3^{2-}]+[OH^-]$ see point *P*) and the equilibrium concentrations $-\log[H^+] = -\log[HCO_3^-] = 5.65$; $-\log[CO_2aq] = -\log[H_2CO_3] = 5.0$; $-\log[H_2CO_3] \approx 7.8$; $-\log[CO_3^{2-}] = 8.5$. *Ref.:* Stumm, W. and J. Morgan, *Aquatic Chemistry,* Wiley-Interscience, New York, 1970, p. 127.

Solubility of Oxides and Hydroxides

If pure solid oxide or hydroxide is in equilibrium with free ions in solution, for example,

$$Me(OH)_2(s) = Me^{2+} + 2OH^- \qquad (18)$$

$$MeO(s) + H_2O = Me^{2+} + 2OH^- \qquad (19)$$

the conventional (concentration) solubility product is given by

$$c^*_{K_{s0}} = [Me^{2+}][OH^-]^2(mole^3 liter^{-3}), \qquad (20)$$

where the subscript "0" refers to solution of the simple, uncomplexed forms of the metal ion.

Sometimes it is more appropriate to express the solubility in terms of reaction with protons, for example,

$$Me(OH)_2(s) + 2H^+ = Me^{2+} + 2H_2O \qquad (21)$$

$$MeO(s) + 2H^+ = Me^{2+} + H_2O. \qquad (22)$$

In the general case for a cation of charge z, the solubility equilibrium for Eqs. (21) and (22) is characterized by

$$c^*_{K_{s0}} = \frac{[Me^{z+}]}{[H^+]}[mole^{(1-z)}liter^{(z-1)} = \frac{c_{K_{s0}}}{K_w^z}, \qquad (23)$$

where K_w is the ion product of water. This constant and also a number of solubility equilibrium constants relevant to natural waters are given in Table 3.

Equation (23) can be written in logarithmic form to express the equilibrium concentration of a cation Me^{z+} as a function of pH:

$$\log[Me^{z+}] = \log^{c^*} K_{s0} - pH. \qquad (24)$$

Equation (24) is plotted for a few oxides and hydroxides in Figure 5.

The constants given here are taken from quotations or selections in (a) L. G. Sillén and A. E. Martell, *Stability Constants of Metal Ion Complexes,* Special Publ., No. 17, the Chemical Society, London, 1964: (b) W. Feitknecht and P. Schindler, *Solubility Constants of Metal Oxides, Metal Hydroxides and Metal Hydroxide Salts in Aqueous Solutions,* Butterworths, London, 1963; (c) P. Schindler, “Heterogeneous Equilibria Involving Oxides, Hydroxides, Carbonates and Hydroxide Carbonates”, in *Equilibrium Concepts in Natural Water Systems, Advance in Chemistry Series,* No. 67, American Chemical Society, Washington, DC, 1967, p. 196; and (d) J. N. Butler, *Ionic Equilibrium, A Mathematical Approach,* Addison-Wesley Publishing, Reading, Mass., 1964. Unless otherwise specified a pressure of 1 atm is assumed.

[a] Most of the symbols used for the equilibrium constants are those given in *Stability Constants of Metal-Ion Complexes* Table from Stumm, W. and J. Morgan, *Aquatic Chemistry,* Wiley-Interscience, New York, 1970, pp. 168 and 169.

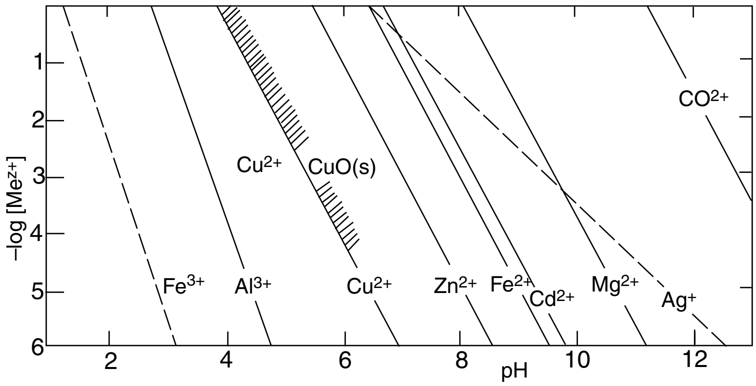

FIGURE 5 Solubility of oxides and hydroxides: free metal ion concentration in equilibrium with solid oxides ore hydroxides. As shown explicitly by the equilibrium curve for copper, free metal ions are constrained to concentrations to the left of (below) the respective curves. Precipitation of the solid hydroxides and oxides commences at the saturation concentrations represented by the curves. The formation of hydroxo metal complexes must be considered for the evaluation of complete solubility of the oxides or hydroxides. Ref.: Stumm, W. and J. Morgan, *Aquatic Chemistry,* Wiley-Interscience, New York, 1970, p. 171.

The relations in Figure 5 do not fully describe the solubility of the corresponding oxides and hydroxides, since in addition to free metal ions, the solution may contain hydrolyzed species (hydroxo complexes) of the form. The solubility of the metal oxide or hydroxide is therefore expressed more rigorously as

$$\mathrm{Me}_T = [\mathrm{Me}^{z+}] + \sum_{1}^{n} [\mathrm{Me(OH)}_n^{z-n}]. \qquad (25)$$

Plots of this equation as a function of pH are given in Figure 6 for ferric hydroxide, zinc oxide, and cupric oxide.

Solubility of Carbonates

The maximum soluble metal ion concentration is a function of pH and concentration of total dissolved carbonate species. Calculation of the equilibrium solubility of the metal ion for a given carbonate for a water of a specific analytic composition discloses whether the water is over-saturated or undersaturated with respect to the solid metal carbonate. In the case of calcite

$$[\mathrm{Ca}^{2+}] = \frac{K_{s0}}{[\mathrm{CO}_3^{2-}]} = \frac{K_{s0}}{C_T \alpha_2} \cdot \qquad (26)$$

Since α_2 is known as a function of pH, Eq. (26) gives the equilibrium saturation value of Ca^{2+} as a function of C_T and pH. An analogous equation can be written for any metallic cation in equilibrium with its solid metallic carbonate. These equations are amenable to simple graphical representation in a log concentration versus pH diagram as illustrated in Figure 7.

Control of Solubility

Solubility calculations, such as those exemplified above, give thermodynamically meaningful conclusions, under the specified conditions (e.g., concentrations, pH, temperature and pressure), only if the solutes are in equilibrium with that solid phase for which the equilibrium relationship has been formulated. For a given set of conditions the solubility is controlled by the solid giving the smallest concentration of solute. For example, within the pH range of carbonate bearing natural waters, the stable solid phases regulating the solubility of Fe(II), Cu(II), and Zn(II) are, respectively, $FeCO_3$ (siderite), CuO (tenorite) and Zn (OH) (CO_3) (hydrozincite).

Unfortunately, it has not yet been possible to determine precise solubility data for some solids important in the regulation of natural waters. Among these are many clays and dolomite ($CaMg(CO_3)_2$), a mixed carbonate which constitutes a large fraction of the total quantity of carbonate rocks. The conditions under which dolomite is formed in nature are not well understood and attempts to precipitate it in the laboratory from solutions under atmospheric conditions have been unsuccessful. These difficulties in ascertaining equilibrium have resulted in a diversity of published figures for its solubility product, $(\{Ca^{2+}\}\{Mg^{2+}\}\{Co_3^{2-}\}2\}^{\dagger}$, ranging from $10^{-16.5}$ to $10^{-19.5}$ (25°C).

The Activity of the Solid Phase

In a solid-solution equilibrium, the pure solid phase is defined as a reference state and its activity is, because of its constancy,

---

† Note that this solubility product is expressed for activities, as represented by { }.

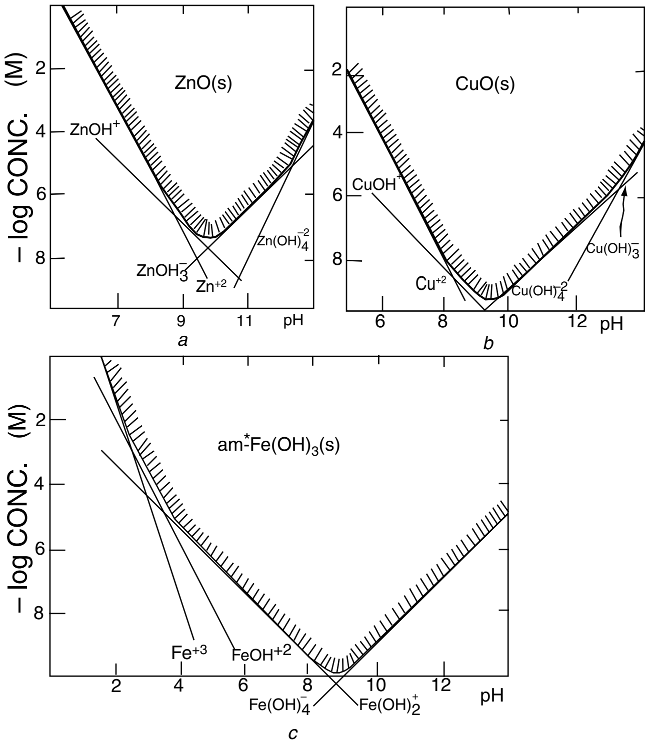

FIGURE 6 Solubility of amorphous $Fe(OH)_3$, ZnO, and CuO. The equilibrium solubility curves for the hydroxo metal complexes and for the free metal ion have been combined to yield the composite curve bordered by the cross hatching. The constituent curves were constructed from the data in Table 3. The possible occurrence of polynuclear complexes, for example $Fe_2(OH)_2^{2-}$, $CU_2(OH)_2^{2+}$, has been ignored. Such complexes do not change the solubility characteristics markedly for the solids considered. Also ignored is complexing with other ligands such as NH_3. Ref.: Stumm, W. and J. Morgan, *Aquatic Chemistry,* Wiley-Interscience, New York, 1970, p. 173.

set equal to unity. This means that the activity of the solid phase is implicitly contained in the solubility equilibrium constant. Therefore, experimental differences from precisely known equilibrium constants can be used to deduce information about the constitution of the solid phase.

There are various factors that affect the activity of the solid phase: (1) the lattice energy, (2) the degree of hydration, (3) solid solution formation, (4) the free energy of the surface and (5) the presence of constituents affecting the purity of the solid.

The solids occurring in nature are seldom pure substances. For example, isomorphous replacement by a foreign constituent in the crystalline lattice is an important factor by which the activity of the solid phase may be decreased.

Redox Equilibria and Electron Activity

There is a conceptual analogy between acid-base and oxidation-reduction reactions. In a similar way that acids and bases have been interpreted as proton donors and proton acceptors, reductants and oxidants are defined as electron donors and electron acceptors. Since free electrons do not exist in solution, every oxidation is accompanied by a reduction and *vice versa.* An oxidant is thus a substance which causes oxidation to occur, while itself becoming reduced.

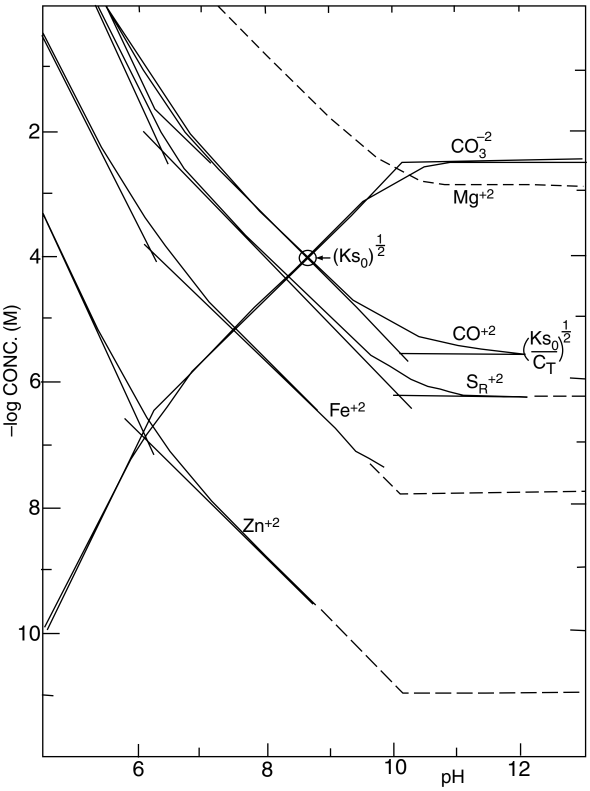

FIGURE 7 Solubility of carbonates in solutions of constant total dissolved carbonate carbon. The maximum soluble metal ion concentration ($[Me^{2+}] = k_{s0}/[(CO_3^{2+}] = K_{s0}/\alpha_2 C_T$) is shown as a function of pH for $C_T = 10^{-2.5}$ M. The acidity constants for $H_2CO_3{}^*$ are indicated on the horizontal axis. Dashed portions of the curves indicated conditions under which $MeCO_3(s)$ is not thermodynamically stable due to the formation of the more stable solid hydroxide or oxide. Ref.: Stumm, W. and J. Morgan, *Aquatic Chemistry,* Wiley-Interscience, New York, 1970, p. 179.

The oxidation states of the reactants and products change as a result of the electron transfer which mechanistically may occur as a transfer of a group that carries one or more electrons. Since electrons are transferred in every redox reaction they can be treated conceptually like any other discrete reacting species, namely, as free electrons. The following redox reaction is illustrative:

$$\begin{array}{ll} O_2 + 4H^+ + 4e = 2H_2O & \text{reduction} \\ 4Fe^{2+} = 4Fe^{3+}\ 4e & \text{oxidation} \\ O_2 + 4Fe^{2+} + 4H^+ = 4Fe^{3+} + 2H_2O & \text{redox} \\ & \text{reaction} \quad (27) \end{array}$$

This treatment of electrons is no different from that of many other species such as hydrogen ions and silver ions, which do not actually exist in aqueous solution as free and unhydrated species but which are expressed as H^+ and Ag^+ in reactions. For example, the H^+ really takes the form of hydrated protons ($H_9O_4^+$) or hydrogen complexes (acids such as HCl).

Redox Intensity

By introducing the definition $pH = -\log[H^+]$, which under idealized conditions is formulated as

$$pH = -\log\{H^+\}, \tag{28}$$

Sørenson (1909) established a convenient intensity parameter that measures the relative tendency of a solution to donate or transfer protons. In an acid solution this tendency is high and in an alkaline solution it is low.

Similarly, Jørgensen (1945) has established an equally convenient redox intensity parameter,

$$p\varepsilon = -\log\{e\}, \tag{29}$$

that measures the relative tendency of a solution to donate or transfer electrons. In a highly reducing solution the tendency to donate electrons, that is, the hypothetical "electron pressure" or electron activity, is relatively large. Just as the activity of hypothetical hydrogen ions is very low at high pH, the activity of hypothetical electron is very low at high $p\varepsilon$. Thus a high $p\varepsilon\delta$ indicates a relatively high tendency for oxidation. In equilibrium equations H^+ and e are treated in an analogous way. Thus oxidation or reduction equilibrium constants can be defined and treated similarly to acidity constants as shown by the following equations:

For protolysis:

$$HA = H^+ + A^- \tag{30}$$

$$\{H^+\}\{A^-\}/\{HA\} = K_{HA}, \text{ or}$$

$$pH = -\log K_{HA} + \log(\{A^-\}/\{HA\}). \tag{31}$$

For the oxidation of Fe^{2+} to Fe^{3+}:

$$Fe^{2+} = Fe^{3+} + e \tag{32}$$

$$\{e\}\{Fe^{3+}\}/\{Fe^{2+}\} = K_{ox}, \text{ or}$$

$$p\varepsilon = -\log K_{ox} + \log(\{Fe^{3+}/Fe^{2+}\}). \tag{33}$$

As seen from Eq. (33) $p\varepsilon$ increases with the ratio of the activities (or concentrations) of oxidized to reduced species.[†]

From the following general reduction reaction:

$$aA + bB + ne = cC + dD$$

the generalized expression for any redox couple is given by

$$\begin{aligned} p\varepsilon &= p\varepsilon^0 - \frac{a}{n^{p^A}} - \frac{b}{n^{p^B}} + \frac{c}{n^{p^C}} + \frac{d}{n^{p^D}} \\ &= \frac{1}{n}\frac{\Delta G}{2.3RT'} \end{aligned} \tag{34}$$

where $pX = -\log[X]$ and

$$p\varepsilon = -\frac{1}{n}\log K_{ox} = \frac{1}{n}\log K_{red} = \frac{1}{n}\frac{\Delta G}{n2.3RT}$$

K_{ox} and K_{red} are the equilibrium constants for the oxidation and reduction reactions; n is the number of electrons transferred in the reaction. ΔG represents the free energy change for the reduction. Thus it is seen that $p\varepsilon$ is a measure of the electron free energy level per mole of electrons.

Equation (34) permits the expression of the redox intensity by $p\varepsilon$ for any redox couple for which the equilibrium constant is known. Numerical illustrations of the calculation of $p\varepsilon$ values (25°C) are given for the following equilibrium systems in which the ionic strength, I,[‡] is assumed to approach O:

a) An acid solution 10^{-5} M in Fe^{3+} and 10^{-3} M in Fe^{2+}.
b) A natural water at pH = 7.5 in equilibrium with the atmosphere ($Po_2 = 0.21$ atm.).
c) A natural water at pH = 8 containing 10^{-5} M Mn^{2+} in equilibrium with $\gamma - MnO_2(s)$.

"Stability Constant of Metal-Ion Complexes" gives the following equilibrium constants (K_{red}):

a) $Fe^{3+} + e = Fe^{2+}$;

$$K = \frac{\{Fe^{2+}\}}{\{Fe^{3+}\}\{e\}}; \log K = 12.53$$

b) $1/2\ O_2\,(g) + 2H^+ + 2e$;

$$H_2O(1)$$

[†] The sign convention adopted here is that recommended by IUPAC (International Union of Pure and Applied Chemistry).

[‡] Ionic strength, I, is a measure of the interionic effect resulting primarily from electrical attraction and repulsions between the various ions; it is defined by the equation $\tau = 1/2\ \Sigma_i C_i Z_i^2$. The summation is carried out for all types of ions, cations and anions, in the solution.

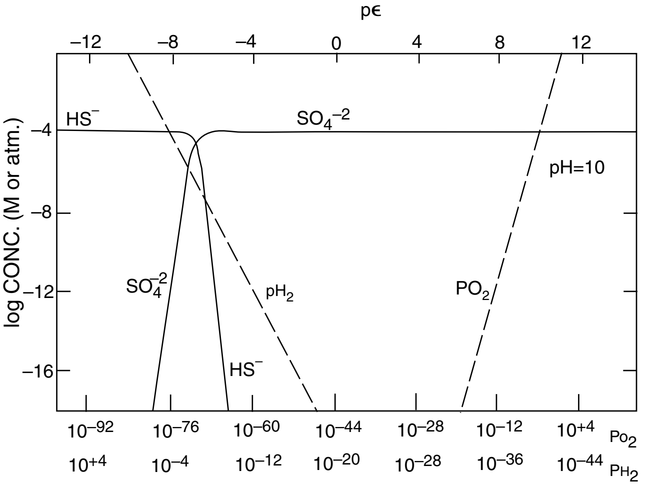

FIGURE 8 Equilibrium distribution of sulfur compounds as a function of pε at pH = 10 and 25°C. Total concentration is 10^{-4} M. The dotted curve shows that solid sulphur cannot exist thermodynamically at pH = 10, since its activity never becomes unity. Figure from Stumm, W. and J. Morgan, *Aquatic Chemistry,* Wiley-Interscience, New York, 1970, p. 311.

$$K = \frac{1}{Po_2^{1/2}\{H^+\}^2\{e\}^2}; \log K = 41.55$$

c) $\gamma-MnO_2(s) + 4H^+ + 2e$

$= Mn^2 + 2H_2O(1);$

$$K = \frac{\{Mn^{2+}\}}{\{H^+\}^4\{e\}^2}; \log K = 40.84.$$

For the conditions stipulated the following pε values are obtained:

a) $p\varepsilon = 12.53 + \log\frac{\{Fe^{3+}\}}{\{Fe^{2+}\}} = 10.53$

b) $p\varepsilon = 20.78 + 1/2\log(Po_2^{1/2}\{H^+\}^2) = 13.11$

c) $p\varepsilon = 20.42 + 1/2\log\frac{\{H^+\}^4}{\{Mn^{2+}\}} = 6.92$

Equilibrium Distribution in the Sulphur System

Figure 8 shows the pε dependence of a 10^{-4}M SO_4^{2-} $-HS^-$system at pH = 10 and 25°C. The reaction is

$$SO_4^{2-} + 9H^+ + 8e = HS^- + 4H_2O(1) \qquad (35)$$

and the redox equilibrium equation is

$$p\varepsilon = 1/8\log K + 1/8\log\frac{[SO_4^{2-}][H^+]}{[HS^-]} \qquad (36)$$

where log *K* (for the reduction reaction) is 10^{34}. Hence,

$$p\varepsilon = 4.25 - 11.25pH + 1/8\log[SO_4^{2-}] - 1/\log[HS^-]$$

or, for pH = 10,

$$p\varepsilon = -7 + 1/8\log[SO_4^{2-}] - 1/8\log[HS^-].$$

HS^- is the predominant S(−II) species at pH = 10. Figure 8 shows that the lines for $[SO_4^{2-}]$ and $[HS^-]$ intersect at pε = −7. The asymptotes for $[SO_4^{2-}]$ have slopes of +8 and 0, whereas those for $[HS^-]$ have slopes of 0 and −8.

Lines for the equilibrium partial pressure of O_2 and H_2 are also given in the diagram. As the diagram shows, rather high relative electron activities are necessary to reduce SO_4^{2-}. At the pH value selected, the reduction takes place at pε values slightly less negative than for the reduction of water. Thus in the presence of oxygen and at pH = 10, only sulfate can exist; its reduction is possible only at pε values less than −6.

Equilibrium Constants for Redox Reactions

Equilibrium constants for some redox processes pertinent in aquatic conditions are listed in Table 4. A quite comprehensive reference source for such constants is *Stability Constants for Metal-Ion Complexes,* L. G. Sillén and A. E. Martell, The Chemical Society, London (1964) and its Supplement (1971). Significantly, the first section of this reference deals with the electron as a ligand, similarly to its treatment above. Another compilation, somewhat outdated though still very useful, is *Oxidation Potentials,* 2nd ed., W. M. Latimer, Prentice-Hall, (1952). This treatise lists redox potentials rather than equilibrium constants, but, as shown in the next section, the latter are readily obtained from the former.

The Determination of pε and Redox Potential

As with pH, pε can be measured with a potentiometer using an indicator electrode (e.g., a platinum or gold electrode) and a reference electrode. The result is read as a potential difference in volts. When a reversible hydrogen electrode, at which the electrode reaction is $H_2 = 2H^+ + 2e$, is used as the reference, the resulting potential difference is termed the redox potential, E_H, where the suffix *H* refers to the hydrogen electrode as the reference. Usually another reference electrode is used, e.g., a calomel electrode, but the addition of a constant factor (i.e., the potential difference between the calomel electrode and the hydrogen electrode) to the observed voltage gives E_H. pε is then readily computed by dividing E_H by a constant factor according to Eq. (27):

$$p\varepsilon\frac{E_H}{(2.3RT/F)},$$

where

F = the Faraday constant (96,500 coulombs per equivalent),

R = the gas constant (8.314 volt-coulombs per degree—equivalent),

and

T = the absolute temperature in degrees Kelvin.

At 25°C, $(2.3\ \omega T/F) = 0.059$ volt.

Both conceptually and computationally, it is more convenient to use the dimensionless pε rather than the more directly measured E_H, as a measure of the redox intensity. Every tenfold change in the activity ratio of Eq. (34) causes a change in pε of one unit divided by the number of electrons transferred in the redox reaction. The fact that one electron can reduce one proton is another reason for expressing the intensity parameter for oxidation in a form equivalent to that used for acidity.

Incidentally, pH is also not measured directly. It is determined by measuring the potential (in volts) of an indicator electrode (e.g., a glass electrode) with respect to a reference electrode. If the hydrogen electrode is used or referred to as the reference electrode, the resulting potential difference is called the acidity potential. The pH is calculated by dividing the acidity potential by 2.3 RT/F.

The Peters-Nernst Equation

Since much literature still describes the electron activity in volts rather than on a scale[†] similar to that for other reagents, the Peter-Nernst equation is still of utility. It is easily expressed by substituting Eq. (37) into Eq. (34):

$$\begin{aligned} E_H &= E_H^0 + \frac{2.3RT}{nF}\log\frac{\{\text{oxidized}\}}{\{reduced\}} \\ &= \frac{-\Delta G}{nF}, \end{aligned} \tag{38}$$

where

$$E_H^0 = (2.3RT/F)p\varepsilon; = \frac{-\Delta G^0}{nF}. \tag{39}$$

Measurement of E_H

It is essential to distinguish between the concept of a potential and the measurement of a potential. Redox or electrode potentials (as listed in "Stability Constants of Metal-Ion Complexes" and other references) have been derived from equilibrium data, thermodynamic data, the chemical behavior of a redox couple with respect to known oxidizing and reducing agents, and from direct measurements of electrochemical cells.

Direct measurement of E_H for natural water environments involves complex theoretical and practical problems in spite of the apparent simplicity of the electrochemical technique. For example, the E_H of aerobic (dissolved oxygen containing) waters, measured with a platinum or gold electrode, does not agree with that predicted by Eq. (38). Even when reproducible results are obtained, they often do not represent reversible Nernst potentials. Among the considerations hindering the direct measurement of E_H are the rates of electron exchange at certain electrodes and the occurrence of mixed potentials. A mixed potential results when the rate of oxidation of one redox couple is compensated by the rate of reduction of a different couple during the measurement. Although aqueous systems containing oxygen or similar oxidizing agents will usually give positive E_H values and anaerobic systems will usually give negative ones, detailed quantitative interpretation with respect to concentrations of redox species is generally unwarranted.

Since natural waters are normally in a dynamic rather than an equilibrium condition, even the concept of a single oxidation–reduction potential characteristic of the aqueous system as a whole cannot be justified. At best, measurement can give rise to an E_H value applicable to a particular redox reaction or to redox species in partial chemical equilibrium and even then only if these redox agents are electrochemically reversible at the electrode surface at a rate that is rapid compared with the electron drain or supply by the measuring electrode system.

pε–pH *Diagrams*

A pε–pH stability field diagram shows in a panoramic way which species predominate at equilibrium under any condition of pε (or E_H) and pH. The primary value of a pε–pH diagram is its simultaneous representation of the consequences of the equilibrium constants of many reactions for any combination of pε and pH. Figure 9 shows stability fields for the various species pertinent to the chlorine system. These diagrams are readily constructed from thermodynamic data such as those listed in Table 4.

Log Concentration—pε Diagrams

The predominant redox species are depicted as a function of pε or redox potential in pε-log concentration diagrams. Upper or lower bounds of pε values for the occurrence of specific redox reactions are immediately evident from these double log-arithmetic diagrams. Such diagrams, constructed from the data in Table 4 with pH = 7, are shown in Figure 10 for a few elements in the biochemical cycle.

[†] With dilute solutions it is convenient to express concentrations on a minus log concentration scale, e.g., $pNa^+ = -\log[Na^+]$.

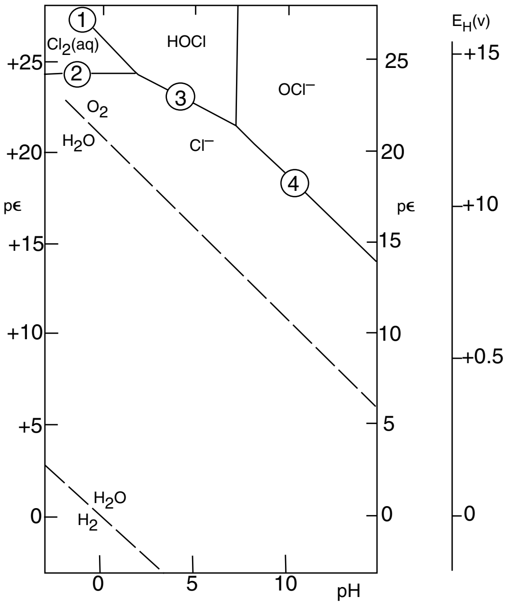

FIGURE 9 Stability field diagram for the chlorine system: pε versus pH. The curves labelled 1,2,3 and 4 represent equilibria derived from Eqs. (25) and (26) of Table 4 and pK_a for HOCl: This latter value is 7.53 at 25°C and is represented by the vertical line between HOCl and OCl$^-$ stability fields. In dilute solutions Cl$_2$ (aq) exists only at low pH. Cl$_2$, OCl$^-$, and HOCl are all unstable or metastable in water since they are all slowly reduced by water as shown by the position of their stability fields, with respect to the H$_2$O–O$_2$ equilibrium curve. Figure from Stumm, W. and J. Morgan, *Aquatic Chemistry,* Wiley-Interscience, New York, 1970, p. 320.

The boundary conditions for the stability of water (Figure 10(d)) are given at high pε values by the oxidation of water to oxygen:

$$1/2\ H_2O = 1/4\ O_2 + H^+ + e \qquad (40)$$

and at low *pε* values by the reduction of water to hydrogen

$$H_2O + e = 1/2\ H_2 + OH^-. \qquad (41)$$

Water in equilibrium with the atmosphere ($P\ o_2 = 0.21$ atm.) at pH = 7.0 (25°C) has a pε = 13.6 (E_H = 0.8 volt.)

Figure 10(a) gives the relationships among several oxidation states of nitrogen as a function of pε. For most of the aqueous range of pε, N$_2$ gas is the most stable species. However, at large negative pε values ammonia becomes predominant and for pε greater than +12 nitrate dominates pH = 7. The fact that the nitrogen gas of the atmosphere has not been converted largely into nitrate under the prevailing aerobic conditions at the land and water surfaces indicates a lack of efficient biological mediation.

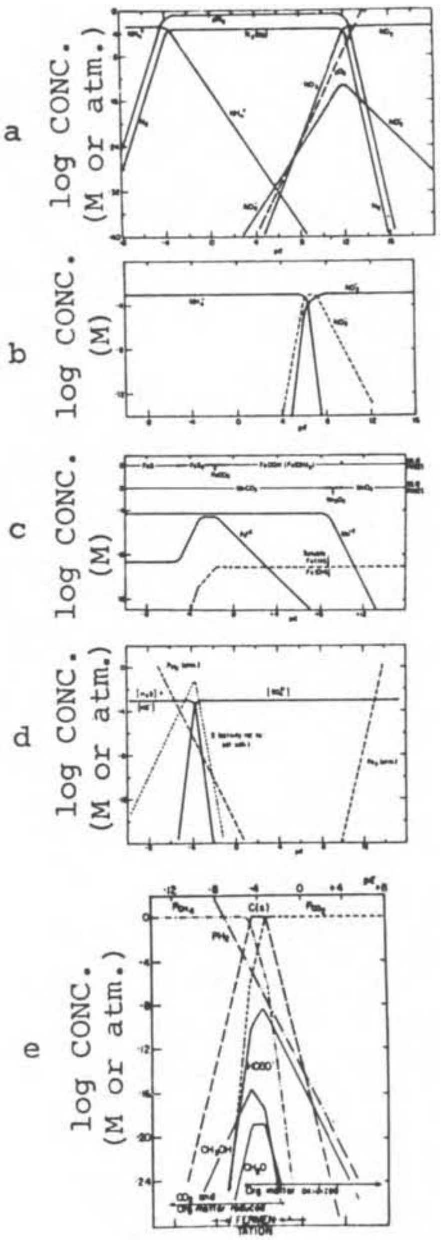

FIGURE 10 Equilibrium concentrations of biochemically important redox components as a function of pε at a pH of 7.0. These equilibrium diagrams have been constructed from equilibrium constants listed in Table 3 and 4 for the following concentrations representative of natural water systems: pH = 7.0; C_T (total carbonate carbon) = 10^{-3} M; [H$_2$(aq)] = [H$_2$S(aq)] + [HS$^-$] + [SO$_4^{2-}$] = 10^{-5}M; [NO^{3-}] + [NO^{2-}] + NO^{4+}] = 10^{-3}M; $p_{N2}{}^2$ = 0.78 atm. and thus [N$_2$(aq)] = 0.5 × 10^{-3}M. Figure from Stumm, W. and J. Morgan, *Aquatic Chemistry,* Wiley-Interscience, New York, 1970, p. 331.

TABLE 4

Equilibrium constants of redox processes pertinent in aquatic conditions (25°C)

	Reaction	$p\varepsilon°(= -\log K)$	$p\varepsilon°(W)$[a]
(1)	1/4 O_2(g) + H^+ (W) + e = 1/2 H_2O	+20.75	+13.75
(2)	1/5 NO_3^- + 6/5H^+ (W) + e = 1/10 N_2(g) + 3/5 H_2O	+21.05	+12.65
(3)	1/2 MnO_2 (S) + 1/2HCO_3^- + 3/2 H^+ (W) + e = 1/2$MnCO_3$(s) + 3/8 H_2O	+20.46	+9.96 +8.46
(3a)	1/2 MnO_2(s) + 2H^+ (W) + e = 1/2 Mn^{2+} + H_2O	+20.42	+6.42
(4)	1/2 NO_3^- + H^+ (W) + e = 1/2 NO_2^- + 1/2 H_2O	+14.15	+7.15
(5)	1/8 NO_2 + 5/4 H^+ (W) + e = 1/8 NH_4^+ + 3/8 H_2O	+14.90	+6.15
(6)	1/6 NO_2^- + 4/3 H^+ (W) + e = 1/6 NH_4^+ + 1/3 H_2O	+15.14	+5.82
(7)	1/2 CH_3OH + H^+ (W) + e = 1/2 CH_4(g) + 1/2 H_2O	+9.88	+2.88
(8)	1/4 CH_2O + H^+ (W) + e = 1/4 CH_4(g) + 1/4 H_2O	+6.94	−0.06
(9)	FeOOH(s)+ HCO_3^- + 2H^+ (W) + e = $FeCO_3$(s) + 2H_2O	+15.33	+1.33 −1.67[b]
(9a)	Fe^{3+} + e = Fe^{2+}	+12.53	+ 12.53
(10)	1/2 CH_2O + H^+ (W) + 3 = 1/2 CH_3OH	+3.99	−3.01
(11)	1/6 SO_4^{2-} + 4/3 H^+ (W) + e = 1/6 S(s) + 2/3 H_2O	+6.03	−3.30
(12)	1/8 SO_4^{2-} + 5/4H+ (W) + 3 = 1/8 H_2S(g) + 1/2 H_2O	+5.75	−3.50
(13)	1/8 SO_4^{2-} + 9/8 H^+ (W) + e = 1/8 HS^- + 1/2 H_2O	+4.13	−3.75
(14)	1/2 S(s) + H^+ (W) + e = 1/2 H_2S(g)	+2.89	−4.11
(15)	1/8 CO_2(g) + H^+ (W) + e = 1/8 CH_4(g) + 1/4 H_2O	+2.87	−4.13
(16)	1/6 N_2(g) + 4/3 H^+ (W) + e = 1/3 NH_4^+	+4.68	−4.68
(17)	1/2 ($NADP^+$) 1/2 H^+ (W) + e =1/2 (NADPH)	−2.0	−5.5[c]
(18)	H^+ (W) + e = 1/2 H_2(g)	0.0	−7.00
(19)	Oxidized ferredoxin + e = reduced ferredoxin	−7.1	−7.1[d]
(20)	1/4 CO_2(g) + H^+ (W) + e = 1/24 (glucose) + 1/4 H_2O	−0.20	−7.20[e]
(21)	1/2 $HCOO^-$ + 3/2H^+ (W) + e = 1/2 CH_2O + 1/2 H_2O	+2.82	−7.68
(22)	1/4 CO_2(g) + H^+ (W) + e = 1/4 CH_2O + 1/4 HO_2	−1.20	−8.20
(22a)	1/4 HCO_3^- + 5/4 H^+ (W) + e = 1/4 CH_2O + 1/2 H_2O	+0.76	−7.99 −8.74[b]
(23)	1/2 CO_2(g) + 1/2 H^+ (W) + e = 1/2 $HCOO^-$	−4.83	−8.73
(24)	1/2 $C1_2$(aq) + e = $C1^-$	+23.6	+23.6
(25)	HOCl + H^+ (W) + e = 1/2 $C1_2$ (aq) + H_2O	+26.9	+19.9

[a] (*W*) signifies that the pH = 7.

[b] These data correspond to (HCO_3^-) = 10^{-3}M rather than unity and so are not exactly $p\varepsilon(W)$; they represent typical aquatic data conditions more nearly than $p\varepsilon(W)$ values do.

Table from Stumm, W. and J. Morgan, *Aquatic Chemistry*, Wiley-Interscience, New York, 1970, p. 318.

Because of these peculiarities in equilibria with N_2, Figure 10(b) has been constructed for the metastable equilibria between NO_3^-, and NO_2^- by assuming the transition between bound nitrogen and N_2 to be hindered. This diagram shows that the shifts in relative predominance of the three species, NH_4^+, NO_2^- and NH_3^- occur within a rather narrow $p\varepsilon$ range. That each of these species has a dominant zone within this range would seem to be a contributing factor to the highly mobile characteristics of the fixed species of the nitrogen cycle. Note that the relevant species of N (−III) at pH = 7 is NH_4^+ rather than NH_3 since the ammonia system $pK_a = 9.3$.

The reduction of SO_4^{2-} to H_2S or HS^- provides a good example of the application of equilibrium concepts to aquatic relationships. Figure 10(d) shows that significant reduction of SO_4^{2-} to H_2S at pH = 7 requires $p\varepsilon < -3$. The biological enzymes that mediate this reduction must therefore operate at or below this $p\varepsilon$. Because the system is dynamic rather than static only an upper bound can be set in this way, for the excess driving force in terms of $p\varepsilon$ at the mediation site cannot be determined by equilibrium computations. Since, however, many biologically mediated reactions seem to operate with relatively high efficiency in utilizing free energy, it

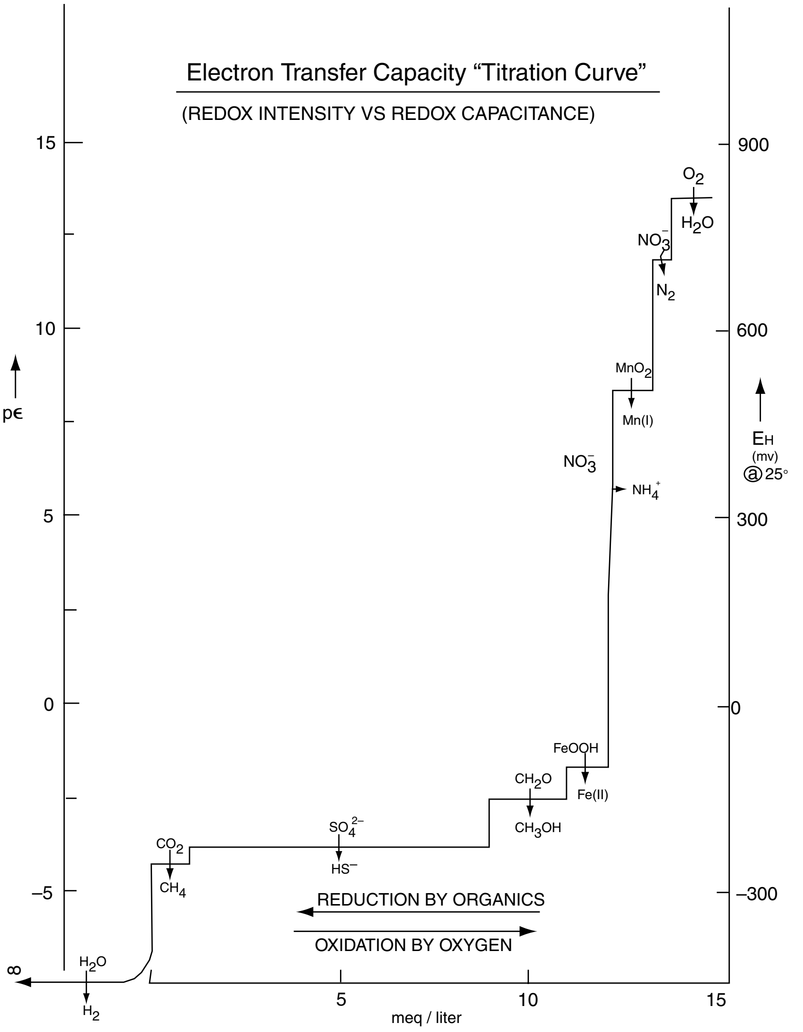

FIGURE 11 Electron transfer capacity "Titration Curve." In a system with excess organic material, the redox intensity falls as the electron acceptors are successively reduced. This diagram was constructed from the redox intensities and initial concentrations (expressed as electron equivalents) listed in Table 3. The reactions indicated on the curve proceed sequentially during the stagnation period in the deeper waters of a polluted lake, vertically downward or temporally in sediments, sequentially after starting an anaerobic digester and chronologically in ground water contaminated with organic nutrients.

appears likely that the operating p pε value does not differ greatly from the equilibrium value. The diagram also indicates the possibility of formation of elemental sulfur within a narrow pε range at neutral and low pH.

The major feature of the carbon system, shown in Figure 10(e), is simply the interconvertibility of C(IV) to C (−IV): i.e., the reduction of carbon dioxide bicarbonates and carbonates to methane and the reverse oxidation reactions. Formation of solid carbon is thermodynamically possible close to $p\varepsilon = -4$ but its inclusion does not change other relationships. Other carbon compounds exist under equilibrium conditions only at very small concentrations ($<10^{-9}$ M). The existence of myriad synthetic and biochemical organic compounds at ambient pε levels is due to their exceedingly slow rates of equilibration to CO_2 or CH_3 or, in the case of the complicated organic structures in living systems, to the constant input of energy.

Microbial Mediation and Free Energy of Redox Reactions

To survive and hence reproduce, microorganisms must not only capture a significant fraction of the thermodynamically available energy but must also acquire this energy at a rate compatible with the maintenance of life. Thus the salient capability is that of power production per unit biomass and therefore kinetics (or the rate of movement toward equilibrium) should be considered as well as thermodynamics. To provide for such energy production microorganisms have developed highly efficient and specific biological compounds (enzymes) which catalyze energy yielding reactions and cell constituent producing processes.

Organisms do not oxidize organic substrates or reduce O_2 or SO_4^{2-}; they only mediate those reactions which are thermodynamically possible, or more specifically, the electron transfer occurring in these reactions. The pε range in which certain oxidation or reduction reactions are possible may be estimated by calculating the equilibrium concentrations of the relevant species as a function of pε. Since, for example, SO_4^{2-} can be reduced only below a given pε or redox potential, an equilibrium model can characterize the pε ranges in which reduction of sulfate is possible and is not possible. Such models are graphically presented in Figure 11, where all the reactions are amenable to microbial mediation. These diagrams manifest the use of pε as a parameter that characterizes the ecological milieu in a restrictive fashion.

The data in Table 4 permit the calculation of combinations of the listed half reactions to give complete redox reactions. Those that are thermodynamically possible are always accompanied by a decrease in free energy. The free energy change of the complete redox reaction, $\Sigma\Delta G$, is easily calculated from the pε values through rearrangement of Eq. (34):

$$\sum \Delta G = -2.3\,RT \times [(n\mathrm{p}\varepsilon)_{\text{for reduction}} \sum (n\mathrm{p}\varepsilon)_{\text{for oxidation}}]. \tag{42}$$

If $-\Delta G$ is negative, the reaction can occur. Combinations that lead to energetically possible reactions are given in Table 3. All of these reactions are mediated by microorganisms.

WATER FLOW

PROPERTIES OF FLUIDS

The fluid properties most commonly encountered in water flow problems are presented in the following paragraphs. The International System of units is used throughout the discussion unless otherwise stated to the contrary.

The unit of *mass, m,* is the kilogram (kg). A mass of one kg will be accelerated by a force of one newton at the rate of 1 m per sec^2.

The *density, ρ,* of a fluid is its mass per unit volume and is expressed in kilograms per cubic meter.

The *specific weight, γ,* is the weight per unit volume and denotes the gravitational force on a unit volume of fluid and is expressed in newtons per cubic meter.

Fluid density and specific weight are related by the expression:

$$\rho = \frac{\gamma}{\mathbf{g}} \tag{1}$$

in which **g** is the acceleration due to gravity.

The *specific gravity* of a fluid is found by dividing its density by the density of pure water at 4°C.

The relative shearing force required to deform a fluid gives a measure of the *viscosity* of the fluid. An increase in temperature causes a decrease in viscosity of a liquid and *vice versa.* Consider the space between two parallel plates (Figure 1) which is filled with fluid; the bottom plate remains at rest while the upper plate moves with velocity V under an applied force. The velocity of the fluid particles will range from V at the top boundary to zero at the bottom as they will assume the same velocity as the boundary in which they are in contact. Experiments have demonstrated that the shear stress, τ, is directly proportional to the rate of deformation, du/dy. Mathematically, this can be written as:

$$\tau = \frac{\mathrm{d}u}{\mathrm{d}y} \cdot \tag{2}$$

Equation (2) is known as Newton's equation of viscosity. The constant of proportionality, μ, in newton-second per square meter (N-s/m^2), is termed the coefficient of viscosity, the dynamic viscosity or the absolute viscosity.

The *kinematic viscosity, v,* is defined as the ratio of the coefficient of viscosity to the density and is expressed in

$$v = \frac{\mu}{\rho} \cdot \tag{3}$$

A more proper term for *surface tension, σ,* would be surface energy. Surface tension is a liquid surface phenomenon and is caused by the relative forces of cohesion, the attraction of liquid molecules for each other, and adhesion, the attraction of liquid molecules for the molecules of another liquid or solid. Surface tension has the units of newtons per meter (N/ m). When a liquid surface is in contact with a solid, a contact angel θ, greater than 90° results with depression of the liquid surface if the liquid does not "wet" the tube such as mercury and glass. If the solid boundary has a greater attraction for a liquid molecule than the surrounding liquid molecules, then the contact angle is less than 90°C and the liquid is said to "wet" the wall leading to a capillary rise as in the case of water and glass.

Table 1 gives the values of the fluid properties discussed in the preceding paragraphs for a few common fluids.

PRESSURE FLOW

Friction Formulae

Darcy-Weishbach's Equation The Darcy-Weishbach formula was first proposed empirically but later found by dimensional reasoning to have a rational basis:

$$h_f = \frac{fLV^2}{2\mathbf{g}D} \tag{4}$$

in which f = friction factor, L = pipe length, V = mean velocity, D = diameter, h = head loss, **g** = acceleration due to gravity.

Equation (4) was derived for circulation sections flowing full and the equation itself is dimensionally homogeneous. It can be extended to other cross-sections provided these shapes are not too different from circular; in this case, the equation has to be transformed by using the hydraulic radius, R, instead of the diameter, D:

$$h_f = \frac{fLV^2}{8\mathbf{g}R}, \tag{5}$$

where $r = D/4$ for flow at full bore. The use of Darcy's equation in the form given by Eq. (5) is sometimes extended to open channel flow.

The determination of the friction factor, *f,* depends on the flow regime, that is, whether the flow is laminar, critical, transitional, smooth, turbulent or rough fully turbulent.

Laminar Flow Consider the mean pipe velocity, *V,* as given by Hagen-Poiseuille's equation for laminar flow:

$$V = \frac{\gamma SD}{32\mu} \tag{6}$$

in which S = energy slope.

Combining Eq. (4) with Eq. (6) and noting that $S = H_f/L$, $\gamma = \rho \mathbf{g}$, and $\nu\mu/\rho$, the friction factor is given by:

$$f = \frac{64}{R_e}, \tag{7}$$

where $R_e = \nu D/\gamma$ is the Reynolds number. Eq. (7) can be used for all pipe roughness as the friction factor in laminar flow is independent of the wall protuberances and is inversely proportional to the Reynolds number. The energy loss varies directly as the mean pipe velocity in laminar flow which persists up to a Reynolds number of about 2000.

The velocity profile, which has a parabolic distribution, can be obtained from Hagen-Poiseuille's equation. The velocity, *u,* at any radius, *r,* of the pipe of diameter, *D,* is given by:

$$u = \frac{\gamma S}{4\mu}\left(\frac{D^2}{4} - r^2\right). \tag{8}$$

At the centre line, the velocity is a maximum:

$$u_{\max} = \frac{\gamma SD^2}{16\mu} \tag{9}$$

The mean velocity is:

$$u_{\text{mean}} = (u_{\max})/2 = \frac{\gamma SD^2}{32\mu}. \tag{10}$$

Critical Flow From a Reynolds number of about 2000 and extending to 4000 lies a critical zone where the flow may be either laminar or turbulent. The flow regime is unstable and no equation adequately describes it.

Smooth Turbulent For pipes fabricated from hydraulically smooth materials such as copper, plexiglass and glass, the flow is smooth turbulent for a Reynolds number exceeding 4000. The von Karman-Nikuradse smooth pipe equation is:

$$\frac{1}{\sqrt{f}} = 2\log_{10}(R_e\sqrt{f}) - 0.80. \tag{11}$$

Equation (11) indicates that the friction factor depends on the fluid properties and deceases with increasing Reynolds number.

Rough Fully Turbulent Nikuradse experimented with pipes artificially roughened with uniform sand grains. The results were fitted to the theory of Prandtl–Karman to give the well known rough-pipe equation:

$$\frac{1}{\sqrt{f}} = 2\log_{10}(D/\varepsilon) + 1.14. \tag{12}$$

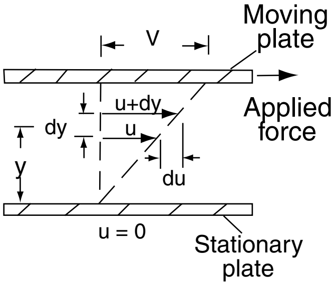

FIGURE 1 Fluid shear.

TABLE 1
Fluid properties

Fluid	Temperature °C	Mass density kg/m^3	Specific weight kN/m^3	Dynamic viscosity N-s/m^3	Kinematic viscosity m^2/s	Surface tension N/m
Water	0	1000	9.81	1.75×10^{-3}	1.75×10^{-6}	0.0756
—	5	1000	9.81	1.52×10^{-3}	1.52×10^{-6}	0.0754
—	10	1000	9.81	1.30×10^{-3}	1.30×10^{-3}	0.0742
Mercury	20	13,570	133.1	1.56×10^{-3}	1.15×10^{-7}	0.514
Sea water	20	1028	10.1	1.07×10^{-3}	1.04×10^{-6}	0.073

Equation (12) states that beyond a certain Reynolds number, when the flow is fully turbulent, the friction factor is influenced only by the relative roughness,*ε/D* and independent of the Reynolds number.

Transition Flow Most commercial pipe flows do not follow either the smooth pipe or rough pipe equations. Colebrook and White proposed a transitional flow equation which would be asymptotic to both:

$$\frac{1}{\sqrt{f}} = -2\log_{10}\left(\frac{e/D}{3.7} + \frac{2.51}{R_e\sqrt{f}}\right). \tag{13}$$

Equation (13) approaches the smooth pipe equation for low and the rough pipe equation for high values of the Reynolds number respectively. Unlike Nikuradse's ε, which represents the actual height of the sand grains, the ε of Colebrook—White's equation is not an actual roughness dimension but a representative height describing the roughness projections. It is referred to as the equivalent sand-grain diameter since the friction loss it represents is the same as the equivalent sand-grain diameter; Table 2 gives experimentally observed values:

TABLE 2
Equivalent sand-grain diameter

Pipe material	ε (mm)
Riveted steel	9.14
Rough concrete	3.05
Smooth concrete	0.31
Steel	0.05

Moody Diagram (Moody, 1944.) The Moody Diagram (Figure 2) summarises and solves graphically the four friction factor equations Eqs. (7), (11), (12), (13) as well as delineating the zones of the various flow regimes. The line separating transitional and fully turbulent flow is given by Rouse's equation:

$$\frac{1}{\sqrt{f}} = \frac{R_e}{200}\frac{\varepsilon}{D}. \tag{14}$$

Mannning's Equation The Manning equation, although originally developed for open channel flow, has often been extended for use in pressure conduits. The equation is usually favored for rough textured material (rough concrete, unlike rock tunnels) and cross-sections that are not circular (rectangular, horseshoe). It is most commonly given in the form:

$$v = \frac{1}{N}R^{2/3}S^{1/2}, \tag{15}$$

in which N = roughness coefficient. Equation (15) can also be transformed to:

$$h_f = 19.6N^2\frac{L}{R^{4/3}}\frac{V^2}{2\mathbf{g}}, \tag{16}$$

$$S = \frac{Q^2N^2}{A^2R^{4/3}}. \tag{17}$$

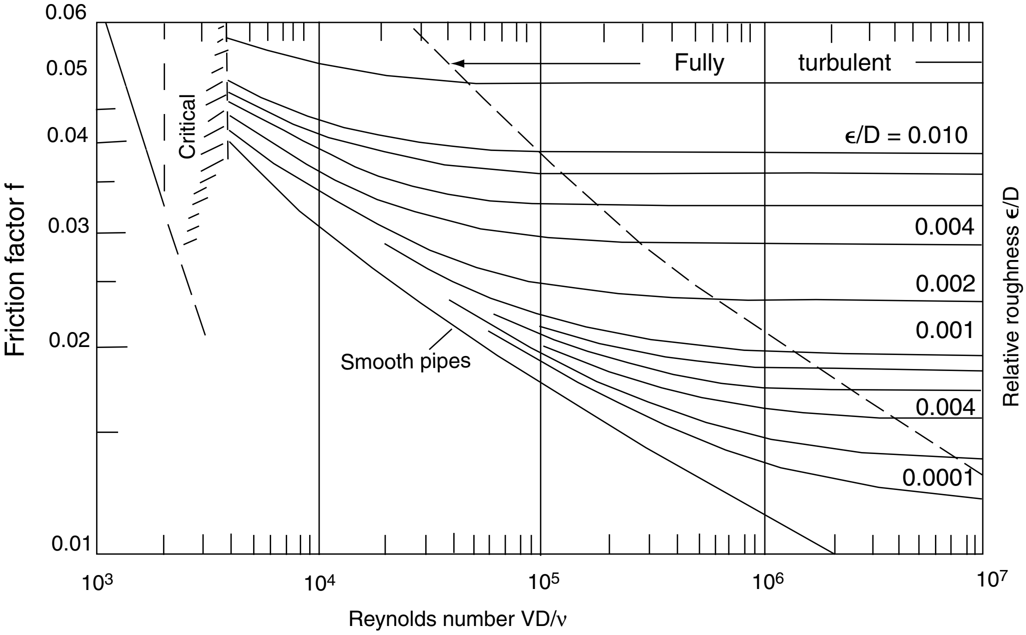

FIGURE 2 Pipe friction factors.

The dimension of the roughness coefficient, N, is frequently taken as $L^{1/6}$ as the equation by itself is not dimensionally homogenous. Table 3 provides values of Manning's N for the more widely used pipe materials.

Hazen-William's Equation This equation is used mainly in sanitary engineering.

$$V = 0.36CR^{0.63}S^{0.54}, \tag{18}$$

where C = roughness coefficient. Typical values of the Hazen-William's C is given in Table 4.

Energy Losses Due to Cross-Sectional Changes, Bends and Valves

Cross-Sectional Changes

Expansion Energy loss in an expansion is principally a form loss:

$$h_{\text{exp}} = \left[1 - \left(\frac{D_1}{D_2}\right)^2\right]^2 \frac{V_1^2}{2\mathbf{g}}, \tag{19}$$

in which D = diameter of the conduit, and subscripts 1 and 2 denote upstream and downstream values. From Eq. (19), if D_2 is very large compared to D_1, such as the discharge into a reservoir, the entire velocity head is lost.

TABLE 3
Normal values of Manning's N

Material	N
Brass	0.010
Corrugated metal	0.024
Glass	0.010
Concrete, unfinished	0.014
Vitrified clay	0.014
Steel	0.012
Cement	0.012
Brick	0.013

TABLE 4
Hazen-William's C

Material (new)	C
Cast iron	130
Welded steel	119
Riveted steel	110
Concrete	130
Wood-stave	120
Vitrified clay	110

Contraction The contraction loss equation can be expressed in terms of the downstream velocity, V_2, as:

$$H_{\text{con}} = \left(\frac{1}{C_c} - 1\right)^2 \frac{V^2}{2\mathbf{g}}. \tag{20}$$

Typical values of the coefficient of contraction, C_c, are given in Table 5.

Entrance Loss The head loss at the entrance of a conduit can be compared to that of a short tube:

$$h_{\text{ent}} = \left(\frac{1}{C^2} - 1\right)\frac{V^2}{2\mathbf{g}} \tag{21}$$

$$h_{\text{ent}} = K_{\text{end}} \frac{V^2}{2\mathbf{g}}, \tag{22}$$

in which C = coefficient of discharge, K = entrance loss coefficient. Typical values of C and K are given in Table 6.

Transition In gradual contractions and expansions, the lead losses are calculated in terms of the difference of velocity heads in the upstream and downstream pipes:

$$\text{Gradual contraction: } h_{tc} = K_{te}\left(\frac{V_2^2}{2\mathbf{g}} - \frac{V_1^2}{2\mathbf{g}}\right), \tag{23}$$

$$\text{Gradual expansion: } h_{tc} = K_{te}\left(\frac{V^2}{2\mathbf{g}} - \frac{V^2}{2\mathbf{g}}\right). \tag{24}$$

K_{tc} values vary from 0.1 to 0.5 for gradual to sudden contractions. Values of K_{tc} range from 0.03 to 0.80 for flare angles of 2° to 60°.

TABLE 5
Coefficient of contraction

A_2/A_1	C_c
0.25	0.64
0.50	0.68
0.75	0.78
1.00	1.00

TABLE 6
Values of C and K_{ent}

Type of entrance	C	K_{ent}
Circular bellmouth	0.98	0.05
Square bellmouth	0.93	0.16
Fully rounded	0.95	0.10
Moderately rounded	0.89	0.25
Sharp cornered	0.82	0.50

Bends The effect of the presence of bends is to induce secondary flow currents which are responsible for the additional energy dissipation:

$$h_b = K_b \frac{V^2}{2\mathbf{g}}. \tag{25}$$

The bend loss coefficient, K_b, depends on the ratio of the bend radius, *r,* to the pipe diameter, *d,* as well as the bend angel. For a 90° bend and *r*/*d* ratio varying from 1 to 12, values of K_b range from 0.20 to 0.07.

Gates and Gate Valves The gate and gate valve loss can be expressed as:

$$h_g = K_g \frac{V^2}{2\mathbf{g}} \tag{26}$$

The value of the loss coefficient, K_g, for gates depends on a variety of factors. The value of K_g for the case having the bottom and sides of the jet suppressed ranges from 0.5 to 1.0. for typical values of K_g for gate valves see Table 7.

TABLE 7

K_g for gate values

Fully open	0.2
$\frac{3}{4}$ open	1.3
$\frac{1}{2}$ open	5.5
$\frac{1}{4}$ open	24.0

Exit Loss In general the entire velocity head is lost at exit and the exit loss coefficient, K_e is unity in the equation:

$$h_e = K_e \frac{V^2}{2\mathbf{g}}. \tag{27}$$

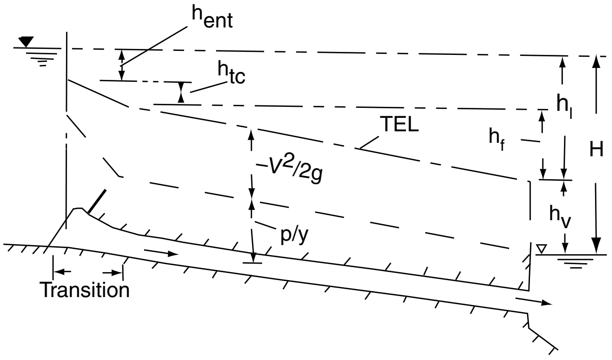

FIGURE 3 Energy relations.

Energy-discharge Relation

In pressure conduit flow, the water is transmitted through a closed boundary conveying structure without a free surface. Figure 3 illustrates graphically the various forms of energy losses which could take place within the conduit. The following energy relation can be written:

$$h_l = h_{\text{ent}} + h_{\text{tc}} + h_f \tag{28}$$

in which h_{end} = entrance loss, h_{tc} = transition loss, h_f = skin friction loss. If *H* denotes the total head required to produce the discharge and h_v represents the existing velocity head,

$$H = h_1 + h_v. \tag{29}$$

Writing Eq. (29) in terms of the velocity heads and their respective loss coefficients,

$$\begin{aligned} H = C_l \frac{V_2^2}{2\mathbf{g}} = \Bigg[& K_{\text{ent}} \frac{V_1^2}{2\mathbf{g}} + K_{\text{tc}} \left(\frac{V_2^2}{2\mathbf{g}} - \frac{V_1^2}{2\mathbf{g}} \right) \\ & + f \frac{LV_2^2}{2\mathbf{g}D_2} + K_v \frac{V_2^2}{2\mathbf{g}} \Bigg], \end{aligned} \tag{30}$$

where K_v = combined velocity head and exit loss coefficient. By the continuity equation:

$$A_1V_1 = A_2V_2 \tag{31}$$

and

$$\frac{V_1^2}{2\mathbf{g}} = \frac{A_2^2}{A_1^2} \frac{V^2}{2\mathbf{g}}.$$

Equation (30) could be expressed as,

$$\begin{aligned} H &= C_l \frac{V_2^2}{2\mathbf{g}} \\ &= \frac{V_2^2}{2\mathbf{g}} \left[K_{\text{ent}} \left(\frac{A_2}{A_1} \right)^2 + K_{\text{tc}} \left(1 - \frac{A_2^2}{A_1^2} \right) + \frac{fL}{2gD_2} + K_v \right] \end{aligned} \tag{32}$$

in which

$$C_l = \left[K_{\text{ent}} \left(\frac{A_2}{A_1} \right)^2 + K_{tc} \left(1 - \frac{A_2^2}{A_1^2} \right) + \frac{fL}{2\mathbf{g}D_2} + K_v \right] \tag{33}$$

$$V_2 = \frac{1}{C_l^{1/2}} \sqrt{2\mathbf{g}H} \tag{34}$$

$$\begin{aligned} Q = A_2V_2 &= \frac{A_2}{C_1^{1/2}} \sqrt{2gH} \\ &= CA_2\sqrt{2\mathbf{g}H}, \end{aligned} \tag{35}$$

in which $C = 1/C_l^{1/2}$ is the discharge coefficient. Equation (35) can be readily extended to multiple conduits in parallel.

Pipe Networks

Introduction The Hardy Cross method is most suitably adapted to the resolution of pipe networks. The statement of the problem resolves itself into:

1) the method of balancing heads is directly applicable if the discharges at inlets and outlets are known,
2) the method of balancing flows is very suitable if the heads at inlets and outlets are known.

It is assumed that:

a) sizes, lengths and roughness of pipes in the system are given,
b) law governing friction loss and flow for each pipe is known,
c) equations for losses in junctions, bends, and other minor losses are known. These relations are most conveniently expressed in terms of equivalent lengths of pipes.

The objectives of the analysis are:

a) to determine the flow distribution in the individual pipes of the network,
b) to compute the pressure elevation heads at the junctions.

In applying the Hardy Cross Method, two sets of conditions have to be satisfied:

a) the total change in pressure head along any closed circuit is zero:

$$\sum H = 0, \tag{36}$$

b) the total discharge arriving at any nodal point equals the total flow leaving it:

$$\sum Q = 0. \tag{37}$$

For the pressure head change in any closed path, the clockwise positive sign convention is used.

For the discharge continuity requirement at a nodal point, the inward flow positive sign convention is adopted.

The friction head loss equation is used in the form:

$$H = rQ^2. \tag{38}$$

Using Darcy's formula:

$$H = \frac{fLV^2}{2\mathbf{g}D} = \left(\frac{8fL}{\mathbf{g}\pi^2 D^5}\right)Q_2$$

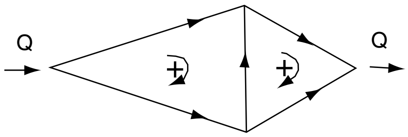

FIGURE 4 Pipe network.

and

$$r = \frac{8fL}{\mathbf{g}\pi^2 D^5}.$$

Method of Balancing Heads Based on the condition required by Eq. (36), the following equations for any closed pipe loop results (Figure 4):

$$\sum H = \sum r(Q_0 + \Delta Q)^2 = 0, \tag{39}$$

where Q_0 = assumed flow in the circuit for any one pipe, ΔQ = required flow correction. Expanding Eq. (39) and approximating by retaining only the first two terms, the flow correction ΔQ, can be expressed as:

$$\Delta Q = \frac{-\sum rQ_0^2}{\sum 2rQ_0}. \tag{40}$$

Method of Balancing Flows Utilising the continuity requirement at a pipe junction as given by Eq. (37), the head correction, ΔH, at anodal point is given by the equation:

$$\Delta H = \frac{\sum \left(\frac{H}{r}\right)^{1/2}}{\sum \frac{1}{2H}\left(\frac{H}{r}\right)^{1/2}}. \tag{41}$$

In both Eq. (40) and (41), the proper sign conventions must be used in the numerators.

OPEN CHANNEL FLOW

Introduction

Open channel flow refers to that class of water discharge in which the water flows with a free surface. The stream flow is said to be *steady* if the discharge does not vary with time. If the discharge is time dependent, the water flow is termed *unsteady. Uniform* flow refers to the case in which the mean velocities at any cross-section of the stream are identical; if these mean velocities vary from one cross-section to another, the flow is considered *non-uniform.* Steady uniform flow requires the conveyance section of the stream channel to be prismatic. Where the water surface profile is controlled principally by channel friction, this phenomenon is known as *gradually varied flow.* For the type of flow in which the water surface changes substantially within a very short channel length due to a sudden variation in bed slope or cross-section, this category is referred to as *rapidly varied flow.*

Open channels fabricated from concrete are often rectangular or trapezoidal in shape. Canals excavated in erodible material have trapezoidal cross-sections. Although sewer pipes are closed sections, they are still considered as open channels so long as they are not flowing full; these cross-sections are usually circular.

Channel Friction Equation

The most widely used open channel friction formula is the Manning equation as mentioned earlier in pressure flow:

$$Q = \frac{1}{N} A R^{2/3} S^{1/2} \tag{42}$$

$$S = \frac{Q^2 N^2}{A^2 R^{4/3}}. \tag{17}$$

Manning's equation in hydraulic engineering is used for fully turbulent flow and, as such, the values of Manning's N apply to this flow regime.

In a natural tortuous stream channel, the mean value of Manning's N can be obtained from the following considerations:

1) estimate an equivalent basic N_s, for a straight channel of that material,
2) select modifying values of N_m for non-uniform roughness, irregularity, variation in shape of cross-section, vegetation, and meandering,
3) sum the basic, N_s together with the modifying values to obtain the total mean N.

TABLE 8
Values of Manning's N

Basic N_S for straight channels	
Type of channel	N_s
Earth	0.010
Sand	0.012
Fine gravel	0.014
Rock	0.015
Coarse gravel	0.028
Cobbles and boulders	0.040
Modifying values of N_m	N_s
Irregularity	0.005 to 0.020
Changes in shape	0.005 to 0.020
Vegetation	0.005 to 0.100
Meander	0.10 N_s to 0.40 N_s

Normal values of Manning's N for straight channels and various modifying values are given in Table 8. The total mean N value for the channel is obtained from the relation:

$$N = N_s + \sum N_m. \tag{43}$$

Energy Principles

In deriving the energy relationships for open channel flow, the following assumptions are normally used:

1) a uniform velocity distribution over the cross-section is assumed, that is, the velocity coefficient, α, in the velocity head term, $\alpha V^2/2\mathbf{g}$, is taken as unity. In practice, the value of α depends on the shape of the stream channel and has an average value of about 1.02 which makes this assumption sufficiently valid.
2) streamlines are essentially parallel,
3) channel slopes are small.

Consider the water particle of mass, m, and of weight, W (Figure 5). The elevation and pressure energies of the particle are Wh_1; and Wh_2 respectively. Thus, the potential energy of the water particles is, $W(h_1 + h_2)$ and is independent of its elevation over the flow cross-section. As the kinetic energy is $WV^2/2\mathbf{g}$ the total energy of the water particles, e is:

$$e = W\left(h_1 + h_2 + \frac{V^2}{2\mathbf{g}}\right). \tag{44}$$

$$Z + D = h_1 + h_2 \tag{45}$$

and noting that the total flow passing the cross-section is γQ the total energy of the water passing the cross-section per second, E_t is given by:

$$E_t = \gamma Q\left(Z + D + \frac{V^2}{2\mathbf{g}}\right). \tag{46}$$

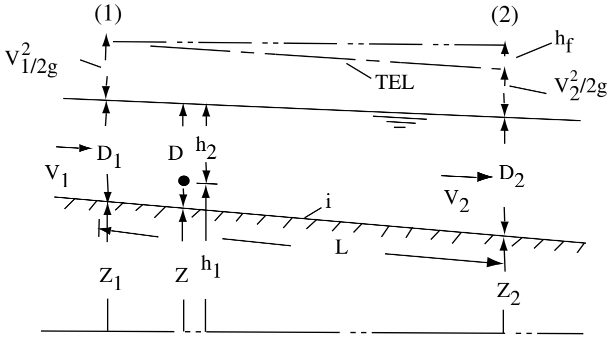

FIGURE 5 Energy principles.

Thus, the energy per unit weight of water passing the cross-section per second, *H* is:

$$H + Z + D + \frac{V^2}{2\mathbf{g}}. \tag{47}$$

The term, $z + D + V^2/2\mathbf{g}$ is known as the total head or total energy level (TEL); the latter name is used here. The slope of the total energy level line is the energy gradient or friction slope and gives the rate of energy dissipation in the flow.

The energies at Sections 1 and 2 are related by the expression:

$$z_1 + D_1 + \frac{V_1^2}{2\mathbf{g}} = Z_2 + D_2 + \frac{V_2^2}{2\mathbf{g}} + \frac{Q^2N^2}{A^2R^4} \tag{48}$$

in which the Manning equation is used to calculate the friction slope and the mean values for the flow area, *A,* and the hydraulic radius, *R,* are to be used.

Flow Regimes

Critical Flow The specific energy, *E,* is defined as the total head referred to the channel bottom (Figure 6):

$$E = D + \frac{Q^1}{2\mathbf{g}A^2}. \tag{49}$$

Differentiating Eq. (47) with respect to *D* and equating the derivative to zero to obtain its minimum value,

$$\frac{dE}{dD} = 1 - \frac{Q^2}{\mathbf{g}A^3}\frac{dA}{dD} = 0. \tag{50}$$

Noting that $dA = TdD$, Eq. (50) becomes:

$$\frac{Q^2}{\mathbf{g}} = \frac{A^3}{T}. \tag{51}$$

Equation (51) is the fundamental equation for critical flow and is applicable to all shapes of cross-sections.

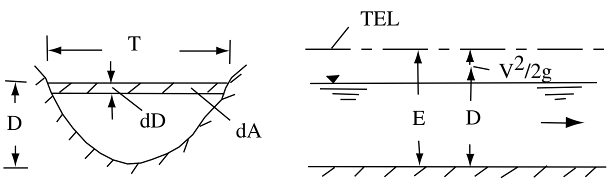

FIGURE 6 Derivation of critical flow.

If the mean depth of the flow section is defined as $D_m = A/T$, substitution of this relation into Eq. (49) would give the significant expressions:

$$\frac{V_c^2}{2\mathbf{g}} = \frac{D_m}{2} \tag{52}$$

and

$$\frac{V_c}{\sqrt{\mathbf{g}D_m}} = 1. \tag{53}$$

At critical flow, Eq. (52) demonstrates that the velocity head equals one-half the mean depth and Eq. (53) indicates that the Froude number equals unity.

Specific Energy Diagram for Rectangular Channel For a rectangular channel, $Q = qB$ in which q = discharge per unit width, B = channel width, and Eq. (49) becomes,

$$E = D + \frac{q^2}{2\mathbf{g}D^2}. \tag{54}$$

A plot of Eq. (54) for any given constant unit discharge gives Figure 7, which is known as the *specific energy diagram.* The

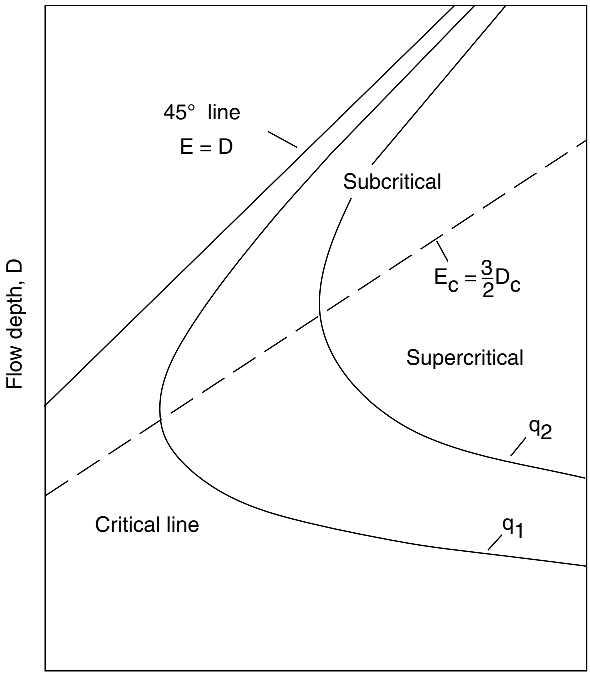

FIGURE 7 Specific energy diagram.

following flow regimes could be defined with reference to the specific energy diagram.

Subcritical flow denotes tranquil flow in which the Froude number and the mean velocity are less than unity and the celerity of the gravity wave respectively.

Critical flow represents the discharge phenomenon where: (1) for a constant specific energy, the discharge is a maximum; (2) the specific energy is a minimum for a constant discharge; (3) the critical velocity equals the celerity of a small gravity wave; (4) the Froude number equals unity; (5) the critical depth is also the depth of minimum pressure-momentum force.

Supercritical flow which is also known as shooting or rapid flow, is that state of water flow where the Froude number and mean velocity exceed unity and the speed of transmission of a surface wave respectively.

Based on the equations developed earlier for critical flow, particular formulae can be derived for a rectangular section:

$$D_c = \left(\frac{q_c}{\mathbf{g}}\right)^{1/3} \tag{55}$$

$$D_c = \frac{2}{3}(E_c) \tag{56}$$

$$D_c = \frac{V_c^2}{\mathbf{g}} \tag{57}$$

$$\frac{V_c}{\sqrt{\mathbf{g}D_c}} = 1. \tag{58}$$

Flow Transition The concept of the *normal depth* is an important parameter in the study of flow transition. For a given channel and any fixed discharge, uniform flow will occur at one unique depth. It is the depth attained in a long channel when the component of gravity force is just balanced by the frictional resistance of the channel.

When the normal and critical depth are equal, the flow is critical and the bed and energy slopes are the same. The channel bed then has a *critical slope.* The bed slope is termed *mild* when the normal depth exceeds the critical depth; the bed slope is then less than the critical energy slope and the flow regime is subcritical. When the normal depth lies below the critical depth and, hence, the bed slope is greater than the critical energy slope, the channel slope is considered to be *steep* and the supercritical flow regime prevails.

When water makes a transition from a channel with a mild slope to another with a steep slope, or vice versa, the flow passes through the critical depth close to the junction of the two channels. The section in which the water depth is critical defines a channel control. The weir acts as a control when water flows over it as critical depth is attained there.

Hydraulic Jump A hydraulic jump occurs when supercritical flow makes a transition to subcritical flow. A common occurrence of a hydraulic jump takes place at the base of a chute spillway. Figure 8 shows the energy momentum and depth relations for a hydraulic jump and also defines the symbols to be used.

In developing the equations for the hydraulic jump, the following assumptions are used:

1) the bed slope is considered small and neglected,
2) frictional resistance along the bed and sides of the channel are omitted.

Consider the control volume between Sections (1) and (2). Applying the impulse-momentum principle:

$$F_1 - F_2 = \frac{\gamma}{\mathbf{g}}Q(V_2 - V_1) \tag{59}$$

or

$$F_1 + \frac{\gamma}{\mathbf{g}}QV_1 = F_2 + \frac{\gamma}{\mathbf{g}}QV_2 \tag{60}$$

in which F_1 and F_1 denote the hydrostatic forces at sections 1 and 2 respectively. The term $(F + \gamma/\mathbf{g}QV)$ is given the name pressure-momentum force. Let A = flow area, $\bar{y}$ = distance of centroid of flow area from surface; then they hydrostatic force = $\gamma A\bar{y}$ and Eq. (60) can be written as:

$$A_1\bar{y}_1 + \frac{Q^2}{\mathbf{g}A_1} = A_2\bar{y}_1 + \frac{Q^2}{\mathbf{g}A_2}. \tag{61}$$

Equation (60) states the condition for the formation of a hydraulic jump and suggests a graphical solution. A plot of Eq. (60) for any fixed discharge is shown in Figure 8. For any given up-stream supercritical water depth, which is usually known such as at the toe of a spillway, the subcritical hydraulic jump depth or *sequent* depth can be obtained from the graph.

For a rectangular cross-section channel and utilising the continuity relation:

$$Q = V_1A_1 = V_2A_2. \tag{62}$$

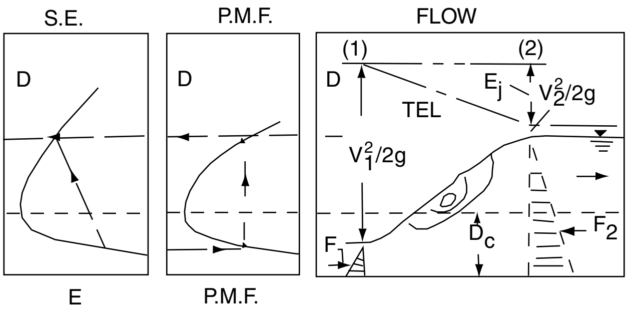

FIGURE 8 Hydraulic jump relations.

Equation (6) can be written as:

$$\frac{D_2}{D_1} = \frac{1}{2}(\sqrt{1+8F_1^2}-1), \tag{63}$$

where $F_1 = V_1/\sqrt{(\mathbf{g}D_1)}$ is the upstream Froude number.

The energy loss E_j across the hydraulic jump on a horizontal floor can be obtained by coming Eqs. (61), (62) and the energy equation:

$$D_1 + \frac{V_1^2}{2\mathbf{g}} = D_2 + \frac{V_2^2}{2\mathbf{g}} + E_j \tag{64}$$

to give:

$$E_j = \frac{(D_2 - D_1)^3}{4D_1D_2}. \tag{65}$$

The head loss E_j is graphically shown in the specific energy and flow diagrams (Figure 8).

Surface Water Profiles

Non-uniform Differential Equation Using the notation given in Figure 9, the energy relations can be expressed as:

$$iL + D + \frac{V^2}{2\mathbf{g}} = S\mathrm{d}L + (D + \mathrm{d}D) + \left(\frac{V^2}{2\mathbf{g}} + \mathrm{d}\frac{V^2}{2\mathbf{g}}\right) \tag{66}$$

$$\mathrm{d}L = \frac{\mathrm{d}(D + V^2/2\mathbf{g})}{(i - S)} \tag{67}$$

$$\frac{\mathrm{d}E}{\mathrm{d}L} = (i - S). \tag{68}$$

For a finite length, ΔL, Eq. (67) becomes:

$$\begin{aligned}\Delta L &= (L_2 - L_1)\\ &= \left(\frac{(D_1 + V_1^2/2\mathbf{g}) - (D_2 + V_2^2/2\mathbf{g})}{i - Q^2N^2/A^2R^{4/3}}\right),\end{aligned} \tag{69}$$

where the Manning equation is used to calculate the energy slope. Flow computation must start at a control section where all the flow parameters are known. The calculation proceeds upstream for subcritical and downstream for supercritical flow. In Eq. (69), the solution of the reach length, ΔL, is direct if the immediately upstream depth, D_2, is given a value. If ΔL is given a value, D_2 has to be solved by trial. This method of computing surface water profiles is suitable for regular channels.

Classification of Flow Profiles Twelve distinct types of non-uniform profiles have been systematically classified (Figure 10).

1) Firstly, the curves are identified according to bed slopes as mild (M), steep (S), horizontal (H), critical (C) and adverse (A).
2) Secondly, numbers are assigned to flow regions. The numerical 1 refers to actual flow depths exceeding both critical (D_c) *and normal* (D) depths. For flow depths less than both critical and normal, the number 3 is affixed to it. The numeral 2 is for depths intermediate between critical and normal.

Water Profiles in Irregular Channels The river channel has to be divided into panels (Figure 11) with the side panels conveying overbank flow. Let Q = total flow, Q_c = central channel discharge, Q_l = left overbank flow,

Q_r = right overbank flow. The continuity condition requires that:

$$Q = Q_c + Q_l + Q_r, \tag{70}$$

By Manning's Equation:

$$Q = \frac{1}{N_c}A_cR_c^{2/3}S^{1/2} + \frac{1}{N_l}A_lR^{2/3}S^{1/2} + \frac{1}{N_r}A_rR_r^{2/3}S^{1/2}. \tag{71}$$

The energy slope, S, has been taken as the same for Q_c, Q_l, Q_r; this assumption seemed to be justified in practice. Due to different channel roughness, vegetative and other obstructions, Manning's N for the three flow panels would

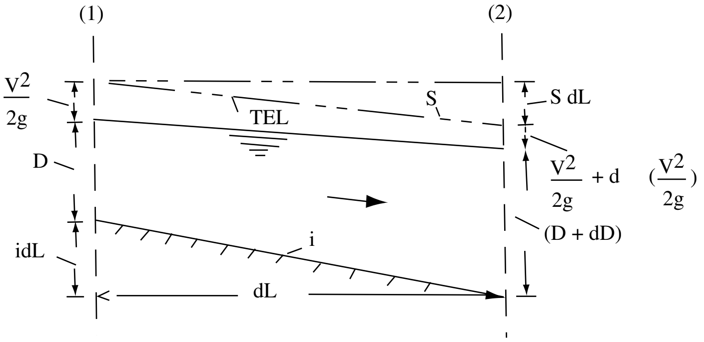

FIGURE 9 Non-uniform flow derivation.

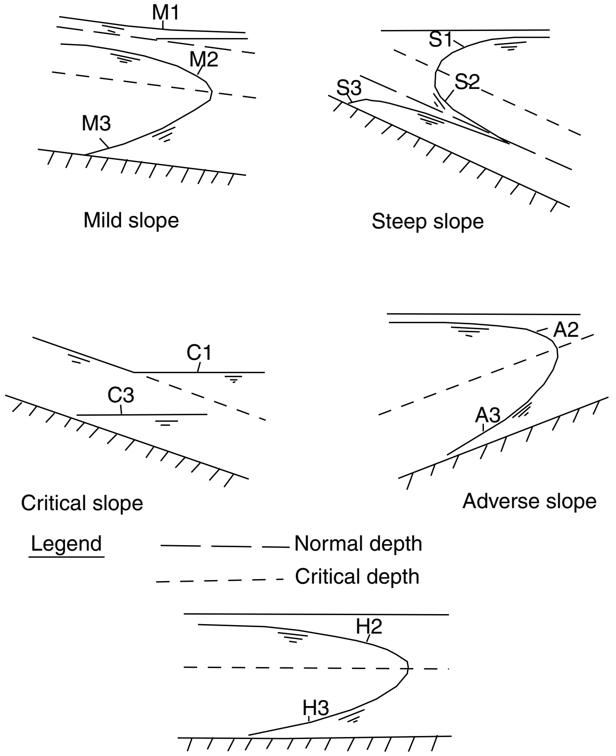

FIGURE 10 Surface water profiles.

not have the same values. As the energy gradient, S, is common to the panels in Eq. (71), water level versus energy slope curves can be plotted for any selected discharge for water level computations. The energy equation for the step method of surface profile calculation can conveniently be written in the form:

$$WL_2 + \frac{1}{2\mathbf{g}}\frac{Q^2}{A_2^2} = WL_1 + \frac{1}{2\mathbf{g}}\frac{Q^2}{A_1^2} + \bar{S}L_{1,2}. \tag{72}$$

If in practice, the change in kinetic head, $(Q^2/2\mathbf{g}A_2^2 - Q^2/2\mathbf{g}\,A_1^2)$ is small and could be removed from Eq. (72), this would greatly simplify the work. In determining the wetted perimeter for the calculation of the hydraulic radius, only the water-channel contact lines are relevant and the water-water contact lines between panels are excluded.

FLOW IN ERODIBLE CHANNELS

Introduction

Flow in erodible channels can be divided into two types, namely, canal and river flows. Blench describes canal flow as possessing there degrees of freedom due to its ability to adjust itself with respect to its flow depth, bed slope, and side widths which are taken to be the dependent variables. River flow, in addition to having the three degrees of freedom of canals, has a fourth degree by virtue of its ability to meander.

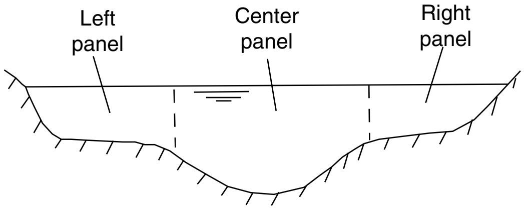

FIGURE 11 River channel division.

It is assumed that constant maintenance of canals suppresses the canal's tendency to meander. The water-sediment flow is usually regarded as the independent parameter.

In the concept of flow in mobile channels where the transport of sediment is an integral part of the system, two philosophies have emerged. Based on the work of Lindley (1919), Lacey (1952), Inglis (1949), and Blench (1953, 1966) in India and Pakistan, the regime theory has evolved. On the other hand, the United States Bureau of Reclamation under the direction of Lane (1952, 1953) developed the tractive force method.

Regime Theory for Canals

The regime theory postulates that for given water-sediment flow and bed material, there exists a regime channel which determines uniquely the flow area, cross-sectional shape and bed slope. The regime channel is considered a stable channel which on the average will neither silt nor scour. The flow occupying the regime channel is the dominant discharge and it is also variously referred to as the formative, regime, or bank-full discharge.

Lacey's Equations Based on extensive flow observations of the canals in India, Lacey (1952) proposed a set of formulae for alluvial channels with sandy mobile beds with the discharge ranging from 25 cfs to 2500 cfs, the bed material size varying from 0.2 mm to 0.6 mm and with the quantity of solids conveyed being less than 50 ppm:

Wetted perimeter: $$P = 2.67\,Q^{1/2} \tag{73}$$

Flow area: $$A = \frac{1.25Q^{5/6}}{f^{1/3}} \tag{74}$$

Bed slope: $$S = \frac{0.0054f^{5/3}}{Q^{1/6}} \tag{75}$$

Silt factor: $$f = 8d_{\text{inch}}^{1/2}. \tag{76}$$

From the above equations, the following two equations can be derived:

Mean velocity: $$V = 0.895_r^{1/6}Q^{1/6}$$

TABLE 9
Values of the bed factor

Material	$(F_s)_{\max}$	Remarks
Very sandy loam banks	0.1	Erosion if > $(F_s)_{\max}$
Silty clay loam	0.2	Erosion if > $(F_s)_{\max}$
Very cohesive banks	0.3	Erosion if > $(F_s)_{\max}$

Flow depth:
$$D = \frac{0.473Q^{1/3}}{f^{1/3}}. \tag{77}$$

Blench's Equations Blench (1953, 1966), using the concept that canals possessing three degrees of freedom must, therefore, have three basic equations to describe their motion, presented the stream equations for small bed load as:

$$V^2 D = F_b \tag{78}$$

$$\frac{V^2}{B} = F_s \tag{79}$$

$$\frac{V^2}{\mathbf{g}DS} = 3.63(VB/v)^{1/4}. \tag{80}$$

In Eq. 78, F_b is bed factor and the equation itself expresses the statement that channels with similar water-sediment flows tend towards the same Froude number in relation to a suitable depth. Equation (79) describes the scouring action on the hydraulically smooth sides and defines the side Factor, F_s. The dissipation of energy per unit mass of water per unit time in the channel is given by Eq. (80) in which S is the energy gradient.

For appreciable bed load, Eq. (80) becomes:

$$\frac{V^2}{\mathbf{g}DS} = 3.63\left(1+\frac{C}{233}\right)\left(\frac{VB}{v}\right)^{1/4}, \tag{81}$$

where C is the bed load charge in parts per hundred thousand by weight of fluid discharge.

The bed factor, F_b, for sand of subcritical flow is given by the empirical equations:

$$F_b = F_{b0}(1+0.12C) \tag{82}$$

$$F_{b0} = 1.9\sqrt{d_{mm}} \tag{83}$$

in which F_{b0} = zero bed factor and is the value of F_b when C tends to zero, d_{mm} = median bed material size by weight in millimeter. As a guide to the value of the side factor, F_s, the following table has been suggested by Blench (1966).

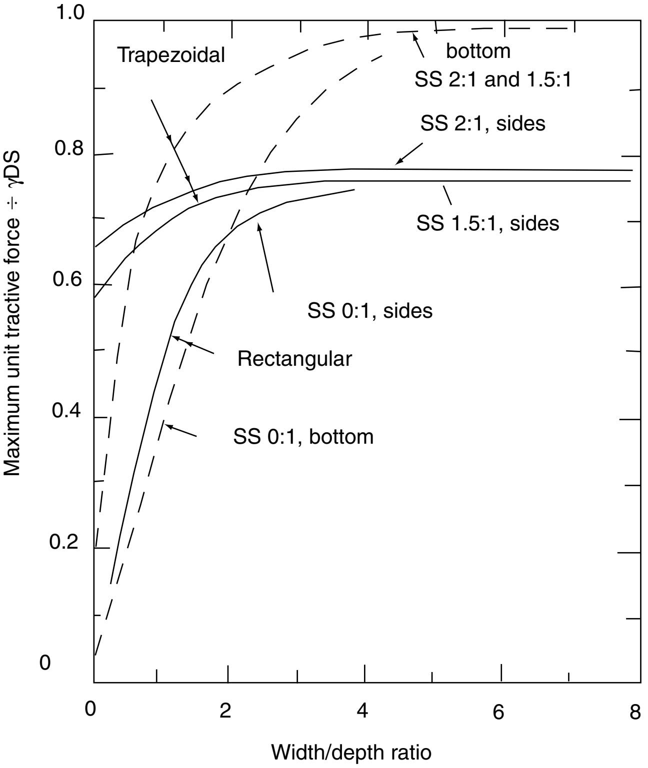

FIGURE 12 Maximum tractive force.

Tractive Force Method for Canals

Unit Tractive Force The stability of an erodible channel depends on (a) the resistance of the material lining the bottom and sides against the erosive force of the stream and (b) the ability of the stream to transport the sediment load without giving rise to significant deposition.

The shear or drag force exerted by the water on the bed and sides of the channel is termed the tractive force. The average unit tractive force, τ, in uniform flow is the component of the gravity force acting on the water parallel to the channel bottom per unit area, thus:

$$\tau = \gamma RS. \tag{84}$$

For wide channels, the flow depth can replace the hydraulic radius:

$$\tau = \gamma DS. \tag{85}$$

The distribution of tractive force has been investigated by the United States Bureau of Reclamation (Lane, 1952; 1953, Olsen and Florey, 1951, 1952). The maximum values of the unit tractive force for the bottom and sides of rectangular and trapezoidal cross-sections are given in Figure 12.

Tractive Force Ratio A soil particle of effective area, A_e, resting on the side of a channel is acted on by the tractive

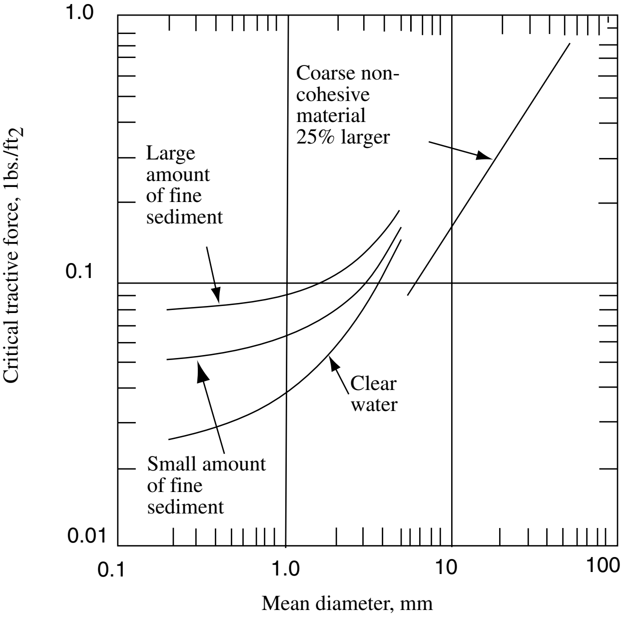

FIGURE 13 Critical tractive force for canals.

force, $A_e\tau_s$, in the direction of the flow and the gravity force component, $W_s \sin\varphi$ which attempts to cause the particle to roll down the side slope, where τ_s = unit tractive force on the side of the channel, W_s = submerged weight of the particle, φ = angle of the channel side. The resultant of these two forces, F, is:

$$F = (W_s^2 \sin^2\varphi + A_c^2\tau_s^2)^{1/2}. \qquad (86)$$

The motion of the article is resisted by its frictional force (R):

$$R = W_s \cos\varphi \tan\theta, \qquad (87)$$

where tan θ is the coefficient of friction and θ is the angle of repose of the material.

Equating Eq. (86) and (87) for the condition of impending motion and solving for τ_s:

$$\tau_s = \frac{W_r}{A_e}\cos\varphi\tan\theta\left(1-\frac{\tan^2\varphi}{\tan^2\theta}\right). \qquad (88)$$

A similar equation can be written for the case of a particle on a level bed when motion is impending, thus:

$$\tau_l = \frac{W_r}{A_e}\tan q, \qquad (89)$$

where τ_1 denotes the unit tractive force on the level bed.

The tractive force ratio, K, is defined as, τ_s/τ_l is obtained by dividing Eq. (87) to Eq. (88) and simplifying:

$$K = (1-\sin^2\varphi/\sin^2\theta)^{1/2}. \qquad (90)$$

From Eq. (89) it can be seen that the tractive force ratio, K is a function of the side slope and angle of repose of the material only.

Critical Tractive Force The permissible tractive force is the maximum unit tractive force that will not cause significant scour of the material lining the channel bed on a level surface. It is often found from laboratory observations and is known as the critical tractive force. It is influenced by the amount of organic matter and fine suspended sediment in the water. The effect of the fine sediment is to increase the allowable critical tractive force. Figure 13 shows curves of permissible tractive forces as recommended by the United States Bureau of Reclamation.

River Engineering

In river flows, a greater number and range of factors have to be considered in addition to those parameters used in the analysis of canals. These variables include bigger size bed materials, large suspended and bed sediment loads, unsteady and a wide variation of flood flows, meandering and braiding, large changes in stream channel cross-sections, obstructions to flow, and other factors involved. An analysis of river engineering is, therefore, beyond the scope of this chapter. Readers are recommended to consult the works of Blench (1966), Shen (1971, 1972), Inglis (1949) and Leopold, Wolman and Miller (1964). More specialized treatment of sediment transport, bedforms and stream geometry can be found in the publications of Einstein (1972), Leopold and Maddock (1953), Richardson and Simons (1967), Yalin (1971), Kennedy (1963), Christensen (1972), and Ackers (1964). Standard texts which cover the subject more formally include those of Graf (1971), Henderson (1966), Raudkivi (1967) and Leliavsky (1955).

FLOW WITH AN ICE COVER

A river flowing with an ice cover has, in addition to the bed and side frictional forces, the shear resistance imposed by a buoyant boundary represented by the floating ice cover. Chee and Haggag (1984) have developed equations concerning floating boundary stream flow which are reproduced here. The essential concepts and assumptions are first discussed.

A channel with a buoyant cover can be divided into two subsections as shown in Figure 14. The flow in subsection (1) is influenced by the bed and sides while subsection (2) is controlled by the cover. The two subsections are divided by a separation surface which represents the locus of no shear and maximum velocity. The equations of energy, continuity,

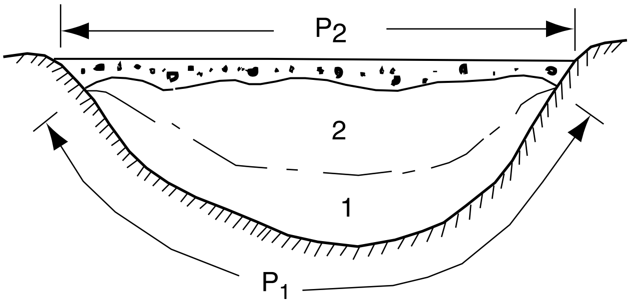

FIGURE 14 Ice covered channel.

and momentum are applicable to each subsection individually as well as to the entire channel cross-section.

Composite Roughness Equation

The Reynolds form of the Navier-Stokes equation was used to develop the shear distribution and the velocity profile was obtained using the Prandtl-von Karman mixing length theory. In addition, a channel momentum equation and the flow resistance formula of Manning were utilised to derive the relationship for the division surface separating the two flow subsections as

$$(0.66)\frac{R^{1/6}}{N_q \mathbf{g}^{1/2}} = \frac{(\lambda^{1/2}-1)}{1-N_1/N_2\lambda^{2/3}}\left[\alpha+(1-\alpha)\lambda\right]^{1/6} \qquad (91)$$

in which R = hydraulic radius of entire channel, N_1, N_2 = Manning's roughness for the bed and cover respectively, $\mathbf{g}$ = acceleration due to gravity, $\lambda = R_1/R_2$ is hydraulic radius ratio of the bed subsection to the cover subsection, $\alpha = P_1/P$ is the wetted perimeter ratio of the entire channel to the bed subsection. The division surface is found by solving for λ using Eq. (91).

The complete roughness, N, of an ice-covered channel is given by

$$\frac{N_1}{N} = \left[1+(1-\alpha)\lambda\right]^{-5/3}\left[\alpha+(1-\alpha)\frac{N_1}{N_2}\lambda^{5/3}\right]. \qquad (92)$$

WATER: PROPERTIES, STRUCTURE, AND OCCURRENCE IN NATURE

THE CYCLE OF WATER

The Origin of the Hydrosphere

The assumption that the elemental composition originally present in all regions of the solar system was similar to that currently present in the sun furnishes a paradox in the marked deficiency of the unreactive noble gases, such as neon and argon, on the planet earth. Thus it is assumed that these gases, as well as those of comparable molecular weight such as water, nitrogen, oxygen, and carbon dioxide, escaped from the earth's surface before the planet cooled down. Thus the accumulation of the water necessary to form the hydrosphere by condensation of any primordial envelope of steam is inconsistent with the conditions of the primitive earth.

Rather, degassing, after the formation of the earth, is considered to be the mechanism through which the "excess volatiles" of water, nitrogen, chlorine, and so on accumulated on the earth's surface. According to Rubey, if only 1% of the water emerging from hot springs and related phenomena is truly juvenile water, then this process would have been sufficient to produce the oceans and hence the hydrosphere.

The Hydrologic Cycle and Solar Energy

The dynamic equilibrium or steady state existing between evaporation, precipitation, percolation, and runoff comprises the hydrologic cycle.

Except for the small amount of radioactive energy and heat transfer from within the earth, the sun provides the energy to run this complex cycle by evaporating surface water and heating the humid air, which then results in stirring of the weather systems. Four-fifths of the solar energy radiating toward the earth actually reaches the earth's surface. This incoming energy totals 1.6×10^{18} watts, about one-third of which recharges the hydrologic cycle by vaporization. Under normal conditions it requires about 540 calories per gram to evaporate water.

Evaporation

Of the 3.61×10^{20} grams per year evaporated from the sea, approximately 90% is returned directly to the ocean in the various forms of precipitation. The remaining 10% is transported in the atmosphere and eventually released on the land masses, as illustrated in Figure 1.

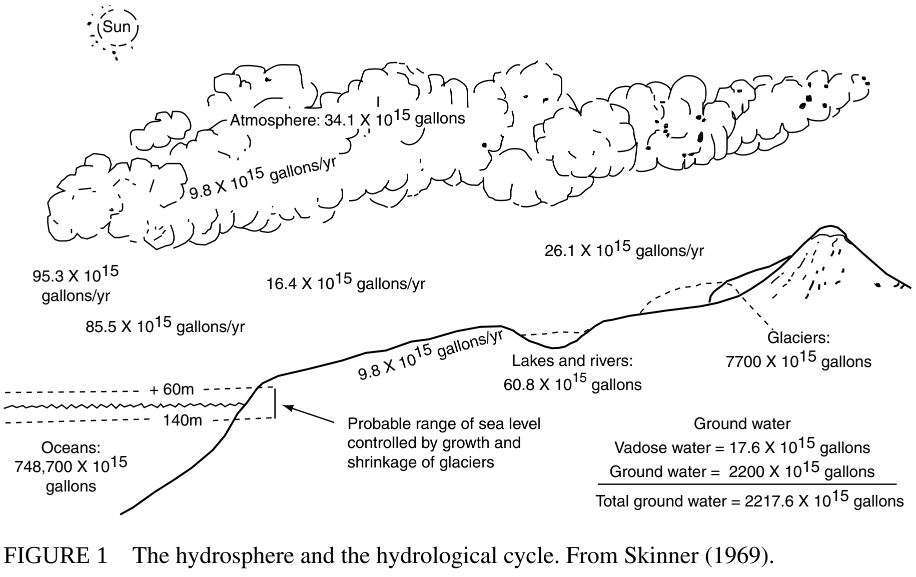

FIGURE 1 The hydrosphere and the hydrological cycle. From Skinner (1969).

Evaporation from the land, 6.21×10^{19} gms per year, is dependent on the soil and climatic conditions. It is strongly influenced by the relative humidity. For a given atmospheric water content, the relative humidity increases and the evaporation decreases as the temperature falls. Wind enhances evaporation by continually removing the vaporized water and thus locally lowering the relative humidity. With all other factors equal, sea water containing 3.5% salts will evaporate 3.5% more slowly than fresh water. Barometric pressure has little direct effect on the rates of evaporation.

Transpiration

Water loss from land is enhanced by the transpiration process by which plants and other photosynthetic organisms draw solutions containing essential growth nutrients from the soil to provide for maintenance and growth. The excess fluid is exuded to the atmosphere through the mesophyll cells. From 97 to 99% of the water which enters plants from soil is lost by evaporation from the leaves. The amount of dry matter produced in graphs per 1000 grams of water transpired is called the transpiration efficiency. Odum has estimated typical efficiencies to be 2 or less, with drought-resistant crops such as sorghum and millet having only slightly higher values. An acre of red maple trees in a soil with ample moisture may lose water sufficient to cover the acre with 0.7 meter of water during a single growing season. Transpiration is also affected by the factors governing evaporation, as well as light and soil conditions.

Atmospheric Water

The water in the atmosphere amounts to 1.29×10^{19} grams or approximately one-tenth of that in all fresh water lakes and is responsible for the pressure differences which create weather. It has been estimated that without this atmospheric water blanket, radiational cooling would reduce the earth's average surface temperature from 15°C to about 0°C. Low humidity desert environments often experience temperatures of 65°C during the day and below freezing at night. Under ordinary conditions the water vapor in the air allows only 20% of the earth's surface heat to radiate back through the atmosphere directly. As previously mentioned it is through the atmosphere that fresh water evaporated from the sea is transported over the global land masses.

Precipitation

Precipitation of atmospheric moisture occurs only when the temperature of an air mass is lowered to or below the point of saturation, the dew point. Air temperature is lowered by combinations of the following phenomena:

1) heat loss by infrared radiation,
2) adiabatic cooling as large air masses expand under reduced pressure after they have risen or been lifted to higher altitudes and
3) temperature decrease due to mixing with cooler air masses.

During the condensation of water the heat of vaporization, 540 cals. per gram is released. Various mechanisms of coalescence account for the different forms of precipitation such as rain, snow, hail and sleet. Condensation at ground level is responsible for the formation of dew, frost, and rime or hoarfrost.

The unequal worldwide distribution of precipitation, which varies from 0 to 10 meters per year, is determined to a large extent by the movement of large air masses or weather systems as directed by the profiles of mountain ranges.

The total precipitation, its annual distribution and the balance between precipitation and evapo-transpiration are the chief limiting factors that determine the resulting climax biotic communities for terrestrial ecosystems. The following average annual precipitations are general biotic determinants: 0 to 10 inches, deserts; 10 to 30 inches, grass lands, savanna or open woodland; 30 to 50 inches, dry forest; and greater than 50 inches, wet forest. Thus, the supply of water not only severely limits man's own agricultural, domestic and industrial activities but also dictates the products of nature. As ecologists have pointed out, the availability of water, more than any other factor, determines the ultimate population of a geographic province.

The influence on the earth is affected not only by the quantity of water which reaches the land masses from the sea but also by the natural processes which follow. Some precipitation is intercepted directly by the flora and soon evaporates. Some rainfall may never reach the ground. For example, in hot deserts rain on its downward flight through warm dry air often completely re-evaporates.

Runoff and Ground Water

Precipitation reaching the surface at rates greater than those of infiltration, evaporation and surface retention, will flow overland in drainage systems which may eventually reach the sea. This overflow is termed runoff. Although the 8.33×10^{21} grams of ground water which exists is a massive quantity, it moves too slowly to act as a significant transport process in the over-all hydrologic cycle. In fact, rapid withdrawal from the ground at a given site can cause serious local depletion.

Water from the hydrocycle which infiltrates into the ground water systems extracts soluble mineral matter from soil, sand and rock. According to King, "Water partakes of and is conditioned by the character of the land on which it falls, and through which it flows."

Hydrologic Weathering

These surface and subsurface waters weather natural geologic formations through physical, chemical and biological means. Physical weathering of formations is the initial mechanical weathering action which, through cycles of freezing and thawing, mechanical stress reversals, and swelling and contracting, exposes rock and mineral surfaces to chemical weathering processes.

Chemical weathering results from changes in the chemical environments surrounding the minerals; i.e., from environments conducive to their formation to those in which they are no longer thermodynamically stable. Specifically, these are chemical conditions which subject the minerals to hydrolysis, oxidation, and reaction with aqueous carbon dioxide. The minerals also react with weak organic acids, which can be considered biological weathering, since these acids result from the microbially mediated decay of biomass. Whereas surface runoff streams erode, transport and eventually deposit much of their suspended weathering products in river beds on the ocean, the dissolved species generally remain in solution.

Global Ice

Most of the earth's fresh water exists as ice in glaciers and in ice sheets, which together comprise about 2% of the earth's total water and which cover about 10% of the earth's land masses with thicknesses of up to several thousand feet. These solid forms may well be the most potent of the agencies that have changed and shaped the surface of the earth, according to King. Their mass causes the land to sink and their physical force performs erosion, transport, and deposition of mineral matter.

Ocean Currents

Water eventually returns to the sea with the wastes of nature such as dissolved minerals and suspended matter and, ever more significantly, also the wastes of man. To the sea belongs 97% of the planet's water. The sea is not a stagnant reservoir; instead it contains large "rivers" such as the Gulf Stream, which convey huge masses of water and perhaps more important great quantities of heat. For example, if the temperature difference between the warm current of the Gulf Stream and the cold receiving water is 20°F then each cubic mile of water can transfer about 2×20^{14} BTU.

Determinants of Physical–Chemical Properties

The properties of water and its interactions with other substances are in a class by themselves. The chief contributant to the anomalous physical characteristics of water and to many of its chemical properties is its powerful intermolecular forces, with which it attracts not only its own molecules, but also those of many other substances. The main intermolecular attractive force of water is hydrogen bonding which in turn results from the nature of the chemical bonds holding the atoms of the individual water molecule together.

Hydrogen Bonds

Hydrogen bonding is a special case of dipole-dipole interaction resulting from the molecular polarization when the hydrogen atom is covalently bonded to a highly electronegative atom. Such a condition produces a large dipole moment by displacing the electrons of the shared bond, which includes the sole electron of the hydrogen atom, toward the negative atom and gives a strong partial ionogenicity to the bond and a strong positive character to the hydrogen atom. This leaves an intense unshielded electric field on the other side of the hydrogen nucleus which can attract the unshared electrons of the negative atoms of other molecules.

STRUCTURAL AND PHYSICAL PROPERTIES

Electronic Structure of Water

A model of the single isolated water molecule with its electronic cloud is shown in Figure 2. The three nuclei are surrounded by ten electrons, with the two 1s electrons of the oxygen atom confined to the vicinity of its nucleus. The other eight electrons make up the four orbitals which point to the vertices of a somewhat distorted tetrahedron. Two of the four orbitals are directed along the OH bonds, and the so-called lone pair electrons constitute the remaining two orbitals which project above and below the H–O–H molecular plane. These lone pair electrons provide regions of negative electrification, which can attract the positively charged nuclei of hydrogen atoms in other water molecules thereby giving rise to hydrogen bonds. The charge distribution within the molecule results in the relatively large dipole moment of 1.84×10^{-18} esu.

Molecular Structure of Water

The planar H–O–H angle in the water molecule is 104°31, and the OH bond length is 0.9572 Angstrom. The symmetric group is C_2v: it has twofold axis of rotational symmetry, C_2, (the line bisecting the H–O–H angel) and a plane of reflection, v passing through this axis and normal to the plane of the molecule.

Precise calculations indicate that the average electron distributions forming the covalent OH bonds do not lie directly along the lines form the oxygen nucleus to the hydrogen nuclei, but are bent inward. Furthermore, the normal mode analysis of vibrational spectrum of the two OH bonds shows that the equilibrium length of one bond is dependent on the

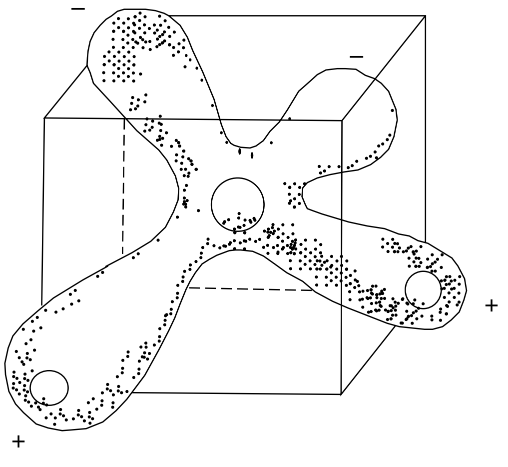

FIGURE 2 Single isolated water molecule with associated electronic cloud. Note the two regions of negative electrification which project above and below the H–O–H plane. From Horne (1970).

length of the other bond. The interdependence of the two OH bonds is also observed in their different dissociation energies. At 0°K, the dissociation energies. At 0°K, the dissociation energy of H–OH is 117.8 kilocalories per mole or 5.11eV whereas these respective values for H–O are 101.5 and 4.40. Thus the energy of formation of a water molecule from the individual atoms is −219.3 kilocalories per gram-mole.

The Vapor Phase of Water

In the vapor phase, water is mostly monomeric with the occurrence of an occasional dimer and, perhaps, a very rare trimer. At low pressure and low temperature the molecules do not interact to any appreciable extent.

The Solid Phases of Water

The structure of the solid phases of water is relatively well known compared to that of the liquid phase. Kamb (1972) recognizes 13 distinct ice phases by including among the distinctions certain "temperature dependent order-disorder" phenomena. The transition points and the densities of these phases are listed in Table 1.

Ordinary Ice

Ordinary ice, ice I, also known as I_h ($I_{hexagonal}$), is the only solid phase stable at normal low pressures. The presence in each water molecule of the two lone pairs of electrons on the oxygen atom and the two protons in approximately tetrahedral geometry create the opportunity for four intermolecular hydrogen bonds resulting in a coordination number of four for the ice structure. The arrangement of the oxygen atoms is isomorphous with tridymite, one of the crystalline forms of silica, and with wurtzite, a crystalline form of zinc sulfide. As shown by X-ray diffraction, ice I is a hexagonal lattice with each oxygen atom surrounded tetrahedrally by four other oxygen atoms at a distance of 2.76A. The oxygen atoms form what many authors call "puckered" hexagonal rings. Each ring layer is a mirror image of its neighbors. The hexagonal arrangement of ice I gives rise to an open structure thereby explaining the low density of ordinary ice, 0.9168 g/cm^3 at 0°C, relative to its melt, 0.99987 g/cm^3 at 0°C.

The OH bond length has been determined to be 0.99 Å by studies of stretching vibrations. As Figure 3 illustrates, a hydrogen atom occupies one of two possible positions on each O–O line, amounting therefore to four hydrogen atoms around each oxygen consistent with the tetrahedral spacing of the oxygen atoms. These allowable positions are 1.05Å from each molecule along the O–O axis. Early theoretical work by Pauling based on the residual entropy in ice at 0°C predicted that over a sufficiently long time interval, the hydrogen atom between the two oxygen atoms occupies each of these positions half of the time. This was later confirmed by neutron diffraction experiments.

The Polymorphs of Ice

The other crystalline forms of ice can be produced at various pressures and temperatures. The P–V–T surface illustrated in Figure 4 defines the regions of stability for the various polymorphs. Ice I*c* (I_{cubic}) has the same unambiguous half-hydrogen distribution as I_h, and thus the same configurational entropy. At about −90°C its cubic crystalline structure readily converts to the hexagonal form, ice I_h, at a rate dependent on its previous history.

Vitreous ice is so named since it is considered to be a glass. This amorphous structure is formed by the condensation of vapor below −150°C. Warming above this temperature transforms it irreversibly to I*c*, and then to I*h* upon further heating.

TABLE 1
The ice phases

			Limits of temperature range		
Phase	Density g cm^{-3}	Pressure kb	Lower °C	Upper °C	Transition at upper limit

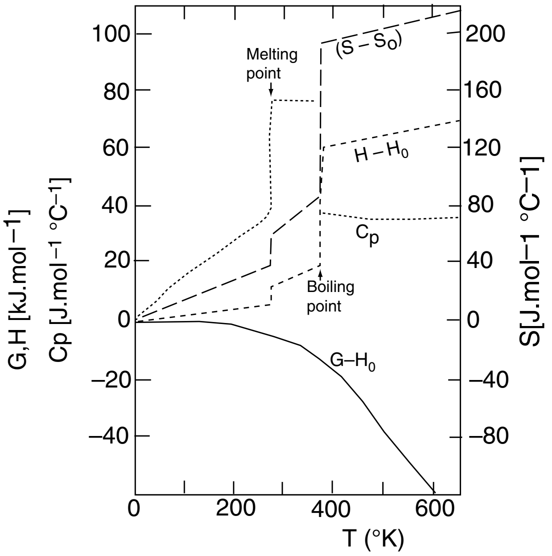

FIGURE 4 Enthalpy, free energy, and isopiestic heat capacity of H_2O at 1 atmosphere pressure, calculated from heat capacity measurements.

Ice II though VII are formed at high pressure but can subsequently exist at atmospheric pressure. Ice II is produced by a transition from ice III at about −100°C. The oxygen atoms of ice II, whose rhombohedral unit cell contains 12 water molecules, are apparently in the same tetrahedral positions as those in ice III, and the volume change of transition is very small but the resulting spatial ordering yields a much lower dielectric constant. Ices, II, III, V, and VI, all of which contain distorted hydrogen bonds, have internal energies only several tenths of a kilocalorie per gram-mole greater than ice I. In comparison, the internal energy of liquid water at 0°C is 1.88 kilocalories per gram-mole greater than that of ice I.

The crystal lattice of ice V is a monoclinic unit cell with 28 eater molecules. Ices IV, VII and VIII have extremely high densities of 1.38, 1.57, and 1.63 grams/cm^3, respectively. These high densities result from interpenetrating but not interconnecting structures. According to Fletcher "dense packing is achieved by placing water molecules upon two separate, completely hydrogen bonded four-coordinated lattices which are allowed to interpenetrate so that the molecules of one lattice occupy the cavities of the other." Thermodynamic criteria indicate that ice VI is probably metastale. Ice VII forms at 22 to 200 kilobars; only one additional allotrope, ice VIII, has been identified in this high pressure range.

Tables 2 and 3 from Kamb (1972) and Eisenberg (1969) summarize the properties of the ice polymorphs.

The Structure of Liquid Water

Liquid water is a highly structured liquid in which the tetrahedral condition observed in ice is still evident. The structure of liquid water still remains a greater enigma than highly complex molecules such as DNA and hemoglobin. Nevertheless, newly acquired data of various properties have increased the constraints operative in the hypothesis of models for the liquid structure.

$$H_T = H_0 = \int_0^T C_p dT + \Delta H_{pc} \qquad S_T - S_0 = \int_0^T \frac{C_p}{T} dT + \Delta S_{pc}$$

$$G_T - G_0 = H_0 - TS_T$$

The subscript "pe" indicates phase change. Thermodynamic constants for phase change are given in Table 4. (Figure after Eisenberg and Kauzmann, 1969; data from Dorsey 1941).

An acceptable model must explain anomalous properties of liquid water such as the following listed by Krundel and Eliezer (1971):

1) The density maximum at 4°C above the melting point.
2) A liquid specific heat approximately twice that of the solid.
3) The extraordinary large heat of fusion.
4) The increase in the coefficient of thermal expansion with increasing pressure (or, equivalently, the decrease in compressibility with temperature rise) between 0°C and 45°C compared with a decrease in this coefficient under same conditions for normal liquids.
5) The singular decrease in viscosity with increasing pressure (in the temperature range 20°C) to a minimum near 1000kg/cm^2, above which the normal increase is exhibited.
6) The exceptional dependence on pressure of the dielectric constant, the self-diffusion coefficient and other thermodynamic and transport properties.

TABLE 2

Structural characteristics of ice polymorphs[a]

Ice	I	Ic	II	III	V	VI	VII	VIII
Number of nearest neighbors	4	4	4	4	4	4	8[b]	8[b]

[a] Entries, except where noted, refer to −175°C and 1 atm pressure. Data for ices I and Ic are from Lonsdale (1958); data for the high-pressure polymorphs are from Kamb and Datta (1960), Kamb (1964), Kamb (1965 *a, b*), Kamb (1967), and Kamb *et al.* (1967).

[b] 4 are hydrogen-bonded to central molecule.

[c] At −130°C

[d] At 25 kbar. In quenched ice VII at atmospheric pressure the nearest-neighbor distance is 2.95 Å (Bertie *et al.,*1964)

The model must also be consistent with the interpretations from infrared, nuclear magnetic resonance, Raman, and X-ray spectra of liquid water.

Eisenberg has outlined the sequence by which most of the current theories have been developed. Experimental evidence and some intuition support the postulation of a model after which it is translated into mathematical terms, often by expressing as a simple partition function containing several variable parameters. The number of adjustable parameters has typically ranged from 9 to 18. The thermodynamic expressions derived from the partition function are fitted to the empirical measurements by varying the parameters. That the model furnishes a good correlation is not necessarily proof of its validity, due to the inductive nature of the method.

The different water models may be roughly divided into two classes: the continuum models (also called homogeneous or uniform models) and the mixture models (also called solution models). Models in both classes achieve partial success in explaining the properties of water.

The models of People and Frank—Wen, representative of the continuum and the mixture classes, respectively, are summarized here. Eisenberg and Kauzmann give a comprehensive review of the various models.

The People Distorted Bond Model

The continuum theories ascribe essentially complete hydrogen bonding to water, at least at low temperature. Associated with the hydrogen bonds is a distribution of angles, distance, and energies. The average bond energy varies with temperature due to the changes in the distributions of bond lengths and bond angle distortions.

People's model (1951) postulates that when ice melts, the hydrogen bonds become more flexible and disorder is introduced into the structure by the bending and stretching of the bonds rather than by breaking them. Thus the water molecules in the liquid phase, like those in the ice, retain a coordination number of four. All the molecules have essentially the same environments, thereby giving rise to the continuum. The model allows for a continuous spectrum of induced hydrogen bond disorder. This model is strongly supported by Raman and infrared spectral studies of liquid water. As Fletcher (1970) points out, "the uniform model of Pople stands or falls on the energy required to bend the hydrogen bond joining two molecules which are already participating in hydrogen bonds to other molecules." Pople and Lennard-Jones propounded that a significant percentage of broken hydrogen bonds in liquid water in thermodynamically impossible since the hydrogen bond energy between two water molecules is 4.5kcal/mole whereas the latent hat of fusion is 1.4kcal/mole and the average thermal energy, *RT,* 0°C is 0.5 kcal/mole.

The Frank–Wen Flickering Cluster Model

The flickering cluster model described water as a mixture of hydrogen bonded clusters surrounded by monomeric water. Frank and Wen (1957) treat the formation of hydrogen bonds in water as a cooperative phenomenon, with a sizeable covalent contribution to the energy of the bond. The existence of a hydrogen bond on one of the hydrogen atoms of water promotes the tendency of the other hydrogen to form a similar bond to another neighboring molecule. According to Krindel and Eliezer (1971), "Frank and Wen considered that hydrogen bonded molecules are mutually polarized, the resulting charge separation being such that the free ends of the associated molecules have a higher affinity for further hydrogen bonding than the ends of non-hydrogen bonded molecules." This susceptibility to further hydrogen bonding gives the process an element of positive feedback until the disaggregating thermal energies from the additional molecules supply negative compensation. Thus the formation of one

hydrogen bond tends to a cluster while the breaking of one hydrogen bond leads to the dissociation of a cluster, thereby resulting in clusters flickering into and out of existing with half-lives estimated at 10^{-10} to 10^{-11} second.

Though the model does not define the details of the organization of the water molecules, the clusters are thought to be compact and highly hydrogen bonded. The existence of a single dielectric relaxation time and a structural relaxation time approximating the neutron residence time appear to rule out the presence of Frank–Wen clusters in pure water according to Davis and Jarzynski.

Thermodynamics and Physical Properties

The isopiestic (1 bar) heat capacity of water, and the thermodynamic functions derived from the heat capacity, are given in Figure 4. The heat capacity of liquid water is almost twice that of ice at 0°C or steam at 100°C. Whereas the heat capacity of ice and steam is primarily due to vibrational energy, there is in liquid water an additional configurational heat capacity related to the energy involved in alterations in the structure of water. The thermodynamic constants for the phase changes of water are given in Table 4. The relatively low heat of fusion of water is evidence that the hydrogen bonding in the ice structure remains intact to some degree during fusion; the extremely high heat of vaporization reflects the disappearance of hydrogen bonding upon vaporization (Westall and Stumm, 1980).

P–V–T Relationships The density of water reaches a maximum at 4°C above the melting point (Figure 5). This extraordinary maximum may be explained as the result of two counteracting phenomena: as the temperature of liquid water is increased, (i) the open four-coordinated structure of water is further broken down, decreasing the volume; (ii) the amplitude of anharmonic intermolecular vibrations increases, increasing the volume. Below 4°C the first effect predominates.

The pressure-temperature curve for water is given in Figure 6. The triple point, at which ice, liquid water, and water vapor coexist at equilibrium, is a convenient reference state: T = 0.01°C, P = 6.11 mbar.

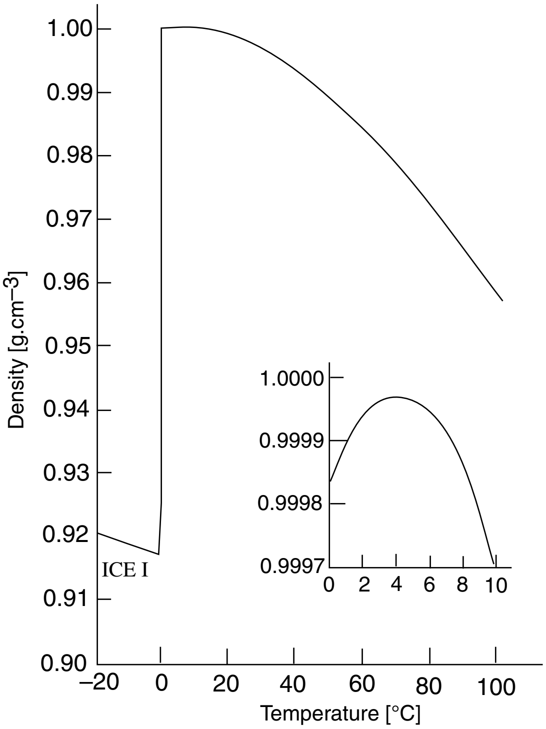

FIGURE 5 The density (at 1 atm) of ice and liquid water as a function of temperature. The inset shows the density in the domain of its maximum. (Data for ice from Eisenberg and Kauzmann, 1969; data for water from Kell, 1967).

Dielectric constant The dielectric properties of water result from (1) electronic and atomic polarization of molecules (formation of induced dipoles) and (2) the orientation of permanent dipoles. The high value of the dielectric constant of water is chiefly the result of the orientation of permanent dipoles, whereby not only the orientation of individual molecules, but also the mutual orientation of neighboring molecules, is important. For comparison, the dielectric constant of ice I is 91 at 0°C, and that of liquid water is 88 at the same temperature. As the temperature is increased, the degree of orientation of the molecules, and the dielectric constant, decreases (Figure 7).

The preceding discussion dealt with the dielectric properties of water in a static electric field. In a high frequently alternating electric field, the permanent dipoles can no longer reorient with the variable electric field; then the observed dielectric constant is due solely to the induced dipoles. For liquid water the value of this high frequently dielectric constant, ε, is between 4.5 and 6.0.

Viscosity The shear viscosity of water can be defined by the equation

$$\tau_{zx} = -\mu \frac{dv_x}{d_x}$$

where τ is the shear stress (force in the x-direction per unit area normal to z) to maintain the velocity gradient dv_x/dz in the z-direction, in the fluid of viscosity μ. The viscosity of water approximately doubles in the range between 25°C and 0°C (Figure 8).

CHEMICAL PROPERTIES OF NATURAL WATERS

Natural waters acquire their chemical characteristics by dissolution of and by chemical reactions with solids, liquids, and gases with which they have come into contact during the various parts of the hydrologic cycle. Waters vary in their chemical composition, but these variations are at least partially understandable if the environmental history of the water and the chemical reactions of the rock-water-atmosphere systems are considered. Dissolved mineral matter is provided by the crustal materials of the earth; water disintegrates and dissolves mineral rocks by weathering. Gases and volatile substances participate in these processes. As a first approximation, seawater may be interpreted as the result of a gigantic acid-base titration: acids of volcanoes (sulfur dioxide, hydrochloric acid, hydrogen sulfide) reacting with bases of rocks (oxides, carbonates, silicates). The composition of fresh water similarly may be represented as resulting from the interaction of the carbon dioxide of the atmosphere with mineral rocks. The earth may be regarded as a heat engine which extracts energy from solar radiation in order to drive winds, ocean currents, hydrogeochemical cycles (cycles of water and rocks) and life cycles. Water, acting as a transport medium as well as a chemical reagent, gradually converts primary rocks into soil, sediments, and sedimentary rocks (Figure 9).

Weathering Processes

Dissolution reactions due to weathering take place because many constituents of the earth's crust are thermodynamically unstable in the presence of water and the atmosphere. Most important among the weathering reactions is the incongruent

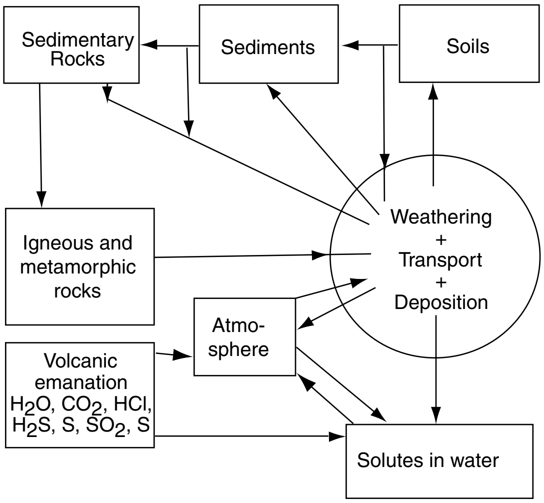

FIGURE 9 Interaction between the cycles of water and rocks.

(partial) dissolution of aluminium silicates which may be represented schematically as follows:

$$\mathrm{Me-Al-silicates(s)} + \mathrm{H_2CO_3}^{*} + \mathrm{H_2O} =$$
$$n\mathrm{HCO_3}^{-} + \mathrm{H_4SiO_4} + \mathrm{Me}^{n+} + \mathrm{Al-silicate(s)}, \text{(a)}$$

where Me is a cation such as Na^+ or Ca^{2+}. Table 5 shows examples of this type as well as weathering reactions of limestone (calcite).

In essence, primary minerals are converted into secondary minerals. The secondary minerals are frequently structurally ill-defined or X-ray amorphous. The structural breakdown of aluminium silicates is accompanied by a release of cations and usually of silicic acid. As a result of such reactions solution increases during the weathering process, the solid residue has a higher acidity than the original aluminium silicate.

Because $H_2CO_3^*$ is usually the acid in the attack of water on the primary silicates, HCO_3^- is the predominant anion in most fresh waters. Because of respiration by organisms, the CO_2 composition in soils can be a few hundred times larger than that in the atmosphere. Correspondingly ground waters tend to contain higher concentrations of HCO_3^- and other solutes. Minerals of the kaolinite group are the main alteration products of the weathering of feldspar. In addition to kaolinites, montmorillonites and micas are also found as intermediates or end products. Mica (illite) has been identified as an intermediate in the decomposition of potassium feldsparorthoclase.

The dissolution kinetics of feldspars may cause them to reach their final products through temporally stable intermediates. Virtually all bonds must be broken in the tetrahedric aluminium framework before the structure can be rearranged to a lattice having six coordination bonds around the aluminium as in kaolinite. Understandably, the rate of reaction is very slow. Physical weathering processes, that is, processes which by physical or mechanical means alter the size and hence the specific surface area of the minerals, enhance reaction rates since the weathering processes take place only at the rock-water interface.

TABLE 5
Examples of typical weathering reactions[a]

quartz

$CaCO_3(s) + H_2CO_3^* = Ca^{2+} + 2HCO_3^-$

calcite

$Al_2O_3 \cdot 3H_2O(s) + 2H_2O = 2Al(OH)_4^- + 2H^+$

gibbsite

$Ca_5(PO_4)_3(OH)(s) + 4H_2CO_3^* = 5Ca^{2+} + 3HO_4^{2-} + 4HCO_3^- + H_2O$

apatite

II. Incongruent dissolution reactions

$NaAlSi_3O_8(s) + H_2CO_3^* + 9/2H_2O$

albite (Na-feldspar) =

$Na^+ + HCO_3^- + 2H_4SiO_4 + 1/2Al_2Si_2O_5(OH)_4(s)$

kaolinite

$7NaAlSi_3O_8(s) + 6H_2CO_3^* + 20H_2O$

albite (Na-feldspar) =

$6Na^+ + 6HCO_3^- + 10H_4SiO_4 + 3Na_{0.33}Al_{2.33}Si_{3.67}O_{10}(OH)_2(s)$

Na-montmorillonite

$Al_2Si_2O_5(OH)_4(s) + 5H_2O = 2H_4SiO_4 + Al_2O_3 \cdot 3H_2O$

kaolinite gibbsite

$CaMg(CO_3)_2(s) + Ca^{2+} = Mg^{2+} + 2CaCO_3(s)$

dolmite calcite

[a] After Stumm and Morgan (1981).

The composition of water is obviously influenced by these weathering reactions. While Ca^{2+}, HCO_3^-, H^+, and perhaps Mg^{2+} may be controlled by dissolution carbonate rocks, the source of Na^+, K^+, and H_4SiO_4, and possibly also of Ca^{2+} and Mg^{2+}, is the silicate minerals that make up 70% or more of the rocks in contact with underground waters and streams.

Figure 10 gives in an abbreviated periodic table the important elements typically found in fresh and sea water, their dominant forms of occurrence and their representative concentrations. A recent survey of the frequency distribution of various constituents of terrestrial waters by Davies and DeWiest (Figure 11) shows that many of the aquatic constituents exhibit little natural variation in their concentrations.

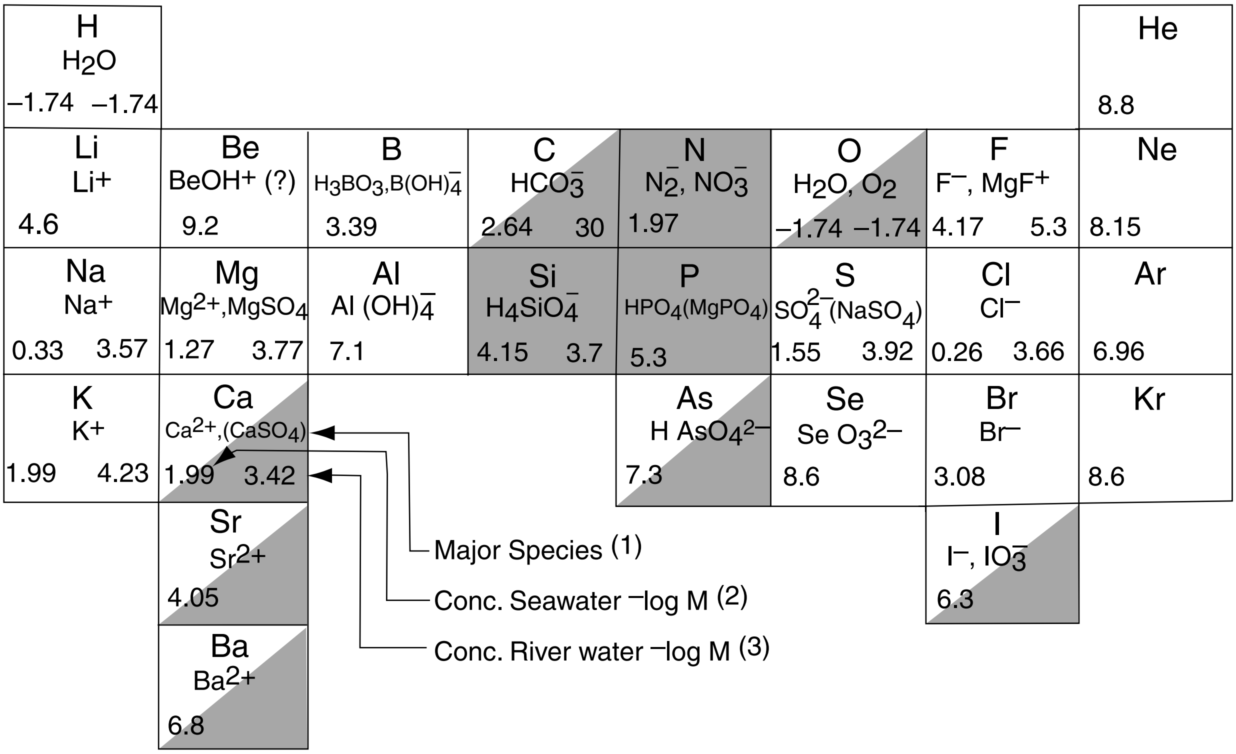

FIGURE 10 Some of the more important elements in natural waters, their form of occurrence and concentrations. Elements whose distribution is significantly affected by biota are shaded. P, N, and Si (fully shaded) often become depleted in surface waters. a) Species in parentheses are major ion pairs in sea water. b) Concentrations (M = mol/1) valid for seawater from P.G. Brewer in *Chemical Oceanography,* Volume 1, J.P. Riley and G. Skirrow, eds, Academic Press, London 1975. c) From A.D. Livingstone, Chemical Components of River and Lakes, US Geol. Survey Paper, 440 G, 1963.

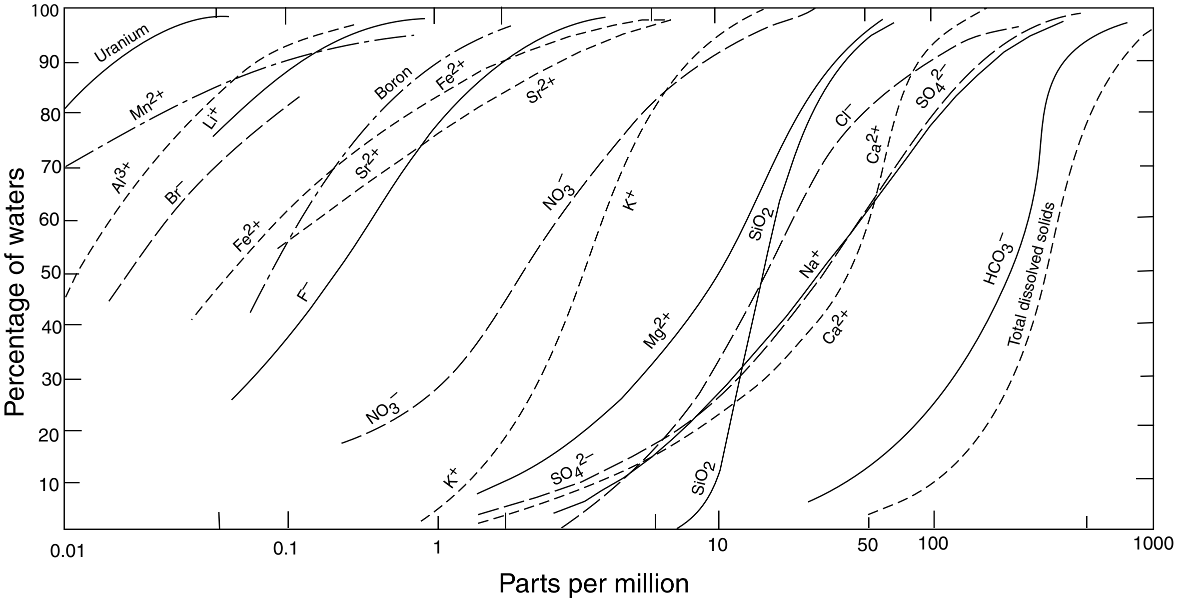

FIGURE 11 Cumulative distribution of inorganic species terrestrial waters. The curves represent the percentage of waters with concentrations below that indicated on the horizontal axis. Data are mostly from the United States from various sources. S.N. Davies and R.C.M. Dewiest, *Hydrogeology,* Wiley, New York, 1966.

Because the relationship between geological environment and water composition depends upon so many interdependent variables, and because there is no substantial variation in each genetic type of water, no reliable generalizations are possible with such a small number of examples. A few qualitative characteristics are apparent from Table 6. As expected, ground waters have higher ionic strengths than surface waters. This results from the difference in CO_3 partial pressure to which these two types of waters are exposed. In comparing waters Nos. 5, 6 and 7, the influence of calcium plagioclase, which is less stable than the silicic rocks, becomes apparent. Sandstone beds are important aquifers and as sedimentary rocks may often contain carbonates besides grains of quartz. Thus the pH of sandstone waters tends to be higher than that of waters from igneous rocks. Shales are laminated sediments whose constituent particles have sizes similar to those of clay. Most of these fine-grained sediments were deposited in saline environments. The relatively high HCO_3^- concentrations of slate ground waters may be due to high CO_2 concentrations resulting from oxidation of organic carbon. Waters from limestone and dolomite contain substantial quantities of Ca^{2+}, Mg^{2+}, and HCO_3^-, the concentrations of which are usually controlled by carbonate equilibria.

The Composition of the Ocean–Atmosphere System

Goldschmidt (1933) suggested that for each liter of presently existing sea water, 600 grams of igneous rocks had reacted with about 1 kilogram of volatile substances (H_2O, HCL, CO_2, etc.). Concomitantly formed during this process were about 600 grams of sediments and three liters of air.

As seen in Figure 10, the solute proportion introduced by rivers differs from that in seawater; in other words, simple concentration of freshwater does not produce ocean water. An important group of constituents of the ocean-atmosphere system (Cl^-, N_2, rare gases) is controlled largely by degassing of the earth. The concentration of O_2 is controlled by the biological reactions of photosynthesis and respiration. Mineral reactions control the concentrations of major cations.

Many constituents (e.g., CO_2, O_2, NO_3^-, HPO_4^-, and H_4SiO_4) are involved in biological cycles in the sea; their distribution and redistribution depend upon the physical circulation of the water and the settling and mineralization of plankton.

Water as a Life Preservation System; Photosynthesis and Respiration

Photosynthesis may be viewed conceptually as an energy consuming process leading to products of high oxidation intensity (organic matter). Respiration is the reverse reaction, the combination of the products of photosynthesis with the release of energy. The photosynthesis/respiration reaction may be written (simplified) as

$$CO_2 + H_2O \quad \underset{\text{respiration}}{\overset{\text{photosynthesis}}{}} \quad CH_2O + O_2.$$

In the aquatic environment the reaction may be written more precisely to include trace elements and to reflect the constitution of algal protoplasm.

$$106CO_2 + 16NO_3^- + HPO_4^2 + 122H_2O + 18H^+ \underset{R}{\overset{P}{}}$$
$$C_{106}H_{263}O_{110}N_{16}P_1 + 138O_2.$$

The relationship between photosynthesis/respiration and the nutrient cycle is seen in Figure 12.

The distribution of chemical species in the waters and in the sediments are strongly influenced by an interaction of mixing cycles and biological cycles. Radio-isotope measurements may often be used to establish the time scale of some of these processes. Similarly, evaluation of the fractionation of stable

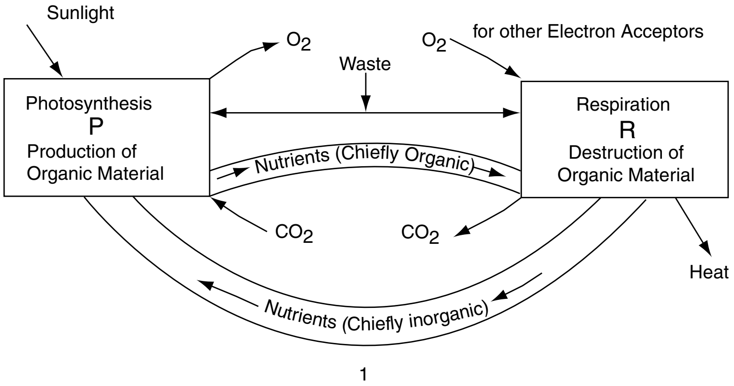

FIGURE 12 Photosynthesis and the nutrient cycle. Solar energy and inorganic nutrients including inorganic runoff are converted by photosynthesis into chemical energy stored within the organic material of algae and plants. Heterotrophic consumers and bacteria mobilize this energy by degrading the organic nutrients including organic waste during respiration and other oxidative process. A steady state of continuous circulation of biochemical materials is indicative of unpolluted water.

isotopes aids the quantitative interpretation of biogeochemical and environmental processes and cycles (Broeker, 1974).

Organic Carbon

The cycle of carbon in natural wastes is especially important because it is interrelated with the cycles of all other elements. Furthermore, the organic material produced in the oceans constitutes one of man's most significant marine resources.

Most of the carbon in the earth's crust has cycled through organisms and plants; as a result it has been incorporated into unstable but long-lived biochemical structures. Information on the catabolic pathway of organic life substances permits prediction of the type of organic substances to be found in natural waters. Table 7 gives a greatly condensed and simplified survey of the decomposition products of life substances and includes an abbreviated list of specific organic compounds reportedly found in natural bodies.

In fresh water bodies one typically encounters concentrations of a few milligrams carbon per liter, but occasionally (e.g., in bog or swamp waters) concentrations may be as high as 50 mg C per liter. In the oceans the concentrations of organic carbon range from 0.5 to 1.2 mg C per liter, with the higher values occurring in the surface waters. Particulate organic carbon, including planktonic organisms, generally accounts for

From Stumm and Morgan (1981).

about 10% of the total organic carbon. In much of the ocean there is a "soluble" organic carbon concentration of around 500 micrograms C per liter, with the higher values occurring in the surface concentration of some 50 μg C per liter, all ultimately derived from a surface phytoplankton population equivalent to a concentration of about 5 μg C per liter. Below a depth of 400 to 600 meters the concentration variations in organic carbon become very slight. This suggests that materials present in deep waters are resistant to further metabolic decomposition.

WATER QUALITY CRITERIA AND WATER POLLUTION CONTROL

In a broad sense, pollution has been defined as an alteration of man's surroundings in such a way that they become unfavorable to him. This implies that pollution is not solely caused by contaminants or pollutants added to the environment but can also result from other direct or indirect consequences of man's action. Anything that produces a maladjustment of the ecological balance constitutes pollution.

Every ecosystem has a rather delicate balance of inputs and outputs. Ecological unbalance results, for example, when the rate of extraction of an element (e.g., by mining) by man exceeds the natural rates of cycling or when the output of a product (e.g., crops or forests) is maximized.

Disturbance of the Balance between Photosynthesis and Respiration

Pollution of surface waters frequently results from a disturbance in the balance between photosynthesis (P) and respiration (R). (Reactions (c) and (d)). As Figure 13 illustrates, this balance is upset by adding either an excess of organic wastes or an excess of inorganic algal nutrients (e.g., phosphorus and nitrogen compounds). In the first case (P ! R), heterotrophic processes tend to dominate and dissolved oxygen may become exhausted due to the biochemical oxygen demand and ultimately NO_3^-, SO_4^{2-}, and CO_2 may become reduced to N_2(g), NH_4^+, HS^- , and CH_4(g). In the second case, the incipient result is progressive accumulation of autotrophic biomass (e.g., algae and aquatic plants). Eventually this biomass decomposes enhancing the rate of respiration, which again may reduce dissolved oxygen levels. In either case the initial perturbation is followed by a readjustment, such as a shift in biological species, that finally leads to a new balance.

The P–R balance may also be distributed by a localized, physical separation of the P and R functions. For example, in a stratified lake an excessive production of algae and oxygen in the upper layers may be paralleled by anaerobic conditions (i.e., lack of dissolved oxygen) at the bottom because much of the photosynthetic oxygen escapes to the atmosphere and does not become available to heterotrophs in the deeper water layers.

When P–R, the organic material is decomposed as fast as it is produced photosynthetically. Such a balance,

$$\text{Import}_{\text{org.material}} + \text{P} \; ; \; \text{Export}_{\text{org.material}} + R,$$

is necessary to maintain a water in an aesthetically pleasing condition.

The Pollutants

Much of our concern in the future should be with the fact that most of the energy dissipation by our industrial society for agriculture, landscaping, urban construction and other interventions of civilization ultimates causes a simplification of the ecosystem: specifically, a reduction of the food web and a shortening of the food chains. Generally the less complex a natural

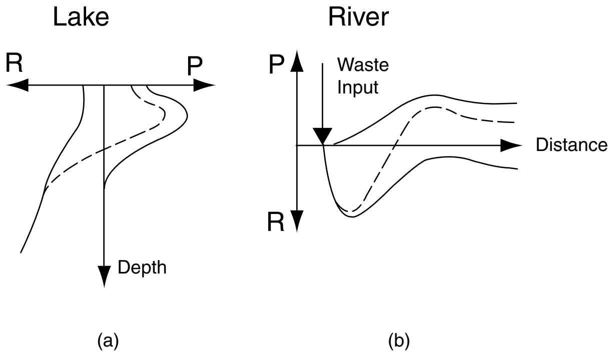

FIGURE 13 Separation of photosynthesis and respiration in polluted lakes and rivers. The separation of photosynthesis and respiration causes pollution by impeding the circulation of chemical constituents with consequent localized increases in photosynthetic or heterotrophic microbial populations. The dashed curves represent the net disturbance of the P–R balance and are indicative of the net rate of oxygen production or consumption.

a) Vertical separation of the P–R functions in lakes can be induced by inorganic nutrients, chiefly nitrogen and phosphorus, which fertilize surface algal growth. Upon settling, the algae stimulate bacterially mediated oxygen utilization and other redox reactions of lower pϵ. The resultant anaerobiosis stifles higher trophic levels.

b) Longitudinal separation of the P–R functions in rivers can be caused by localized injection of organic waste, which stimulates increased bacterial activity and concomitant oxygen consumption. The resultant mineralized nutrients enhance algal growth downstream which upon decay exerts an oxygen demand still further along the river.

ecosystem, that is the smaller the number of species (less diversity), the more liable it is to perturbations and to catastrophe.

Most of the conscious and reasonably successful efforts of environmental and sanitary engineers have been and may well continue to be directed towards the removal of organic carbon of *biological* wastes. For many natural waters, however, other pollutants are ecologically more harmful and may become even more so in the future. As shown earlier, inorganic fertilizing elements are often more serious pollutants than biological wastes for most of our lakes, estuaries, and littoral waters. While biological wastes and inorganic fertilizers cannot yet cause substantial alterations (besides local and temporal transients) in the composition and biology of the oceans, the invasion of the seas by man-made chemicals (e.g., persistent petrochemicals) may cause substantial modification of ecological interrelations in the marine environment.

Conventional biological waste treatment expedites the breakdown of those organic compounds that would eventually be degraded in receiving waters whose self-purification capacities are not overloaded. Such treatment is relatively inefficient with regard to many synthetic organic chemicals. Thus, for many inland waters more emphasis upon the elimination of refractory carbons is necessary.

The inability of some rivers and lakes to readjust rapidly to their initial conditions after even minor shock loadings (e.g., of pesticides or excess quantities of organic wastes) is frequently indicative of a loss of diversity (heterogeneity) in the aquatic biological communities. While many refractory chemicals, at the low concentrations encountered, do not impair the dissolved oxygen balance and do not interfere with the apparent health and survival of fish, they may prevent some fish from returning to their streams of birth for breeding. Often an environmental stress and a decrease in community diversity is signaled by the disappearance of a species, for example, a salmon in a particular stream.

Because of the continuous increase in industrial energy generation, heat will become one of the most significant water pollutants of the future. Woodwell (1969), has shown that many types of environmental disturbances (chronic irradiations, exposure to SO_2, pollution by pesticides, hydrocarbons, heavy metals, excess nutrients) cause similar and roughly predictable gross changes in ecosystems. In each case there is a shift away from complex arrangements of specialized species toward monotone, away from tight nutrient cycles toward loose ones with terrestrial systems becoming overloaded, away from stability toward instability.

Global Aspects of Water Pollution

A comparison of the fluxes of materials resulting from geologic processes and weathering with those of substances introduced by civilization (e.g., agricultural and industrial wastes) shows the relative importance of the role of man as a geological agent and manipulator.

The energy fixed by all plants on the surface of the earth is approximately 8×10^{17} kilocalories per year. Man's metabolism (3×10^{15} kilocalories per year) plays a minor role in the physiology of the biosphere. Man in his capacity to manipulate nature dissipates from 10 to 20 times (in developed countries, 50 to 100 times) as much energy as he requires for his metabolism. Much of the energy utilized by our industrialized society causes localized simplification of the ecosystem and tends to accelerate the cycling of individual elements.

Some of the fluxes caused by man's manipulation are of similar magnitude to those which do not involve man. The combustion of fossil fuels may introduce some elements into the atmosphere and subsequently into the hydrosphere at rates comparable to those of natural processes.

Strong Acids in Rainwater

Rainwaters often contain strong acids. These acids are formed from atmospheric pollutants (HCl, HNO_3, H_2SO_4) (Figure 14).

Chemical Management of Water and Waste Water Quality

Assigning a level of quality to water is relative and depends on the user of the water. For example, different quality criteria apply to drinking waters, to waste water effluents and to receiving waters. Table 8 summarizes some of the objectives of chemical unit processes typically used in water and waste treatment. Water treatment schemes often include several of these processes since generally no single one can achieve the desired water quality objectives. Pertinent chemical reactions in the management of water and waste water are listed in Table 9.

Precipitation reactions are used to remove objectionable ionic species from solution. Hard water containing calcium and magnesium ions, which form insoluble films with soap, is softened by precipitating the ions as calcium carbonate and magnesium hydroxide. Iron and manganese which cause undesired turbidity and stain surface are removed by oxidation and precipitation. Phosphate, a critical aquatic nutrient, can be precipitated as aluminium, iron or calcium solids.

Ion exchange involves the interchange of ions between a solid polymer resin and solution and is used in water treatment for softening and demineralization.

Coagulation is a physico-chemical process involving the agglomeration of colloidal particles for subsequent removal by sedimentation and filtration. The addition of chemical coagulants enhances the mutual attachment of colloidal particles by reducing the repulsive forces acting between these particles (destabilization). In water and waste water treatment practice the hydrolyzed metal ions of Al and Fe(III) salts are commonly used as coagulants. Initial particle contact due to thermal motion (perikinetic coagulation) is normally augmented by the introduction of velocity gradients in solution by slow mixing (orthokinetic coagulation).

The coagulation process may be aided by the addition of macromolecular polymers (polyelectrolytes) which bridge dispersed colloidal particles. Such destabilization is frequently called flocculation.

Gaseous chlorine is one of the economically most useful disinfectants for municipal and industrial waters. During

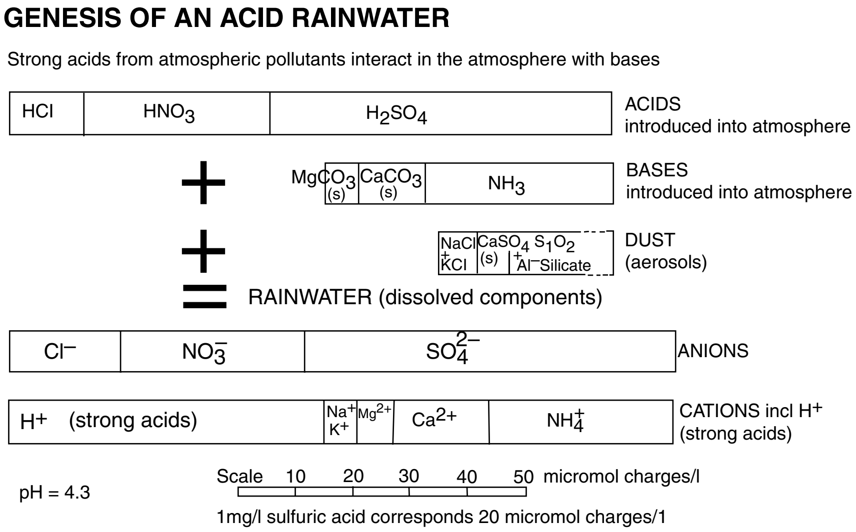

FIGURE 14 Strong acids in rainwater. The acid-base reaction involved in the genesis of a typical acid rainwater. Acids formed from atmospheric pollutant react in the atmosphere with bases and dust particles. The resulting rainwater contains an excess of strong acids. H_2SO_4 originates mostly from S in fossil fuels; after combustion the SO_2 formed is oxidised to SO_3 which gives, with H_2O, H_2SO_4; HNO_3 originates from NO and NO_2. These molecules are formed in the combustion of fossil fuels and to a large extent in the combustion of the automobile engine. For each molecule of NO one of HNO_3 is formed, for example, $NO + O_3 \rightarrow NO_2 + O_2$; $3NO_3 + H_2O \rightarrow 2HNO_3 + NO$. HCl may largely originate from the combustion of Cl-bearing polymers, for example, polyvinyl chloride, in refuse incinerations. Most bases in the atmosphere are often of natural origin. Atmospheric dust may contain carbonates (calcite and dolomite). NH_3 is released from many soils (together with urea). (From Stumm and Morgan, 1981.)

the chlorination process diatomic chlorine gas hydrolyses in solution to form hypochlorous acid and hydrochloric acid. Hypochlorous acid is a stronger disinfectant in its undissociated form (HOCI). Aqueous chlorine, a powerful oxidizing agent, will react with reduced compounds by the formation of chloramines by reaction with aqueous ammonia. (Also see Water Chemistry.)

Water pollution control and improvement of water quality cannot solely depend on water purification and waste treatment. Various physical and biological means of stream management must be directed towards restoring an ecological balance. Because unlimited growth in energy dissipation is incompatible with maintenance of ecological stability and high quality of life, the ecological constraints demand the alteration of social and economic activity toward a situation where resources and materials are recycled.

TABLE 9

Reactions pertinent to the chemical management of water and waste water quality

(Reagent used are underlined)

Precipitation softening

a) Carbonate hardness (temporary or non-incrustant hardness)

$$Ca^{2+} + 2HCO_3^- + \underline{Ca(OH)_2} = 2CaCO_3(s) + 2H_2O$$

$$Mg^{2+} + 2HCO_3^- + \underline{2Ca(OH)_2} = Mg(OH)_2(s) + 2CaCO_3(s) + 2H_2O$$

b) Non-carbonate hardness (permanent or incrustant hardness)

$$Ca^{2+} + SO_4^{2-} + \underline{Na_2CO_3} = CaCO_3(s) + 2Na^+ + SO_4^{2-}$$

$$\begin{aligned} Mg^{2+} + SO_4^{2-} + Ca(OH)_2 + \underline{Na_2\mathit{CO}_3} &= Mg(OH)_2(s) + CaCO_3(s) \\ &\quad + 2Na^+ + SO_4^{2-} \end{aligned}$$

Iron and manganese removal

$$2Fe^{2+} + \underline{\frac{1}{2}O_2(g)} + 5H_2O = 2Fe(OH)_3(s) + 4H^+$$

$$Mn^{2+} + \underline{\frac{1}{2}O_2(g)} + H_2O = MnO_2(s) + 2H^+$$

$$Fe^{2+} + HCO_3^- + \underline{OH^-} = FeCO_3(s) + H_2O$$

Phosphate removal

$$\underline{AI^{3+}} + H_nPO_4^{n-3} = AIPO_4(s) + nH^+$$

$$\underline{Fe^{3+}} + H_nPO_4{}^{n-3} = FePO_4(s) + nH^+$$

$$10Ca^{2+} + 6H_nPO_4{}^{n-3} + \underline{(n+2)OH^-} = Ca_{10}(PO_4)_6(OH)_2(s) + nH_2O$$

Ion exchange

WATER REUSE

A commonly accepted definition of water reuse is that the water that will be further utilized will still be under the control of the first user. An early example of water reuse involved the sale of secondary wastewater effluent from the Back River Treatment Plant in Baltimore to the Bethlehem Steel Sparrows Point Plant. The Sparrows Point Plant was served by wells, which were close to brackish Baltimore Harbor. Excessive pumping of the wells led to saltwater intrusion, and low saltwater concentrations made the well water unsuitable for some operations. Steel rollers pit when applied water contains 5 mg/l chloride ion. Wolman recommended that the treated wastewater effluent be used for some rough operations, such as quenching. An 8-mile pipeline was installed to carry the effluent to the industrial plant. Drawdown on the wells was reduced significantly, and the city of Baltimore received revenue for a previously discarded product.

Water reuse can be regarded as a conservation strategy. Here the discussion will deal with reclamation of used water. Desalination, or desalting, is covered in another chapter (see "Desalination"). Guidelines and design standards have been developed for water reclamation and water reuse as alternatives to disposal of surface receiving waters. Table 1 lists water-reuse applications. It should be noted that other uses will be found.

All water is reused. It may be used and used again in its journey from deposition as rain to eventual mixing with the sea. Available water is not always near the point at which it is required. Economics of supply is important, and pumping cost may dictate the source chosen.

In many cases, water for industrial processes must be of much higher quality than that used for drinking. In water-poor areas reused water has long been accepted, even for drinking. In general, however, public-health authorities have not looked favorably on this use. A poll found that 50% of the people surveyed did favor reclaimed water for drinking.

Water usually is not immediately available for reuse. With more stringent regulations governing effluent quality coming into effect, these higher-quality discharges may become more practical for water reuse.

Conventional primary and secondary wastewater treatment alone are not normally sufficient to prepare wastewater for any but the coarsest uses. Further, or tertiary, treatment will be required. Secondary, or biological, treatment will remove about 90% of influent suspended solids and BOD (biochemical oxygen demand). BOD and COD (chemical oxygen demand) do not themselves affect suitability of the effluent for reuse but are indications of the unstable nature of the effluent. These will be reduced in the natural decomposition cycle.

Some compounds are not removed in conventional wastewater-treatment processes. These substances, termed "refractory," range from simple inorganic compounds to large synthetic organics such as pesticides, herbicides, and surfactants. In an essentially closed system, high concentrations of unwanted materials would soon result from continued recycling. In Table 2, components of typical tap water are compared with those of a typical secondary effluent.

Stream quality or other water sources might be improved enough by removal of BOD and suspended solids. In some cases it is possible to save large amounts of water by process changes and improved housekeeping, and water reuse might not be necessary.

If used water is not yet suitable for reuse after conventional treatment, it may be blended with clean water and the mixture rendered acceptable. However, in many cases tertiary treatment will be required. A common definition of tertiary treatment is any treatment in addition to secondary treatment by which further removals are achieved. A classification of wastewater-treatment processes is presented in Table 3.

Chlorination, ozonation, and application of ultraviolet light are not considered tertiary processes. Chemical precipitation, by itself, is primary treatment. However, applied after secondary treatment, it can give a high-quality effluent. An insoluble compound is formed and the resulting precipitate sweeps other material from suspension. Neutralization of charge on colloids and agglomeration of particles, including microorganisms, give a clear effluent. Phosphates are removed by addition of soluble aluminum or iron salts. Lime is usually added to produce hydroxide floc.

Filtration may be necessary for further particulate removal after chemical precipitation. In this case filtration is not straining out of the suspended matter. The primary mechanism is adsorption of the suspended matter onto the surface of the granular filter media. Sand, anthracite, and garnet are commonly used filter materials. A mixed-media filter has a greater effective depth than does a comparable sand filter. When a filter clogs, it may be backwashed by water alone or a mixture of water and air. A filter acts as a fluidized bed during backwashing.

Diatomaceous-earth filtration is also practiced. A layer of diatomaceous earth is placed over a relatively loose septum to

TABLE 1

Type of Reuse	Applications
Urban public access (unrestricted)	Parks, playgrounds, schools, residences, toilet flushing, air conditioning, fire protection, construction, fountains, and ponds
Urban public access (controlled)	Golf courses, cemeteries, and highway medians
Agriculture (food crops)	Irrigation needs of food crops the type of reuse water is further classified as food crops consumed raw or processed
Agriculture (nonfood crops)	Irrigation needs for crops used as fodder, fiber and seed crops, pastureland, commercial nurseries, and sod farms
Recreation (no restriction)	Recreational activities with no imposed restriction on body contact
Recreation (restricted)	Noncontact recreational activities such as fishing and boating
Environmental uses	Creating wetlands, enhancing natural wetlands, and maintaining or supplementing stream flows
Industrial uses	Cooling system makeup and washdown
Groundwater recharge	Infiltration basins, percolation ponds, and injection wells for aquifer recharge
Indirect potable reuse	Discharge of highly treated reclaimed water into surface well or groundwater for potable water use

TABLE 2

Component	Tap Water, mg/l	Secondary Effluent, mg/l
BOD	2	20
COD	2	100
Alkylbenzenesulfonates (ABS)	0.4	6.8
Cations		
Na^+	50	125
K^+	3	13
NH_4^+	0.1	16
Ca^{++}	42	60
Mg^{++}	16	19
Anions		
Cl^-	66	143
NO_2^-	0.15	1.5
NO_3^-	5	12
HCO_3^-	198	296
CO_3^{--}	0.1	1.0
SO_4^{--}	56	84
SiO_2^{--}	29	43
PO_4^{--}	8.1	25
Hardness (as $CaCO_3$)	158	235
Alkalinity	164	242
Total dissolved solids	382	700
pH	8.0	7.4

TABLE 3

Process	Substances Treated
Biological	
Conventional secondary	BOD, COD, suspended solids, microorganisms
Modifications of conventional	BOD, COD, suspended solids, microorganisms,
Secondary	nutrients
Anaerobic denitrification	Nitrates
Algal harvesting	Nitrates and phosphates
Chemical	
Ammonia stripping	Ammonia nitrogen
Ion exchange	Nutrients
Electrodialysis	Salts
Chemical precipitation	Suspended solids, phosphates
Physical	
Activated carbon adsorption	Organic matter, suspended solids
Sedimentation	Suspended solids, microorganisms
Filtration	Suspended solids, microorganisms
Microstrainers	Very small particles
Reverse osmosis	Salts
Distillation	Salts
Foam separation	Detergents
Vapor-compression evaporation	Concentration of wastewater
Wasteheat evaporation	Concentration of wastewater
Steam stripping	Hydrogen sulfide, ammonia

screen out suspended solids down to 0.5 to 1.0 µm. This type of filter clogs rapidly and must be backwashed frequently.

Both vacuum and pressure filters are used for tertiary treatment. About 85% of influent turbidity is removed in a vacuum filter. Application rates in the range of 0.5 to 1.0 gpm/ft^2 are common for both types of filters. These low rates make both vacuum and pressure filters unsuitable in large installations.

Microstrainers are rotating drum screens with extremely fine stainless steel or polyester fabric having openings in the range of 15 to 60 µm. Flowing liquid enters the effluent end of the horizontal drum and passes through the mesh to the effluent end. The mesh rotates with the drum while trapping solids. A spray of treated effluent washes the retained solids into a hopper, from which they are lead to final disposal. Ultraviolet radiation inhibits microbial growth. At intervals of 7 to 28 days the mesh is washed with chlorinated water for control of slime growth. Wash water is about 3 to 5% of the total treated water. Microstrainer removal efficiencies are 30 to 55% of applied BOD and 40 to 60% of suspended solids.

Preparation of effluents of exceptional quality involves "effluent polishing." Plant effluent is collected in a sump, pumped through tube settlers, and then sent through a mixed-media filter bed. Filter effluent is collected in storage tanks. These tanks serve the dual roles of reservoir for filter backwash water and chlorine contact chamber. The tube-settler–mixed-media combination removes phosphate when preceded by coagulation and flocculation. These units are suitable for production of a high-quality effluent when the applied influent has a suspended-solids concentration as high as 2000 mg/l (0.2%).

Hard detergents such as ABS (alkybenzenesulfonate) are not removed by conventional biological treatment. ABS has been replaced almost completely in household detergents by linear compounds, but foam continues to be a problem. Foam-separation techniques have been applied for removal of refractories such as organic hydrates and nitrogenous compounds. Air is pumped through spargers, producing small bubbles. Rising bubbles collect suspended solids and surface-active substances. Foam collects at the top and is removed and collapsed, yielding a waste concentrate. In some installations waste flows downward, while gas spargers at the bottom give countercurrent flow.

Activated carbon has long been used for removal of tastes, odors, and color. It has not been suitable for treatment of waters with high concentrations of organic matter because the surface area available for adsorption is soon exhausted at the influent end of a packed bed. However, a fluidized bed of granular activated carbon gives a more uniform concentration gradient throughout the bed. Removal rates of 70% for BOD and 80% for COD are possible with activated carbon adsorption. Carbon is regenerated in multistage hearth furnaces in a stream-air mixture. About 5% of the carbon is lost with each regeneration.

Hard waters are softened by ion exchange. Calcium and magnesium ions are exchanged for a cation in the resin, usually sodium, and 100% of sulfate, 95% phosphate, 85% nitrate, and 45% COD are removed by ion exchange. Color and organic matter are removed by cationic and anionic mixed beds, but organic matter tends to foul the beds. Cost and frequency of regeneration are disadvantages.

Cross-flow membrane-separation technologies of microfiltration, ultrafiltration, reverse osmosis, and nanofiltration may be defined on the basis of pore size or removal function. Membranes are commonly rated by their molecular-weight cutoff, the maximum molecular weight of a compound that will pass through the membrane. Microfiltration removes suspended submicron material but does not remove truly dissolved material. Ultrafiltration removes nonionic solute. These may be organic macromolecules. Microfilters and ultrafilters may be regarded as sieves. Reverse osmosis involves a solution or suspension flowing under pressure through a membrane and the product being withdrawn on the low-pressure side. This process can treat dissolved-solid concentrations of 1 mg/l to 35,000 mg/l and particles ranging in size from less than 1 nm to 600 nm. The treated material must be nonfouling. Frequently, it is necessary to pretreat in order to avoid membrane fouling. Recent advances have been mostly in membrane development. Pilot studies for particular applications may be required. Energy costs can be quite significant in process economics. Mass transfer in reverse osmosis comes about due to pressure difference across a membrane. Nanofiltration rejects dissolved ionic contaminants, but to a lesser degree than in reverse osmosis.

In electrodialysis, direct current is applied to a series of alternating anionic and cationic membranes. Anions pass through anion-permeable membranes but are prevented from migrating through cationic permeable membranes. Electrodialysis deals only with ionic species, but reverse osmosis can be shared with electrodialysis.

Vapor-compression evaporation and waste-heat evaporation remove water from contaminants instead of removing contaminants from water. Application of these processes is most economical when waste heat is readily available, such as industrial installations. Water thus produced is of high quality. However, organic substances that steam-distill or form azeotropes may appear as contaminants. A distinct advantage is concentration of residue. Transportation costs are thus reduced. Use of excess heat for these processes can reduce the amount of cooling water required.

Oxidation ponds are shallow ponds into which wastewater is led. Also called sewage lagoons, these ponds have long been in use in Europe but are not popular in North America. Public resistance has been on aesthetic grounds. A secondary effluent can be further purified in these ponds, and the water produced is suitable for many purposes. Algal action and surface aeration make this an aerobic process. Depth is an important consideration. The pond must be shallow enough to allow penetration of sunlight, but it must be deep enough to keep from being choked by aquatic weeds. Four feet is a common depth. Some installations have aerators at the pond center.

Water reuse is an art as well as a science. The processes presented here are commonly used in preparation of wastewater for immediate reuse. However, the particular situation under study must dictate the economics of reuse. The ultimate level of reuse is the dominant factor in deciding if reuse is practical.

WATER TREATMENT

INTRODUCTION

Water, of course, is used for many purposes associated with human activity. In its natural state it occurs in and on the ground in subsurface and surface reservoirs. The quality and reliability of a source of water will vary considerably, both in time and space. This means that characteristics (chemical, physical, and biological) will differ greatly depending upon the location and type of source. It also means that a given source may vary over the seasons of the year.

Thus, in the selection of a water source, consideration is usually given to the use to which the water will ultimately be put so as to minimize the cost of treatment. Simultaneously consideration must be given to the reliability of the source to provide an accurate and constant source of supply. It will be seen later in this section that a groundwater supply may enjoy the benefit of requiring little or no treatment, while a surface supply such as a river, pond or lake may require considerable and perhaps seasonally varying treatment. However, a surface supply is visible and therefore more reliable whereas a groundwater supply may just disappear with no warning or notice.

In certain areas, freshwater is so scarce that the source must be accepted and choices are not available. The history of water treatment dates back to the early Egyptian civilizations where the murky waters of the Nile River were held in large open basins to allow the mud to settle out. The earliest archeological records of a piped water supply and wastewater disposal system date back some five thousand years to Nippur of Sumaria.[1] In the Nippur ruins there exists an arched drain with an extensive system of drainage from palaces and residences to convey wastes to the outskirts of the city. Water was drawn through a similar system from wells and cisterns.

The earliest records of water treatment appear in the Sanskrit medical lore and Egyptian wall inscriptions.[2] Writings from about 2000 BC describe how to purify "foul water" by boiling in copper vessels, exposing to sunlight, filtering through charcoal and cooling in an earthenware vessel. There is little concerning water treatment in the Old Testament, but Elisha under instruction from the Lord "healed" certain waters so that "there shall not be from thence any more death or barren land." This "healing" was accomplished when Elisha "went forth unto the spring of the waters and cast salt in there …" It is not clear if this "salt" was a fertilizer to help grow crops or if it was some chemical to render the water safe.

Settling was first introduced as a modification of decanting apparatus used for water or wine. This apparatus was pictured on the walls of the tombs of Amenhotep II and Rameses II in the 15th and 13th Centuries BC. An engineering report on water supply was written by the then water commissioner for Rome in AD 98. He described an aqueduct with a settling basin.

In 1627 the experiments of Sir Francis Bacon were published just after his death, and were the first to describe coagulation as well as sedimentation and filtration as a means of treating drinking water. The first filtered supply of water for an entire town was built in Paisley, Scotland in 1804. Starting with a carted supply, a piped distribution system was added in 1807.[2]

However it was not until 1854, in London, that it was demonstrated that certain diseases could be transmitted by water. Dr. John Snow suggested that a cholera outbreak in a certain area in London resulted directly from the use of the Broad Street pump, and was in fact the source of infection in the parish of St. James. Dr. Snow recommended that the use of the pump should be discontinued and the vestrymen of the parish agreeing, the disease subsequently abated in that area.

The discovery was all the more incredible as the germ theory of disease, defined by Pasteur and subsequently postulated by Koch, had not at that time been clarified. Subsequently disinfection of water by addition of chlorine was introduced on a municipal scale. This step, together with an adequate and sanitary distribution system, probably did more to reduce the deaths due to typhoid and cholera and any other single item.

In 1854, cholera claimed a mortality of 10,675 people in London, England. In 1910, the death rate from typhoid fever in the City of Toronto, Canada, was 40.8 per 100,000. By 1931 it had fallen to 0.5 per 100,000. These improvements all related to the extensive water purification and sterilization techniques which are being introduced to municipal water treatment systems during that period.[3]

In general, the treatment processes of water can be subdivided into three groups: physical, chemical, and biological processes. The biological processes are generally reserved for waters grossly contaminated with organic (putrescible) carbon such as sewage or industrial waste waters. These waters are not normally considered as suitable for drinking supplies, but undoubtedly as demand for water increases *all* available sources will have to be examined. However, for the present purposes we will consider that the biological stabilization of originally polluted waters will be dealt with under the section on wastewater treatment. It should, however, be realized that there is a very fine line between treated wastewater discharged into a water body and the use of that water body as a source for drinking water and the treatment of the wastewater before discharge. Clearly in those areas where wastes are still not treated prior to release, a water treatment plant is essentially dealing with the treatment of diluted wastewater.

We must therefore determine the significance of water quality before we examine the types of treatment necessary to achieve this quality. Water quality very much depends upon the use for which the water was intended. For example, industrial boiler feed water requires a very low hardness because the hardness tends to deposit on the pipes in the boiler system and reduces the efficiency of the heat transfer. However, if the hardness of the boiler feed water is zero, the water tends to be very corrosive and this of course is also very undesirable for a boiler system.

If the water is to be used for a brewery or a distillery, a number of other chemical parameters are important. If the water is to be used for cooling then clearly the temperature is one of the most important parameters.

In the past the methods for setting standards for water supplies was very much a hit and miss affair and relied pretty well upon the philosophy of "If no one complains, all is well." Clearly, that is not a very satisfactory criterion. There are a number of drinking water standards or objectives published by various nations of the world, such as the World Health Organization International and European Drinking Water Standards (1963 and 1961), the US Public Health Service Drinking Water Standards (1962) and Objectives (1968). These standards are established on the principle that water in a public water supply system must be treated to the degree which is suitable for the highest and best use. The highest and best use for water of course is human consumption. This can frequently be argued as a rather unnecessary quality when one considers that much water which is processed in a municipal plant is used for watering lawns, washing cars and windows. However, the difficulty in ensuring that a second-class, perhaps unsafe water supply is not used as a potable supply is extremely difficult. It will be found that very few cities have a dual water supply representing a drinking water system and a non-potable system.

A few large cities, particularly when they are adjacent to large standing bodies of water, occasionally have a fire water supply system where the water is taken untreated from the lake or river and pumped under high pressure through a system connected only to fire hydrants and sprinklers.

Thus, assuming that natural water requires some kind of treatment in order to achieve certain predetermined standards, and the process of treating these waters can be subdivided into physical and chemical processes, the remainder of this section will deal with the physical and chemical methods of treating water for municipal or industrial use.

WATER SOURCES

The magnitude of the problem of supplying water to the major cities of the world is in fact a huge engineering problem. According to a US Department of Commerce estimate, the cities of the United States in 1955 with a total population of 110 million produced and distributed 17 billion gallons of water daily to their domestic, commercial, and industrial consumers. Of this, 12.88 billion gallons were from surface water sources which usually, it will be seen, require more elaborate treatment, whereas the remaining 4.12 billion gallons came from groundwater sources—only a small proportion of which would require treatment.[4] The most voluminous source of water is the oceans. It is estimated that they contain about 1060 trillion acre-feet.[5] Clearly this water is of little value as a potable source, but it certainly remains the main reservoir in the hydrologic cycle.

It can be seen from Figure 1 that evaporation is the first step in the purification of ocean water, and this requires the full energy of the sun in order to accomplish. Precipitation, percolation, and runoff are all parts of the cycle of water which is without a beginning or an ending. Of the water which falls upon the earth, part of it directly runs off to the nearest stream or lake, and part of it infiltrates down to the groundwater table and percolates through the groundwater, also into a stream or lake. Transpiration takes place through the leaves of green plants, and evaporation takes place from the groundwater, where it surfaces through swamps, lakes or rivers, and of course from the ocean. Of the water that soaks into the ground, part of it is retained in the capillary voids near the surface. Thus it can be said that the potential sources of water for society consist of wells, which are drilled or dug down to the groundwater table and withdraw water from that level; springs, which are natural outcroppings of groundwater table through rocks or ground; rivers, where the groundwater table has naturally broken through the ground and flown in a certain direction sufficiently to gouge out a channel for the water to flow in; lakes, where large bodies of water gather usually somewhere along a river system; and finally the ocean, if not other sources are available and the ocean is close by. The benefit derived from the costly treatment required to desalinate the ocean under these circumstances is outweighed by the necessity of having a fresh water source at any cost.

There are new water sources which exist deep in the earth's crust. These sources are rarely considered, due to the high salt and sulphur content which is frequently found in them.

The recycling of used water of course is a further source which may be tapped directly. It can be seen from the hydrologic cycle that all water is being continually reused, but the direct recycling of municipal treated sewage into the potable treatment plant is being considered in some water-scarce areas.

Some of the advantages and disadvantages which might be listed for the various sources of water are as follows:

1) Wells provide usually an extremely pure source of potable water. Rarely is any treatment required of this water, certainly before it is safe to drink, although certain industrial uses may require the removal of some of the soluble salts such

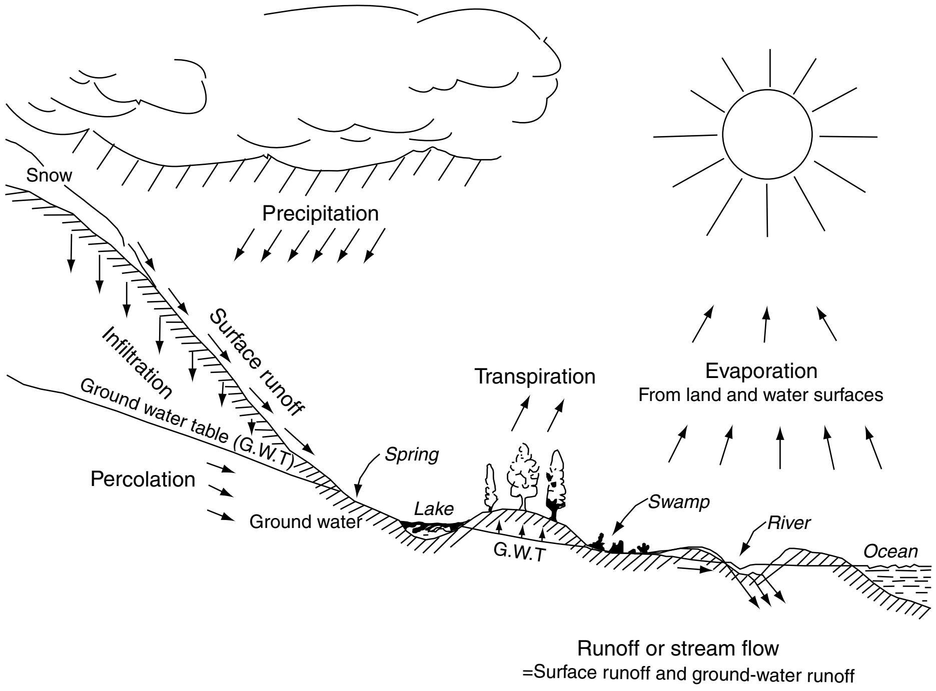

FIGURE 1 Hydrologic cycle (Fair and Geyer, Water Supply and Wastewater Disposal).

as hardness. One of the major disadvantages of wells is that they cannot be observed and therefore must be considered as somewhat unreliable. Frequently it has been experienced in the country, if a drought has persisted for a few days or a few weeks (depending on the environment) and the well has been pumped unusually hard, that the well will run dry. There is never very much warning of this kind of occurrence and therefore for a municipal supply it has the distinct disadvantage of being considered somewhat unreliable.

2) Springs are similarly unreliable, and have a further disadvantage in that they require a rather elaborate engineering system to capture them and concentrate them into one manageable system. Also, springs require rather a large protected area to ensure that man does not pollute this environment, thereby rendering the springwater unsafe.
3) Rivers tend also to be a little unreliable, although they do have the advantage that they can be observed and to some extent controlled through dams and other waterflow structures. Thus it can be seen, if the water level is falling, that a municipality may wish to impose water use restrictions to conserve water until such time as further augmentation of the supply is received through the hydrologic cycle. One of the major problems with a river source is that there is a considerable variation in the quality of the water. During the high flow flood period, there is frequently a considerable amount of silt and organic material which is washed off the ground, whereas at other times of year the water may be relatively clean and require remarkably little treatment prior to distribution. This of course means that water treatment facilities must be installed to deal with the worst possible condition, and at other times of the year it may not in fact be necessary and therefore the equipment lies idle.
4) Lakes and manmade reservoirs, due to the nature of flow through them, have a certain stability both from the point of view of quantity and quality. Undoubtedly, water coming from a lake or a reservoir would require far more elaborate treatment than would water from a well. However, the extreme reliability and the predictability of supply may well outweigh the considerations of cost of treatment. This of course is subject to an economic feasibility study.
5) Oceans. A good deal of attention is currently being focused on the desalination of ocean water, and some attention will be paid to this subsequently in this section. It should, however, be remembered that the ocean is only, economically available to these communities which are immediately adjacent to the ocean. This leaves a very large area of hinterland in most continents which does not have access to the sea. Thus the

desalting of sea water as a major water source has a restricted application to small islands and those coastal stretches of countries where fresh water reserves are either not available or not reliable.

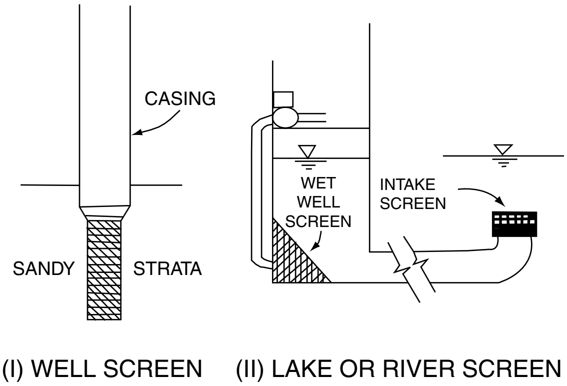
6) Recycled water. A considerable amount of research has been undertaken in the United States and elsewhere for the renovation of treated wastewater for the purposes of returning it directly into the potable supply. Some rather complex chemical and physical processes are required to make this a satisfactory process, and the details of many of these processes will be described subsequently in the next section of this chapter.

PHYSICAL TREATMENT

The items of treatment described under this section will be only those which alter the physical properties of the water or represent a unit process which is physical in nature. All of the processes described may be used individually, collectively or in any combination, in order to accomplish a predetermined water quality.

Screens

Whatever the source of water, it is necessary to insert some kind of screen in the system in order to prevent the passage of solids into the subsequent steps of water treatment. If the source of water is simply a well, the screens tend to be simply designed to prevent the admission of sand from the water-bearing strata into the pumping system. Where water supply is drawn from rivers or lakes, the intakes usually have to be screened and built of corrosion-resistant materials in order to prevent the admission of fish or logs or any other undesirable solids into the system. Intake screens are usually provided with openings approximately equal to one and one-half to two times the area of the intake pipe. The purpose of this is to ensure that the velocity through the screens is sufficiently low to prevent jamming of the screens. On occasion other screens are required as a backup system within the water treatment plant.



(I) WELL SCREEN (II) LAKE OR RIVER SCREEN

FIGURE 2

In some locations where it is found that seasonally algal blooms become a nuisance, a new type of screening known as microstraining has been introduced. Microstrainers are a very fine weave of stainless steel wire with apertures sufficiently small to prevent the passage of the microscopic algae which is normally found in an algal bloom. Such a screening system is normally only required on a seasonal basis and in certain locations where these problems are prevalent. Microstraining is conducted at such a very small diameter orifice that it is sometimes considered to be a part of a filtration process.

Coagulation

Although the basis of coagulation is in fact chemical treatment and will be discussed in the next section, the coagulation process itself (sometimes referred to as flocculation) is accomplished by a physical process involving the gentle agitation of the fluid which allows the small suspended particles to collide and agglomerate into heavier particles or flocs and settle out. Flocculation or coagulation is the principle used in the removal of turbidity from water. It will be shown subsequently that colloidal or very finely divided material will not settle very rapidly. Various processes have been employed to accomplish flocculation. Some of these are; diffused air, baffles, transverse or parallel shaft mixers, vertical turbine mixers, to mention but a few.

The most common type of flocculator used today is the paddle type, the other methods having shown some disadvantage such as being too severe for the fragile floc, or being too inflexible, or being too costly to operate. Horizontally mounted paddles, either located transverse or parallel to the floor, consist of a shaft with a number of protruding arms on which are mounted various blades. The shaft rotates at a very slow rate of 60 to 100 rpm, causing a very gentle agitation which results in the flocculation of the particles. The time required for the flocculation process is very carefully controlled and strongly related to the dosage of chemical which is used. The chemicals used and the chemistry of this process will be described later.

Prior to the flocculation step which has just been described, occurs a flash mixing step when the chemicals are added and mixed very rapidly at high speed to get uniform distribution of the chemical in the stream. A variety of devices are used for this rapid mixing operation; frequently one of the most common includes the low lift pumps which are usually located adjacent to the intake where the water is lifted up into the treatment plant. Here of course the chemicals must be pumped into the pump casing at a higher pressure than the pump is producing, and the mixing takes place in the casing of the pump.

Other devices frequently used are venturi flumes, air jets, paddles, turbines, propellers, the latter being one or the most favored and most widely used of the rapid mixing devices. It usually is composed of a vertical shaft driven by a motor

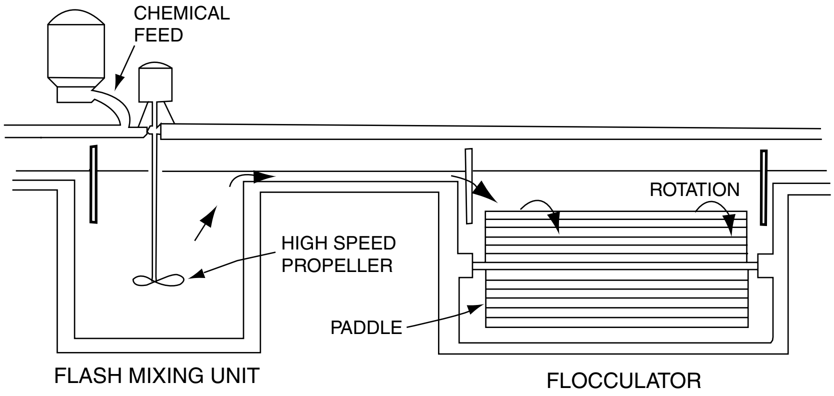


FIGURE 3

on which one or more propeller blades are mounted. Baffles are frequently used to reduce the vortexing about the propeller shaft. Vortexing hinders the mixing operation. Detention periods are usually of the order of one to five minutes, usually at the lower end of this range. Considerable study has been done on the baffling arrangement in a flash mixing unit, and a variety of arrangements have been shown to be successful.

Sedimentation

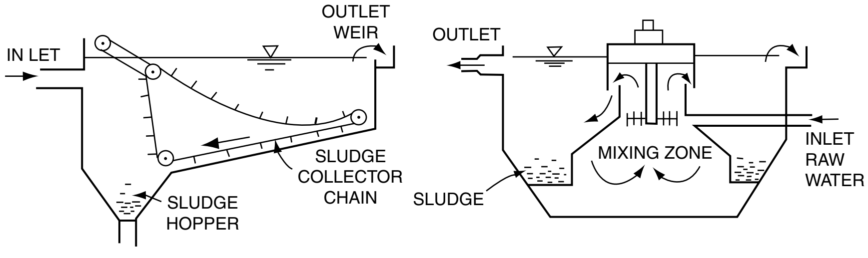
Sedimentation or settling may be accomplished by a variety of means and mechanisms, depending on the material which is to be settled from the liquid.

Discrete settling This type of sedimentation is primarily concerned with the settling out of non-flocculent discrete particles in a fairly dilute system. The primary feature of this type of settling is that the particles do not flocculate and therefore their settling velocity and particle size remain the same throughout the period of settling. It will be seen later that this is quite different from other forms of settling.

The particles in discrete settling will accelerate until the fluid/drag reaches equilibrium with the driving force acting on the particle. In other words, the resistance of the water is equal to the accelerating force of gravity of the particle. When this velocity is reached, it will not increase. This is known as the terminal settling velocity, and it is normally achieved quite rapidly. The loading rate which is used frequently for the design of a settling tank is known as the overflow rate and may be expressed in cubic feet per square foot per day based on the area. It can be seen that cubic feet per square foot per day is in fact the same as feet per day, or in fact a simple velocity. This velocity is defined as the settling velocity of the particles which are removed in this ideal basin if they enter at the surface.

Overflow rates or surface loadings of 150 gallons per day per square foot of tank surface are not unusual where the settling and sand, silt or clay are being accomplished by plain sedimentation.

Flocculent settling The primary difference between this type of settling and the previous one is that in a flocculent system the larger particles subsiding at a slightly higher rate



LONGITUDINAL SETTLING TANK

CIRCULAR COMBINATION SETTLING FLOCCULATOR
(Accelator by Infilco)

FIGURE 4

will overtake and coalesce with smaller particles to form even larger particles, which in turn increase the overall settling rate. Clearly, the greater the liquid depth, the greater will be the opportunity for this type of contact. There is no mathematical relationship which can be used to determine the general effect of flocculation on sedimentation, and empirical data is still required by studying individual laboratory cases. As a result, in flocculent settling the removal of suspended matter depends not only on the clarification rate but also on the depth.

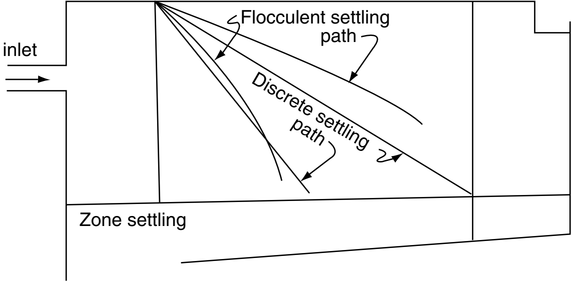
This is one of the significant differences between non-flocculent and flocculent settling.

Zone settling The previous two types of settling described have one property in common, and that is that they both deal with dilute suspensions. Zone settling, on the other hand, deals with very concentrated suspensions where it is assumed that one particle will in fact interfere with the settling rate of another particle. It is clear that in the type of discrete settling, where the particles are somewhat non-reactive and usually quite dense such as sand, the difference between dilute suspensions and concentrated or hindered suspensions is less apparent, so the zone settling phenomenon is usually considered for the flocculating materials. When the particles reach the vicinity of the bottom of the settling tank, a more concentrated suspension zone will be formed and the settling particles will tend to act in concert and reduce the overall rate of subsidence.

It can clearly be seen that in a water treatment plant, particularly if coagulation is applied to remove turbidity, all three types of settling will occur and any settling tank which is designed must take into account all three types (Figure 5).

Filtration

As described earlier, it has been found even in the early Egyptian days that passing water through sand resulted in a reduction in suspended and colloidal matter, and resulted in a further clarification of the water. Water which is on occasion extremely turbid should, of course, first of all be treated by some coagulation or settling or combination of both. However, water which is normally not too turbid may be directly applied to filters or water which has previously been treated by sedimentation and/or coagulation may also be applied to filters to provide the final polishing and the production of clear, aesthetically acceptable water.



Combined Settling Pattern

FIGURE 5

The filtration process actually consists of three phenomena occurring simultaneously (Figure 6).

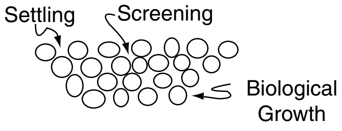
Settling takes place in the small settling basins which are provided between the particles. Screening takes place where particles which are larger than the interstices will be retained simply physically because they cannot pass through. And finally, a biological action takes place through bacterial growth which may occur on the particles of the filter which may occur on the particles of the filter which grow at the expense of the soluble organic carbon passing through in the water. This latter phenomenon is not a very satisfactory way of removing organic carbon, because it does tend to plug up the filter fairly rapidly and reduce its effectiveness.

Filters have been developed through the ages through a series of steps which are mainly related to their operating characteristics or the material which is used as a filtering medium.

Slow sand filter The slow sand filter is, as it suggests, a process whereby water is allowed to pass very slowly through the system at rates of 2.5 to 7.5 million gallons per acre per day.

Although this type of filter has been used traditionally and has been very effective in the past, it has certain operating disadvantages in that it cannot readily be cleaned. While some of these filters are still in use in some parts of the Orient, in Europe and North America, where labor tends to be more costly, other types of filters have been developed. When the difference in water level between the outlet and the water over the filter becomes too great, the filter is taken out of service and the top inch or two of sand is removed from the bed and may or may not be replaced with fresh sand before the filter is put back into operation (Figure 7).

Rapid sand filter A far more popular and common process for the filtration of water is the rapid sand filter. Instead of sitting on a sand bed of approximately three feet, as is the case in the slow sand filter, the bed is twelve to thirty inches thick and supported on a layer of gravel or other coarse grain, heavy material six to eighteen inches thick. Filtration rates on the rapid sand filter are of the order of three to four gallons per square foot per minute. Occasionally



Filtration Phenomena

FIGURE 6

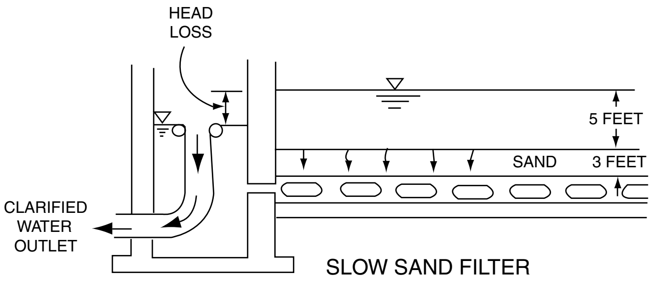


FIGURE 7

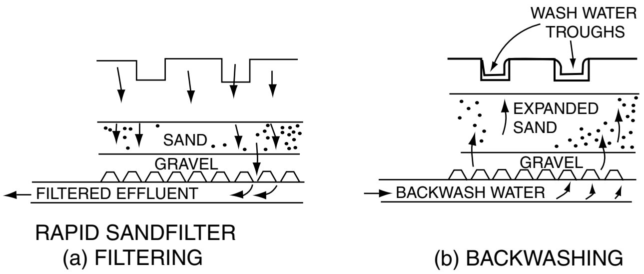

FIGURE 8

a plant is designed to operate at two gallons per square foot per minute, but provided for an overload when necessary (Figure 8).

The cleaning of the rapid sand filter, instead of throwing the filter out of service, is accomplished by simply backwashing. This is accomplished by passing clean water backwards through the filter at a high velocity. This velocity should not be greater than the terminal settling velocity of the smallest particle of sand which is in the filter which is not to be washed over the side. Through this mechanism the sand bed is expanded and the sand is lifted and floated while the particles rub mechanically against one another and wash off the foreign material. The dirty water is washed away in drains. After this has been conducted for a few moments, the filter is allowed to go back into service and the head loss is now smaller so the rate of flow through the filter is increased once more.

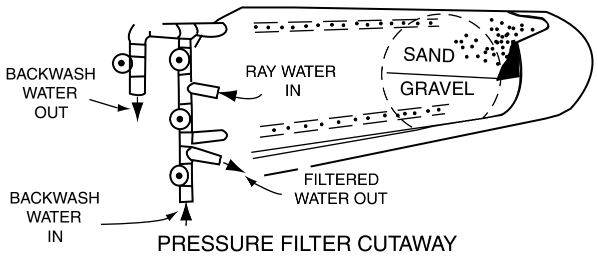

FIGURE 9

Pressure filters Whereas the rapid sand filter is indeed a gravity filter, a pressure filter is somewhat the same type of system only pressure is applied to the water to pass it through the filter. The most common household unit nowadays would be the swimming pool filter, where the water is pumped vertically through the sand and the filter, and when the head loss through the filter becomes excessive as registered on the pressure gauge, the operator will reverse the flow through the filter, accomplishing the backwash described above (Figure 9).

Diatomaceous earth filter Diatomaceous earth is the silicious residue of the bodies of diatoms which were deposited in past geological ages and now form extensive beds where they are mined. The earth is processed and ground, and the silica particles are extremely irregularly shaped and thus provide a very good porous coating. The diatomaceous earth filter was developed by the army for field use to remove certain chlorine-resistant organisms responsible for dysentery.

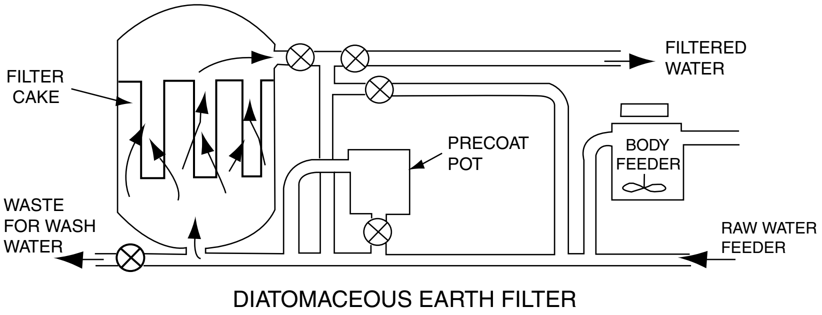

FIGURE 10

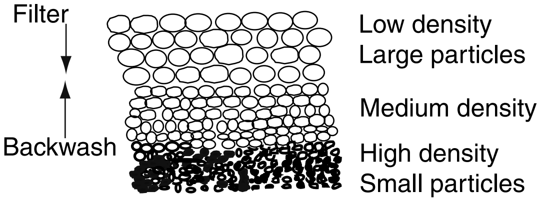

FIGURE 11

The filter medium is supported on a fine metal screen or a porous material. There are three steps in the filtration cycle. There are three steps in the filtration cycle. First of all, the deposit of a pre-coat, which is a thin layer of diatomite deposited on the filter element. The second step is the actual filtration and the body feed addition. The reason why body feed is continually added to the filter is to reduce the amount of clogging that occurs at the surface. This also permits significantly longer filter runs. The third step, when the pressure drops or the filtration rate reaches such a low very thin film over or under the source of irradiation. Commercial equipment is currently being developed for the individual water supply of the small household or institution, and is gaining some acceptance in some quarters. The irradiation of water by ultra-violet light of suitable wave-lengths for a proper period of time will kill bacteria, spores, molds, and viruses and in fact all microorganisms. The bactericidal wave-lengths extend from about 2000 to 2950 Å (angstrom units) with a maximum effect around 2540 Å.

CHEMICAL TREATMENT

The unit operations of chemical coagulation, precipitation, ion exchange and stabilization all produce change in the chemical quality of the water. Some of these are aimed at the removal of the suspended and colloidal substances, others are aimed at the removal of dissolved substances. Finally, some chemicals are simply added for their own sake, but these will not be discussed in this section.

To understand some of the basic chemistry of the treatment processes, it is first of all essential to understand a phenomenon known as chemical equilibrium and reaction velocities. An analogy might be considered as the physical equilibrium between ice and water.

$$\text{Ice} \underset{\text{Add Heat}}{\overset{\text{Remove heat}}{\leftrightharpoons}} \text{Water}$$

If the ice-water system is maintained at 0°C, then molecules of water are transferred from the solid to the liquid state and back again at the same rate. The addition of heat or the removal of heat from the system will result in the equilibrium moving in one direction or the other. The same principles might be applied to what is known as ionic equilibrium, which, like molecular equilibria, are subject to a shift under given stresses.

As an example, we might consider pure water

$$H_2O \rightleftharpoons H^+ + OH^-.$$

Certain stresses will give rise to an increase in hydrogen ion concentration (H^+). The expression of this shift is a reduction in pH, whereas an increase in the OH^- concentration brings about an increase of pH. One of the most important equilibria which exists in natural waters is the relationship between carbon dioxide and carbonate ion, which is shown in the following four equilibrium expressions.

$$CO_2\ (\text{gas}) \rightleftharpoons CO_2\ (\text{solution}) \quad (1)$$

$$CO_2\ (\text{solution}) + H_2O \rightleftharpoons H_2CO_3 \quad (2)$$

$$H_2CO_2 \rightleftharpoons H^+ + HCO_3^- \quad (3)$$

$$HCO_3^- \rightleftharpoons H^+ + CO_3^-. \quad (4)$$

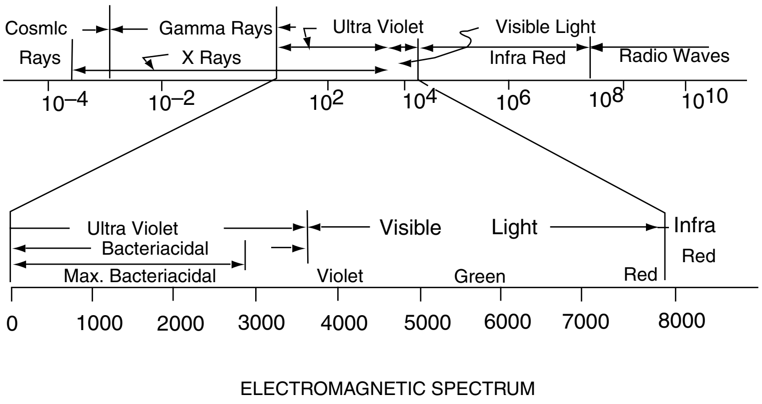

FIGURE 12

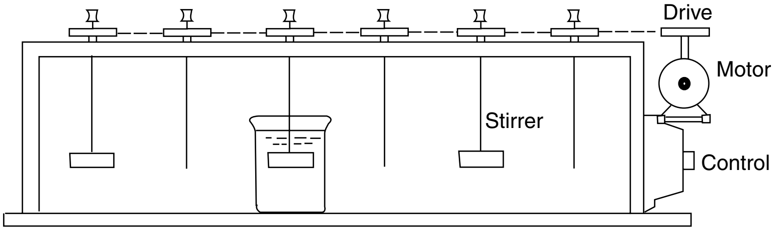

FIGURE 13 Jar test equipment—coagulant dosage varied in each jar to determine optimum concentration.

The equilibrium of the first of these equations is purely physical, since the solubility of gas and water is determined by the pressure of that gas and the temperature and a number of other physical parameters.

Coagulation

The principle function of chemical coagulation is known as destabilization, aggregation, and binding together of colloids. Alum, or aluminum sulphate, ($Al_2(SO_4)_3 \cdot 18H_2O$) is one of the most common coagulants which may be added to a water system. Such a coagulant possesses tiny positive charges and therefore has the ability to link together with negatively charged color or turbidity particles by mutual coagulation. Alum also reacts with the natural alkalinity (carbonate-bicarbonate system) of the water to produce a precipitate which is usually thought to be aluminum hydroxide. If the reaction takes place with natural alkalinity, it may be expressed as follows:

$$\begin{gathered}Al_2(SO_4)_3 \cdot XH_2O\ 3Ca(HCO_{32}) \rightarrow 2Al(OH)_3 + 3CaSO_4 \\ + XH_2O + 6CO_2.\end{gathered}$$

In the event that there is insufficient natural alkalinity for this to occur, then calcium oxide (lime) may be added to create the same effect. Because this system is very poorly understood, the optimum dosage required in practice has to be done by trial and error through a series of tests known as jar tests.

In these jar tests, the flash mixing and flocculation steps described previously are stimulated at various concentrations of alum and the clarification which takes place and the reduction of turbidity and the rate at which the floc settles are all observed in order to determine the optimum dosage of coagulant. If too much coagulant is added, then the colloidal system which is primarily negatively charged will become supersaturated by the aluminum system which is primarily positively charged and the suspension will become restabilized and this can be observed by conducting jar tests over a wide range of concentrations of coagulant.

The reason why alum is so generally used is that it is highly effective over a wide pH range in waters of vastly different chemical make-up. Other materials such as ferrous sulphate are occasionally used to increase the settling rate of plankton and thus increase the time of the filter run, making the filter process more efficient.

Precipitation

There are two important processes which are associated with precipitation in the treatment of water. One is the reduction of hardness (calcium and magnesium) and the other is the reduction of iron and manganese.

Water Softening The lime-soda-ash process involves the addition of $Ca(OH)_2$ and Na_2CO_3 to water. The reactions which occur are as follows:

$$Ca(HCO_3)_2 + \underset{\text{Lime}}{Ca(OH)_2} \rightarrow \underline{2CaCO_3^+} + 2H_2O \tag{1}$$

$$Mg(HCO_3)_2 + Ca(OH)_2 \rightarrow MgCO_3 + \underline{CaCO_3} + 2H_2O \tag{2}$$

$$MgCO_3 + Ca(OH)_2 \rightarrow \underline{Mg(OH)_2} + \underline{CaCO_3} \tag{3}$$

$$CaSO_4 + \underset{\text{Soda Ash}}{Na_2CO_3} \rightarrow \underline{CaCO_3} + Na_2SO_4. \tag{4}$$

In this reaction it can be seen that the lime is added to precipitate the carbonate hardness, while the soda ash provides the carbonate ion to precipitate the non-carbonate hardness.

Precipitation of Iron and Manganese Normally, iron and manganese are only highly soluble if they are in their ferrous (Fe^{2+}) and manganous (Mn^{2+}) forms. Normally, these two metals will only occur in this form if there is an absence of dissolved oxygen. However, on occasions when the water is particularly acid, such as might occur in mine drainage areas, the metals may remain in solution even though a very high dissolved oxygen is present. Under these circumstances, aeration is frequently sufficient to drive off the surplus carbon dioxide, increase the pH and bring about a natural precipitation of these materials in their ferric and manganic form. In order to catalyze or accelerate this reaction, the water is frequently caused to trickle over coke or crushed stone, or to flow upward through some contact material. This allows deposits of iron and manganese to accumulate on the surfaces and catalyze the further precipitation of ferric and manganic oxides.

If the pH of the system is forced to values higher than 7.1, the positively charged ferric hydroxide particles may be adsorbed on the negatively charged calcium carbonate particles and a stable colloidal suspension may result. Iron and manganese are objectionable constituents of water supplies because they impart a brown colour to laundry goods and frequently will stain household plumbing fittings.

Precipitation of iron and manganese can also be satisfactorily accomplished by using the lime-soda-ash process as described above for softening.

Ion Exchange

Ion exchange units are most frequently used for softening waters, but are also used by certain industries for the production of de-ionized water. This is quite common in the brewery industry, where an attempt is made to strip the water down to its most pure constituents so that water in one part of the world is similar to water in other parts of the world. Following de-ionization, breweries and often distilleries will reconstitute the water so that the water used for the production of a certain type of beer will be the same all over the continent and not have the variations which were characteristic of beers when native waters were used for their production.

The chemistry of the ion exchange process is shown below, where a cation resin which will exchange the sodium (Na^+) for the calcium and magnesium (Ca^{2+}, Mg^{2+}). When the resin is saturated with calcium and magnesium, a regeneration is required such as is used in household water softening units, when a very strong brine solution is forced back through the resin and in turn displaces the calcium and magnesium into the backwash line and restores the sodium on the resin for further softening.

$$\text{Softening } Na^2 + \begin{matrix} Ca \\ Mg \end{matrix} \left[\begin{matrix} (HCO_3)_2 \\ SO_4 \\ Cl_2 \end{matrix} \quad \rightarrow \quad \begin{matrix} Ca \\ \\ Mg \end{matrix} \right] \qquad (1)$$

$$R + \left[\begin{matrix} 2NaHSO_4 \\ Na_2SO_4 \\ 2NaCl \end{matrix} \right.$$

$$\text{Regeneration } \left. \begin{matrix} Ca \\ Mg \end{matrix} \right] R + 2NaCl \rightarrow Na_2R + \left. \begin{matrix} Ca \\ Mg \end{matrix} \right] Cl_2 \qquad (2)$$

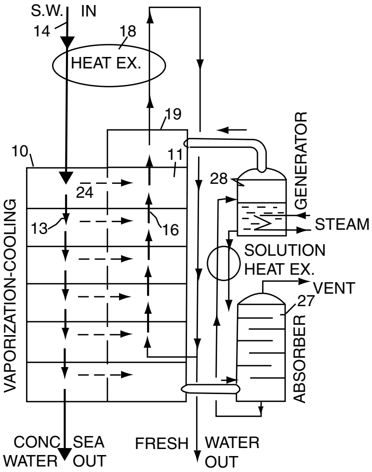

FIGURE 14 Conventional multistage flash evaporation – MSF evaporating and cooling of hot feed brine (vertical arrows down) on left side at successively lower pressures after heating to highest temperature in prime heater (PH) at top; vapors (horizontal arrows) from MSF, passing to preheat the sea water by condensation-heating on right side; fresh water condensate passing stagewise from top to discharge at bottom; additional sea water coolant (dotted line) rejecting heat in lower stages, withdrawing of vapors from prime heater to be condensed in half-stage (dashed lines) increasing the production of fresh water.

Desalination

Although the principles of desalination were fully known in Julius Caesar's time, the energy requirements of this process are presently so high that these will be usually considered as a last resort after all other water sources have been explored. Water quality is frequently referred to as fresh, brackish, sea water or brine. Fresh water normally contains less than 1000 mg/liter of dissolved salts, while brackish water ranges from 1000–35,000 mg/liter of dissolved salts. Sea water contains 35,000 mg/liter of dissolved salts, whereas brine contains very much more from salt water by a semi-permeable membrane, the fresh water will tend to flow into the salt water to equalize the concentration of salts on both sides of the membrane. Bearing in mind that the membrane will not allow the salts to pass back, it is clear that a certain pressure which is known as the osmotic pressure is forcing the fresh water through to the brine side of the membrane. If a force greater than this osmotic pressure is applied on the sea water side, then fresh water will flow backwards through the semi-permeable membrane at a rate proportional to the incremental pressure over the osmotic pressure. In practice, quite high pressures are required in order to get a useful volume of water to pass through the membrane—such pressures as 40–100 kg per square centimeter. This has been shown to work for waters of fairly high dissolved solids, but the structural properties of the membranes must be fairly well developed and of course the membranes must be very well supported. Membranes used for this type of process are frequently cellulose acetate or some derivatives thereof. The power requirement for this process is considerably less than electrodialysis, but it is a

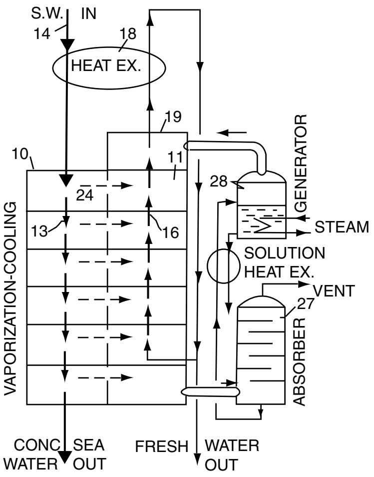

FIGURE 15 Vapor reheat with vapor recompression by absorption (from US Patent 3,288,686). Vapor reheat MSF, vapors formed in low pressure stage pass to Absorber, 27, and are absorbed in the hydrophilic liquid from solution heat exchanger, which cycles through heat exchanger to evaporator or generator, 28, for concentration at higher pressure. Vapors leave at higher pressure to half-stage, 19, to supply prime heat to evaporator.

process which offers considerable promise for the desalination of brackish waters.

The Vacuum Freezing Process Cooled saline water passes into a low pressure chamber where flash evaporation brings about further cooling. Close to freezing ice crystals will form with a brine coating, and washing of these crystals will yield fresh water from the washed ice. Small plant application appears to be feasible at the moment. Considerable development work on this was done by the Technion Institute in Israel.

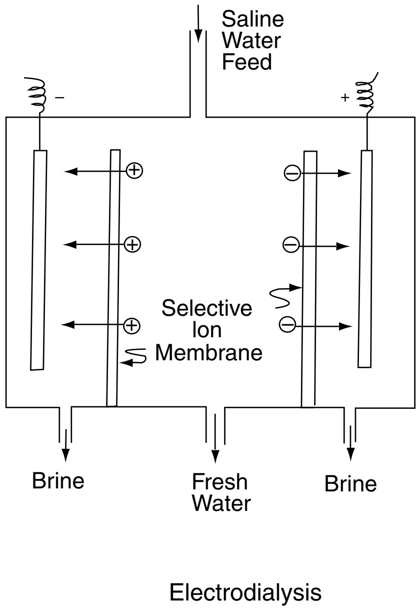

FIGURE 16

A Secondary Refrigerant Process This involves the use of a second hydrocarbon refrigerant, such as butane, that will not mix with water. A great deal of care must be exercised

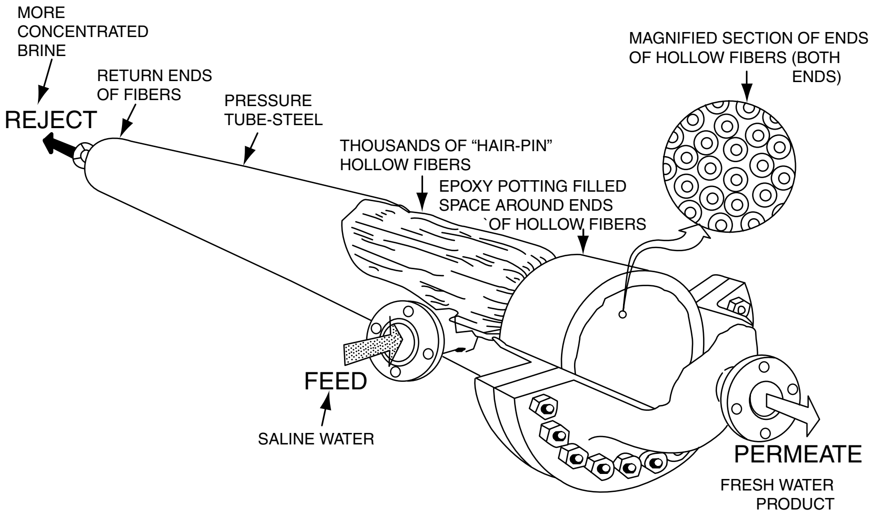

FIGURE 17

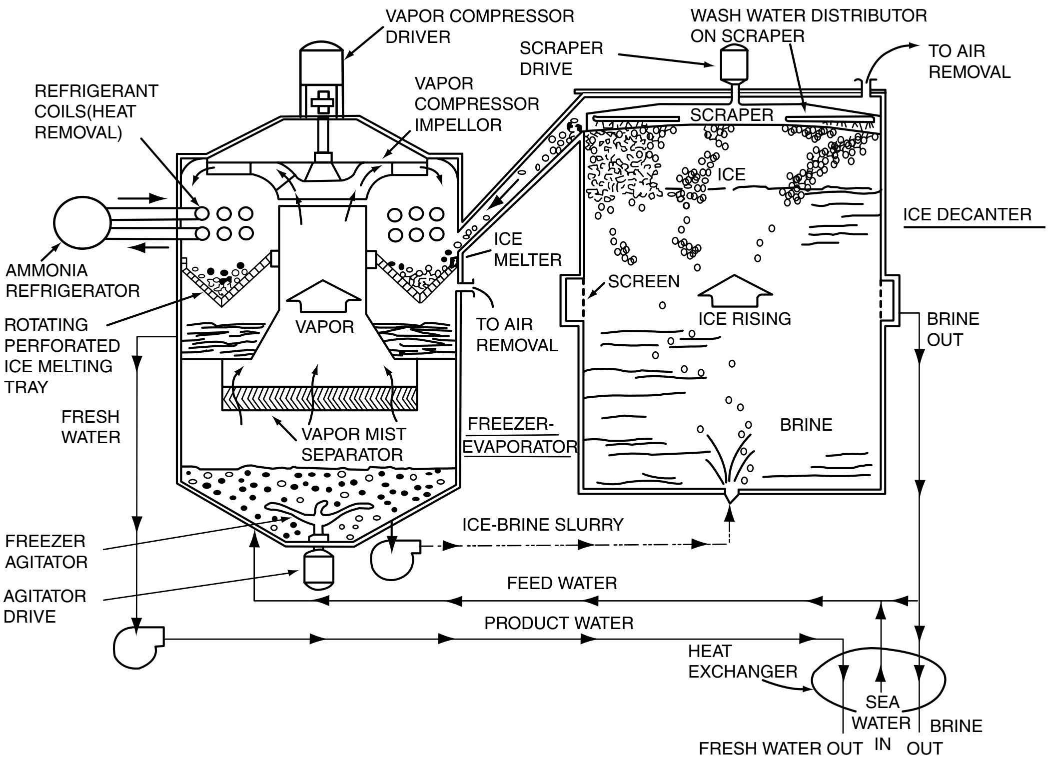

FIGURE 18 Vacuum freezing process

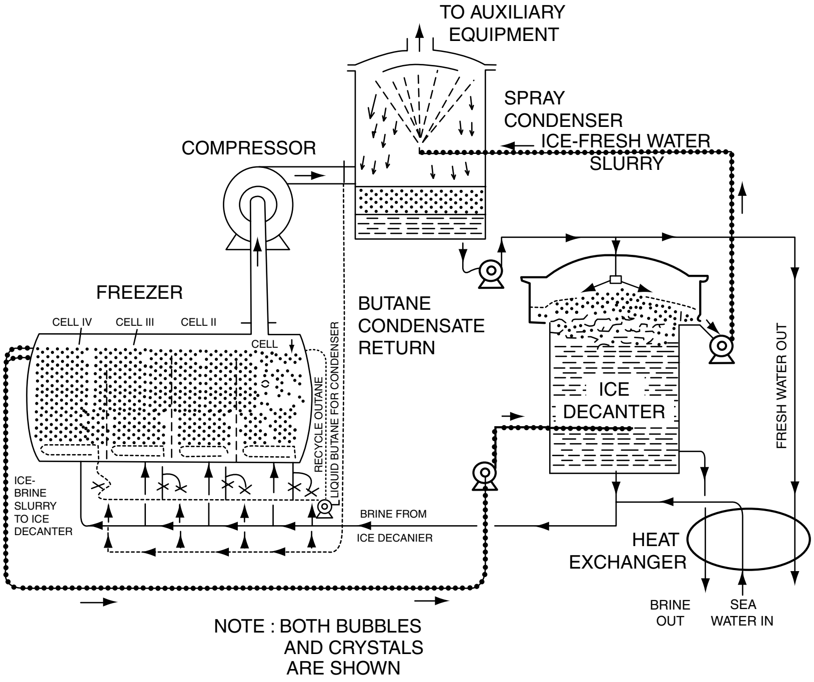

FIGURE 19 Secondary refrigerant freezing process

here to ensure that the product is stripped of butane; otherwise serious explosion hazards exist. It has a low energy input and has minimized corrosion and scale-forming properties. However, so far this process has not been examined on a very large-scale basis.

Other Processes There are a number of other processes which are being considered for desalination, such as solar distillation, but so far this has been restricted to use on a very small scale such as survival kits. Ion exchange, such as was described previously, has some potential here but it is very much limited down to approximately 3000 mg/liter solids. A hydrate process has been considered where propane is added to form a hydrate and react with the water, leaving the salt behind. Then the propane hydrate is decomposed to recover the propane and the water; this one is rather difficult to handle.

Disinfection

As mentioned earlier, water has long since been identified as a means of distributing pathogenic organisms among society. The purpose therefore of disinfecting water supplies is to prevent the spread of water-borne disease by destroying pathogenic organisms. Most of the physical and chemical treatment processes described previously will remove most of the micro-organisms to some extent. However, very small numbers of microorganisms which are viable and pathogenic are all that are required to bring about disastrous epidemics. Thus, disinfection is considered to be a necessary final step before treated water is delivered to a municipal system. This may not be the case in certain industrial supplies.

A physical process for disinfection was previously described using ultra-violet irradiation. Other forms of chemical disinfectant are the halogens such as chlorine, bromine, iodine, and the powerful, unstable oxidant, ozone. In North America chlorination is the most common of the disinfectant processes used, for two reasons. Firstly, it is fairly simple to handle, can be manufactured inexpensively in bulk and delivered to the site, can be applied under fairly controlled conditions, and can maintain a measurable residual in the water supply to indicate safety at all points on a water distribution system. The first attempt at continuous chlorination of a public water supply was made in England during 1904, and subsequently in 1908 in Jersey City, New Jersey, USA. There are certain disadvantages of chlorination, in that a high residual chlorine will bring about a taste which is unacceptable to many people; and chlorine furthermore will react with certain micro-constituents of water, such as phenols, to bring about substantial odors (chlorophenols) quite out of proportion to the concentration of the causative chemicals. The addition of chlorine to water releases a group of substances, all of which have some disinfecting properties. The substances so released are:

1) hypochlorite ion(OCl);
2) hypochlorous acid (HOCl);
3) monochloramine (NH_2Cl);
4) dichloramine ($NHCl_2$);
5) nitrogen trichloride (NCl_3);
6) organic compounds containing chloride; and
7) chlorine dioxide (ClO_2).

Hypochlorite ion and hypochlorous acid are known collectively as free available chlorine residuals. The following substances are known as chloramines: NH_2Cl, $NHCl_2$, NCl_3, and organic chlorine compounds. The chloramines are brought about by the reaction of hypochlorous acid with ammonia

$$NH_3 + HOCl \rightarrow NH_2Cl + H_2O$$
$$NH_2Cl + HOCl \rightarrow NHCl_2 + H_2O$$
$$NHCl_2 + HOCl \rightarrow NCl_3 + H_2O.$$

The process which brings about the various chloramines are shown above. Chlorination is applied in a series of different forms as follow:

Superchlorination This process represents the addition of very high concentrations of chlorine which are intended to oxidize not only the pathogenic and potential pathogenic microorganisms in the system, but also to oxidize those organic compounds which might bring about taste and odor. Following superchlorination, a step involving dechlorination which involves the addition of sulphur dioxide, sodium bisulphite, or sodium sulphite or some similar reducing agent. The bisulphite is frequently used in practice because it is cheaper and more stable.

If there is any amount of ammonia naturally present in the water, a strange phenomenon will occur such as shown above in the graph. On the initial part of the graph, labelled 1 to 2, the ratio (molar) of chlorine to ammonia is less than one and the residual chlorine is essentially all monochloramine. In the next section, between 2 and 3, the oxidation of ammonia and reduction of chlorine continue until the complete oxidation reduction occurs at point 3. At this point once again, all the residual chlorine is in the

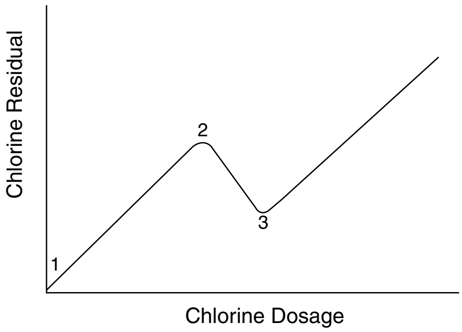

FIGURE 20

form of monochloramine. Beyond point 3, all chlorine added remains in solution. This phenomenon is known as break-point chlorination, and in order to ensure satisfactory disinfecting properties chlorination must go beyond the break-point 3 on the curve.

In certain instances, such as when phenols are present in the water, small concentrations of free available chlorine will combine with the phenols, forming chlorphenols which produce a distinctive taste and odor at very, very small concentrations. When this occurs, chlorine dioxide is frequently used as a disinfecting agent as this does not react with the phenols but in fact destroys them.

Other substances which are used for disinfecting purposes are the other halogens such as bromine and iodine, although these are not commonly used in water supplies. Occasionally they have been used in swimming pools for similar purposes.

Ozone is a particularly effective disinfectant, but it has certain disadvantages in that it must be manufactured on the site, using fairly sizeable and expensive capital equipment. No residual can be maintained due to the instability of the substance, and the methods of detection are rather imperfect. However to compensate for this, the disinfecting properties of ozone are considerably greater than chlorine.

VOC REMOVAL

Treatment of Volatile Organic Compounds Found in Groundwater Sources

With the advent of technological advances in testing of water supplies and concerns regarding possible contamination of groundwater sources, many water supply systems have focused on the treatment of Volatile Organic Compounds (VOC's). VOC's are man-made chemicals, some of which have been shown to be carcinogenic. VOC's are generally found in industrialized settings where substances such as cleaning fluids, degreasers or solvents have been disposed of improperly.

The treatment of VOC's utilizing conventional water treatment techniques involving flocculation, sedimentation and filtration are relatively ineffective at reducing VOC concentrations. VOC's may be treated by either packed tower aeration (air stripping) or granular activated carbon (GAC) absorption. Details of the two treatment techniques are as follows:

Packed Tower Aeration (Air Stripping)

Aeration is the process where air and water are brought into contact for the purposes of transferring volatile substances from water to air. This process is commonly referred to as air stripping. Air stripping basically involves the transfer of dissolved gas molecules from the liquid phase to the gas phase. There are two major factors which determine the removal efficiency of various volatile compounds by air stripping; 1) the ratio of concentration of VOC's in the gaseous phase to the concentration of VOC's in the aqueous phase at equilibrium, and 2) the rate at which equilibrium is obtained.

Numerous types of aeration devices have been used where air stripping can occur. Some of these alternatives involve diffused aeration, spray aeration and water fall aeration.

In packed towers or stripping towers, water flows downward by gravity and air is forced upward. The tower is filled with various forms of packing material which serves to continuously disturb the liquid flow, creating and improving the air-to-water interface. Packed towers typically have void volumes in excess of 90 percent which allows for a large liquid-air interface and minimizes the pressure drop through the column, an operating cost consideration. Packed towers, which are currently in service, have provided VOC removals in the 95–99.9 percent range. A schematic of a typical airstripping facility is shown on Figure A.

There are three major design factors controlling the mass transfer of VOC's from water to air.

Packing depth—is the primary factor influencing removal efficiency. Increasing the packing depth will increase the removal efficiency of the tower.

Tower diameter—controls the liquid loading rate as measured in gallons per minute per square foot, (GPM/sq. ft.). The lower the liquid loading rate, the greater the removal efficiency due to the increased air-to-water interaction zone.

Air-to-water ratio—is the most influential parameter with respect to removal efficiency. Generally, the removal efficiency increases as the air-to-water ratio is increased.

In stripping towers, packing materials are used to provide high void volumes together with high surface area. The water flows downward by gravity and air is forced upward. The raw, untreated water is evenly distributed on the top of the packing with either spray or distribution trays and the air is forced through the tower by either blowers or induced draft fans.

Many options exist for packings involving a variety of shapes and materials. Packings are available in plastic, metal and ceramic. Plastics are best suited for water treatment because of their durability and low cost.

Since the mass transfer of VOC's is basically accomplished by passing significant quantities of air through a fixed quantity of water, the air-to-water ratio can be varied by either, i) increasing the diameter of the column, or ii) increasing the air blower capacity. Hence, an optimum balance of tower diameter and blower size must be evaluated. Given a specific water loading rate and a packing selection, the air-to-water ratio determines the height of the stripping tower required to provide the specified removals.

Various liquid loading rates are evaluated to optimize the tower diameter versus air pressure drops. Once the tower diameter is determined, a cost analysis comparing capital and operating cost is determined. A matrix of air-to-water ratios and depth of packing is then developed to determine the optimum design.

Granular Activated Carbon (GAC)

The removal of VOC's through adsorption involves passing the contaminated water through a medium of adsorbent, such as activated carbon, where the VOC's will adhere (stick) to its surface. Adsorbates which could possibly be used to remove VOC's from groundwater include granular activated carbon (GAC) and powdered activated carbon (PAC). GAC exhibits a wide range of effectiveness in adsorbing various compounds and generally tends to adsorb high-molecular weight compounds more readily than low-molecular weight substances such as VOC's. However, GAC is currently the best available adsorbent for the removal of VOC's.

Powdered activated carbon has been used traditionally for the removal of trace organics associated with causing taste and odors in drinking water. PAC typically requires coagulation and sedimentation facilities to be effective and is not normally used for groundwater treatment.

GAC has a spectrum of effectiveness like aeration; however, the process is more complicated and water quality can have an influence on performance. The adsorption of VOC's can be affected by the amount of background organic carbon, generally measured as total organic carbon. High background organic content can result in lower adsorption capacity.

GAC contractors also require regeneration or replacement when the material becomes saturated with contaminants. The life of the GAC is dependent upon the concentrations of the contaminants present, the flow rate through the media and the required effluent concentrations. GAC contractors have a reported removal efficiency of 99%. A schematic of a typical GAC facility is shown in Figure B.

A combination of aeration-adsorption can also be a highly effective method of reducing VOC levels to very low concentrations. This combination is quite attractive when several different types of contaminants are present. However, the corresponding cost of treatment increases dramatically.

VOC Treatment with Granular Activated Carbon (GAC)

GAC treatment can employ either a gravity or pressure system. The gravity disrepair is generally used in surface water treatment plants and operates in a manner similar to a gravity sand filter.

In groundwater treatment systems, a pressure disrepair (contactor) is generally used and involves a pressurized vessel which can accommodate flow rates at high pressures and allow direct discharge to an existing distribution system.

Numerous GAC contactors are currently in use for the removal of VOCs and a significant amount of data is available on this form treatment.

GAC contactors would involve vertical steel pressure vessels which would allow the raw water to enter the top of the vessel and pass downward through the carbon bed.

The treated water is collected at the bottom of the vessel utilizing a header-lateral arrangement or a bottom plate with nozzles. The collected water would then be disinfected and discharged to the distribution system for consumption.

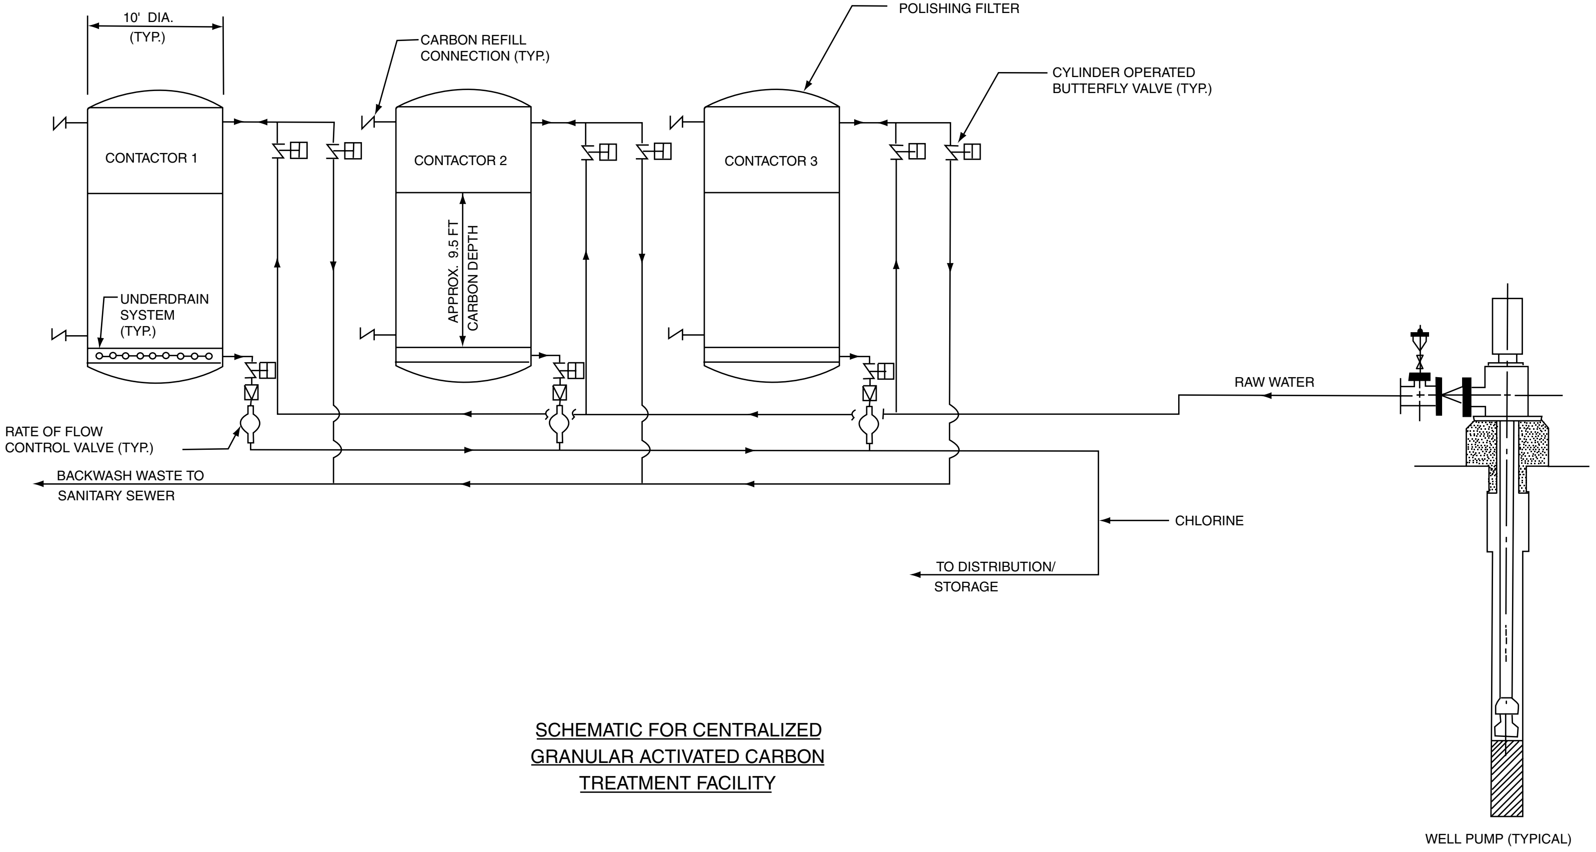
Since the contactor is essentially a filter, the vessel would be equipped with backwashing facilities. The carbon filters would not require frequent backwashing. The contactor backwash waste would be disposed of by discharging to the nearby holding pond and subsequently to the sanitary sewer system. Connections would also be provided to readily remove the spent carbon and to readily install the new material.

As a general rule, aeration is most effective with low-molecular weight, highly volatile substances, while adsorption works best with high-molecular weight compounds with a low solubility. The selection of the treatment alternative is based on many factors such as the contaminant(s), concentrations of contaminants, groundwater quality, site constraints, pumping system configuration as well as other factors.

Air stripping facilities, by their nature, require the existing pumping facilities to be modified as well as the need to install a second pumping system. Existing pumping systems must be modified to produce less head (pressure) in order to direct water to the stripping tower. The tower will dissipate the energy provided by the well pump as the water passes through the tower and into the clearwell below. From the clearwell, the water must be repumped to the water system for use. As such, the economic feasibility of an air-stripping facility must account not only for the capital and operating expenses of the stripping facility, but must also account for modifications to existing well pump(s) and the costs associated with repumping the water supply for use.

Unlike an air-stripping facility, a pressurized carbon contactor does not utilize mechanical equipment as part of the treatment process. Most often, existing pumping facilities may remain unchanged if a small head loss (which would result in a slightly reduced flowrate) can be tolerated. After water is pumped through the contactor, it is discharged directly to the distribution system for use. As such, GAC facilities have a major advantage over air strippings due to ease of operation and the ability to discharge directly to existing systems without repumping.

There is a move toward privatization of public water (and wastewater) operations. There are advantages and disadvantages associated with this. The Contractor assumes responsibility for operating results. If a plant has a staff that is too large or inadequately trained, a for-profit operation can be expected to introduce greater efficiency in operation. At times, public office holders have introduced privatization to show a better municipal financial picture than is the actual case. The Contractor may not practice proper maintenance or may try to operate with a staff that is too small. This may be reflected in poor operating results and the public agency charged with oversight can be expected to take action if the public health is threatened. Each case is unique and each decision to privatize must be evaluated taking into account all pertinent factors.



SCHEMATIC FOR CENTRALIZED GRANULAR ACTIVATED CARBON TREATMENT FACILITY

NOTE: CONCEPTUAL SCHEMATIC ARRANGEMENT SHOWN IS FOR PARALLEL OPERATION. ADDITIONAL VALVING WOULD BE REQUIRED FOR SERIES OPERATION.

No. 6: An oil for use in burners equipped with preheaters permitting a high-viscosity fuel	150	—	2.00[f]	—	—	—	—	—	—	—	300	45	—	—	(638)	(92)	—	—

---

[a] Recognizing the necessity for low-sulfur fuel oils used in connection with heat treatment, nonferrous metal, glass ceramic furnaces, and other special uses, a sulfur requirement may be specified as follows:

Grade of fuel oil	*Sulfur, (Max %)*
No. 1	0.5
No. 2	21.0
No. 4	No limit
No. 5	No limit
No. 6	No limit

Other sulfur limits may be specified only by mutual agreement between the purchaser and the seller.

[b] It is the intent of these classifications that failure to meet any requirement of a given grade does not automatically place an oil in the next lower grade unless in fact it meets all requirements of the lower grade.

[c] Lower or higher pour points may be specified whenever required by conditions of storage or use. However, these specifications shall not require a pour point lower than 0°F under any conditions.

[d] Report as passing when the copper test strip shows no gray or black deposit.

[e] The 10% point may be specified at 440°F maximum for use in other than atomizing burners.

[f] The amount of water by distillation plus the sediment by extraction shall not exceed 2.0%. The amount of sediment by extraction shall not exceed 0.50%. A deduction in quantity shall be made for all water and sediment in excess of 1.0%.

TABLE 11

The Nordwijk Declaration on Climate Change (Nov. 6, 1989)

(1) The composition of the earth's atmosphere is being seriously altered at an unprecedented rate due to human activity. Based on our current understanding, society is being threatened by man-made changes to the global climate.

(2) While there are still uncertainties regarding the magnitude, timing and regional effects of climate change due to human activity, there is a growing consensus in the scientific community that significant climate change and instability are most likely over the next century.

Predictions available today indicate potentially severe economic and social dislocations for future generations.

Assuming these predictions, delay in action may endanger the future of the planet as we know it.

(3) Fortunately, there is a growing awareness among the world population and their political leaders that action is needed. The basic principle of ecologically sustainable development has gained wide currency following the report of the World Commission on Environment and Development. This principle should be fundamental to efforts to tackle the problem of climate change and atmospheric pollution. The protection of the ozone layer is being addressed by the 1985 Vienna Convention on the Protection of the Ozone Layer and the 1987 Montreal Protocol on Substances that Deplete the Ozone layer. Further strengthening of control measures contained in the Protocol was called for all the London Conference on Saving the Ozone Layer in March 1989 and the first meeting of the parties to the Montreal Protocol at Helsinki in May 1989. A decision will be taken by the second meeting of the contracting parties to be held in London in 1990. The process aims at phasing out the production and consumption of chlorofluorocarbons (CFCs) controlled under the Montreal Protocol by the year 2000 by the developed countries. The should also phase out other controlled substances which deplete the ozone layer as soon as feasible. Developing countries should also phase out these substances as soon as possible after their technology and resource needs are met.

(4) Global warming is being addressed by the Intergovernmental Panel on Climate Change (IPCC), which was established by UNEP and WMO, and recognized by UN General Assembly Resolution 43/53 on Protection of global climate for present and future generations of mankind. The Hague Declaration of March 1989 put forward challenging ideas for international co-operation, and legal and institutional measures. The 15th session of the UNEP Governing Council and the XLI session of the WMO Executive Council in 1989 requested their executive heads to begin preparations for negotiations on a framework convention on climate; these negotiations should be initiated as soon as possible after the interim report of the IPCC is adopted. This interim report will be reviewed at the Second World Climate Conference in November 1990. The 1989 Economic Summit agreed that a framework convention on climate change setting out general principles was urgently required and that specific protocols containing concrete commitments could be fitted into the framework as scientific evidence requires and permits. The Economic Summit also strongly advocated common efforts to limit emissions of carbon dioxide and other greenhouse gases. The July 1988 declaration of the states, parties to the Warsaw Treaty, and the meeting of non-aligned countries in Belgrade in September 1989 also addressed the issue of climate change. The Tokyo Conference on Global Environment and Human Response Towards Sustainable Development was held in September 1989. The Langkawi Declaration on Environment issued by the Commonwealth Heads of Governments in October 1989 stated the need to take new action to address the serious deterioration in the environment, including climate change. Given this base it is now time for governments of all countries to commit themselves to the IPCC, to strengthen and to extend the process of addressing climate change.

(5) Measures to limit climate change will have other significant benefits such as reducing acidification, protecting the ozone layer, preserving biodiversity and other natural resources, preventing mean sea-level change and promoting sustainable development.

(6) The Conference recognizes the principle of the sovereign right of states to manage their natural resources independently. The Conference also reaffirms that global environmental problems have to be approached through international co-operation. Solving the external debt problem of developing countries, and establishing fair economic and commercial relationships between industrialized and developing countries would assist developing countries in creating appropriate conditions to protect the environment.

(7) Climate change is a common concern of mankind. All countries should now, according to their capabilities and the means at their disposal, initiate actions and develop and maintain effective and operational strategies to control, limit or reduce emissions of greenhouse gases. As a first step, they should take those actions which are beneficial in their own right. Industrialized countries, in view of their contribution to the increase of greenhouse gas concentrations, and in view of their capabilities, have specific responsibilities of different kinds: i) they should set an example by initiating domestic action, ii) they should support, financially and otherwise, the action by countries to which the protection of the atmosphere and adjustment to climate change would prove to be an excessive burden and iii) they should reduce emissions of greenhouse gases, also taking into account the need of the developing countries to have sustainable development. Developing countries establishing industrial facilities for the first time have a unique opportunity to include up-to-date technologies for controlling the emissions of greenhouse gases.

(8) For the long term safeguarding of our planet and maintaining its ecological balance, joint effort and action should aim at limiting or reducing emissions and increasing sinks for greenhouse gases to a level consistent with the natural capacity of the planet. Such a level should be reached within a time frame sufficient to allow ecosystems to adapt naturally to climate change, to ensure that food production is not threatened and permit economic activity to develop in a sustainable and environmentally sound manner. Stabilizing the atmospheric concentrations of greenhouse gases is an imperative goal. The IPCC will need to report on the best scientific knowledge as to the options for containing climate change within tolerable limits. Some currently available estimates indicate that this could require a reduction of global anthropogenic greenhouse gas emissions by more than 50 per cent. These estimates should be the subject of further examination by the IPCC.

(9) While striving to preserve the global environment, it is important to work at the same time to ensure stable development of the world economy, in line with the concept of "sustainable development." Effort and action should include: i) the phasing-out of CFCs controlled by the Montreal Protocol, which are responsible for about one fifth of projected global warming, by national action and international co-operation in the context of the Montreal Protocol. This includes financial assistance and transfer of technology and information. In this connection, it is important that the substitutes for CFCs also should not contribute significantly to the global warming problem, ii) action especially by industrialized countries to limit or reduce CO_2-emissions, iii) action to reduce deforestation, prevent soil erosion and desertification; increase afforestation, and sound forest management in the temperate as well as the tropical zones, iv) action to limit or reduce the emissions of all greenhouse gases other than CO_2 and their precursors and to increase the sinks for such substances and v) intensified efforts for technological breakthrough, for example with regards to renewable energy and removal and re-utilization of CO_2.

(10) The conference recommends that appropriate fora, including the IPCC, consider the necessity and efficiency of the introduction of the concept of CO_2-equivalence. This would provide a single parameter to describe the radiative effects of the various greenhouse gases, including CFCs. Such a concept, after taking into account other environmental considerations, creates a basis for negotiations in response measures for different greenhouse gases in the most cost-effective manner. The Conference further recommends the development of common definitions and the harmonization of methods to calculate CO_2-emissions.

(11) All countries should increase co-operation in developing new, environmentally sound technologies, to improve existing technologies and increasingly to use these technologies in order to limit climate change or adapt to it. Maximum use should be made of existing international organizations, institutions and mechanisms, governmental and non-governmental, for technology co-operation with and transfer to interested countries, especially developing countries. Factors that impede effective transfer of appropriate technologies should be identified and measures implemented to overcome these impediments.

(12) Progress in reducing atmospheric pollution depends not only on technical and economic issues but also on attitudinal and conceptual changes. All countries, especially industrialized countries, should recognize the need to make their socio-economic activities and life-styles environmentally sound. Improved dissemination of information and better training of personnel is needed, both at the national and international level. Public awareness programmes, including school curricula, should include the issue of climate change and its connection with the way individuals use energy and other natural resources. Wider public awareness can be supported by increased scientific evidence arising from systematic research and monitoring activities. The Conference calls upon the non-governmental organizations to participate, in co-operation with international, regional and national authorities, in the efforts that are needed to respond to the problems of global warming, more specifically in the field of education and awareness building.

(13) Many countries, especially developing countries will require assistance in identifying the causes of anthropogenic climate change, in establishing its extent and effect and also in responding to it. They will need help in acquiring, using, developing and maintaining technologies that are appropriate to their industrial, energy, transport, forestry and agricultural infrastructure. Industrialized countries will take steps to facilitate the transfer to developing countries of technologies to limit the global climate change through financial assistance and other mechanisms to overcome the incremental costs of acquiring and using these technologies. Furthermore, the capabilities of these countries should be increased so that they can develop appropriate technologies themselves. In this context the concept of assured access to appropriate technologies in relation to proprietary rights needs to be explored.

Given this stage of development of the issue of climate change, the Conference more specifically:

CARBON DIOXIDE (CO_2)

—(14) *Urges* all countries to take steps individually and collectively, to promote better energy conservation and efficiency and the use of environmentally sound energy sources, practices and technologies with no or minimum environmentally damaging characteristics. These policies should be reflected in short and long term energy policies and be pursued by all relevant sectors, including industry and transport, taking into account the need of developing countries for an adaptation period in order to enable them to meet their technological and other developmental needs. One direct means of allowing markets to incorporate the risk of climate change could be to ensure that the prices of all fuels reflect their full social, long run marginal and environmental costs and benefits.

—(15) *Agrees* that it is timely to investigate quantitative emission targets to limit or reduce CO_2 emissions and encourages the IPCC, in their interim report due in 1990, to include an analysis of target options.

—(16) *Recognizes* the need to stabilize, while ensuring stable development of the world economy, CO_2 emissions and emissions of other greenhouse gases not controlled by the Montreal Protocol. Industrialized nations agree that such stabilization should be achieved by them as soon as possible, levels to be considered by the IPCC and the Second World Climate Conference of November 1990. In the view of many industrialized nations such stabilization of CO_2 emissions should be achieved as a first step at the latest by the year 2000.

Urges all industrialized countries to support the process of IPCC through the investigation of the feasibility of achieving targets to limit or reduce CO_2 emissions including e.g. a 20 per cent reduction of CO_2 emission levels by the year 2005 as recommended by the scientific World Conference on the Changing Atmosphere in Toronto 1988.

Urges all industrialized countries to intensify their efforts in this respect, while ensuring sustainable development and taking into account the specific circumstances of individual countries.

—(17) *Agrees* that industrialized countries with, as yet relatively low energy requirements, which can reasonably be expected to grow in step with their development, may have targets that accommodate that development.

—(18) *Calls* on the IPCC to present the analysis and conclusions referred to above in the Second World Climate Conference in November 1990.

—(19) *Agrees* that developing countries endeavour to meet future targets for CO_2- emissions and sinks, with due regard to their development requirements and within the limits of their financial and technical capabilities. International co-operation, whenever available, would be a contributing factor for greater action. New processes or industries to be introduced should, as far as possible, incorporate technologies which are more energy-efficient and produce less pollution than present technologies.

—(20) *Agrees* that developing countries will need to be assisted financially and technically, including assistance with training, i.e. by strengthening relevant mechanisms to ensure that they will be in a position to manage, develop, and conserve their forest resources in a sustainable and environmentally sound manner. They will also contribute to combatting erosion and desertification. Recognition by the market of the total value of forests, including non-wood values, is a precondition for developing countries' being able to successfully use such financial and technical assistance for sustainable forest management.

—(21) *Agrees* to pursue a global balance between deforestation on the one hand and sound forest management and afforestation on the other. A world net forest growth of 12 million hectares a year in the beginning of next century should be considered as a provisional aim.

Requests the IPCC to consider the feasibility of achieving this aim. To this end; the world deforestation rate should be slowed inter alia through the suppression of acid rain and other pollutants of fires and through the reduction of pressures on biota. Sound forest management practices should be encouraged and at the same time vigorous forestry programmes should be developed in both temperate and tropical zones; biological diversity should be maintained; strategies addressing climate change issues through forest management and afforestation should be integrated with strategies addressing the sustainability of other forest based values resulting in full multiple-use plans where appropriate, but with due consideration of the people living in or dependent on forest land.

Welcomes the work of the Tropical Forestry Action Plan and the International Timber Trade Organization in pursuit of these goals.

CHLOROFLUOROCARBONS (CFCs)

—(22) *Welcomes* the commitment of the industrialized countries to amend the Montreal Protocol and to phase out the production and consumption of controlled chlorofluorocarbons by the year 2000, and of other controlled ozone depleting substances as soon as feasible.

Urges all countries to become Parties to the Vienna Convention for the Protection of the Ozone Layer and to the Montreal Protocol. To facilitate this broad participation suitable amendments of the Montreal Protocol should be considered urgently by the Parties to the Protocol.

Urges industrialized countries to use financial and other means to assist developing countries in phasing out their production and consumption of controlled substances as soon as possible, by providing them with sufficient means to enable them to meet their target date. The development of alternative technologies and products in developing countries should be promoted.

OTHER GREENHOUSE GASES

—(23) *Recommends* that the development and implementation of specific means of limiting the atmospheric concentrations of greenhouse gases other than CO_2 and CFCs should be energetically pursued, taking into consideration the special situation of developing countries.

MINISTERIAL MEETING

—(24) *Recognizes* the need to convene a Ministerial Conference to review the interim report of the IPCC. The conference endorses the plan of the organization by WMO, UNEP, UNESCO and ICSU of such a meeting as part of the Second World Climate Conference in November 1990.

FUNDING

—(25) *Recommends* that existing institutions for development and financial assistance including the Multilateral Development Banks, Bilateral Assistance Programmes, the relevant United Nations organizations and specialized agencies, and scientific and technological organizations should give greater attention to climate change issues within their environmental and other relevant programmes by providing expanded funding including concessional funding. In addition, regional and subregional co-operation should be reinforced and funded so as to address and implement the required action at that level.

—(26) *Recommends* that additional resources should, over time, be mobilized to help developing countries take the necessary measures to address climate change and that are compatible with their development requirements.

Further *recommends* that the scope of resources needed must be assessed. Such assessments should include inter alia country studies and the capabilities of existing institutions and mechanisms to meet the financing needs identified, similar to the approaches developed under the Montreal Protocol.

Further consideration should be given to the need for funding facilities including a clearinghouse mechanism and a possible new international fund and their relationship to existing funding mechanisms, both multilateral and bilateral. Such funding should be related to the implementation of a future climate convention and associated protocols. In the meantime the donor community is urged to provide assistance to developing countries to support actions addressing climate change.

—(27) *Recommends* that, initially, international funding be directed towards
(i) funding of a CFC phase-out in developing countries in the context of the Montreal Protocol;
(ii) promoting efficient use of energy, including appropriate end use technologies, increasing the use of non-fossil fuels and switching to energy sources with lower greenhouse gas emissions, and the use of renewable energy sources;
(iii) increased financial support for forest production and forest management improvement, for example through the Tropical Forestry Action Plan (TFAP), the Plan of Action to Combat Desertification, the International Tropical Timber Organization (ITTO) and other relevant international organizations;
(iv) assisting developing countries in planning how to address problems posed by climate change;
(v) supporting developing countries to enable their participation in the IPCC process and the other international meetings on this subject;
(vi) conducting research and monitoring;
(vii) arranging for technology transfer to and technology development in developing countries;
(viii) promoting public awareness, education and institutional and manpower development.

The use of financial resources could subsequently be extended inter alia to major energy sources with little or no environmentally damaging characteristics and for steps to reduce other global man-made emissions of greenhouse gases.

RESEARCH AND MONITORING

—(28) *Urges* all countries and relevant organizations to increase their climate change research and monitoring activities and to provide for adequate data bases on emissions. *Also urges* states to co-operate in, and provide increasing support for, international co-ordination of these activities building on international programmes such as the World Climate Programme and the International Geosphere-Biosphere Programme, and on the present roles of the UNEP, WMO, ICSU, IEA, UNESCO, IOC, and other competent international organizations and bodies. The enhancement and strengthening of operational aspects of their work should be examined.

Recommends that more research should be carried out by 1992 into the sources and sinks of the greenhouse gases other than CO_2 and CFCs, like methane (CH_4), nitrous oxide (N_2O) and tropospheric ozone (O_3), including further research on the effect of the ocean on the concentration of radiatively active gases in the atmosphere.

CLIMATE CHANGE CONVENTION

—(29) 1. *Urges* all countries to join and intensify the ongoing work within UNEP and WHO through the IPCC with respect to the compilation of elements for a framework convention on climate change so that negotiations upon it can start as soon as possible after the adoption of the interim report of the IPCC.
2. *Recommends* that such convention will be framed in such a way as to gain the adherence of the largest possible number and most suitably balanced spread of countries.

3. Agrees that to this end the framework convention and associated protocols should commit the parties inter alia to:
   —enhancement of research and systematic observation of climate, aimed at detecting and monitoring climate variations and change;
   —action to deal with greenhouse gas emissions and the effects of global warming;
   —address to particular financial needs of the developing countries in the access to and transfer of technology; and
   —strengthen sustainable forest management.
4. *Agrees* further that in developing the framework convention on climate change special attention should be given to ensuring that provision is made for appropriate decision making procedures and powers.
5. *Urges* all involved or to be involved in the negotiations to do their utmost to conclude these negotiations to ensure adoption of the convention as early as 1991 if possible and no later than at the Conference of the United Nations on Environment and Development in 1992.
6. *Considers* that in the preparation of the framework convention and protocols the relevant aspects of the Vienna Convention on the Protection of the Ozone Layer should be taken into account, as well as innovative approaches as may be required by the complex character of the problem.

—(30) *Recommends* that this declaration and the supporting papers be conveyed to the IPCC at the conclusion of this Conference for further consideration and action.

LIST OF PARTICIPATING COUNTRIES

Argentina
Australia
Austria
Bangladesh
Belgium

Bolivia
Brazil
Bulgaria
Cameroon
Canada

China
Colombia
Costa Rica
Cuba
Denmark

Egypt
Finland
France
Gambia
German Democratic Republic

Germany, Federal Republic of
Ghana
Greece
Guinea
Hungary

India

TABLE 12

The following excerpts from the Kyoto Protocol of the United Nations Framework Convention on Climate Change are presented without comment:

The Parties to this Protocol,

Being Parties to the United Nations Framework Convention on Climate Change, hereinafter referred to as "the Convention",

In pursuit of the ultimate objective of the Convention as stated in its Article 2,

Recalling the provisions of the Convention,

Being guided by Article 3 of the Convention,

Pursuant to the Berlin Mandate adopted by decision 1/CP.1 of the Conference of the Parties to the Convention at its first session,

Have agreed as follows:

ARTICLE 1

For the purposes of this Protocol, the definitions contained in Article 1 of the Convention shall apply. In addition:

1. "Conference of the Parties" means the Conference of the Parties to the Convention.
2. "Convention" means the United Nations Framework Convention on Climate Change, adopted in New York on 9 May 1992.
3. "Intergovernmental Panel on Climate Change" means the Intergovernmental Panel on Climate Change established in 1988 jointly by the World Meteorological Organization and the United Nations Environment Programme.
4. "Montreal Protocol" means the Montreal Protocol on Substances that Deplete the Ozone Layer, adopted in Montreal on 16 September 1987 and as subsequently adjusted and amended.
5. "Parties present and voting" means Parties present and casting an affirmative or negative vote.
6. "Party" means, unless the context otherwise indicates, a Party to this Protocol.
7. "Party included in Annex I" means a Party included in Annex I to the Convention, as may be amended, or a Party which has made a notification under Article 4, paragraph 2(g), of the Convention.

ARTICLE 2

1. Each Party included in Annex I, in achieving its quantified emission limitation and reduction commitments under Article 3, in order to promote sustainable development, shall:

(a) Implement and/or further elaborate policies and measures in accordance with its national circumstances, such as:
  (i) Enhancement of energy efficiency in relevant sectors of the national economy;
  (ii) Protection and enhancement of sinks and reservoirs of greenhouse gases not controlled by the Montreal Protocol, taking into account its commitments under relevant international environmental agreements; promotion of sustainable forest management practices, afforestation and reforestation;
  (iii) Promotion of sustainable forms of agriculture in light of climate change considerations;
  (iv) Research on, and promotion, development and increased use of, new and renewable forms of energy, of carbon dioxide sequestration technologies and of advanced and innovative environmentally sound technologies;
  (v) Progressive reduction or phasing out of market imperfections, fiscal incentives, tax and duty exemptions and subsidies in all greenhouse gas emitting sectors that run counter to the objective of the Convention and application of market instruments;
  (vi) Encouragement of appropriate reforms in relevant sectors aimed at promoting policies and measures which limit or reduce emissions of greenhouse gases not controlled by the Montreal Protocol;
  (vii) Measures to limit and/or reduce emissions of greenhouse gases not controlled by the Montreal Protocol in the transport sector;
  (viii) Limitation and/or reduction of methane emissions through recovery and use in waste management, as well as in the production, transport and distribution of energy;

(b) Cooperate with other such Parties to enhance the individual and combined effectiveness of their policies and measures adopted under this Article, pursuant to Article 4, paragraph 2(e)(i), of the Convention. To this end, these Parties shall take steps to share their experience and exchange information on such policies and measures, including developing ways of improving their comparability, transparency and effectiveness. The Conference of Parties serving as the meeting of the Parties to this Protocol shall, at its first session or as soon as practicable thereafter, consider ways to facilitate such cooperation, taking into account all relevant information.

2. The Parties included in Annex I shall pursue limitation or reduction of emissions of greenhouse gases not controlled by the Montreal Protocol from aviation and marine bunker fuels, working through the International Civil Aviation Organization and the International Maritime Organization, respectively.

3. The Parties included in Annex I shall strive to implement policies and measures under this Article in such a way as to minimize adverse effects, including the adverse effects of climate change, effects on international trade, and social, environmental and economic impacts on other Parties, especially developing country Parties and in particular those identified in Article 4, paragraphs 8 and 9, of the Convention, taking into account Article 3 of the Convention. The Conference of the Parties serving as the meeting of the Parties to this Protocol may take further action, as appropriate, to promote the implementation of the provisions of this paragraph.

4. The Conference of the Parties serving as the meeting of the Parties to this Protocol, if it decides that it would be beneficial to coordinate any of the policies and measures in paragraph 1(a) above, taking into account different national circumstances and potential effects, shall consider ways and means to elaborate the coordination of such policies and measures.

ARTICLE 3

1. The Parties included in Annex I shall, individually or jointly, ensure that their aggregate anthropogenic carbon dioxide equivalent emissions of the greenhouse gases listed in Annex. A do not exceed their assigned amounts, calculated pursuant to their quantified emissions limitation and reduction commitments inscribed in Annex B and in accordance with the provisions of this Article, with a view to reducing their overall emissions of such gases by at least 5 per cent below 1990 levels in the commitment period 2008 to 2012.

2. Each Party included in Annex I shall, by 2005, have made demonstrable progress in achieving its commitments under this Protocol.

3. The net changes in greenhouse gas emissions by sources and removals by sinks resulting from direct human-induced land-use change and forestry activities, limited to afforestation, reforestation and deforestation since 1990, measured as verifiable changes in carbon stocks in each commitment period, shall be used to meet the commitments under this Article of each Party included in Annex I. The greenhouse as emissions by sources and removals by sinks associated with those activities shall be reported in a transparent and verifiable manner and reviewed in accordance with Articles 7 and 8.

4. Prior to the first session of the Conference of the Parties serving as the meeting of the Parties to this Protocol, each Party included in Annex I shall provide, for consideration by the Subsidiary Body for Scientific and Technological Advice, data to establish its level of carbonstocks in 1990 and to enable an estimate to be made of its changes in carbon stocks in subsequent years. The Conference of the Parties serving as the meeting of the Parties to this Protocol shall, at its first session or as soon as practicable thereafter, decide upon modalities, rules and guidelines as to how, and which, additional human-induced activities related to changes in greenhouse gas emissions by sources and removals by sinks in the agricultural soils and the land-use change and forestry categories shall be added to, or subtracted from, the assigned amounts for Parties included in Annex I, taking into account uncertainties, transparency in reporting, verifiability, the methodological work of the Intergovernmental Panel on Climate Change, the advice provided by the Subsidiary Body for Scientific and Technological Advice in accordance with Article 5 and the decisions of the Conference of the Parties. Such a decision shall apply in the second and subsequent commitment periods. A Party may choose to apply such a decision on these additional human-induced activities for its first commitment period, provided that these activities have taken place since 1990.

5. The Parties included in Annex I undergoing the process of transition to a market economy whose base year or period was established pursuant to decision 9/CP.2 of the Conference of the Parties at its second session shall use that base year or period for the implementation of their commitments under this Article. Any other Party included in Annex I undergoing the process of transition to a market economy which has not yet submitted its first national communication under Article 12 of the Convention may also notify the Conference of the Parties serving as the meeting of the Parties to this Protocol that it intends to use an historical base year or period other than 1990 for the implementation of its commitments under this Article. The Conference of the Parties serving as the meeting of the Parties to this Protocol shall decide on the acceptance of such notification.

6. Taking into account Article 4, paragraph 6, of the Convention, in the implementation of their commitments under this Protocol other than those under this Article, a certain degree of flexibility shall be allowed by the Conference of the Parties serving as the meeting of the Parties to this Protocol to the Parties included in Annex I undergoing the process of transition to a market economy.

7. In the first quantified emission limitation and reduction commitment period, from 2008 to 2012, the assigned amount for each Party included in Annex I shall be equal to the percentage inscribed for it in Annex B of its aggregate anthropogenic carbon dioxide equivalent emissions of the greenhouse gases listed in Annex A in 1990, or the base year or period determined in accordance with paragraph 5 above, multiplied by five. Those Parties included in Annex I for whom land-use change and forestry constituted a net source of greenhouse gas emissions in 1990 shall include in their 1990 emissions base year or period the aggregate anthropogenic carbon dioxide equivalent emissions by sources minus removals by sinks in 1990 from land-use change for the purposes of calculating their assigned amount.

8. Any Party included in Annex I may use 1995 as its base year for hydrofluorocarbons, perfluorocarbons and sulphur hexafluoride, for the purposes of the calculation referred to in paragraph 7 above.

9. Commitments for subsequent periods for Parties included in Annex I shall be established in amendments to Annex B to this Protocol, which shall be adopted in accordance with the provisions of Article 21, paragraph 7. The Conference of the Parties serving as the meeting of the Parties to this Protocol shall initiate the consideration of such commitments at least seven years before the end of the first commitment period referred to in paragraph 1 above.

10. Any emission reduction units, or any part of an assigned amount, which a Party acquires from another Party in accordance with the provisions of Article 6 or of Article 17 shall be added to the assigned amount for the acquiring Party.

11. Any emission reduction units, or any part of an assigned amount, which a Party transfers to another Party in accordance with the provisions of Article 6 or of Article 17 shall be subtracted from the assigned amount for the transferring Party.

12. Any certified emission reductions which a Party acquires from another Party in accordance with the provisions of Article 12 shall be added to the assigned amount for the acquiring Party.

13. If the emissions of a Party included in Annex I in a commitment period are less than its assigned amount under this Article, this difference shall, on request of that Party, be added to the assigned amount for that Party for subsequent commitment periods.

14. Each Party included in Annex I shall strive to implement the commitments mentioned in paragraph 1 above in such a way as to minimize adverse social, environmental and economic impacts on developing country Parties, particularly those identified in Article 4, paragraphs 8 and 9, of the Convention. In line with relevant decisions of the Conference of the Parties on the implementation of those paragraphs, the Conference of the Parties serving as the meeting of the Parties to this Protocol shall, at its first session, consider what actions are necessary to minimize the adverse effects of climate change and/or the impacts of response measures on Parties referred to in those paragraphs. Among the issues to be considered shall be the establishment of funding, insurance and transfer of technology.

ARTICLE 4

1. Any Parties included in Annex I that have reached an agreement to fulfill their commitments under Article 3 jointly, shall be deemed to have met those commitments provided that their total combined aggregate anthropogenic carbon dioxide equivalent emis-sions of the greenhouse gases listed in Annex A do not exceed their assigned amounts calculated pursuant to their quantified emission limitation and reduction commitments inscribed in Annex B and in accordance with the provisions of Article 3. The respective emission level allocated to each of the Parties to the agreement shall be set out in that agreement.

2. The Parties to any such agreement shall notify the secretariat of the terms of the agreement on the date of deposit of their instruments of ratification, acceptance or approval of this Protocol, or accession thereto. The secretariat shall in turn inform the Parties and signatories to the Convention of the terms of the agreement.

3. Any such agreement shall remain in operation for the duration of the commitment period specified in Article 3, paragraph 7.

4. If Parties acting jointly do so in the framework of, and together with, a regional economic integration organization, any alteration in the composition of the organization after adoption of this Protocol shall not affect existing commitments under this Protocol. Any alteration in the composition of the organization shall only apply for the purposes of those commitments under Article 3 that are adopted subsequent to that alteration.

5. In the event of failure by the Parties to such an agreement to achieve their total combined level of emission reductions, each Party to that agreement shall be responsible for its own level of emissions set out in the agreement.

6. If Parties acting jointly do so in the framework of, and together with, a regional economic integration organization which is itself a Party to this Protocol, each member State of that regional economic integration organization individually, and together with the regional economic integration organization acting in accordance with Article 24, shall, in the event of failure to achieve the total combined level of emission reductions, be responsible for its level of emissions as notified in accordance with this Article.

ARTICLE 5

1. Each Party included in Annex I shall have in place, no later than one year prior to the start of the first commitment period, a national system for the estimation of anthropogenic emissions by sources and removals by sinks of all greenhouse gases not controlled by the Montreal Protocol. Guidelines for such national systems, which shall incorporate the methodologies specified in paragraph 2 below, shall be decided upon by the Conference of the Parties serving as the meeting of the Parties to this Protocol at its first session.

2. Methodologies for estimating anthropogenic emissions by sources and removals by sinks of all greenhouse gases not controlled by the Montreal Protocol shall be those accepted by the Intergovernmental Panel on Climate Change and agreed upon by the Conference of the Parties at its third session. Where such methodologies are not used, appropriate adjustments shall be applied according to methodologies agreed upon by the Conference of the Parties serving as the meeting of the Parties to this Protocol at its first session. Based on the work of, *inter ali*a, the Intergovernmental Panel on Climate Change and advice provided by the Subsidiary Body for Scientific and Technological Advice, the Conference of the Parties serving as the meeting of the Parties to this Protocol shall regularly review and, as appropriate, revise such methodologies and adjustments, taking fully into account any relevant decisions by the Conference of the Parties. Any revision to methodologies or adjustments shall be used only for the purposes of ascertaining compliance with commitments under Article 3 in respect of any commitment period adopted subsequent to that revision.

3. The global warming potentials used to calculate the carbon dioxide equivalence of anthropogenic emissions by sources and removals by sinks of greenhouse gases listed in Annex A shall be those accepted by the Intergovernmental Panel on Climate Change and agreed upon by the Conference of the Parties at its third session. Based on the work of, *inter ali*a, the Intergovernmental Panel on Climate Change and advice provided by the Subsidiary Body for Scientific and Technological Advice, the Conference of the Parties serving as the meeting of the Parties to this Protocol shall regularly review and, as appropriate, revise the global warming potential of each such greenhouse gas, taking fully into account any relevant decisions by the Conference of the Parties. Any revision to a global warming potential shall apply only to commitments under Article 3 in respect of any commitment period adopted subsequent to that revision.

ARTICLE 6

1. For the purpose of meeting its commitments under Article 3, any Party included in Annex I may transfer to, or acquire from, any other such Party emission reduction units resulting from projects aimed at reducing anthropogenic emissions by sources or enhancing anthropogenic removals by sinks of greenhouse gases in any sector of the economy, provided that:
(a) Any such project has the approval of the Parties involved;
(b) Any such project provides a reduction in emissions by sources, or an enhancement of removals by sinks, that is additional to any that would otherwise occur;
(c) It does not acquire any emission reduction units if it is not in compliance with its obligations under Articles 5 and 7; and
(d) The acquisition of emission reduction units shall be supplemental to domestic actions for the purposes of meeting commitments under Article 3.

2. The Conference of the Parties serving as the meeting of the Parties to this Protocol may, at its first session or as soon as practicable thereafter, further elaborate guidelines for the implementation of this Article, including for verification and reporting.

3. A Party included in Annex I may authorize legal entities to participate, under its responsibility, in actions leading to the generation, transfer or acquisition under this Article of emission reduction units.

4. If a question of implementation by a Party included in Annex I of the requirements referred to in this Article is identified in accordance with the relevant provisions of Article 8, transfers and acquisitions of emission reduction units may continue to be made after the question has been identified, provided that any such units may not be used by a Party to meet its commitments under Article 3 until any issue of compliance is resolved.

ARTICLE 7

1. Each Party included in Annex I shall incorporate in its annual inventory of anthropogenic emissions by sources and removals by sinks of greenhouse gases not controlled by the Montreal Protocol, submitted in accordance with the relevant decisions of the Conference of the Parties, the necessary supplementary information for the purposes of ensuring compliance with Article 3, to be determined in accordance with paragraph 4 below.

2. Each Party included in Annex I shall incorporate in its national communication, submitted under Article 12 of the Convention, the supplementary information necessary to demonstrate compliance with its commitments under this Protocol, to be determined in accordance with paragraph 4 below.

3. Each Party included in Annex I shall submit the information required under paragraph 1 above annually, beginning with the first inventory due under the Convention for the first year of the commitment period after this Protocol has entered into force for that Party. Each such Party shall submit the information required under paragraph 2 above as part of the first national communication due under the Convention after this Protocol has entered into force for it and after the adoption of guidelines as provided for in paragraph 4 below. The frequency of subsequent submission of information required under this Article shall be determined by the Conference of the Parties serving as the meeting of the Parties to this Protocol, taking into account any timetable for the submission of national communications decided upon by the Conference of the Parties.

4. The Conference of the Parties serving as the meeting of the Parties to this Protocol shall adopt at its first session, and review periodically thereafter, guidelines for the preparation of the information required under this Article, taking into account guidelines for the preparation of national communications by Parties included in Annex I adopted by the Conference of the Parties. The Conference of the Parties serving as the meeting of the Parties to this Protocol shall also, prior to the first commitment period, decide upon modalities for the accounting of assigned amounts.

ARTICLE 8

1. The information submitted under Article 7 by each Party included in Annex I shall be reviewed by expert review teams pursuant to the relevant decisions of the Conference of the Parties and in accordance with guidelines adopted for this purpose by the Conference of the Parties serving as the meeting of the Parties to this Protocol under paragraph 4 below. The information submitted under Article 7, paragraph 1, by each Party included in Annex I shall be reviewed as part of the annual compilation and accounting of emissions inventories and assigned amounts. Additionally, the information submitted under Article 7, paragraph 2, by each Party included in Annex I shall be reviewed as part of the review of communications.

2. Expert review teams shall be coordinated by the secretariat and shall be composed of experts selected from those nominated by Parties to the Convention and, as appropriate, by intergovernmental organizations, in accordance with guidance provided for this purpose by the Conference of the Parties.”...............

ARTICLE 28

The original of this Protocol, of which the Arabic, Chinese, English, French, Russian and Spanish texts are equally authentic, shall be deposited with the Secretary-General of the United Nations.

DONE at Kyoto this eleventh day of December one thousand nine hundred and ninety-seven.

IN WITNESS WHEREOF the undersigned, being duly authorized to that effect, have affixed their signatures to this Protocol on the dates indicated.

ANNEX A

Greenhouse gases

Carbon dioxide (CO_2)
Methane (CH_4)
Nitrous oxide (NO_2)
Hydrofluorocarbons (HFCs)
Perfluorocarbons (PFCs)
Sulphur hexafluoride (SF_6)

Sectors/source categories

Energy Fuel combustion Energy industries Manufacturing industries and construction Transport
Other sectors Fugitive emissions from fuels Solid fuels Oil and natural gas
Other Industrial processes Mineral products Chemical industry Metal production
Other production

Production of halocarbons and sulphur hexafluoride
Consumption of halocarbons and sulphur hexafluoride
Solvent and other product use Agriculture Enteric fermentation Manure management
Rice cultivation Agricultural soils Prescribed burning of savannas Field burning of agricultural residues
Other

ANNEX B

Party Quantified emission limitation or reduction commitment

(Percentage of base year or period)
Australia 108 Austria 92 Belgium 92 Bulgaria* 92 Canada 94 Croatia* 95 Czech Republic* 92
Denmark 92 Estonia* 92 European Community 92 Finland 92 France 92 Germany 92
Greece 92 Hungary* 94 Iceland 110 Ireland 92 Italy 92 Japan 94 Latvia* 92
Liechtenstein 92 Lithuania* 92 Luxembourg 92 Monaco 92 Netherlands 92 New Zealand 100
Norway 101 Poland* 94 Portugal 92 Romania*92 Russian Federation* 100 Slovakia* 92
Slovenia* 92 Spain 92 Sweden 92 Switzerland 92 Ukraine* 100
United Kingdom of Great Britain and Northern Ireland 92 United States of America 93

---

* Countries that are undergoing the process of transition to a market economy.

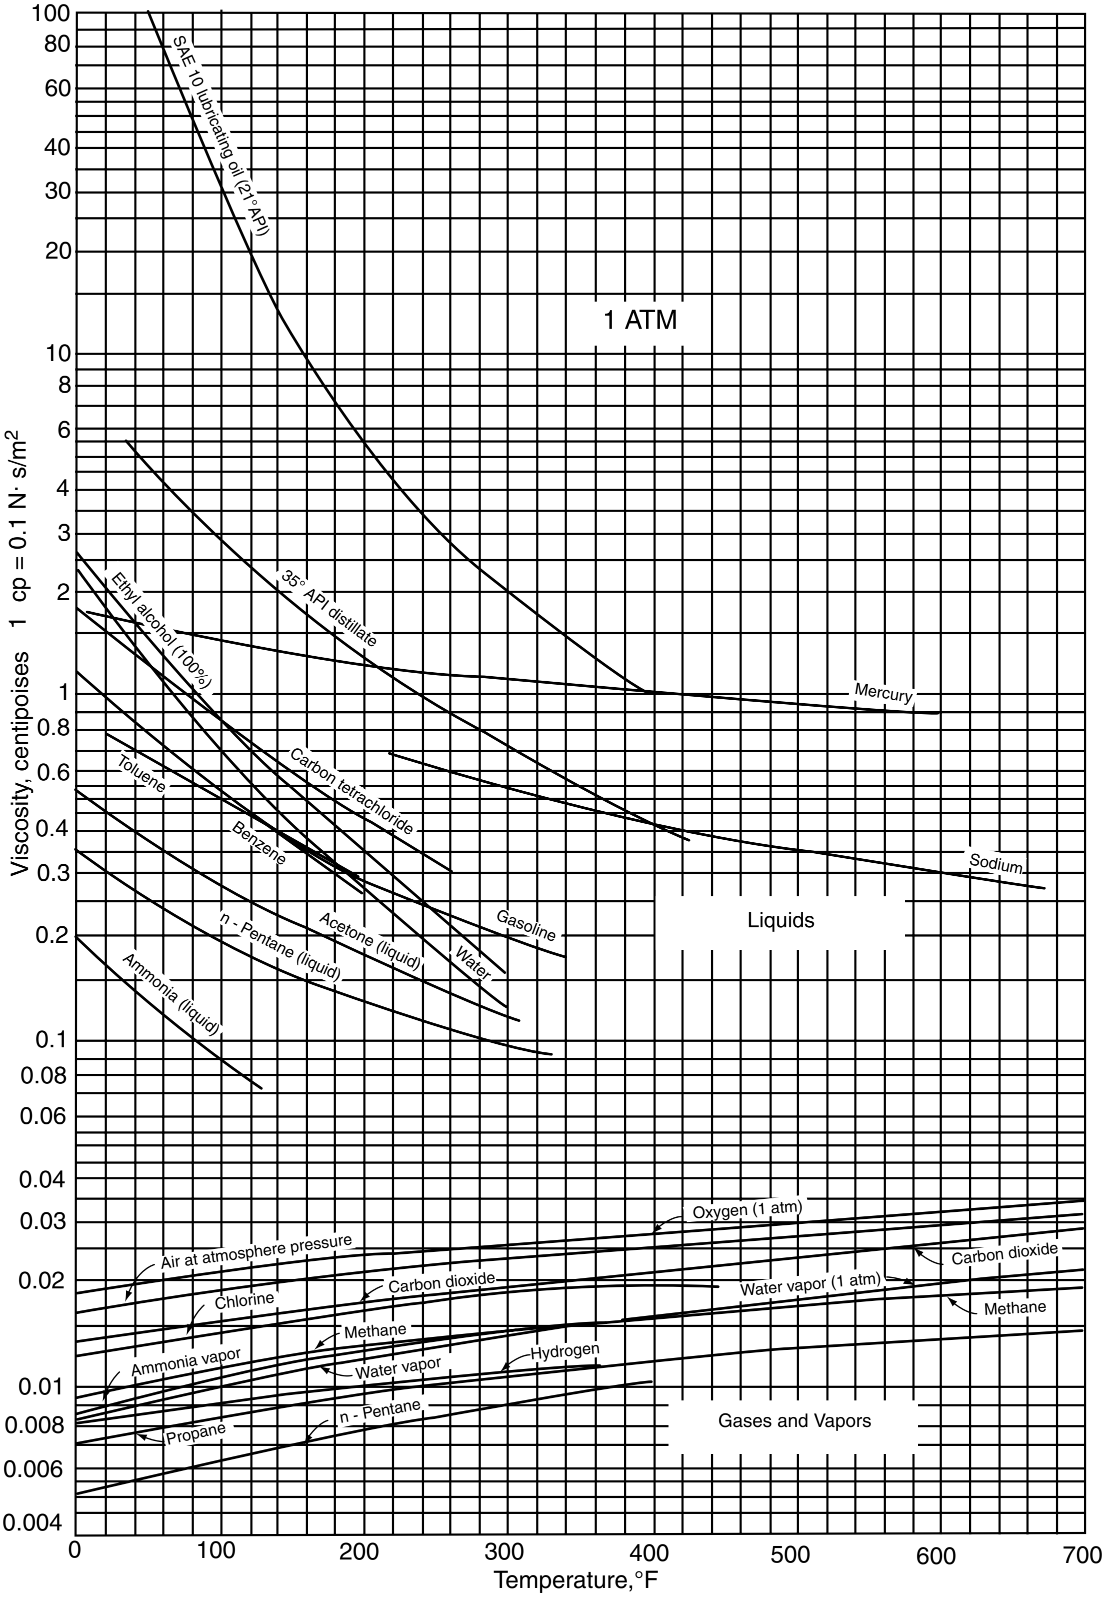

FIGURE 3 Viscosities of fluids as a function of temperature. Adopted from G. G. Brown and Associates, *Unit Operations,* John Wiley & Sons, New York, 1950.

ACRONYMS AND ABBREVIATIONS

AA—Atomic Adsorption
AAAS—American Association for the Advancement of Science
ALARA—As Low As Reasonably Achievable
ALARP—As Low As Reasonably Practicable
ALPCO—Association of Local Air Pollution Control officers (U.S.)
ALAT—Alamine Amino Transferase
ALK—Alkalinity
ALLEA—All European Academies
AM—Annual-Maximum
AMA—American Medical Association
AMD—Acid Mine Drainage
AMO—Atlantic Multidecadal Oscillation
AMP—Adenosine Monophosphate
AMU—Atomic Mass Unit
ANDRA—National Waste Disposal Organization (France)
ANL—Argonne National Laboratory (U.S.)
ANOVA—Analysis of Variance
ANP—National Petroleum Agency (Brazil)
ANPR—Advanced Notice of Proposed Rulemaking (U.S.)
ANSI—American National Standards Institute
ANS—American Nuclear Society
ANTLE—Affordable Near Term Low Emissions
ANWR—Alaska National Wildlife Refuge
AOAC—Association of Official Agricultural Chemists
AOC—Area of Concern (U.S.)
AOC—Assimilable Organic Carbon
AOCS—American Oil Chemists Society
AOGCM—Atmospheric-Ocean General Circulation Model
AONB—Area of Outstanding Natural Beauty (UK)
AOT—Advanced Oxidation Technology
AOX—Organochlorine
APC—Adenomatous Polyposis Coli
APC—Air Pollution Control
APCA—Air Pollution Control Association
APCS—Air Pollution Control System
APDC—Ammonium Pyrolidinodithiocarbonate
APEG—Airborne Particle Expert Group
APEM—Association of Professional Engineers of Manitoba
APHA—American Public Health Association
APHIS—Animal and Plant Health Inspection Service (U.S.)
API—American Petroleum Institute
APS—Aerodynamic Particle Size
APS—American Physical Society
AQCR—Air Quality Control Region (U.S.)
AQEI—Air Quality Exposure Index
AQMD—Air Quality Management District
ARAR—Applicable or Relevant and Appropriate Requirement
ARB—Air Resources Board
ARBRE—Arable Biomass Renewable Energy
ARDS—Acute Respiratory Distress Syndrome
ARM—Aluminized Red Mud
ARM—Availability, Reliability and Maintainability
ARMS—Agricultural Resources Management Study
AROI—Acceptable Range of Oral Intake
ARS—Absorption Refrigeration System
ARS—Agricultural Research Service (U.S.)
AS—Activated Sludge
AS—Australian Standard
ASBR—Anaerobic Sequencing Batch Reactor
ASCE—American Society of Civil Engineers
ASEE—American Society for Engineering Education
ASHRAE—American Society of Heating, Refrigerating and Air Conditioning Engineers
ASLB—Atomic Safety Licensing Board (U.S.)
ASME—American Society of Mechanical Engineers
ASPEN—Advanced Systems for Process Engineering
ASSE—American Society of Safety Engineers
AST—Aboveground Storage Tank
ASTM—American Society for Testing and Materials
ASTMS—Association of Scientific, Technical and Management Staffs
ASV—Anode Stripping Voltammetry
ATOC—Acoustic Thermometry of Ocean Climate
ATOFMS—Aerosol Time-of-Flight Mass Spectrometer
ATP—Adenosine Triphosphate
ATP—Advanced Technology Program (U.S.)
ATS—Automatic Tracking Service
ATSDR—Agency for Toxic Substances and Disease Registry (U.S.)
au—Absorbance Unit
AWEP—Association of Women in Environmental Professions
AWG—Association of Women Geoscientists
AWIS—Association for Women in Science
AWMA—Air and Water Management Association
AWRA—American Water Resources Association
AWSE—Association of Women in Science and Engineering (UK)
AWWA—American Water Works Association

BABFO—British Association for Biofuels and Oil
BACT—Best Available Current (Control) Technology
BAF—Biological Amplification Factor
BALF—Bronchoalveolar Fluid
BANANA—Build Absolutely Nothing Anywhere Anytime
BAP—Benzo-(a)-Pyrene
BAP—Biomass-Associated Product
Bara—Bar Absolute
BART—Best Available Retrofit Technology
BAT—Best Available Technology
BATNEEC—Best Available Technology Not Entailing Excessive Cost (UK)
BBADCP—Broad Band Acoustic Doppler Current Profiler
BBL—Barrels
BCC—Bioaccumulative Chemicals of Concern
BCDL—Beverage Container Deposit Legislation
BCF—Bio-Concentration Factor
BCT—Best Conventional Technology
BD—Butadiene
BDAT—Best Demonstrated Available Technology
BDO—Butanediol
BDOC—Biodegradable Organic Carbon
BDS—Biocatalytic Desulfurization
BEDI—Brownfields Economic Development Initiative
BEI—Biological Exposure Indices
BEP—Board for the Engineering Profession (UK)
BER—Board for Engineering Regulation (UK)
BESS—Battery Energy Storage System
BFSS—Bioremediation in the Field Search System
BGB—Brilliant Green Bile
BGS—British Geological Survey
BHA—Butylated Hydroxy Anisole
BHC—Benzene Hexachloride
BHC—Lindane
BHET—Bis-Hydroxyethylene Tetraphthalate
BHT—Butylated Hydroxy Toluene
BICER—Baikal International Center for Ecological Research
BID—Background Information Document
BIF—Boilers and Industrial Furnaces
BIOMOVS—Biospheric Model Validation Study
BLL—Blood Lead Levels
BLM—Bureau of Land Management (U.S.)
BMB—British Medical Bulletin
BMP—Best Management Practices
BN—Base Neutral
BNA—Base Neutral Acid Extractable
BNFL—British Nuclear Fuels PLC
BNL—Brookhaven National Laboratory (U.S.)
BNR—Biological Nutrient Removal
BOD—Biochemical Oxygen Demand
BOHC—British Occupational Hygiene Society
BOOS—Burner Out of Service
BPBR—Batch Packed Reactor Bed
BPD—Biocidal Products Directive (EU)
BPEO—Best Practicable Environmental Option
BPL—Beta Propiolacetone
BPM—Best Practicable Means
BPWTT Best Practicable Waste Treatment Technology
Bq—Becquerel
BRE—Building Research Establishment (UK)
BREEAM—Building Research Establishment Environmental Assessment Management
BRH—Bureau of Radiological Health (U.S.)
BRWM—Board on Radioactive Waste Management
BS—British Standard
BSE—Bovine Spongiform Encephalopathies
BSERT—Building Services Engineering Research and Technology (UK)
BSI—British Standards Institution
BSL-4—Biosafety Level 4
BSP—Biosafety Protocol
BT—Biotechnology
BTC—Breakthrough Curve
BTEX—Benzene, Toluene, Ethylbenzene and Xylene
BTF—Biotrickling Filter
BTU—British Thermal Unit
BTWC—Biological and Toxin Weapons Convention
BTX—Benzene-Toluene-Xylene
BV—Bed Volume
BWEA—British Wind Energy Association
BWR—Boiling Water Reactor

C—Celsius (Centigrade)
CA—Cellulose Acetate
CAA—Clean Air Act (UK) (U.S.)
CAAA—Clean Air Act Amendment (U.S.)
CAD—Computer Aided Design
CaFCP—California Fuel Cell Partnership
CAE—Computer Aided Engineering
CAfE—Community Action for Energy
CAFE—Corporate Average Fuel Economy
CAM—Computer Assisted Mapping
CAMP—Continuous Air Monitoring Program
C and S—Capture and Storage
CANDU—Canadian Heavy Water Moderated Reactor
CAP—Chemical Analysis Parameter
CAP—Coagulant Aid Polymer
CAP—Common Agricultural Policy (EU)
CARB—California Air Resources Board
CARL—Conservation and Recreation Lands (U.S.)
CASSIOPEE—Association of Western European Waste Disposal Organizations
CATNIP—Cheapest Available Techniques Not Involving Prosecution (UK)
CBA—Cost-Benefit Analysis
CBED—Convergent Beam Electron Diffraction
CBER—Center for Biologics Evaluation and Research
CBI—Confidential Business Information
CBO—Congressional Budget Office (U.S.)
CBOD—Carbonaceous Biochemical Oxygen Demand
CBR—Crude Birth Rate
CCAA—Canadian Clean Air Act
CCAR—Closed-Cycle Air Refrigeration
CCD—Charged-Coupled-Device
CCDT—Calcium Carbonate Deposition Test
CCGT—Combined Cycle Gas Turbine

CCI—Clean Coal Initiative
CCL—Climate Change Levy
CCL—Contaminant Candidate List (U.S.)
CCME—Canadian Council of Ministers of the Environment
CCMS—Committee on the Challenges of Modern Society
CCP—Combined Cool and Power
CCPE—Canadian Council of Professional Engineers
CCR—Council for Chemical Research
CCSM—Community Climate System Model
CCT—Clean Coal Technology
CDAA—2-Chloro-N, N-Diallyl Acetamide
CDC—Centers for Disease Control and Prevention (U.S.)
CDD—Chlorinated Dibenzo-p-Dioxin
CDEC—2-Chlorallyl-N, N-Diethyldithiocarbamate
CDER—Center for Drug Evaluation and Research
CDF—Chlorinated Dibenzofuran
CDI—Capacitive Deionization
CDI—Continuous Deionization
CDI—Critical Density Index
CDM—Clean Development Mechanism
CDRH—Center for Devices and Radiological Health
CDWG—Canadian Drinking Water Guidelines
CEA—Cumulative Environmental Assessment
CEA—Atomic Energy Commission (France)
CEAA—Canadian Environmental Assessment Act
CEAB—Canadian Engineering Accreditation Board
CEARC—Canadian Environmental Assessment Research Council
CEC—Cation Exchange Capacity
CEC—Commission of the European Communities
CECAB—Canadian Environmental Certification Approvals Board
CEES—Complex Ecological-Economic System
Cefic—European Chemical Industry Council
CEGB—Central Electricity Generating Board (UK)
CEM—Continuous Emissions Monitoring
CEMS—Continuous Emission Monitoring System
CEN—European Committee for Standardization
C ENG—Chartered Engineer (UK)
CEN/SCK—Nuclear Research Organization (Belgium)
CEPA—Canadian Environmental Protection Act
CEQ—Council on Environmental Quality (U.S.)
CERCLA—Comprehensive Environmental Response, Compensation and Liability Act (U.S.)
CERN—European Laboratory for Particle Physics
CESER—Countermeasures: Environmental and Socio-Economic Response
CETP—Common Effluent Treatment Plant
CFB—Circulating Fluidized Bed
CFBC—Circulating Fluidized Bed Combustion
CFBC—Circulating Fluidized Bed Combustor
CFC—Chlorofluorocarbons
CFC—1,1,2-Trichloro-1,2,2-Trifluoroethane
CFD—Computational Fluid Dynamics
CFR—Code of Federal Regulations (U.S.)
CFR—Continuous Flow Reactor
CFS—Canadian Forest Service
CFS—Cubic Feet per Second
CFSTR—Continuous Flow Stirred Tank Reactor
CFV—Clean Fuel Vehicle
CGCM—Coupled General Circulation Model
CGDF—Coal Gasification Development Facility
CG/HCCS—Coordinating Group for the Harmonization of Chemical Classification Systems
CGIAR—Cooperative Group of International Agricultural Research Centers
CGL—Comprehensive General Liability
CGMP—Current Good Manufacturing Practice
CGSB—Canadian General Standards Board
CHIP—Chemical Hazards Information Profile
CHL—Chlorophyll
CHP—Combined Heat and Power
CHPA—Combined Heat and Power Association
CHP/HP—Combined Heat and Power/Heat Pump
CHS—Contact Hypersensitivity
CI—Confidence Interval
CI—Cumulative Impact
Ci—Curie
CIA—Chemical Industries Association (UK)
CIA—Cumulative Impact Assessment
CIB—Conseil International du Baitment Pour Recherche, l'Etude et la Documentation
CIBSE—Chartered Institution of Building Services Engineers (UK)
CIEH—Chartered Institution of Environmental Health (UK)
CIH—Chartered Institute of Housing (UK)
CIP—Clean in Place
CISTI—Canadian Institute for Science and Technical Information
CITES—Convention on International Traffic in Endangered Species
CJD—Creutzfeldt-Jacob Disease
CL—Criterion Level
CLAIRE—Contaminated Land Applications in Real Environments
CLARINET—Contaminated Land Rehabilitation Networks for Environmental Technologies
CLD—Chemiluminescence Detector
CLER—Carbon-Limited Enrichment
CM—Combustible Matter
CMA—Chemical Manufacturers Association (U.S.)
CMC—Critical Micelle Concentration
CMD—Count Mean Diameter
CMDL—Climate Monitoring and Diagnostic Laboratory (U.S.)
CMPU—Chemical Manufacturing Process Unit
CMR—Complete Mix Reactor
CNC—Condensation Nucleus Counter
CNG—Compressed Natural Gas
CNI—Consiglio Nazionale Ingegneri (Italy)
CNISF—Conseil National des Ingenierus et Scientifiques de France
CNL—Compound Noise Level
CNL—Corrected Noise Level
CNP—National Research Council (Italy)

CNRS—Centre National de la Recherche Scientifique (France)
CNSIF—National Council of French Engineers and Scientists
COD—Chemical Oxygen Demand
COGEMA—Nuclear Waste Processing Organization (France)
COH—Coefficient of Haze
COHb—Carboxyhemoglobin
COM—Coastal Oceanographic Model
COMEAP—Committee on the Medical Effects of Air Pollution
CONCAWE—Conservation and Clean Air and Water in Europe
COP—Coefficient of Performance
COP—Conference of the Parties (UNFCCC)
CoPA—Control of Pollution Act (UK)
Co-PCB—Coplanar Polychlorinated Biphenyl
COPD—Chronic Obstructive Pulmonary Disease
COPUS—Committee on the Public Understanding of Science (UK)
COS—Carbonyl Sulfide
CO2eq—Carbon Dioxide Equivalent
COVRA—Nuclear Waste Disposal Organization (Holland)
CP—Coarse Particle
CPC—Condensation Particle Counter
CPCB—Central Pollution Control Board (India)
CPF—Cancer Potency Factor
CPI—Chemical Process Industries
CPSC—Consumer Product Safety Commission (U.S.)
CPVC—Chlorinated Polyvinyl Chloride
CQC—2,6-Dichloroquinonechlorimide
CR—Community Respiration
CR—Conditioned Response
CRADA—Cooperative Research and Development Agreement
CREATE—Centre for Research, Education and Training in Energy
CRM—Capture-Recapture Method
CRNL—Chalk River Nuclear Laboratories (Canada)
CRT—Continuously Regenerating Trap
CS—Conditioned Stimulus
CSB—Chemical Safety (and Hazards Investigation) Board
CSCE—Canadian Society for Civil Engineering
CSH—Calcium Silicate Hydrate
CSI—Common Sense Initiative (U.S.)
CSIR—Council for Scientific and Industrial Research (India) (South Africa)
CSIRO—Commonwealth Scientific and Industrial Research Organization (Australia)
CSMA—Chemical Specialties Manufacturers Association
CSO—Combined Sewer Overflow
CSOD—Carbonaceous Sediment Oxygen Demand
CSPE—Canadian Society for Professional Engineers
CSPI—Center for Science in the Public Interest
CSR—Center for Scientific Review (U.S.)
CSS—Combined Sewer System
CSSP—Council of Scientific Society Presidents
CST—Capillary Suction Time
CST—Carbon Storage Trust
CSTR—Continuous Flow Stirred Tank Reactor
CTG—Control Techniques Guideline
CTI—Climate Technology Initiative
CTR—Council for Tobacco Research
CVI—Children's Vaccine Initiative
CVC—Constant Volume Sampler
CWA—Chemical Warfare Agent
CWA—Clean Water Act (U.S.)
CWC—Chemical Weapons Convention
CWO—Catalytic Wet Oxidation
CWS—Coal-Water Slurry
CZARA—Coastal Zone Act Reauthorization Amendments
CZMA—Coastal Zone Management Act (U.S.)

DAD—Decide, Announce and Defend
DADA—Decide, Announce, Defend and Abandon
DAF—Dissolved Air Flotation
DAS—Data Acquisition System
dB—Decibel
dB (A)—Decibel A-Weighted
DBMCA—Dibromo-p-methyl-carboxyazo
DBMS—Database Management Systems
DBOOM—Design, Build, Own, Operate and Maintain
DBP—Disinfection By-Product
DBPC—Di Tertiary Butyl-P-Cresol
DBPP—Disinfection By-Product Precursor
DBT—Dibutyltin
DBT—Dimethyldibenzothiophene
DC—Delta Commission (Holland)
DCB—4,4′ -Dichlorobiphenyl
DCE—1,2–Dichloroethylene
DCER—Dwelling Carbon Emission Rate
DCL—Design Control Limit
DDA—4,4′ -Dichlorodiphenylacetic Acid
D/DBP—Disinfectant/Disinfection Byproduct Rule (U.S.)
DDD—1,1-Dichloro-2,2-Bis (p-chlorophenyl)-Ethane
DDE—1,1-Dichloro-2,2-Bis (p-chlorophenyl)-Ethylene
DDT—Dichlorodiphenyltrichloroethane
DDVP—2,2-Dichlorovinyl Dimethyl Phosphate
DE—Diatomaceous Earth
DEA—Diethanolamine
DEC—Department of Environmental Conservation
DEET—Diethyltoluamide
DEFRA—Department of the Environment, Food and Rural Affairs (UK)
DEG—Diethylene Glycol
DEP—Department of Environmental Protection
DER—Discrete Emission Reduction (U.S.)
DERC—Discrete Emission Reduction Credits (U.S.)
DES—Diethylstilbesterol
DETR—Department of the Environment, Transport and Regions (UK)
D/F—Dioxin/Furan
DFE—Design for Environment
DFB—Diffusion Fiber Bed
DHA—District Health Authority (UK)
DHEP—Di (2-Ethylhexyl) Phthalate

DHEW—Department of Health, Education and Welfare (U.S.)
DHHS—Department of Health and Human Services (U.S.)
DHSS—Department of Health and Social Security (UK)
DIAL—Differential Absorption Lidar
DIH—Division of Industrial Hygiene (U.S.)
DiP—Discussion in Principal
DL—Detection Limit
DL—Difference Limen
DMA—Differential Mobility Analyzer
DMDS—Dimethyldisulfide
DME—Dimethyl Ether
DMHRF—Dual Media High Rate Filtration
DMI—Danish Meteorological Institute
DMR—Discharge Monitoring Report
DMS—Dimethylsulfide
DMSO—Dimethyl Sulfoxide
DMT—Dimethyl Tetraphthalate
DNA—Deoxyribonucleic Acid
DNAPL—Dense Non-Aqueous Phase Liquid
DNB—Dinitrobenzene
DNIP—Di-Isononyl Phthalate
DO—Dissolved Oxygen
DOC—Dissolved Organic Carbon
DOD—Department of Defense (U.S.)
DOE—Department of Energy (UK) (U.S.)
DoE—Department of the Environment (UK)
DoH—Department of Health (UK)
DOL—Department of Labor (U.S.)
DOM—Dissolved Organic Matter
DOT—Department of Transport(ation) (Canada) (UK) (U.S.)
DPBA—Diphenylbenzamidine
DPE—1,1-Diphenylethylene
DPKO—Dipyridyl Ketone Oxime
DPW—Department of Public Works
DQI—Data Quality Indicator
DQO—Data Quality Objective
DRE—Destruction and Removal Efficiency
DRI—Development of Regional Impact
DS—Degree of Succession
DS—Dry Scrubber
DS—Dry Solids
DSCD—Danish Research Agency Committee on Scientific Dishonesty
DSM—Demand Side Management
DSR—Dissimilatory Sulfate Reducing
DTH—Delayed Type Hypersensitivity
DTI—Department of Trade and Industry (UK)
DTLR—Department for Transport, Local Government and the Regions (UK)
DTPA—Diethylenetriaminepentaacetic Acid
DWF—Dry Weather Flow
DWL—Derived Working Limit
DWT—Deadweight Ton

EA—Energy Amplifier
EA—Environmental (Agency) (Authority) (UK)
EA—Environmental Assessment
EA—Environmental Audit
EAA—Electrical Aerosol Analyzer
EAC—Extruded Activated Carbon
E and C—Engineering and Construction
EAGE—European Association of Geoscientists and Engineers
EANET—Acid Deposition Monitoring Network in East Asia
EAP—Emergency Action Plan
EAPS—Environmental Aspects in Product Standards
EARP—Environmental Assessment and Review Process
EASST—European Association for the Study of Science and Technology
EB—Ethylene Glycol Monobutyl Ether
EBDC—Ethylene Bisdithiocarbamate
EBI—European Bioinformatics Institute
EBRD—European Bank of Reconstruction and Development
EB/S—Ethylbenzene/Styrene
EC—Effective Concentration
EC—Electrical Conductivity
EC—Engineering Council (UK)
EC—European Code
EC—European Commission
EC—European Community
ECCP—European Climate Change Programme
ECEPA—Environmental Challenge for European Port Authorities
ECF—Elemental Chlorine Free
EC_{50}—Mean Effective Concentration
ECHS—Environmental Clearing House System
ECL—Exposure Control Limit
ECMWF—European Center For Medium Range Weather Forecasting
ECOSS—Environmental Coalition of South Seattle
ECTFE—European Fluorochemicals Technical Committee
EC2000—Engineering Criteria 2000
ECU—Extractable Copper
ED—Electrodialysis
ED—Exposure Dose
ED—Exposure Duration
ED—Extractive Distillation
EDC—Electron Donor Compound
EDC—Ethylenedichloride
EDF—Environmental Defense Fund
EDF—European Development Fund
EDI—Electrodeionization
EDI—Electronic Data Interchange
EDIP—Environmental Design of Industrial Products
EDR—Electrodialysis Removal
EDR—Electrodialysis Reversal
EDTA—Ethylenediaminetetraacetate
EDXRA—Energy Dispersive X-Ray Analysis
EEA—Economic Espionage Act (U.S.)
EEA—European Environment Agency
EEB—European Environment Bureau
EEBPP—Energy Efficiency Best Program
EEC—European Economic Community
EELS—Electron Energy Loss Spectroscopy

EEMD—Environmental and Energy Management Directorate (UK)
EES—Environmental Extension Service
EF—Emissions Factor
EFCE—European Federation of Chemical Engineers
EFCEA—European Federation of Consulting Engineers Associations
EFFS—European Flood Forecasting System
EFR—External Floating Roof
EG—Ethylene Glycol
EGA—Exhaust Gas Analyzer
EGL—Energy Grade Line
EGR—Exhaust Gas Recirculation
EGSB—Expanded Granular Sludge Bed
EGTC—Exhaust Gas Test Cell
EHC—Environmental Health Criteria
EHO—Environmental Health Officer (UK)
EHS—Environmental Health and Safety
EHS—Extremely Hazardous Substance
EI—Energy Institute (UK)
EIA—Energy Information Administration (U.S.)
EIA—Environmental Impact Assessment
EIA—Environmental Investigation Agency (UK)
EIC—Energy Industry Council
EIC—Engineering Institute of Canada
EIO-LCA—Economic Input-Output Life-Cycle Assessment
EIP—Eco-Industrial Park
EIS—Environmental Impact Statement
EJ—Environmental Justice
EKMA—Empirical Kinetic Modeling Approach

Gy—Gray

ha—Hectare
HA—Humic Acid
HAA—Haloacetic Acids
HAc—Acetic Acid
HACCP—Hazard Analysis of Critical Control Point
HAD—Hazards Assessment Document
HAP—Hazardous Air Pollutant
HAZMAT—Hazardous Material
HAZOP—Hazard and Operability Study
HBD—2-Hydroxyisobutyl Amide
HBM—2-Hydroxyisobutric Acid Methyl Ester
HCFC—Hydrochlorofluorocarbon
HCS—Hazard Communication Standard
HDM—Home Dust Mite
HDPE—High Density Polyethylene
HDS—Hydrodesulfurization
HDTMABr—Hexadecyltrimethyl Ammonium Bromide
HECA—Home Energy Conservation Act (UK)
HEES—Home Energy Efficiency Scheme (UK)
HEI—Health Effects Institute
HEL—Highly Erodible Land
HEPA—High Efficiency Particulate Air
HERP—Human Exposure/Rodent Potency
HEST—Hazardous Element Sampling Train
HEV—Hybrid Electric Vehicle
HEW—Department of Health, Education and Welfare (U.S.)
HF—Hydrogen Fluoride
HFC—Hydrofluorocarbon
HFE—Hydrofluoroether
HFO—Heavy Fuel Oil
HGH—Human Growth Hormone
HGL—Hydraulic Grade Line
HGM—Hazardous Gas Monitor
HGMS—High Gradient Magnetic Separation
HHS—Department of Health and Human Services (U.S.)
HIPPS—High Performance Power Systems
HIUI—Health Institute of the Uranium Industry (Czechoslovakia)
HIV—Human Immuno-Deficiency Virus
HLB—Hydrophilic-Lipophilic Balance
HLLW—High Level Liquid Waste
HLW—High Level Radioactive Waste
HM—Heavy Metal
HMDE—Hanging Mercury Drop Electrode
HMIP—HM Inspectorate of Pollution (UK)
HMNII—HM Nuclear Installations Inspectorate (UK)
HMSO—HM Stationary Office
HON—Hazardous Organic Neshap (National Emissions Standards for Hazardous Air Pollutants) (U.S.)
HPA—Health Protection Agency (UK)
HPA—Hetero Polyanion
HPC—Heterotrophic Plate Count
HPLC—High Performance Liquid Chromatography
HPS—Health Physics Society
HQ—Health Quotient
HR—Humidity Ratio
HRA—Halogen Resistant Azole
HRGC—High Resolution Gas Chromatography
HRS—Hazard Ranking Score (U.S.)
HRSA—Health Resources and Services Administration (U.S.)
HRT—Hydraulic Residence Time
HRTEM—High-Resolution Transmission Electron Microscopy
HSC—Health and Safety Commission (UK)
H6CB—3,3′ 4,4,4′ ,5-Hexachlorinated Biphenyl
HSCT—High Speed Civil Transport
HSDB—Hazardous Substances Data Base
HSE—Health and Safety Executive (UK)
HSWA—Hazardous and Solid Waste Amendments (U.S.)
HSWA—Health and Safety at Work Act (UK)
HTE—Horizontal Tube Evaporator
HTF—Heat Transfer Fluid
HTFW—High Temperature Fluid Wall
HTH—High Test Hypochlorite
HTlc—Hydrotalcite-Like-Compounds
HTME—Horizontal Tube Multiple Evaporator
HTU—Hydro Thermal Upgrading
HTRW—Hazardous, Toxic and Radioactive Waste
HUD—Department of Housing and Urban Development (U.S.)

HVAC—Heating, Ventilating and Air Conditioning
HVOC—Halogenated Volatile Organic Compound
HWC—Hazardous Waste Combustion
HWE—Healthy Worker Effect
HWI—Hazardous Wastes Inspectorate (UK)
HWIR—Hazardous Waste Identification Rule (U.S.)
HWL—High Water Level

I/A—Innovative and Alternative
IA—Index of Agreement
IAEA—International Atomic Energy Agency
IAHE—International Association for Hydrogen Energy
IAP—Indoor Air Pollution
IAP—Inter-Academy Panel
IAQ—Indoor Air Quality
IARC—International Agency for Research on Cancer
IAWPRC—International Association on Water Pollution Research and Control
IAWQ—International Association on Water Quality
IBC—International Bulk Container
IBRD—International Bank for Reconstruction and Development (World Bank)
IC—Internal Combustion
ICAA—International Council of Chemical Associations
ICAR—Indian Council of Agricultural Research
ICBEN—International Commission on the Biological Effects of Noise
ICBG—International Cooperative Biodiversity Grants Program
ICD—International List of Diseases, Injuries and Causes of Death
ICE—Institution of Civil Engineers (UK)
IC_{50}—Mean Inhibitory Concentration
ICIDI—Independent Commission on International Development Issues
ICP—Integrated Contingency Plan (U.S.)
ICPD—International Conference on Population and Development
ICP-OES—Inductively Coupled Plasma Optical Emission
ICR—Industrial Cost Recovery
ICR—Information Correction Rule
ICRAM—Central Institute for Scientific and Technological Research Applied to the Sea (Italy)
ICRP—International Commission on Radiological Protection
ICSU—International Council of Scientific Unions
ICT—Information Communication Technology
ICT—International Critical Table
IDEA—International Development Association
IDF—Intensity Duration Frequency
IDGEC—Institutional Dimensions of Global Environmental Change
IDLH—Immediately Dangerous to Life and Health
IDNDR—International Decade for Natural Disaster Reduction
IDSE—Initial Distribution System Evaluation
IDWSSD—International Drinking Water Supply and Sanitation Decade
IE—Cationic Exchange
IE—Institute of Energy (UK)
IEA—International Energy Agency
IEC—International Electrotechnical Commission
IEE—Institute of Electrical Engineers (UK)
IEEE—Institute of Electrical and Electronics Engineers
IESWTR—Interim Enhanced Surface Water Treatment Rule (U.S.)
IFB—Impaction Fiber Bed
IFC—International Finance Corporation
IFGR—Induced Flue Gas Recirculation
IFP—Institut Francais du Petrole (France)
IFR—Internal Floating Roof
IGBP—International Geosphere-Biosphere Program
IGC—Index of Grassland Condition
IGCC—Integrated Gasification Combined Cycle
IGO—Intergovernmental Organization
IGS—Inert Gas System
IGT—Institute of Gas Technology
IGY—International Geophysical Year
IHS—Indian Health Service (U.S.)
I/I—Infiltration/Inflow
IIASA—International Institute for Applied Systems Analysis
IIHE—International Institute for Hydraulic and Environmental Engineering
IJC—International Joint Commission
IKSR—International Commission for the Protection of the Rhine Against Pollution
ILGRA—Interdepartmental Liaison Group on Risk Assessment (UK)
ILO—International Labor Organization
ILW—Intermediate Level Radioactive Waste
IMDG—International Maritime Dangerous Goods Code
IME—Institution of Mechanical Engineers (UK)
IMF—International Monetary Fund
IMI—Imidazolinone
IMIQ—Mexican Institute of Chemical Engineers
IMO—International Maritime Organization
IMR—Infant Mortality Rate
IMS-ICS—Interagency Incident Management System-Incident Command System (U.S.)
INEEL—Idaho National Engineering and Environmental Laboratory (U.S.)
INSA—Institut National des Sciences Appliques (France)
InstE—Institute of Energy
INTRAVAL—International Geosphere Transport Model Validation
INWAC—IAEA Advisory Committee
I/O—Input/Output
IOA—Input-Output Analysis
IOC—Inorganic Chemical
IOD—Immediate Oxygen Demand
IoE—Institute of Energy
IOH—Institute of Occupational Hygiene (UK)
IoP—Institute of Physics (UK)
IOP—Indian Ocean Dipole
IOPC—International Oil Pollution Compensation Fund
IOWG—International Orimulsion Working Group

I/P—Incidence and Prevalence
IP—Inhalable Particles
IP—Institute of Petroleum
IPA—Isopropanol
IPACT—International Pharmaceutical Aerosol Consortium for Toxicology Testing
IPAT—Impact, Population, Affluence, and Technology
IPC—Integrated Pollution Control (UK)
IPCC—Intergovernmental Panel on Climate Change
IPCS—International Program on Chemical Safety
IPM—Inhalable Particulate Matter
IPM—Integrated Pest Management
IPP—Independent Power Producer
IPPC—Integrated Pollution Prevention and Control (EC)
IPPR—Institute for Public Policy Research
IPTS—Institute for Prospective Technological Studies
IR—Inactivation Ratio
IR—Infrared
IRAA—Indoor Radon Abatement Act (U.S.)
IRB—Institutional Review Board
IRIS—Integrated Risk Information System
IRP—Inward Processing Release
IRPP—Institute for Research on Public Policy
IRPTC—International Register of Potentially Toxic Chemicals
IRR—Ionizing Radiations Regulations (UK)
IRUS—Intrusion Resistant Underground Structures
ISA—Ideologically Structured Action
ISA—International Seabed Authority
ISES—International Solar Energy Society
ISI—Indian Standards Institution
ISIE—International Society for Industrial Ecology
ISM—Industrial, Scientific, Medical
ISO—Independent System Operator
ISO—International Standards Organization
ISPE—International Society of Pharmaceutical Engineers
ISRM—In-Situ Redox Manipulation
ISSX—International Society for the Study of Xenobiotics
ISTAS—International Symposium on Technology and Society
ISV—*In Situ* Vitrification
IT—Information Technology
ITC—Interagency Testing Committee (U.S.)
ITD—Ion Trap Detector
ITF—Industry Technology Facilitator
ITM—Ionic Transport Membrane
IUCN—International Union for Conservation of Nature and Natural Resources
IUFoST—International Union of Food Science and Technology
IUGG—International Union of Geodesy and Geophysics
IUPAC—International Union of Pure and Applied Chemistry
IURE—Inhalation Unit Risk Estimate
IWC—International Whaling Commission
IWM—Integrated Waste Management
IWPCC—Interstate Water Pollution Control Compact (U.S.)
IWS—Ionizing Wet Scrubber
IX—Ion Exchange

J—Joule
JAEC—Japanese Atomic Energy Commission
JAERI—Japanese Atomic Energy Research Institute
JAPCA—Journal of the Air Pollution Control Association
JAWWA—Journal of the American Water Works Association
JBR—Jet Bubbling Reactor
JECFA—Joint Expert Committee on Food Additives
JGOFS—Joint Global Ocean Flux Study
JMPR—Joint Meeting on Pesticide Residues
JRSH—Journal of the Royal Society for the Promotion of Health
JTU—Jackson Turbidity Unit
JWPCF—Journal of the Water Pollution Control Federation

K—Kelvin
KASAM—National Council for Nuclear Waste (Sweden)
KAST—Korean Academy of Science and Technology
KT—Clearness Index
kV—Kilovolt
Kw—Kilowatt
Kwh—Kilowatt Hour

LAER—Lowest Achievable Emission Rate
LAI—Leaf Area Index
LANDSAT—Earth Resources Technology Satellite
LANL—Los Alamos National Laboratory (U.S.)
LAPIO—Low API Oil
LAS—Laser Aerosol Spectrometer
LAS—Linear Alkyl Benzene Sulfonate
LASER—Light Amplification by Stimulated Emission of Radiation
LBL—Lawrence Berkeley Laboratory
LBP—Length Between Perpendiculars
LCA—Life-Cycle Assessment
LCC—Life Cycle Costing
LC_{50}—Mean Lethal Concentration
LCI—Life-Cycle Inventory
LCIP—Low Carbon Innovation Programme
LCPD—Large Combustion Plant Directive (EU)
LCR—Lead and Copper Rule
LD—Lethal Dose
LDA—Laminar Directional Airflow
LDAR—Leak Detection and Repair
LDC—Less Developed Country
LDC—London Dumping Convention
LDF—Local Deposition Fraction
LDH—Lactate Dehydrogenase
LD_{50}—Mean Lethal Dose
LDI—Laser Desorption/Ionization
LDPE—Low Density Polyethylene
LEA—Low Excess Air Operation
LED—Light Emitting Diode
LEL—Lower Explosive Limit
LET—Linear Energy Transfer
LFG—Landfill Gas
LFL—Lower Flammability Limit
LIBS—Laser Induced Breakdown Spectrometry

LID—Low Impact Development
LIDAR—Light Detection and Ranging
LILW-LL—Low and Intermediate Level Waste—Long Lived
LILW-SL—Low and Intermediate Level Waste—Short Lived
LLDPE—Linear Low Density Polyethylene
LLNL—Lawrence Livermore National Laboratory (U.S.)
LLW—Low Level Radioactive Waste
LMC—Lime-Magnesium Carbonate
LMO—Living Genetically Modified Organism
LMx—Low Mix Burner
LNAPL—Light Non-Aqueous Phase Liquid
LNB—Low NOx Burner
LNG—Liquefied Natural Gas
LNT—Linear No-Threshold
LOD—Limit of Deposition
LOEC—Lowest Observable Effects Concentration
LOEL—Lowest Observed Effect Level
LOI—Loss on Ignition
LOOP—Locally Organized and Operated Partnerships
LOPA—Layers of Protection Analysis
LPC—Limiting Permissible Concentration
Lpcd—Liters per Capita per Day
LPG—Liquefied Petroleum Gas
LPS—Lipopolysaccharide
LRT—Long-Range Transport
LS—Low Sulfur
LSE—London School of Economics
LSI—Langlier Saturation Index
LSM—Land Surface Model
LSTK—Lump-Sump Turnkey
LSHTM—London School of Hygiene and Tropical Medicine
LTAR—Long Term Acceptance Rate
LTR—Long Range Transport Model
LTVE—Long Tube Vertical Evaporator
LUC—Land Use Classification
LULU—Locally Unacceptable Land Use
LUST—Leaking Underground Storage Tank
LVHV—Low Volume High Velocity
LWL—Low Water Level
LWR—Light Water Reactor

MAA—Mycosporine Amino Acid
MAB—Man and the Biosphere (UNESCO)
MAC—Maximum Acceptable (Allowable) Concentration
MAC—(EEC)—Maximum Acceptable Concentration (European Economic Community)
MACS—Miniature Acid-Condensation System
MACT—Maximum Achievable Control Technology
MAFF—Ministry of Agriculture, Fisheries and Food (UK)
MAH—Maleic Anhydride
MANEB—Trimangol 80, Poligram M, Plantineb 80 PM
MANOVA—Multivariate Analysis of Variance
MA7CD10—Minimum Average 7 Consecutive Day 10 Year Flow
MARAMA—Mid-Atlantic Regional Air Use Management Association (U.S.)
MARC—Major Accident Reporting System (EU)
MAS—Mobile Aerosol Spectrometer
MATC—Maximum Acceptable Toxicant Concentration
MB—Mixed Bed
MBR—Membrane Bioreactor
MBT—Monobutyltin
MBL—Marine Boundary Layer
MC—Microcarrier
MCA—Manufacturing Chemists Association
MCA—Multicriteria Analysis
MCDSS—Multicriteria Decision Support System
MCFC—Molten Carbonate Fuel Cell
MCI—Management Charter Initiative (UK)
MCL—Maximum Contaminant Level
MCLG—Maximum Contaminant Level Goal
MCM—Master Chemical Mechanism
MCPA—4,Chloro-2-Methylphenoxyacetic Acid
MCR—National Institute of Materials and Chemical Research (Japan)
MCRT—Mean Cell Residence Time
MCS—Multiple Chemical Sensitivity
MCTT—Multichambered Treatment Train
mdd—md × day^{-1} × dm^{-2}
MDL—Method Detection Limit
MDNR—Missouri Department of Natural Resources
MDS—Multidimensional Scaling
ME—Multiple-Effect Evaporator
MEA—Monoethanolamine
MEA—Multinational Environmental Agreement
MED—Modified Electrodialysis
MED—Multieffect Distillation
MEK—Methyl Ethyl Ketone
MEMS—Microelectro-Mechanical Systems
MEPA—Meteorology and Environmental Protection Administration (Saudi Arabia)
MESL—Marine Environmental Studies Laboratory (IAEA)
MEUC—Major Energy Users’ Council (UK)
MF—Microfiltration
M/F—Mass/Food Ratio
MFA—Material Flow Accounting
MFN—Most Favored Status
MGD—Million Gallons per Day
mg/L—Milligrams per Liter (ppm)
MHD—Magnetohydrodynamics
MIBK—Methyl Isobutyl Ketone
MICROMORT—One in a Million Chance of Death from an Environmental Hazard
MIE—Magnetic Ion Exchange
MIE—Minimum Ignition Energy
MIGA—Multilateral Investment Guarantee Agency
MIPAES—Microwave Induced Plasma Atomic Emission Spectroscopy
MIPS—Material Intensity per Service Unit
MIR—Maximum Incremental Reactivity
MIR—Maximum Individual Risk
MIRAGE—CEC Radionuclide Geosphere Migration Project
MJO—Madden-Julian Oscillation
MLD—Mean Lethal Dose
MLD—Million Liters per Day
MLSS—Mixed Liquor Suspended Solids

MLVSS—Mixed Liquor Volatile Suspended Solids
MM—Methyl Mercaptan
MMA—Methyl Methacrylate
MMC—Monopolies and Mergers Commission (UK)
MMH—Monoethyl Hydrazine
MMR—Material Morbidity Rate
MMR—Maternal Mortality Rate
MMT—Methylcyclopentadienyl Manganese Tricarbonyl
MoA—Ministry of Agriculture
MoD—Ministry of Defense (UK)
MOEE—Ministry of Environment and Energy (Canada)
MoEF—Ministry of Environment and Forests (India)
MONICA—Monitoring of Trends and Determinants in Cardiovascular Disease
MOX—Mixed Oxide
MPD—Maximum Permissible Dose
MPE—Maximum Permissible Exposure
MPN—Most Probable Number
MPP—Macroporous Polymer
MPPE—Macroporous Polymer Extraction
mppcf—Millions of Particles per Cubic Foot
MPRSA—Marine Protection, Research and Sanctuaries Act (Ocean Dumping Act) (U.S.)
MR—Magnetic Resonance
MR—Mass Removal
MRC—Medical Research Council (UK)
MRDL—Maximum Residual Disinfectant Level
MRDLG—Maximum Residual Disinfectant Level Goal
MRF—Material Recovery Facilities
MRF—Municipal Recycling Facilities
MRI—Mean Recurrence Interval
MRS—Monitored Retrievable Storage
MS—Management System
MS—Mass Spectrometry
MSAT—Mobile Source Air Toxics
MSDS—Material Safety Data Sheets (U.S.)
MSE—Mean Square Estimate
MSG—Monosodium Glutamate
MSHA—Mine Safety and Health Administration (U.S.)
MSL—Mean Sea Level
MSMR—Mean Standardized Mortality Rate
MSS—Multispectral Scanner
MSW—Municipal Solid Waste
MSY—Maximum Sustainable Yield
m.t.—Metric Ton
Mta^{-1}—Million Tons per Year (Annum)
MTB—Multiply Twinned Particles
MTBE—Methyl Tert-Butyl Ether
MTBF—Mean Time between Failures
MtCeq—Million Tons Carbon Equivalent
MTD—Maximum Tolerable Dose
MTHF—Methyltetrahydrofuran
MTI—Mixture Toxicity Index
Mtoe—Million Tons Oil Equivalent
mtoe—Million Tonnes Oil Equivalent
MVC—Mechanical Vapor Compression
MW—Megawatt
MWCO—Molecular Weigh Cutoff
MWT—Multiple Well Tracer Test

N—Newton
NA—Nutrient Agar
NAA—Neutron Activation Analysis
NAAQS—National Ambient Air Quality Standards (U.S.)
NACA—National Agricultural Chemicals Association (U.S.)
NADH—Nicotinamide Adenine Dinucleotide
NAD—Nitric Acid Dihydrate
NADP/NTN—National Atmospheric Deposition Program/National Trends Network
NADW—North Atlantic Deep Water
NAE—National Academy of Engineering (U.S.)
NAFO—North Atlantic Fisheries Organization
NAFTA—North American Free Trade Agreement
Nagra—Waste Disposal Organization (Switzerland)
Naics—North American Industry Classification System
NaNp—Sodium Napthalenide
NAO—National Audit Office (UK)
NAO—North Atlantic Oscillation
NAPAG—National Academics Policy Advisory Group (UK)
NAPAP—National Acid Precipitation Assessment Program (U.S.)
NAPCA—National Air Pollution Control Administration (U.S.)
NaPEG—Sodium Polyethylene Glycol
NAPL—Non-Aqueous Phase Liquid
NAS—National Academy of Sciences (U.S.)
NAS—National Audubon Society
NAST—National Assessment Synthesis Team
NASA—National Aeronautics and Space Administration (U.S.)
NAST—National Assessment Synthesis Team (U.S.)
NAT—Nitric Acid Trihydrate
NB—Nitrobenzene
NB—Nutrient Broth
NBOD—Nitrogenous Biochemical Oxygen Demand
NBS—National Bureau of Standards (U.S.)
NC—Number Concentration
NCAB—National Cancer Advisory Board (U.S.)
NCAR—National Center for Atmospheric Research (U.S.)
NCB—National Coal Board (UK)
NCC—Nature Conservancy Council (UK)
NCDC—National Climate Data Center
NCEA—National Center for Environmental Assessment (U.S.)
NCEES—National Council of Examiners for Engineers and Surveyors (U.S.)
NCEJN—North Carolina Environmental Justice Network
NCEP—National Centers for Environmental Prediction (U.S.)
NCHGR—National Center for Human Genome Research (U.S.)
NCHS—National Center for Health Statistics (U.S.)
NCI—National Cancer Institute (U.S.)
NCI-MS—Negative Chemical Ionization–Mass Spectrometry
NCP—National Contingency Plan (U.S.)

NCRP—National Council on Radiation Protection and Measurements (U.S.)
NCS—Notification of Compliance Status (U.S.)
ND—Not (None) Detected (Detectable)
NDA—New Drug Approval (Application)
NDA—Nuclear Decommissioning Authority (UK)
NDIR—Nondispersive Infrared
NEA—Nuclear Energy Agency (UK)
NEAT—National Environmental Achievement Award
NECI—Network Coordinating Institute
NEDO—New Energy and Industrial Technology Development Organization (Japan)
NEERI—National Environmental Engineering Research Institute (India)
NEL—No Effect Level
NEP—National Energy Policy (U.S.)
NEPA—National Environmental Policy Act (U.S.)
NEPA—National Environmental Protection Agency (PRC)
NERC—National Environmental Research Council (UK)
NERI—National Environmental Research Institute (Denmark)
NERI—Nuclear Energy Research Initiative
NERL—National Exposure Research Laboratory (U.S.)
NESCAUM—Northeast States for Coordinated Air Use Management (U.S.)
NESDIS—National Environmental Satellite Data and Information Center
NESHAP—National Emissions Standards for Hazardous Air Pollutants (U.S.)
NESS—National Environmental Satellite Service (U.S.)
NETA—New Electricity Trading Agreements (UK)
NETCEN—National Environmental Technology Centre (UK)
NETL—National Energy Technology Laboratory (U.S.)
NEXRAD—Next Generation Radar
NF—Nanofiltration
NFFO—Non-Fossil Fuel Obligation
NFIP—National Flood Insurance Program (U.S.)
NFMA—National Forest Management Act (U.S.)
NFPA—National Fire Protection Association (U.S.)
NG—No Guideline Value
NGO—Non-Government Organization (UN)
NGV—Natural Gas Vehicle
NHC—National Hurricane Center (U.S.)
NHEERL—National Health and Environmental Effects Research Laboratory (U.S.)
NHER—National Home Energy Rating (UK)
NHS—National Health Service (UK)
NIAID—National Institute of Allergy and Infectious Disease (U.S.)
NIBS—National Institute of Building Sciences (U.S.)
NICOLE—Network for Industrially Contaminated Land in Europe
NIEHS—National Institute of Environmental Health Sciences (U.S.)
NIH—National Institute of Health (U.S.)
NII—Nuclear Installations Inspectorate (UK)
NIMBY—Not in My Backyard
NIOSH—National Institute for Occupational Safety and Health (U.S.)
NIREX—Nuclear Industry Radioactive Waste Executive (UK)
NIST—National Institute of Standards and Technology (U.S.)
NLER—Nitrogen-Limited Enrichment
NL/h—Normal Liters per Hour
NLM—National Library of Medicine
NMFS—National Marine Fisheries Service (U.S.)
NMC—National Meteorological Centre (UK)
NMHC—Non-Methane Hydrocarbon
NMMAPS—National Morbidity, Mortality and Air Pollution Study (U.S.)
NMOC—Non-Methane Organic Carbon
NMR—Neonatal Mortality Rate
NMR—Nuclear Magnetic Resonance
NMSE—Normalized Mean of the Square of the Error
NMVOC—Non-Methane Volatile Organic Compound
NNI—Noise and Number Index
NNR—National Nature Reserve (UK)
NNR—Net Reproductive Rate
NOAA—National Oceanographic and Atmospheric Administration (U.S.)
NOAEL—No Observable Adverse Effect Level
NOEC—No Observable Effects Concentration
NOEL—No Observed Effect Level
NOHSCP—National Oil and Hazardous Substance Contingency Plan (U.S.)
NOM—Natural Organic Matter
NONHEL—Non-Highly Erodible Land
NOS—National Occupational Standard
NOS—National Ocean Survey (U.S.)
NO2, 3—Nitrite Plus Nitrate
NOx—Nitrogen Oxides
NOy—Reactive Nitrogen
NP—Neutralization Point
NPAA—Noise Pollution and Abatement Act (U.S.)
NPCA—National Parks and Conservation Association (U.S.)
NPDES—National Pollutant Discharge Elimination System (U.S.)
NPL—National Priority List (U.S.)
NPP—Net Primary Production (Productivity)
NPP—Nonprecipitated Phosphorous
NPP—Nuclear Power Plant
NPR—National Performance Review (U.S.)
NPRI—National Pollution Release Inventory (Canada)
NPRM—Notice of Proposed Rule Making (U.S.)
NPS—National Park Service (U.S.)
NPSH—Net Positive Suction Head
NRA—National Rivers Authority (UK)
NRC—Nuclear Regulatory Commission (U.S.)
NRC—National Research Council (Canada) (U.S.)
NRCS—Natural Resources Conservation Service
NRD—Natural Resources Damage
NRDA—Natural Resource Damage Assessment
NRDC—Natural Resources Defense Council

NREL—National Renewable Energy Laboratory (U.S.)
NRMRL—National Risk Management Research Laboratory (U.S.)
NRPB—National Radiological Protection Board (UK)
NRR—Net Reproduction Rate
NRT—National Response Team (U.S.)
NSERC—National Science and Engineering Research Council (Canada)
NSF—National Science Foundation (U.S.)
NFSOM—Near-Field Scanning Optical Microscopy
NSPE—National Society of Professional Engineers (U.S.)
NSPS—New Source Performance Standards (U.S.)
NSR—New Source Review
NTA—Nitrilotriacetic Acid
NTI—Nuclear Threat Initiative
NTN—National Trends Network
NTNU—Norwegian University of Science and Technology
NTP—National Toxicology Program (U.S.)
NTS—Not to Scale
NTSB—National Transportation Safety Board (U.S.)
NTTC—National Technology Transfer Center (U.S.)
NTU—Nephelometric Turbidity Unit
Nu—Nusselt Number
NURP—National Urban Runoff Program (U.S.)
NWP—Numerical Weather Prediction
NWR—National Wildlife Refuge (U.S.)
NWS—National Weather Service (U.S.)
NWTRB—Nuclear Waste Technical Review Board (U.S.)

OA—Overfire Air
OBO—Ore-Bulk-Oil
OCAG—Off-Site Consequences Analysis Guidance (U.S.)
OCCM—Office of Air Quality Planning and Standards Control Cost Manual (U.S.)
OCEF—Overseas Economic Cooperation Fund (Japan)
OCGCM—Ocean Coupled General Circulation Model
OCP—Organopesticides
OCPSF—Organic Chemicals, Plastics and Synthetic Fibers
OCS—Outer Continental Shelf
O.D.—Optical Density
ODA—Overseas Development Agency (UK)
ODP—Ocean Drilling Programme (Australia)
ODP—Ozone Depletion Potential
ODS—Ozone Depleting Substance
OECD—Organization for Economic Cooperation and Development
OEL—Occupational Exposure Limit
O8CDD—Octochloro Dibenzo-p-Dioxin
O8CDF—Dibenzofuran
OEM—Office of Emergency Management (U.S.)
OEM—Original Equipment Manufacturer
OERR—Office of Emergency and Remedial Response (U.S.)
OES—Occupational Exposure Standard (UK)
OES—Office of Endangered Species (U.S.)
OFA—Overfire Air
OHS—Occupational Hygiene Secretariat (UK)
OH & S—Occupational Health and Safety
OIE—Organisation Internationale des Epizooties
OIES—Oxford Institute for Energy Studies (UK)
OLED—Organic Light-Emitting Diode
OLR—Organic Loading Rate
O & M—Operation and Maintenance
OMB—Office of Management and Budget (U.S.)
OMG—Old Mixed Grade
OMT—Open Market Trading
OMTR—Open Market Trading Credits Rule (U.S.)
OMZ—Oxygen-Minimum Zone
ONBC—Overnight Nutrient Broth Culture
ONDRAF—Waste Disposal Organization (Belgium)
OP—Organophosphate
OPA—Oil Pollution Act (U.S.)
OPCW—Organization for Prevention of Chemical Warfare
OPEC—Organization of Petroleum Exporting Countries
OPETS—Organization for the Promotion of Energy Technologies (EU)
OP-FTIR—Open-Path Fourier Transform Infrared
OPLA—High Level Waste Disposal Program (Holland)
OPS—Office of Pipeline Safety (U.S.)
OR—Odds Ratio
ORD—Office of Research and Development (U.S.)
ORI—Office of Research Integrity (U.S.)
ORNL—Oak Ridge National Laboratory (U.S.)
ORP—Oxidation-Reduction Potential
ORSANCO—Ohio River Sanitation Commission (U.S.)
OSAT—On-Site Assistance Team (EC)
OSHA—Occupational Safety and Health Act (U.S.)
OSHA—Occupational Safety and Health Administration (U.S.)
OSPAR—Oslo-Paris Agreement
OSPM—Operational Street Pollution Model
OSPREY—Ocean Swell Powered Renewable Energy (UK)
OST—Office of Science and Technology (UK) (U.S.)
OSW—Office of Saline Water (U.S.)
OSWER—Office of Solid Waste and Emergency Response (U.S.)
OTA—Office of Technology Assessment (U.S.)
OTEC—Ocean Thermal Energy Conversion
OTR—Oxygen Transfer Rate
OTR—Ozone Transport Region (U.S.)
OUR—Oxygen Uptake Rate
OVA—Organic Vapor Analysis
OW—Oil in Water
Ox—Total Oxidants

P—Polystyrene
Pa—Pascal
PA—Polymide
PABA—Para-Amino-Benzoic Acid
PAC—Polyaluminum Chloride
PAC—Powered Activated Carbon
PAC1—Polyaluminum Chloride
PACT—Programme for Alternative Fluorocarbon Toxicity Testing
PAFC—Phosphoric Acid Fuel Cell
PAH—Polynuclear Aromatic Hydrocarbons

PAHO—Pan American Health Organization (WHO)
PAL—Plantwide Applicability Limits
PAN—Peroxyacetyl Nitrate
P and T—Pump and Treat
Paracom—Paris Commission
PARC—Pan African Rinderpest Campaign
PARCCS—Precision, Accuracy, Representativeness, Comparability, Completeness, Sensitivity
PARIS—Program for Assisting the Replacement of Industrial Solvents
PATH—Plan for Analyzing and Testing Hypotheses
PBL—Planetary Boundary Layer
PBMR—Pebble-Bed Modular Reactor
PBS—Package Boiler Simulator
PC—Polycarbonate
PC—Pulverized Coal
PCA—Plate Count Agar
PCA—Principal Component Analysis
PCB—Polychlorinated Biphenyl
PCBP—Polychloro Bi Phenylene
PCBz—Polychloro Benzene
PCCY—Polychlorinated Chrysene
PCD—Particle Charge Detector
PCD—Process Control Diagram
PCDD—Polychlorodibenzo-p-Dioxin
PCDET—Post-Completion Discrete Extraction Test (U.S.)
PCDF—Polychlorinated Dibenzofuran
PCDPE—Polychlorinated Diphenyl Ether
PCE—Perchlorethylene
PCE—Tetrachloroethylene
pCi/L—Picocuries per Liter
PCN—Polychlorinated Napthalene
PCP—Pentachlorophenol
PCPA—Post-Closure Performance Assessment (U.S.)
PCPY—Polychlorinated Pyrene
PCQ—Polychlorinated Quaterphenyl
PCQE—Polychlorinated Quaterphenyl Ether
PCR—Polymerase Chain Reaction
PCV—Positive Crankcase Ventilation
PDA—Potato Dextrose Agar
PDE—Partial Differential Equation
PDF—Probability Density Function
PDO—Pacific Decadal Oscillation
PE—Performance Evaluation
PE—Polyethylene
PE—Professional Engineer (U.S.)
PEA—Performance Evaluation Audit
PEACE—Pollution Effects on Asthmatic Children in Europe
PEC—Process Economic Program
PEELS—Parallel Acquisition Systems
PEFR—Peak Expiratory Flow Rate
PEI—Potential Environmental Impact
PEIs—Professional Engineering Institutions (UK)
PEL—Permissible Exposure Limit
PEM—Proton Exchange Membrane
PEMFC—Proton Exchange Membrane Fuel Cell
PEN—Polyethylene Napthalate
P ENG—Professional Engineer (Canada)
PEO—Professional Engineers Ontario
PER—Partial Exfiltration System
PES—Project Environmental Summary
PES—Public Electricity Supplier
PET—Polyethylene Terephthalate
PF—Phenol-Formaldehyde
PF—Pulverized Fuel
P5CB—3,3' ,4,4' ,5-Pentachlorinated Biphenyl
PFBC—Pressurized Fluidized Bed Combustion
PFC—Perfluoro (Carbon) Compounds
PFD—Process Flow Diagram
PFR—Plug Flow Reactor
PFRP—Process to Further Reduce Pathogens
PFS—Pulverized Fly Ash
PFT—Peak Flame Temperature
PHA—Process Hazard Analysis
PHA—Pulse Height Analysis
PHARE—CEC Program to Assist Eastern European Countries
PHB—Polyhydroxy Butyrate
PHC—Petroleum Hydrocarbons
PHS—Public Health Service (U.S.)
PI—Principal Investigator
PIC—Prior Informed Consent Procedure
PIC—Product of Incomplete Combustion
PIEL—Pharmacologically Insignificant Exposure Limit
PIOT—Physical Input-Output Table
PIRG—Public Interest Research Group (U.S.)
PIXIE—Particle Induced X-Ray Emission
PL—Public Law (U.S.)
PLA—Polylactic Acid
PLC—Programmable Logic Controller
PLL—Probable Loss of Life
PLM—Polarized Light Microscopy
PM—Particulate Matter
PM0.1—Ultrafine Particle
PM2.5—Particles Less than 2.5 Micrometers
PM10—Particles Less than 10 Micrometers
PMA—Phenyl Mercuric Acetate
PMMA—Polymethylmethacrylate
PMN—Phenyl Mercuric Nitrate
PMM—Polymorphonuclear Neutrophils
PMN—Polymorphonuclear Neutrophils
PMN—Premanufacture Notice (U.S.)
PMR—Proportionate Mortality Rate
PNC—Japanese Nuclear Power Corporation
PNdB—Perceived Noise Level
PNGV—Partnership for a New Generation of Vehicles
PNL—Pacific Northwest Laboratory (U.S.)
PNNL—Pacific Northwest National Laboratory (U.S.)
PODAAC—Physical Oceanography Distributed Active Archive
POE—Point of Entry
POHC—Principal Organic Hazardous Constituent
POL—Project Objectives Letter (U.S.)
PolyTHF—Polytetrahydrofuran
POM—Polycyclic Organic Matter

POM—Princeton Ocean Model
POP—Persistent Organic Pollutant
POT—Peaks-Over Threshold
POTW—Publicly Owned Treatment Works (U.S.)
POU—Point of Use
PP—Polypropylene
PP—Precautionary Principle
ppb—Parts per Billion
ppbv—Parts per Billion by Volume
PPE—Personal Protective Equipment
PPEQ—Pre-Project Environmental Questionnaire
ppm—Parts per Million (Milligrams per Liter) (Grams per Cubic Meter)
ppmv—Parts per Million by Volume
ppmw—Parts per Million by Weight
ppt—Parts per Trillion
ppth—Parts per Thousand
PPU—Pertinent Process Unit
Pr—Prandt1 Number
PRA—Paperwork Reduction Act (U.S.)
PRA—Probabilistic Risk Assessment
PRAS—Prereduced Anaerobically Sterilized
PRG—Preliminary Remediation Goals (U.S.)
PRP—Potentially Responsible Party (U.S.)
PRZ—Potential Repository Zone
PS—Polystyrene
PSA—Probabilistic Safety Assessment
PSAC—President's Science Advisory Committee (U.S.)
PSC—Polar Stratospheric Cloud
PSD—Prevention of Significant Deterioration (U.S.)
PSF—Peat-Sand Filter
PSF—Pounds per Square Foot
PSI—Pounds per Square Inch
PSM—Process Safety Management (U.S.)
PSR—Preliminary Safety Report
PSRP—Process to Significantly Reduce Pathogens
PTFE—Polytetrafluoroethylene
P3—Public Performance-Based Permitting Program
PTM—Photochemical Trajectory Model
PTR—Project Tracking Register
PTWI—Provisional Tolerable Weekly Intake
P2—Pollution Prevention
PU—Polyurethane
PULSAR—Phillips' Ultra Low Sulfur Atmospheric Residue
PV—Permanganate Value
PV—Photovoltaic
PV—Polyvinyl
PVA—Polyvinyl Acetate
PVA—Process Vulnerability Analysis
PVC—Polyvinyl Chloride
PVS—Physical Vapor Synthesis
PVT—Photovoltaic/Thermal
PWS—Public Water System
PZC—Point of Zero Charge

QA—Quality Assurance
QACC—Quaternary Ammonium Compounds
QAPP—Quality Assurance Project Plan (U.S.)
QC—Quality Control
QEP—Qualified Environmental Professional
QF—Qualified Facility
QIP—Quality Improvement Program
QPF—Quantitative Precipitation Forecast
QRA—Quantitative Risk Assessment
QSAR—Quantitative Structure Activity Relationship
QUANGO—Quasi Autonomous Non-Governmental Organization
QUARG—Quality of Urban Air Review Group

R—Rankine
R—Universal Gas Constant
r—Roentgen
RA—Rapid Appraisal
RAB—Registrar Accreditation Board
RACT—Reasonably Available Control Technology
Rad—Roentgen-Absorption-Dose
RADWASS—IAEA Publication on Radioactive Waste
RAF—Radiation Amplification Factor
RAMS—Regional Atmospheric Model System
RAP—Rapid Assessment Program
RAR—Reasonable Assumed Resource
RaSoS—Raman Sort Spectrometer
RBC—Rotating Biological Contactor
RBCA—Risk Based Corrective Action
RBE—Relative Biological Effectiveness
RBSL—Risk-Based Screening Levels
RCEP—Royal Commission on Environmental Pollution (UK)
RCM—Regional Climate Modelling
RCO—Regenerative Catalytic Oxidation
RCRA—Resource Conservation and Recovery Act (U.S.)
RCT—Reference Control Technology
R & D—Research and Development
RD & D—Research, Development and Demonstration
RDF—Refuse-Derived Fuel
RDS—Residue-Oil Hydrodesulfurization
Re—Reynolds Number
REACH—Registration, Evaluation, Authorization of Chemicals
RECLAIM—Regional Clean Air Incentives Market (U.S.)
REI—Regional Environmental Initiative
REL—Recommended Exposure Limit
REMA—Regulatory Environmental Modelling of Antifoulants
REO—Renewable Energy Obligation
RERF—Radiation Effects Research Foundation
Rem—Roentgen-Equivalent-Man
Rep—Roentgen-Equivalent-Physical
RF—Radio Frequency
RFBR—Russian Federation for Basic Research
RFCC—Residue-Oil Fluid Catalytic Cracking
REF—Resources for the Future
RFG—Reformulated Gasoline
RFLPS—Restriction-Fragment-Length Polymorphisms
RGH—Renewably Generated Hydrogen
RGR—Relative Growth Rate

RH—Relative Humidity
RHA—Regional Health Authority (UK)
RI—Remedial Investigation
RI—Return Interval
Ri—Richardson Number
RIA—Regulatory Impact Analysis
RIBA—Royal Institution of British Architects
RI-FS—Remedial Investigation and Feasibility Study (U.S.)
RIIA—Royal Institute of International Affairs (UK)
RL50—Residue Half Life
RMCL—Recommended Maximum Contaminant Level
RME—Reasonable Maximum Exposure
RMLT—Regression Models in Life Tables
RMP—Risk Management Program (Plan) (U.S.)
RMR—Required Mass Removal
RNA—Ribonucleic Acid
RNI—Rates of Natural Increase
RO—Renewables Obligation
RO—Reverse Osmosis
ROC—Renewable Obligation Certificate
ROD—Record of Decisions (Superfund) (U.S.)
ROFA 6—Residual Oil Fly Ash (No. 6 Fuel Oil)
RORO—Roll On Roll Off
RoSPA—Royal Society for the Prevention of Accidents (UK)
RP—Return Period
R/P—Reserve/Production
RPA—Radiation Protection Act (UK)
RPA—Renewable Power Association
RPE—Respiratory Protection Equipment
RPP—Radiation Protection Program (Canada)
RPS—Renewable Portfolio Standard
RQ—Reportable Quantity (U.S.)
RR—Relative Risk
RRRR—Reduce/Recovery/Recycle/Reuse
RRT—Relative Retention Time
RS—Royal Society (UK)
RSA—Radioactive Substances Act (UK)
RSC—Reactor Safety Commission (Germany)
RSC—Royal Society of Chemistry (UK)
RSD—Relative Standard Deviation
RSH—Royal Society of Health (UK)
RTD—Residence Time Distribution
RTDF—Remediation Technologies Development Forum
RTO—Regenerative Thermal Oxidation
RVP—Reid Vapor Pressure
RWMAC—Radioactive Waste Management Advisory Committee (UK)

SAED—Selected Area Electron Diffraction
SAGE—Stratospheric Aerosol and Gas Experiment
S and T—Science and Technology
SAR—Sodium Adsorption Ratio
SAR—Specific Absorption Rate
SAR—Structure-Activity Relationship
SARA—Superfund Amendments and Reauthorization Act (U.S.)
SARTOR—Standards and Routes to Registration (UK)
SASS—Source Assessment Sampling System
SAVEII—Specific Action for Vigorous Energy Efficiency (EU)
SBR—Sequencing Batch Reactor
SBR—Stillbirth Rate
SBS—Sick Building Syndrome
SBT—Segregated Ballast Tank
Sc—Schmidt Number
SC—Sierra Club
SCADA—Supervisory Control and Data Acquisition
SCAPS—Site Characterization and Analysis Penetrometer System
SCAQMD—South Coast Air Quality Management District
SCF—Standard Cubic Feet
SCF—Supercritical Fluid
SCOPE—Scientific Committee on Problems of the Environment
SCR—Selective Catalytic Reduction
SCS—Soil Conservation Service (U.S.)
SCW—Supercritical Water
SCWO—Supercritical Wet (Water) Oxidation
SD—Solar Distillation
SD—Standard Deviation
SD—Sustainable Development
SDBS—Sodium Dodecyl Benzene Sulfonate
SDI—Silt Density Index
SDR—Surplus Discrete Reductions (U.S.)
S & DSI—Stiff and Davis Stability Index
SDWA—Safe Drinking Water Act (U.S.)
SEA—Strategic Environmental Assessment
SEARR—South East Asia Rainforest Research Program
SEASAT—Earth Satellite for Sea Surveys
SEC—Site-Specific Energy Consumption
SEC—Size Exclusion Chromatography
SED—Soil Evacuation and Disposal Plan (U.S.)
SEE—Society of Environmental Engineers (UK)
SEER—Surveillance, Epidemiology, and End Results
SEFI—European Society for Engineering Education
SELCHP—South East London Combined Heat and Power (UK)
SEM—Scanning Electron Microscope
SEP—Supplemental Environmental Project
SERC—Scientific and Engineering Research Council (UK)
SERI—Solar Energy Research Institute
SET—Science, Engineering, Technology
SETAC—Society of Environmental Toxicology and Chemistry
SF—Safety Factor
SFIP—Sector Facility Indexing Project (U.S.)
SG—Sustained Growth
Sh—Sherwood Number
SHASE—Society of Heating, Air Conditioning and Sanitary Engineers (Japan)
SHE—Safety, Health and the Environment
SHE—Systeme Hydrologique European
SHP—Shaft Horsepower
SHPO—State Historic Preservation Officer (U.S.)

SHWP—Seismic Hazards Working Party
SI—International System of Units (Systeme International d'Unites)
SI—Saturation Index
SI—Statutory Instruments (UK)
SIC—Standard Industrial Classification (U.S.)
SIL—Safety Integrity Level
SIM—Selective Ion Monitoring
SIMS—Secondary Ion Mass Spectrometry
SIP—Site Implementation Plan (U.S.)
SIP—Sterilization in Place
SIPI—Scientists' Institute for Public Information
SIS—Susceptible-Infected-Susceptible
SKAPP—Scientific Knowledge and Public Policy
SKI—Radiation Protection Institute (Sweden)
SL—Surface Layer
SLAMM—Source Loading and Management Model
SLAPP—Strategic Lawsuit against Public Participation (Canada)
SLM—Supported Liquid Membrane
SMB—Simulated Moving Bed
SMCL—Secondary Maximum Contaminant Level
SMCRA—Surface Mining Control and Reclamation Act (U.S.)
SME—Solar Mesospheric Explorer
SMP—Soluble Microbial Product
SMPS—Scanning Mobility Particle Sizer
SMR—Standardized Mortality Ratio (Rate)
SMZ—Surface Modified Zeolite
SNAP—Significant New Alternatives Policy
SNARL—EPA Suggested No Adverse Response Level (U.S.)
SNCR—Selective Noncatalytic Reduction
SNL—Sandia National Laboratory (U.S.)
SNL—Scottish Nuclear Ltd
SNL—Sense Noise Level
SOA—Secondary Organic Aerosols
SOC—Soluble Organic Compound (Chemical)
SOC—Synthetic Organic Chemical
SOCMI—Synthetic Organic Chemical Manufacturing Industry
SOD—Sediment Oxygen Demand
SOFC—Solid Oxide Fuel Cell
SOI—Southern Oscillation Index
SoPHE—Society of Public Health Engineers
SOx—Sulfur Oxides
SPCC—Spill Prevention Control and Countermeasures
SPE—Solid Phase Extraction
SPE—Survivor Population Effect
SPFC—Solid Polymer Fuel Cell
SPI—Society of the Plastics Industry
SPM—Scanning Probe Microscopy
SPME—Solid-Phase Microextraction
SPOT—Systeme Pour l'Observation de La Terre (France)
SPSS—Sulfur Polymer Stabilization and Solidification
SRC—Science Research Council (UK)
SRF—State Revolving Fund (U.S.)
SR&O—Statutory Regulations and Orders (UK)
SRT—Solids Retention Time
S/S—Solidification/Stabilization
SS—Suspended Solids
SSA—Specific Surface Area
SSBY—Sewage Solids By-Product
SSD—Safe Separation Distance
SSHRC—Social Sciences and Humanities Research Council (Canada)
SSI—Nuclear Safety Inspectorate (Sweden)
SSIT—Society on Social Implications of Technology
SSOW—Source Separated Organic Waste
SSSI—Site of Special Scientific Interest (UK)
SST—Sea-Surface Temperature
SST—Supersonic Transport
SSTL—Site Specific Target Levels
STAPPA—State and Territorial Air Pollution Program Administrators (U.S.)
STEL—Short Term Exposure Limit
STEM—Standard Transmission Electron Microscope
STEP—Septic Tank Effluent Pump
STEP—Standard for Exchange of Production
STM—Scanning Tunneling Microscopy
STORM—Storage Treatment Overflow and Runoff Model
STP—Standard Temperature and Pressure
STS—Supercooled Ternary Solution
SU—Standard Unit
SUVA—Specific Ultraviolet Absorbance
Sv—Sievert
SVE—Soil Vapor Extraction
SVI—Sludge Volume Index
SVIN—Swiss Association of Women Engineers
SVOC—Semivolatile Organic Compound
SVR—Sludge Volume Ratio
SWAMP—Storm Water Assessment, Monitoring and Performance Program (Canada)
SWDA—Solid Waste Disposal Act (U.S.)
SWE—Society of Women Engineers (U.S.)
SWH—Solar Water Heater
SWJ—Sewage Works Journal
SWMM—Stormwater Management Model

TA—Total Alkalinity
TAC—Total Annual Cost
TADC—Tire-Derived Activated Carbon
TAEE—Tert-Amyl Ethyl Ether
TAME—Tert-Amyl Methyl Ether
TAO—Tropical Atmosphere Ocean
TAPPI—Technical Association of the Pulp and Paper Industry
TAW—Technical Advisory Committee on Water Defenses (Holland)
TB—Tracheobronchial
TBT—Tributyltin
TC—Total Coliforms
TCA—Trichloroethane
TCDD—2,3,7,8-Tetrachlorodibenzo-p-Dioxin
TCDF—Tetrachlorodibenzofuran
TCE—Trichloroethylene

TCER—Target Carbon Emission Rate
TCF—Totally Chlorine Free
TCI—Total Capital Investment
TCLP—Toxicity Characteristic Leaching Procedure (Potential) (U.S.)
TCN—Technical Cooperation Network
TCP—Trichloropropane
TCR—Total Coliform Rule
TCU—True Color Unit
TDH—Total Dynamic Head
TDI—Tolerable Daily Intake
TDI—Toluene-2,4-Diisocyanate
TDS—Total Dissolved Solids
TEA—Triethanolamine
TEB—Total Exchangeable Bases
TECSEC—Technical Secretariat
TEL—Tetraethyl Lead
TEL—Total Energy Line
TEM—Total Extractable Matter
TEOM—Tapered Elemental Oscillating Microbalance
TEQ—Toxic Equivalent
TFAP—Tropical Forestry Action Plan
TFE—Tetrafluoroethylene
T4CB—3,3' ,4,4' -Tetrachlorinated Biphenyl
THAA—Total Haloacetic Acids
THC—Thermohaline Circulation
THC—Total Hydrocarbon
THESUS—Thermal Solar European Power Station
THF—Tetrahydrofuran
THM—Chloro-Organics
THM—Thermo-Hydro-Mechanical
THM—Trihalomethane
ThOD—Theoretical Oxygen Demand
THORP—Thermal Oxide Reprocessing Plant
3P—Pollution Prevention Pays
TI—Tobacco Institute
TIC—Total Industry Control
TIE—Toxicity Investigation Evaluation
TIEL—Toxicologically Insignificant Exposure Limit
TIO—Technology Innovation Office (U.S.)
TISE—Take It Somewhere Else
TKN—Total Kjeldahl Nitrogen
TL—Threshold Limit
TLC—Total Lung Capacity
TL, m—Threshold Limit, median
TLV—Threshold Limit Value
TM—Thematic Mapper
TMDL—Total Maximum Daily Load
TMI—Three Mile Island
TMP—Transmembrane Pressure
TN—Total Nitrogen
TNCB—Trinitrochlorobenzene
TNO—Netherlands Organization for Applied Scientific Research
TNO—Total Number of Organisms
TNRCC—Texas Natural Resources Conservation Commission
TOC—Total Organic Carbon
toe—Tonnes Oil Equivalent
TOGA—Tropical Ocean Global Atmosphere
TOMS—Total Ozone Mapping Spectrometer
TOX—Tetradichloroxylene
TP—Total Phosphorous
TPA—Tetraphthalic Acid
TPH—Total Petroleum Hydrocarbons
TPL—Trust for Public Lands
TPP—Tripolyphosphate
TPU—Thermal Processing Unit
TPV—Third-Party Verification
TQ—Threshold Quantity
TQM—Total Quality Management
TRE—Total Resource Effectiveness
TRE—Toxicity Reduction Evaluation
TRI—Toxics Release Inventory (U.S.)
TRIP—Trade Related Intellectual Property
TRS—Total Reduced Sulfur
TS—Total Solids
TSA—Technical Systems Audit
TSCA—Toxic Substances Control Act (U.S.)
TSCATS—Toxic Substances Control Act Test Submission
TSDF—Treatment, Storage and Disposal Facility
TSDHW—Transportation, Storage and Disposal of Hazardous Wastes
TSE—Transmissible Spongiform Encephalopathies
TSP—Total Soluble Phosphorous
TSP—Total Suspended Particulates
TSS—Total Suspended Solids
TT—Treatment Technique
TTHM—Total Trihalomethane
TTNBS—Technology Transfer Network Bulletin System
TTO—Total Toxic Organics
TTO—Troposphere Ozone
TTT & O—Time, Temperature, Turbulence and Oxygen
TUC—Trades Union Congress (UK)
TVC—Thermal Vapor Compression
TVO/IVO—Finnish Nuclear Organization
TWA—Time Weighted Average
TWh—Tetrawatt Hours

UASB—Upflow Anaerobic Sludge Blanket (Bed)
UATI—Union of Technical Associations and Organizations
UBA—German Federal Environmental Agency
UC—Uniformity Coefficient
UCM—Unresolved Complex Mixtures
UCPC—Ultrafine Condensation Particle Counter
UCS—Unconditioned Stimulus
UEIP—Use and Exposure Information Voluntary Project (U.S.)
UEL—Upper Explosive Limit
UF—Ultrafiltration
UFL—Upper Flammability Limit
UKMO—UK Meteorological Office
UL—Underwriters Laboratories
ULCC—Ultra Large Crude Carrier
ULSD—Ultra Low Sulfur Diesel
ULSP—Ultra Low Sulfur Petrol

UMIST—University of Manchester Institute of Science and Technology
UN—United Nations
UNCED—UN Conference on Environment and Development
UNCED—UN Convention on Environmental Diversity
UNCLOS—UN Conference on the Law of the Sea
UNDP—UN Development Program
UNECE—United Nations Economic Commission for Europe
UNEP—UN Environment Program
UNESCO—UN Education, Scientific and Cultural Organization
UNFCCC—United Nations Framework Convention on Climate Change
UNICEF—UN Children's Fund
UNICHAL—International Union of Heat Distributors
UNIDO—UN Industrial Development Organization
UNU—United Nations University
UOD—Ultimate Oxygen Demand
UP—Ultrafine Particle
UPW—Ultrapure Water
URV—Unit Risk Value
USC—U.S. Code
USCG—U.S. Coast Guard
USCGS—U.S. Coast and Geodetic Survey
USDW—Underground Source of Drinking Water
USGS—U.S. Geological Survey
USP—U.S. Pharmacopoeia
USPHS—U.S. Public Health Service
UST—Underground Storage Tank
UV—Ultraviolet
UVR—Ultraviolet Radiation

V—Vinyl
VA—Volatile Acid
VA—Vulnerability Assessment
VBS—Volatile Biofilm Solids
VC—Vapor Compression
VCM—Vinyl Chloride Monomer
VDI—Verein Deutscher Ingenieure
VE—Visual Emissions
VER—Variable Energy Recovery
VFA—Volatile Fatty Acid
VFVA—Vacuum Flash Vapor Absorption
VHAP—Volatile Hazardous Air Pollutant
VITO—Flemish Institute for Technological Research
VLCC—Very Large Crude Carrier
VLF—Very Low Frequency
VLLW—Very Low Level Radioactive Waste
VO—Volatile Organics
VOC—Volatile Organic Compounds (Contaminants) (Chemicals)
VOHAP—Volatile Organic Hazardous Air Pollutant
VOST—Volatile Organic Sampling Train
VPH—Volatile Petroleum Hydrocarbons
VPP—Voluntary Protection Program
VSS—Volatile Suspended Solids
VTE—Vertical Tube Evaporator
VTOC—Volatile Toxic Organic Compound
v/v—Volume/Volume
VVC—Vacuum Vapor Compression

W—Watt
WAC—Weak Acid Cation
WAMAP—IAEA Waste Management Advisory Program
WAS—Waste Activated Sludge
WASP—Water Quality Analysis and Simulation Program
WATRP—IAEA Waste Management Assessment and Technical Review Program
WBGU—German Advisory Council on Global Change
WC—Water Closet
WCED—World Commission on Environment and Development
WCRP—World Climate Research Program
WCS—Wildlife Conservation Society
WCS—World Conservation Strategy
WDF—Waste Derived Fuel
WEAO—Water Environment Association of Ontario
WEC—Wave Energy Converter
WEC—World Energy Conference
WEC—World Energy Council
WEDO—Women and Environment Development Organization
WEF—Water Environment Federation
WEF—World Environment Federation
WEPSD—World Engineering Partnership for Sustainable Development
WES—Women's Engineering Society (UK)
WESP—Wet Electrostatic Precipitator
WFEO—World Federation of Engineering Organizations
WFP—World Food Program
WFS—World Food Survey
WFTO—World Federation of Technology Organizations
Wh—Watt Hour
WHMIS—Waste Hazardous Materials Information System
WHO—World Health Organization
WHRC—Woods Hole Research Center
WID—Waste Incineration Directive (EU)
WIPP—Waste Isolation Pilot Plant
WIRE—World Wide Information System for Renewable Energy
WISE—Women into Science and Engineering
WITT—Women in Trade and Technology (Canada)
WL—Working Level
WLFO—Wet Limestone Forced Oxidation
WLM—Working Level Month
WMO—World Meteorological Organization
WO—Water in Oil
WPCF—Water Pollution Control Federation
WPWP—Western Pacific Warm Pool
WQCV—Water Quality Control Volume
WQI—Water Quality Indices
WQM—Water Quality Management
WRA—Waste Regulation Authority (UK)

WRC—World Resources Council
WRDA—Water Resources Development Act (U.S.)
WRI—World Resources Institute
WRPA—Water Resources Planning Act (U.S.)
WRRA—Water Resources Research Act (U.S.)
WSC—World Solar Commission
WSI—Water-Steam Injection
WSP—World Solar Programme
WSR—World Standardized Rates
WSRA—Wild and Scenic Rivers Act (U.S.)
WSSP—World Solar Summit Process
WTF—Water Treatment Facility
WTO—World Trade Organization
WWF—Wet Weather Flow
WWF—World Wildlife Fund
WWI—World Watch Institute
WWTP—Wastewater Treatment Plant

XLPE—Crosslinked Polyethylene
XRD—X-Ray Diffraction
XRF—X-Ray Fluorescence

Y—Growth Yield Coefficient

ZEV—Zero Emission Vehicle
ZIP—Zero-Incident Performance
ZLD—Zero Liquid Discharge
ZPG—Zero Population Growth

INDEX
