The deleterious response—that is, injury to health or the environment—should be significant. It is counterproductive to the goal of focusing our available resources on significant toxicological problems to include substances that cause only momentary discomfort or quickly reversible physiological change from the types of exposures that can be reasonably expected in daily life. There are no harmless substances if one does not place a limit on the type or extent of exposure. Nitrogen, oxygen, carbon dioxide, and water can all be harmful or even deadly under different types of exposures. Therefore, judgment must be used in making decisions about substances and the possibility of exposures at levels that can cause harm.

Substances that can cause harm by interfering with or destroying the functions of organs can be distinguished from those whose mode of action is attack on cell growth and reproduction.

Thus, the action of cyanide (which prevents tissues from using the oxygen provided by the blood) classifies it as different from a carcinogen (which causes the abnormal proliferation of cells), a mutagen (which changes the genetic material and thus damages new cells), and a teratogen (which changes the cell framework of an embryo).

Quantification of the risk associated with environmental exposures is a major activity of environmental control. Originally, this effort focused on the effects of carcinogens; noncarcinogens were delegated to minority status. Now there is an increased level of concern about effects other than cancer—for example, the impact of synthetic chemicals on the endocrine system that can result in disruptions of the immune system or behavioral problem. The immunotoxicity, neurotoxicity, teratogenicity, and toxicity to specific body tissues of many compounds have not received significant attention in comparison to their mutagenicity and carcinogenicity. There is danger that once a substance's carcinogenicity or noncarcinogenicity has been declared, its other harmful properties will be neglected.

To evaluate the risk from exposure to a specific hazardous material, it is important to obtain as realistic as possible an estimate of the dose received by a representative individual via inhalation, ingestion of food or drink, and other possible ways that substances can be absorbed. In the case of children in contact with soil and other materials, both indoor and outdoor, the possibility of hand-to-mouth exposure must be considered. As an example, an individual living in the vicinity of an operation that releases dioxin into the atmosphere is affected by both inhalation and by the amount of food and water ingested because of possible contamination from fallout. Obtaining the necessary dose data requires knowledge of emission rates and patterns, stack heights and local meteorological conditions, and

TABLE 2
Summary of cancer-associated environmental factors

Factor	Sites	Range of estimates
Diet	Digestive tract, breast endometrium, ovary	35–50%
Tobacco	Upper respiratory tract, bladder, esophagus, kidney, pancreas	22–30%
Asbestos	Upper respiratory tract, others	3–18%
Occupational	Upper respiratory tract, others	4–38%
Alcohol	Upper digestive tract, larynx, liver	3–5%
Infection	Uterine cervix, prostate, and other sites	1–5%
Sexual development, reproductive patterns, and sexual practices	Breast, endometrium, ovary, cervix, testis	1–13%
Pollution	Lung, bladder, rectum	5%
Medical drugs and radiation	Breast, endometrium, ovary, thyroid, bone, lung, blood	1–4%
Natural radiation	Skin, breast, thyroid, lung, bone, blood	1–3%
Consumer products	Possibly all sites	1–2%
Unknown—(e.g. new chemicals, dumps, stress)	All sites	?

the topography of the land and its uses. The behavior patterns of the individual—that is, the time and places occupied, the food and drink ingested and its sources, and the possibility of direct ingestion of contaminated soil through work or play—must be factored in to obtain a realistic dose estimate.

Estimation of the carcinogenic hazard of a substance has become a very complex procedure; however, the general idea can be presented in a model that calculates the individual or aggregate risk based on linear extrapolation from experimental data to zero dose of the curve relating dose to the probability of cancer.

This assumes that there is no threshold for the incident of cancer, i.e., the only exposure for which there is zero probability of cancer is zero exposure. The experimental data most convincing are those derived from studies of the human population supported by documented exposures and incidences of cancer. In most cases such data are not available; therefore animal-study data are used, with conservative factors introduced to compensate for lack of information about interspecies relationships. The safety factors that have been used have been as large as 10,000—that is, in some cases the effects on humans are assumed to take place at exposures that can be as much as 10,000 times less than those causing similar effects on the surrogate species.

The doses are commonly measured in terms of milligrams of chemicals absorbed in the body each day per kilogram of body weight over a lifetime. For the part that is inhaled, it is customary to convert dosage units into micrograms per cubic meter in the inhaled air. For the purposes of this conversion, a body weight of 70 kg is assumed and the inhaled volume is 20 cubic meters per day.

$$1\frac{\text{mg}}{\text{kg-day}} \times 70\frac{\text{kg}}{\text{person}} \times \frac{1}{20}\frac{\text{person-day}}{\text{m}^3}$$

$$\times 1000\frac{\mu\text{g}}{\text{mg}} = 3500\frac{\mu\text{g}}{\text{m}^3}$$

Therefore, a bodily intake of 1 mg per kilogram of body weight per day is equivalent to the inhalation of air containing 3500 μg of the chemical per cubic meter.

The unit risk value (URV) is the cancer probability corresponding to the inhalation over a lifetime of 70 years of air containing 1 μg per cubic meter of the substance—that is, the risk is the ratio of the probability of cancer to the microgram per cubic meter inhaled:

$$\text{URV} = \frac{\text{Probability of cancer}}{\mu\text{g}/\text{m}^3}$$

The URV multiplied by the average concentration inhaled over a lifetime is the individual lifetime risk of cancer:

$$\text{URV} \times \frac{\mu\text{g}}{\text{m}^3} = \text{individual life time risk}$$

The individual risk multiplied by the number in the population is the aggregate lifetime risk.

A commonly used value to describe a hazardous substance is the atmospheric concentration that over a lifetime will result in one cancer per million inhabitants.

$$\text{URV} \times \frac{\mu\text{g}}{\text{m}^3} \times 10^6 = 1$$

$$\frac{\mu\text{g}}{\text{m}^3} = \frac{1}{\text{URV} \times 10^6}$$

HAZARDOUS-WASTE INFORMATION

Information about Superfund locations and hazardous-waste activities in your zip code, city, county, or state can be obtained over the Internet from the U.S. Environmental Protection Agency's (EPA) Envirofacts Data Warehouse.

HYDROLOGY

THE PURPOSES OF HYDROLOGICAL STUDIES

Hydrology is concerned with all phases of the transport of water between the atmosphere, the land surface and subsurface, and the oceans, and the historical development of an understanding of the hydrological process is in itself a fascinating study.[6] As a science, hydrology encompasses many complex processes, a number of which are only imperfectly understood. It is perhaps helpful in developing an understanding of hydrological theory to focus attention not on the individual physical processes, but on the practical problems which the hydrologist is seeking to solve. By studying hydrology from the problem-solving viewpoint, we shall see the interrelationship of the physical processes and the approximations which are made to represent processes which are either imperfectly understood or too complex for complete physical representation. We shall also see what data is required to make adequate evaluations of given problems.

A prime hydrological problem is the forecasting of stream-flow run-off. Such forecasts may be concerned with daily flows, especially peak flows for flood warning, or a seasonal forecast may be required, where a knowledge of the total volume of run-off is of prime interest. More sophisticated forecast procedures are required for the day-to-day operation of flood control reservoirs, hydropower projects, irrigation and water supply schemes, especially for schemes which are used to serve several purposes simultaneously such as hydropower, flood control, and irrigation.

Hydrologists are also concerned with studying statistical patterns of run-off. A special class of problems is the study of extreme events, such as floods or droughts. Such maximum events provide limiting design data for flood spillways, dyke levels, channel design, etc. Minimum events are important, for example, in irrigation studies and fisheries projects. A more complex example of statistical studies is concerned with sequential patterns of run-off, for either monthly or annual sequences. Such sequences are important when testing the storage capacity of a water resource system, such as an irrigation or hydropower reservoir, when assessing the risk of failing to meet the requirements of a given scheme. A specially challenging example of sequential flow studies concerns the pattern of run-off from several tributary areas of the same river system. In such studies it is necessary to try to maintain not only a sequential pattern but also to model the cross-correlations between the various tributaries.

The question of land use and its influences on run-off occupies a central position in the understanding of hydrological processes. Land use has been studied for its influence on flood control, erosion control, water yield and agriculture, with particular application to irrigation. Perhaps the most marked effect of changed land use and changed run-off characteristics is demonstrated by urbanization of agricultural and forested lands. The paving of large areas and the influence of buildings has a marked effect in increasing run-off rates and volumes, so that sewer systems must be designed to handle the increased flows. Although not so dramatic, and certainly not so easy to document, the influence of trees and crops on soil structure and stability may well prove to be the most far-reaching problem. There is a complex interaction between soil biology, the crop and the hydrological factors such as soil moisture, percolation, run-off, erosion, and evapo-transpiration. Adequate hydrological calculations are a prerequisite for such studies.

A long-term aim of hydrological studies is the clear definition of existing patterns of rainfall and run-off. Such a definition requires the establishment of statistical measures such as the means, variances and probabilities of rate events. From these studies come not only the design data for extreme events but also the determination of any changes in climate which may be either cyclical or a longterm trend. It is being suggested in many quarters that air pollution may have a gradual effect on the Earth's radiation balance. If this is true we should expect to see measurable changes in our climatic patterns. Good hydrological data and its proper analysis will provide one very important means of evaluating such trends and also for measuring the effectiveness of our attempts to correct the balance.

A BRIEF NOTE ON STATISTICAL TECHNIQUES

The hydrologist is constantly handling large quantities of data which may describe precipitation, streamflow, climate, groundwater, evaporation, and many other factors. A reasonable grasp of statistical measures and techniques is invaluable to the hydrologist. Several good basic textbooks are referenced,[1,2,3,8,9] and *Facts from Figures* by Moroney, is particularly recommended for a basic understanding of what statistics is aiming to achieve.

The most important aspect of the nature of data is the question of whether data is independent or dependent. Very often this basic question of dependence or independence is not discussed until after many primary statistical measures have been defined. It is basic to the analysis, to the selection of variables and to the choice of technique to have some idea of whether data is related or independent. For example, it is usually reasonable to assume that annual flood peaks are independent of each other, whereas daily streamflows are usually closely related to preceding and subsequent events: they exhibit what is termed *serial correlation.*

The selection of data for multiple correlation studies is an example where dependence of the data is in conflict with the underlying assumptions of the method. Once the true nature of the data is appreciated it is far less difficult to decide on the correct statistical technique for the job in hand. For example, maximum daily temperatures and incoming radiation are highly correlated and yet are sometimes both used simultaneously to describe snowmelt.

In many hydrological studies it has been demonstrated that the assumption of random processes is not unreasonable. Such an assumption requires an understanding of statistical distribution and probabilities. Real data of different types has been found to approximate such theoretical distributions as the binomial, the Poisson, the normal distribution or certain special extreme value distributions. Especially, in probability analysis, it is important that the correct assumption is made concerning the type of distribution if extrapolated values are being read from the graphs.

Probabilities and return periods are important concepts in design studies and require understanding. The term "return period" can be somewhat misleading unless it is clearly appreciated that a return period is in fact a probability. Therefore when we speak of a return period of 100 years we imply that a magnitude of flow, or some other such event, has a one percent probability of occurring in any given year. It is even more important to realize that the probability of a certain event occurring in a number of years of record is much higher than we might be led to believe from considering only its annual probability or return period. As an example, the 200 year return period flood or drought has an annual probability of 0.5%, but in 50 years of record, the probability that it will occur at least once is 22%. Figure 1 summarizes the probabilities for various return periods to occur at least once as a function of the number of years of record. From such a graph it is somewhat easier to appreciate why design floods for such critical structures as dam spillways have return of 1,000 years or even 10,000 years.

ANALYSIS OF PRECIPITATION DATA

Before analyzing any precipitation data it is advisable to study the method of measurement and the errors inherent in the type of gauge used. Such errors can be considerable (Chow,[1] and Ward[5]).

Precipitation measurements vary in type and precision, and according to whether rain or snow is being measured. Precipitation gauges may be read manually at intervals of a day or part of a day. Alternatively gauges may be automatic and yield records of short-term intensity. Wind and gauge exposure can change the catch efficiency of precipitation gauges and this is especially true for snow measurements. Many snow measurements are made from the depth of new snow and an average specific gravity of 0.10 is assumed when converting to water equivalent.

Precipitation data is analyzed to give mean annual values and also mean monthly values which are useful in assessing seasonal precipitation patterns. Such figures are useful for determining total water supply for domestic, agricultural and hydropower use, etc.

More detailed analysis of precipitation data is given for individual storms and these figures are required for design of drainage systems and flood control works. Analysis shows the

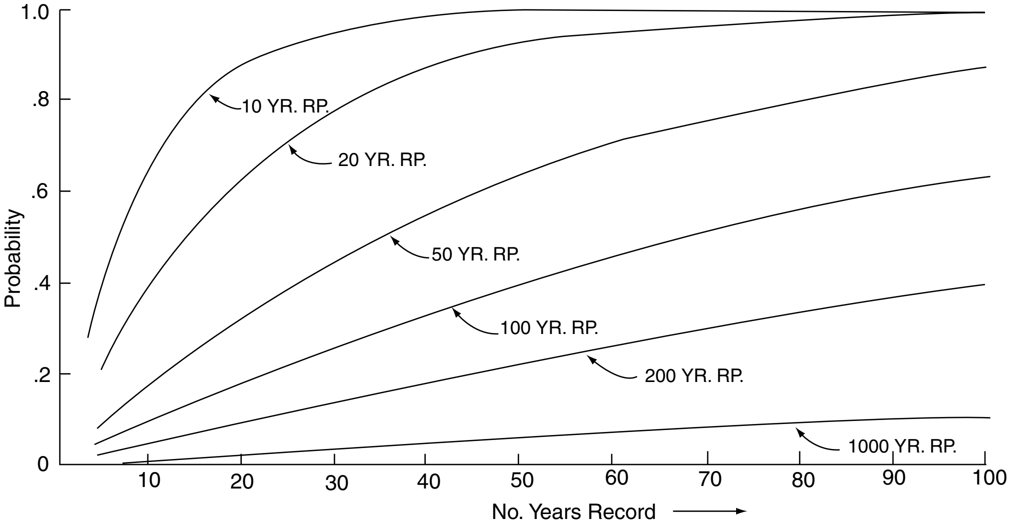

FIGURE 1 Probability of occurrence of various annual return period events as a function of years of record.

relationship between rain intensity (inches per hour) with both duration and area. In general terms, the longer the duration of storm, the lower will be the average intensity of rainfall. Similarly, the larger the area of land being considered, the lower will be the average intensity of rainfall. For example, a small catchment area of, say, four square miles may be subjected to a storm lasting one hour with an average intensity of two inches per hour while a catchment of two hundred square miles would only experience an average intensity of about one inch per hour. Both these storms would have the same return period or probability associated with them. Such data is prepared by weather agencies like the U.S. Weather Bureau and is available in their publications for all areas of the country. Typical data is shown in Figure 2. The use of these data sheets will be discussed further in the section on run-off.

Winter snowpacks represent a large water storage which is mainly released at a variable rate during spring and early summer. In general, the pattern of snowfall is less important than the total accumulation. In the deep mountain snowpacks, snowtube and snowpillow measurements appear to give fairly reliable estimates of accumulated snow which can be used for forecasts of run-off volumes as well as for flood forecasting. On the flat prairie lands, where snow is often quite moderate in amounts, there is considerable redistribution and drifting of snow by wind and it is a considerable problem to obtain good estimates of total snow accumulation.

When estimates of snow accumulation have been made it is a further problem to calculate the rate at which the snow will melt and will contribute to stream run-off. Snow therefore represents twice the problem of rain, because firstly we must measure its distribution and amount and secondly, it may remain as snow for a considerable period before it contributes to snowmelt.

EVAPORATION AND EVAPO-TRANSPIRATION

Of the total precipitation which falls, only a part finally discharges as streamflow to the oceans. The remainder returns to the atmosphere by evaporation. Linsley[2] points out that ten reservoirs like Lake Mead could evaporate an amount equivalent to the annual Colorado flow. Some years ago, studies of Lake Victoria indicated that the increased area resulting from raising the lake level would produce such an increase in evaporation that there would be a net loss of water utilization in the system.

Evaporation varies considerably with climatic zone, latitude and elevation and its magnitude is often difficult to evaluate. Because evaporation is such a significant term in many hydrological situations, its proper evaluation is often a key part of hydrological studies.

Fundamentally, evaporation will occur when the vapor pressure of the evaporating surface is greater than the vapor pressure of the overlying air. Considerable energy is required to sustain evaporation, namely 597 calories per gram of water or 677 calories per gram of snow or ice. Energy may be supplied by incoming radiation or by air temperature, but if this energy supply is inadequate, the water or land surface and the air will cool, thus slowing down the evaporation process. In the long term the total energy supply is a function of the net radiation balance which, in turn, is a function of latitude. There is therefore a tendency for annual evaporation to be only moderately variable and to be a function of latitude, whereas short term evaporation may vary considerably with wind, air temperature, air vapor pressure, net radiation, and surface temperature.

The discussion so far applies mainly to evaporation from a free water surface such as a lake, or to evaporation from a saturated soil surface. Moisture loss from a vegetated land surface is complicated by transpiration. Transpiration is the term used to describe the loss of water to the atmosphere from plant surfaces. This process is very important because the plant's root system can collect water from various depths of the underlying soil layers and transmit it to the atmosphere. In practice it is not usually possible to differentiate between evaporation from the soil surface and transpiration from the plant surface, so it is customary to consider the joint effect and call it evapo-transpiration. This lumping of the two processes has led to thinking of them as being identical, however, we do know that the evaporation rate from a soil surface decreases as the moisture content of the soil gets less, whereas there is evidence to indicate that transpiration may continue at a nearly constant rate until a plant reaches the wilting point.

To understand the usual approach now being taken to the calculation of evapo-transpiration, it is necessary to appreciate what is meant by *potential evapo-transpiration* as opposed to *actual evapo-transpiration.* Potential evapo-transpiration is the moisture loss to the atmosphere which would occur if the soil layers remained saturated. Actual evapo-transpiration cannot exceed the potential rate and gradually reduces to a fraction of the potential rate as the soil moisture decreases. Various formulae exist for estimating potential evapo-transpiration in terms of climatic parameters, such as Thornthwaites method, or Penman or Turk's formulae. Such investigations have shown that a good field measure of potential evapo-transpiration is pan evaporation from a standard evaporation-pan, such as the Class A type, and such measurements are now widely used. To turn these potential estimates into actual evapo-transpiration it is commonly assumed that actual equals potential after the soil has been saturated until some specific amount of moisture has evaporated, say two inches or so depending on the soil and crop. It is then assumed that the actual rate decreases exponentially until it effectively ceases at very low moisture contents. In hydrological modeling an accounting procedure can be used to keep track of incoming precipitation and evaporation so that estimates of evapo-transpiration can be made. The potential evapo-transpiration rate must be estimated from one of the accepted formulae or from pan-evaporation measurements, if available. Details of such procedures are well illustrated in papers by Nash[17] and by Linsley and Crawford[44] in the Stanford IV watershed model.

RUN-OFF: RAIN

It is useful to imagine that we start with a dry catchment, where the groundwater table is low, and the soil moisture

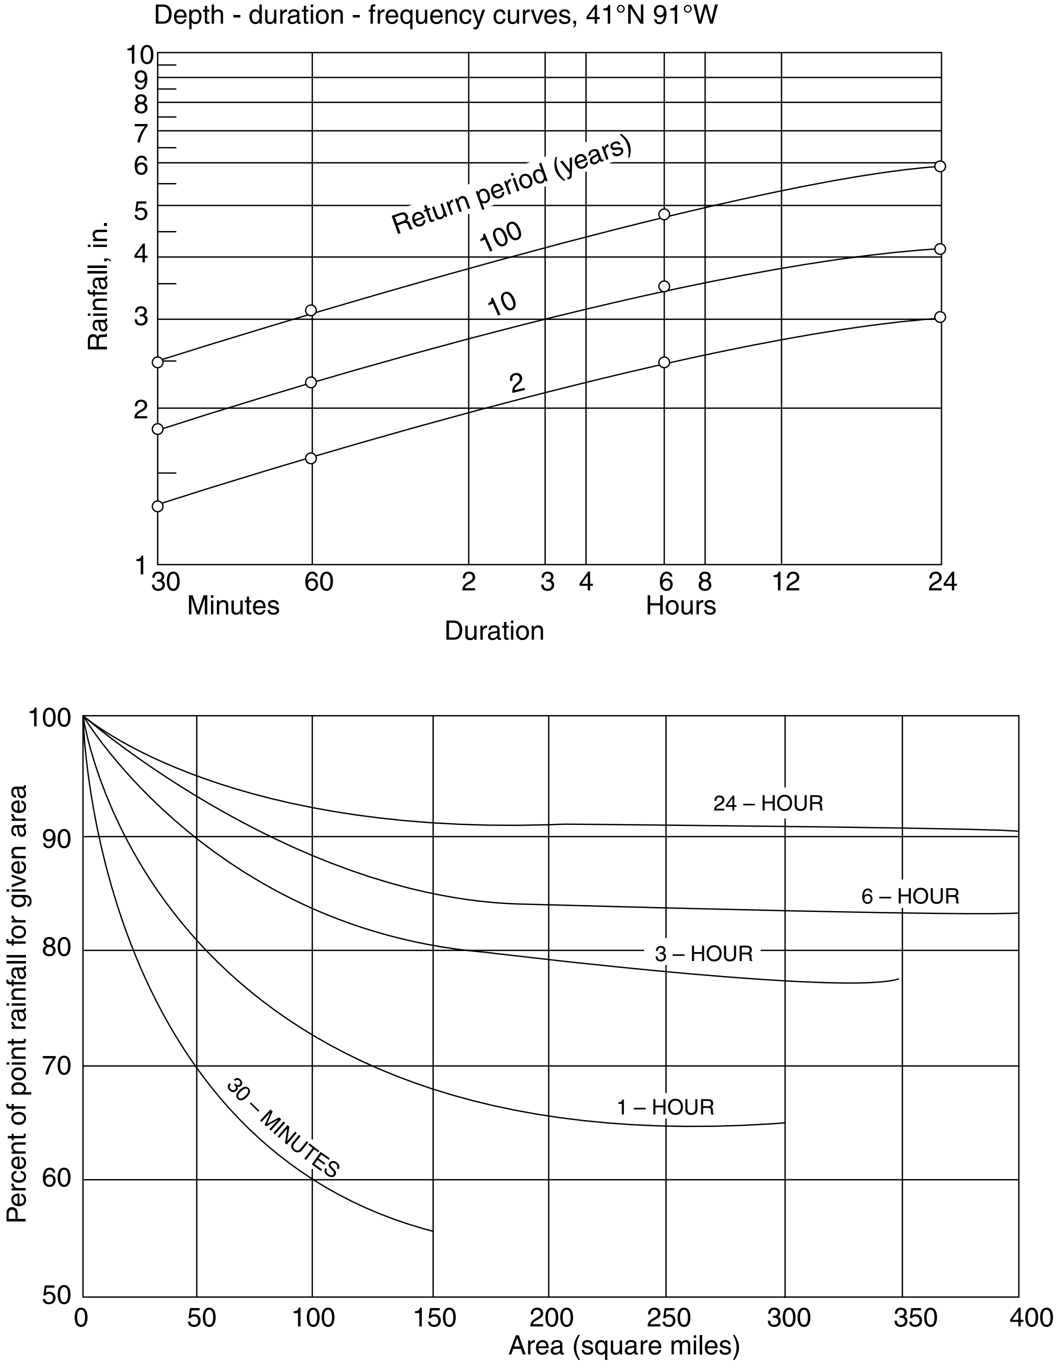

FIGURE 2 Rainfall depth-duration and area-frequency curves (US Weather Bureau, after Chow[1]).

has been greatly reduced, perhaps almost to the point where hygroscopic moisture alone remains. When rain first starts much is *intercepted* by the trees and vegetation and this *interception* storage is lost by evaporation after the storm. Rain reaching the soil *infiltrates* into pervious surfaces and begins to satisfy soil moisture deficits. As soil moisture levels rise, water percolates downward toward the fully saturated water table level. If the rain is heavy enough, the water supply may exceed the vertical percolation rate and water then starts to flow laterally in the superficial soil layers toward the stream channels: this process is termed *interflow* and is much debated because it is so difficult to measure. At very high rainfall rates, the surface infiltration rate may be exceeded and then direct surface run-off will occur. Direct run-off is rare from soil surfaces but does occur from certain impervious soil types, and from paved areas. Much work has been done to evaluate the relative significance of these various processes and is well documented in references (1,2,3).

Such qualitative descriptions of the run-off process are helpful, but are limited because of the extreme complexity and interrelationship of the various processes. Various methods have been developed to by-pass this complexity and to give us usable relationships for hydrologic calculations.

The simplest method is a plot of historical events, showing run-off as a function of the depth of precipitation in a given storm. This method does not allow for any antecedent soil moisture conditions or for the duration of a particular storm.

More complex relationships use some measure of soil moisture deficiency such as cumulative pan-evaporation or the antecedent precipitation index. Storm duration and precipitation amount is also allowed for and is well illustrated by the U.S. Weather Bureau's charts developed for various areas (Figure 2). It is a well to emphasize that the antecedent precipitation index, although based on precipitation, is intended to model the exponential decay of soil moisture between storms, and is expressed by

$$I_N = (I_0 k^M + I_M) k^{(N-M)}$$

where I_0 is the rain on the first day and no more rain occurs until day M, when I_M falls. If k is the recession factor, usually about 0.9, then I_N will be the API for day N. The expression can of course have many more terms according to the number of rain events.

Before computers were readily available such calculations were considered tedious. Now it is possible to use more complex accounting procedures in which soil moisture storage, evapo-transpiration, accumulated basin run-off, percolation, etc. can all be allowed for. These procedures are used in more complex hydrological modeling and are proving very successful.

RUN-OFF: SNOWMELT

As a first step in the calculation of run-off from snow, methods must be found for calculating the rate of snowmelt. This snowmelt can then be treated similarly to a rainfall input. Snowmelt will also be subject to soil moisture storage effects and evapo-transpiration.

The earliest physically-based model to snowmelt was the degree-day method which recognized that, despite the complexity of the process, there appeared to be a good correlation between melt rates and air temperature. Such a relationship is well illustrated by the plots of cumulative degree-days against cumulative downstream flow, a rather frustrating graph because it cannot be used as a forecasting tool. This cumulative degree-day versus flow plot is an excellent example of how a complex day-to-day behavior yields a long-term behavior which appears deceptively simple. Exponential models and unit hydrograph methods have been used to turn the degree-day approach into a workable method and a number of papers are available describing such work (Wilson,[38] Linsley[32]). Arguments are put forward that air temperature is a good index of energy flux, being an integrated result of the complex energy exchanges at the snow surface (Quick[33]).

Light's equation[31] for snowmelt is based on physical reasoning which models the energy input entirely as a turbulent heat transfer process. The equation ignores radiation and considers only wind speed as the stirring mechanism, air temperature at a standard height as the driving gradient for heat flow and, finally, vapour pressure to account for condensation–evaporation heat flux. It is set up for 6 hourly computation and requires correction for the nature of the forest cover and topography. It is interesting to compare Light's equation with the U.S. Crops equation[36] for clear weather to see the magnitude of melt attributed to each term.

By far the most comprehensive studies of snowmelt have been the combined studies by the U.S. Corps of Engineers and the Weather Bureau (U.S. Corps of Engineers[36,37]). They set up three field snow laboratory areas varying in size from 4 to 21 square miles and took measurements for periods ranging from 5 to 8 years. Their laboratory areas were chosen to be representative of certain climatic zones. Their investigation was extensive and comprehensive, ranging from experimental evaluation of snowmelt coefficient in terms of meteorological parameters, to studies of thermal budgets, snow-course and precipitation data reliability, water balances, heat and water transmission in snowpacks, streamflow synthesis, atmospheric circulations, and instrumentation design and development.

A particularly valuable feature of their study appears to have been the lysimeters used, one being 1300 sq.ft. in area and the other being 600 sq.ft. (Hilderbrand and Pagenhart[30]). The results of these lysimeter studies have not received the attention they deserve, considering that they give excellent indication of storage and travel time for water in the pack. It may be useful to focus attention on this aspect of the Corps work because it is not easy to unearth the details from the somewhat ponderous Snow Hydrology report. Before leaving this topic it is worth mentioning that the data from the U.S. studies is all available on microfilm and could be valuable for future analysis. It is perhaps useful at this stage to write down the Light equation and the clear weather equation from the Corps work to compare the resulting terms.

Light's equation[31] (simple form in °F, inches of melt and standard data heights)

$$D = U\left(0.001\,84 T_a \cdot 10^{-0.0000156} + 0.00578\left(e^{-6\cdot 11}\right)\right)$$

where

U = average wind speed (m.p.h.) for 6 hr period
T = air temperature above 32°F for 6 hr period

e = vapor pressure for 6 hr period
h = station elevation (feet)
D = melt in inches per 6 hr period

The U.S. Corps Equation is[36]

$$M = k'(0.00508I_{\mathrm{i}})(1 - a) + (1 - N) \times (0.0212T_{\mathrm{a}} - 0.84) + N(0.029T_{\mathrm{c}}) + k(0.0084U)(0.22T_{\mathrm{a}} + 0.78T\mathrm{d})$$

M = Incident Radiation + incoming clear air longwave + cloud longwave + [Conduction + Condensation]

k' and k are approximately unity.
N = fraction of cloud cover
I_{i} = incident short wave radiation (langleys/day)
a = albedo of snow surface
T_{a} = daily mean temperature °F above 32°F at 10′ level
T_{c} = cloud base temperature
T_{d} = dew point temperature °F above 32°F
U = average wind speed—miles/hour at 50′ level.

Putting in some representative data for a day when the minimum temperature was 32°F and the maximum 70°F, incoming radiation was 700 langleys per day and relative humidity varied from 100% at night to 60% at maximum temperature, the results were:

Light Equation
D = Air temp melt and Condensation melt
$= 1.035 + 0.961$ inches/day
$= 1.996$ inches/day

U.S. Corps Equation
M = incoming shortwave + incoming longwave + air temp. + Condensation
$= 1.424 - 0.44 + 0.351 + 0.59$
$= 1.925$ inches/day.

Note the large amount attributed to radiation which the Light equation splits between air temperature and radiation. It is a worthwhile operation to attempt to manufacture data for these equations and to compare them with real data. The high correlations between air temperature and radiation is immediately apparent, as is the close relationship between diurnal air temperature variation and dewpoint temperature during the snowmelt season. Further comparison of the formulae at lower temperature ranges leave doubts about the influence of low overnight temperatures.

There is enough evidence of discrepancies between real and calculated snowmelt to suggest that further study may not be wasted effort. Perhaps this is best illustrated from some recent statements made at a workshop on Snow and Ice Hydrology.[39] Meier indicates that, using snow survey data, the Columbia forecast error is 8 to 14% and occasionally 40 to 50%. Also these errors occurred in a situation where the average deviation from the long-term mean was only 12 to 20%. For a better comparison of errors it would be interesting to know the standard error of forecast compared with standard "error" of record from the long-term mean. Also, later in the same paper it is indicated that a correct heat exchange calculation for the estimation of snowmelt cannot be made because of our inadequate knowledge of the eddy convection process. At the same workshop the study group on Snow Metamorphism and Melt reported: "we still cannot measure the free water content in any snow cover, much less the flux of the water as no theoretical framework for flow through snow exists."

Although limitations of data often preclude the use of the complex melt equations, various investigators have used the simple degree-day method with good success (Linsley[32] and Quick and Pipes[40,46,47]). There may be reasonable justification for using the degree-day approach for large river basins with extensive snowfields where the air mass tends to reach a dynamic equilibrium with the snowpck so that energy supply and the resulting melt rate may be reasonably well described by air temperature. In fact there seems to be no satisfactory compromise for meteorological forecasting; either we must use the simple degree-day approach or on the other hand we must use the complex radiation balance, vapour exchange and convective heat transfer methods involving sophisticated and exacting data networks.

COMPUTATION OF RUN-OFF—SMALL CATCHMENTS

Total catchment behavior is seen to be made up of a number of complex and interrelated processes. The main processes can be reduced to evapo-transpiration losses, soil moisture and groundwater storage, and flow of water through porous media both as saturated flow and unsaturated flow. To describe this complex system the hydrologist has resorted to a mixture of semi-theoretical and empirical calculation techniques. Whether such techniques are valid is justified by their ability to predict the measured behavior of a catchment from the measured inputs.

The budgeting techniques for calculating evapo-transpiration losses have already been described. From an estimation of evapo-transpiration and soil moisture and measured precipitation we can calculate the residual precipitation which can go to storage in the catchment and run-off in the streams. A method is now required to determine at what rate this effective precipitation, as it is usually called, will appear at some point in the stream drainage system. The most widely used method is the unit hydrograph approach first developed by Sherman in 1932.[16]

To reduce the unit hydrograph idea to its simplest form, consider that four inches of precipitation falls on a catchment in two hours. After allowing for soil moisture deficit and evaporation losses, let us assume that three inches of this precipitation will eventually appear downstream as run-off. Effecitvely this precipitation can be assumed to have fallen on the catchment at the rate of one and a half inches per hour

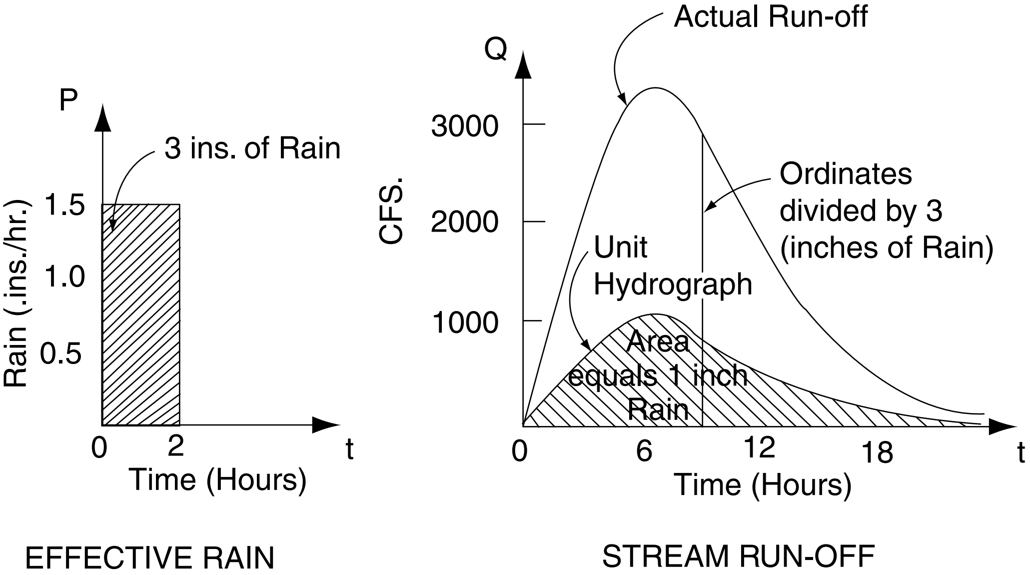

FIGURE 3 Hydrograph and unit hydrograph of run-off from effective rain.

for two hours. This effective precipitation will appear some time later in the stream system, but will now be spread out over a much longer time period and will vary from zero flow, rising gradually to a maximum flow and then slowly decreasing back to zero. Figure 3 shows the block of uniform precipitation and the corresponding outflow in the stream system. The outflow diagram can be reduced to the unit hydrograph for the two hour storm by dividing the ordinates by three. The outflow diagram will then contain the volume of run-off equivalent to one inch of precipitation over the given catchment area. For instance, one inch of precipitation over one hundred square miles will give an area under the unit hydrograph of 2690 c.f.s. days.

When a rainstorm has occurred the hydrologist must first calculate how much will become effective rainfall and will contribute to run-off. This can best be done in the framework of a total hydrological run-off model as will be discussed later. The effective rainfall hydrograph must then be broken down into blocks of rainfall corresponding to the time interval for the unit hydrograph. Each block of rain may contain *P* inches of water and the corresponding outflow hydrograph will have ordinates *P* times as large as the unit hydrograph ordinates. Also, several of these scaled outflow hydrographs will have to be added together. This process is known as convolution and is illustrated in Figure 4 and 5.

The underlying assumption of unit hydrograph theory is that the run-off process is linear, not in the trivial straight line sense, but in the deeper mathematical sense that each incremental run-off event is independent of any other run-off. In the early development, Sherman[16] proposed a unit hydrograph arising from a certain storm duration. Later workers such as Nash[17,23] showed that Laplace transform theory, as already highly developed for electric circuit theory, could be used. This led to the instantaneous unit hydrograph and gave rise to a number of fascinating studies by such workers as Dooge,[18] Singh,[19] and many others. They introduced exponential models which are interpretable in terms of instantaneous unit hydrograph theory. Basically, however, there is no difference in concept and the convolution integral, Eq. (1) can be arrived at by either the unit hydrograph or the instantaneous unit hydrograph approach. The convolution integral can be written as:

$$Q(t) = \int_0^{t<t_0} u(1-\tau)P(\tau)\mathrm{d}\tau \tag{1}$$

Figure 4 shows the definition diagram for the formulation is only useful if both *P,* the precipitation rate, and *u,* the instantaneous unit hydrograph ordinate are expressible as continuous functions of time. In real hydrograph applications it is more useful to proceed to a finite difference from of Eq. (1) in which the integral is replaced by a summation, Eq. (2), and Figure 5.

$$Q_R = \sum_1^M u(m)P(n)\Delta t \tag{2}$$

where *M* is the number of unit hydrograph time increments, and *m, n* and *R* are specified in Figure 2. It should be noted that from Figure 5,

$$m + n = R + 1. \tag{3}$$

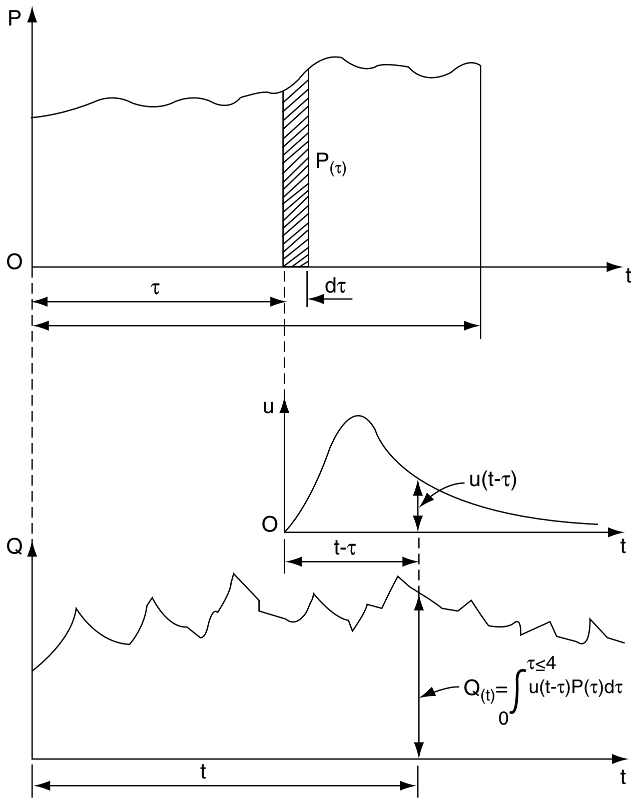

FIGURE 4 Determination of streamflow from precipitation input using an instantaneous unit hydrograph.

Expanding Eq. (2) for a particular value of *R*,

$$Q(10)=u(10)P(1)+u(9)P(2)+\Lambda\ u(1)P(10). \quad (4)$$

The whole family of similar equations for *Q* may be expressed in matrix form (Snyder[20])

$$\begin{pmatrix} Q_1\\ Q_2\\ Q_3\\ .\\ .\\ \\ \\ \\ \\ Q_R \end{pmatrix}=\begin{pmatrix} P_1 & 0 & 0 & . & . & . & . & 0\\ P_2 & P_1 & 0 & & & & & 0\\ P_3 & P_2 & P_1 & 0 & & & & 0\\ . & . & . & & & & . & .\\ . & . & . & . & & & & .\\ P_n & & & & & & & \\ 0 & P_n & & & & & & .\\ 0 & 0 & P_n & & & & & \\ 0 & 0 & 0 & & & & P_1 & 0\\ . & . & . & & & & P_2 & P_1 \end{pmatrix}\begin{pmatrix} u_1\\ u_2\\ u_3\\ .\\ .\\ u_m \end{pmatrix} \quad (5)$$

$\leftarrow m$ columns $\rightarrow$

Or more briefly

$$\{Q\}=[P]\{u\}. \quad (6)$$

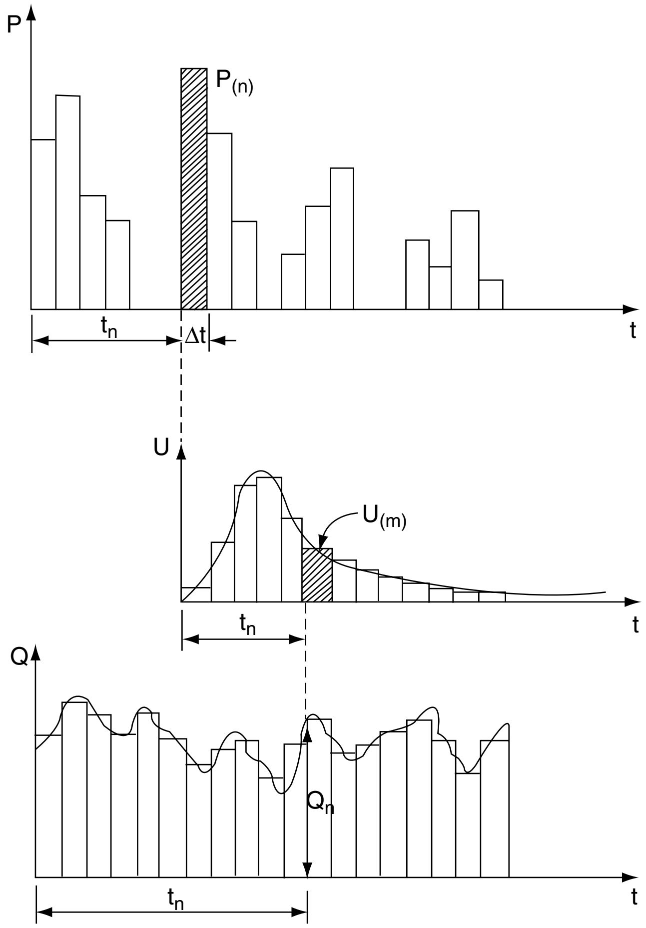

FIGURE 5 Convolution of precipitation by unit hydrograph on a finite difference basis.

Equation (6) specifies the river flow in terms of the precipitation and the unit hydrograph. In practice *Q* and *P* are measured and *u* must be determined. Some workers have guessed a suitable functional form for *u* with one or two unknown parameters and have then sought a best fit with the available data. For instance, Nash's series of reservoirs yields[17,23]

$$u(t)=\frac{1}{(n-1)!}\frac{t^{n-1}}{K^{n}}e^{-t/k} \quad (7)$$

in which there are two parameters, *K* and *n*. Another approach is to solve the matrix Eq. (6) as follows (Synder[21])

$$\{u\}=\left[P^{T}P\right]^{-1}P^{T}\{Q\}. \quad (8)$$

It has already been demonstrated that $R = m + n - 1$ so that there are more equations available than there are unknowns. The solution expressed by Eq. (8) therefore automatically yields the least squares values for *u*. This result will be referred to after the next section.

MULTIPLE REGRESSION AND STREAMFLOW

The similarity of the finite difference unit hydrograph approach to multiple regression analysis is immediately apparent. The flow in terms of precipitation can be written as

$$\begin{aligned} Q_R &= a_1P_t + a_2P_{t+1} + a_3P_{t+2} + \Lambda + a_np_{t+n-1} \\ Q_{R+1} &= a_1P_{t+1} + a_2P_{t+2} + a_3P_{t+3} + \Lambda + a_np_{t+n} \qquad (9) \\ Q_{R+2} &= a_1P_{t+2} + \text{etc.} \end{aligned}$$

Again we can write

$$\{Q\} = [P]\{a\}. \qquad (10)$$

The similarity with Eq. (6) is obvious and may be complete if we have selected the correct precipitation data to correlate precipitation at 6 a.m. with downstream flow at 9 a.m. when we know that there is a 3-hour lag in the system. Therefore, using multiple regression as most hydrologists do, the method can become identical with the unit hydrograph approach.

LAKE, RESERVOIR AND RIVER ROUTING

The run-off calculations of the previous sections enable estimates to be made of the flow in the headwaters of the river system tributaries. The river system consists of reaches of channels, lakes, and perhaps reservoirs. The water travels downstream in the various reaches and through the lakes and reservoirs. Tributaries combine their flows into the main stream flow and also distributed lateral inflows contribute to the total flow. This total channel system influences the flow in two principal ways, first the flow takes time to progress through the system and secondly, some of the flow goes into temporary storage in the system. Channel storage is usually only moderate compared with the total river flow quantities, but lake and reservoir storage can have a considerable influence on the pattern of flow.

Calculation procedures are needed which will allow for this delay of the water as it flows through lakes and channels and for the modifying influence of storage. The problem is correctly and fully described by two physical equations, namely a continuity equation and an equation of motion. Continuity is simply a conversion of mass relationship while the equation of motion relates the mass accelerations to the forces controlling the movement of water in the system. Open channel fluid mechanics deals with the solution of such equations, but at present the solutions have had little application to hydrological work because the solutions demand detailed data which is not usually available and the computations are usually very complex, even with a large computer.

Hydrologists resort to an alternative approach which is empirical; it uses the continuity equation but replaces the equation of motion with a relationship between the storage and the flow in the system. This assumption is not unreasonable and is consistent with the assumption of a stage–discharge relationship which is widely utilized in stream gauging.

RESERVOIR ROUTING

The simplest routing procedure is so-called reservoir routing, which also applies to natural lakes. The continuity equation is usually written as;

$$I - O = \frac{\mathrm{d}S}{dT}, \qquad (11)$$

where

I = Inflow to reservoir or lake
O = Outflow
S = Storage

The second equation relates storage purely to the outflow, which is true for lakes and reservoirs, where the outflow depends only on the lake level. The outflow relationship may be of the form:

$$O = KBH^{3/2} \qquad (12)$$

if the outflow is controlled by a rectangular weir, or:

$$\mathrm{O} = \mathrm{K'H^n} \qquad (13)$$

where K' and n depend on the nature of the outflow channel.

Such relationships can be turned into outflow—storage relationships because storage is a function of H, the lake level. The Eqs. (12) and (13) can then be rewritten in the form

$$O = K''S^{\mathrm{m}}. \qquad (14)$$

Alternatively, there may be no simple functional relationship, but a graphical relationship between O and S can be plotted or stored in the computer. The continuity equation and the outflow storage relationship can then be solved either graphically or numerically, so that, given certain inflows, the outflows can be calculated. Notice the assumption that a lake or reservoir responds very rapidly to an inflow, and the whole lake surface rises uniformly.

During the development of the kinematic routing model described later, a reservoir routing technique was developed which has proved to be very useful. Because reservoir routing is such an important and basic requirement in hydrology, the method will be presented in full.

Reservoir routing can be greatly simplified by recognizing that complex stage–discharge relationships can be linearised for a limited range of flows. It is even more simple to relate stage levels to storage and then to linearise the storage–discharge relationship. The approach described below can then be applied to any lake or reservoir situation, ranging from natural outflow control to the operation of gated spillways and turbine discharge characteristics.

From a logical point of view, it is probably easier to develop the routing relationship by considering storage, or volume changes. In a fixed time interval ΔT, the reservoir inflow volume is $VI(J)$, where J indicates the current time interval. The corresponding outflow volume is $VO(J)$ and the reservoir storage volume is $S(J)$. If the current inflow volume $VI(J)$ were to equal the previous outflow value $VO(J-1)$, then the reservoir would be in a steady state and no change in reservoir storage would occur. Using the hypothetical steady state as a datum for the current time interval, we can define changes in the various flow and storage volumes, where Δ indicates an increment,

$$\Delta VI(J) = VI(J) - VI(J-1) \tag{15}$$

$$\Delta VO(J) = VO(J) - VO(J-1) \tag{16}$$

$$\Delta S(J) = S(J) - S(J-1). \tag{17}$$

To maintain a mass balance for the current time interval,

$$\Delta VI(J) = \Delta S(J) + \Delta VO(J). \tag{18}$$

Using the relationship for a linear reservoir,

$$S(J) = K^{*}QO(J) \tag{19}$$

where $QO(J)$ is the outflow which is equal to $VO(J)/\Delta T$. The corresponding equation for the previous time interval is

$$S(J-1) = K^{*}QO(J-1). \tag{20}$$

Subtracting this equation from Eq. (5) we obtain

$$\Delta S(J) = K^{*}\Delta QO(J). \tag{21}$$

Substituting that $\Delta QO(J) = \Delta VO(J)/\Delta t$,

$$\Delta S(J) = (K/\Delta t)^{*}\,\Delta VO(J). \tag{22}$$

Substituting in equation (4) for $\Delta S(J)$

$$\Delta VI(J) = (K/\Delta t + 1)^{*}\,\Delta VO(J) \tag{23}$$

$$\Delta VO = \frac{1}{1+K/\Delta t} * \Delta VI(J). \tag{24}$$

This equation can be rewritten for flows by substituting $\Delta VO(J)$ equals $\Delta QO(J)^{*}\Delta T$ and $\Delta VI(J)$ equals $\Delta QI(J)^{*}\Delta T$,

i.e.,

$$\Delta QO(J) = \frac{1}{1+K/\Delta t} * \Delta QI(J) \tag{25}$$

where

$$\Delta QI(J) = QI(J) - QO(J-1). \tag{26}$$

Then

$$QO(J) = QO(J-1) + \Delta QO(J). \tag{27}$$

Equation (25) to (27) represent an extremely simple reservoir or lake routing procedure. To achieve this simplicity, the change in inflow, $\Delta QI(J)$, and the change in outflow, $\Delta QO(J)$, must each be changes from the outflow, $QO(J-1)$, in the previous time interval, as defined in a similar manner to Eqs. (15) and (16). The value of K is determined from the storage-discharge relationship, where K is the gradient, dS/dQ. This storage factor, K, which has dimensions of time, can be considered constant for a range of outflows.

When the storage–discharge relationship is non-linear, which is usual, it is necessary to sub-divide into linear segments. The pivotal values of storage, $S(P,N)$, and discharge, $QO(P,N)$, where N refers to the Nth pivot point, are tabulated. Calculations proceed as described until a pivotal value is approached, or is slightly passed. The next value of K is calculated, not from the two new pivotal values, but from the latest outflows $QO(J)$ and from the corresponding storage $S(J)$. The current value of storage is calculated from,

$$\begin{aligned} S(J) &= S(P,N-1) + \Sigma\Delta S \\ &= S(P,N-1) + (QO(J-1) \\ &\qquad - QO(P,N-1)) * K(N-1,N). \end{aligned} \tag{28a}$$

Then the next $K(N,N+1)$ value is calculated,

$$K(N,N+1) = \frac{S(P,N+1) - S(J)}{QO(P,N+1) - QO(J)}. \tag{28b}$$

This procedure maintains continuity for storage and discharge, and is easy to program because no iterations are required.

It will be noted that the routing procedure can be carried out without calculating the latest storage value: only inflows and outflows need be considered. The storage value at any time can be calculated from Eq. (19), which states that there is always a direct and unique relationship between storage, $S(J)$, and outflow, $QO(J)$.

In summary, the factor $1/(1 + K/\Delta t)$ in Eq. (25), represents the proportion of the inflow change, $\Delta QI(J)$ which becomes outflow. The remaining inflow change becomes storage. The process is identical for increasing or decreasing flows: when flows decrease, the changes in outflow and storage are both negative. Eqs. (25) and (27), the heart of the matter, are repeated for emphasis,

$$\Delta QO(J) = \frac{1}{1+K/\Delta t} * \Delta QI(J) \tag{25}$$

$$QO(J) = QO(J-1) + \Delta QO(J). \tag{27}$$

CHANNEL ROUTING

The assumptions of reservoir routing no longer hold for channel calculations. The channel system takes time to respond to an input. Also, storage is a function of conditions at each end of the length of channel being considered, rather than just the conditions at the outflow end.

The simplest channel routing procedure is the so-called Muskingum method developed on the Muskingum River (G.T. McCarthy,[24] Linsley[2]).

Channel routing is also based on continuity, Eq. (11). Before it can be utilized this equation must be rewritten in finite difference form

$$\frac{I_1 + I_2}{2} + \frac{O_1 + O_2}{2} = \frac{S_2 - S_1}{t}. \tag{29}$$

Also, some assumption must be made from which storage can be computed. The Muskingum method linearizes the problem and assumes that storage in a whole channel reach is completely expressible in terms of inflow and outflow from the reach, namely

$$S = K[xI + (1 - x)O]. \tag{30}$$

Substituting from (16) in (15), following Linsley,[2] the result obtained is,

$$O_2 = c_0 I_2 + c_1 I_1 + c_2 O_1 \tag{31}$$

where c_0, c_1 and c_2 are functions of K, x and t and $c_0 + c_1 + c_2 = 1$. The influence of x is illustrated in Figure 6. Extending this equation to N days:

$$\begin{aligned} O_N = {} & c_0 I_N + c_1 I_{N-1} + c_2 c_0 I_{N-1} + c_1 c_2 I_{N-2} \\ & + c_2^2 c_0 I_{N-2} + c_2^2 c_1 I_{N-3} + \Lambda \\ & + c^{N-2} c_1 I_1 + c_2^{N-1} O_1. \end{aligned} \tag{32}$$

Usually, because c_0, c_1 and c_2 are less than one, terms in c_3 and higher are ignored, but whatever the simplification, the result is of the form

$$\begin{aligned} O_N = {} & a_1 I_N + a_2 I_{N-1} + a_3 I_{N-2} + a_4 I_{N-3} \\ & + a_5 I_{N-4} \text{ etc.} \end{aligned} \tag{33}$$

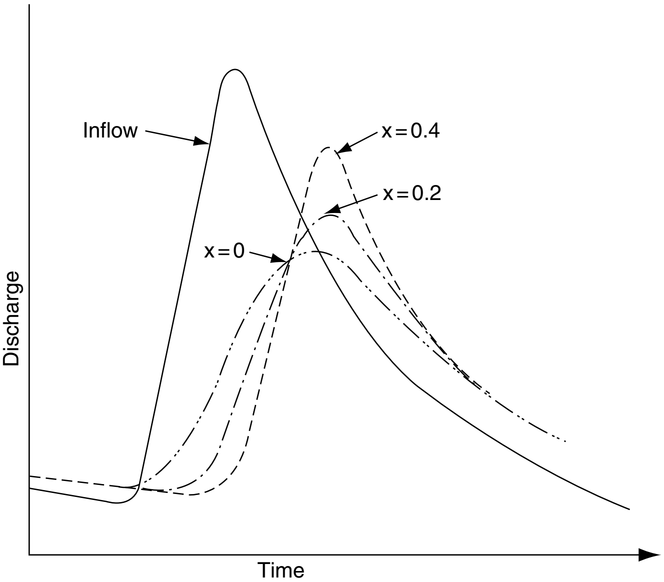

FIGURE 6 Muskingum routing: to illustrate the influence of x on outflow hydrograph (after Linsey[2]).

Once again the set of equations for O_1 to O_R can be written as

$$\{O\} = [I]\{a\}. \tag{34}$$

(N.B. The use of I for inflow is unfortunate and leads to confusion with the identity matrix. Also O is confusable with the null matrix.) It must be admitted that, from the theory, only a_1, a_2 and a_3 are independent, but in practice the precision with which a solution can be obtained for c_0, c_1 and c_2 does not justify calculating a_4, a_5 etc. from the first three. The best approach at this stage is once more to resort to least squares fitting, recasting Eq. (34) in the form of Eq. (8.)

Many hydrologists calculate the routing coefficients by evaluating K and x in the traditional graphical method.

Many assumptions are made in the Muskingum method, such as the linear relationship between storage and discharge, and the implied linear variation of water surface along the reach. In spite of these assumptions the method has proved its value.

Another difficulty which occurs with the Muskingum method usually occurs when the travel time in the reach and the time increments for the data are approximately equal, such as when the travel time is about one day and the data available is mean daily flows. From the strict mathematical viewpoint, the time Δt should be a fraction of the travel time K, otherwise flow gradients such as dO/dt are not well represented on a finite difference basis. However, it is still possible to use time increments Δt greater than K if the flow is only changing slowly, but caution is necessary. The reason for caution is that the C values in Eq. (31) are a function of $\Delta t/K$ and are not constant.

Solving for the C's in terms of K, x and Δt:

$$C_0 = -\frac{x + 0.5(\Delta t/K)}{1 - x + 0.5(\Delta t/K)} \tag{35a}$$

$$C_1 = \frac{x + 0.5(\Delta t/K)}{1 - x + 0.5(\Delta t/K)}. \tag{35b}$$

Hence,

$$C_2 = -\frac{1 - x - 0.5(\Delta t/K)}{1 - x + 0.5(\Delta t/K)} \tag{35c}$$

$$C_0 + C_1 + C_2 = 1. \tag{35d}$$

To illustrate the influence of Δt and K, some synthetic data as used to construct Figure 7. Values for K and x were chosen and when values of C_0, C_1, and C_2 were calculated for different values of Δt. In addition, an assumed inflow was routed using the K and x values and using a time interval Δt which was small compared with K. These resulting inflows and outflows were then reanalyzed for C_0, C_1, and C_2 using time increments five times greater than the original Δt. Such Δt values exceeded K. The new estimates of C_0, C_1, and C_2 are also plotted in Figure 7. Note the general agreement in shape of the C_0 and curves, etc. Exact agreement is lost because of the diminishing accuracy of the d*O*/d*t* terms, etc. as Δt increases. Note also how rapidly the *C* values change when Δt is approximately equal to *K*.

These remarks are not necessarily meant to dissuade hydrologists from using the Muskingum method. The intention is to illustrate some of the pitfalls so that it may be possible to evaluate the probable validity or constancy of the coefficients (Laurenson[22]). The worst situation appears to be when Δt ; *K,* because in real rivers *K* decreases with rising stage and the *C* values are very sensitive to whether Δt is just less than or greater than *K*.

A very real problem in the application of the Muskingum method, and in fact of any channel routing procedure, is the problem of lateral inflow to the channel reach. Given the inflows and outflows for the reach as functions of time, it is necessary to separate out the lateral flows before best fit values of *K* and *x* can be determined. The lateral flows will, in general, bear no relationship to the pattern of main streamflows. Sometimes it is possible to use flow measurements on a local tributary stream as an index of total lateral flow. The cumulative volume of lateral flow can be determined by subtracting summed inflows from summed outflows. The measured tributary flow can then be scaled up to equal the total lateral flow and these flows can then be subtracted from the reach outflows. This residual outflow can be used in the determination of the Muskingum coefficients.

Sometimes it is possible to find periods of record where lateral flows are small or perhaps have a more predictable pattern, such as during recession periods. Also, the routing coefficients can be refined by an iterative procedure and by using various sets of data, although not infrequently it is found necessary to define Muskingum coefficients for different ranges of flow, because real stream flow is not linear as is assumed in the model.

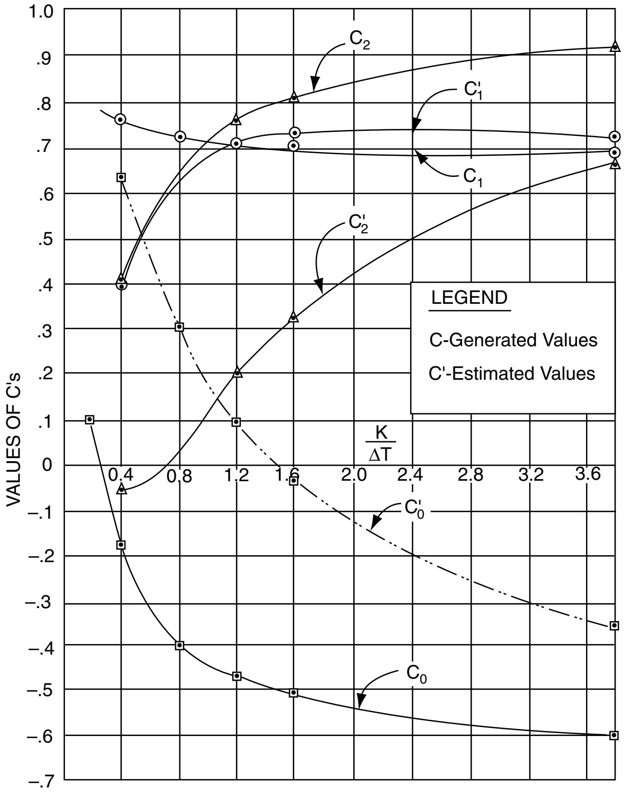

FIGURE 7 Muskinghum coefficients as a function of storage and routing period.

KINEMATIC WAVE THEORY

It has been known for many years that flood wave movement is much slower that would be expected from the shallow water wave theory result of $\sqrt{gy}$. Seddon[25] showed as early as 1900 that flood waves on the Mississippi moved at about 1.5 of river velocity. The theoretical reasons for this slowness of flood wave travel have only been realized during the last twenty years. The theory describing these waves is known either as monoclinic wave theory or kinematic wave theory.

Kinematic wave theory has suffered from neglect because of its usual presentation in the literature. The common approach is to start with the continuity equation and a simplified Manning equation. These equations are combined to yield Seddon's Law that flood waves travel at about 1.5 times the mean flow velocity. Such an approach restricts the method to an unalterable flood wave translating through the channel system. Although such a simple model has the benefit of approximating the real situation, much more useful and general results are available by setting up the two equations in finite difference form and carrying out simultaneous solution on a computer. In particular the method handles lateral inflow with great ease and also calculates discharge against time, eliminating the guess work from the time calculation.

Kinematic wave theory can be seen to be a simplification of the more general unsteady flow theory in open channels, for which the equation of motion and the continuity equation can be written (Henderson and Wooding[4,26])

$$S_0 - \frac{\partial y}{\partial x} - \frac{v}{g}\frac{\partial v}{\partial x} - \frac{1}{g}\frac{\partial v}{\partial t} = \frac{v^2}{c^2 R} \tag{36}$$

Bed-Slope Depth Slope Convective Acceln. Local Acceln. Friction term

$$\frac{\partial Q}{\partial x} + B\frac{\partial y}{\partial t} = \delta i\left(\text{lateral inflow}\right). \tag{37}$$

In different situations various terms in equation (36) become negligible. In tidal flow the friction and bed-slope terms are sometimes omitted, although this simplification is not strictly necessary. In this way the positive and negative characteristics are obtained with propagation velocities of $u \pm \sqrt{gy} = dx/dt$. At the other end of the spectrum is kinematic wave theory in which the bedslope term is assumed to overpower the other three terms on the left hand side, namely, depth slope, convective and local acceleration. Hence kinematic wave are friction controlled. Equation (36) is therefore reduced to

$$S_0 = \frac{v^2}{c^2 R}. \tag{38}$$

To combine Eqs. (36) and (38) into the simplest characteristic form, it is assumed that *R,* the hydraulic radius, may be replaced by *y.* Then Eq. (38) yields

$$Q = vBy = B.Cy^{3/2} S_0^{1/2}. \tag{39}$$

Substituting for in (37) by differentiating Eq. (39)

$$\frac{3}{2} BCS_0^{1/2} y^{1/2} \frac{\partial y}{\partial t} + B\frac{\partial y}{\partial t} = \varepsilon \tag{40}$$

The left hand side is the total differential d*y*/d*t* if the term

$$\frac{3}{2} CS_0^{1/2} y^{1/2} = \frac{\mathrm{d}x}{\mathrm{d}t} = \text{wave velocity.} \tag{41}$$

The important fact that monoclinical waves can only propagate down-stream with a wave velocity given, in the simple case, by Eq. (41), is well known, as is best discussed by Lighthill and Witham.[27] As previously mentioned, as an empirical result, Eq. (41) dates back to Seddon[25] and his study of flood wave movement.

Comparing kinematic wave theory with channel routing, Eq. (37) can be recast in exactly the same form as Eqs. (29) and (30) if the lateral in flow term is ignored. The difference in the two methods depends on the second equation chosen, which is basically a stage–discharge relationship. Channel routing, as illustrated by the Muskingum method, assumes a linear relationship between stage and discharge to arrive at Eq. (30) for storage. Kinematic theory uses a simplified equation of motion which is usually either the Chezy or Manning equation.

In a further development of kinematic theory researchers such as Hyami[29] have shown that the influence of channel storage can be included and this results in an extra term which is effectively a diffusion term:

$$\frac{\partial y}{\partial t} + c\frac{\partial y}{\partial x} = K\frac{\partial^2 y}{\partial t^2} \tag{42}$$

Solutions of this equation are approximately of the form:

$$y = y_0 e^{-ax} \cos(bt - ax) \tag{43}$$

This solution assumes a sinusoidal wave profile, and the solution is seen to be delayed as it moves downstream and also it decays in amplitude. It is seen that effectively an exponential damping term is introduced by the inclusion of diffusion.

Such relationships are complex and cumbersome, demanding detailed data on the channels which often is not available. Inspection of the resulting equations reveals a similarity to the old lag and route method. The author has used a simplified method based on these equations which has proved itself to be very successful.[46] The method uses a variable travel time calculated from the velocity-stage curves for the upstream end of the given channel reach. The kinematic result of approximately 1.5 times channel velocity is used, although a best fit result can be found by optimization. The flow is then routed through a simple linear reservoir, the size of which is related to the channel storage. This reservoir allows a check to be kept on continuity and also it provides an exponential decay term as demanded by the diffusion term in the full kinematic theory. For relatively steep rivers like the Fraser River in British Columbia, one linear reservoir is adequate. Less steep streams may require two reservoirs, but two reservoirs should be adequate in that a two-parameter exponential will fit almost any curve imaginable.

The simple channel routing procedure has been found to be very powerful because it approximates the true physical behavior very closely. It yields a simple non-linear behavior and models the well documented flood wave subsidence. On the Fraser River system the method proved very successful in separating out the very large lateral flows which are characteristic of that particular river system, and this separation was really the key to the modeling of the whole system behavior.

ARTIFICIAL GENERATION OF STREAMFLOW

If streamflows can be considered to be statistically distributed, then it may be possible to establish statistical measures of their distribution. Such statistical measures will be the mean flow, the variance and perhaps some correlation between successive flows. It may also be possible to determine the nature of the distribution, such as normal, or log normal. If such parameters can be found, then these parameters can be used to regenerate data with the same statistical patterns.

The reason for such data regeneration is not apparent until we examine the purposes for which such data can be used. If we are given some 30 years of streamflow data, it is possible to make reasonable estimates of the statistical parameters of, say, monthly or annual flows. The 30 years of record will contain only a very few extreme events, such as floods or prolonged droughts, and will therefore not impose very severe tests on any water resource system which is storage dependent, such as a hydro system or an irrigation project. Generated data could presumably be constructed for very long periods of time and would, if the procedure is justified, reproduce many more extreme flows and consecutive run-off patterns which will test the proposed resource system more thoroughly. The statistical risk of failure can then be evaluated.

This is the aim of streamflow generation studies. Whether the methods currently in use are adequate or valid is still under debate. The aims are sound and the methods promising, if used with caution and an awareness of the intrinsic assumptions.

It is worthwhile comparing the artificial generation methods with the approaches previously used. It has been customary to construct a test period or sequence from the recorded data. As an example, it was not unusual to use the three driest years of record and assume that they occur in successive years. This became the design drought. Without care to evaluate just how extreme an event this might be, such a method might lead to either over or under design. Hopefully, streamflow generation will lead to more balanced designs, especially as experience with the techniques and the techniques themselves improve.

To consider the generation techniques, it is first of all important to appreciate that streamflow forms a time series which can be highly dependent or almost entirely independent according to the time interval chosen. Daily flows are usually highly correlated with each other; monthly flows may still have a reasonable serial correlation, but annual flows may be almost totally independent. Certainly it is usual to assume that annual flood peaks are independent.

The simplest streamflow model assumes that there is no long term trend in the run-off pattern, so that the mean flow for the period of record is a reasonably good estimate of the long term mean. Also it is assumed that the standard deviation from the mean is a good measure of the dispersion of flows around the mean. The model expresses:

Generated flow = Mean flow + Random Component i.e.,

$$Q_i = \bar{Q}_j + t_i \sigma_j \tag{44}$$

i refers to synthetic sequence, *j* to historic sequence.

Q_i = synthetic streamflow for month *i*
= is mean flow for same month
t_i is random normal deviate with mean zero and variance unity (Available in most computer libraries)
σ_j is standard deviation of flows for month *j.*

The random component is seen to be made up of the calculated standard deviation multiplied by a random variable t_i which is generated by a random number generation, and has a statistical distribution which is the same as the normal random error. The variable t_i therefore redistributes σ_j in a random Gaussian fashion.

A more sophisticated model by Thomas and Fiering[42,43] includes the memory that this month's flow has of last month's flow. This memory is described by serial correlation:

Generated Flow = Mean Flow + Serial Component + Random Component
i.e.,

$$Q_{i+1} = \bar{Q}_{j+1} + b_j\left(Q_i - \bar{Q}^j\right) + t_i \sigma_{j+1}\left(1 - r_j^2\right)^{1/2} \tag{45}$$

The additional symbols are

b_j is regression coefficient for serial correlation of *j* and *j* + 1 month
r_j is correlation coefficient between *j* and *j* + 1 month.

It will be noticed that when a serial component is introduced, the random component must be correspondingly decreased by the factor $(1-r_j^2)^{1/2}$ so that there is not a net increase in flow.

Many other synthetic streamflow methods have been tried or suggested but at the present time only the simple models [Eq. (44) and (45)]. Thomas and Fiering's model[43] seem to be in use by practising hydrologists. Also, the reader should appreciate, that the methods are not without their problems, for generated flows may go negative, so that modeling of droughts is questionable. However, a study of the statistical frequency of failure may still be better than the old methods.

So far, generation techniques have been discussed only for a single streamflow record. If a whole river basin with several reservoirs on different tributaries and on the main stream is being studied, then a much more difficult problem arises. It is not difficult to generate artificial data for each tributary or for the main stream. But such data will have none of the cross-correlation which exists in real data. That is to say, with the real data, if flows are high in one tributary, then probably the other tributaries are also reasonably high. This cross-correlation is difficult to preserve in generating techniques. It is discussed at great length by Fiering but the method suggested for preserving cross-correlations is very demanding on computer storage and time.

The writer wonders whether use of a physically based computer model of a river basin, coupled to a random generation of precipitation events both for one area of storm and intensity of storm might not produce data more economically and with the correct statistical interdependence.

HYDROLOGICAL SIMULATION

Simulation is a very broad term covering many types of mathematical and physical procedures. The streamflow generation techniques already discussed are one type of simulation. Analogue computer models and physical flow models are also simulations. Digital computer models for simulation may be based on statistics entirely or on the physical behavior of various components of the system. Some models may be a mixture of both physical and statistical methods.

Although the types of simulation models vary widely, their aims are similar, namely to describe the behavior of a complex system so that predictions of system behavior can be made from some specified input. These predictions may be short-term flood-flow predictions to give flood warning, especially for operation of flood protection schemes. Alternatively, predictions may be needed to evaluate water resource schemes and to examine the influence of storage, diversion, consumptive use, etc. on the system of operation.

STATISTICAL TECHNIQUES

Many simulations, particularly run-off forecasts, have been based on multiple regression analysis. Flow has been treated as the dependent variable and many factors such as precipitation, antecedent precipitation, sunshine hours, etc. have been used as the independent variables.[13] Such methods have had at least moderate success. The difficulties with the method have been that many of the so-called independent variables are in reality somewhat related, for example, rainfall is inversely correlated with sunshine hours. Also, the lack of true functional relationship usually means that coefficients for one year's data vary for other years or for periods of higher or lower flow, and therefore forecast precision in inherently limited and evaluation of changes to the system, such as introduction of reservoirs is not feasible.

The deficiencies of multiple regression analysis have been somewhat overcome, according to some investigators, by the use of multivariate analysis. The principle component techniques select the most significant relationship even if the data is interrelated. However, this type of analysis is still blind to the physics of the system. Examples of this technique and the theory are given in Kendall, Snyder and Wallis[10,14,15] and the reader can consult these for more details.

Monte Carlo methods, of which the stream generation is a simple example, have been proposed and used. Such methods have had staggering success in some fields of physics, such as nuclear studies. The classic example was the original study of critical mass for the atomic bomb. Such success led people to hope for more general applications. But even the keenest exponents of such methods agree that they are no substitute for an understanding of the physical behavior of the system. The writer considers that such statistical techniques are a reasonable approach if there is no physically based alternative. Experience with constructing physically based simulation models shows immediately how valuable it is to incorporate a functional relationship which bears some resemblance to the physical system. An example of this statement is the unit hydrograph approach which can be considered as a simple simulation model. The actual physical behavior of a catchment seems to be well described by a unit hydrograph. As soon as such a unit hydrograph is introduced, it becomes a relatively simple matter to relate cause and effect, which in that case is precipitation and run-off. A similar result can be achieved if the correct data is used in a multiple regression analysis, but such data selection presupposes a knowledge of the system behavior.

PHYSICAL COMPUTER SIMULATION MODELS

Qualitatively, we can describe the behavior of a hydrologic system. The catchment soil layers have storage which decreases and delays run-off and permits evapo-transpiration to occur. The lake and channel system further delays flows and modifies the shape of the outflow hydrograph. Groundwater supplies a highly damped outflow which is significant during dry spells. Quantitatively we may know the precipitation input and the run-off output, although there may be data error, especially in the precipitation. There may also be data from which estimates of potential evapo-transpiration can be made. Presumably data will also be available of such matters as lake areas, stage-discharge relationships, catchment areas, and elevations, and the details of the streamflow network.

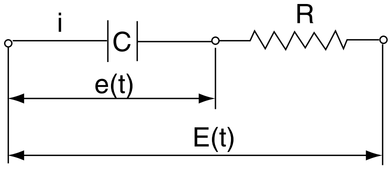
It is important to realize what can be discovered about a system simply from studying the input to the system and the output from the system, as has been very well demonstrated by Nash.[23] He considers a simple electrical system made up of a capacitor and a resistance as shown in Figure 8. Then if $E(t)$ is considered to be the input and $e(t)$ the output it can be shown that

$$e(t) = \frac{1}{1+RCD} E(t) \tag{46}$$

where D is the differential operator. Hence we can solve for $e(t)$ if $E(t)$ is given. Alternatively if $e(t)$ and $E(t)$ are given we can solve for RC as a lumped term, but we can never find the separate values for R and C. Therefore when we construct a simulation model, we may be able to correctly model the output from the input, although the parameters used in the model may be lumped terms describing various factors in the real system.

Hydrological systems are considerably more complex than the above example and it is important to realize that we cannot start to "fit" the model to the data until we have simulated the total system behavior. Also, in general, the system will not be linear like the simple electrical network, so that response becomes a function of flow.

In constructing a simulation model we must first of all decide the factors or processes which should be included to correctly and adequately describe the system. Each factor must then be approximately fitted using any data or knowledge which we may have. It is a basic rule that these factors, such as evaporation, unit hydrograph, soil moisture storage, etc. should be modeled with as few parameters as possible, as long as adequate description of a process is not jeopardized. This minimization of parameters has been well named



$$E(t) = e(t) + Ri(t)$$

$$i(t) = C\frac{de}{dt}$$

$$\therefore e(t) = \frac{1}{1+CRD} E(t)$$

FIGURE 8 Simple system demonstrating non-separability of *R* and *C* (after Nash).

as the "principle of parsimony." The final optimization of the model parameters is done when the whole model is complete. One parameter at a time is adjusted in a step by step process until best fit values are obtained.

To illustrate the process we shall consider a simple model, Quick and Pipes.[47]

WATERSHED MODELING IN MOUNTAIN CATCHMENTS

The rain and snowmelt run-off processes in rugged mountain catchments appear, at first sight, to be highly complex. Rain, snow, temperature, and soil and rock composition of the watershed all are highly variable at different elevation levels in the watershed.

In reality this apparent complexity is simplified by the orographic influences. The strong orographic gradients of behavior impose a useful discipline on the various processes. In particular, there tends to be a greater areal uniformity of precipitation and temperature within each elevation zone. This uniformity of behavior by elevation zone, if proved to be real, offers a great simplification of the most difficult of hydrologic behavior, namely the variation of rain and snow and temperature over an area.

The UBC Watershed model was designed to take advantage of the strong orographic discipline which exists in a mountain watershed. The primary purpose in designing the model was to provide a tool for forecasting flood run-off, but in reality, its most useful purpose has become the day to day forecasting of run-off for hydropower production. The model can also be used as a research tool to investigate the total system behavior of a mountain catchment. Such research investigations are highly dependent on the accuracy and distribution of the meteorological and hydrological data base.

Design of the UBC Watershed Model

There are five main subdivisions of the total model namely meteorological data processing, snowmelt calculation, soil moisture budget, routing of flow components to channel outflow point, and statistical evaluation of model performance. These subdivisions will be discussed briefly. A complete description of model design and use is given in Quick and Pipes.[49]

Meteorological data processing Meteorological data is available only at discrete points. In many situations, only one data station may exist and that station may be in the valley and perhaps not even in the watershed itself. Even when more than one data station exists, there is still the technical problem of distributing the point data to all elevations and regions of the watershed.

It is assumed that the orographic influences are the strongest and that these orographic effects are modified by the moisture content of the air mass. Usually there is no direct information on vapor pressure values, and therefore indirect indications of moisture status are used. For example, temperature range during the day is used as an indicator of relative humidity. A low daily temperature range is associated with humid conditions when the temperature lapse rate will be approximately equal to the saturated adiabatic rate. A high daily temperature range is assumed to indicate that maximum temperature will vary at the dry adiabatic rate, but minimum temperature will tend to show a very low lapse rate. A simple functional relationship is therefore defined between temperature lapse rate and the daily temperature range.

Orographic precipitation gradients are made functionally dependent on the rates of saturated dry adiabatic lapse rates corresponding to the observed temperatures. The larger the difference between saturated, L_S, and dry, L_D, lapse rates, the greater is the convective instability of the air mass, so that convective instability is measured by

$$\frac{L_D - L_S}{L_D}. \tag{47}$$

If the air mass is already very unstable, then the orographic effects will be moderate. The orographic opportunity is therefore expressed as

$$\text{orographic opportunity} = 1 - \frac{L_D - L_S}{L_D} \equiv \frac{L_S}{L_D}. \tag{48}$$

When this ratio approaches 1, the orographic effect on precipitation is high, whereas when the ratio decreases, the orographic effect is weaker. It will therefore be appreciated that orographic effects will be large during the winter, when temperatures are low, and L_S is more nearly equal to L_D. On the other hand, in the warm summer weather, because L_S is then much lower than L_D, the orographic effects will be much weaker.

This simple functional variation of precipitation gradients has proved to be a very valuable tool in distributing meteorological data and has resulted in considerable improvement in forecast accuracy.

Snowmelt calculation The strong elevation dependence of snowmelt supports the use of temperature indices for the calculation of snowmelt. The simple degree day method probably accounts for 80% of the snowmelt process, but there are periods of extreme melt when radiation and condensation melt become important additional factors. The snowmelt algorithms used in the UBC Watershed model have been discussed in a previous paper, but, in summary, additional temperature terms are added to account for radiation and condensation, Quick and Pipes.[46] Radiation is represented by the daily temperature range and condensation is handled by using the minimum temperature as an approximation for the dew point temperature. Under warm summer conditions this dew point assumption is usually good and this is the only time when the extra terms are significant. The snowmelt equation, for forested areas, when slightly simplified, is

$$BM = \left\{ TM + \left(\frac{TX - TN}{k_1} + TN \right) * \frac{TN}{k_2} \right\} * PTM \tag{49}$$

where

BM = Daily melt in an elevation band
TM = Mean daily temperature
TX = Maximum daily temperature
TN = Minimum daily temperature
PTM = Point melt factor (Assumed value 2.1 mm/°C/Day)

k_1, k_2 are constants (assumed value, $k_1 = 8$, $k_2 = 10°C$).

A modified formulation is used for open areas, where additional weighting is given to the maximum temperature and this equation is also used for glaciated regions

$$BM = \left(TX + \frac{TN}{k_2} * TN \right) * PTM \tag{50}$$

A negative melt budget is maintained during ripening periods and following cold periods.

The soil moisture budget When designing a watershed model, there is considerable computational advantage if all the non-linear watershed behavior can be concentrated in one section of the model. This advantage is even greater if the non-linearities are handled completely in each time step, rather than being distributed over the many time steps of the routing procedure.

In the UBC watershed model, non-linearities have been confined to the soil moisture budget section of the model. The soil moisture budget section subdivides the total rain and snowmelt inputs into fast, medium, slow and very slow components of run-off. This subdivision of the total run-off depends on the present status of each section of the soil moisture and groundwater components, and so the subdivision process is non-linear. The degree of non-linearity is in the hands of the model designer and his concept of the various hydrologic processes. For example, in the UBC model, the non-linearities are greatest at the soil surface, where the subdivision between fast and medium run-off is determined by soil moisture deficit conditions. In contrast, the deep groundwater zone has no non-linear behavior within itself; it simply accepts what finally arrives. This gradation of non-linear behavior, which is maximum at the surface and decreases with depth, is probably realistic in mountain conditions, but might require redesign for some soil conditions in flat terrain.

Once the flow has been subdivided into components of run-off, each component can be routed separately to the watershed outflow point. Some models might assume that water can be exchanged between the various run-off components as the water migrates towards the stream system. Although it is probably quite realistic to make such an assumption, it also introduces considerable complexity and extra data handling. More complex versions of Sugawara's[51] tank model could be designed to operate in this fashion.

The routing process itself can also be linear or non-linear. If a linear routing procedure is used, then each flow increment can be routed independently of any other flow, and the routing procedure is computationally simple. Non-linear routing, on the other hand, can become quite complex.

The simplicity of linear routing procedures is attractive to the model designer, but such simplicity is only of value if it is also a realistic representation of actual run-off processes. In the following section, some brief consideration will be given to the physical nature of the various run-off processes and to their mathematical representation.

Two major types of routing procedure are widely referred to in the literature: unit hydrograph routing, Nash[17] and kinematic routing, Hayami.[29] More complex procedures, usually referred to as hydraulic routing, are not usually used within watershed models, but are occasionally used in some more detailed channel routing procedures. The unit hydrograph is defined as a linear process Sherman,[16] yet, some workers make changes to hydrograph shape for extreme rainfall events. This non-linearing of the unit hydrograph can be avoided by recognising that total watershed response is made up of several different unit hydrograph responses, as shown schematically in the figure. Soil moisture budgeting switches varying amounts of water to the various run-off components, so that the composite hydrograph can be more peaked or less peaked according to the severity of the storm. Kinematic routing can be linear or non-linear according to the assumed functional form between incoming volume and flow rate. In channels, this relationship is usually expressed as a velocity-depth or a discharge-area relationship.

THE UNIT HYDROGRAPH

For the unit hydrograph to be truly linear, then, as Nash[23] has pointed out, storage and outflow must be linearly related. A cascade of storages will then yield various possible hydrograph shapes. This simple model assumes a uniform instantaneous input of run-off volume over an δA in time δt. A real watershed receives a non-uniform input of run-off volume over an area, A, in a finite time period, t. Strictly speaking, a watershed should be subdivided into regions where uniform input is a reasonable approximation. With such a subdivision, the final outflow hydrograph would become not only a function of watershed shape and varying response characteristics of sub-areas, but also of rain and snowmelt distribution across the watershed. For example, there should be a recognizable difference between rainfall response and snowmelt response. Snowmelt, which is highly temperature dependent, is greatest at low elevations and least at the top of the watershed. Rain, on the other hand, undergoes orographic enhancement, so that it is greatest at the highest parts of the watershed and least in the valley portions. This orographic effect is always present to some extent, but, as a general rule, the warmer the air mass, the less is the orographic enhancement. In addition to this complete reversal of elevation dependent distribution of run-off, there is also a considerable contrast in the intensities of water input from rain and snow events. Snowmelt, even under quite extreme snowmelt conditions, rarely exceeds 80 mm of water equivalent per day, and some 75% of this melt occurs during the daylight period. Rainfall daily volumes can be considerably greater and can occur over much shorter time periods. These contrasting areal distribution and time distribution effects are partly self-compensating. Snowmelt is greatest at low elevations which tends to make hydrograph response more peaked, but the lower intensity of snowmelt tends to produce a flatter response. Rain, on the other hand, is of greater intensity, producing a higher peak outflow, but is greatest in the more remote regions of the watershed, which has a tendency to reduce the peak flow. There seems to be little or no conclusive data to test this contrast between rain and snow response. This lack of conclusive data may be that the difference between rain and snow events are small, or because the data base is not sufficiently detailed and accurate to demonstrate any difference.

Returning to the question of the watershed routing, some simple theoretical models will be examined to explore the representativeness of linear routing models.

The linear routing process is usually assumed to represent a relationship between the outflow, *QO,* and storage *S,* of a linear reservoir, with a storage constant *K,*

$$S = K(QO). \tag{51}$$

Cascades of such linear reservoirs are used to produce a range of unit hydrograph responses to inputs of rain or snowmelt. A linear Weir is not a structure which can easily be imagined as part of a watershed system, because it is much more realistic to imagine flow through various interstices and flow paths in the soil layers and to assume such flow to be friction controlled. Such a conceptualisation leads to examination of the groundwater flow equations, for example, the Darcy equation,

$$Q = KA\frac{\mathrm{d}y}{\mathrm{d}x}. \tag{52}$$

The area of flow, *A,* can be represented by a width, *B,* and a saturated depth of flow, *y.* Assuming *B* to be constant, then *y* is a linear measure of storage. The equation can be linearized if it is assumed that d*y*/d*x* is constant for all flows, an assumption which might be reasonable for steep mountain catchments where the ground slope dominates the flow process. Eq. (6) might therefore be reduced to the linear flow-storage equation, like Eq. (5).

A single storage-flow relationship produces an instantaneous unit hydrograph response which is a simple exponential decay, as given by the Nash single reservoir result. Even such a simple model, when convoluted with the time distributed input of effective rainfall, will produce a typical time distribution of outflow, modeling the rising and falling limbs of a unit hydrograph. It is not even strictly necessary to resort to a cascading of linear storages, although, from a modeling viewpoint, a cascade of storages offers a flexible method of controlling hydrograph shape.

Other frictionless and friction-controlled equations can also be shown to imply relationships between storage and flow, but many of the relationships are non-linear, for example, a Weir formula and the Manning equation,

Weir: $$Q = KBH^n \tag{53}$$

Manning: $$Q = \frac{A}{n}R_h^{2/3}S_0^{1/2}. \tag{54}$$

In these equations *H* and R_h can be considered as expressions of storage.

A more interesting relationship can be derived from consideration of kinematic wave behavior. Following Lighthill and Whitham's work and later work by Henderson and Wooding, many authors have proposed that kinematic wave behavior is very representative of hydrologic run-off processes, Lighthill and Whitham,[27] Quick and Pipes,[48] either from watersheds or in channels. The starting point of the kinematic approach is the continuity equation

$$\frac{\partial Q}{\partial x} + B\frac{\partial y}{\partial t} = 0. \tag{55}$$

Re-writing and comparing with the total differential of *y,*

$$\frac{\partial Q}{\partial y}\frac{\partial y}{\partial x} + B\frac{\partial y}{\partial t} = 0 \tag{56}$$

and

$$\frac{\mathrm{d}y}{\mathrm{d}t} = \frac{\mathrm{d}x}{\mathrm{d}t}\frac{\partial y}{\partial x} + \frac{\partial y}{\partial t} = 0. \tag{57}$$

These equations are equivalent if,

$$\frac{1}{B}\frac{\partial Q}{\partial y} = \frac{\mathrm{d}x}{\mathrm{d}t} = C. \tag{58}$$

So far these results only have the restriction that *Q* should be a function of *y* only. Consider the special case when *Q* is a linear function *y,* as previously argued for the Darcy groundwater equation,
i.e.,

$$Q = ky. \tag{59}$$

Then, solving for *C,*

$$C = \frac{1}{B}\frac{\mathrm{d}Q}{\mathrm{d}y} = \frac{k}{B} = \text{constant}. \tag{60}$$

The wave travel time, *T,* for a catchment dimension or channel length, *L,* is

$$T = \frac{L}{C} = \frac{LB}{k} = \text{constant}. \tag{61}$$

Therefore we have a system in which any and all discharges, *Q,* travel through the catchment or channel in exactly the same travel time. The outflow response for any level of flow is therefore only dependent on *y,* which is a measure of storage in the system. Following Henderson and Wooding's analysis of rainfall run-off,[26] the resulting run-off unit hydrograph would have a constant shape, which for the simplified situation is a simple triangle. Convolution of this triangular hydrograph with the effective rainfall will again yield a typical outflow hydrograph. Very accurate data would be needed to distinguish between this final outflow hydrograph and the result from the linear reservoir discussed earlier.

It therefore appears that the use of linear routing is not too unreasonable. Further justification will depend on the results of watershed modeling which are discussed in the next section.

MODEL CALIBRATION AND ASSESSMENT OF PERFORMANCE

Some examples of model calibration will be given for a region in the Upper Columbia River basin (Figure 9). The watersheds, such as the Jordan River and Spillimacheen, selected for calibration purposes are deliberately of moderate size, some 200 to 500 km^2. Too small a watershed responds too quickly and requires a data base time increment of a few hours, whereas the size suggested above can be modeled using daily data. The calibration for these smaller watersheds forms an excellent basis for modeling the larger watershed regions of several thousand square kilometers used in forecasting mainstream flows.

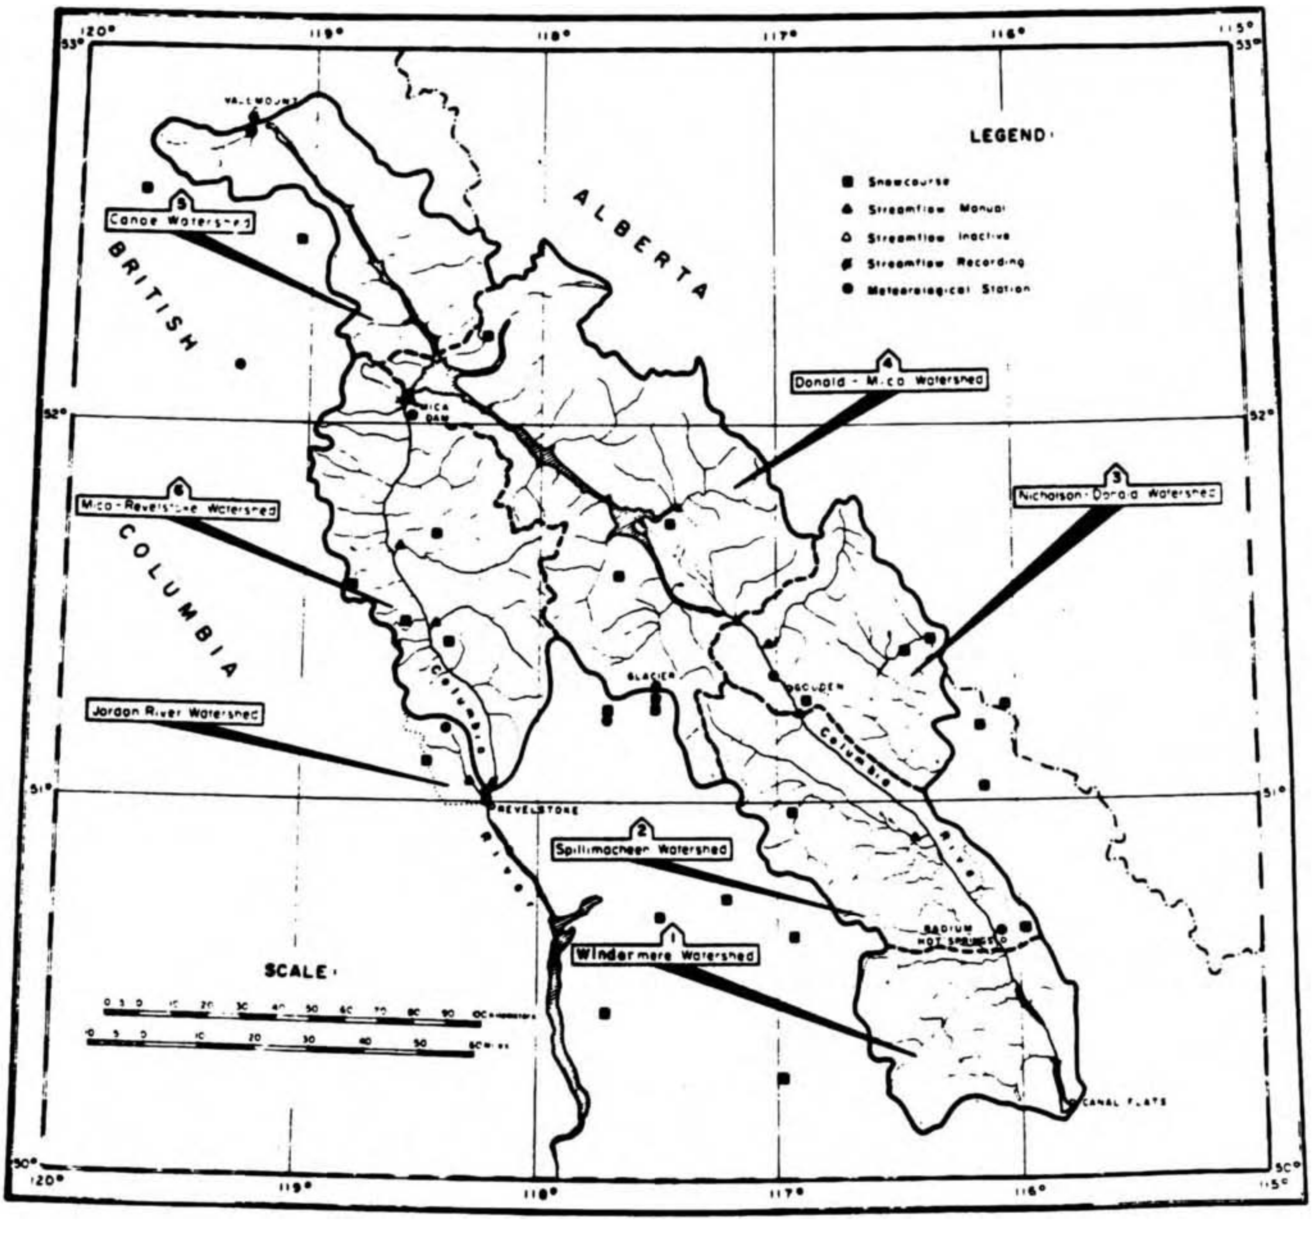


FIGURE 9 Map of Upper Columbia basin (indicate Spill & Jordan)—Remove Goldstream.

One of the first steps in calibrating a watershed is to study the orographic precipitation gradients. The model algorithm describing the variation of precipitation with elevation and temperature is calibrated by comparing calculated snowpacks at various time intervals with the snowcourse measurements, as shown in Figure 10. The complete comparison during accumulation and depletion of snowpacks requires estimation of precipitation by elevation, the form of precipitation, rain or snow, and the snowmelt occurring at various times. The temperature lapse rate is therefore an important ingredient in this part of the analysis, influencing both melt rates and orographic gradients.

Reconstitution of outflow hydrographs is the next stage of model calibration and two examples which have been presented in detail previously, Quick and Pipes[48,50] will be briefly outlined. The Jordan River example, Figure 11, illustrates the considerable improvement which is achieved by using temperature based snowmelt equations which account for additional radiation melt and condensation melt components. For comparison, the melt calculated from only the mean air temperature is plotted. In periods of extreme snowmelt, the melt rate can be approximately double the rate that might be estimated from mean temperature alone. For the example given, plots of temperature and precipitation at a base station are presented for comparison with the outflow hydrograph.

In another example illustrated in Figure 12 for the Spillimacheen River, an earlier paper, Quick and Pipes (1977) discussed and compared the accuracy attainable using different

single data station and combinations of data stations. None of the data stations were in the watershed. One valley data station exhibited far less precipitation than the mountain stations, varying in frequency, duration, and amount. The study showed that the nearest station, which was also near the mid-elevation of the basin and in a similar climatic zone, gave the best results, superior even to a combination of stations. Such a mid-elevation station reduced data extrapolation errors and is more representative of amount, duration, and frequency of precipitation and of the actual basin temperature regime. For the data tested, the errors of maximum peak flow, monthly volumes and hydrograph shape, measured by residual variance, were all less than 5%.

In summary, simulation techniques should be kept as simple as possible, provided that representation of reality is not jeopardized. As much precalibration as possible for each element of the model should be done during the model construction, using good common sense. The value of graphical fitting should be utilized because, by use of graphical representation, the mind is able to handle large quantities of data simultaneously. Final fitting of the model is done when the main simulation blocks have been assembled, and at this point it is useful to have a simple quantitative measure of the goodness of fit. Several measures have been proposed, but Nash's[23] is as good as any. This measure is calculated by subtracting the recorded output from the simulated output for each time increment. These differences are squared and summed to give a *residual variance.* The optimization can then proceed to minimize this residual variance.

REPRESENTATIVE DESIGN APPLICATIONS

Minor Design Problems

Such structures as small dam spillways, road culverts, small bridges, etc. require estimation of a design flood. The approach by which such a design flood can be estimated is shown diagrammatically in the flow diagram Figure 13.

First it must be decided whether rain floods or snowmelt floods are likely to be limiting and it may be necessary to calculate each before a conclusion can be reached.

Secondly, the response time of the catchment must be considered and this is typically characterized by the unit hydrograph, especially the time from the start of run-off to the peak.

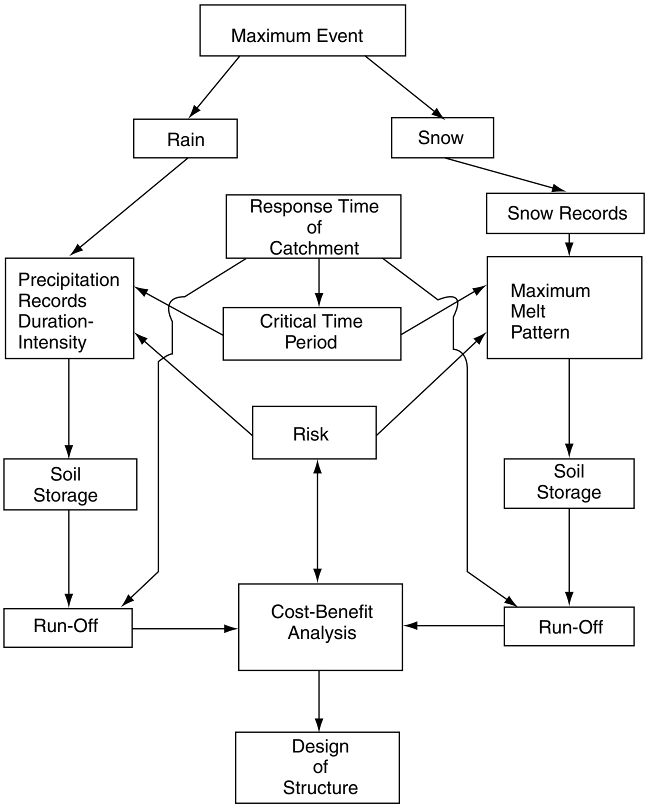

FIGURE 13 Estimation of design flood for a small spillway or road culvert, etc.

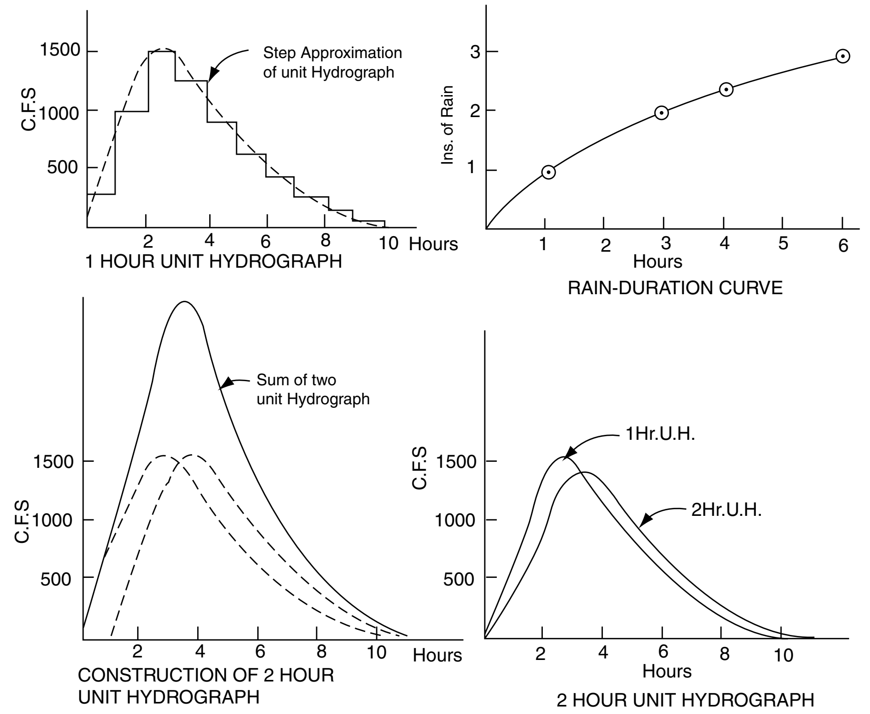
Thirdly, the precipitation records for rain events must be examined. In many instances data for the catchment may not exist, but representative data from adjacent areas may be available. Such data must be analyzed to yield duration-intensity plots for given return periods, or probabilities and for the catchment area in question.

The unit hydrograph data and the precipitation data must now be combined to determine the critical period of run-off. As an example, starting with the 1 hour unit hydrograph, it is easy to superimpose several 1 hour unit hydrographs to obtain 2 hour, 3 hour, 4 hour, etc. unit hydrographs. These longer duration unit hydrographs have relatively lower peaks as is illustrated in Figure 14. However, the greater volume of rain in longer duration storms may give a higher resultant peak and such a situation is illustrated in the figure.

A similar calculation for snowmelt would yield a maximum flow for run-off. Note that, for small catchments, the diurnal temperature variations impose limitations on the maximum snowmelt run-off because the high temperatures only last for a limited number of hours each day.[30,31,32]

Once the peak flow has been determined for a given rain or snow event probability, a first design of the structure should be made. The costs can be estimated and also damages resulting from higher floods can be at least approximated. At this point the cost of added protection can be considered and the assumed risk can be reevaluated.



PEAK RUN-OFF	RAIN	U.H.PEAK	RUN-OFF-RAIN x U.H.PEAK
1 Hour Storm	1.0 inch	1540	1540 C.F.S
2	1.7	1290	2190
3	2.0	1290	2580
4	2.5	1125	$\boxed{2810}$ Max.
5	2.75	990	2720

Critical Duration is 4 Hour Storm of 2.5 ins. of Rain, which produces maximum Run–off of 2810 C.F.S.

FIGURE 14 Determination of critical storm duration for a given catchment.

Experience of similar structures is very useful at this stage, especially in evaluating such added constraints as possible log jams or the influence of siltation or erosion (Bureau of Reclamation[54]).

Major Spillway Design Floods

Large dams are a particularly challenging design problem from many viewpoints. In particular, the consequences of failure due to inadequate spillway design have given rise to numerous extensive hydrological studies and the development of suitable techniques. For such a major structure it is usual to calculate design floods by several methods, as discussed in such references as Kuiper and Linsley.[52,53]

The first method is based on extreme probability theory as previously discussed in the statistics section. The analysis of extreme independent time series is based on the work of Fisher and Tipper[11] and is well illustrated by Gumbel.[12] The big question is what level of risk to assume, and probabilities of 1:1000 to 1:10,000 are not uncommon for such projects. The economic arguments reveal that the spillway cost is often small compared with the havoc that could occur if the dam failed. Hence it is quite usual for spillways to be designed for much more rare events than the design flood used for the rest of the system. Clearly the determination of the spillway design flood involves the incorporation of a large safety factor, but it is still necessary to make as good an estimate as possible of the true probability of such an event.

The second method for estimation of design floods is the *maximum probable flood*[1] approach. The physical processes involved in producing a flood are studied. In some areas, such as the North-Western part of North America, snowmelt is the principal factor for large rivers. Elsewhere rain floods may be limiting. Probable maximum precipitation can be estimated by storm maximization,[55] or by statistical methods. A simple approach was developed by Hershfield[56] and has been called the poor man's probable maximum precipitation, the PMPMP. It is necessary to study the weather patterns which produce either high snowmelt or high rainfall intensities. Storm patterns, durations, and movements can be studied. The storm movement can be crucial for a large river for it is not unknown for storms to move downstream at a rate similar to the flood wave movement, so that considerable reinforcement of the flood can take place. On northern rivers like the Mackenzie, which flows to the north, snowmelt and ice breakup occur from south to north, resulting in build up of ice jams and floods. There is also the question of combination of rare events such as rain on snow or several consecutive storms. Concerning rain on snow, it is noticeable that the snow-covered areas are the ones which mainly contribute to run-off, probably because the snowmelt has already primed the soil and also because the 100% humidity of the warm air during rain can produce considerable condensation melt.

The calculation of flood run-off from such storm or melt patterns requires a run-off simulation calculation of the type previously discussed. The resulting flood flow may be modified by the reservoir storage until maximum permissible reservoir stage is reached. From then on the spillway must be capable of passing the total flood, less any flow passed through the turbines or diverted to irrigation.

A third approach, which is often of comfort to the designer, is to compare the design flood with that used on other similar rivers. Careful comparison and cross-correlation may help to confirm the reasonableness of the final design values.

Standard project floods[1] can be determined by similar processes and used for the design of other aspects of a scheme, such as downstream diking and channel protection schemes. In this case the resulting damage from failure may not be so widespread and may not endanger life. It is not unusual for such design floods to be only a fraction of the value of a spillway design flood, perhaps half.

Complex Systems

Usually a complex water resource system involves the operation of storage or even several storages. Such operation aims to minimize flood risk at one extreme and drought risk at the other end of the scale. The scheme must satisfy various complex demands for such uses as hydro-power, irrigation, fisheries requirements, water supply, water quality, and navigation. Recreation is also now a demand of increasing importance and imposes limitations regarding water levels on beaches or in marinas. Water intakes and wastewater effluent lines set additional limitations. Water quality also sets demands on minimum flows, water temperature, lake levels, etc.

An important aspect of river basin behavior which has long been neglected is the effect of the alteration of run-off pattern on the ecological balance and erosion patterns downstream. Hydrological studies can supply the biological ecologists with information on how flood levels and seasonal run-off patterns will change with given schemes so that harmful effects can be recognized before damage is done.

Added to this complexity is the question of run-off forecast accuracy which can greatly influence the efficiency of water utilization. In the evaluation of such schemes hydrology is seen in its most necessary and challenging role. The hydrologist is called on to develop accurate forecasts of run-off. He also must simulate the total system behavior and then subject the system to sequences of run-off patterns generated from the characteristics of the recorded data. The resulting performance of the system is then analyzed from the economic viewpoint and, frequently, projections must be made into the future to estimate eventual demands and trends and system capability. In this type of problem the whole technical capability of the hydrologist is utilized and as techniques and data improve so the conflicting requirements of water use, water quality, recreation, and flood control can be better reconciled.

I

INDOOR AIR POLLUTION

PART 1

Laboratory work and chemical testing involves procedures that could contaminate the air inside occupied spaces. The nature of the contaminants varies widely: high humidity from steam baths, odors from hydrogen sulfide analyses, corrosion capabilities of alkalies and acids, solubility of acetone, explosive properties of perchloric acid, health hazards of bacteriological aerosols, and poisonous properties of nickel carbonyl. Ideally, best procedure is *not to emit*; but the next best is to remove or exhaust directly and as close to the point of origin for safety of laboratory personnel and protection of property.

To achieve this end, the accepted methods used for containment and removal of contaminants is by restricting the contaminant procedures to within an enclosure or hood. Simultaneously the air is drawn across the hood face to capture and remove the contaminants before escaping into the room.

In the design of a fume exhaust system utilizing hoods the following factors must be analyzed and evaluated: Capture velocities, Fume hood design, Seven basic hood designs, Makeup air source, Air distribution, Exhaust system, Exhaust duct materials, Exhaust air treatment, Special systems.

CAPTURE VELOCITIES

Air flow rates required for hood exhaust systems are based on a number of factors, the most important of which is *capture velocity.* For most applications these will range from 50 to 200 fpm. The lower figure is used to control contaminants released at low speed into relatively quiet room air (15 to 25 fpm). The higher figure is used to control contaminants released at high rates. Under special conditions hood face velocities as low as 25 fpm have been used with industrial type hoods.

Conclusions regarding optimum face velocity selection are rather mixed. In conceptual design of a lab facility this is given much thought and argument, especially when air conditioning is to be included. For every 1000 cfm of air exhausted through hoods, 3 to 4 tons of refrigeration are required to be added to system capacity for makeup air. At $1,000 per ton of refrigeration the cost of exhausting 1000 cfm could range from $3,000 to $4,000. This certainly adds to hood burden and capital outlay.

Some design emphatically forbid hood face velocities less than 100 fpm. Attempts have been made to relate face velocity to hood service by compromising fume hood usage with the added responsibility of supervision by laboratory personnel to insure that fume hood usage is restricted to the type contaminant for which face velocities were selected. To this end, Brief (1963) offers a method of hood classification as a step toward economy of design and operation. He classified type “S” hoods for highly toxic contaminants (threshold limit values less than 0.1 ppm) as having face velocities from 150 to 130 fpm. Type “A” hoods for moderately toxic contaminants (TLV’s of less than 100 ppm) can be sized for face velocities of 100 to 80 fpm. Hoods for non-toxic contaminants, Type “B” (TLV’s above 100 ppm), are sized for a face velocity from 60 to 50 fpm.

It should be emphasized that TLV’s should be used with care and not as sole criteria since they represent airborne concentrations that most workers may be exposed to repeatedly during a normal work day of 8 hours duration for a working lifetime.

Fume hood efficiency depends on the amount of air exhausted and hood design. To assure flexibility of operation and maximum safety to lab personnel, a fume hood should be designed for exhaust air rates ample for complete removal of all contaminants. This may be a logical step when only one hoods or two are involved in a single facility. However, with more than two, generous exhaust through all hoods can impose a heavy initial and operating cost penalty on the air conditioning system. From actual experience with laboratory design, it is difficult to select a one-hood design that will satisfy all situations.

FUME HOOD DESIGN

The function of a hood exhaust system is to protect the lab technician from exposure. Thus, the heart of the system is the hood and the design begins with the hood, which is, at best, a compromise between the ideal and the practical. Basically, a hood is a simple box, Figure 1(a). Without the necessary indraft shown for the basic ventilated hood, Figure 1(b), the material inside the hood can become airborne and be emitted into the room by one or a combination of the following normal laboratory operations: thermal action and convection currents, mechanical agitation, aspirating action by cross currents of the air outside the box. Material can escape from the basic hood only through the door or opening in front. However, in the simple ventilated hood, contaminants are kept inside by the action of the air flowing into the opening. To contain and keep the material from escaping, sufficient air must be exhausted to create and maintain an indraft through the face of the hood opening.

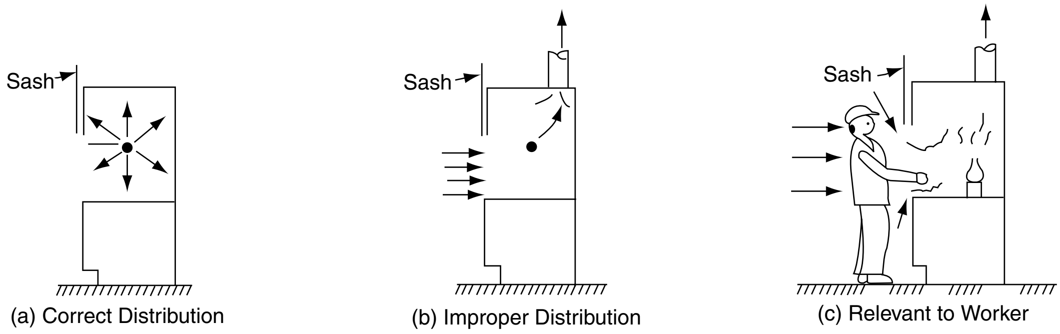
Hoods should control contaminated air so that the contaminant does not reach the breathing zone of the lab technician in significant quantities.

Nearly all hood designs presently in use attempt to provide protection in three ways: a mechanical shield, direction of air movement, dilution of contaminant by mixing with large volumes of air inside the hood. The mechanical shield comprises the hood sash. When an experiment is being set up the sash is in the raised position. In many experiments, the sash is lowered two-thirds the way down or even closed off entirely while an unattended experiment is being carried out. Only the occasional visit by the technician is needed. Care should be exercised not to lower the sash to a level that can cause too high an indraft velocity with attendant overcooling or snuffing out of a burner flame. Protection is provided by the direction of air flow across the back of the worker and into the hood proper, past the equipment within the hood and thence into the exhaust system, Figure 1(c). Lastly, because large amounts of air are being moved through the hood, dilution of the contaminated air takes place readily and further reduces the hazard of breathing hood air.

SEVEN BASIC HOOD DESIGNS

Seven basic hood designs are in use, all as shown in Figures 2a–2g.

1) *Conventional hood* (Figure 2a)
All exhausted air taken from the room. This is the simplest, low in initial cost and effective. However, high exhaust air rates place a heavy burden on air conditioning capital cost and operation.
2) *Conventional hood with reduced face velocity* (Figure 2b)
An attempt to compromise hood effectiveness to reduce air conditioning load chargeable to the hoods. Although low in relative cost, it does reduce air conditioning load but its effectiveness in removing fumes generated within the hood is weakened.
3) *Conventional hood with use factor* (Figure 2c)
Exhaust hoods may be needed at random intervals and it is not likely that they would be simultaneously. As with other types of air conditioning loads, there is a usage or diversity factor that is apparent, yet difficult to define precisely. This factor depends upon judgment, experience, and logic. For example, a large number of hoods in a laboratory room does not necessarily mean all hoods will be operating at one time since the number of lab personnel will be limited and thus reflect on the number of hoods in operation. On the other hand, it is the policy of some laboratories to keep *all* hoods in operation 24 hours a day, even though they are used intermittently. So much depends on the management of the facility and it behooves the designer to explore the total operation with the ultimate user.
4) *Internally supplied hood* (Figure 2d)
Required makeup air is fed directly inside the hood without affecting the overall room air conditioning. This air need not be cooled in summer but merely tempered in winter. Although an additional air handling system is required, the saving on the air conditioning load can offset



(a) Correct Distribution (b) Improper Distribution (c) Relevant to Worker

FIGURE 1 Flow directions through hoods.

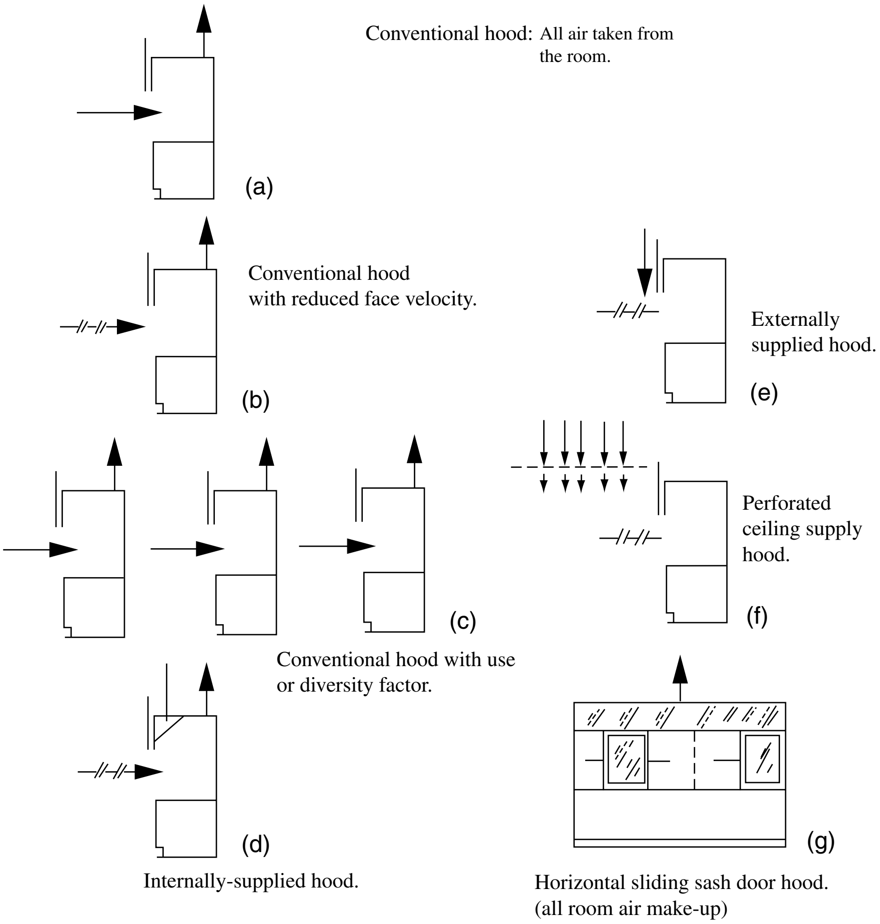


FIGURE 2 Hood designs.

this. Cost of hood runs medium to high but unless carefully designed and balanced fume removal effectiveness can be poor.

5) *Externally supplied hood* (Figure 2e)
Because of the additional duct system required such a system is relatively more expensive, relatively low cost effect on air conditioning, and because air is being exhausted across the hood face, fume removal effectiveness is good.
6) *Perforated ceiling supply hood* (Figure 2f)
This allows ample opportunity for the conditioned air to mix with room air and it becomes often necessary to sensibly cool but not dehumidify this auxiliary supply. Because air is exhausted across the hood face, fume removal effectiveness is good.
7) *Horizontal sliding sash hood* (Figure 2g)
Compared to the conventional hood with its vertical sliding door, the horizontal sliding ash unit presents much less area to be exhausted and total exhaust is thereby reduced. Relative cost of the hood is low and since less air is exhausted, air conditioning costs are low. Air conditioning and fume removal effectiveness are good.

To keep hood face disturbances to a minimum high velocity streams from the air conditioning system should not be permitted to disturb the even, smooth flow of air across the hood face.

MAKEUP AIR SOURCE

Makeup air to balance that exhausted is the most essential design feature of any hood exhaust system. When a fume hood is operating poorly, closer analysis will most often show inadequate makeup air supply. There is no air for the hood to "breathe" and an improperly sized makeup system will starve the fume hood and restrict its intended operation.

Some designs depend on air drawn from adjoining corridors and office spaces. Introduction of makeup air by indirect means is an economical approach. However, such a system can lead to balancing problems and cross-contamination between laboratory spaces. Positive introduction of air from corridors and office spaces by use of transfer fans can improve this. It has been found that the most reliable, flexible, and easily maintained system arrangement is that in which an adequate supply of outside conditioned air as makeup is supplied to the laboratory space to balance the air being exhausted. It is good practice to supply a little less makeup air this way than that being exhausted. A slight negative pressure will be maintained, drawing air through door louvers from corridors or adjacent offices.

Air exhausted from a hood is *never* recirculated so that hood burden goes up. Operating costs can be reduced by supplying makeup air from an auxiliary source instead from the cooling system. The air handled is filtered and tempered in winter only. Of the seven basic hood designs, numbers 4d, 4e, and 4f make use of the auxiliary system. An auxiliary system can be either a central unit or unitary type with an outside air inlet for each laboratory. Correct selection of the type of makeup air system can be made only by an engineering analysis and flow sheet of the hood exhaust system.

One of the most important characteristics of an exhaust system is that at some point the system must end and discharge to atmosphere. Unfortunately, while the exhaust system has ended at this point, the problems associated with that exhaust system may have just begun. If too much air discharged from an exhaust system is recirculated through the supply system not much good has been accomplished. If by poor design the exhaust air is not properly located with respect to the intakes of other supply systems, potentially disastrous results can be attained. Many poor designs are commonplace. The real cure for this type of problem is not higher exhaust velocities, higher stacks, better weather caps, better separation of discharge and intake openings, or other, although one or more of these can contribute to the cure. The real remedy must start back at the source of contamination itself.

Because the pattern of natural air flow around buildings is not predictable, contamination by the location of vent effluents and air intakes is difficult to put to practice. Halitsky[2] (1963) and Clarke[3] (1967) have advanced theoretical knowledge and rule of thumb that aid greatly in the solution of such problems.

AIR DISTRIBUTION

In review, air movement within each room of a laboratory complex must be such that a definite flow pattern will be maintained throughout the building along with flow from non-contaminated to potentially contaminated areas. To bring about this differential flow pattern, the nature barriers between the various classes of rooms will assist. The pattern will also be assisted by supplying outside clean air to the non-contaminated and semi-contaminated areas and by exhausting air only from the moderately and extremely contaminated areas. In general, supply fans should take suction from the upper portions of the building. Also, the exhaust fans should discharge to the outdoors through stacks of varying heights depending on adjacent structures. To help, the building should be maintained at a slight positive pressure with respect to the outdoors. Laboratory rooms should be maintained at a negative pressure with respect to the surrounding rooms.

Only an adequate supply of makeup air to satisfy exhaust needs will keep the building in balance. This certainly implies there must be an excess of supply over exhaust needs. In actual installations, experience shows that when two fans are exhausting from the same space with no provision for makeup air, the stronger fan will take command and outside air will enter the room through the weaker fan system. When there are multiple exhaust hoods and no makeup air, with one hood off, outside air can downdraft through the idle fan. When a fan must exhaust from a room without makeup, fan capacity will be reduced from design and will result in less control at the hood.

EXHAUST SYSTEM

The exhaust system being under negative pressure will cause leakage flow to be drawn into the system and contamination will be confined. Best location for an exhaust fan serving hoods is on the roof. Then all exhaust ductwork will be on the suction side of the fan and indoors. But this is not always possible. If the fan location must be indoors, say just above the hood, then careful attention must be paid to duct tightness on the discharge side. When flammable material is handled, mounting fan on roof is a distinct advantage because explosion-proof construction may not be required of the fan motor. However, fan wheel should be non-ferrous and inside casing should be epoxy coated for corrosion protection.

EXHAUST DUCT MATERIALS

In many buildings ductwork is often concealed in ceilings or inside walls, making duct inspection and replacement a major problem. Where this condition exists it is reasonable to use ductwork with long life expectancy. For chemicals used in laboratories, galvanized iron and black iron ductwork are highly susceptible to corrosion. Stainless steel, transite, polyvinyl chloride-coated steel or fiberglass-reinforced plastic (FRP) ductwork will not require early replacement for such corrosive service but are costly. Actually, selection of materials will depend on the nature and concentration of contaminants or chemical reagents, space conditions, cost, accessibility. Whatever materials are selected, duct joints must be leaktight and the ductwork should have ample supports. For best service life all longitudinal duct seams should be run along the top panel. An extensive duct system should have inspection and cleaning facilities. Ducts that could develop condensation loading should pitch toward a pocket in the bottom of the run and be provided with a trapped drain.

Type 316 passive stainless steel may be used for bacteriological, radiological, perchloric acid and other general chemical purposes. 316 stainless steel is easy to work but is not suitable for chemical hoods handling concentrated hydrochloric and sulfuric acids.

EXHAUST AIR TREATMENT

Gases that are bubbled through reaction mixtures and then discharge to the hood are generally, by their nature, reactive enough to be completely eliminated by a scrubber of some design. For materials that are acidic, a simple caustic scrubber is all that is necessary to assure essentially complete control. Similarly, for materials of a basic nature, an acid scrubber may be used to advantage. For those materials that do no react rapidly with either caustic or acidic solutions, a column filled with activated charcoal will always provide the desired control.

Perchloric acid is highly soluble in water and hoods have been developed with packed sections built into the hood superstructure and provided with water wash rings in the ductwork downstream of the scrubber to prevent buildup of perchlorates which are explosive on contact. Fume hoods handling highly radioactive materials should have HEPA filters upstream and downstream of the hood. For highly hazardous bacteriological experiments safety can be achieved only by incineration of the exhaust air stream, which is heated to about 650°F to destroy the bacteria.

SPECIAL SYSTEMS

Lowered Sash Operation

A hood exhaust fan maintains proper capture velocity when the sash is wide open, but the exhaust's hood's vertically sliding sashes are sometimes lowered to within a few inches of the work surface when the hood is in operation. A method in use to reduce waste of conditioned air and also to achieve a more constant face velocity over the range of sash positions is the use of a 2-speed fan for each hood. When the sash is pushed up the fan runs at high speed. A micro-switch mounted in the hood is tripped by the sash when it is lowered below a predetermined position. The volume of air the fan will pull on low speed is adequate to maintain desired face velocity for the smaller cross-sectional area. The proper placement of the switch setting can be 50 to 60% of the vertical face opening, i.e., the fan would go on low speed when the sash is lowered to 50 to 60% of opening. This holds for all exhaust hoods despite differences in hood dimensions and other variations in exhaust systems. It has been found to apply equally as well to hoods with minimum face velocities of 80, 100, and 125 fpm. The volume of conditioned air that is normally lost is reduced by about one-third when the sash is below the set point.

In a conventional hood with a single speed fan, the excessively high face velocities experienced at low sash settings and the cooling effect on the backs of lab personnel using the hood has an overall adverse effect. Further, still, when the laboratory technician stands in front of a hood in operation his body presents an obstruction to the flow of air into the hood. Thus, a low pressure area develops in the space between the man and the hood. Under certain conditions, the resulting low pressure area can cause fumes to be aspirated from the hood and out into the room. The reduction in face velocity using the 2-speed fan reduces the probability of such a hazardous condition developing.

Type "S" hoods should be provided with fan speeds so that at no point across the hood face should a velocity greater than 250 fpm exist. Another way to control this velocity is to provide by-pass dampers in the exhaust duct just downstream of the hood itself. By-pass hoods are made to accomplish this effect by providing this feature in the hood structure itself.

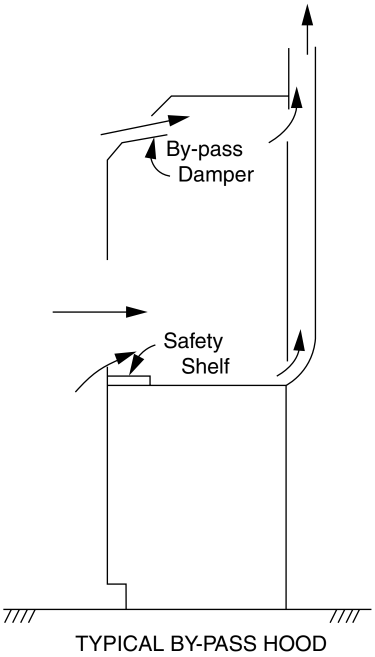
By-Pass Hoods

These provide for a constant rate of room exhaust and uniform face velocities at any door position. They stabilize the room exhaust and the room they supply. The by-pass may be an integral part of the hood itself. As the hood door begins to close, the damper starts to open. Another important aspect and advantage of the by-pass hood is that the hood interior is continuously being purged of fumes even while the door is closed tight. For the by-pass hood see Figure 3.

Supply Air Hoods

Two types are commercially available. The first has auxiliary air introduced outside and in front of the sash, normally from the overhead position. In this design the auxiliary air supply is drawn into the sash opening as a part of the room air. Relative cost of this type compared to the conventional is high. Relative cost of air conditioning is low because amount of room air exhausted is reduced. Air conditioning effectiveness, fume removal effectiveness, and convenience to lab personnel are good. However, acceptability to local authorities should be investigated. See Figure 4(a).

In the second type, auxiliary air is fed directly into the hood on the inside. Relative cost is high, cost of air conditioning is low, air conditioning effectiveness is good, but fume removal effectiveness is poor. Because effective face velocities can drop



TYPICAL BY-PASS HOOD

FIGURE 3

below the safe value needed to prevent leakage of fumes, its use is discouraged by many health authorities. See Figure 4(b).

Induction Venturi

For many fume exhaust applications such as those involving hazardous fumes or gases, the conventional exhaust method of passing gases through the fan casing could be potentially hazardous. With exhaust from perchloric acid fume hoods in particular, a build-up of crystals can occur on duct walls and fan. This crystalline growth is explosive under normal conditions and special treatment of such a system is mandatory.

To overcome this, there are commercially available induction venturi systems with water wash facilities. Since perchloric acid crystals are highly soluble this system is provided with spray rings or nozzles and are washed down internally at regular intervals. Drainage is provided to a trough attached to the back of the hood table (see Figure 5). System operation is accomplished by introducing a high velocity air stream jet inside a specially designed venturi. This in turn induces a flow of gas into the venturi inlet. This induced flow can then be used to exhaust the hood without any of the gas having to pass through the fan. Venturi is usually of stainless steel (316L). Blower is mild steel. Such a system used to exhaust 12000 cfm against ½″ w.g. required a primary flow of clean air of 500 cfm and ¾ hp fan motor.

Other perchloric acid fume exhaust systems use fans of PVC construction but wash the gas stream upstream of the fan. Its construction is also PVC. Each hood should be provided with its own exhaust system; no combinations should be manifolded. Organic compounds must be avoided in the construction of the system as well as the chemical used in testing inside the hood.

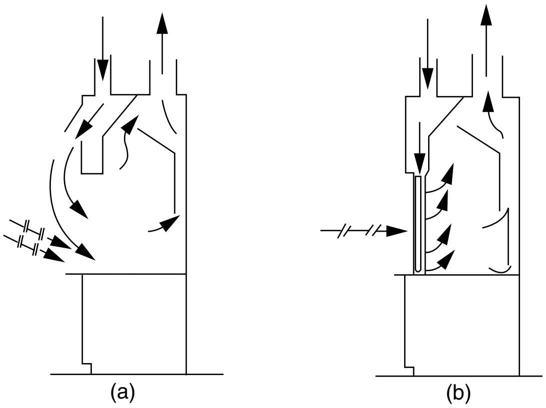
Multihood Single Fan System

Should each fume hood be provided with its own exhaust fan or should several hoods be serviced by one fan common to all? A common exhaust duct and fan system may be used if the facility handles similar and compatible chemical reagents. In the consideration of exhaust systems for a chemical research facility, where the chemical nature of the reagents to be used cannot be predicted in advance, or cannot be controlled, safest procedure is to use separate and individual exhaust fans and ducts.

DESIGN PROCEDURE

For a most economical design and the use of the various criteria outlined herein the following procedure is suggested:

1) Set inside conditions of dry bulb temperature and relative humidity in the upper range of the comfort zone. Since relative humidity is critical to operating costs, place greater emphasis on this aspect.
2) Select a hood face velocity sufficiently high to control the type hazard, using the recommendations outlined in reference 1. Review hood



(a)

(b)

FIGURE 4 Auxiliary air supply schematic.

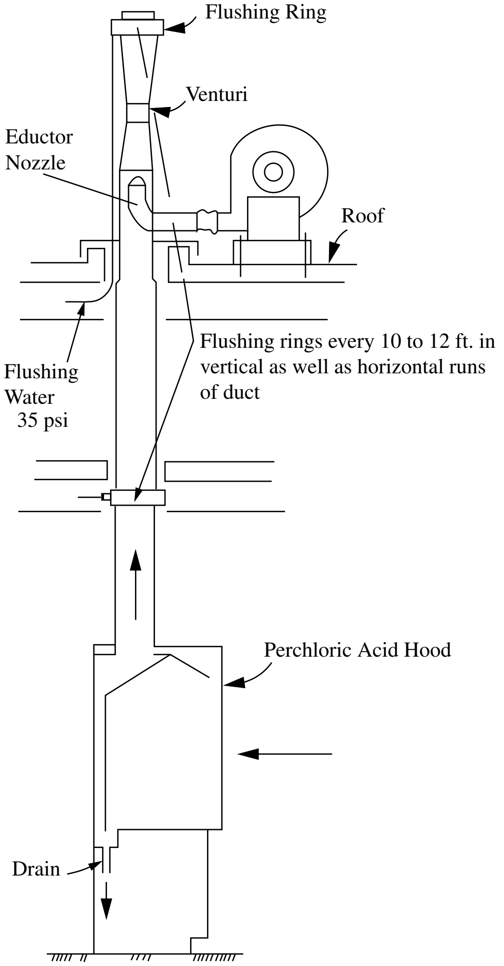


FIGURE 5 Induction venturi system.

operation carefully since not all hoods require same face velocities.

3) In cooperation with laboratory management determine the minimum number of hoods requiring continuous operation. Determine if a hood or hoods can operate intermittently or a minimum and estimate if its exhaust flow can be eliminated insofar as its effect on air conditioning load is concerned.
4) Avoid the use of hoods to store material and merely provide local exhaust.
5) Determine the acceptability of face screens or shields or horizontal sliding panels.
6) Locate hoods so that they are set clear of doorways and frequently traveled aisles.
7) Determine if laboratory management is willing to take a "slip" in room conditions when more air is exhausted than is originally planned.
8) Consider use of perforated ceiling supply hood arrangement with conditioned air supply through ceiling diffusers for spot cooling effect.

General

Exhaust stack should be vertical and straight and discharge up; no weather caps should be used. Brief[1] suggests when open-face velocities exceed 125 fpm, install an atmospheric damper downstream of the hood just before the exhauster to prevent excessive indraft velocities when conventional hoods are used. At high face velocities, laboratory equipment placed within the hood should be set so that points of release of contaminant are at least 6 inches back of the hood face. This can be ensured by placing a ¼ inch thick edging 6 inches wide on the bench top near the hood entrance face. Brief[1] found that concentrated head loads within the hood proper, exceeding 1000 watts per foot of hood width created thermal vectors that require higher face velocities for control. Obstruction of hood face by large objects is discouraged; blockage causes control problems.

PART 2

Factors to Be Considered in Fume Hood Selection

In the selection of a fume hood the following factors should always be considered:

Space

- What actual space requirements will be required?
- What are the future requirements?
- What physical space is available?

Function

- What chemicals and procedures will be involved in this application? (Highly corrosive, TLV, etc.)
- High heat procedures?
- Extremely volatile?

Location

- Are your present ventilation capabilities adequate and will they be taxed by the new hood installation?
- Is the area where the hood will be installed adequately suited to the new installation? For instance, high traffic areas give rise to undesirable crosscurrents and cause materials to be drawn from hoods. Hoods should not be installed next to doors but preferably in corners.
- Is the operation such that the use of an auxiliary air system might compromise the safety of the operator? Safety is paramount in any hood application.

Hood Construction Materials

Although basic hood design has changed very little, many advances have been made in the materials from which hoods are constructed. Here are some of the basic materials and their more distinctive features.

Wood

- Generally poor chemical resistance.
- Inexpensive to fabricate and modify in the field.
- Can present a fire hazard in applications involving heat and flame.
- Poor light reflectivity causes a dark hood interior.

Sheet Metal (Cold rolled steel or aluminum)

- Requires secondary treatment for chemical resistance.
- Demands extreme care to avoid damaging the coating since corrosion can occur in damaged areas.
- "Oil canning" due to thin-gauge metal causes noise in operation.
- Relatively inexpensive.
- Usually heavy and cumbersome to install.

Fiberglass

- Excellent chemical resistance.
- Lightweight for ease of installation or relocation.
- Easily modified in field with readily available tools.
- Sound-dampening because of physical construction.
- Some inexpensive grades can cause fire hazards and are not chemically resistant.
- Available with good light reflective properties for a light and bright work space.
- Shapes are limited to tooled mold configurations, and can be moulded with covered interiors.

Cement/Asbestos (Transite)

- Excellent chemical resistance.
- Has inherent sound dampening qualities.
- Excellent fire resistance.
- Heavy and difficult to install.

- Extremely brittle, requiring care in handling to avoid breakage.
- Poor light reflectivity.
- Stains badly when exposed to many acids, etc.
- Easily modified in field with only minor tooling difficulties.
- Inexpensive.

Stainless Steel

- Better general chemical resistance than cold rolled steel.
- Not well suited to many acid applications.
- Generally provided in type 316 for specific applications to which it is well suited such as perchloric acid.
- Heavy and expensive.
- Difficult to modify in field.
- Excellent fire resistance.

Polyvinyl Chloride

- Excellent chemical resistance except for some solvents.
- Good fire-retardant properties.
- Particularly well suited to acid digestion applications such as sulfuric and hydrofluoric.
- Easily modified in field.
- Generally not available in molded configurations.
- Expensive.
- Distorts when exposed to intense direct heat.

Stone

- Excellent chemical resistance.
- Excellent fire resistance.
- Difficult and extremely heavy to install.
- Extremely difficult to field modify.
- Expensive.

WALK-IN HOOD

This type of hood was not mentioned in Part I but will be now included. The walk-in hood is a standard hood whose walls extend to the floor, thus providing sufficient space to accommodate a more elaborate experimental setup requiring additional height. Such hoods have double or triple hung sashes, which may be raised and lowered to provide access to any part of the setup while the remaining space is enclosed to contain fumes. The back baffle of such a hood extends over the full height of the hood and is equipped with at least three adjustable slots to regulate the amount of air passing over various parts of the setup.

SPECIAL PURPOSE FUME HOODS

Perchloric Acid Fume Hood

Due to the potential explosion hazard of perchloric acid in contact with organic materials, this type hood must be used for perchloric digestion. It must be constructed of relatively inert materials such as type 316 stainless steel, Alberene stone, or ceramic coated material. Wash-down features are desirable since the hood and duct system must be thoroughly rinsed after each use to prevent the accumulation of explosive residue. Air flow monitoring systems are recommended to assure 150 fpm open face velocity operation. An additional monitoring system for the wash-down facilities is also recommended.

Radiological Fume Hoods

Hoods used for radioactive applications should have integral bottoms and covered interiors to facilitate decontamination. These units should also be strong enough to support lead shielding bricks in case they are required. They should also be constructed to facilitate the use of HEPA filters.

Canopy Fume Hoods

Canopy fume hoods are a type of local exhauster which normally has limited application in a laboratory. Their main disadvantage is the large amount of air required to provide an effective capture velocity. Since the contaminant is drawn across the operator's breathing zone, toxic materials can be quite dangerous. A canopy hood can, however provide a local exhaust for heat or steam.

INTEGRAL MOTOR-BLOWERS

Many hoods are available with motors and blowers built directly into the hood superstructure. From the standpoint of convenience, the hood is relatively portable and can be installed easily. A built-in motor-blower should not be used for highly toxic applications since it causes a positive pressure in the exhaust system ductwork and any leaks in the duct could spill the effluent into the lab area. There may be more noise associated with this type hood since the motor-blower is closer to the operator.

Fume Discharge

Each individual exhaust fan on the roof should have its own discharge duct to convey the fumes vertically upward at a high velocity as far above the topmost adjacent roof as possible. Failure in this will result in potential recirculation of fumes into building air intakes and will be particularly hazardous to personnel who use the roof for maintenance, research, or relaxation.

As the wind blows over the leading edge of a roof parapet, as shown in Figure 6, a disturbance is created that sweeps from the edge of the parapet up over the top of the building. Above the boundary of this disturbance, wind flow is undisturbed. Below the boundary, the influence of the sharp edge of the building creates eddy currents that can pocket fumes released at the roof. This is known as the wake cavity. Unless fumes are discharged into the undisturbed air stream above the boundary, where they can be carried away, they will remain relatively undisturbed and undiluted on the roof and in the lee of the building, where they can enter the building air intakes either on the roof or at ground level. When this happens, all the care taken in the design of a good fume exhaust system

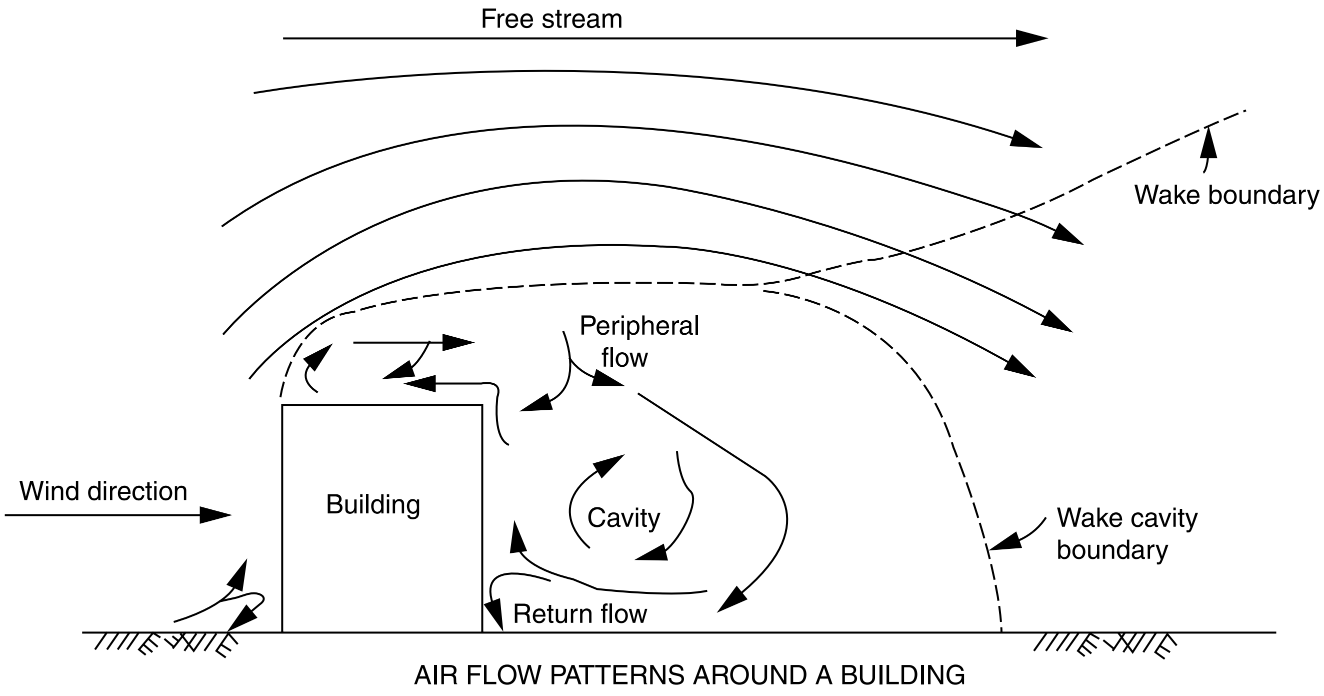

FIGURE 6

may be nullified. And with the present concern over air pollution, failure to disperse the fumes may give rise to legal action against the building owner.

Fume absorbers such as charcoal have been proposed to relieve the fume disposal problem, so have air washers and catalysts. These devices have not been used because the kinds and amounts of fumes released are constantly changing in research and are therefore unpredictable.

Despite the number of warnings in the literature, rain caps, cone shaped covers or hoods fastened to the tops of vertical stacks—are still being used to prevent rain from entering exhaust stacks. It is important that their use be avoided completely. There are several simple stack arrangements that will prevent entry of rain into exhaust stacks when fans are not operating. One such arrangement is shown in Figure 7.

BUILDING AIR INTAKES

In high-rise research buildings, mechanical equipment is frequently installed in the penthouse and in the basement. Because of the possibility of recirculating fumes released from or near the roof, outdoor air is often taken at the second floor level on the prevailing wind side of the building, and away from fume exhausts. Assistance in determining the prevailing wind direction at the building site may be obtained from the local weather bureau.

BASIC PERFORMANCE CRITERIA

The following may be used as a general guide for the selection of hood blower systems that will provide optimum average face velocities for various exhaust materials. Tables listing the TLV for various chemical compounds may be obtained from the American Conference of Governmental Industrial Hygienists.

Very low toxicity level materials	
Noxious odours, nuisance dusts and fumes	80 fpm
General lab use	
Corrosive materials	
Moderate toxicity level materials (TLV of 10–1000 ppm)	100 fpm
Tracer quantities of radioisotopes	
Higher toxicity level materials (TLV less than 10 ppm)	125–150 fpm
Pathogenic microorganisms	
High alpha or beta emitters	
Very high toxicity level materials	(TLV less than 0.01 ppm) An enclosed glove box should be used

HOW TO CUT AIR CONDITIONING COSTS

As a rule of thumb, each 300 cfm of air exhausted through hoods requires one ton of refrigeration. Current operating costs are about 50 to 60 dollars per ton of air conditioning for a four month period. Installed equipment averages about $1,000 per ton. So, a hood exhausting at 900 cfm would require about three tons of air conditioning at a capital expense of $150 to $180 per season. However, if the same hood had

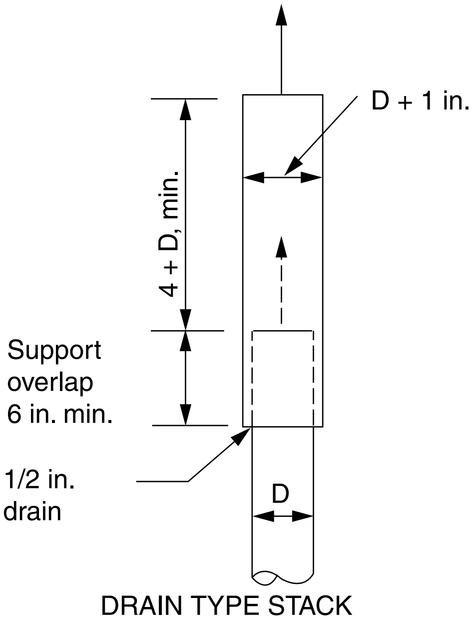

FIGURE 7

the Add-Air feature supplying 50% untempered air, $1,500 would be saved in capital equipment and $75 to $90 to annual operating costs. (Figures are in 1992 $.)

MAINTENANCE AND TESTING

Since the hood performance may be affected by the cleanliness of the exhaust system and the direction of rotation of the exhaust fan, it is important to provide a maintenance schedule of inspections and performance testing throughout the year to make certain that the fume hoods are operating safely and efficiently.

If filters are used to remove dust and other particulates from the exhaust air, they must be periodically inspected and replaced if necessary. Corrosion of ductwork and damper mechanisms should be watched and debris should be removed from inside the ducts, especially at startup time. Excessive corrosion of ducts may cause leakage of air into the system or the failure of balancing dampers that will affect capture velocities well below their design figures. Remember to check fan rotation since this most often causes poor exhaust performance.

PERFORMANCE TESTING

Two performance tests should be conducted periodically on all hoods. One for fume leakage and the other for face velocity. The test for fume leakage consists of releasing odorous fumes such as ammonia or hydrogen sulfide within the hood. If fumes are detected outside the hood, especially around the face opening, the capture velocity at the sash opening may be inadequate, or there may be an interfering air disturbance. Cleaning the exhaust system, adjusting the air flow damper, or increasing the fan speed may improve the performance if low face velocity seems to be the problem. If, on the other hand, leakage seems to be caused by interference from an auxiliary air supply stream or other velocity near the sash, the nature of the interference may be investigated as follows: placing liquid titanium tetrachloride on masking tape around the periphery of the sash opening. Observations can then be made of the path of visible fumes to determine where there is spillage into the room. Smoke bombs have also been used to determine flow patterns at sash openings and to identify interference.

A hot wire anemometer is usually used to measure actual face velocity. This is done as a traverse over the entire sash opening, including especially all edges and corners. The overall face velocity average is obtained by averaging the velocity readings at prescribed positions of the traverse.

These testing procedures are difficult to standardize and are dependent on subjective observations. Thus, they are considered to be unadaptable and inadequate. The *American Society of Heating, Refrigeration, and Air Conditioning Engineers* (ASHRAE) has set up a research project for developing fume hood performance criteria and new test procedures for such laboratory equipment.

SAFETY FEATURES

Interconnection of Hoods

If two or more hoods independently serve a single room or an interconnecting suite of rooms, all of the hoods in these rooms should be interconnected so that the operation of one will require the operation of all. If this is not done, there is a strong possibility that fumes will be drawn from a hood that is not operating to makeup air demands of those in operation.

Alarm for Hood Malfunction

All hoods should be equipped with safety devices such as sail switches to warn personnel that the air volume exhausted from the hood has dropped to a point where it will not provide sufficient capture velocity for safe operation.

Fire Dampers

Most building codes require fire dampers in all ducts that pass through fire walls and floors. However, it is important *not* to install them in fume exhaust systems. Should a fire occur in a hood, or if heat from a fire nearby such a damper should cause the damper to close, the fume backup into the facility would prove disastrous.

EXHAUST FROM LABORATORIES

A laboratory should exhaust 100% of the air fed to it. If the materials that are being handled or tested in the laboratory are hazardous enough to need a hood, the presence of these materials in itself should dictate 100% exhaust. An accidental spill or accidental release of materials at a bench or hood can result in recirculation throughout the entire building. Accidental recirculation is a serious hazard and should be guarded against.

GLOSSARY OF TERMS RELATED TO FUME HOOD SELECTION

Baffle: An air director mounted off the hood's inner surface which causes air to move in specific patterns.

Blower: An air moving device utilizing a rotating impeller within a housing to exhaust air.

BTU: (British Thermal Unit) The amount of heat required to raise one pound of water one degree Fahrenheit.

Capture Velocity: Air velocity at the hood opening necessary to overcome opposing air currents and cause contaminants to flow into the hood.

CFM: (Cubic Feet per Minute) A volume of air moved per minute.

Duct: A pipe system used to convey and constrain a moving air stream.

Ejector: An air moving system which consists of a high pressure air source passing through a Venturi nozzle, creating a suction at the nozzle entry.

Face Velocity: The speed of air measured in feet per minute across the fume hood sash opening perpendicular to the sash.

HEPA Filter: A High Efficiency Particulate Air Filter rated 99.97% effective on particles 0.3 micron or larger.

Inches of Water: A unit of pressure equal to the pressure exerted by a column of water one-inch high at standard temperature.

Manometer: An instrument for measuring pressure. It is essentially a U-tube filled with a liquid, normally water or mercury.

Negative Pressure: Pressure within a system below that of atmosphere, causing an inward flow of air.

Plenum: An air compartment maintained under pressure which serves as a reservoir for a distribution duct.

Positive Pressure: Pressure within a system above that of atmosphere, causing an outward flow of air.

Scrubber: A device used to wash effluent air streams for removing contaminants.

Static Pressure: The pressure exerted in all directions when air moves through a duct system creating a resistance to air flow. Measured in inches of water.

TLV: (Threshold Limit Value) The amount of air-borne toxic materials that represents the maximum concentration to which an average person may be exposed for 8-hours a day with no adverse effects. (Usually expressed in parts per million.)

Transport Velocity: The minimum velocity required to move particulates in the air stream.

LABORATORY SAFETY GUIDELINES

Safety rules should be followed at all times. A shortcut may save you a few minutes, but cost you your life. Here are a few guidelines that may make your laboratory safer.

Hoods: Chemical hoods effectively remove toxic and flammable vapors. Equipment in use should be completely enclosed in a hood with adequate room allowed for experimental procedures. When the apparatus is too large to be housed in a hood and there is no possibility of toxic or flammable materials being released, anchored shields of safety or wired glass should envelope the equipment. Hoods are not designed to be used as storage areas. Remove unused equipment and chemicals and store them in their proper places.

Emergency Equipment and Procedures: Well-equipped chemical laboratories have eye-wash fountains, deluge safety showers, fire blankets, fire extinguishers, and emergency exits. This equipment should be tested periodically. In addition, being familiar with the locations and uses of the equipment may save you needed time during an emergency.

Personal Protection: Rubber aprons, asbestos gloves, safety glasses, full face shields, and approved respirators protect you from spills, burns, spattering chemicals, flying fragments, and irritating fumes. In addition, the laminated safety glass doors on chemical fume hoods protect you from mishaps in the hood.

Health Monitoring: When biological agents or carcinogens are used in the laboratory, special medical control programs are necessary to monitor the workers' health. If radioactive materials or radiation-producing equipment such as an X-ray diffraction unit are used, dosimeters or film badges should be worn to monitor exposures.

Labeling: Chemicals must be prominently and accurately labelled. When a small quantity of material is removed from a large container, immediately label the smaller container. Containers for hazardous chemicals should have precautions such as "poison" or "flammable"; indicated under the label. After you have completed working with a particular material, return the container to storage or dispose of the material. Nothing should be left in open containers.

Equipment should be labeled U.L. or C.S.A. listed and meet all federal and local electrical codes.

Eating, Drinking, and Smoking: Food, beverages, and cigarettes, pipes, or cigars should not be permitted in the chemical laboratory under any circumstances. Chemical glassware should never be used to hold food. Always wash your hands well before eating, drinking, or smoking.

Pipetting: Never pipette toxic, corrosive, or radioactive chemicals by mouth; always use a rubber bulb or syringe.

Glassware: Cracked or chipped glassware should be discarded to prevent cuts or scratches which can cause further complications if chemicals contact the injury.

Always place a towel or cloth over glass tubing being cut or broken. Fire polish sharp ends. When inserting a rod or piece of glass tubing through a perforated stopper, wrap a towel around your hand for protection.

Waste Disposal: Disposal of hazardous waste materials requires special handling.

Place all broken glass in specially marked metal containers—never in waste baskets or containers used for paper or rags.

Flush dilute acids and alkalies down the drain with large quantities of water.

Never pour flammable liquids not miscible with water, compounds that give off toxic vapors, or corrosive materials down the drain. Special disposal containers are needed for each of these wastes.

Storage: An efficiently placed storage room is essential for everyone's safety. Chemical storage rooms should be equipped with fire doors, safety lights, fire extinguishers, as well as good ventilation and sprinkler systems.

Remember

Carefully group liquid reagents to prevent hazardous combinations which may produce fumes, fire, or explosion.

Segregate incompatible materials.

Keep volatile liquids away from ignition sources such as heat, flames, or electric sparks.

Store large or heavy containers and apparatus near the floor.

Store all solvents in safety cans.

Store and frequently vent drummed chemicals according to supplier's instructions.

Secure compressed gas cylinders.

Replace valve caps when not in use.

Smaller laboratories that don't have separate storage rooms should have noncombustible storage cabinets. Large quantities of flammable solvents should be placed outside in ventilated, noncombustible buildings.

Housekeeping: Good housekeeping is essential for safe laboratory operation. All passages, exits, safety showers, fire extinguishers, electrical controls, and stairways must be kept clear of equipment and obstructions. Remove unused equipment or chemicals from work spaces. Clean up spilled chemicals immediately to prevent dangerous chemical combinations, burns, or slips and falls.

FUTURE TRENDS

We may expect stricter enforcement of existing local and Federal regulations for the safe handling of toxic materials. New regulations may dictate high fume hood face velocities and increased exhaust volumes which place an increased load on air tempering and exhaust systems. Because of this, work involving small apparatus will probably be relegated to glove box enclosures. Larger hood enclosures will more than likely be fitted with horizontal sliding doors or sashes rather than the current vertical rising sash. This type of hood would provide full access to the larger hood interior, but would require opening only the areas needed by the operator. This would result in lower exhaust volumes even at the increased face velocities and provide an integral safety shield if required.

Reported measurements of airborne bacteria and fungi have been sparse (see Institute of Medicine, 2004, for a summary). Viable bacteria concentrations, found in homes in the U.S.A. ranged from 2220–4006 CFU/m^3 (i.e., colony forming units per cubic meter of air). In Finland, homes and day care centers with moisture problems and winter conditions had unit concentrations as high as 35,000 CFU/m^3 (Hyvarinen et al., 2001).

INDUSTRIAL ECOLOGY

INTRODUCTION

Industrial ecology is an emerging field of study that deals with sustainability. The essence of industrial ecology was defined in the first textbook of the field in this way:

> Industrial ecology is the means by which humanity can deliberately and rationally approach and maintain sustainability, given continued economic, cultural, and technological evolution. The concept requires that an industrial system be viewed not in isolation from its surrounding systems, but in concert with them. It is a systems view in which one seeks to optimize the total materials cycle from virgin material, to finished material, to component, to product, to obsolete product, and to ultimate disposal. Factors to be optimized include resources, energy, and capital. (Graedel and Allenby, 2003, 18)

Industrial ecology is industrial and technological in the sense that it focuses on industrial processes and related issues, including the supply and use of materials and energy, adoption of technologies, and study of technological environmental impacts. Although social, cultural, political, and psychological topics arise in an industrial-ecology context, they are often regarded as ancillary fields, not central to industrial ecology itself (Allenby, 1999).

Industrial ecology's emphasis on industries and technologies can be explained with the "master equation" of industrial ecology. Originating from the IPAT equation (impact, population, affluence, and technology; Ehrlich and Holdren, 1971; Commoner, 1972), the master equation expresses the relationship between technology, humanity, and the environment in the following form:

$$\begin{aligned} \textit{Environmental impact} &= \textit{Population} \times \frac{\textit{GDP}}{\textit{Person}} \\ &\quad \times \frac{\textit{Environmental impact}}{\textit{Unit of GDP}} \end{aligned} \tag{1}$$

where GDP is a countrys or region's gross domestic product, the measure of industrial and economic activity (Graedel and Allenby, 2003, pp. 5–7; Chertow, 2000a).

In this equation, the *population* term, a social and demographic one, has shown a rapid increase in the past several decades, and continues to increase. The second term, *per-capita GDP,* is an economic indicator of the present population's wealth and living standards. Its general trend is rising as well, although there are wide variations among countries and over time. These trends make it clear that the only hope of maintaining environmental interactions in the next few decades at an acceptable level is to reduce the third term, *environmental impacts per unit of GDP,* to a greater degree than is the product of the increases in the first two terms—a substantial challenge! This third term is mainly technological and is a central focus of industrial ecology.

The name "industrial ecology," combining two normally divergent words, relates to a radical hypothesis—the "biological analogy." This vision holds that an industrial system is a part of the natural system and may ideally mimic it. Because biological ecology is defined as the study of the distribution and abundance of living organisms and the interactions between those organisms and their environment, industrial ecology may be regarded as the study of metabolisms of technological organisms, their use of resources, their potential environmental impacts, and their interactions with the natural world.

The typology of ecosystems has been characterized as three patterns (Figure 1a–c). A Type I system is a linear and open system that relies totally on external energy and materials. In biology, this mode of action is represented by Earth's earliest life forms. A Type II system is quasi-cyclic, with much greater efficiency than Type I. However, it is not sustainable on a planetary scale, because resource flows retain a partially linear character. Only a Type III system possesses a real cyclic pattern, with optimum resource loops and external reliance only on solar energy. This is how the natural biosphere behaves from a very long-term perspective.

The evolutionary path from Type I to Type III taken by nature (from open to cyclic, from unsustainable) provides perspective on the evolution of industrial ecosystems. Historically, the industrial system has mimicked the Type I pattern, with little concern about resource constraints. The best of today's industries come close to Type II (Figure 1d), and a Type III industrial system is a vision of a possible sustainable future for industrial ecosystems.

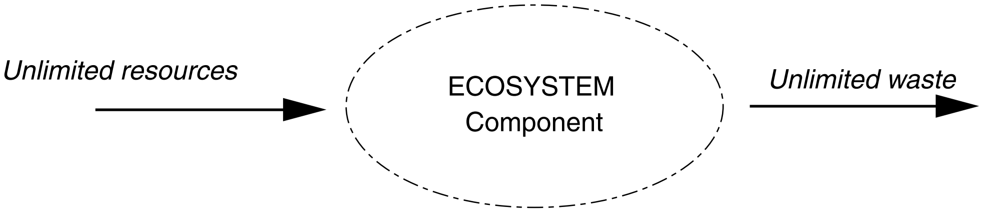
The biological analogy has been explored in other ways as well. From a metaphysical perspective, industrial ecology's philosophy might be labeled as: "nature as model," "learning from nature," and "orientation by nature" (Isenmann, 2002).

In this context, industrial firm-to-firm interactions have been examined by ecological food-web theory (Hardy and Graedel, 2002), and the theoretical approaches of thermodynamics and self-organization have also been applied to these systems (Ayres, 1988).

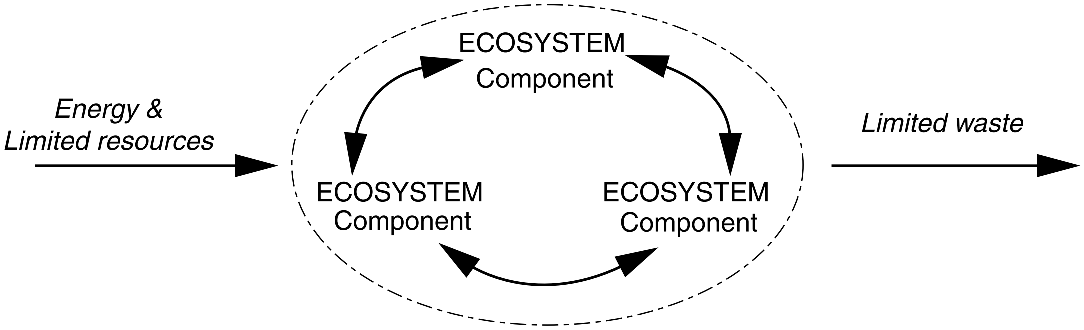
The interaction between the worlds of industry and ecology emphasizes that industrial ecology is a systems science that places emphasis on the interactions among the components of the systems being studied. This systems orientation is manifested in several of the research topics of the field, including life-cycle analysis, industrial metabolism, system models and scenarios, and sustainability assessment (Lifset and Graedel, 2002), topics that are discussed below.

THE ORIGINS OF INDUSTRIAL ECOLOGY

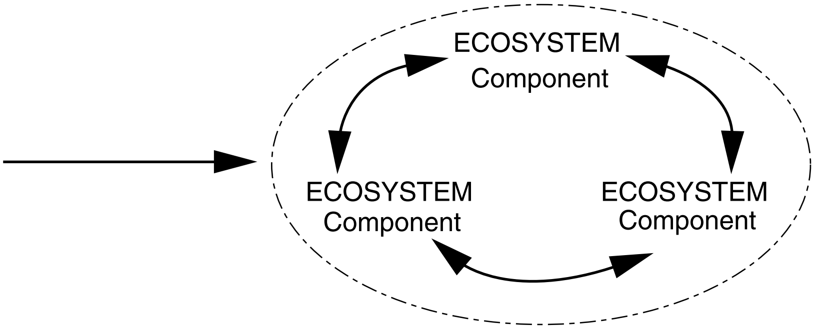
For many thousands of years, nature dominated the human-nature relationship. This dominance was reversed by the growth of agriculture and especially by the industrial revolution of the 1800s. The implications for nature of this



(a) Type I: linear material flows

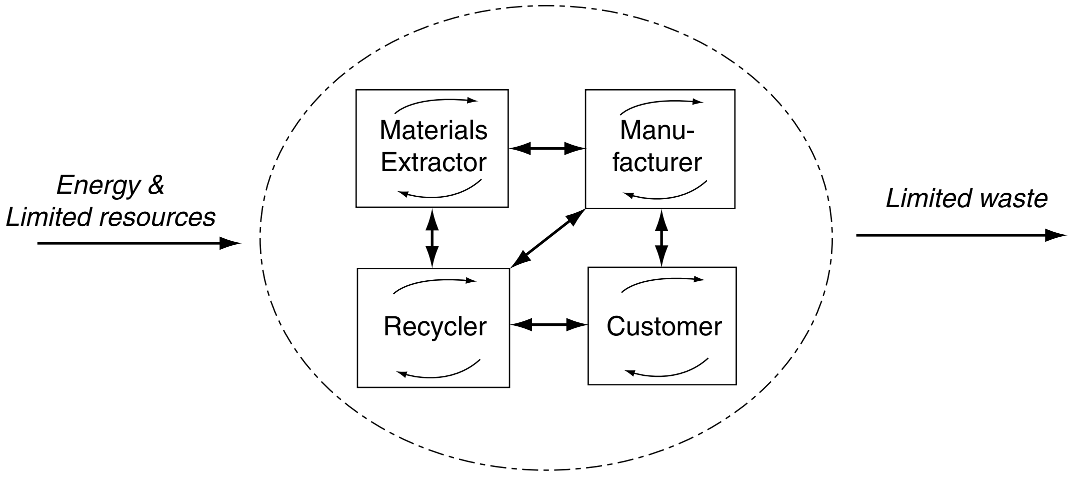


(b) Type II: quasi-cyclic material flows



(c) Type III: cyclic material flows

FIGURE 1 Typology of ecosystems. From Graedel and Allenby, 2003; Lifset and Graedel, 2002. (a) Type I: linear material flows; (b) Type II: quasi-cyclic material flows; (c) Type III: cyclic material flows; (d) Type II industrial ecosystem.



(d) Type II industrial ecosystem

FIGURE 1 (*continued*)

transformation were called out in the third quarter of the twentieth century by several seminal environmental thinkers (Carson, 1962; Lovelock, 1988; Ward *et al.*, 1972). The publication of the Club of Rome's report *The Limits to Growth* also received considerable public attention (Meadows *et al.*, 1972). That report predicted that economic growth could not continue indefinitely because of Earth's limited availability of natural resources, as well as its limited capacity to assimilate pollution of various types. Most of the Club of Rome's dire projections about resource exhaustion have not thus far come to pass. Nonetheless, the issue of the sustainability of human civilization has become a concern of global scope and reach.

The concept of industrial ecology, in which the technology–environmental linkage is explicitly recognized and addressed, can be traced to the early 1920s (Erkman, 1997, 2002). However, 1989 is generally viewed as the formal year of birth of the field (Figure 2). In that year, R. Frosch, then vice president of the General Motors Research Laboratories, and his colleague N. Gallopoulos developed the concept of industrial ecosystems in their seminal article "Strategies for Manufacturing" (Frosch and Gallopoulos, 1989). Their view was that an ideal industrial system would function in a way analogous to its biological counterparts. In such an industrial ecosystem, the waste produced by one process would be used as a resource for another process. No waste would therefore be emitted from the system, and the negative impacts to the natural environment would be minimized or eliminated. This analogy between biological and industrial systems was the conceptual contribution that led ultimately to the new field of industrial ecology.

Industrial ecology's growth since the early 1990s has been marked by a series of institutional milestones, including the first textbook (*Industrial Ecology;* Graedel and Allenby, 1995), the first university degree program (created by the Norwegian University of Science and Technology [NTNU] in 1996), T. E. Graedel's appointment as the first professor of industrial ecology in 1997, the birth of the *Journal of Industrial Ecology* in 1997, and the foundation of the International Society for Industrial Ecology (ISIE) in 2001. As a consequence of these activities, an academic community of industrial ecologists has been formed, research methodologies are being developed and refined, and industrial ecology is being practiced all over the world.

INDUSTRIAL ECOLOGY'S TOOLBOX

Given an evolving field with a wide and evolving scope, industrial ecology's toolbox has become equipped with a variety of methods of approaching the concepts and practices of interest. Three of the most common tools, material-flow analysis (MFA), life-cycle assessment (LCA), and input-output analysis (IOA), are discussed below from a methodological point of view.

Material-Flow Analysis

MFA is "the systematic assessment of the flows and stocks of materials within a system defined in space and time. It connects the sources, the pathways, and the intermediate and final sinks of a material" (Brunner and Rechberger, 2004, p. 3), thus providing information on the systemic utilization of the material within the given boundaries.

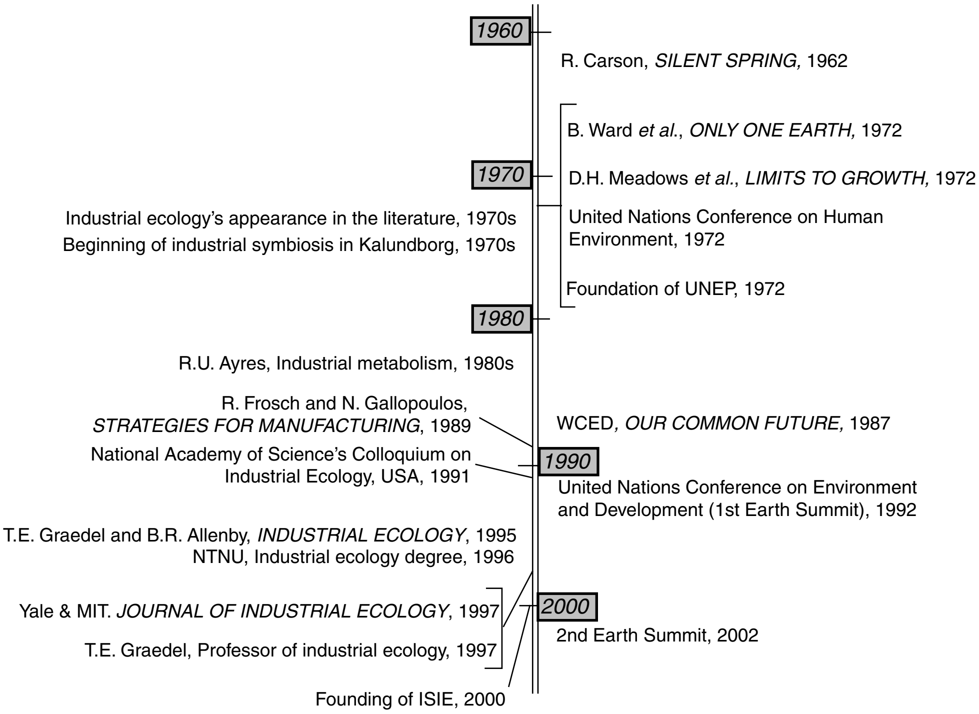


FIGURE 2 Industrial ecology and sustainable development: time line of events.

The principal terminology used in MFA studies is as follows (Graedel and Allenby, 2003, pp. 284–289; Brunner and Rechberger, 2004, pp. 34–40):

Substance: Any (chemical) element or compound composed of uniform units
Material: Substances and combinations thereof, both uniform and nonuniform
Goods: Entities of matter with a positive or negative economic value, comprised of one or more substances
Process: The operation of transforming or transporting materials
Flux: The rate at which an entity enters or leaves a process
Budget: An accounting of the receipts, disbursements, and reserves of a substance or material
Cycle: A system of connected processes that transfer and conserve substances or materials

The central principle upon which MFA is based is that of mass balance, which states that the mass of all inputs into a process equals the sum of the mass of all outputs and any mass accumulation (or depletion) that occurs within. This renders the results of MFA useful for studies of resource availability, recycling potential, environmental loss, energy analysis, and policy studies. MFA may be performed on a local scale and from a technical engineering perspective (as in Type A in Table 1), or, on a broader scale, associated with a geopolitical or socioeconomic dimension (as in Type B in Table 1; Bringezu and Moriguchi, 2002). In each case there is the potential for achieving a better understanding of the materials aspects of the process or entity under study, as well as identifying opportunities for achieving improvements.

Life-Cycle Assessment

LCA is a tool broadly used by industrial ecologists to identify and quantify the environmental impacts associated with a product, progress, service, or system across its “cradle-to-grave” life stages. Unlike the more targeted examination of a product or process in order to understand and quantify its direct environmental impacts, the use of a life-cycle perspective enables one to examine the direct and indirect environmental effects of an object through the stages of extraction of raw materials; various manufacturing, fabrication, and transportation steps; use; and disposal or recycling.

LCA began in the United States in 1969, in an effort to compare several types of beverage containers and determine which of them produced the lesser effect on natural resources and the environment (Levy, 1994; U.S. EPA, 2004). Since the 1990s, the Society for Environmental Toxicology and Chemistry in North America and Europe and the U.S. Environmental Protection Agency (EPA) have worked to promote consensus on a framework for conducting life-cycle inventory analysis and impact assessment. In 1993, the International Organization for Standardization

TABLE 1
Types of material-flow-related analysis

Type of analysis	A		
	a	b	c
Objects of primary interests	Specific environmental problems related to certain impacts per unit flow of:		
	substances	materials	products
	e.g., Cd, Cl, Pb, Zn, Hg, N, P, C, CO_2, CFC	e.g., wooden products, energy carriers, excavation, biomass, plastics	e.g., diapers, batteries, cars
	Within certain firms, sectors, regions		
	B		
	a	b	c
	Problems of environmental concern related to the throughput of:		
	firms	sectors	regions
	e.g., single plants, medium and large companies	e.g., production sectors, chemical industry, construction	e.g., total or main throughput, mass flow balance, total material requirement
	associated with substances, materials, products		

Source: Bringezu and Moriguchi, 2002. (With permission)

(ISO) included LCA in its ISO 14000 environmental certification process. As a result of these efforts, an overall LCA framework and a well-defined inventory methodology have been created.

LCA consists of three phases (Udo de Haes, 2002):

Goal and scope definition: A phase to set the purposes and boundaries of a study, such as geographic scope, impact categories, chemicals of concern, and data-availability issues

Life-cycle inventory analysis: The most objective and time-consuming process, in which the energy, water, and natural resources used to extract, produce, and distribute the product, and the resulting air emissions, water effluents, and solid wastes, are quantified

Life-cycle impact assessment: An evaluation of the ecological, human-health, and other effects of the environmental loadings identified in the inventory

These three phases are usually being followed by an *interpretation* phase in which the results from the above processes are tracked and possibilities for improvement are discussed.

Data availability and uncertainty are continuing concerns of LCA, as are the time and expense required. As a result, there have been efforts to streamline, or simplify, LCA to make it more feasible while retaining its key features (e.g., Curran, 1996).

Input-Output Analysis

IOA is a technique of quantitative economics introduced by Leontief in 1936 (Leontief *et al.*, 1983, p. 20; Polenske, 2004). In this approach, an input-output table is constructed to provide a systematic picture of the flow of goods and services among all producing and consuming sectors of an economy. IOA also registers the flow of goods and services into and out of a given region. The mathematical structure of the basic input-output models is simple:

$$\mathbf{x} - \mathbf{A}\mathbf{x} = \mathbf{y} \tag{2}$$

where **x** is a vector of outputs of industrial sectors and **y** is a vector of deliveries by the industries to final demand. **A** is a square matrix of input-output coefficients; each element a_{ij} represents the amount of sector *i*'s output purchased by sector *j* per unit of *j*'s output (Leontief *et al.*, 1983, p. 23).

IOA approaches material cycles by replacing the monetary flows with material ones. Its initial demonstration was a projection of U.S. nonfuel-minerals scenarios, completed by the creator of the input-output method in the early 1980s (Leontief *et al.*, 1983, pp. 33–205). The analogous approach for physical flows is termed a "physical input-output table" (PIOT). It is the product of the efforts of scholars from various disciplines between the 1970s and 1990s, and has been applied to establish the material accounting system of several countries (Strassert, 2001, 2002). Duchin did the pioneer work to bring the IOA approach to industrial ecology (Duchin, 1992). More recently, the IOA approach has been linked with LCA to produce a new method: economic input-output LCA (EIO-LCA; Matthews and Mitchell, 2000).

INDUSTRIAL ECOLOGY IN PRACTICE

Micro-Level Practice

Micro industrial ecology's practices are mostly centered on firms and their products and processes. Firms are the most important agents for technological innovation in market economies. The persistent supply of greener products from greener processes in facilities constitutes the microfoundations of world environmental improvement. In addition, a present firm is not a sole "policy taker" any more. To overcome the low efficiency of command-and-control environmental regulation, many firms have become "policy makers," so far as the relationship between technology and the environment is concerned.

Pollution prevention (P2), also termed "cleaner production," is industry's primary attempt to improve upon passive compliance with environmental regulations. In P2, attention is turned to reducing the generation of pollution at its source, by minimizing the use of, and optimizing the reuse or recycling of, all materials, especially hazardous ones. The pioneer of this approach is 3M's Pollution Prevention Pays (3P) program in 1975. It succeeded in avoiding 1 billion pounds of pollutant emissions and saved over $500 million for the company from 1975 to 1992. Many companies were spurred to learn 3M's approach, and according to a recent survey, pollution prevention has become an importance operational element for more than 85% of manufacturing companies (Graedel and Howard-Grenville, 2005).

While pollution prevention addresses a manufacturing facility as it finds it, design for environment (DfE) is transformational: it attempts to redesign products and processes so as to optimize environmentally related characteristics. Often used in concert with LCA, DfE enables design teams to consider issues related to the entire life cycle of products or processes, including materials selection, process design, energy efficiency, product delivery, use, and reincarnation. DfE practices are currently being implemented by many firms, large and small.

DfE is mainly a technological approach. It can address a wide range of environmental issues throughout a product's life cycle. However, its capability to address some environmental impacts, especially in disposal of end-of-life products, is limited: it can facilitate, but cannot ensure, recycling. However, the approach designated "extended producer responsibility" (EPR) complements the firm-level practice from the perspective of policy. In this regard, most Organization of Economic Cooperation and Development countries encourage manufacturers to take greater responsibility for their products in use, especially in postconsumer stages. EPR follows the "polluter pays principle," transferring the costs of waste management from local authorities to those producers with greater influence on the characteristics of products (Gertsakis et al., 2002).

It is foreseeable that the acceptance of EPR will, in turn, intensify DfE activities in many firms. We thus begin to see a sequence of environmentally related steps by responsible industrial firms. The first is pollution prevention, which is centered within a facility. The invention and adoption of LCA next expands a company's perspective to include the upstream and downstream life stages of its products. Later on, a core issue—sustainability—is brought to the table. Some assessment methods have been developed to quantify a facility's sustainability, although this remains a work in progress as of this writing.

Meso-Level Practice

Most interfirm practices of industrial ecology relate to the concept of industrial symbiosis and its realization in the form of eco-industrial parks (EIPs). As Chertow (2000b) puts it: "Industrial symbiosis engages traditionally separate industries in a collective approach to competitive advantage involving physical exchange of materials, energy, water, and/or by-products. The keys to industrial symbiosis are collaboration and the synergistic possibilities offered by geographic proximity" (314).

The classic example of industrial symbiosis is Kalundborg, a small Danish industrial area located about 100 km west of Copenhagen. Its industrial symbiosis began in the 1970s as several core partners (a power station, a refinery, and a pharmaceutical firm) sought innovative ways of managing waste materials (Cohen-Rosenthal *et al*., 2000).

Over time, many other industries and organizations have become involved; the result is a very substantial sharing of resources and a larger reduction in waste (Figure 3).

Industrial symbiosis thinking is implemented by but not confined to EIPs. Chertow (2000b) has proposed a taxonomy of five different material-exchange types of industrial symbiosis:

1. Through waste exchanges (e.g., businesses that recycle or sell recovered materials through a third party)
2. Within a facility, firm, or organization
3. Among firms co-located in a defined EIP
4. Among local firms that are not co-located
5. Among firms organized "virtually" across a broader region

Only Type 3 can be viewed as a traditional EIP. No matter which type, or on what scale, industrial symbiosis has proven to be beneficial both to industries and to the environment.

Macro-Level Practice

At macro scales (e.g., a city, a country, or even the planet), MFA has proven to be an important tool for considering the relationships between the use of materials and energy use,

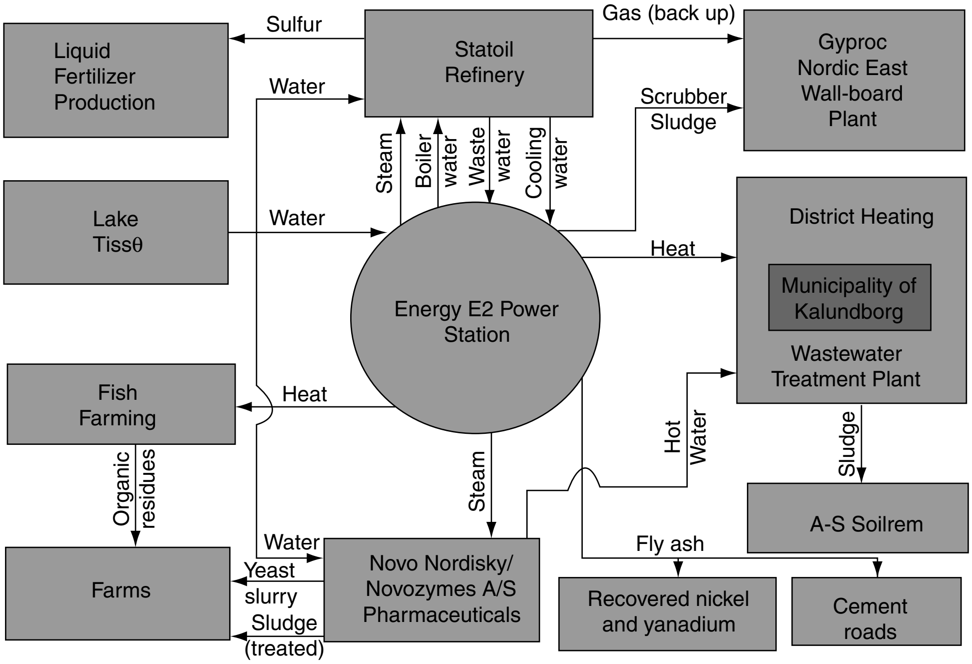

FIGURE 3 Industrial symbiosis at Kalundborg, Denmark. From Chertow, 2000b; updated by M. Chertow.

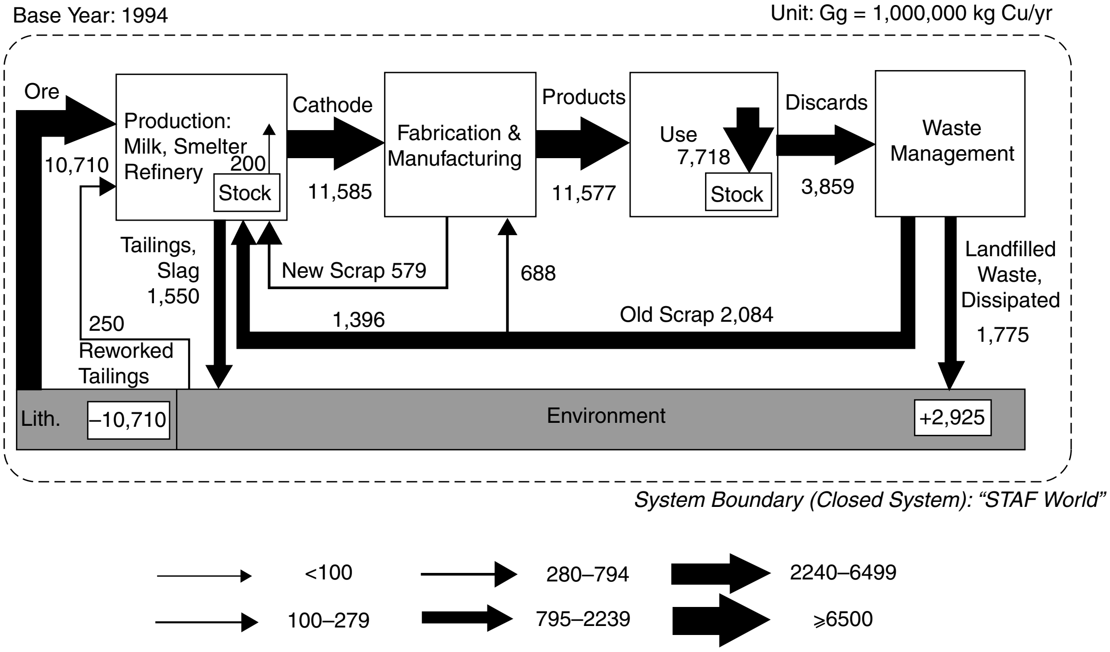

FIGURE 4 Global anthropogenic copper cycle in 1994. From Graedel *et al.*, 2004.

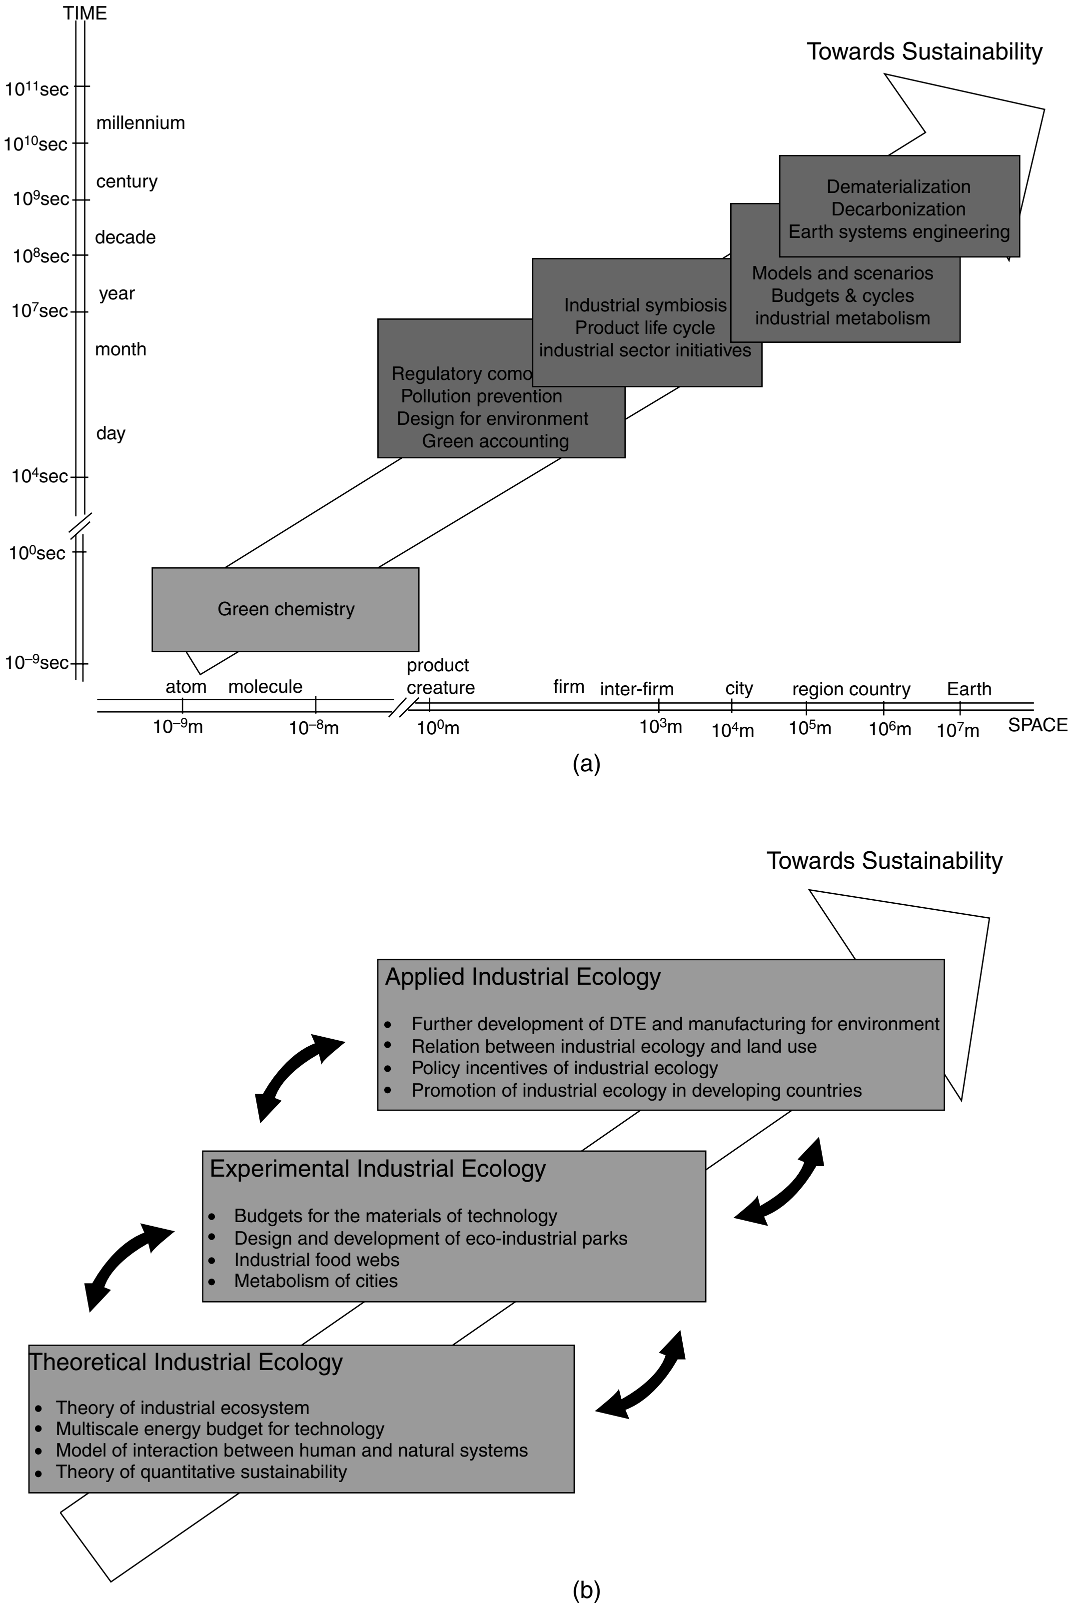

FIGURE 5 A graphical framework of industrial ecology. (a) The spacetime of industrial-ecology tools and methods; (b) An industrial-ecology roadmap.

environmental impact, and public policy. An example, the global copper cycle in 1994, is shown in Figure 4. During 1994, global copper inputs to production were about 83% ore, 11% old scrap, 4% new scrap, and 2% reworked tailings. About 12 Tg of copper entered into use, while nearly 4 Tg were discarded, giving a net addition to in-use copper stock of 7–8 Tg.

Some 53% of the copper that was discarded in various forms was recovered and reused or recycled through waste management. The total environmental loss, including tailings, slag, and landfills, was more than 3 Tg and equaled one third the rate of natural extraction. All of this information provides perspectives impossible to achieve from a less comprehensive analysis.

Material-flow studies can address another macro issue of industrial ecology—dematerialization, which is the reduction in material use per unit of service output. Dematerialization can contribute to environmental sustainability in two ways: by ameliorating material-scarcity constraints to economic development, and by reducing waste and pollution. Dematerialization may occur naturally as a consequence of new technologies (e.g., the transistor replacing the vacuum tube), but can also result from a more efficient provisioning of services, thus minimizing the number of identical products needed to provide a given service to a large population.

SUMMARY

It is difficult to provide a holistic and systematic picture of a young field with its evolving metaphors, concepts, methods, and applications. We attempt to do so graphically, however, in the "spacetime" display of Figure 5a. In this figure, the tools and methods of industrial ecology are located dimensionally, with time and space increasing from the bottom left to the upper right, as does complexity. The figure demonstrates that industrial ecology operates over very large ranges of space and time, and that its tools and methods provide a conceptual roadmap to sustainability.

As an emerging field, industrial ecology has a long list of areas where research and development are needed (Figure 5b). The urgent theoretical needs are to develop general theories for industrial-ecosystem organization and function, and to relate technology more rigorously to sustainability. Experimental industrial ecology needs to complete a set of analytical tools for the design of EIPs, the dynamics of industrial food webs, and the metabolism of cities. Finally, applied objectives can be fulfilled through maintaining the progress of DfE, developing the policy-related aspects of industrial ecology, and promoting industrial ecology in developing countries. The tasks are substantial, but carrying them out is likely to provide a crucial framework for society in the next few decades, as we seek to reconcile our use of Earth's resources with the ultimate sustainability of the planet and its inhabitants, human and otherwise.

INDUSTRIAL HYGIENE ENGINEERING

INTRODUCTION

It can be said that the industrial or occupational physician and nurse are in the front line of industrial health and the contribution they make with regard to diagnosis, establishment of causes, treatment and rehabilitation are of great importance to the health of the workers. But once the potential cause of ill health or discomfort is established it is usually the engineer who is required to design out the problems. Thus the engineer has a most positive contribution to make in the maintenance of good health amongst the working population. The engineer is in the forefront of industrial medicine and as such can make as great a contribution as the medical profession because he or she is in the position to modify the industrial process, or to apply some environmental control system to the workplace, such that workers' exposure to physical, chemical or biological insults can be minimised.

When discussing workplace pollution from airborne materials such as dusts, fumes, gases, vapours and mists, it is useful to first define the outcome of various degrees of overexposure which may result from ineffective, faulty or non-existent pollution controls. In simple terms these may be considered under the categories shown below:

1) The stochastic effects, where the probability of developing a disease increases with dose, as with carcinogens or sensitizers.
2) The acute effects, characterized by rapid absorption and effect due to sudden exposure, typical of asphyxiants.
3) The subacute effects, resulting from repeated and extended exposures over a period of hours or days, an example of which would be the early symptoms of narcosis.
4) The chronic effects, resulting from continued absorption over a long period of time, e.g., materials leading to fibrosis of the lung.
5) The combination of any of the above.

The effects of exposure of workers to heat, noise and radiation also fall into the above categories. Not only will the degree of control depend upon the potential hazard but the requirement for back up and monitoring systems will, to a great extent, be determined by the potential consequences of failure of the control measures. This chapter will discuss in further detail the engineering considerations in designing control measures for workplace environments.

In designing control systems it is necessary to define the objectives such that the alternative engineering options can be seen in perspective. The basic techniques of workplace control are: substitution of a less hazardous material or process, segregation or enclosure of the operation, suppression of emission, ventilation extraction at source, ventilation dilution to reduce concentration in the general atmosphere.

The success of the selected control method will be judged by its ability to reduce personal risk by minimizing worker exposure and absorption. Furthermore the control method should remain effective and maintain the same degree of protection over the working life of the process.

Unfortunately, failure and ineffectiveness of control systems are only too well known and examples are common: enclosures that are left open: ventilation systems that fall into disrepair or are not used due to shopfloor objections to noise, or cold draughts produced as a result of careless or incompetent design; work procedures that are impossible to follow; personal protection that cannot be worn for any length of time. Many more examples could be cited but to the unfortunate recipient failure to protect means a risk to health irrespective of the reason.

Potential risk should be assessed by examining the possible results of failure of the control system. Where chronic hazards exist an occasional transient failure may not be too serious but in the case of sensitizers and carcinogens any overexposure could have serious implications, and, in the case of asphyxiants, failure could be fatal. Thus, in the case of acute hazards the control system should be adequate to prevent even momentary peaks above the control limit. On the other hand, where there are no materials with serious acute hazards, short excursions above a chosen standard level may be permissible provided that the average dose is controlled. Where potential failure could have serious consequences then the engineering software specifications need to be more stringent, i.e., there may be a need for built-in redundancy and back-up controls. The interpretation of control standards and specifications should only be undertaken by a competent industrial hygienist.

As the achievement of comfort is also an objective, physiological and psychological factors should not be overlooked. To allow for human factors in designing controls it is necessary to move outside the realm of pure engineering.

A successful control technique can only be designed by a systematic approach, looking at both hardware and software requirements. Each aspect of the problem can be seen as a link in a chain, if one link fails the worker can become over-exposed to the hazard.

Using the philosophy of preferring a safe place to a safe person, it is usual to examine first the source of the hazard then working backwards to those at risk. When examining the suitability of any strategy it is important to be clear about the degree of protection offered and the consequence of any failure of the control systems.

It is usually best to consider the choice of engineering control systems in the order in which the problem evolves, that is: first tackle the source, then the means of transmission and lastly the exposed population.

The Source

The purpose of dealing with the source is to reduce the potential for emission and this can be achieved in a variety of ways depending upon the nature of the operation.

1) The process: the problem may be eliminated by changing the process so that no hazard is created.
2) Substitution: by replacing the toxic material for one with a lower hazard potential.
3) Enclosure: plant and layouts can be modified to isolate the source of emission or where possible enclosures can be built around the sources.
4) Extract ventilation: where toxic materials are being released into the atmosphere extraction at the source can capture any emitted substances.
5) Suppression at source: wet methods can be used to prevent dust being emitted provided means are available to handle the wetted dust and drying out is prevented.

The Means of Transmission

Once the material is released the means of transmission is usually the air which is eventually breathed by the worker. Thus the hazard can be reduced by one of the following means:

1) Isolation: working systems can be devised to ensure that at times of noxious emission the area is unoccupied or workers are located at sufficient distance to reduce exposure to an acceptable level.
2) Ventilation: in the case of airborne pollutants their concentration can be reduced by dilution ventilation or the workers can be bathed in a supply of cleaned fresh uncontaminated air; in the case of heat the air may be treated via an air conditioning system.
3) Shielding: certain radiations can be blocked by a shield between the source and the worker.

The Exposed Population

Finally, the worker's exposure can be minimized by examining his position in relation to the hazard as follows:

1) Enclosure: the worker can be enclosed in a suitably treated and conditioned refuge.
2) Job Rotation: the duration of exposure and hence the absorbed dose can be reduced by suitable job rotation involving a larger number of workers over a shorter period.
3) Education, Training and Method Study: the workers' awareness of potential hazards can be heightened by training linked to a careful examination of the work methods that are being adopted.
4) Personal Protection: respirators, resistant clothing, hearing defenders, can be employed to reduce contact and to shield exposed and vulnerable parts of the body.
5) Automation: use of automation to either eliminate or reduce the exposure time of the worker is a costly but sometimes necessary alternative.

THE HARDWARE

Control at Source

By far the best approach to minimizing emission at source is to modify the process or the material, provided care is taken to ensure that alternative hazards are not created. The substitution of a safer material for a toxic one has commonly been adopted, typical examples being in the case of paint solvents where xylene and toluene were substituted for the carcinogenic benzene and in foundry work where shot blasting was substituted for silicosis inducing sand blasting.

More commonly it is possible to rearrange the work procedure and methods so that emissions are minimized. Where powders and friable materials such as minerals are transported within a process, the greatest emissions of dust usually occur at the points of transfer from one container to another or from one mode of transport to another. Bags of raw material are emptied into hoppers, hoppers feed on to conveyors, conveyors tip onto other conveyors or to bins; powders are shovelled or blended by hand into open vessels, each stage of the process releasing dust into the air. Where volatile liquids are used they are often poured from one vessel to another or left standing uncovered for periods of time. Where surface coatings are applied, volatile solvents have to evaporate or cure before the coating is complete. This also applies to quick drying printing inks. In many cases the coated surfaces are allowed to dry in the open air of the workplace.

In most cases the emission of dust and vapours can be minimized by enclosure or by redesigning the process so that the escape of pollutants is reduced. The enclosures can be fitted with extract ventilation but often it is just sufficient to enclose as much as possible allowing minimal openings for access. If it is necessary to fit extraction then the smaller the cross-sectional area of the openings the lower the ventilation rate need be. Unfortunately, enclosure obscures visibility, thus where it is necessary to observe the process inside, provision has to be made for simple viewing panels of plate glass or transparent plastic. Video monitors or electronic indicators can also be used.

Redesign of processes can be as simple as fitting special covers on containers and matching discharge ports to entry holes or as complicated as total automatic handling throughout. With materials handling dramatic improvements on hygiene can often be achieved by using sealed transfer systems, eliminating the potential for inhalation and skin contact. Where liquids are transferred the simple use of a discharge nozzle extending below the liquid surface can reduce the evaporation. It is wise to think through every stage of the process noting places where emission is highest. An experienced outsider can often notice features which are missed by the people who are in closest contact. This should be done before the costly expedient of extract ventilation is adopted.

When redesigning new plant it is important to involve experienced health, hygiene and safety professionals in the early stages as often the environmental aspect of production processes are considered too late to have any effect on the installation. Often plant is installed and commissioned before environmental hazards are realized and then there is a great reluctance to make modifications. It should be borne in mind that the high apparent cost of process redesign can often be offset against the reduced capital and running costs of supplementary control, monitoring and maintenance which is required of an inferior process. Also the relation between workforce and management is greatly improved with obviously safer processes.

Extract Ventilation If it is difficult to adopt process redesign or satisfactory enclosure then pollutants can be captured before they are generally released by means of some type of hood, slot or enclosure inside which a negative air pressure has been generated. Air will thus flow in by virtue of the difference in pressure between the mouth of the device and the surround. If the contamination from the process can be moved into the hood by means of the airflow, then some degree of control will be achieved. The air in the hood is removed by a fan via ducting to an outlet or air cleaning system. Any contaminant not drawn in will remain free to disperse within the workroom where it may be inhaled by the operator or other personnel. It is therefore important to consider the patterns of the airstream in the vicinity of the work where the success or failure of the extract system is often determined.

Providing no obstructions exist around a hood, then air will flow in from all directions in a zone of influence which is approximately spherical in shape with the mouth of the hood at its center (Figure 1). The air velocity at any point in that sphere being approximately related to the hood entry velocity by the inverse square of the distance from the hood (Dallavale, 1952).[10] By careful selection and location of screens the shape of the airstreams can be adjusted to reduce unwanted airflow from uncontaminated areas thus increasing the flow of air drawn through the zone of pollution emission.

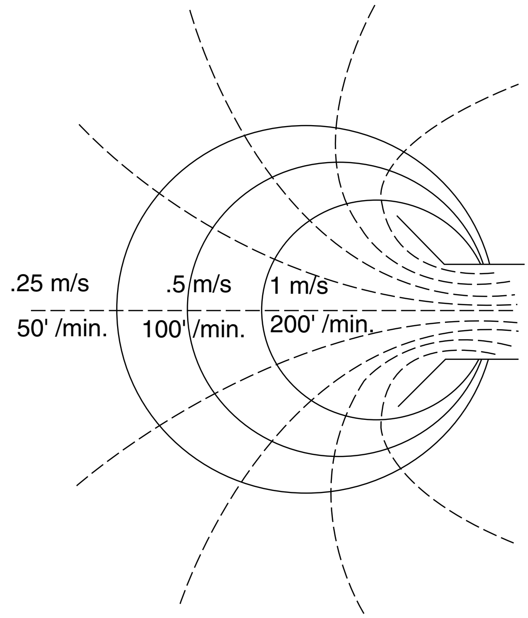

FIGURE 1 Airflow patterns and velocity contours at the mouth of a suction inlet.

For most operations a minimum velocity (capture velocity) is defined as that velocity at which the energy of motion of the contaminant can be overcome thus drawing it into the hood. In the case of the release of welding fumes for example a velocity of at least 0.5 m/s (100 ft/min) is usually required to overcome the thermal motion of the plume (ACGIH). In processes where the velocity of emission of the contaminants is high as with grinding or where high cross draughts exist then higher capture velocities may be necessary. Conversely in certain work, such as paint finishes and gas shielded welding, too high an airflow may affect the finished product. Thus a control envelope bounded by upper and lower velocity contours may have to be defined. That is, the hood should be sited so that the source of pollution lies between chosen velocity contours and preferably on the centerline of the slot.

Centreline velocities can be predicted in relation to the distance from the mouth of the opening using the expressions given below (Fletcher, 1977).[12]

$$\frac{VA}{Q} = \frac{V}{V_0} = \frac{1}{0.93 + 8.58\alpha^2}$$

where

$$-\alpha = xA^{-1/2}\left(\frac{W}{L}\right)^{-\beta}$$

and

$$\beta = 0.2\left(xA^{-1/2}\right)^{-1/3}$$

and

V = centreline velocity at distance x from the hood

V_0 = mean velocity at face of hood

L = length of hood

W = width of hood

$A = L \times W$

Q = required volume flow rate.

The solution of these expressions can be made simpler by the use of the nomogram in Figure 2.

In the use of the above expressions the dimensions L and W will depend upon the size and shape of the point or points of emission of the pollutant, V should be the capture velocity and Q will be the calculated volume flow rate of air to provide the required capture velocity at distance x from the hood.

The relative location of the operator, hood and source of contaminant can also have considerable bearing on the effectiveness of control. Whilst a system utilising the flow energy of the plume to assist the airflow may require less air volume, this will be ineffective if the operator is located between the source and the hood. It should be borne in mind that the operator is acting as a bluff body in a streamline airflow, creating turbulence which can bring back contaminants into the breathing zone. Exposure levels will also be contributed to by secondary emission from contaminants that are not captured. The shape of the workpiece can also influence airflow patterns at the point of emission directing contaminants to remote areas away from the mouth of the hood. In welding, for example, whilst stance and the use of a headshield can help to minimize these effects (Akbarckhanzadeh, 1979) there will still be some residual fume and gases in the breathing zone when using simple extraction hoods or slots.

When designing a hood for ventilation control, it is better to start with an idea of providing maximum enclosure of the source of contaminant. Thus it is prudent to design a booth or enclosure first then progressively remove sections of it to make a practical design. Unfortunately as the size of the openings increase so does the required volume flow rate of air and effectiveness of the extraction may decrease. The use of cardboard and a portable fan to produce a full scale "mock up" model can be an invaluable aid to empirical design, giving an opportunity to judge control effectiveness and ergonomic performance.

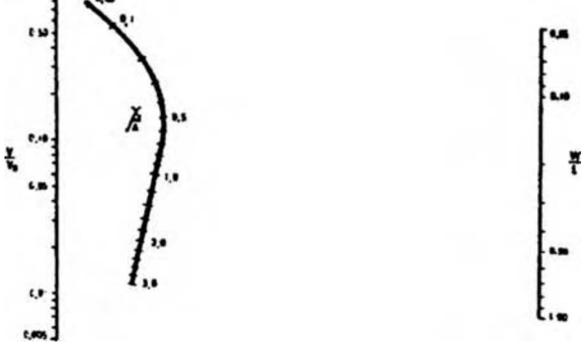

FIGURE 2 Nomogram for the solution of hood entry equations.

Difficulties arise where work processes require access on all sides to facilitate production techniques or where the source of contamination is moving. In the case of benchwork requiring all-round access, narrow slots pulling over a short distance or assisted by supply jets (Hughes, 1988)[16] of air can be used, as can perforated or slotted bench tops through which air is drawn, thus the ventilation hardware occupies the minimum of space. Where moving sources of pollution occur it is possible to use hoods with flexible ducting supported on cantilever arms or crane type supports allowing flexibility over a wide area. It may be necessary to provide clamps or other devices to ensure that the hood is located to achieve good capture and will move with the source. Care must be taken to ensure that the use of the extract system does not hinder the operation or it may fall into disuse to operator resistance. Operationally portable hoods often fail to achieve the degree of control required due to the practical imposition of regularly having to accurately reposition the device, thus it is important to ensure that such devices are lightweight, well balanced and quick and simple for the operator to use.

The hood may also be designed and built into the tool as with portable sanders, grinders and saws. This technique known as low volume high velocity (LVHV) exhaust uses small volumes of air at relatively high velocities. The hood can be an annular slot or multi-hole type operating on a vacuum of 20 kPa (150 mm Hg) at a volume of 16 liter/sec (35 ft^3/min). When these are accurately positioned much of the contaminant can be controlled. However, although this system has the advantage of low volume requirements and portability there are several disadvantages which often preclude its use. The LVHV head has a limited envelope of control due to the low volume of air extracted and workpiece shape, misalignment of exhaust orifice or lack of maintenance can seriously disrupt the efficiency of collection. The weight of the tool plus its extract also presents problems of manoeeverability and acceptability to workers.

Transmission

Once the pollutant has escaped from its source and is airborne or is broadcast many workers in the vicinity can be at risk. With wide area sources capture may be impossible.

Segregation of the worker from the source of pollution by carefully planned production routines can often be used to reduce the potential for exposure. For example processes which give rise to airborne materials can be carried out in separate areas or at times when the building is otherwise unoccupied, operators remaining in the areas can be provided with protective clothing. Local extraction, as described in the previous section can be employed but its effectiveness is limited because of the wide area now involved. Therefore it may be necessary to resort to diluting the airborne material to a safe level by providing quantities of uncontaminated air sufficient for the purpose.

General Ventilation Although control efficiency is considerably less than with a well designed extract system the technique is usually easy to operate and is less susceptible to mechanical or software failure. But because of its limitation it should only be applied to places where the pollutant is of low toxicity and such that localized clouds of high concentrations cannot occur.

Dilution ventilation is based on the fact that a cloud of contaminant mixes with the surrounding air thus reducing the concentration in the resulting mix.

Assuming complete mixing the concentration of a pollutant emitted at a rate of R m^3/s into an airstream flowing at a rate of Q m^3/s is given by:

concentration (in m^3 of pollutant per m^3 of air)

$$= \frac{R}{Q}$$

but is more commonly expressed as a percentage.

$$\text{Concentration (per cent)} = \frac{R}{Q} \times 100$$

or a parts per million

$$\text{concentration (ppm)} = \frac{R}{Q} \times 10^6.$$

These concentrations are expressed as volume for volume but if a mass per volume concentration is required then the density of the substance should be used as shown below:

$$\text{mass concentration (in kg/m}^3\text{)} = \frac{R}{Q} \times D$$

where D is the density of the airborne substance in kg/m^3

$$\text{or mass concentration (in mg/m}^3\text{)} = \frac{R}{Q} \times D \times 10^6.$$

It must be noted that in the case of airborne solvent vapors the density of the vapor is not the same as the density of the liquid but can be calculated from:

$$\text{Vapor density at STP} = \frac{M}{22.4}\ \text{Kg/m}^3$$

where M is the molecular mass of the vapor.

With dilution ventilation it is necessary to calculate the required volume flow rate of air to dilute the pollutant to a desired concentration i.e. to the TLV or below. The calculation can be summarized in the following expressions:—

$$\text{Required flow rate } Q = \frac{R \times 10^6 \times K}{C}$$

where C is the chosen concentration of the pollutant in parts per million and K is a safety factor. The units of R and Q must be consistent, that is, if R is in m^3/s then Q will be the same.

Where the solvent vapors are concerned Q can be found by:—

$$Q = \frac{r \times 22.4 \times 10^6 \times K}{M \times \mathrm{C}}\ \text{m}^3/\text{s}$$

where r is the rate of evaporation of the solvent in kg/s.

The determination of the safety factor K is a matter of judgment and experience and depends upon the relationship between the source of pollution and the airflow distribution of the diluting air, the uniformity of emission and the toxicity of the pollutant. Where there is good mixing between the diluting air and the pollutant and rates of emission are uniform and the pollutant is of a low toxicity then K could be as low as 2 or 3.

The figures calculated from the above formulae should be used with great caution as dilution on its own has little effect on the source of contaminant, serving only to reduce the workers' exposure by minimizing the dose accumulated from the general working environment. If the pattern of airflow in the vicinity of the operator can be modified then a greater effect on the breathing zone concentration can be achieved (see section, *Displacement*).

In practice, airflow patterns in buildings are complex, the energy of motion of the contaminant often giving rise to a plume effect which can remain in a concentrated cloud for some time. Considerable energy in the form of a high air velocity would be required to disperse it. In the case of hot fume the plume can rise and form a layer in the upper parts of the building and some gases in their concentrated form can also do this if they are less dense than air. Likewise concentrated clouds of denser gas released into still air can form layers in the floor or pour into sumps and trenches. When dispersing such accumulations air velocities in excess of 2 m/s (400 ft/min) are required but the whole operation must be undertaken with care to prevent spread into other occupied areas.

However if there is no risk of a contaminant with acute hazard potential accumulating in areas which may become occupied, then the motion of a concentrated plume may be used to good effect. Careful location of screening and exhaust points can be used to remove the concentrated material without the need to distribute and dilute. As a result much greater effectiveness can be achieved at much lower air volumes. Here empirical studies of contaminant flow patterns are required to assess ventilation requirement, the previous formulae being inappropriate.

The Exposed Population

Where the hazard cannot be controlled at source or is not effectively controlled during the transmission stage then it is necessary to examine the exposed population in order to engineer an environment around them which will minimize their exposure.

This can be done in three ways:

1) released into still air by air displacement so that they are bathed in an uncontaminated airstream,
2) by the use of conditioned refuges or enclosures,
3) by the provision of personal protective clothing.

Displacement Correct selection of airflow patterns can serve to reduce the flow of airborne contamination in the breathing zone. Displacement depends upon the creation of a diffused clean air flow over the worker and towards the work, thus carrying away the products of the work, preferably towards some form of extraction system. The provision of work station supply ventilation also has corresponding economies in the volumes of air required, as compared to a system ventilating the whole building. Thus, displacement at the work station can help to reduce the high cost of heating replacement air during winter months. However, care must be taken to ensure that local turbulence is minimized so that the effectiveness of the control is maintained. This technique is most suited to well defined work stations. Working posture and stance also needs to be carefully considered to ensure success.

Thermal comfort of the worker must be considered so that the combination of air temperature and velocity is such that cold draughts are not experienced at the work station. To this end the air supply diffusers must be carefully chosen and the supply air temperature accurately controlled to suit the air velocity at the worker. This is particularly important where air is discharged from above and behind the worker as the back, the neck and the back of the head are parts of the body most sensitive to cold draughts. It should be noted that air at a temperature above normal room temperature can feel cold if it is flowing at a sufficiently high velocity. Charts showing the relationship between air velocity and temperature and the part of the body affected (Houghton *et al.*, 1938) in a room at 24°C are shown in Figure 3.

The relationship is expressed as the number of people complaining of discomfort as a percentage of the number tested. As an example from Figure 3 it can be seen that a draught velocity of 0.2 m/s at a temperature of 1.0°C below room ambient of 24°C blowing on occupants' necks will give a feeling of coolness and will not be acceptable to 20% of the room occupants whereas the same draught blowing on the ankle region will discomfort only about 9% of the occupants.

Conditioned Refuges Isolating the worker from an uncongenial environment is a technique which is often adopted where the process being worked is too large or too expensive to control locally. Isolation cubicles can be used to protect from noise, ionizing radiation, heat and cold as well as from airborne toxins. in most cases the enclosure will require ventilating and possibly air conditioning and the amounts of air to be supplied will require some calculation. As a general rule each person enclosed will require 10 litre/sec of fresh air but this amount can be varied depending upon the size of the enclosure and whether smoking is permitted or not.

If air conditioning is required the airflow rate will generally be in excess of that required for fresh air alone and some recirculation will be normal. The volume of air required for air conditioning will depend upon the heat gain to the space and can be calculated from the expression:—

$$Q = \frac{S}{1.2\Delta t}\ \text{m}^3/\text{s}$$

where

S = the sensible heat gain to the room in kW
Δt = the difference in temperature between the room air and the supplied conditioned air °C.

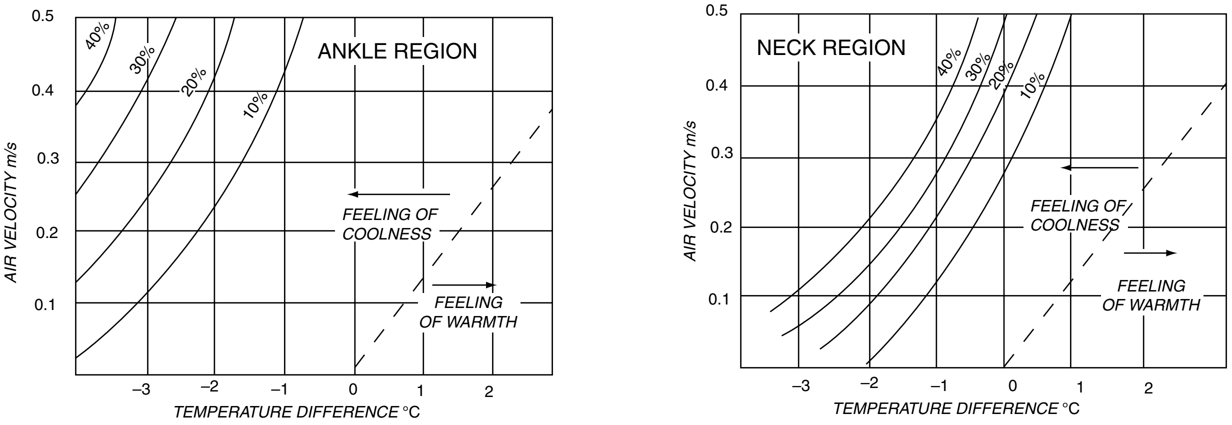

FIGURE 3 Percentage of room occupants objecting to draughts.

Thus a balance has to be made between Q and Δt and this will be influenced by draughts as illustrated in Figure 3.

Personal protection Often considered to be the last resort in reducing worker dose it has been shown (Crockford, 1976)[8] that personal protection can play a major role in an "integrated control programme". It can be used as a single control item as a tool to assist in the smooth operation of a process or it can be used as a "fall back" feature as part of a system with built in redundancy. It has most application where the area of emission is too large to be effectively controlled by other means or in operations where the hazard only occurs for periods of short duration and in a predictable manner and where the alternative control measures are too costly to be a reasonable alternative.

Hitherto most respiratory protective equipment has been uncomfortable to wear for long periods and workers have been reluctant to make full use of it but with the introduction of the self-contained ventilated helmets much of the worker resistance has disappeared. The development of such helmets has put a new light on protection in hitherto traditionally dusty industries.

Finally, aspects of personal hygiene can be included in this section. Absorption by routes other than inhalation can be minimized by frequent washing, the provision of clean work clothing daily, the prevention of eating, drinking and smoking in the workplace.

Ventilation System Design

From the formulae and diagrams already given, having determined the volume flow rate of air to undertake a specific ventilation task and, in the case of extraction, having established the dimensions of the inlet it is necessary to design the remainder of the hardware that make up the ventilation system. Textbooks abound in this topic (Hemeon, 1963; Alden and Kane, 1970; McDermot, 1976) so only an outline of the procedures involved will be given.

Hoods etc. In the case of the extract hood many configurations are given (ACGIH, 1995) to suit a variety of workplace situations. But as every workplace and building varies it is necessary to adapt the designs to fit. This should be done in conjunction with a production engineer so that the flow of the work is not hindered by the presence of the ventilation hardware which tends to impede the transport of raw materials, finished products and can restrict the mobility and visibility of the workforce.

Ducts With regard to ducting to transport air from one part of the workplace to another it is necessary to sketch on a plan and elevation of the workshop the best position for it to be sited. It is usually more convenient to site in the roof, ceiling or spaces above the workplace but the accessibility of overhead cranage must be considered in the layout.

Fittings such as bends, changes of section, branch pieces and dampers are necessary to accommodate multiple intakes and to avoid obstructions forming part of the building fabric or production equipment. Thus the installation will consist of lengths of straight duct plus fittings. As more fittings are added and the duct runs become longer and more complex so the energy required to transport the air increases.

Having sketched the layout it is then necessary to determine the dimensions of each item. For identification purposes it is useful to label each section where there is a change of dimension or direction of airflow. Thus each component can be labelled as AB, BC, etc. and, as such, is suitable for entering into a computer ducting program (Malchaire, 1981; Clapp *et al.*, 1982; Betts, 1984).

With regard to straight ducts the cross-sectional shape can be either rectangular or circular but cross-sectional area is important.

For a given airflow rate the narrower the duct the higher the average air velocity as given by the simple expression:

$$\text{Volume flow rate, } Q = VA$$

where A is the cross-sectional area of the duct at the point where V is known. Where airborne particles are to be conveyed via the ducting then a minimum air velocity must be maintained that will prevent the particles from settling out inside. This velocity is known as the *Transport Velocity* and will vary with the type of particle being transported but as a guide a velocity of 20 m/s (4000 ft/min) will ensure that most particles remain airborne.

Thus having established a volume flow rate and a transport velocity, the cross-sectional area is determined from the above formula. In this situation a circular cross-section is more suitable.

Where transport velocities are not important then a compromise has to be made between the higher energy consumption of narrow ducting and the higher capital cost of wide ducting. Also the passage of air through ducts creates noise which can become obtrusive in quiet situations. As a general rule air-speeds in excess of 5 m/s (1000 ft/min) can create noticeable noise. The cross-sectional shape of the duct is influenced by the size of the space into which it is to be fitted. A circular section will always use less material than a rectangular for a given area but often it is easier to fit rectangular ducts into areas where space is limited as in false ceilings of buildings.

The energy required to move air through the ducting is expressed as a pressure which is necessary to overcome fractional resistance and turbulence caused by the materials of manufacture. Ducting is commonly made of galvanized sheet steel but other materials such as brick, concrete and various plastics can be used each of which provides a different frictional resistance. Charts are published (ACGIH, 1988; CIBS, 1970) giving pressure losses for various diameters of duct for a wide range of airflow rates. If other materials are used the ducting can be assumed to be of sheet steel as above but the resulting pressure losses must be multiplied by a factor depending upon the nature of the material. These factors are published for the commoner materials (CIBS, 1970) or are available from the manufacturer.

Pressure losses in the fittings can either be calculated as an equivalent length of straight duct (ACGIH, 1988) or by a factor which must be multiplied by the velocity pressure in the ductwork (CIBS, 1970; Daley, 1978).

In order to establish the type and size of fan to provide the motive power to move the air it is necessary to establish the total pressure loss throughout the system by adding the losses for each item from one end to the other including any filters and discharge louvres. The chosen volume flow rate plus the total pressure required will identify the fan which can be chosen from catalogues. If a multi-branched system having several extract or supply points is designed then the total volume flow of the fan is the sum of the flows in each of the terminals but the total pressure loss is that from the furthest end to the other and must not include pressures lost in intermediate branches.

Multi-branch duct systems need to be properly balanced to ensure that the correct flow rate is passing through each branch. This can be done either by inserting dampers in each branch and adjusting the dampers to provide the correct flow or by inherently balancing the system by careful selection of duct sizes in each branch, also constant volume flow devices can be inserted to automatically set the branch to the required flow. Where dust is to be carried then any obstruction inside the duct such as a damper becomes a place on which dust can be trapped leading to possible deposition and alteration of flow characteristics, therefore inherent balancing is to be preferred.

Also damper balanced systems have the disadvantage that individual control dampers can be tampered with and adjusted to the detriment of all the other branches in the system. Once a system is balanced then the dampers should be locked in their set positions.

Fans Fan types vary widely and are named: propeller, axial flow, cross flow, mixed flow and centrifugal depending upon their geometric shape. Some have their electric motors in the airstream and some have them outside. If dirty, hot or corrosive air is handled then it is important to ensure that the motor is out of the airstream. Also many atmospheres contain inflammable gases or vapours then flameproof motors and switchgear are required to minimize explosion risks. In some countries it is a legal requirement that where handling flammable gas mixtures, fan motors must also be out of the airstream.

Fan impellers and casings are made of various materials to suit the type of air and contaminant that is being handled. Corrosive contaminants will quickly destroy mild steel fans; thus plastic or stainless steel is required, this would also apply to the materials of the ductwork and fittings. Also impellers accidentally striking the casing as they rotate can give rise to sparking thus where there is an explosion or fire risk materials that produce high temperature or high energy sparks such as aluminium or magnesium or any alloys of those elements must not be used.

A fan performs according to a characteristic curve of pressure against volume flow rate which depends upon its geometric shape and speed of rotation of the impeller (Figures 4–6). The position of the duty point on this curve is governed by the resistance to airflow of the ventilation system against which it has to work. The resistance of the system can be represented by a curve whose shape is a parabola passing through the origin of the form: resistance pressure proportional to volume flow rate squared ($p \propto Q^2$); see Figure 7. The fan efficiency also varies over its range of duties; thus, it is important to choose one whose duty point on the system lies on the most efficient part of the characteristic curve. The manufacturer will advise on this and most fan catalogues indicate efficiencies.

The majority of fans are driven by electric motors although other sources of motive power can be used. Fan drives can either be direct, where the impeller is keyed on to the shaft of the motor or through some drive arrangements such as V-belts and pulleys, gearboxes or variable speed couplings. It is unusual for direct driven fans to be variable in speed unless the electric motor itself has the facility of speech change. Changes of speed can be arranged with V-belt drives

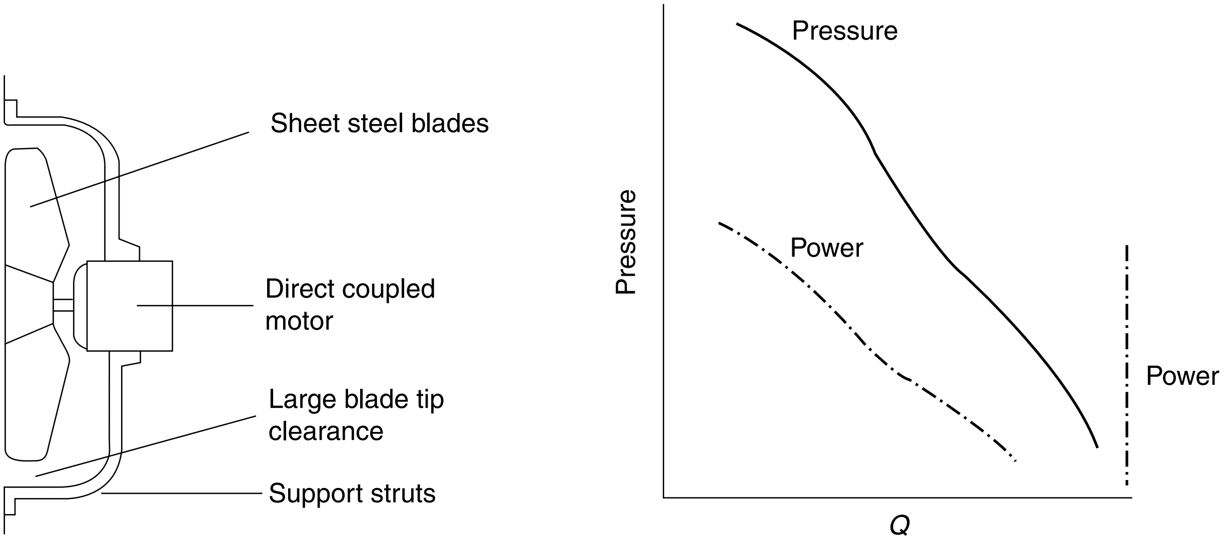

FIGURE 4 Propeller fan and graph showing its characteristic curves.

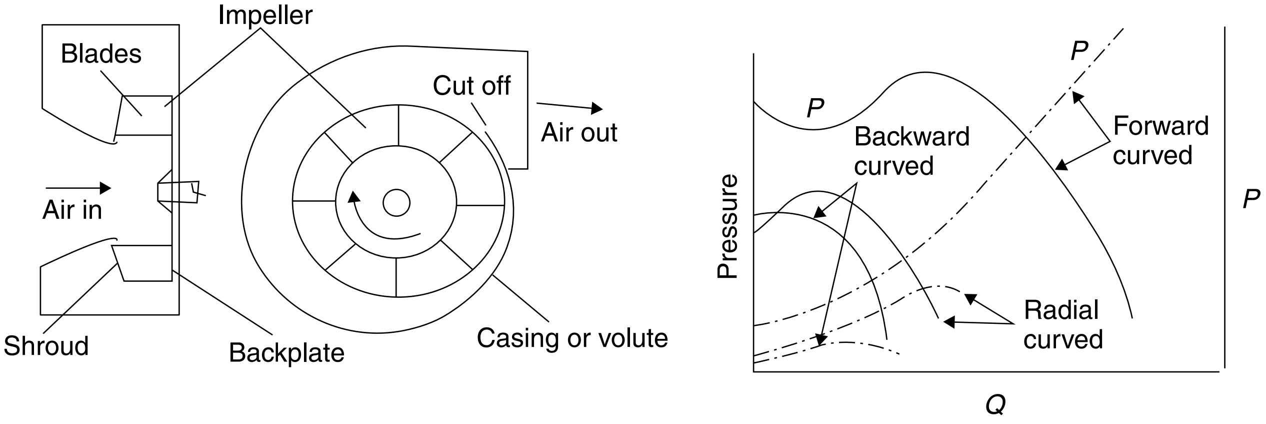

FIGURE 6 Centrifugal fan and graph showing its characteristic curves.

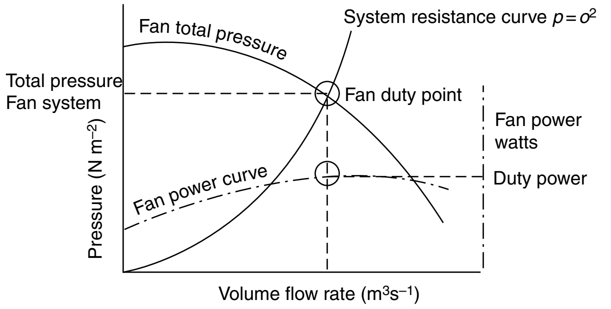

FIGURE 7 Matching of fan and system.

by changing the diameter of the drive and driven pulleys and with gearboxes by changing the spur wheels. If increases in fan speed are contemplated they should be done in consultation with the manufacturer as motor and shaft loadings, impeller materials and bearing sizes are designed for a particular maximum duty and power in mind and any increase over and above the manufacturers' maximum can lead to failure of one of the above components and could cause a serious accident.

Air Cleaning and Filtration This topic can be divided into two fields of speciality depending upon the nature of the dust and its concentration in the airstream. Where air is supplied to a workplace from outside then its particulate concentration is low but of a wide range of sizes and materials. Filtration is required to clean it to the standard required of that workplace, which in some cases can be very stringent, for example, in clean room atmospheres.

In the case of captured air from a dust emission source the loadings can be very high but often of a specified material and of a limited size range often much larger in aerodynamic diameter than with external air pollution. This requires the use of different techniques to provide the necessary air quality standard.

In the former case filtration is by inertial separation using the particles' changes of direction as it zig-zags its way through dry fabric filter media. The particle is caught on the surface of the material which is sometimes coated with a viscous medium to assist capture and to improve loading capacity. The size of the particle captured will depend upon the matrix size of the medium. Filter materials consist of cotton, wool, nylon, viscose fibers, paper, glass fiber, asbestos, cellulose and many others and are either packed in disposable cells or are on a continuous roll which is automatically wound on as the resistance increases.

Where high concentration particulate cleaning is involved mechanical devices imparting centrifugal action are used to collect the larger particles. Cyclone separators and other dry centrifugal cleaners can be used but where particles are sticky or in a moist atmosphere wet methods such as venturi scrubbers, water cabinets, and wet centrifugal devices are employed. These techniques are more effective for large particles rather than small which require large area dry fabric devices such as bag and sleeve filters with reverse jet purging. Where higher collection efficiencies are required for smaller particles then multi-stage filtration using as the last stage inertial filters, may also be used. Cleaning air for gaseous pollutants is more difficult involving a variety of tower scrubbers, washers and absorbers (Dorman, 1974).

Energy and Cost Implications of Extract Ventilation The energy required to provide extraction ventilation can be considered in two parts: that which is required to move the air through the system to overcome the friction losses and that which is required to heat incoming air from outside to replace that which is discarded.

Friction losses The power required to overcome the friction losses can be calculated from the simple expression:

$$\text{Power} = \frac{pQ}{\eta}\,\text{Watt}\,(\text{Joule/sec})$$

where

p = total pressure loss through the system in Pa (N/m^2)
Q = total volume flow rate flowing in m^3/s
η = overall efficiency of the fan and prime mover, usually the fan drive and motor.

Thus, if the system is run continuously for a period of time, the total energy required can be calculated in kJ or kW hours and converted to a monetary equivalent based upon the fuel tariff in operation.

Replacement Air Whenever air is thrown away to outside, replacement air enters the building. This may enter via a properly designed make-up air system or it can find its way in via breaks in the building fabric such as doors, windows, discontinuities in the building. No matter which way it enters, if the building is to be maintained at comfort condition, then entering air requires tempering, usually in the form of heating in the winter and in some places cooling in the summer. The theoretical power required can be calculated from the formula

$$\text{Power} = \rho V \cdot C \Delta t \; Watt$$

where

V is the volume flow rate of air entering m^3/s
ρ is the density of that air in kg/m^3
C is the specific heat of the air in kJ/kg°C
Δt is the difference in temperature between inside air and outside.

For most engineering applications this formula can be approximated to power $= 1.2V\,\Delta t$ Watt. Figure 8 shows a chart for calculating power required for heating and friction losses.

When the duration of operation is taken into account the overall theoretical cost of heating or cooling can be calculated, but it must be remembered that the type of fuel and the efficiency of conversion and tariff in operation at the time must be considered in order to obtain a realistic costing.

In most situations at most times of the year the cost of tempering the incoming air far outweighs the friction costs (Gill, 1980)[13].

Difficulties with Extract Systems

Many systems are unpopular or unsuccessful because they allow the pollutants to escape in sufficient volumes to hazard workers health or comfort. Faulty design, installation, maintenance and procedures can all lead to difficulties. Some of the commoner faults found under these headings are listed below.

Faulty Design

1) The point of release for the pollutant is too far away from the suction inlet,
2) insufficient enclosure has been provided to prevent the escape of pollutants,
3) the airflow may be restricted by a poor backup ductwork system,
4) the wrong fan has been chosen,
5) the fan performance may be restricted due to bad inlet conditions,
6) outside wind and weather conditions are affecting the system,
7) if multi-branched, the system may be out of balance,
8) no provision made for heated "make-up" air to enter,
9) discharges adjacent to air inlets, allowing recirculation of contaminant.

Faulty Installation

1) Fans wired wrongly affecting their direction of rotation leading to reversed flow,
2) with two stage fans, one stage installed the wrong way round,
3) ductwork badly jointed allowing leakages of air,
4) obstructions left in ductwork during installation,
5) controlling dampers may not be functioning correctly or properly anchored.

Faulty Maintenance

1) Ducts can be restricted or blocked due to a build-up of deposits inside,

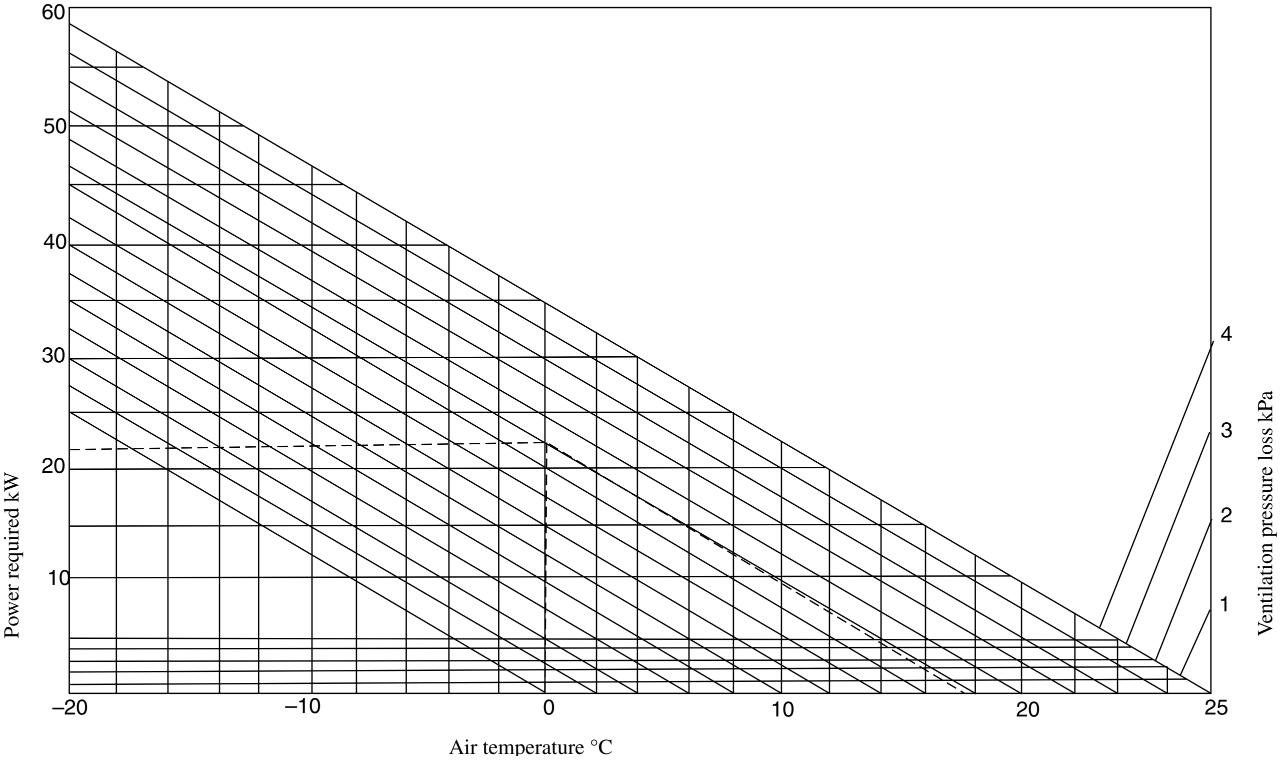

FIGURE 8 Chart for estimating energy requirements for heating.

2) Ducts can be damaged allowing leakage or restriction,
3) Fan blades can be deposited with dirt,
4) Fan blades can be corroded or worn away,
5) Fan motors can be seized or corroded due to being in an uncongenital airstream,
6) Dampers can be corroded, seized or deposited with dirt,
7) Filters or air cleaners can be blocked or missing,
8) Weather protection devices may be corroded or damaged.

Faulty Procedures Ventilation systems are often left to the shop floor operators to control either by an on/off switch or by opening and closing dampers when required. There is a danger that the system is not turned on because of unpopularity or that the opening and shutting of dampers unbalances the system particularly if all dampers are left fully open. Arguments can occur on the shop floor because of unpopularity often as a result of faulty design and systems are left switched off. No ventilation system should be controlled thus but it should be interlocked electrically with the process so that it is running when the process is. Multibranch systems must be either inherently balanced or have their controlling dampers locked in position.

Air Conditioning

Air conditioning plant is normally designed to take air at outside conditions which varies in temperature and moisture content from the very cold and dry in the depth of winter to warm and moist in the height of summer. The plant either heats and humidifies or cools and dehumidifies the air to supply it to the spaces to be ventilated at such a temperature and moisture content to deal with the heat gains and losses and the moisture gains and losses in that space.

Room heat gains and losses vary in intensity with time over the day and year due to variations in the use of the space such as changes in occupancy and/or the use of machinery, plant and equipment, external influences such as movement of the sun and variations in outside air temperature.

Room moisture gains occur due to occupancy and the evaporation of water from plant and equipment in use. Moisture losses are rare but do occur in certain textile and paper manufacturing plants.

If several rooms have similar patterns of heat and moisture gains and losses, they can be grouped together into a zone which can have the same supply of air, conditioned by common controls and plant.

Because the supplied air is the vehicle for heating and cooling, larger volume flows are normally required just for providing fresh air, therefore, for reasons of economy, whenever possible, some extracted air is recirculated and only that amount is discarded which is sufficient to balance the amount of fresh air brought in. The ratio of fresh air to be recirculated can be fixed the same all the year round or variable to take advantage of outside conditions. Programmed outside thermostats controlling motorized dampers achieve this. Some partial air conditioning systems use 100% recirculation and rely on natural infiltration of air to provide the necessary refreshment.

Processes The air conditioning processes for which items of plant are required are as follows:

1) sensible heating, requiring a heater battery supplied with either hot water, steam or refrigerant or electrically powered,
2) humidification requiring either a water spray or a controlled jet of steam,
3) cooling and dehumidification requiring a cooler battery supplied with either chilled water or refrigerant, the process involving cooling the air to below its dew point so that water condenses out.

Plant items are assembled in the correct combination to suit the particular design problem. The systems divide themselves into three basic types:

—The air systems where the required supply conditions are generated centrally, the air being ducted to the rooms. Hot water is supplied from a central boiler plant and air cooling is provided directly from the evaporator of a refrigeration plant or by means of chilled water from a center refrigeration plant.

—The air and water systems in which only sufficient air required for ventilation purposes is handled centrally and ducted to the rooms, the remaining heat transfer being achieved in room units containing finned coils supplied with heated or chilled water over which some room air is continually being passed. Heated and chilled water is provided from a central boiler and water chilling plant.

—The unitary of self-contained systems where the complete air handling and heat transfer plant is sited in the room, the necessary ventilation air being drawn from outside local to the room usually via a hole in the wall or window.

There are many variations of these basic types of systems.

Possible Problems Faults in air conditioning systems usually result in discomfort for the room occupants and give rise to vociferous complaints, which take one or more of the following forms: too hot, too cold, cold draughts, dry throats, too humid, a feeling of stuffiness, unpleasant odours, too noisy. Most of these can be measured or sensed by the investigator. Faults can be divided into: inherent design faults, installation deficiencies, maintenance deficiencies and malfunction of components.

Inherent design faults include:

1) badly sited air inlets and outlets
2) undersized heat transfer components
3) omission of humidification or de-humidification facilities
4) bad siting of thermostats
5) insufficient provision of fresh air supply.

Installation deficiencies include:

1) badly or wrongly connected ducts
2) air leakage
3) badly sited thermostats
4) control dampers and valves functioning incorrectly.

Maintenance deficiencies include:

1) blocked filters
2) no filters
3) dirty heat transfer surfaces and fan blades
4) control dampers and valves out of adjustment
5) thermostats and their associated controlling mechanisms and circuits out of adjustment
6) heating or cooling plant in poor condition.

The breakdown or malfunction of any item of plant or control systems will lead to the creation of an unsatisfactory environment.

An air-conditioning system operates as an integrated design, an alteration of any one item will unbalance the others thus plant should not be tampered with by inexperienced or unqualified personnel. In most cases the identification of faults and the provision of remedial action should be left to a qualified and experienced environmental/heating and ventilation/air-conditioning engineer.

SOFTWARE CONSIDERATIONS

The range of options available for the control of the working environment is diverse and it is all too easy to make a choice based upon what is the easiest to install and implement, but the control must be capable of providing protection over the operational life of the process. Thus monitoring and maintenance must be built in to the operational side of the system. Continued effectiveness depends upon the awareness of the workforce and their supervisors and managers. Regular checks on the working environment and the performance of the control measure must be made and a procedure laid down and adhered to to record the results of the checks and to implement remedial measures if the system is failing in any way. This can be made easier if the control system is seen as an integral part of the production process warranting the same attention as a production machine.

A planned education and training programme may be required to introduce the operators and management to the importance of the control measure and to explain how it works and what could go wrong and what the consequences are of a malfunction.

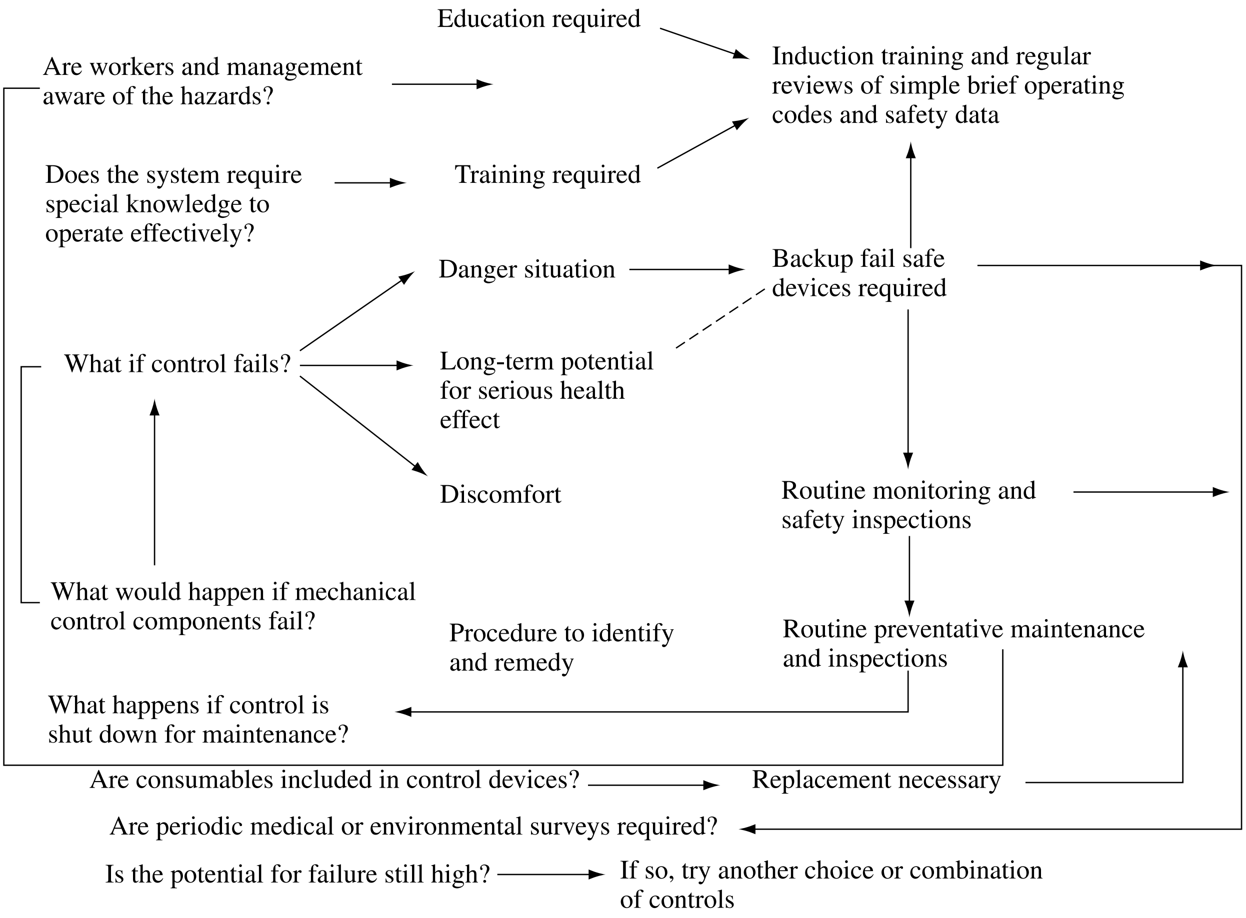

FIGURE 9 Control choice "software" considerations.

To monitor effectiveness of the control may require routine medical and biological checks of workers and environmental monitoring by competent persons and it may be necessary to provide an independent review and situation report to ensure worker acceptability.

It may be useful to introduce a software algorithm (Alesbury, 1980) posing certain questions and providing courses of action following the replies. One such algorithm is offered in Figure 9.

All the above can best be achieved by a genuine desire to make the workplace safe and directions for this can only come from senior management with full consultation and cooperation of the workforce.

INDUSTRIAL WASTE MANAGEMENT

INTRODUCTION

Industries produce large volumes of wastes that may include a wide variety of chemicals containing most toxic pollutants. It has been estimated that there are over 300,000 water-using factories in the United States.[1] As the population grows, the need for manufactured goods will also increase. As a result, the volume of industrial wastes is expected to grow faster than that of municipal wastes. Some of the industrial wastes can be treated jointly in municipal wastewater treatment plants, but others must be pretreated at the source.

In recent years, industrial wastewater management has undergone vast changes. Under legislative mandates and technological advancement, industries are recognizing the need and benefits of using water for several different purposes in descending order of required cleanliness before final treatment and release to the environment. This multiple, cascade, or sequential reuse of water minimizes the need for new water supplies, and reduces and concentrates wastes. A benefit of water and residual reuse may be an economical closed-loop, a zero discharge system that requires minimum make-up water to function.

Presented here is an overview of industrial pollution control legislation and standards, Standard Industrial Classification, industrial waste survey and monitoring, and wastewater treatment systems for selected industries.

INDUSTRIAL POLLUTION CONTROL LEGISLATION AND STANDARDS

Water Pollution Control Legislation

Although water pollution legislative history in the United States had its beginning with the Refuse Act of 1899, the Federal Water Pollution Control Act Amendments of 1972 (PL 92-500) marked the greatest commitment to eliminating pollutants in the nation's lakes, rivers, and streams.[2] The following is a summary of the last 40 years of water pollution control legislation enacted by the Congress of the Unites States.

- Federal Water Pollution Control Act of 1948
- Federal Water Pollution Control Act of 1956
- Federal Water Pollution Control Act Amendments of 1961
- Water Quality Act of 1965
- Clean Water Restoration Act of 1966
- Water Quality Improvement Act of 1970
- Federal Water Pollution Control Act Amendments of 1972
- Clean Water Act of 1977
- Clean Water Act Amendments of 1980
- Clean Water Act Amendments of 1981
- Water Quality Act of 1987

The 1972 and 1977 laws are collectively known as the Clean Water Acts.[3,4] They clearly express a serious national interest in water quality and reflect a strong public commitment to end water pollution. This legislation establishes deadlines for terminating pollution, enforcement provisions by federal, state, and local governments, and a greater federal degree of control over the quality of the nation's waters. The discharge of pollutants into the nation's waters is prohibited unless a permit is obtained under the *National Pollutant Discharge Elimination System* (*NPDES*). There are about 50,000 industrial and 16,000 municipal NPDES permits at the present time.[5] These permits are issued by the states and must be renewed every 5 years. The NPDES permit records effluent limits and spells out requirements for monitoring and recording. Restrictions on amounts of specific pollutants that a given facility may discharge into surface waters are, in general, based on national effluent guidelines. Industry has responded positively to the mandates of the law in meeting the discharge limits based on the *best available* treatment technologies as defined by EPA. Under the NPDES permitting program effluent limitations are established for toxic pollutants for various industrial categories. In a similar manner, *industrial pretreatment standards* are being developed for all pollutants that are discharged into the *publicly owned treatment works* (POTW). Under the pretreatment regulations, two types of federal pretreatment standards are established: (1) prohibited discharges and (2) categorical standards.

Prohibited discharges to sewers or POTWs are those that cause a fire or explosion hazard, corrosion, obstruction, and slug discharges and heat discharges. Categorical standards are developed for those pollutants that are incompatible, that is, those that interfere with the operation of or pass through POTWs, or contaminate the sludge and other residues from POTWs.

Substances considered for categorical standards are those for which there is substantial evidence of carcinogenicity, mutagenicity, and/or teratogenicity; substances structurally similar to aforementioned compounds; and substances known to have toxic effects on human beings or aquatic organisms at sufficiently high concentrations and which are present in the industrial effluents. There are many specific elements or compounds that have been identified as priority pollutants. These include metals, organics, cyanides, and asbestos.

To provide incentives, the Clean Water Act offered federal cost sharing to cover 75 percent of treatment plant construction. In the 1987 amendments, Congress set up a mechanism for states to develop revolving loan funds to pay for future pollution control facilities.[6]

Toxic Substance Control Act

The Toxic Substance Control Act of 1976 (TSCA), was enacted to regulate the introduction and use of new hazardous chemicals.[7] Under TSCA regulations, industry must furnish data on the anticipated production, usage, and health effects of all new chemical substances and mixtures before they are manufactured for commercial distribution. TSCA also regulates the manufacture, processing, use, and final disposal of all chemical substances.

The Resources Conservation and Recovery Act of 1976 (RCRA) restricts the disposal of hazardous waste into the atmosphere, bodies of water, or on land.[8] Thus RCRA was enacted to protect the quality of groundwater, surface water, the land, and the air from contamination by solid wastes.

The Hazardous and Solid Waste Amendments of 1984 (HSWA) emphasized the protection of groundwater through the use of leachate collection (double liners), and monitoring of underground tanks; upgraded criteria for disposing of municipal solid wastes in landfills; and established new requirements for the management and treatment of small quantities of hazardous wastes.[9]

The Comprehensive Environmental Response Compensation and Liabilities Act of 1980 (CERLA), the so-called Superfund legislation, was designed primarily to address the problem or the financial cleaning of abandoned or illegal hazardous waste sites.[10] The Superfund Amendments and Reauthorization Act of 1986 (SARA) provided funds and a timetable and guidance for cleanup standards.[11]

The Pollution Prevention Act of 1990 restates the waste reduction mandate in the 1984 HSWA amendments to RCRA. A pollution prevention office within the EPA was also created by this law along with the expansion of the reporting requirements of the SARA, emergency planning, and community right-to-know provisions. Organizations subject to these provision are required to report the steps taken to achieve waste reduction.[12]

STANDARD INDUSTRIAL CLASSIFICATION

The U.S. Government Standard Industrial Classification (SIC) lists 20 broad industry types bearing two-digit identification numbers. More specific classification of industry is achieved through three and four digit systems. As an example, Standard Industrial Classification 20 is for Food and Kindred Products; 202 for Dairy Products; and 2021, 2022 and 2023 for Creamery Butter, Cheese, and Condensed and Evaporated Milk.[13]

MAJOR CONTAMINANTS—INDUSTRIAL SOURCES AND EFFECTS

The initial step in the rational development of industrial pollution control is to identify and characterize the major industrial contaminants. Generally pollutants can be classified in three basic categories. These categories and parameters are listed below:

(A) Physical Properties

Temperature
Insoluble components
Floating, settleable and suspended matters
Color
Odor
Foamability
Corrosiveness
Radioactivity

(B) Chemical Composition

Organic matter
Inorganic matter
Total dissolved solids
Acid-Base
pH
Acidity
Alkalinity
Nutrients
Nitrogen
Phosphorus
Extractables
Oil
Grease
Reaction
Oxidizing
Reducing
Chlorine demand

(C) Biological Effects

Decomposition
Biodegradable
Nonbiodegradable
Toxic
Organic—phenols, pesticides, polychlorinated biphenyls (PCB), benzidine, etc.
Inorganic—heavy metals and cyanide
Pathogens

Industrial sources as well as major water quality effects of some of these materials are summarized in Table 1.[14]

TABLE 1
Major contaminants—industrial source and effect

Type of contaminant	Industrial source (some examples)	Some major effects
Inorganic salts	Oil refinery, desalination plants, munitions manufacturing and pickle curing	Interferes with industrial usage municipal (drinking water), and agriculture (irrigation water)
Acids and/or alkalies	Chemical manufacturing, tanneries	Corrosion of pipelines and equipment, kills fish
Organic matter	Tanneries, canneries, textile mills etc.	Food for bacteria and thus depletes oxygen
Suspended matter	Paper mills, canneries, etc.	Suffocates fish eggs, degrades stream appearance
Floating solids and liquids	Slaughterhouse, oil refinery	Unsightly, odorous, interferes with oxygen transfer
Heated water	Cooling waters from most industries and power plants	Accelerates bacterial action, lowers total oxygen saturation level
Color	Textile, tanneries, metal finishing, and chemical plants	Objectionable appearance
Toxic chemicals	Munitions manufacturing, metal plating, steel mills, petrochemicals, etc.	Alters stream biota and animal diversity
Microorganism	Pharmaceutical, combined municipal—industrial plants	Unsafe for drinking and swimming
Radioactivity	Nuclear power plants, chemical laboratories	Concentrates in fish, harmful for drinking
Foam-producing matter	Glue manufacturing, slaughterhouse, detergent manufacturing	Aesthetically objectionable

INDUSTRIAL WASTE SURVEY

Industrial waste surveys are conducted to develop knowledge of the waste streams from a specific industry. A survey provides information on sewer lines, waste routing, and material balance. Since an industrial waste survey provides an understanding of the waste flow through the plant, and the potential for water and residual reuse, a majority of the industries find that the survey expenditures yield an excellent return.[15,16]

Sewer Map

Of prime importance for any industry in operation at a site is the development of an up-to-date sewer map showing water, wastewater, and sanitary and storm drains. Locating sewer lines and establishing the manufacturing sources responsible for different waste streams becomes a time-consuming and complex problem in older facilities. Piping diagrams are seldom updated as changes are made over the years. The sewer map should include details such as pipe size; location and type of water supply and drain connections to each processing unit; direction of flow; location of roof and floor drains; manholes; catch basins and control points. To develop a realistic sewer map tracer, studies may be needed. Commonly used tracers are dyes, floats (wood chips, cork floats, and stoppered bottles), and smoke.

Flow Sheet

A flow sheet is prepared for each operation in the entire plant. It should show all raw materials, additives and products, by-products, and liquid and solid wastes. All primary discharges from each process, and the type, period, and duration of each operation should also be indicated on the flow sheet.

Mass Balance

After developing the flow sheet the next step is to obtain the amounts of raw materials, additives, products, and wastes for each operation. From the material balance, the extent of solid and liquid waste characteristics may be determined. This mass balance acts as a check on the waste quantities determined in the preliminary sampling and analysis. It also provides preliminary estimates of flows and parameters to be measured.

Location of Sampling Stations

Sufficient sampling stations should be established to determine the waste load at all of the major processes which contribute wastes. A desirable feature of the sampling station is that the flow be known. If flow is not known, it may be established by use of a flow measurement device. The sampling stations should be easily accessible with adequate safeguards, and wastewater should be well mixed.

Coordination with Production Staff

It is necessary that the efforts of the production staff be fully coordinated during the industrial waste survey. The input and information supplied by the production staff is valuable in identifying the frequency of batch dumps, spills, overflows, and continuous discharges.

SAMPLING AND MONITORING

The basis for industrial pollution abatement programs rests upon information obtained by sampling and monitoring of various waste streams. Serious problems or inaccurate information may result if sampling procedures and test parameters are selected in a careless or naive manner.

Flow Measurement

An essential part of the wastewater sampling and monitoring program is the collection of flow data. A knowledge of flow rate, flow variability, and total flow is essential. A variety of flow measuring devices are available. the selection of the proper measuring method or device will depend on factors such as cost, accessibility, type of flow, and character of waste. A list of many different types of methods and devices commonly used for wastewater flow measurement are given in Table 2.[2]

Sampling

It is essential that waste stream samples be truly representative of the waste discharge. Waste conditions may vary both in magnitude and composition over a 24-hour period. Therefore, care should be taken in selecting the method of sampling, frequency and duration, sample handling, and parameters to be measured. All these items are briefly discussed below.

Method of Sampling

Two most common methods of sampling are known as *grab samples* and *composite samples.* Either may be obtained manually or automatically. Grab samples are single batch samples taken at a given time. Composite or integrated samples are taken at constant time intervals usually over a 24-hour period, then mixed in proportion to flow at the time of sampling to obtain one representative sample of the total flow for the day.

Grab samples provide valuable information at low cost. They are recommended where: (1) condition or quality remains relatively uniform over long periods; (2) the effect of slug loads are desired; (3) concentration of certain constituents are needed for adjustment of chemical feed; (4) flow is intermittent; and (5) the sample requires immediate analysis due to instability of the constituents.

Composite sampling is done to obtain the average quality data for the day. Continuous samplers that take a sample volume in proportion to the flow are desirable. Another type of composite sampler removes samples on the hour and deposits it into different bottles. A volume of sample from each bottle is mixed manually in proportion to flow to obtain the composite

TABLE 2
Types of flow measurement devices commonly used for measuring wastewater discharges

Flow Measurement Devices	Principle of Flow Measurement
1. For pressure pipes	
a. Venturi meter	Differential pressure is measured
b. Flow nozzle meter	Differential pressure is measured
c. Orifice meter	Differential pressure is measured
d. Electromagnetic meter	Magnetic field is induced and voltage is measured
e. Turbine meter	Uses a velocity driven rotational element (turbine, vane, wheel)
f. Acoustic meter	Sound waves are used to measure the velocity
2. For open channels	
a. Flumes (Parshall, Palmer-Bowlus)	Critical depth is measured at the flume
b. Weirs	Head is measured over a barrier (weir)
c. Depth measurement	Float is used to obtain the depth of flow in the sewer, and velocity is calculated from slope
d. Acoustic meter	Uses sound waves to measure velocity and depth
3. Computing flow from freely discharging pipes	
1. Pipes flowing full	
a. Nozzles and orifices	Water jet data is recorded
b. Vertical open-end flow	Vertical height of water jet is recorded
2. Pipe partly flowing full	
a. Horizontal open-end pipe	Dimensions of free falling water jet are obtained
b. Open flow nozzle (Kennison nozzle or California pipe method)	Depth of flow at free falling end is determined
4. Miscellaneous methods	
a. Dilution method	A Constant flow of a dye tracer is used
b. Bucket and stopwatch	A calibrated bucket is used and time to fill is recorded
c. Pumping rate	Constant pumping rate and pumping duration are recorded

average sample for the day. Individual hourly samples are the grab samples representing the condition at that instant.

Frequency and Duration of Sampling

The frequency of sampling depends on the flow rate, wastewater characteristics, and variability in quality and volume. The expected range in flow rate and waste concentration should be determined by a preliminary survey. Although most of the time the frequency is one sample per hour, the frequency for highly variable waste streams could be as high as one sample every three minutes.

An intensive plant survey will generally last between five to ten days of normal plant operation. Since the treatment facilities must be designed to treat the highest pollution load expected, it is important to consider seasonal variations (if applicable).

Sample Handling

In order to obtain a representative sample it is necessary for the sampling point to have sufficient hydraulic turbulence. Sufficient volume of the sample must be obtained to perform all analyses planned. The minimum volume of grab sample should be between one to two liters. Sample containers and sampling device should be clean and uncontaminated. Before the sample is taken, the container should be rinsed several times with the wastewater. Each sample should be labeled with an identification card containing the following information: date and time, sample location, method of sampling (grab or composite), and notation of information obtained from field analyses of parameters that may change before laboratory analyses are made (temperature, pH, appearance).

The sample should be analyzed as quickly as possible. Storage should be in a manner that insures that the characteristics to be analyzed are not altered. Refrigeration in most instances is necessary. In some cases a special chemical may have to be added to prevent changes in chemical or biological characteristics.

Parameters Measured

A major item in any industrial monitoring program is the cost of analytical measurement. It is important that the parameters be properly selected to represent inplant waste streams; and waste characterization, treatment and reuse requirements. In some cases the necessary analyses will be time-consuming and relatively expensive. In many cases, an alternative analytical technique may be used that are less expensive. Major constituents of interest in industrial pollution monitoring are listed in Table 1.

Analytical Considerations

Good analytical procedures are of the utmost importance in a monitoring program. The basic references for wastewater analytical procedures and techniques are EPA publications, Standard Methods for Examination of Water and Wastewater, and ASTM Standards.[17–20] The analysis may fall into several major categories including routine wet chemistry, selective ion electrodes, automated wet chemistry, and bioassary tests.

Data Analysis

Data obtained through a well-planned and executed monitoring program will provide valuable information for waste process selection, plant design and operation, and assist the industry in evaluating the manufacturing process. The monitoring program may result from changes in chemical use and/or industrial process, inplant spills or dumping of baths. Variability of the parameters may be random or cyclic. The data should be analyzed to establish the fluctuations with time, location, work shifts, and type of operation.

Statistical techniques should be used to develop relationships such as average or mean, standard deviation and extreme conditions, and regression coefficients. With a knowledge of basic probability theory and the use of statistical techniques, such as least squares, curve fitting, analysis of variance, regression and correlation analysis, chi-squared goodness of fit, and others, it is possible to construct mathematical models and curves for almost any level of precision desired. Such techniques help to evaluate information having wide variations, so that an estimate of the best value of the parameter being measured can be developed. For more information the reader should consult several excellent references on statistical methods.[21–24]

TREATMENT PROCESSES

Industrial wastewater treatment utilizes a number of unit operations and processes to achieve the desired degree of treatment. The collective treatment schematic is called a flow scheme, flow diagram, flow sheet, process train, or flow schematic. Basic considerations for developing a flow scheme include: (1) the manufacturing process and its flow scheme; (2) characteristics of wastewater streams and degree of treatment; (3) requirements of the regulatory agency; (4) construction cost; (5) level of expertise of treatment plant operation personnel; and (6) operation and maintenance costs.[2]

The wastewater treatment facilities are designed to process liquids and solids or sludges. It is essential that in-plant waste management and control techniques be utilized if cost-effective methods of liquid and solids treatment are to be attained. Some application of in-plant controls include waste reduction, waste segregation, water conservation and recycle, and process modifications. Generally, controlling wastes within the plant is much more cost-effective than implementation of treatment. Certain innovative processes that reduce waste production have resulted in improved process yield or by-product recovery and utilization.

Waste Reduction

A basic materials balance procedure should be developed that accounts for all materials that enter and leave an individual department or processing area. Some specific waste reduction measures include: (1) materials balance accounting; (2) improved process control; (3) more effective cleanup procedures; (4) regular preventive maintenance; and (5) by-product recovery. Poor maintenance and cleanup procedures in many industrial plants are a major source of wasteload generation.

Product spills should be avoided, and when they occur, the waste should be handled in a manner that will minimize the contribution of wasteload to the plant. Proper housekeeping procedures should be developed and implemented.

Waste Segregation

It is important to segregate all wastes in accordance with the physical and chemical properties of the contaminants, potential to react, and their treatability. Important properties are suspended solids, acidity, basicity, organic matter and biodegradability, volatility, and toxic organics and inorganics. Efforts should be made to minimize dilution of waste streams prior to treatment and/or recovery of residuals. Diluted streams should be handled separately.

Water Conservation and Recycle

Water conservation and recycle consist of minimizing the raw water supply and maximizing the amount or wastewater reuse within the plant. The net effect of water conservation and recycle is the reduction of wastewater volume and to concentration of wasteloads.

Each process should be investigated to minimize water supply requirements and the potential for substituting recycled or reclaimed wastewater for fresh water. Water quality requirements for most industrial processes will govern the feasibility or extent of water reuse. However, in every industry using water for washing, rinsing, or cooling, some form of countercurrent flow or recycling can probably be implemented for maximum reuse. Some specific recommendations for water conservation and recycle include: (1) dry (nonwater) cleaning method, (2) water meters at each department to make operators conscious of usage, (3) automatic valves that close when water is no longer required, (4) regular preventive maintenance programs that include leak surveys, and (5) cleanup with high-pressure, low-volume rinse sprays.[16]

Process Modification

In-plant process modifications, though more costly to implement than simple operational changes, may be very effective in controlling wasteload generation. Process modifications may consist of individual unit process changes, or changes to a complete process line. The cost-effectiveness of such modifications will depend on the relative reduction in wasteloads. In older industrial plants, required process modifications may be accomplished during the installation of newer and more efficient equipment. In the design of new plants, each process should be evaluated with respect to use of more efficient equipment for maximum water conservation and minimum wasteload generation.

Liquid Treatment Systems

The removal of various contaminants from the liquid depends on the nature of the impurities and their concentrations. Coarse and settleable inorganic and organic solids are generally removed in sedimentation facilities. Oil and grease is removed by skimmers. The removal of dissolved organics is readily achieved in biological or chemical or physicochemical treatment processes. For example, chemical oxidation-reduction reactions and precipitation are used for removal of heavy metals. Carbon adsorption can be used to remove refractory organics. Ion exchange and membrane processes are suitable for demineralization and byproduct recovery. Major physical, chemical, and biological treatment processes used for liquid treatment are summarized in Table 3. For extensive presentations on these processes the readers should refer to several excellent publications that provide detailed discussions on the theory and design of wastewater treatment processes.[2, 25–31]

Sludge and Brine Processing and Disposal

Safe handling and disposal of residues and brines produced in various treatment units are of equal importance. Solids portions include screenings, grit, scum, organic and inorganic sludges. Brines (high mineral concentrates) are produced from ion exchange, reverse osmosis, and electrodialysis units. In general, the sludge processing and disposal methods include thickening, stabilization, and dewatering or evaporation of liquid. Several of the unit operations and processes used for sludge and brine handling and disposal are illustrated in Figure 1.

MAJOR INDUSTRIAL WASTES AND TREATMENT

It should be recognized that to truly understand the waste problem of any industry, a lifetime serious effort on the part of a qualified waste engineer may be required. Production methods of each industry are normally different. As a result, the treatment process train needed for the waste streams should be individually designed. The purpose of this section is to review the origin and characteristics of wastewater and methods of wastewater treatment for six major industries. In the following discussion, the reader will find a brief summary of the major liquid wastes, their origin, characteristics and current methods of treatment for food, paper and allied products, chemical, petroleum, metals, and power generation industries. For a detailed study on these topics the readers should refer to several references on the subject included in the list of references.[32–35]

Food Industry

There are approximately 50,000 food processing plants in the total food processing industry in the United States.

Food processing is a low-profit margin, highly competitive industry. Water is required for washing, blanching,

TABLE 3

Major physical, chemical, and biological treatment unit operations and processes used for liquid treatment

Unit Operations and Processes	Principal Applications
Screening	Racks or bar screens are the first step in wastewater treatment. They are used to remove large objects.
Flow equilization	Used to dampen the flow rate and mass loading.
Skimming	Used for oil separation where free oil is floated to the surface of a tank and then skimmed off. The oil separator specified by *American Petroleum Institute* is commonly used.
Dissolved Air Flotation (DAF)	Process used to remove suspended solids, and oil and grease from the waste stream. Uses dissolved air to produce line bubble that float the solids.
Foam separation	Process used to remove minute concentrations or refractory organics and heavy metal ions. Contaminants are carried up by rising bubbles to the pool surface where they are deposited as the bubbles exit.
Sedimentation	Use to remove settleable solids.
Neutralization	Process used to neutralize acidic or alkaline waste streams prior to chemical and/or biological treatment.
Precipitation	Dissolved solids in solution are chemically transformed into insoluble form. Process is extensively used to precipitate phosphorous and heavy metals. Heavy metals are generally precipitated as hydroxide through the addition of time or caustic to a pH of minimum solubility.
Chemical Oxidation	Used to oxidize pollutants to terminal end products. Common oxidants are Cl_2, O_3, H_2O_2, and $KMnO_4$. Oxidation of iron and manganese is used for precipitation. Cyanides, sulfides and many organics arc destroyed by oxidation.
Chemical Reduction	Used to precipitate certain ions from solutions, e.g., hexavalent chromium. Also many oxidizing agents are destroyed by reduction. Common reducing agents are ferrous sulfate, sodium metabisulfite, and sulfur dioxide.
Coagulation	Used to agglomerate suspended materials so that efficient settling can take place. Commonly used chemicals are alum, iron salts, and polymers. The process consists of chemical feed, flash mix and flocculation basins.
Suspended growth biological reactor	Biological process using suspended biomass to remove dissolved organics. Principal variation is an activated sludge process.
Attached growth biological reactor	Biological process using attached biomass to remove dissolved organics. Principal variations are a trickling filter and a rotating biological contactor (RBC).
Anaerobic Processes	Attached or suspended microbial process operated in the absence of oxygen. Normally used to treat high strength organic wastes. Methane is produced as an energy source. Sludge (biomass) production is small.
Oxidation Pond	Large basins (normally earthern) used for waste storage and treatment. Treatment is achieved by natural processes of settling and biological decomposition.
Aerated Lagoon	Basins (normally earthern and frequently with plastic liners) with aeration equipment where waste are aerated over long periods of time. The waste characteristics are altered by biological oxidation.
Land Treatment	Organic waste is applied over land for treatment. Common application methods are slowrate irrigation, rapid infiltration, and overland flow.
Nitrification	Process is used to convert ammonia nitrogen to nitrate nitrogen. It can be achieved in suspended or attached growth biological reactors.
Denitrification	Nitrite nitrogen and nitrate nitrogen are reduced to nitrogen gas by microorganisms. Denitrification is achieved under anaerobic condition in suspended or attached growth reactors. An organic source such as methanol is needed.
Disinfection	Process used to reduce the number of water borne pathogens in water. Normally applied to effluents of wastewater treatment plants containing microbes. Chlorination and ozonation are the most common methods.
Ammonia stripping	Ammonia gas is air stripped from the wastewater, normally by using stripping tower. High pH values are required.
Breakpoint Chlorination	Ammonia nitrogen is oxidized to nitrogen gas by breakpoint chlorination in a mixing basin.
Filtration	Used to polish the effluent by removing total suspended solids and turbidity. Biological activity in the filter bed may reduce some of the biochemical oxygen demand (BOD).
Carbon adsorption	Used to remove soluble refractory organics from wastewater effluent.
Ion Exchange	A demineralization process in which the cations and anions in wastewater are selectively exchanged for the ions in an insoluble resin bed. When the resin capacity is used up it is regenerated by using high concentrations of the original ions that are exchanged for the polluted ions attached to the resin. Flow from regeneration is composed of highly concentrated brine.
Reverse osmosis or ultrafiltration	A demineralization process applicable to production of high-quality water from effluent. The water permeates through semipermeable membrane at high pressure, producing high-quality water in one stream and a high concentration of mineral ions in another.
Electrodialysis	A demineralization process where electrical potential is used to transfer the ions through ion-selective membranes. Produces two streams; one high in mineral content and the other free of minerals.

THICKENING	STABILIZATION	CONDITIONING	DEWATERING	DISPOSAL
Concentrates solids	Reduces pathogens, and eliminate offensive odors	Enhances water removal	Removes moisture and produces sludge cake	Used for ultimate disposal of residues
1. Gravity	1. Chlorine oxidation	1. Chemical	1. Vacuum filter	1. Evaporation of brine
2. Flotation	2. Line stabilization	2. Elutriation	2. Filter press	2. Incineration
3. Centrifugation	3. Heat treatment	3. Heat treatment	3. Horizontal belt filter	3. Wet Oxidation
	4. Aerobic digestion		4. Centrifugation	4. Pyrolysis
	5. Anaerobic digestion		5. Drying beds	5. Composting
				6. Land filling
				7. Deep well injection

FIGURE 1 Alternative unit operations and processes for sludge and brine processing and disposal.

pasteurization, cleaning process, equipment, and cooling of final product. The waste is generally characterized by high BOD and suspended solids. The estimated total wastes from food industry for the United States in 1968 was:

320 million cubic meters of wastewater discharged
360 million kg of BOD generated
180 million kg of suspended solids generated
8 billion kg of solids residuals

Table 4 is a brief summary of major liquid wastes, their origin, characteristics and applicable methods of treatment for several major industries in the food industrial category.

Paper and Allied Products Industry

Pulp is produced by mechanically or chemically processing wood or other vegetative materials to extract usable cellulosic fibers as an aqueous slurry. The pulp slurry may be used directly in paper making or it may be shipped elsewhere for processing into paper products. The pulp and paper industry is the ninth largest industry in the United States. The major group of the industries in the pulp and paper industry are pulp mills, paper mills, paperboard mills, miscellaneous converted paper products, paperboard containers and boxes, and building paper and board mills.

The fundamental industrial operations are divided into two major categories: pulp mill and paper mill. The pulp mill operation includes wood preparation, pulping, deinking, pulp washing, screening and thickening, and bleaching. Paper mill operations include stock preparation, paper machine operation, and finishing. Table 5 provides a summary of these operations, origin of major wastes, major characteristics, and treatment methods.

Chemical Industry

The chemical industry is highly diversified and supplies products for virtually every other industry. The number of synthetic compounds manufactured is estimated to range between 500,000 and 600,000, and a host of new products is introduced every year. The chemical products may be used as primary, intermediate, or finished products.

The chemical processing industry has a variety of special pollution problems due to the vast number of products manufactured. The treatment processes combine processing, concentration, separation, extraction, by-product recovery, destruction, and reduction in concentration. The wastes may originate from solvent extraction, acid and caustic wastes, overflows, spills, mechanical losses, etc. Origin of major wastes, characteristics, and treatment and disposal of wastes in several major chemical industries are summarized in Table 6.

Petroleum Industry

The petroleum industry is one of the most important manufacturing industries in the country. It is a complex industry utilizing complex combination of interdependent operations engaged in the storage and transportation, separation of crude molecular constituents molecular cracking, molecular rebuilding, and solvent finishing to produce petrochemical products. Each process is responsible for production of many waste streams containing oil, chemical oxygen demand (COD), phenol, sulfide, chloride, and others. Treatment may involve oil separation, precipitation, adsorption, and biological treatment. The refining operations may be divided into many major categories. Wastewater characteristics, origin of major wastes, characteristics, and treatment and disposal methods from several major processes are summarized in Table 7.

Metals Industry

Primary metal processing and fabricated metal products manufacturing comprise the metals industries. The most important end uses of the products of the metals industries are automobiles, machinery, appliances, electrical equipment, structures,

TABLE 4
Summary of industrial wastes from major food industry

Industries Producing Waste	Origin of Major Wastes	Major Characteristics	Major Treatment and Disposal Methods
Canned goods	Trimming, culling, juicing and blancing of fruits and vegetables	High in suspended solids, colloidal and dissolved organic matter	Screening, lagooning, soil absorption by spray irrigation
Dairy products	Dilutions of whole milk, buttermilk, and whey	High in dissolved organic matter, mainly protein, fat, and lactose	Biological treatment aeration, RBC, trickling filtration, activate sludge, whey recovery
Brewed and distilled beverages	Steeping and pressing of grain; residue from distillation of alcohol; condensate from stillage evaporation	High in dissolved organic solids, containing nitrogen and fermented starches or their products	Recovery, concentration by centrifugation and evaporation, RBC; trickling filtration; use in feeds; anaerobic biological treatment followed by aerobic biological treatment
Meat and poultry products	Stockyards; slaughtering of animals; rendering of bones and fats; residues in condensates; grease and wash water; picking chickens	Organic matter, blood, other proteins, and fats and oils	Screening, settling and/or floatation, trickling filtration, RBC, activated sludge, recovery for animal food products
Animal feedlots	Excreta from animals	High in organic suspended solids and BOD	Land disposal and anaerobic lagoons
Beet sugar	Transfer, screening, and juicing waters; drainings from lime sludge; condensates after evaporator; juice and extracted sugar	High in dissolved and suspended organic matter, containing sugar and protein	Reuse of wastes, coagulation, lagooning, activated sludge, trickling filter, anaerobic process
Cane sugar	Spillage from extraction, clarification, evaporation cooling, and condenser waters	Variable pH, soluble organic matter with relatively high BOD of carbonaceous nature	Neutralization, recirculation, chemical treatment, some selected aerobic oxidation

TABLE 5
Summary of industrial wastes from several major operations in pulp and paper industry

Major Industrial Operations	Origin of Major Wastes	Major Characteristics	Major Treatment and Disposal Methods
Pulp mill			
Wood preparation	Log transportation and storage, debarking and chipping	Solid wastes, hydraulic debanking uses water	Incineration, water is recycled through lagoons
Pulping	Mechanical pulping, kraft pulping, sulfide pulping	Suspended solid, BOD, liquors containing high BOD, sulfide, mercaptans, high pH	Sedimentation, recovery if sodium hydroxide and sodium sulfide, aeration
Deinking	Removal of ink	Contains dirt and clay fillers, chemicals and usually alkaline	Sedimentation and coagulation
Pulp washing, screening, and thickening	Washing action, centrifugal cleaning, gravity and vacuum thickening	Liquor contains pulp fibres	Pulp fibres are recorded and recycled
Bleaching	Bleaching of pulp fibers by chlorine solution	Contains chlorine, low pH, high TDS	Dechlorination, neutralization
Paper mill			
Stock preparation	Addition of filter, colors, chemicals, and screening	Color, clay fillers, chemicals, high TDS	Coagulation and reuse
Paper machine	Removal of free water	Contains fibres and fillers. Known as white water. TSS, TDS and BOD	Fibers reclaimed, liquid wastes treated by coagulation, activated sludge
Finishing and converting	Surface improving, size cutting. Mostly dry process	Little or no liquid waste, mainly solid waste	Recycled in pulping operation, incineration

furniture, and containers. There are approximately 35,000 establishments in the United States. The industry uses approximately 32 billion cubic meters of water per year. Four percent of the plants use 92 percent of the water. These industries generate wastewaters which vary in quantity and quality. Table 8 provides the reader with a brief summary of the major liquid wastes, their origin, characteristics, and methods of treatment in four major metals industries.

TABLE 6
Summary of industrial wastes from several major chemical industries

Industries Productng Wastes	Origin of Major Wastes	Major Characteristics	Major Treatment and Disposal Methods
Acids and Alkalies	Dilute wash waters; many varied dilute acids and bases	Low or high pH, low organic content	Unflow or straight neutralization, coagulation and sedimentation
Detergents	Washing and purifying soaps and detergents	High in BOD and saponified soaps	Flotation and skimming, precipitation with $CaCl_2$
Explosives	Washing TNT and guncotton for purification, washing and pickling of cartridges	TNT, colored, acid, odorous, and contains organic acids and alcohol from powder and cotton, metals, acid, oils, and soaps	Flotation, chemical Precipitation, biological treatment, aeration, chlorination of TNT, neutralization, adsorption
Pesticides	Washing and purification of products	High organic matter, benzene ring structure, toxic to bacteria and fish, acid	Dilution, storage, activated-carbon adsorption, alkaline chlorination
Phospate and phosporus	Washing, screening, floating rock, condenser bleed-off from phospate reduction plant	Clays, slimes and oils, low pH, high suspended solids, phosphorus, silica and fluoride	Lagooning, mechanical clarification, coagulation and settling of refined waste
Formaldehyde	Residues from manufacturing synthetic resins and from dyeing synthetic fibers	Normally high BOD and formaldehyde, toxic to bacteria in high concentrations	Trickling filtration, absorption on activated charcoal
Plastics and resins	Unit operations from polymer preparation and use; spills and equipment washdowns	Acids, caustic, dissolved organic matter such as phenols, formaldehyde, etc.	Discharge to municipal sewer, reuse, controlled-discharge
Fertilizer	Chemical reactions of basic elements. Spills, cooling waters, washing of products, boiler blowdown	Sulfuric, phosphoric, and nitric acids; minerals elements, P, S, N, K, Al, NH_3, NO_3	Neutralization, detain for reuse, sedimentation, air stripping of NH_3, lime precipitation
Toxic chemicals	Leaks, accidental spills, and refining of chemicals	Various toxic dissolved elements and compounds such as Hg and PCBs	Retention and reuse, change in production, neutralization and precipitation, carbon adsorption

TABLE 7
Summary of wastes generated from various oil refinery operations

Major Industrial Operations	Origin of Major Wastes	Major Characteristics	Major Treatment and Disposal Methods
Crude oil and product storage	Primary fractionation of oil and water, spills and leakages	High concentrations of emulsified oil, COD, TSS	API separation, DAF, settling, aeration
Crude desalting	Chemical desalting, heating and gravity separation of oil	Emulsified and free oil, ammonia, phenol, sulfide, TSS, high BOD and COD	API separation, DAF, activated sludge, carbon adsorption
Cracking	Thermal cracking or catalytic cracking, fractionation, steam stripping, and overhead accumulators or fractionators	BODs, COD, ammonia, phenol, sulfides, cyanides, and alkalinity	Chemical oxidation, biological treatment carbon adsorption
Polymerization	Catalytic reaction, acid, removal action, and gas stabilizer	Alkaline waste stream, high in sulfide, mecaptans, and ammonia	Acid catalysts recycled, carbon adsorption
Alkylation	Catalytic reaction caustic and water wastes, neutralization of hydrocarbon streams	Oil, sulfides, TSS, fluoride	Neutralization, chemical oxidation, sedimentation

TABLE 8

Origin, characteristics, and treatment of wastes in four major metal industries

Industries Productng Wastes	Origin of Major Wastes	Major Characteristics	Major Treatment and Disposal Methods
Steel	Coking of coal, washing of blast-furnace flue gases, and pickling of steel	Low pH, acids, phenol, ore, coke, limestone, alkali, oils, mill scale, and fine suspended solids	Neutralization, recovery and reuse, chemical coagulation
Iron-foundry products	Wasting of used sand by hydraulic discharge	High suspended solids, mainly sand; some clay and coal	Selective screening, drying of reclaimed sand
Metal container	Cutting and lubricating metals, cleaning can surface	Metal fines, lubricating oils, variable pH, surfactants, dissolved metals	Oil separation, chemical precipitation, collection and reuse, lagoon storage. Final carbon adsorption
Metal-plated products	Stripping of oxides, cleaning and plating of metals	Acid, metals, toxic, low volume, mainly mineral matter	Alkaline chlorination of cyanide; reduction and precipitation of chromium; lime precipitation of other metals

Power Generation Industry

The power generation industry uses large volumes of water for cooling purposes. It is estimated that total cooling water demand for power generation is in excess of 400 billion cubic meters per year. This is approximately one-fifth of the total runoff in the United States.[33] Direct discharge of cooling water in streams, lakes, and estuaries has an impact on water quality and the ecosystem in three ways: it pollutes the water thermally, it subjects aquatic organisms to a variety of physical stresses as it is pumped through the plant, and it pollutes the water chemically.

Types of Cooling Systems

Basically, there are three ways of dissipating heat: once through cooling systems, cooling ponds, and cooling towers. The average condenser water requirement and consumptive use for different cooling systems are summarized below:[36]

Condenser requirement	120 liters per KWH
Consumptive use:	
once through	0.7 liter per KWH
cooling ponds	1.0 liter per KWH
cooling tower	1.4 liter per KWH

A general discussion on three types of heat dissipating systems is given below:[37]

Once Through Cooling The most common and least expensive method for removing heat from power plant condensers is a once-through-cooling system. The system requires large intake structures and has the largest environmental impact. Aquatic organisms are forced through the condenser tubes resulting in high mortality. The 2 to 5°C warmer discharge upsets stratification, lowers dissolved oxygen, increases the metabolic rate of aquatic animals, and increases undesired bacteria.

Cooling Ponds The cooling water is circulated through cooling ponds in a closed-loop. Cooling occurs by evaporation, conduction, and long-wave radiation. Land area of the ponds are generally 0.5–1 hectare/MW.

Cooling Towers Cooling towers are used to eliminate discharge of heated water into natural bodies of water. There are two types of cooling towers: natural-draft and mechanical-draft. Natural-draft cooling towers rely on natural air circulation to dissipate waste heat to the atmosphere. The mechanical-draft cooling towers use induced drafts to promote evaporative heat transfer. Both require heat transfer between water and air. Dry cooling towers use a temperature driving force between the water inside the tubes and air flowing past the tubes.

Wastewater Treatment

Chemical discharges from the power-generation industry result from makeup water treatment; chemicals added to plant cooling water or steam generator; products of corrosion, erosion, wear, or chemical reaction from plant system; and residuals from pollution control equipment. The chemicals generally controlled in effluent discharge permits are: pH, PCBs, TSS, oil and grease, heavy metals, free and total residual chlorine, phosphorus, and corrosion inhibitors.[34] Treatment methods generally used for removal of contaminants include: neutralization, coagulation, and precipitation of corrosion inhibitors, TSS, heavy metals and phosphorus; flotation or American Petroleum Institute (API) separator for oil and grease; ion-exchange or reverse osmosis for TDS control; and evaporation for concentration and residue recovery and disposal.

INSTRUMENTATION: WATER AND WASTEWATER ANALYSIS

INTRODUCTION

In the observation of our pollution problems there seems to be an attitude of separation on the part of the human observer from the polluted lake or stream. In reality water is so pervasive in our life; it is such a large part of our bodily mass and surrounds us in clouds, fog, rain, snow, lakes, rivers, and oceans. We seem to accept its presence without much thought. However, we all are part of the ecosystem and, therefore, pollution is an intimate condition of our lives—not something unconnected to us. Much of the human population appears to have been separated from their ecological heritage and membership. Perhaps this is the reason pollution is so endemic to our world; many people had seen pollution as something displaced from their intimate reality.

In the last thirty years the threat and cause of damage to ecological and human health from polluting surface and ground water and acid rain and snow, as well as air pollution, global warming, and the destruction of the ozone layer has increasingly occupied our consciousness and our everyday life. The society from young school children to adults reading newspapers and watching television are aware that we are heirs to serious environmental problems. Polls indicate the great extent of this concern. Recently the concerns of various national governments have led to international conferences dealing with the ozone problem and discussion of global warming. Perhaps the convergence of several environmental conditions that threaten to change planet earth's ecological system have awakened the irresponsible amongst the citizenry, government administrators, scientists and engineers, and the industrial establishment to finally realize that we are all part of the ecological system and have a vital interest in the control of pollution.

The Clean Water Acts of the U.S. Congress and environmental action of various States and similar actions in Canada have resulted in some improvement in natural water quality in North America. The role of the Green parties and the citizenry has had a similar effect in Western European nations. In Eastern Europe there is increasing concern about pollution problems. Much remains to be done in the areas of irrigation, non-point source pollution, acid rain and snow, the effect of air pollution on water pollution, protection of ground water from hazardous wastes, and the further reduction of pollution from industrial sources. Extensive human effort and resources have been dedicated to detect and measure water pollutants and understand their effect on human populations and on the ecological system, as well as on the collection and rectification of wastewater in treatment facilities. However, much more remains to be done.

A realistic primer may help us to visualize the overall effects of water pollution. Sitting by an ecologically healthy lake or stream, we observe a proliferation of life—plants and animals familiar and cherished by us. Comparing that to our experience of being next to a polluted water body, we would notice different plants, not attractive to us and the presence of foul offensive odors. (However for a lake acidified by acid rain, very clear waters, devoid of life, are observed.) The system has changed from being aerobic (presence of dissolved oxygen) to anaerobic (lack of dissolved oxygen). The water body has changed so that it is no longer attractive to us nor can it serve as a water resource. A lack of dissolved oxygen in the water has changed the living conditions so that anaerobic fauna and flora can reside there. Two conditions can cause this situation: i.e., an excess of nutrients (such as nitrates or phosphates) serving to facilitate the growth of plants and an excess of biodegradable organic matter serving as food for the microbial population. These pollutants originate from human biological waste and human activities such as agriculture and industry.

An excess of biodegradable organic matter leads to an accelerated growth of the microbial population. Since they are aerobic and require dissolved oxygen in the water for respiration, a large population could deplete the dissolved oxygen supply leading to the asphixiation of fish, other animals and insects and the death of plants. Then anaerobic fauna and flora will flourish producing reduced gaseous substances, such as ammonia and hydrogen sulfide. These gases are toxic and unpleasantly odiferous. Although water can be reaerated by the air above its surface to provide a supply of dissolved oxygen, the process is very slow allowing for the conditions of oxygen depletion to exist for long periods of time.

Another mechanism leading to the same result is caused by an excess of nutrients. The presence of excessive amounts of nitrates and phosphates spur algae growth in the water body. The upper layers of algae shield the lower layers from sun light. This situation causes death of the lower layers of algae adding large amounts of biodegradable organic matter to the water body and an explosion in microbiological growth. Thus, through the action described above the dissolved oxygen content is greatly reduced and anaerobic conditions develop. Another category of pollution are the toxic substances entering water bodies, such as some synthetic organic materials and toxic metals and non-metals: they cause the death of aquatic plants and animals disrupting the water ecosystem. Non-biodegradable substances may be toxic, cause problems due to their physical nature, or detract from the beauty of nature.

From a consideration of the foregoing descriptions of the mechanisms of pollution effects, a number of parameters for the determination and control of water pollution can be listed. For example degradable organic matter, non-biodegradable substances, dissolved oxygen, nitrates and phosphates, and toxic metals, non-metals and organic matter are classes of substances requiring methods of analysis.

However the previous and rather bare outline of the pollution scenario does not expose the complex problems in describing the ecological mechanisms affected by pollution and their attendant solutions. The definition of a problem is necessary if one is to prescribe a solution. The more complete the definition, the more precise and comprehensive the proposed interpretation can be. Unfortunately, we do not have the luxury of unlimited time to adequately define the various environmental problems; we must institute actions using the knowledge at hand and update and improve our interim solutions as we approach a more complete definition of each of the problems. Indeed, the answers to the problems of water pollution and abatement have been undertaken in this vein.

The large question, what do we measure, brings us to the complexity of the issue, since what we measure is connected to why we measure a particular property or component. The attempt to answer these questions cannot be undertaken in this relatively short article, however, a very limited response will be given to these questions.

This article will describe the operation and use of chemical instrumentation both in the laboratory and in monitoring instrumental systems, for data collection necessary for refining the definition of the environmental water problems, monitoring of processes to treat wastewaters and drinking water, and the ecological monitoring of natural waters.

WATER AND WASTEWATER ANALYSIS

In the last fifty years the advances in electronics have made possible the development of the sophisticated instrumentation and computer systems which serve very well the purposes described herein. Development of chemical sensors and their combination with instrumentation has resulted in the laboratory and monitoring chemical measurement instruments so commonly found in laboratories, environmental monitoring systems and manufacturing plants. In addition the interfacing of these instruments and computer systems results in effective and creative data handling, computation, and prediction.

A general consideration of the analysis of water and wastewater samples brings forth several factors to consider. What characteristics need to be monitored and for what reasons? How do we obtain a representative sample of the source to be analyzed and how do we preserve its integrity until an analysis is completed? What constitutes our present methodology and with what biological, chemical, physical and instrumental means do we carry out these measurements? However, a primary consideration in answering these questions relates to the nature of water and wastewater samples.

The Nature of Water-Related Samples and Sampling Considerations

Nature of Water-Related Samples The category of water and wastewater samples can include water samples, sludges, benthic muds, plant matter and so forth. Samples may be taken from a number of systems: for example, natural water bodies, process streams from wastewater treatment and manufacturing plants, benthic environments, marshes, etc. Different procedures for sampling can be required for each variety of sample based on their unique chemical, physical, and/or biological nature.

Water is alluded to as the universal solvent for good reasons; it is the best solvent humans experience. In addition to dissolved substances water can also transport insoluble, suspended, and/or colloidal matter. Thus, a sample can contain components in a number of physical states: i.e.; dissolved, in ionic and molecular form; insoluble, as are bubbles of gas, and suspended and colloidal chemical substances; and biological organisms in a variety of sizes. The determination of the identity and concentration of unique chemical and biological components is important. The presence of these components give to the water sample biological, chemical, and physical characteristics—such as physiological qualities, acidity, alkalinity, color, opacity and so forth.

Sludges and mud samples are heterogeneous mixtures containing water with dissolved matter and the sampling procedure must not change the composition of the mixture. Plant matter, having its own unique characteristics, requires the proper procedures for sampling.[1] Many samples display time-based changes once taken from the source for a host of reasons. Changes are evident over various time scales. For example suspended matter settles during a time period as determined by particle size giving a change in opacity and/or color, chemical reactions may occur amongst components, gases and volatile substances may diffuse to the surface of the sample and evaporate, gases or volatile substances in the air space above the sample may condense and dissolve at the sample interface, etc. Substances in benthic samples can experience air oxidation and plant matter can lose moisture and so forth. All of these changes present a deviation of the sample's composition and characteristics from the source. The seriousness of the changes depend on the purpose of the analysis and its use. There must be no perturbation of the sample composition or physical characteristics which will nullify or seriously distort the analysis results and be detrimental to the purposes of the analysis.

Preservation is a means of preventing decomposition and change of various biological or chemical components in the sample. Standard Methods provides a treatment for the preservation of specific components in a variety of samples where preservation is possible (see Table 1).[2]

Sampling Considerations Two types of changes must be considered in order to define and carry out a proper sampling program, i.e., time-based changes in the source to be sampled and in the sample taken from the source.

Time-based changes in the source may be short or long term. The short-term changes taking place are indicative of biological, chemical, and/or physical interactions in the time span assigned to repetitive sampling. Long-term changes in the sources are related to ecological trends. It is important to be aware of each of these types of changes so that sample storage changes are not mistaken for sample source changes.

In order to obtain a legitimate sample of water or wastewater for analysis one must understand the nature the sample and its time-based changes. Once a sample taken from the source it may begin to change for many reasons as discussed in the previous section, IIA,*1*. The sample must be representative of the sample source, that is it must have the same biological, chemical, and physical characteristics of the source at the time the sample is taken. Therefore the sampling procedure must not cause a change in the sample relative to the source if there is to be an accurate correspondence between the sample analysis and the nature of the sample source at the time the sample was taken.

To prevent confusing the two variables, ecological changes in the source and interactions in the sample that can occur in the same time span in a series of samples, preservation of the samples is undertaken to deter changes after sampling. However, preliminary sampling and testing may be necessary to indicate the type of time-based changes occurring. Then a reliable program can be established with some certainty.

Three kinds of sampling schemes are undertaken in consideration of the sample source characteristics—grab, composite and integrated samples.

A grab sample is one taken at a given time and place. If the source doesn't change greatly during a long passage of time or within a large distance in all directions from the sampling point, the grab sample is useful. The results from grab samples are said to represent the source for the given values of distance from sampling location and time. However a time and place series of grab samples is needed to establish the constancy of analytical values for different times and distances from the original grab sampling point. With that information the sampling frequencies and times for a sampling program can be established. The sampling of solids, such as, benthic muds and sludges, requires great care in order to obtain truly representative samples.

A series of samples collected and blended to give a time-averaged sample is known as a composite or time-composite sample. In another procedure the volume of each sample of the series collected is proportional to flow of the sample source, namely the water body or waste stream. The samples of various volumes are composited to provide the final time-composite sample. This type of sample gives an average value over a time period and saves analysis time and cost. Sampling frequencies and the total time span of the series depends on the source. Composite sampling may be used for process streams to determine the effect of unit processes or to monitor a plant outfall for daily or shift changes. However, biological, chemical, and physical parameters that changes on storage during the sampling time period can't be reliably determined in time-composited samples and another sampling protocol is needed (see Table 1).

At times, simultaneous samples are needed from various locations within a given source, such as a river or lake. Grab samples are then composited, usually based on volumes proportional to flow, and are called integrated samples. These samples are used to determine average composition or total loading of the source which varies in composition in its breadth and depth. The sampling program for such sources is complex and requires careful consideration for each unique source.

Water and Wastewater Parameters

A large number of water quality parameters are utilized in the characterization, management and processing of water and wastewater. Table 2 lists a number of these parameters separated into three categories—physical, chemical and biological. It is obvious that only some parameters are considered to be pollution factors because they indicate conditions of water during processing or in the natural state. The STORET system of the USEPA lists more than four hundred parameters separated into six major groups and is used for the analysis, collection, processing and reporting of data.[3] Table 3 gives a sampling of groups of parameters in this system. Not all of these parameters are used frequently, since many are rather unique to particular waste effluents. In actuality, a very small number are used in the analysis of a particular sample.

Water quality parameters may be divided into two groups, specific and non-specific water quality parameters. Specific parameters refer to chemical entities of all types, e.g., ions, elements, compounds, complexes, etc. For example, in Table 2 some specific parameters are ammonia, all metals listed, dissolved oxygen, nitrates, sulfates, and so forth. Non-specific parameters are included in three categories and some examples are as follows: chemical (hardness, alkalinity, acidity, BOD [biochemical oxygen demand], TOC [total organic carbon], COD [chemical oxygen demand], chlorine demand), physical (salinity, density, electrical conductance, filterable residue), and physiological (taste, odor, color, turbidity, suspended matter). Many of these non-specific parameters are

TABLE 1

Summary of special sampling or handling requirements[a,*]

Determination	Container[†]	Minimum Sample Size *mL*	Sample Type[‡]	Preservation[§]	Maximum Storage Recommended/ Regulatory
Acidity	P, G(B)	100	g	Refrigerate	24 h/14d
Alkalinity	P, G	200	g	Refrigerate	24 h/14 d
BOD	P, G	1000	g	Refrigerate	6 h/48 h
Boron	P	100	g, c	None required	28 d/6 months
Bromide	P, G	100	g, c	None required	28 d/28 d
Carbon, organic, Total	G	100	g, c	Analyze immediately: or refrigerate and add H_3PO_4 or H_2SO_4 to pH $<$ 2	7 d/28 d
Carbon dioxide	P, G	100	g	Analyze immediately	stat/N.S.
COD	P, G	100	g, c	Analyze as soon as possible, or add $H_2SO_4$to pH $<$ 2; refrigerate	7 d/28 d
Chloride	P, G	50	g, c	None required	28 d
Chlorine, residual	P, G	500	g	Analyze immediately	0.5 h/stat
Chlorine dioxide	P, G	500	g	Analyze immediately	0.5 h/N.S.
Chlorophyll	P, G	500	g, c	30 d in dark	30 d/N.S.
Color	P, G	500	g, c	Refrigerate	48 h/48 h
Conductivity	P, G	500	g, c	Refrigerate	28 d/28 d
Cyanide:					
Total	P, G	500	g, c	Add NaOH to pH $>$ 12, refrigerate in dark[#]	24 h/14 d; 24 h if sulfide present
Amenable to chlorination	P, G	500	g, c	Add 100 mg $Na_2S_2O_3$/L	stat/14d; 24 h if sulfide present
Fluoride	P	300	g, c	None required	28 d/28 d
Hardness	P, G	100	g, c	Add HNO_3 to pH $<$ 2	6 months/6 months
Iodine	P, G	500	g, c	Analyze immediately	0.5 h/N.S.
Metals, general	P(A), G(A)	500	g	For dissolved metals filter immediately, add HNO_3 to pH $<$ 2	6 months/6 months
Chromium VI	P(A), G(A)	300	g	Refrigerate	24 h/24 h
Copper by colorimetry*					
Mercury	P(A), G(A)	500	g, c	Add HNO_3 to pH $<$ 2, 4°C, refrigerate	28 d/28 d
Nitrogen:					
Ammonia	P, G	500	g, c	Analyze as soon as possible or add H_2SO_4 to pH $<$ 2, refrigerate	7 d/28 d
Nitrate	P, G	100	g, c	Analyze as soon as possible or refrigerate	48 h/48 h (28 d for chlorinated samples)
Nitrate + nitrite	P, G	200	g, c	Add H_2SO_4 to pH $<$ 2, refrigerate	none/28 d
Nitrite	P, G	100	g, c	Analyze as soon as possible or refrigerate	none/48 h
Organic,					
Kjeldahl*	P, G	500	g, c	Refrigerate; add H_2SO_4 to pH $<$ 2	7 d/28 d
Odor	G	500	g	Analyze as soon as possible; refrigerate	6 h/N.S.
Oil and grease	G, wide-mouth calibrated	1000	g, c	Add HCl to pH $<$ 2, refrigerate	28 d/28 d
Organic compounds:					
MBAS	P, G	250	g, c	Refrigerate	48 h
Pesticides*	G(S), TFE-lined cap	1000	g, c	Refrigerate; add 1000 mg ascorbic acid/L if residual chlorine present	7 d/7 d until extraction; 40 d after extraction
Phenols	P, G	500	g, c	Refrigerate, add H_2SO_4 to pH $<$ 2	*/28 d

(*continued*)

TABLE 1
Summary of special sampling or handling requirements[a,*] (*continued*)

Determination	Container[†]	Minimum Sample Size *mL*	Sample Type[‡]	Preservation[§]	Maximum Storage Recommended/ Regulatory[#]
Purgeables* by purge and trap	G, TFE-lined cap	2 × 40	g	Refrigerate; add HCl to pH < 2; add 1000 mg ascorbic acid/L if residual chlorine present	7 d/14 d
Oxygen, dissolved:	G, BOD bottle	300	g		
Electrode				Analyze immediately	0.5 h/stat
Winkler				Titration may be delayed after acdification	8 h/8 h
Ozone	G	1000	g	Analyze immediately	0.5 h/N.S.
PH	P, G	50	g	Analyze immediately	2 h/stat
Phosphate	G(A)	100	g	For dissolved phosphate filter immediately; refrigerate	48 h/N.S.
Salinity	G, wax seal	240	g	Analyze immediately or use wax seal	6 months/N.S.
Silica	P	200	g, c	Refrigerate, do not freeze	28 d/28 d
Sludge digester gas	G, gas bottle	—	g	—	N.S.
Solids	P, G	200	g, c	Refrigerate	7 d/2–7 d; see cited reference
Sulfate	P, G	100	g, c	Refrigerate	28 d/28 d
Sulfide	P, G	100	g, c	Refrigerate; add 4 drops 2*N* zinc acetate/ 100 mL; add NaOH to pH > 9	28 d/7 d
Taste	G	500	g	Analyze as soon as possible; refrigerate	24 h/N.S.
Temperature	P, G	—	g	Analyze immediately	stat/stat
Turbidity	P, G	100	g, c	Analyze same day; store in dark up to 24 h, refrigerate	24 h/48 h

* See text for additional details. For determinations not listed, use glass or plastic containers; preferably refrigerate during storage and analyze as soon as possible.

[†] P = plastic (polyethylene or equivalent); G = glass; G(A) or P(A) = rinsed with 1 + 1 HNO_3; G(B) = glass, borosilicate; G(S) = glass, rinsed with organic solvents or baked.

[‡] g = grab; c = composite.

[§] Refrigerate = storage at 4°C, in the dark.

very important in water and wastewater characterization and instruments are available to measure specific and non-specific parameters.

Methodology

The large variety of tests carried out on water and wastewater samples and sources have been codified and are included in the laboratory reference in the United States entitled "Standard Methods for the Examination of Water and Wastewater" and is commonly referred to as Standard Methods. This compendia of methods is regularly updated. At the present time the 19th edition published in 1995 is in use[2] and a supplement was issued in 1996. Supplements are used to update methods on an ongoing basis in order not to unduly prolong the publication of the new edition. However not more than one supplement appears to have been published for each edition.

Three professional organizations jointly write and edit this manual—the American Public Health Association, the American Water Works Association and the Water Environment Federation (formerly the water pollution Control Federation). It is published by the American Public Health Association. Over five hundred professionals belonging to these organizations and others participate in Standard Methods. It was first published in 1905 and an interesting history of its genesis is given in the preface to the 19th edition.[2]

At one time methods were segregated between water and wastewater test methods, however, since the 14th edition in 1976, that division ceased. In the 19th edition, methods are classified in ten groups: Introduction, Physical Aggregate Properties, Metals, Inorganic Nonmetallic Constituents, Aggregate Organic Constituents, Individual Organic Constituents, Radioactivity, Toxicity, Microbiological Examination, and Biological Examination.

TABLE 2
Some water quality parameters[a]

Physical	Chemical	Biological
Color	Acids or alkali	Algae
Conductivity	Ammonia	Bacteria
Odor	Biochemical oxygen demand (BOD)	Pathogens
Radioactivity	Calcium	Protozoa
Solar radiation intensity	Chloride	Viruses
Suspended solids or sludges	Chlorophyll	
Temperature	Chemical oxygen demand (COD)	
Turbidity	Dissolved oxygen	
	Hardness	
	Heavy metals:	
	Chromium	
	Copper	
	Iron	
	Lead	
	Manganese	
	Mercury	
	Magnesium	
	Nitrate, nitrite	
	Organic compounds:	
	Detergents	
	Herbicides	
	Pesticides	
	Phenol	
	Oils and greases	
	Oxidation–reduction potential	
	pH	
	Phosphates	
	Potassium	
	Sodium	
	Sulfate	
	Total organic carbon (TOC)

Twenty-five years ago the dearth of instrumentation was used in Standard Methods.[4] However, in the present edition the following instrumentation is employed in the methodologies: molecular spectroscopy (visible, uv, ir), atomic spectroscopy (absorption, flame, ICP), chromatography (gas, ion, liquid), mass spectrometry (GC/MS, gas chromatography/mass spectrometry), electro-analytical techniques (polarography, potentiometric and amperometric titrations, selective ion electrodes), radio-activity counters (gas filled and semiconductor detectors and scintillation counters), and automated continuous-flow methods.

Also included in Standard Methods are aspects such as safety, sampling, mathematical treatment of results, reagents, apparatus etc. It is fortunate, indeed, that such a comprehensive work is available and that it is regularly revised. Enlightened editorial leadership and the many members of the Standard Methods committees in the last twenty years can be credited for the steady increase in the inclusion of instrumentation in Standard Methods. In the increasing complexity of environmental and ecological problems and guidance of Standard Methods is a valuable and practical support in obtaining necessary analytical data.

The American Society for the Testing of Materials, ASTM, is an important compendium for the analysis of raw and finished material products. A large section is devoted to the analysis of water and wastewater in the context of processing and usage.[5]

The EPA has published instrumental methods for the analysis of priority pollutants and other substances controlled by Federal legislation.[6]

Types and Purposes of Instrumentation and Computer Systems

The development of a large variety of analytical instrumentation has been a boon to water and wastewater characterization, research, management, and process control. In addition to the requirements of the process industries, the needs of the water and wastewater area have spawned the development of some specialized laboratory, monitoring and process control instrumentation. Some examples are the total carbon and organic carbon analyzers, biological oxygen analyzers and the residual chlorine analyzer. Monitoring and data acquisition systems, in conjunction with this instrumentation, are increasingly used in wastewater management and plant process control. Certainly a number of physical parameters such as temperature, flow rate, pressure and liquid level have been measured instrumentally in the process industries, including wastewater treatment plants, predating the development of this wide variety of analytical instrumentation.[7]

Instruments utilized in the measurement of parameters important to wastewater analysis, treatment and management can be divided into two categories based on application. Monitoring of water bodies and waste treatment processes require monitoring instruments which are characterized by ruggedness and capability of unattended operation and data storage and/or transmission. A second category, laboratory instruments, in many instances, may be more sophisticated, sensitive to the surrounding environment and also have data storage and transmission capabilities. Each type has its specific utility in the scheme of analysis and data acquisition for wastewater characterization and processing. In many instances monitoring instruments are laboratory devices which were ruggedized and prepaared for field use. Thus the variables measured and the principles of operation are the same in many cases. Some examples of variables measured by laboratory and monitoring instrumentation are pH, conductivity, DO (dissolved oxygen), specific cations and

TABLE 3
Number of STORET listings for water analysis

Parameters by groups	Example	Number of parameters in group
General physical and chemical	Alkalinity, COD, iron turbidity, zirconium	149
Physical observations	Algae, foam, oil	12
Radionuclides	Gross alpha and beta, strontium-90	141
Microbiological	Coliform by MPH and MF, total plate count	18
Organic materials		
Carbon adsorption data	Chloroform and alcohol extractables	12
Natural organics	Chlorophyll, tannins	4
Synthetic organics	ABS, phenols	2
Halogenated hydrocarbons	Aldrin, heptachlor, toxaphene	62
Phosphorated hydrocarbons	Malthion, parathion	10
Miscellaneous pesticides	Silvex	8
Treatment-related observations	Available chlorine	6

anions, and a variety of specific and nonspecific parameters by automated analyzers. However, the instrumental appearance and some unique functions related to unattended operations may differ.

Monitoring and data acquisition systems are also considered in this article. In the control of wastewater treatment systems and plants, data may be obtained exclusively from monitoring instrumental systems or a combination including data from laboratory instruments via a laboratory data system and/or from data entered through terminals.

Analytical instrumentation can be classified according to principles based on various physical phenomena. These general categories are spectroscopy, electrochemistry, radiochemistry, chromatography, and automated chemical analysis. The instrumentation described in this article is organized according to these categories.

INSTRUMENTATION

Structure of Instruments

An instrument is a device that detects a physical property or chemical entity through the conversion of a physical or chemical analytical signal to an energy signal, usually electrical, with subsequent readout of the energy signal.

Three main parts comprise an instrument: that is a chemical or physical sensor, signal conditioning circuits, and readout devices. The sensor develops a signal, usually electrical, in response to a sample property and the signal conditioning circuit modifies the signal in order to allow convenient readout display of the signal. Finally, a readout device displays the signal, representative of the sample, in terms of a reading on an analogue or digital meter, a recorder chart, an oscilloscopic trace, etc. Figure 1 delineates the three major parts and functions of an instrument, sample properties (measurand) to be measured, and instrumental criteria.

Sensors A sensor, the primary contact of the instrument with the sample, is a device that converts the input energy derived from a sample property to an output signal, usually electrical in nature. The relationship between the input energy (measurand), Q_1, and the output energy, Q_0, is expressed in the form:

$$Q_0 = f(Q_1) \tag{1}$$

and is known as the transfer function. The sensitivity is given in the equation

$$S = dQ_0/dQ_1. \tag{2}$$

When the transfer function is linear, the sensitivity is constant throughout the sensor's range. However, the sensitivity (gain or attenuation factor) is dependent on the value of the differential fraction in equation 2. The sensor threshold is the smallest magnitude of input energy necessary to obtain a measurable change in the output.

Readout signals may be digital, *D* (discrete), or analog, *A* (continuous), in form and are a function of the nature of the input signal and the sensor and the design of the signal conditioning circuits. These signals are interconvertible using *A*/*D* or *D*/*A* devices. Fast reacting sensors and circuits, however, are utilized for producing digital signals, where, formerly, analog signals were obtained.

Two varieties of sensors, chemical and physical, are in use on various instruments. The physical sensor allows the conversion of physical energy from one to another. One example is a photocell that converts an impinging light beam

Measurand Sample property	$\xrightarrow[\text{Signal}]{\text{Input}}$	**Sensor** Energy transducer	$\xrightarrow[\text{Signal}]{\text{Transducer}}$	**Signal conditioning** Signal modification	$\xrightarrow[\text{Signal}]{\text{Output}}$	**Readout** Types
Light		Light		Amplification		Analog
Absorption		Photocell		Arithmetic operation		Meter
Emission		Photographic plate		Chopping		Oscilloscope
Thermal		Thermal		Comparison to reference		Recorder
Conductivity		Thermocouple		Digitization		Digital
Temperature		Katharometer		Rectification		Nixie display
Heat capacity		Thermister		Stabilization		Point plotter
		Bolometer				Printer
Electrical		Electrical				Tape, paper, or magnetic
Redox		Electrode pair				*Instrument*
Electrolytic conductivity		Electrodes, AC system				*Criteria*
Ionic activity		Membrane electrode				Band width
Mechanical		Mechanical				Noise figure
Mass		Balance force transducer				Sensitivity
Density		Force transducer				Signal-to-noise
Viscosity		Hydrometer				Time constant
Surface tension		Viscosity pipet				Error
Nuclear		Nuclear				Hysteresis
(X-ray, $\beta.\gamma$)		Ionization tubes				Nonlinearity
Emission		Scintillation counters				Scale
Absorption		Photographic plates				Zero displacement
		Cloud chamber				
		Semiconductor detectors				

FIGURE 1 Diagram of instrumental functions. Reprinted from Ref. (4), p. 1442 by courtesy of Marcel Dekker, Inc.

to an electrical signal and is used in spectrometers. A second example is a piezoelectric crystal-based sensor that converts a mechanical force to an electrical charge translatable to a potential. The piezoelectric effect is reversible; an electric charge will cause a mechanical dislocation in the crystal. Another example of a physical sensor is a platinum resistance thermometer where the resistance of a platinum wire is altered by a change in temperature.

Chemical sensors are devices that allow the analyte or target material through one of its specific chemical parameters to ultimately generate an energy signal, usually electrical, in a transducer through the agency of a selective chemical or physical chemical reaction. A transducer is a material structure inside of which or on whose surface the specific chemical or physical chemical reaction takes place leading to the generation of the energy signal. Thus, there are two parts to the chemical sensor, the interface zone or area where the selective reaction takes place and the usually non-specific transducer.[8] Figure 2 illustrates, functionally, the parts of a chemical sensor.

An example of a chemical sensor is a potentiometric electrode. Here the selective chemical reaction, the redox reaction of the analyte, is in equilibrium at the electrode surface imposing a potential that is proportional to the logarithm of the concentration of the analyte as described by the Nernst equation. For example, a copper electrode in a solution of copper ions will take on a potential in response to the concentration of copper ions. The logarithm of the copper ion concentration is proportional to the electrode potential. Another illustration of a chemical sensor is an amperometric electrode, where a current arises due to the redox reaction of the analyte when the electrode is at the appropriate potential. The concentration of the analyte is proportional to the magnitude of the current. A platinum electrode maintained at the redox potential for the silver/silver ion redox system will detect the concentration of silver ions. A membrane electrode is another type of chemical sensor. The fluoride electrode consists of a lanthanum fluoride (LaF_2), thin, crystal membrane. On the outside surface, the sample side of the membrane, the fluoride ions, F^-, from the sample are attracted electrostatically to the lanthanum ion, La^{3+}, at the surface of the membrane to form a complex. The complexed entities do not penetrate very deeply into the surface. The amount of F^- complexed is a direct function of its activity (see Section III,B,2,*a*) and represents a selective physical chemical reaction. A membrane potential arises because the opposite side of the membrane is exposed to a standard activity of F^- giving a net difference in potential between the two sides. The membrane potential is the non-specific electrical signal of the sensor.

Signal-Conditioning Circuits These circuits modify the signal produced by the sensor so as to provide an accurate representation of the sensor signal with optimal electrical characteristics to drive the readout device. In Figure 1 a number of signal conditioning modes are given and can be

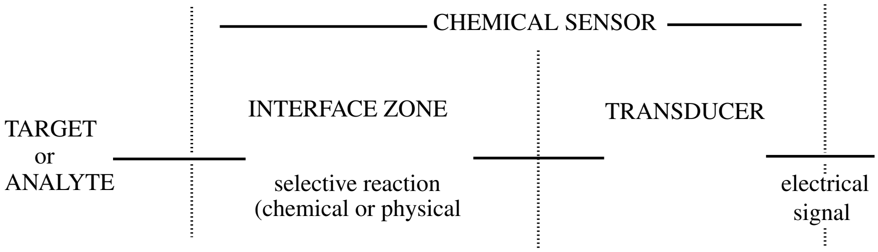

FIGURE 2 Chemical sensor.

placed in four categories—modification of sensor output, amplification, mathematical operation, and signal modification for readout.

The electrical components used in these circuits are of two types, active and passive elements. Active elements, such as solid state devices add energy to a circuit; whereas passive elements, such as resistors, capacitors, inductors, diodes add no energy. Both elements are combined to form active and passive circuits. Active circuits change signals in a complex way. Passive elements are used in active circuits to provide necessary conditions for the proper functioning of active circuits. Some active devices are ionization chambers, vacuum phototubes, operational amplifiers and gas discharge tubes.

Readout Devices The sensor signal modified by the conditioning circuits is ultimately converted into a visual form by the readout device or output transducer. The readout signal may be analog or digital requiring a compatible readout device. Analog readout devices comprise recorders, meters, oscilloscopes, photographic plates and integrators; printers, computers and digital meters with optical displays provide digital readouts. A digital computer may be interfaced to an instrument, in order to compute values from a digital output signal and produce a hard (printed) copy of the data using a printer. Analog output signals may be digitized in order to utilize a computer. The advantages of digital outputs are the statistical benefit derived from counting and analog outputs are advantageous in feedback control systems.

Analog Devices The automatic recording potentiometer or potentiometric recorder has been, over the years, the most frequently used readout device providing a continuous trace on a chart of an analog signal. Its operation is based on a low power servomechanism utilizing a feedback system. The instrumental signal to be measured is compared to a standard reference signal. The amplified, difference or error signal activates the pen-drive motor moving the pen on the chart to a position representing the magnitude of the analog signal. The control of the pen, based on the error signal, denotes the feedback system and the total system is referred to as a servomechanism.[9,10] Two types of recorders, the *Y*-time or *X–Y,* allow the recording of a signal, *Y,* as a function of time or of two signals representing the ordered (data) pair, *x, y,* respectively. In the *Y*-time device, a constant-speed motor moves the chart in the *x* direction while the servomechanism deals with the *y* signal. The *X–Y* recorder has two servo-systems, one for each signal, *x* and *y.* However, recorders may be limited by the rate that the data flows from the instrument. Some recorders can adequately respond to signals during fast scans. For example fast scans in cyclic voltammetry of about 1 volt/sec. can be transcribed using a recorder, however, at faster rates an oscilloscope is necessary.

Almost any instrument can utilize a potentiometric recorder. A *Y*-time analog recorder is commonly used to trace gas and liquid chromatograms; the abscissa, *X* axis, is for retention volume or time and the ordinate is for the detector response.

The oscilloscope is a measuring device with complicated circuitry that allows accurate display and measurement of non-sinusoidal or complex waveforms. The oscilloscope's basic part is the cathode ray tube, CRT. A CRT is a vacuum tube containing an electron gun pointing to a fluorescent screen at the tube's end. The electron gun provides a beam whose movement is controlled by two sets of deflector plates perpendicular to each other. The plates receive the signals representing the waveforms. These analog signals are displayed on a fluorescent screen as *Y*-time or *X-Y* curves. The display is photographed to provide a hard copy of the analog data. The oscilloscope can display data that is generated at high rates, since there are no mechanical movements used in manipulating the electron beam. Where very fast events must be recorded, an oscilloscope is an effective readout device.[11] (See the previous paragraph on the potentiometric recorder.) Oscilloscopes have facilities to store, compare, and manipulate signals.

Analog meters are based on the D'Arsonval meter movement. The electrical current signal passing through a moving coil, to which is fixed a pointer, induces a magnetic field in the coil. A static magnetic field from a permanent horseshoe magnet surrounds the coil. The interaction between the two fields causes the movement of the coil: the degree of movement is determined by the magnitude of the signal current. Analog meters require the analyst to interpret or read the output signal value by the position of the indicator needle or pointer using a calibrated scale mounted on the meter. A resistance placed in series with the meter movement allows the measurement of voltage. Resistance may also be measured with the meter. One weakness of this device is its low internal resistance causing loading errors by high impedance signals.[11]

A meter is used in the analysis of single samples or samples analyzed, serially, at a slow rate on a spectroscopic instrument at one frequency or wavelength. Meters also are employed to indicate proper adjustment of potentials, currents, temperatures, etc. for various instruments.

An electronic voltmeter, EVM, is more sensitive and accurate than the D'Arsonval-based meter previously described, particularly for signals with high impedance. The internal resistance is 10 Mohms (megaohms, 10^6 ohms) or more for d.c. (direct current) signals and 1 Mohm for a.c. (alternating current) signals. The circuits use solid state devices compared to the earlier device, a VTVM (vacuum tube voltmeter). Current and resistance is measurable with the EVM. Its application parallels those for the D'Arsonval-based meter.[11]

A photographic plate or film may be used to collect data in the time domain where all the data are displayed simultaneously, that is a spectrum in emission spectroscopy. The radiation in the dispersion pattern of the sample reflected or transmitted from the prism or grating impinges on the photographic plate.

Electronic integrators determine the area under a curve and are superior in precision to the ball and disk integrator and the several hand methods widely utilized. They may be based on operational amplifier or transistor circuitry. Some potentiometric recorders have a second pen controlled by an integrator and the density of the pen's excursions determine the area under the curve. This last type is not as convenient as the electronic integrators that can correct for baseline changes. Chromatographic peak areas for GC and HPLC (high performance liquid chromatography), anodic stripping analysis peaks, spectroscopic curves, etc. are integrated as a means of quantitation and analysis of an analyte.

Analog computers are available but are not used now to any great extent.

Digital Devices The digital computer or microprocessor interfaced to the instrument brings a broad capability to the display and processing of instrumental data. Data reception and storage is convenient when real time computation and display are not required. Mathematical calculations, including the areas under curves, graphic and tabular displays, correlation with previously collected data, and many other operations can be carried out at one's convenience. Real time processing can be accomplished on a time-sharing basis or with a dedicated computer. The visual display is at a video monitor and a printer provides a hard (printed) copy of the raw and calculated data, graphs, and other information. Computer devices include microprocessors and micro-, mini-, and mainframe computers. The instrument must be carefully interfaced to the computer and this task requires much electronic skill. Instruments providing spectral readouts, the need for number crunching and repetitive analyses can benefit greatly from a computer interface. Some instruments that utilize Fourier transform analysis require a computer capability and many instrumental techniques have been revolutionalized by computer use. The use of the computer[12] in the reduction of noise in instrumental signals by ensemble and boxcar averaging has greatly improved the quality of instrumental data.[12]

Digital meters measure analog signals and provide a digital readout. A/D conversion of the analog input is accomplished electronically. The digital data is displayed as numeric images using solid state devices such as LEDs, light emitting diodes, and LCDs, liquid crystal displays, and lamps such as, NIXIE, neon, and incandescent bulbs. The LED is the more convenient device because its seven segment readout display uses lower currents and voltages than the lamp displays. The LED's red image, due to the semiconductor gallium arsenide doped with phosphorus, may be increased in intensity by using more semiconductor in the LED. The image color of LEDs may be fabricated to be green or yellow, also.[11,13] LCDs operate by means of polarizing light. They use reflected light for viewing, a seven-segment and dot matrix readout display, an a.c. voltage, consume very little power and are more fragile than LEDs.[14] The LCDs and LEDs are the newest and most convenient display devices.

Digital meters can be used in place of the analog variety. The former are more accurate and easier to read.

Instrumental Parameters and Definitions Instrumental characteristics of operation and data treatment and statistics are defined by a number of parameters. A definition of each term is as follows:

- The range of frequencies (information) in the signal is called the bandwidth. During amplification, some amplifiers cannot respond to the range of frequencies in the signal producing an amplified signal with a narrower bandwidth.
- The baseline is the signal obtained when no sample is being examined and reflects the noise inherent in the instrument.
- Calibration is the process relating instrument response to quantity of analyte. In general a series of standard solutions or quantities of analyte are analyzed on the instrument taking reagent blanks into account and using a similar matrix as the sample under consideration. The quantity-response data are plotted to provide a calibration curve where error bars indicate the precision of the method.[15] Other calibration procedures such as the methods of standard additions[16] and of internal standards[17] have advantages in specific situations. The former is helpful in ameliorating interferences from the sample matrix and the latter in correcting for changes in instrument response particularly in GC, and ir (infrared) and emission spectroscopy.[18]
- The gain refers to the ability to amplify a signal and is the ratio of the output to input signal. The

gain may refer to voltage, current or power amplification and its input and output impedances.

- Noise refers to random signals, usually continuous, that restricts the lower detection limit and accuracy of the signal. Noise arises from electronic components and environmental sources and cannot, at times, be completely eliminated.
- The ratio of the amplitude of the signal to that of the noise is called the signal-to-noise, S/N, ratio. This ratio gives the ability to distinguish between signals and noise, that is a measurement of the quality of an instrument. One cannot usually distinguish the signal from the noise when the ratio is less than about 2 or 3.
- Resolution or resolving power is the capability of displaying two signals differing slightly in value. The resolving power, *R,* of a monochrometer concerns absorption of emission spectral signals,

$$R = \lambda / d\lambda \tag{3}$$

is the wavelength under consideration and $d\lambda$ is the difference of wavelength between the two signals. In mass spectrometry resolution refers to the separation of two mass peaks *Ms* and *Ms* + *dMs,* where *dMs* is the difference in masses so that

$$R = Ms/dMs. \tag{4}$$

For resolution for chromatographic methods see Part Two Section III,B,4,*a*.

- Response time refers to the time needed for a pen of a potentiometric recorder to travel the total vertical distance on the *Y* axis.
- Sensitivity, *S,* describes the ratio of the change in the response or output signal, dI_0 of the instrument to a small change in the concentration or amount of the analyte, *dC.* The ratio is given as follows:

$$S = dI_0/dC. \tag{5}$$

- Linear dynamic range, LDR, describes the mathematical relationship between amount or concentration of the analyte and the response of the instrument. An increase in the analyte quantity results in a linear increase in response. The size of the range of quantities accommodated by the instrument response is the key factor for this parameter. For example in voltammetry the LDR is 10^{-8} to 10^{-3} M (molar), five orders of magnitude, in (ultraviolet) uv–visible spectrophotometry, about 10 to 100, and for a GC with a FID (flame ionization detector) the LDR extends from 10^{-1} to 10^{7} ng (nanograms, 10^{-9} grams) or eight orders of magnitude. Obviously the sensitivity remains constant in contrast to a non-linear dynamic relationship.
- The reagent blank or blank in a spectroscopic determination is the signal obtained by the solution of the reagents without any analyte. The sample matrix is important to include, if known, in the blank. In many instances the effect of the matrix is determined indirectly.
- Accuracy defines, mathematically, the absolute error, e_a, inherent in the method when comparing the analytical result, x_i, with the true value, x_t, of the analyte content of the sample.

$$e_a = (x_i - x_t). \tag{6}$$

Preparing a standard sample containing an accurately known concentration of the analyte is required. This is not a simple task, because homogeneity of any mixture is difficult to obtain and ascertain.

- The precision of a method is concerned with the repeatability of the analytical results for a number of analyses on the same sample. There are several ways of expressing precision; standard deviation is a very effective and meaningful measure. The standard deviation, *sd,* for small sets of data is given as follows:

$$sd = \left[\sum_{i=1}^{N} (x_i - x_a)^2 / No - 1 \right]^{1,2}. \tag{7}$$

Here x_i is the experimental value, x_a, the average of the experimental values, and *No,* the number of values. The standard deviation is a measure of the average uncertainty of all the measurements in the data set, x_i, that is $x_1, \ldots, x_N$.[18,19]

Types of Instruments

Analytical instruments can be classified according to categories based on various physical phenomena. The general categories used in this article are spectroscopy, electrochemical analysis, radiochemical analysis, chromatography, and automated analysis. Table 4 illustrates these categories.

Spectroscopy

Introduction Spectroscopic instruments include optical and other types of instruments. The optical instruments analyze electromagnetic radiation, emr, while other spectroscopic instruments deal with sound, mixtures of ions, electrons, and other forms of energy. Other optical methods utilize instruments that make refractometric and polarimetric measurements. Refractometric measurements will be discussed in the section on liquid chromatography.

Spectroscopy, classically, is that area of science where the electromagnetic radiation, emr, emitted from or absorbed

TABLE 4
Bases for instrumental methods

Energy interaction	Process	Instrumental method
EMR, range	Absorption of emr	x-ray, uv/vis atomic & ir spectrophotometry
Emr/magnetic field	Absorption of emr in a magnetic field	NMR spectroscopy
e^-, ions, or electric field	Ion formation/seperation in electric or magnetic field	Mass spectroscopy
Electricity (arc, spark), heat (flame, plasma)	Emission of emr	x-ray, uv/vis, flame emission spectroscopy
Emr, x-ray	Emission of electrons	x-ray photoelectron spectroscopy (XPS or ESCA)
Emr, uv	Emission of electrons	UV photoelectron spectroscopy (UPS)
x-ray or e^-	Emission of electrons	Auger spectroscopy
Emr, uv/vis	Emission of acoustic energy	Photoacoustic spectroscopy
None	Emission via radioactive decay	Radiochemical methods
Emr, range	Fluorescence & phosphorescence of emr	x-ray uv/vis[1], & atomic fluorescence spectroscopy
Emr, vis	Scattering of emr by particles	Nephelometry, turbidimetry
Emr, vis	Scattering of emr by molecules	Raman spectroscopy
Emr, x-ray	Diffraction	x-ray diffraction
Emr, vis	Refraction (bending of light beam)	Refractometry
Emr, uv/vis	Rotation of plane-polarised light	Polarimetry
Emr, uv/vis	Rotation as a function of wavelength	Optical rotatory dispersion
Emr, uv/vis	Rotation using circularly polarized light	Circular dichroism
Electricity	current measurement	Amperometry, coulometry, polarography, voltammetry
Electricity	pass current/weigh-plated material	Electrogravimetry
Electricity	potential measurement	Chronopotentiometry, potentiometry
Electricity	resistance/conductance measurement	Conductometry
Heat	weight loss vs increasing temperature differential temperature vs increasing temperature heat flow to sample vs increasing temperature. Temperature vs volume of reagent	Thermogravimetric analysis. Differential thermal analysis. Differential scanning calorimetry. Enthalpimetric methods

by a substance is resolved into its component wavelengths indicating its intensity and presented as a spectrum. In this category absorption, emission, and photoluminescence (fluorescence and phosphorescence) spectroscopy using x-ray, ultraviolet–visible (uv–vis), and ir radiation, and the measurement of turbidity, or suspended matter by nephelometry and turbidimetry, are included. However, today in a broader sense, spectroscopy includes the following: resolution of electrons of many energies by uv and x-ray photoelectron, Auger etc. spectroscopy; sound waves by acoustic spectroscopy; ions by mass number by mass spectroscopy; and absorption of radiowaves by atoms and electrons exposed to a magnetic field in nuclear magnetic resonance and electron spin resonance spectroscopy. The phenomena of absorption, emission, photoluminescence (fluorescence and phosphorescence), and scattering are the bases of spectroscopic instruments.

b. Spectroscopic instruments

Spectroscopic instrumentation is differentiated with respect to the wavelength range of the instrument, that is x-ray, uv, visible, and ir and type of instrument, i.e. absorption, emission, photoluminescence (fluorescence and phosphorescence), and turbidity. The energy sources, sample cells, wavelength selection devices (gratings, prisms, filters, crystals) and sensors may differ for these various instruments. These parts are listed in Figure 3 for the wavelength regions of from 100 to 40,000 nm (nanometer, 10^{-9} meters). X-ray and non-optical spectroscopic instruments are not included.

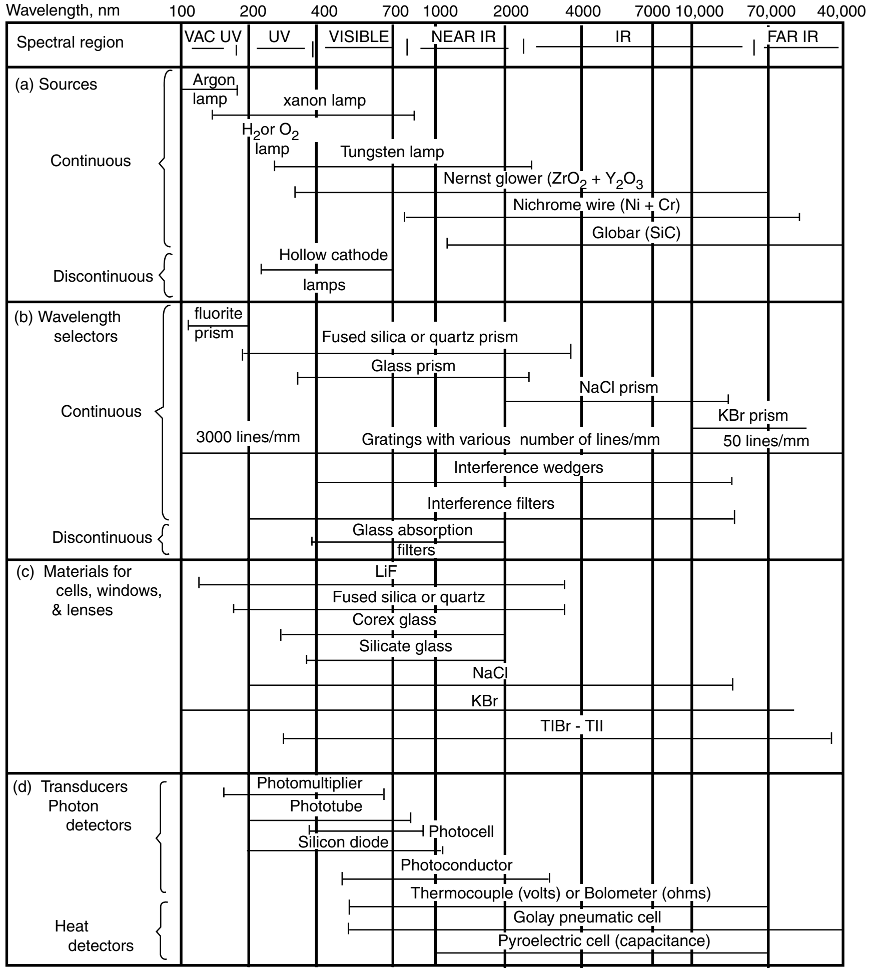

FIGURE 3 Components and materials for optical spectroscopic instruments. (Courtesy of Prof. A. R. Armstrong, College of William and Mary.)

The types of instruments can be characterized by some simple diagrams regardless of wavelength range as given in Figure 4. The basic difference between absorption and emission spectroscopy is the use of a transmitted emr energy source in the former, while in the latter, the sample is stimulated in a thermal or electrical energy source to emit radiation. Photoluminescence (fluorescence and phosphorescence), stimulated by emr, is observed usually perpendicular to the stimulating beam. In nephelometry instrumentation similar to photoluminescence is utilized; turbidimetry can employ absorption instrumentation.

A brief description of the basic parts of the instruments using these phenomena follows.

(1) Energy sources

As noted from the diagrams above, all but emission instrumentation use energy sources that irradiate the sample. In Figure 3 the sources are indicated as a function of the wavelength range of their radiant emissions. Various lamps, i.e., argon, xenon, H_2 (hydrogen) and D_2 (deuterium), and solid state radiators give continuous emissions, i.e., a range of contiguous wavelengths and are used in molecular spectroscopic instrumentation. Photoluminescence and nephelometric instruments use these sources.

For atomic absorption instruments hollow cathode lamps are utilized. They are line (discontinuous) sources providing unique radiation with a narrow bandwidth characteristic of particular element. An individual lamp is usually employed for each element. Some multielement lamps are available.

X-ray sources include x-ray tubes or radioactive sources. The x-ray tube consists of a tungsten cathode that emits electrons when heated. The electrons accelerated by a large potential strike the metal anode generating x-rays characteristic of

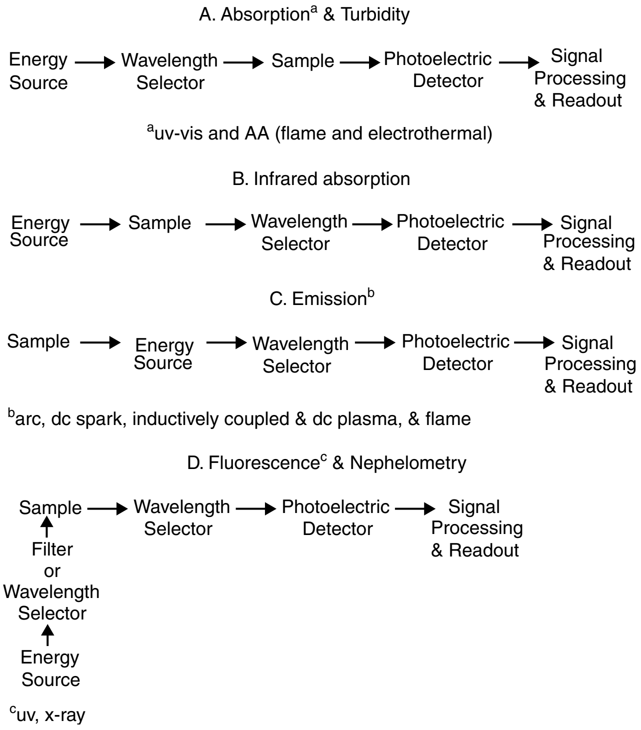

FIGURE 4 Outline of spectroscopic instrumentation.

the particular metal target. Metals such as chromium, copper, iron, molybdenum, rhodium, silver, tungsten and others comprise the anode target. A number of radioisotope sources emit useful x-rays, e.g., iron-55 yields manganese K radiation, cadmium-109 gives silver K radiation, and cobalt-57 provides iron K radiation.

(2) Sample interface

The sample is usually presented as a solution contained in a cell made of material transparent to source radiation for absorption and photoluminescence (see Figure 3). Solid samples are also used. Potassium bromide disks containing homogeneously distributed powdered analyte are used in ir absorption methods.

However in atomic absorption spectroscopy the sample is atomized in a flame, plasma or thermal heat source. In effect the sample container is that volume of flame, plasma or heat source.

Solutions, as well as solid samples in the form of pressed disks, pieces of solids, or solid solutions in borax, are conveniently analyzed in an x-ray fluorescence instrument. Solutions of sufficient thickness are the best sample preparations because of their homogeneity; they may be contained in mylar cells. Obviously the solvent must not contain heavy atoms that fluoresce. Sample surfaces are directly exposed to the x-ray beam (see Figure 5).

In emission instruments the solid sample is placed in an energy source environment, e.g., an electrical arc or spark, a flame, or plasma.

(3) Wavelength selectors

The wavelength selector allows isolation of a particular wavelength segment of the source or transmitted beam. A monochrometer is a selector comprising a grating or a prism which disperses or separates the radiation continuously over a considerable wavelength region. The effective bandwidth of the wavelength, isolated by slits placed before the sample, is quite narrow, 1 nm or less. The grating operates on the principle of interference and the prism by dispersion.

Other wavelength selectors are interference and absorption filters. Their effective bandwidths are about 20 to 50 nm, respectively; they are not continuous. An interference wedge is continuous over a region with an effective bandwidth of 20 nm.

The dispersing device, a single crystal mounted on a rotating table or goniometer (see Figure 5a), is the wavelength selector used in x-ray spectrometers. A specific wavelength and its second and third orders of reflection are diffracted at a given angle of the beam to a particular plane of the crystal. The angle of diffraction depends on the "d" or interplanar spacing of the crystal and the wavelength and is defined by Bragg's law. Some examples of diffracting crystals with their unique wavelength ranges are topaz—0.24 to 2.67 Å, sodium chloride—0.49 to 5.55 Å, and ammonium diphosphate—0.93 to 10.50 Å. (An angstrom, Å, is 10^{-8} cm.) Unlike a prism or a grating that disperses a total spectrum in the spectral regions of the source of radiation, the x-ray monochrometer diffracts a unique wavelength and its orders of reflection depending on the angle of the beam to the crystal plane.

(4) Detectors

In Figure 3 the variety of transducers are listed with their wavelength range of detection. Following is a description of the most commonly used detectors grouped according to their wavelength range.

(a) Uv/visible

(i) Photovoltaic (barrier layer) cells

This detector, which generates its own signal, is sensitive to radiant energy in the visible (350 to 750 nm) region. Light shining on a semiconductor coating, such as selenium or copper(I) oxide plated on an iron or copper electrode, generates a current at the metal–semiconductor interface. A second electrode, a transparent coating of gold or silver on the outer surface of the semiconductor, collects the electrons formed by the action of radiant energy on the semiconductor. The magnitude of the photocurrent is proportional to the number of photons/sec impinging on the semiconductor. This detector is insensitive to low light levels, slow in response, shows a tendency to suffer fatigue, and has a high temperature coefficient. However, photovoltaic cells are rugged, require no separate source of energy and are low in cost. They are used in inexpensive filter photometers.

(ii) Vacuum photoemissive tubes[20]

In a photoemissive detector two electrodes, a cathode with an electron emissive coating and an anode, are enclosed in an evacuated tube. When the saturation potential is applied

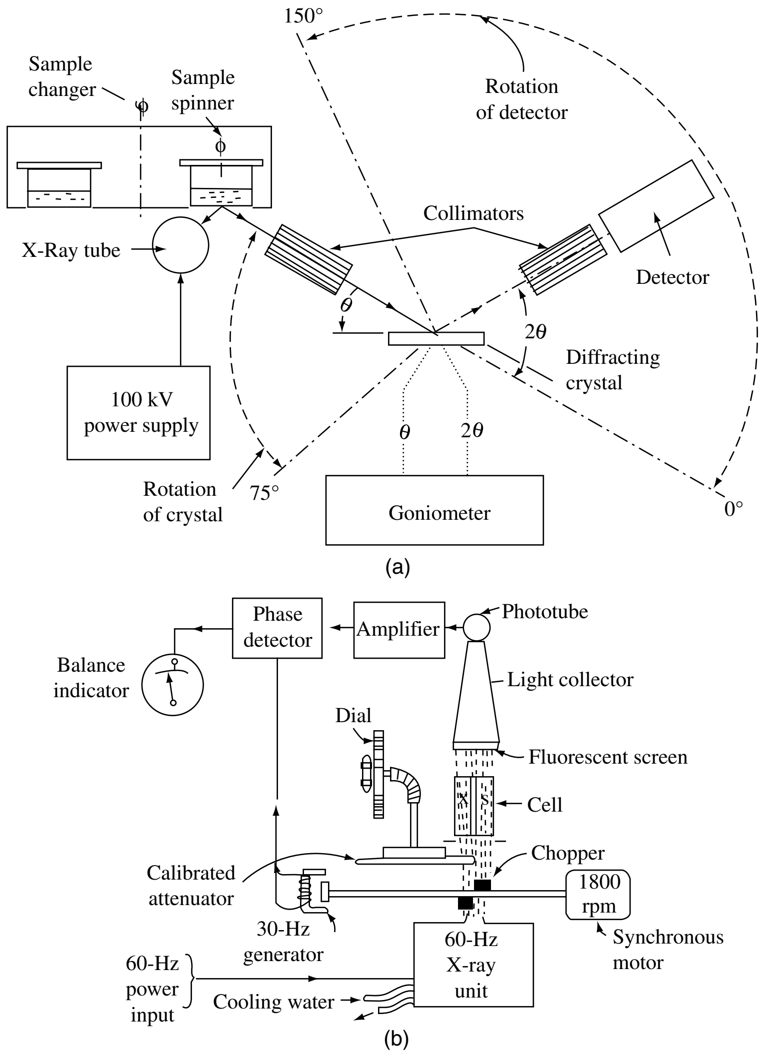

FIGURE 5 (a) Geometry of a plane-crystal x-ray fluorescence spectrometer. Note that the angle of the detector with respect to the beam, 2θ, is twice that of the detector to the crystal face, θ. (Courtesy of Philips Electronic Instruments.) (b) Nondispersive x-ray absorptiometer. (Courtesy of General Electric Co.)

across the electrodes, the radiant energy or photons cause emission of photoelectrons. The photoelectrons are collected at the anode giving rise to a photocurrent. The photocurrent is proportional to the power or radiant energy of the light beam and is independent of the applied potential (see Figure 6). The eleven chemical compositions of various photoemissive cathode coatings determine the wavelength range and sensitivity varying from the uv to the near ir spectral regions. The window in the tube must be transparent to wavelength of interest. The dark current is a small current flowing when no light falls on the cathode and is due to thermal energy and electron emission from potassium-40,[40] K, in the glass tube. It limits the sensitivity of the detector. Although this detector has about one tenth the sensitivity of the photovoltaic cell, its signal may be amplified because of its large internal electrical resistance compared to the photovoltaic detector. The photoemissive detector is used for higher intensity radiation and lower wavelength scanning rates than used with other detectors.

(iii) Photomultiplier tubes[20]

A photomultiplier tube contains a photoemissive cathode followed by a sequential, electron multiplying assemblage of about nine dynodes (electrodes) as illustrated in Figure 7. The voltage of each succeeded dynode increases by 75 to 100 volts. Photoelectrons from the photoemissive cathode are accelerated by the voltage increase of the first dynode causing the release of several electrons for each impinging photoelectron. This multiplier effect continues as the electrons

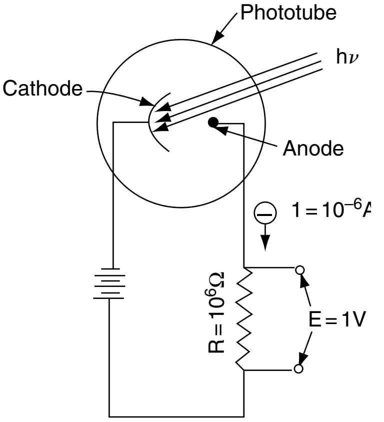

FIGURE 6 Simple phototube circuit. (Reprinted from Ref. (176), p. 441 by permission of Prentice Hall, Inc., Englewood Cliffs, New Jersey.)

contact the succeeding dynodes accelerated by ever higher voltages. A cascade of a large number of electrons is collected by the anode of the ninth dynode. The final photocurrent can be amplified, electronically, before readout. The gain, *G,* can be calculated as follows:

$$G = (fs)^n \tag{8}$$

where *fs,* the secondary emission factor for each stage, depends on the dynode emissive coating and *n* is the number of dynode stages. Using values for *fs* of 3 to 10 for older dynode emissive coatings and 50 for newer coatings and *n* equal to 9 results in gains of about 10^4, 10^9 and 10^{15}, respectively. The response times can vary from 0.5 to 2 nsec (nanosec, 10^{-9} sec). The dark current can be decreased considerably by cooling the photomultiplier detector. Since the dark current is a fairly constant value it may be subtracted or automatically nulled using a potentiometer. The

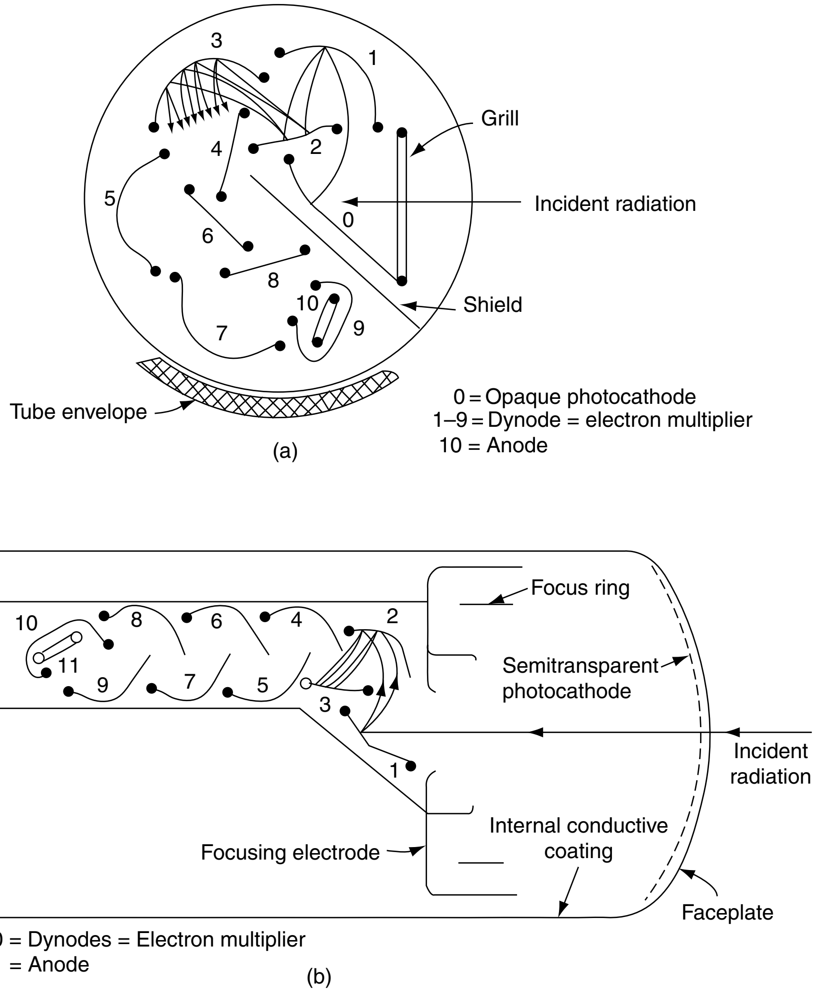

FIGURE 7 Photomultiplier Design. (a) The Circular-Cage Multiplier Structure in a Side-on Tube and (b) The Linear-Multiplier Structure in a Head-on Tube. (Courtesy of the General Electric Company.)

photomultiplier tube is the most widely utilized detector in optical spectroscopic instruments.

(iv) Photodiodes

The photodiode, PD, is a small wafer of silicon dioxide with a shallow layer of *p* and *n* material of the top and bottom surfaces, respectively, to which are attached electrodes. The device is reverse biased. When photons impinge on the optically-active *p* diffusion region, electrons promoted to the conduction band generate a photocurrent that is proportional to the intensity of the optical light beam. The PD detectors are about ten times more sensitive than the vacuum photoemissive tube and are mostly responsive in the visible and near ir regions. Some tubes are sensitive to the uv region at about 200 nm. A lens is optically coupled to each small PD wafer.

Linear arrays or vidicon tubes of these multichannel detectors allow nearly simultaneous detection of a spectrum of wavelengths in instruments operated in the spatial mode (see Section III,B,1,*b,5* Instrumental ensembles), where the detectors are swept electronically. Optical multichannel analyzers consisting of a monochromater, a multichannel detector and a computer are used in flame emission and uv/visible spectrophotometers.[21]

(b) Infrared detectors[22,23]

There are two categories of detectors used for the spectral region above 1.2 μm (micrometer, 10^{-6} m) namely, heat and semiconductor detectors.

(i) Thermocouples and thermopiles

A thermocouple is formed when two wires of a metal are separately joined to the opposite ends of a wire of a dissimilar metal. If the two dissimilar metal junctions are maintained at different temperatures, a thermoelectric current will flow in the circuit. Therefore, if one junction is maintained at a constant temperature, a thermoelectric current will be generated proportional to the temperature of the second junction. The changes in the intensity of incident ir radiation can be detected in ir spectrophotometers using this type of detector. The sensitivity is 6 to 8 microvolts per microwatt and a temperature difference of 10^{-6}°C is detectable (see Figure 8). A thermopile, consisting of a number of series-connected thermocouples, may be miniaturized through thin film techniques to provide an effective ir detector. It has an 80 msec (millisec, 10^{-3} sec) response time with a flat response below a frequency of 0.35 Hz (Hertz).

(ii) Golay cell

The Golay cell is a pneumatic device similar to a gas thermometer. The ir radiation shining on the blackened surface of a sealed cell containing xenon gas causes the gas to expand and distort a diaphragm, a part of the cell wall. The moving diaphragm may be coupled to one plate of a capacitor transducing an ir intensity to a capacitance. In another mechanism the beam of ir radiation is reflected from the mirrored diaphragm surface to impinge on a photocell. The area of coverage of the beam on the photocell changes as a function of the movement of the diaphragm. The intensity of the ir radiation affects the area of the beam that impinges on the photocell and ultimately the magnitude of the photocurrent. The ir beam must be optically focused on the detector. Its response time is 20 msec. Sensitivity is about equal to that of the thermocouple detector. In the far ir it is an excellent detector (see Figure 3).

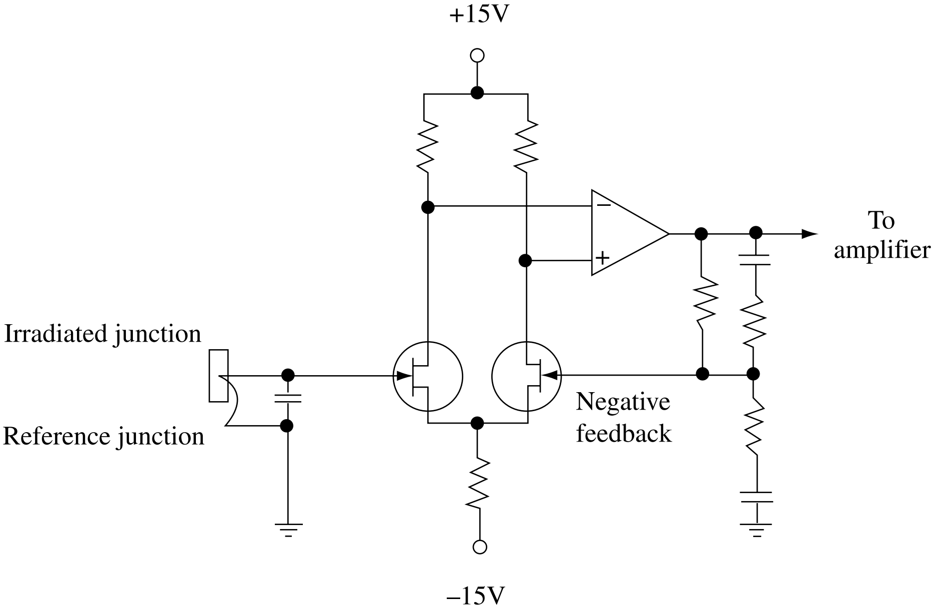

FIGURE 8 Thermocouple and preamplifier (Reprinted from Ref. (180). With permission from the *Journal of Chemical Education*.)

(iii) Pyroelectric detector

The pyroelectric detector is a thin wafer of material such as, $LiTaO_3$ and $LiNbO_3$, placed between two electrodes to form a capacitor. The detector material is a non-centrosymmetrical crystal whose internal electric field is changed as a function of temperature when it is below its Curie temperature. This detector is based on the change of the capacitance of a substance with temperature and is sensitive to the rate of change of the detector temperature. The changing radiation is modulated by chopping or pulsing because the detector ignores steady unchanging radiation. Therefore this detector has a much faster response time than those dependent on temperature directly. Depending on the circuit parameters, the response times may be 1 msec or 10 μsec and the responsivity (detector output/incident radiation) is 100 or 1, respectively. This detector has a large ir range (see Figure 3).

(iv) Photoconductive and photovoltaic detectors

Photoconductive detectors are crystalline semiconductor devices that experience an increase in conductivity upon interaction with a photon. The increase of conductivity is due to the freeing of bound electrons by energy absorbed from the radiation. A Wheatstone bridge is used to measure the change in conductance (see following Section III,B,*2,d.*). The semiconductor materials include the metallic selenides, stibnides or sulfides of cadmium, gallium, indium or lead.

Lead sulfide is commonly used as a detector in the near infrared, 800 to 2000 nm, where it exhibits a flat response. The cell consists of a thin layer of the compound on a thin sheet of quartz or glass kept under vacuum.

Photovoltaic detectors have been discussed for uv/vis spectroscopic instruments (see Section III,B,1,*b.(4),*(a), (*i*)). For ir applications the *p*-type indium antimonide detector, cooled by liquid nitrogen, is available with a sensitivity limit at 5.5 μm. However the two types of lead in telluride detectors extend the ir range. One detector, cooled with liquid nitrogen, has a range of 5 to 13 μm and a second one, cooled with liquid helium, has a range of 6.6 to 18 μm. A minimum response time of 20 nsec (nanosec. 10^{-9} sec) is achieved with these detectors.

(c) X-ray detectors

Gas-filled and semiconductor detectors and signal processors and readout used in the measurement of radioactivity (see Sections III,B,*3,*b,(*1*),(a) and (b) and (2)) are the applicable in x-ray spectroscopy.

(5) Instrument ensembles

The design of an instrument depends on its use and monetary considerations. The several main modes of design are designated temporal, spatial and multiplex. In turn each of these are of the dispersive or nondispersive type.[24]

In the temporal category the instrument scans sequentially, in time, the wavelength in order to determine the intensity. Dispersive systems employ monochrometers that are rotated so as to position the selected wavelength on an aperature or slit preceding the sample or detector. Nondispersive systems utilize a series of absorption or interference filters that are interchangeable.

Spatial systems display the total spectrum with simultaneous determination of the radiation intensities. For a dispersive instrument a monochrometer provides the dispersed radiation and a multichannel detector to detect their intensities. Multichannel detectors utilized are a detector array (silicon diode array or vidicon tube), a number of individual detectors properly positioned, or a photographic plate. In nondispersive systems the radiation beam is divided into a number of beams and each passes through a unique filter followed by a detector.

Multiplex systems employ a single data channel where all the components of the signal are observed simultaneously. A Fourier transform is usually employed to resolve the complex signal into its components requiring the use of a computer. There are distinct advantages to Fourier transform spectroscopy: namely, increased S/N ratio, increased energy throughput, large precision in wavelength measurement, and facility in its use. However, thus far the instrument is costly to acquire and maintain. No further comment will be made in this article about these instruments.[25,26]

Dispersion instruments give more spectral detail because the wavelength selected has a narrower bandwidth wavelength spread. However non-dispersive instruments are usually cheaper, more rugged and have a higher signal to noise ratio. Filter instruments are used frequently in monitoring equipment.

(6) Absorption instrumentation

In the absorption process, radiation passes through the sample and a specific pattern of absorption of different wavelengths occurs leading to a spectrum for that sample. For each wavelength the amount of light absorbed will differ and therefore the amount of transmitted light vary for each wavelength. The intensity of transmitted light is inversely proportional to the concentration of sample and is measured in absorbance, Ab, units. The spectrum is the qualitative factor of identification while the intensity of the transmitted radiation is the quantitative measure. Light is absorbed in the uv and visible region by electrons in the atoms or molecules of a sample. Some elements are identified by atomic absorption, AA, and some functional groups and species by uv/vis spectroscopy. Absorption in the ri is due to vibrational and rotational activity of atoms in molecular groupings, such as functional groups, double, triple, and conjugated bonds, etc.

The spectroscopic curve or an instrument reading provides an absorbance value for a chosen wavelength from which the concentration of the absorbing substance can be computed. The absorbance value represents the degree of attenuation of the radiation of specific wavelength by absorbing substances in the sample solution in the cell. A constant, the absorptivity, *a,* or molar absorptivity, *e,* can be calculated for a pure substance for a given wavelength and solvent. The mathematical relationship between the concentration of a substance, *C,* the path length of the sample cell, *b,* and its absorbance units, *Ab,* is expressed as follows:

$$\text{molar absorptivity, } e = Ab/(b,\text{cm})(C,\text{moles/L}) \qquad (9)$$

$$\text{absorptivity, } a = Ab/(b,\text{cm})(C,\text{g/L}). \qquad (10)$$

The absorptivity, *a,* can be expressed in a number of concentration terms (g/L, grams/Liter and mg/ml, milligrams/milliliter) and path length terms (cm, centimeters and mm, millimeters).

Equations 9 and 10 are a statement of Beer's Law indicating a linear relationship between the absorbance and the concentration for fixed conditions. In analytical determinations the concentration can be calculated using equations 9 or 10. Also used in analysis is a calibration curve, whose slope is absorptivity. It can be drawn using concentrations and corresponding absorbance values. Beer's Law prevails for many substances, but there are deviations for some substances due to chemical, instrumental, and physical phenomena.

(a) Uv/visible instrumentation[27]

A uv/visible instrument consists mainly of uv and visible energy sources (lamps), a wavelength selector (grating, prism or filter), reference and/or sample cell, a detector (photodetector or photomultiplier) and a readout device (recorder, analog or digital meter, etc.) (see Figure 4A). Figures 9 and 10 illustrate the arrangement of these parts for photometers and spectrophotometers, respectively. The distinction between the two types of instruments is that a photometer uses a filter and a spectro photometer a grating or prism as a wavelength selector. In Figure 9 the difference between a single and double beam instrument is shown and the arrangement also refers to a spectrophotometer. The various parts that transmit the light beam such as lens, cells, mirrors, transmission gratings and prisms must be transparent to uv light and be fabricated of fused silica or quartz. Flint glass can be used in the visible region.

(b) Infrared instrumentation[28]

Figure 11 is a schematic of a double beam ir spectrophotometer. The parts and functions are similar to a un/visible instrument, however the arrangement differs—the light beam passes through the sample and then the wavelength selector in contradistinction to the uv/visible instrument (see Figures 4A, 9, and 10). Materials transparent to ir are the alkali metal chloride, bromide, and iodide salts.

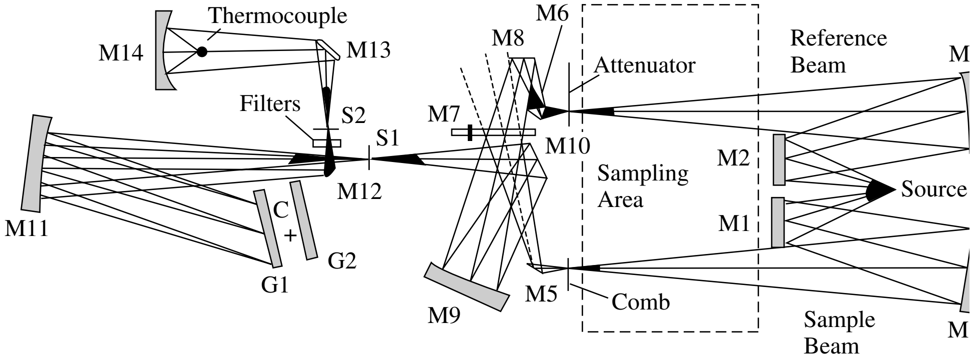

FIGURE 11 Schematic diagram of a typical double-beam infrared spectrophotometer. The symbol M1 through M14 indicate mirrors; S1 and S2 indicate slits; and G1 and G2 indicate gratings. (Courtesy of the Perkin-Elmer Corporation.)

(c) Atomic absorption instrumentation[29]

A schematic for a single beam atomic absorption spectrophotometer is given in Figure 12. Both flame and electrothermal atomizers may be utilized in this instrumentation (see Figure 4A). The hollow cathode lamp is the energy source generating uv or vis radiation that passes through the sample. The flame or thermal area of the electrothermal device acts as the sample cell where the sample solution that has been nebulized (formed into a fine aerosol) is atomized. (Atomization is the formation of free atoms through thermal energy in the flame or thermal area.) The flame is generated from various fuel mixtures: acetylene and the oxidants air, oxygen or nitrous oxide; hydrogen and the aforementioned oxidants; and natural gas and air or oxygen. Each of these mixtures as well as the fuel/oxidant ratio determines the flame temperature, a critical condition for atomization.

(7) Emission instrumentation[30,31]

Emission of emr by elements and some chemical entities, energized by flames, plasmas, and arc, is the basis of emission spectroscopy. The electrons are energized and move to higher energy levels on absorption of the energy. On relaxation, the electron returns to a lower energy level and the absorbed energy is emitted as radiation.

Emission methods give rise to atomic spectra by a series of atomization techniques: namely, flame, inductively coupled argon plasma (ICP), electric arc and spark, and direct current argon plasma, DCP (see Figure 4B). An emission spectrophotometer capable of using plasma and arc and spark sources is illustrated in Figure 13.

(8) Photoluminescence instrumentation

The occurrence of fluorescence and phosphorescence (photoluminescence) refer to substances which on excitation by radiation emit light on relaxation of the excited species. In resonance fluorescence the wavelengths of excitation and emission are the same. However, in many cases the wavelength of emitted radiation is longer than that of the exciting radiation. The difference in fluorescence and phosphorescence is the time delay between excitation and emission. The former is quite small ($<10^{-6}$ sec), while the latter has a time delay of several seconds or longer. Fluorescence can occur in a number of organic and metal-organic complex molecules, and gases on excitation with uv light.

(a) Uv/visible[32]

A general schematic for this instrumentation is given in Figure 4C. Fluorescence of molecular substances is measured

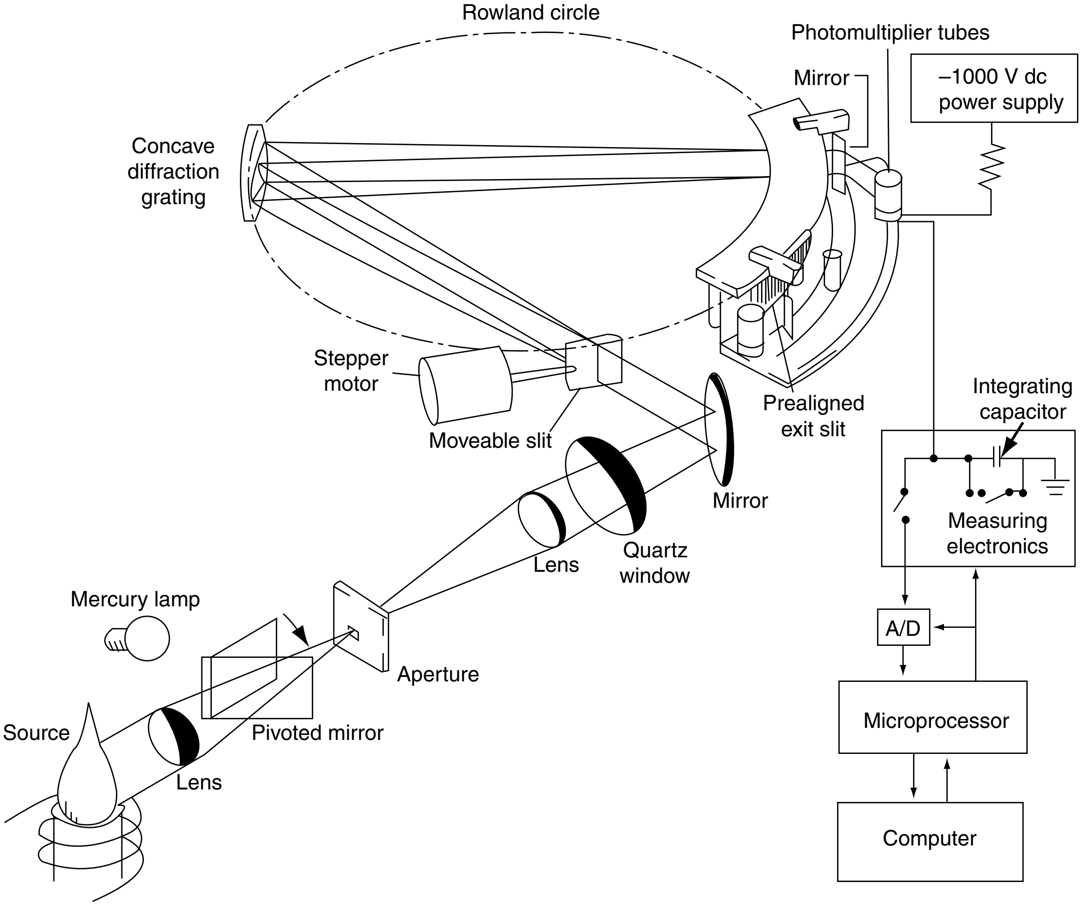

FIGURE 13 A plasma multichannel spectrometer based upon Rowland circle optics. (Courtesy of Baird Corp./IMC Bedford, MA.)

in a fluorometer (see Figure 14) or a spectrofluorometer (see Figure 15).

(b) Atomic[33,34]

Atomic fluorescence is a fairly new instrumental method that has been used for environmental samples. The instrumental arrangement is given in Figure 4C. Because of the dearth of commercial sources of the instrument and no large benefits compared to other atomic spectroscopic instruments there is a small number of literature citations for its use.

(c) X-ray[35]

X-ray fluorescence spectroscopic instrumentation utilizes an x-ray source, i.e., x-ray tube or radioactive source, to energize electrons of the inner orbitals of atoms which on

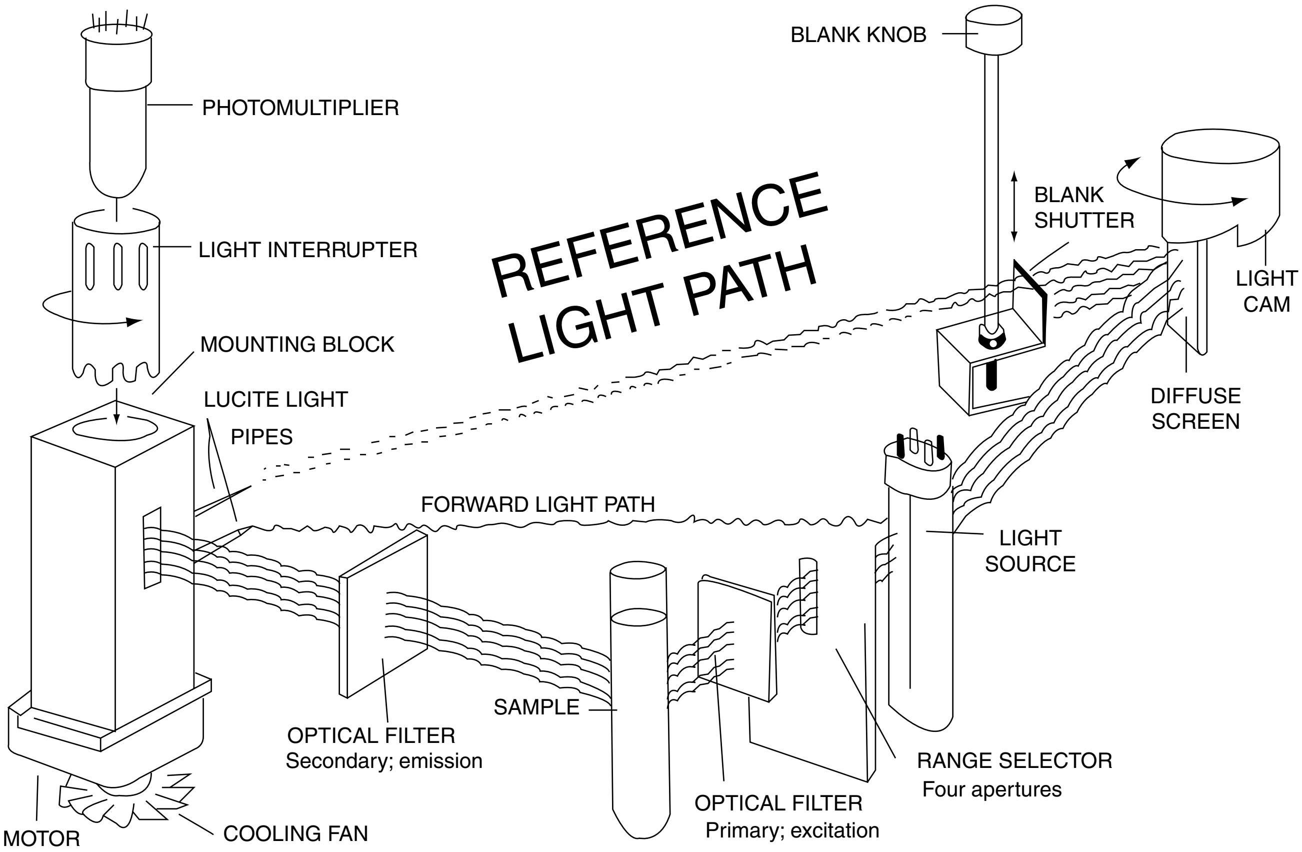

FIGURE 14 The Model 112 Turner Digital Filter Fluorometer. (Courtesy of the Turner Division of Unipath, Mountain View, CA.)

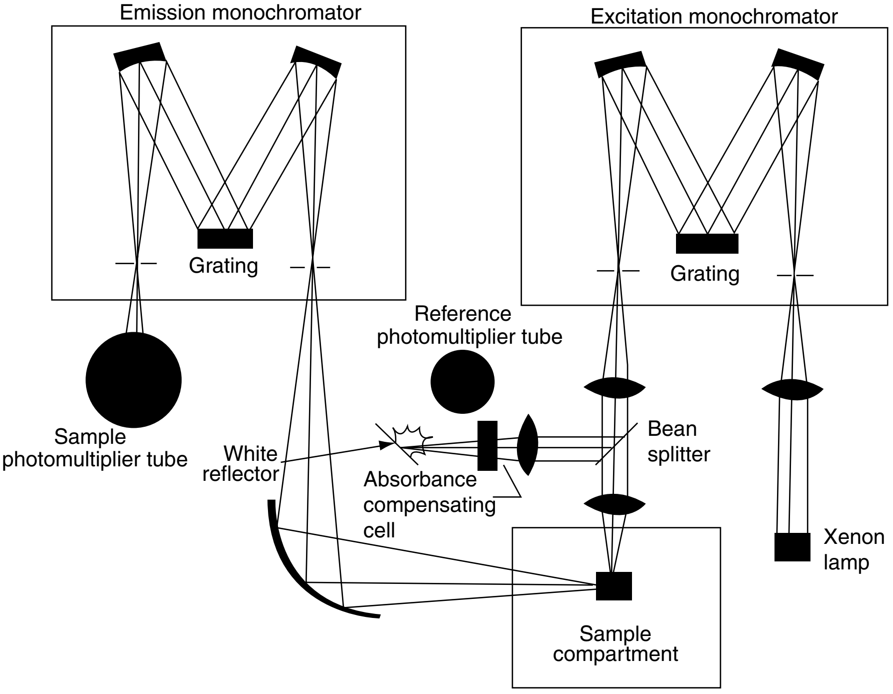

FIGURE 15 A spectrofluorometer. (Courtesy of SLM Aminco Instruments, Urbana, IL.)

relaxation emit fluorescence emission. The wavelengths in the fluorescence emission are unique for different elements. This information may be delineated by wavelength or energy dispersion instruments (see Figure 4C). Wavelength dispersion is carried out with a crystal as a diffraction grating with subsequent detection by a gasfilled detector (see Figure 5), while energy dispersion may be accomplished by a lithium-drifted silicon detector and energy-discriminative electronic circuits (see Figure 16). Non-dispersive instruments use filters.

Elements with atomic numbers greater than 7 (oxygen = 8) fluoresce on irradiation with x-rays. Useful irradiating wavelengths extend from 0.5 to 2.5 Å. Due to the large absorption of wavelengths greater than 2.5 Å by air and spectrometer windows, elements of atomic numbers below 22 (titanium) cannot be detected. Elements with lower atomic numbers can be detected with a change of atmosphere; down to aluminium (atomic no. = 13) in helium and to boron (atomic no. = 5) in a vacuum.

(9) Nephelometric & turbidimetric devices[36]

The presence of turbidity, suspended matter and colloids, in liquid results in the scattering of a beam of incident light passing through the liquid. The scattering process is elastic; the wavelength of incident and scattered light is the same. Particle shape and size distribution, size relative to the wavelength of the incident light, concentration of particles, and molecular absorption effect the angular distribution of scattered light intensity. Since the scattering phenomenon is so complicated analytical results are empirical depending on the use of standards. However, differences in the design of instruments leads to different values for the same standard.

Turbidimetry refers to the measure of the decrease in the intensity of a beam of light undergoing scatter by suspended or colloidal particles in a liquid. If the transmittance is less than 90%, this method is effective. A filter photometer illustrated in Figure 9 is a suitable instrument.

If the intensity of the scattered beam is measured at an angle to the transmitted beam, then the phenomenon is known as nephelometry. Right angle scatter is commonly used for a number of readings, although forward scatter is more sensitive to large particles. Stray light caused by scratches, dirt or condensation on cell walls leads to a positive error. Figure 14, a simple fluorometer, measuring scattered light at 90° can be employed for nephelometric measurements. A surface scatter instrument shown in Figure 17 is used to eliminate stray light. No cell is employed since the flowing water sample surface is directly illuminated with the light beam. Figure 18 illustrates a low range turbidimeter.

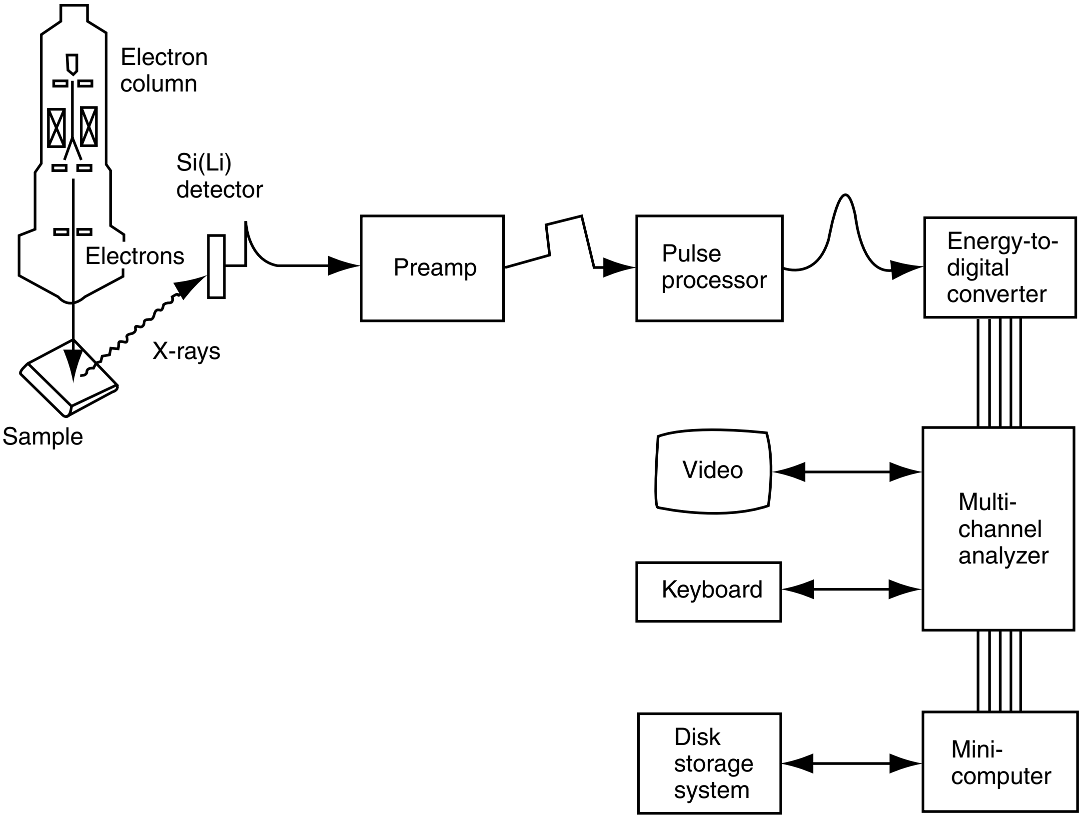

FIGURE 16 Components of a typical energy-dispersive microanalysis system. The Si(Li) detector is cooled in a liquid nitrogen cryostat. The charge pulse from the Si(Li) detector is converted in the preamp to a step on a voltage ramp. The pulse processor converts the signal to a well-shaped voltage pulse with an amplitude proportional to the energy of the x-ray. (Courtesy of the Kevex Instruments, Inc.)

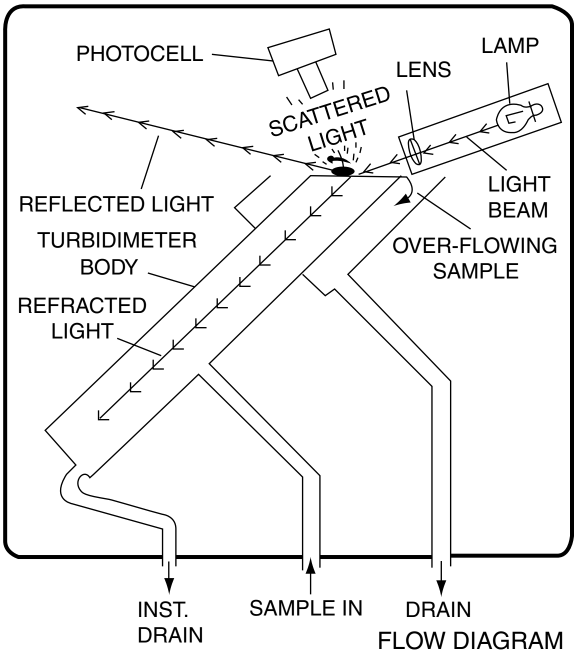

FIGURE 17 Surface scatter turbidimeter. (Used with permission of Hach Co., Loveland, CO.)

(The names turbidimeter and nephelometer appear to be used interchangeably to describe a device measuring turbidity from the intensity of scattered light.) The unit of measurement is the NTU, nephelometric turbidity unit.

Colored constituents in the sample can cause error by absorbing light. A correction can be made in a number of ways: namely, by using a wavelength of light not absorbed by the solution, by making an absorption reading of the clarified solution, or using an instrument that combines both readings.[37]

(10) Other spectroscopic instruments

Mass spectrometry is treated in the gas chromatography/mass spectrometry Part Two Section, *4,c,(2),(a)*. NMR (nuclear magnetic resonance) spectroscopy is not discussed in this article. The technique is, indeed, a most fruitful means of identifying chemical entities and their structures. However, the use in water analysis is not a primary activity. In the identification for known natural and anthropogenic materials its use would be invaluable. No doubt the next edition of this article or an expansion of this article will contain a section on NMR spectroscopy.

(c) Applications of spectroscopic instruments

Standard Methods[2] includes a number of spectroscopic methods using various instruments for the analysis of metals (see Table 5). Colorimetric methods using uv/vis absorption spectroscopy are available in Standard Methods for the following non-metals: bromide, fluoride, iodide, residual chlorine, cyanide, ammonia, nitrate, nitrite, phosphate, sulfide and sulfite. The determination of turbidity in water by nephelometry and the analysis of sulfate ion by a turbidimetric method appears in Standard Methods.[2] See Part Two Section C for more applications.

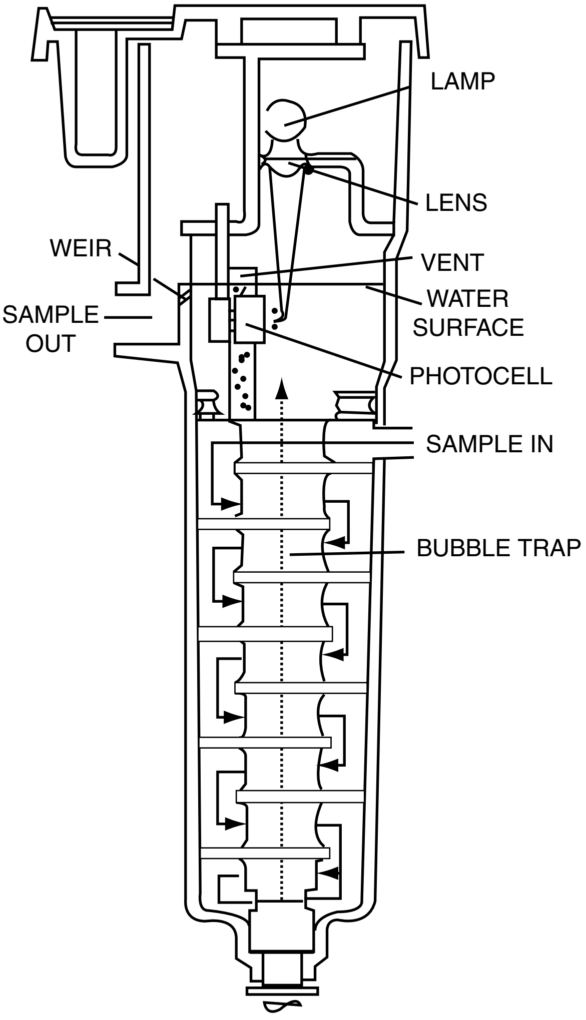

FIGURE 18 Low range turbidimeter. (Used with permission of Hach Co., Loveland, CO.)

2. Electroanalytical instrumentation

Electroanalytical chemistry encompasses a wide variety of analytical measurements and includes three different types of correlations. The first type concerns the relationship between potential, current, conductance (or resistance), charge (or capacitance) and the analyte. For the second is the determination, during the titration, of the analyte and, ultimately, the endpoint by electrochemical means. The conversion of the analyte by an electric current to a convenient gravimetric or volumetric form is the third type. In this section a number of methodologies and their corresponding instruments will be discussed. They include potentiometry, voltammetry, amperometry, coulometry, conductance measurements, and titrations using potentiometry and amperometry for endpoint detection.

TABLE 5

Metals Analysis by Spectroscopy[a]

Metals	Atomic Absorption	Method	Flame
Sb, Bi, Cd, Ca, Cs, Cr Co, Cu, Au, Ir, Fe, Pb Li, Mg, Mn, Ni, Pd, Pt K, Rh, Ru, As, Na, Sr Tl, Sn, Zn		direct aspiration	air-acetylene
Al, Ba, Be, Mo, Os Rh, Si, Th, Ti, V		direct aspiration	N_2O-acetylene
[b]Al, Sb, As, Ba, Be Cd, Cr, Co, Cu, Fe, Pb Mn, Mo, Ni, Se, Ag, Sn		electrothermal	none
[c]Cd, Cr, Co, Cu, Fe Pb, Mn, Ni, Ag, Zn		chelation[d]/ extraction[e]	air-acetylene

Potentiometric Instruments An instrument consisting of an electrochemical cell containing indicating and reference electrodes and electronic means for measuring cell potential to within 0.001 volt (depending on the accuracy desired) may be optimized to measure concentrations of various ions and molecules. The indicating electrode is the sensor which gives the specific electrochemical detection of the analyte in question, while, the function of the reference electrode is to provide a stable reference potential for the indicating electrode. The potential of the indicating electrode changes as a function of the concentration of the analyte according to the Nernst equation,

$$E = E^0 - (0.0591/n)\text{Log }\alpha_{red}/\alpha_{ox}. \quad (11)$$

The activities of the reduced and oxidized species are α_{red} and α_{ox}, respectively, n is the number of electrons in the redox reaction and E^0 is the standard reduction potential of the redox couple when the activity is one.

For species, Sp, its activity, α_{Sp}, is a variable related to its concentration in Moles/L. The symbol, [Sp], represents the concentration of Sp in Moles/L. The α_{Sp} is defined by the equation,

$$\alpha_{Sp} = f[Sp]. \quad (12)$$

The activity coefficient, f, varies inversely with the ionic strength of the solution. (Ionic strength is a function that can be calculated from the concentration of ions in solution and their ionic charges.) Therefore, at high concentrations of electrolytes, the ionic strengths are high, and the activity coefficients, small, less than one. Activity and concentration are approximately equal when the ionic strength is low and f is equal to values between 0.90 to 1.

We shall make a simplifying, practical, and slightly erroneous substitution replacing activity with concentration [Moles per liter] as follows:

$$E = E^0 - (0.0591/n)\text{Log}[\text{red}]/[\text{oxid}]. \quad (13)$$

A convenient expression for the log of the concentration of some species if the p function. By definition it is

$$pF = \text{Log } 1/[F]. \quad (14)$$

The most common p function is pH, defined by Log $1/[H^+]$ as measured by a glass electrode (a membrane electrode). However this function applies to other species, e.g., pOH, pCa, pNO_3 etc. The p functions can replace the log of the reciprocal of the concentration terms.

The specificity of the indicating electrode is determined by the materials of construction and the structure. There are several types of indicating electrodes, metallic electrodes of the first, second, and third kinds and membrane (selective) electrodes including glass, solid-state, liquid membrane, gas sensing, and enzyme and microbial electrodes. The latter two electrodes can be of the potentiometric and amperometric types. For organizational convenience and simplicity all these electrodes shall be discussed in this section entitled, potentiometric instrumentation.

(1) Metallic electrodes[12]

An electrode of the first kind of a metal wire, rod or plate in equilibrium with its metallic ion in solution. For example, a silver indicating electrode, a silver wire, in contact with silver ions, Ag^+, gives the potential mathematically described by the Nernst equation,

$$E = E^0 - (0.0591/n)\text{Log } 1/[Ag^+] \quad (15a)$$

$$e = E^0 - (0.0591/n)\text{ pAg} \quad (15b)$$

Metallic electrodes of inert metals such as platinum, gold, palladium, etc. and non-metals such as carbon and boron carbide may be used as indicating electrodes when the redox couples are soluble species as Fe^{2+}/Fe^{3+}. However the electrode response is not always reversible for some combinations of electrodes and redox couples leading to nonreproducible potentials.

An electrode of the second kind consists of a metal electrode whose surface is coated with a slightly soluble salt of that metal or a metal electrode in contact with a solution containing a low concentration of a complex of that metal. An example of the former is a mercury electrode coated with slightly soluble mercurous chloride making the electrode potential sensitive to chloride ion concentration in the solution. Most reference electrodes are of the former type. Two examples are the calomel (mercury/mercurous chloride) and the silver/silver chloride electrodes. Figure 19 is a schematic of a calomel reference electrode.[38] A solution of known concentration of chloride ion bathes the electrode allowing the potential to remain constant. Potassium chloride concentrations at several different levels, 0.1 or 1.0 M or saturated are often used providing several different reference electrodes. As predicted by the equilibrium and Nernst equations for the calomel reference electrode (see equations 16a and 16b), different chloride ion concentrations will result in different potentials.

$$Hg_2Cl_2(s) + 2e \rightleftharpoons 2Hg(1) + 2Cl- \quad (16a)$$

$$E = E^0 - (0.0591/n)\text{Log } [Cl^-]^2 \quad (16b)$$

Since $Hg_2Cl_2(s)$ and Hg(1) are a solid (s) and liquid (1), respectively, insoluble and not in ionic form in the electrode electrolyte (see Figure 19), they are not represented in the Nernst equation. (2e represents the number of electrons taking part in the reaction.) Similar equations can be written for the silver/silver chloride reference electrode.

A metal electrode made sensitive to a second metal is an electrode of the third kind. The metal electrode is immersed in the analyte solution containing a small concentration of the metal complex and of a similar complex of the second metal. The electrode potential is dependent on the concentration of the ion of the second metal.[39]

(a) Oxidation–reduction potential, ORP[40]

The measurement of the ORP of a system can provide valuable information about its oxidative state. It must be understood that the ORP value is the overall potential of the system being measured, not necessarily at equilibrium, and very seldom relates to one species. With caution in interpretation in mind, the ORP value can be used essentially in two area: biological and chemical inprocessing measurements and control.

The ORP measurement is made in a cell using a nonpolarizing indicating electrode, a reference electrode and a suitable potential readout device—an electronic voltmeter. The indicating electrode, an electrode of the third kind, is usually a noble metal such as gold or platinum in the form of a wire or button. The redox system equilibrates electronically with the indicating electrode and the reference electrode. For the following system,

$$M^{b+} + (b - a)e \rightleftharpoons M^{a+} \quad (17)$$

one can write the reduction potential, $E_{Mb\,+\,/Ma\,+}$, using the Nernst equation, where b and a are the number of charges and $b > a$, and E^0 is the standard reduction potential of the system.

$$E_{Mb+/Ma} + = E^0_{Mb+/Ma+} - 0.0591/(b - a)\log \alpha_{Ma+}/\alpha_{Mb+} \quad (18)$$

If one assembles a cell to measure the ORP of this system using an indicating electrode and a standard hydrogen electrode, the cell potential value measured is the potential of the

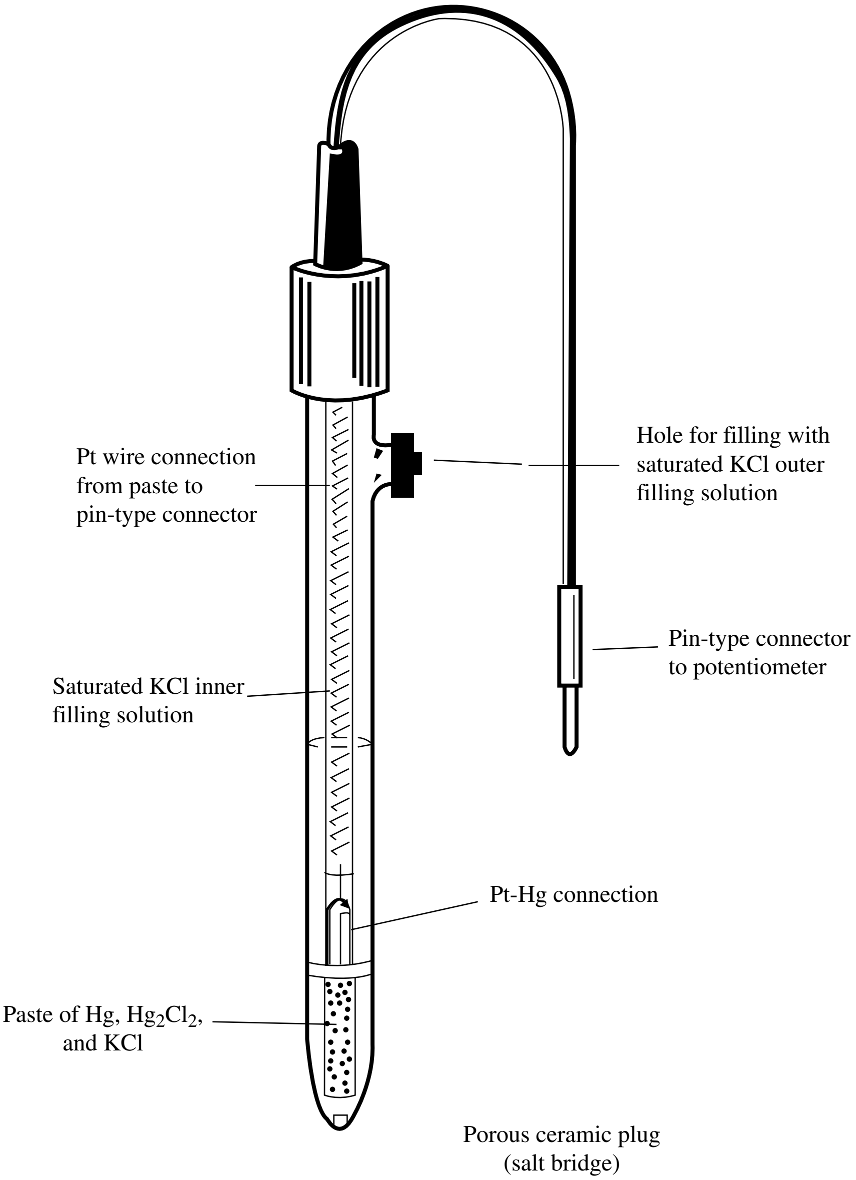

FIGURE 19 Commercial saturated calomel reference electrode. (Courtesy of Thomas Scientific.)

indicating electrode, $E_{Mb+/Ma+}$, since the potential of the standard hydrogen electrode is zero. This potential is referred to as, E_h, the "h" referring to the standard hydrogen electrode. The sign, however depends on the sign of the standard reduction potential, E^0, and the relative concentrations of M^{b+} and M^{a+}. In the cell the sign of E_h depends on the direction of the flow of the electron current; if the flow is from the hydrogen to the indicating electrode, the ORP is negative and flow in the opposite direction indicates a positive value.

However, since the standard hydrogen electrode is not practical to use, a calomel or silver-silver chloride reference electrode is conveniently employed. The cell potential is then designated, E_c, when a calomel reference electrode is used. The E_c value is converted to the E_h or ORP value using the standard potential for the calomel reference electrode, as follows:

$$E_h = E_c + E_c^o . \tag{19}$$

The ORP or E_h measuring cell can be standardized readily using a saturated solution of quinhydrone. However, gold electrodes show no concentration dependence, whereas platinum electrodes show a marked dependence in the quinhydrone solution.[41]

The ORP values can be expressed as pE. The value of pE measures redox power, at equilibrium. Large positive values indicate a strongly oxidizing environment and smaller or negative values a strongly reducing environment. Varying values for pE of −10 to 14 are found in water systems. E_h − pH limits for natural environments and E_h values for sanitary engineering processes have been published.[42,43,44]

(2) Membrane electrodes[45,46,47]

Membrane electrodes are those electrodes that contain a selective membrane that responds to the presence of specific ions or molecules. In these electrodes a potential develops across a selective membrane, ideally, in response to a specific ion or molecule. However, the mechanism of physical and/or electrochemical action differs for the different types of membrane electrodes. The membrane, the differentiating feature of these electrodes, can be crystalline, glass, or a porous polymer. All membrane electrodes contain, internally, a reference electrode and a known standard activity of the analyte ion (see Figure 20). Membrane electrodes are quite different from metal electrodes in their electrochemical and physical mechanisms and structural design. However, as in all potentiometric measurements the membrane (indicating) electrode forms a cell with the reference electrode. Therefore, potentiometric measurements using selective electrodes have two reference electrodes; the external reference in the sample solution and the internal reference that is part of the selective electrode. Those substances important in wastewater analysis and detected by these electrodes are listed in Table 6.

Two subdivisions of membrane electrodes can be envisioned: namely, ion- and molecular-selective electrodes. In this article the electrodes are categorized as follows: glass, solid-state, liquid membrane, gas sensing and enzyme and microbial electrodes. The latter three electrodes detect molecules, whereas the first three are sensitive to cations and anions. Enzyme and microbial electrodes are designed to operate in either the potentiometric or amperometric mode. For simplicity both types will be treated in this, the potentiometric instruments section. However the type will be clearly indicated.

(a) Glass electrodes[48]

The glass electrode commonly refers to the glass membrane electrode used to measure pH (or hydrogen ion activity or concentration). A glass electrode may also be sensitive to cations of sodium, potassium, lithium, and silver[49]. This electrode has a selective membrane, a thin glass bulb of specific chemical composition, that responds most sensitively to a specific cation. Inside of the bulb is an internal standard analyte solution of known activity and a reference electrode; the outside surface contacts the sample solution (see Figure 20).

The mechanism of the function of the glass membrane is quite involved and the following explanation is offered.[50] The glass membrane has an inner dry layer, about 50 μm thick, sandwiched between 5–100 nm thick layers of hydrated glass (silicic acid gel): that is, the hydrated layers are on the inside and outside surfaces of the glass bulb. The hydrated glass layer attracts specific cations via an ion exchange or adsorption mechanism to, most likely, an ionic fixed sites. Conductivity is due to transport through the dry layer, ideally by the specific ion, but actually by a cation such as sodium, Na^+; hydrogen ion, H^+, is not transported through the dry layer. The inside layer interfaces with a fixed standard analyte concentration and therefore a fixed quantity of cations on its sites, while the outside layer contacts the sample solution whose analyte activity may vary with each sample. A membrane potential develops due to the difference of charge between inside and outside hydrated layers.

The glass electrode must be standardized with solutions of known cationic activity, since the glass membrane does not respond ideally giving rise to errors due to asymmetry potentials, non-ideal transport effects, etc. These electrodes have very high resistances, therefore direct-reading, solid-state instruments with large internal resistances are required: that is, an electronic voltmeter. The instrument has an adjustment to corret the meter reading during the standardization.

(b) Solid-state electrodes[46,47]

Solid-state electrodes are of two kinds: The homogeneous type is fabricated from insoluble, crystalline, metallic salts, while the heterogeneous type is of insoluble, non-crystalline

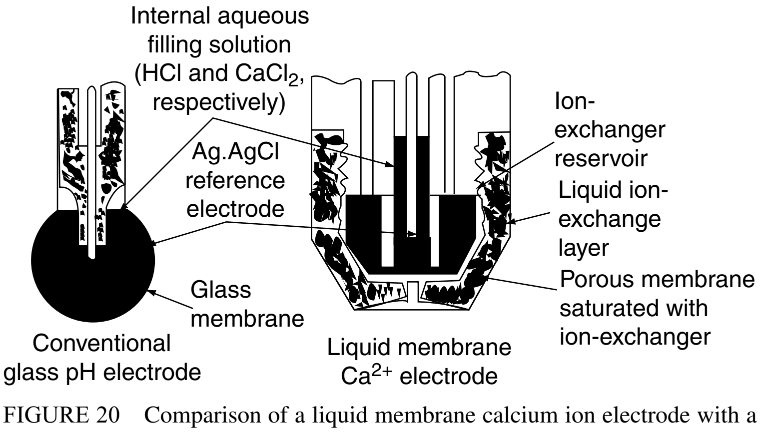

FIGURE 20 Comparison of a liquid membrane calcium ion electrode with a glass electrode. (Orion Research Inc.: Boston, MA with permission.)

precipitates of metallic salts. The first type is made of a slice of a single crystal, a pressed pellet, or a casting from molten material of the crystalline metallic salt, that comprises the selective electrode membrane. Insoluble metallic precipitates encapsulated in inert, polymer matrices constitute the second type.

The fluoride electrode, a homogeneous solid-state electrode, is composed of a 10 mm diameter disk of lanthanum fluoride, LaF_3, doped with europium fluoride, to increase conductivity. The crystalline slice of LaF_3 is 1–2 mm in thickness. Figure 21 illustrates a solid-state electrode. The internal solution in a fluoride electrode serves two purposes: It bathes the membrane with a known standard activity of fluoride ions and provides the internal silver/silver chloride reference electrode with a known activity of chloride ion.

The inside and outside layers of the LaF_3 membrane ionize as follows:

$$\underset{\text{surface}}{LaF_3} \rightleftharpoons \underset{\textit{surface}}{LaF_2^+} + \underset{\text{solution.}}{F^-} \tag{20}$$

The amount of charge on each face depends on the fluoride concentration in the sample (outside) or the standard (inside) solutions. The layer interfacing with the lower concentration of fluoride ions will have a positive charge with respect to the other face; the equilibrium will favor the ionization leaving a surplus of positively charged LaF_2^+ ions in the layer. This difference of charge mirrors the variation in fluoride concentration of the two solutions giving rise to the membrane potential. The differences in the chemical potentials for the two ion exchange equilibria for the two faces results in the membrane potential (see equation 20). There is some similarity to the mechanism encountered in the glass electrode.

The pF value is expressed in terms of the cell potential, Ev, a constant, 0.0591, and Le, a combination of the internal and external reference electrode potentials and junction potentials, and an expression for the activity of the internal standard.

$$PF = (Le - Ev)/0.0591 \tag{21}$$

The fluoride electrode, which may be used in a temperature range of 0 to 80°C, detects fluoride ion concentrations of saturated to 10^{-6}M (0.02 ppm, parts per million). Limitation of detection is controlled by the solubility of the lanthanum fluoride. A lower solubility leads to a lower detection limit, other factors being constant. Except for hydroxyl ion, OH^-, this electrode is uniquely selective for fluoride ion; measurements at pH values above 8 (OH^- activity $>10^{-4}$) result in serious error. For 0.1 M OH^- and 0.001 M F^- there is, approximately, a 10% error. At pH values below 5 (H^+ activity $>10^{-5}$) hydrogen ions associate with fluoride ions to form the hydrogen fluoride molecule. The fluoride ion activity is, therefore, decreased. Since the fluoride electrode does not respond to the HF molecule, the electrode can only indicate the free fluoride ions in solution. The error is due to this chemical equilibrium pointing to the specificity of this electrode. The fluoride electrode most closely fulfills the conditions of an ideal, ion specific electrode.

Other solid-state electrodes of interest are Br^-, Cd^{2+}, Cl^-, Cu^{2+}, CN^-, F^-, I^-, Pb^{2+}, Ag^+/S^{2+}, and SCN^-. (See Table 7 for a list of commercially available solid-state electrodes.) These electrodes provide measurement of their respective ions, overall, in the concentration range of 1 to 10^{-8} M. Each electrode has its own unique interferences.[51] Some mixed, insoluble, silver salt electrodes have multiple detection capabilities. A membrane containing an equivalent molar content of silver sulfide and halide (Cl^-, Br^- or I^-) ion will detect silver ion (similar to a metal electrode of the first kind) and sulfide, S^{2-}, ion (Similar to an electrode of the second kind). An electrode, similar to one of the third kind, is a mixture of silver sulfide with cadmium, lead or copper(II) sulfide yielding an electrode sensitive to cadmium, lead or copper(II), respectively.

(c) Liquid membrane electrodes[51]

Liquid membrane electrodes can detect a variety of mono and divalent anions and cations for example, BF_4^-, Ca^{2+}, $C10_4^-$, NO_3^-, K^+ and water hardness ($Ca^{2+} + Mg^{2+}$).[51] The membrane is a porous polymer disk which is filled with a water-immiscible, organic solvent containing a dissolved organic ion exchanger or chelating agent (neutral carrier). Figure 22

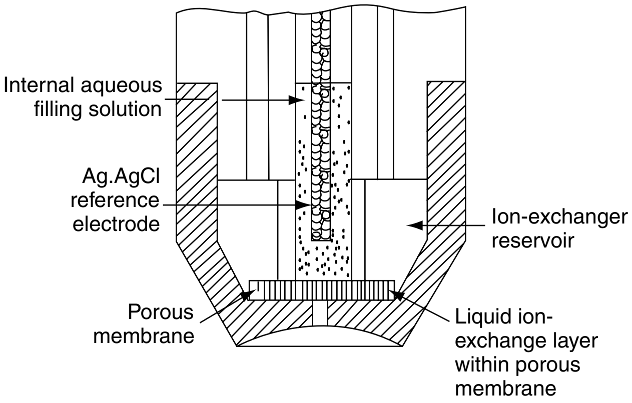

FIGURE 22 Construction of liquid ion-exchange electrode. (Orion Research Inc.: Boston, MA with permission.)

depicts the general structure of a liquid membrane electrode. Another rendition of the membrane is a hydrophobic polymer (e.g. polyvinyl chloride) film formed with the organic ion exchanger or chelating agent as an integral part of the membrane ensemble disk.

As seen in Figure 22, the membrane mediates between the standard analyte solution and the sample solution. The ion exchanger or chelating agent dissolved in the immiscible organic solvent layer (a straight chain alcohol) permits cations or anions to diffuse between the two aqueous phases, sample and standard. After some period of time, equilibrium will be established to provide a stable, membrane potential, meter reading. A calcium ion, Ca^+, electrode utilizes the ion exchanger, bis(2-ethylhexyl) phosphoric acid, $[(RO)_2POOH]$, where R = 2-ethylhexyl.

At each interface the following equilibrium is established.

$$[(RO)_2POO]_2Ca \rightleftharpoons 2(RO)_2POO^- + Ca^{2+} \qquad (22)$$

The pCa value is expressed in terms of the cell potential, E_v, and two constants, 0.0591 and Le (see equation 21) as follows:

$$pCa = 2(Ev - Le)/0.0591. \qquad (23)$$

The potassium electrode utilizes a chelating agent, valinomycin, an antibiotic and a microcyclic ether, that selectively complexes potassium ions. Thus the potassium electrode is composed of a 10^{-4} to 10^{-7} M solution of valinomycin dissolved in decane in the porous polymer disk (see Figure 22). The internal solution contains a known activity of potassium chloride; the chloride ion is for the silver/silver chloride reference electrode and the potassium ion, K^+, for the reference potassium activity. The electrode selectivity for K^+ over Na^+ is 3,800 times, an excellent specificity factor.

(d) Gas-sensing electrodes[12]

A gas-sensing electrode assembly featured in Figure 23 is effective for the analysis of gases. This electrode assembly is actually a cell with an indicating glass electrode, a silver-silver chloride reference electrode and a cell containing internal solution. The gas diffuses through the membrane into the thin layer of internal solution where a chemical reaction takes place generating some soluble reaction products. A specific product of this reaction that is proportional to the concentration of the analyte in the sample is detected by a selective electrode sensitive to the specific reaction product.

Two types of gas-permeable membranes are used in this assembly, homogeneous and microporous. The former is a thin (0.01 to 0.03 mm) silicon rubber membrane which allows the gas to "dissolve" in the membrane and leave by dissolving in the internal solution. A microporous membrane, about 0.1 mm thick, is prepared from hydrophobic polymers (polypropylene or polytetrafluoroethylene) and contains pores about 1 μm in diameter. Water, electrolytes and other polar substances are excluded from these membranes, but gases easily penetrate the membrane effusing through pores into the internal solution. In this manner the gaseous analyte in a solution or in a gas sample is separated from the sample matrix.

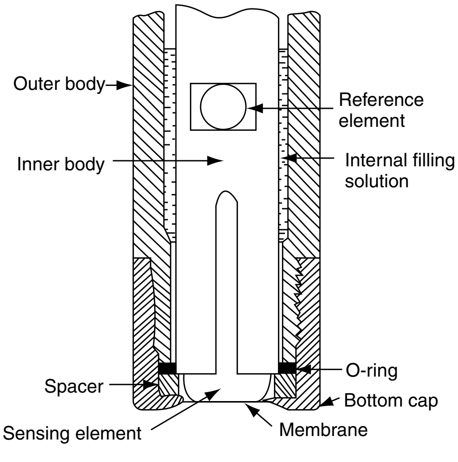

FIGURE 23 Construction of the gas-sensing electrode. For example, in the CO_2 gas-sensing electrode, the filling solution containing bicarbonate ion, HCO_3^-, forms a thin film between the sensing element, a glass electrode, and the membrane. A suitable reference electrode, e.g., SCE or Ag/AgCl can be the reference element. The CO_2 gas diffusing into the thin film reacts chemically with the HCO_3^- forming hydrogen ion, H^+, that is detected by the glass electrode. See the text and equations 24–26 for the chemical mechanism of the CO_2 gas-sensing electrode. (Orion Research Inc.: Boston, MA with permission.)

An example of a gas sensing probe is the ensemble illustrated in Figure 23 used in physiological investigations to measure carbon dioxide, CO_2, content of gas or water samples. The CO_2 in the sample travels through the membrane dissolving in the internal solution. The internal solution contains a relatively high concentration of bicarbonate ion HCO_3^-. The reaction which takes place between the dissolved CO_2 and water in the internal solution is

$$CO_2\,(aq) + H_2O \rightleftharpoons HCO_3^- + H^+. \tag{24}$$

The equilibrium (K and K′ are equilibrium constants) taking place in equation 24 is written

$$K = \left[HCO_3^-\right]\left[H^+\right]/\left[CO_2\right]. \tag{25}$$

Since the $[HCO_3^-]$ is relatively high in the internal solution, then the equation can be written

$$[H^+] = K'[CO_2]_{\text{external.}} \tag{26}$$

Measurement by the glass electrode for the hydrogen ion activity will yield the CO_2 analyte concentration. An important feature of this gas sensing assembly is that the analyte never comes in contact with the selective ion electrode.

Nitrogen dioxide, NO_2, can be detected in the presence of the gases, namely, CO_2, SO_2 and NH_3, using a nitrate electrode because of the following equilibrium

$$2NO_2\,(aq) + H_2O \rightleftharpoons NO_2^- + NO_3^- + 2H^+. \tag{27}$$

In Table 8 gas-sensing ensembles available commercially are listed.[12]

TABLE 8
Gas-sensing electrodes

Gas	Detected ion	Sensing Electrode[b]
CO_2	H^+	glass
NH_3	H^+	glass
Diethyl amine	H^+	glass
HCN	CN^-	silver (Ag_2S)
HF	F^-	fluoride (LaF_3)
H_2S	S_2^-	silver (Ag_2S)
NO_2	H^+ or NO_3^-	glass or nitrate
SO_2	H^+	glass

The substances in the parentheses indicate the composition of the solid-state electrode.

(e) Enzyme and microbial electrodes[45,54–56]

Enzyme and microbial electrodes can be an amperometric, membrane, or a conductometric electrode convered by a film or membrane containing the immobilized enzyme or microbial organisms. A permeable membrane intervenes between the enzyme or microbial film and the electrode (see Figure 23). In the course of measurement the analyte diffuses through the immobilized enzyme undergoing an enzymatic reaction. One of the participants of the reaction, product or reactant, is sensed by the electrode. These devices provide a unique combination of two selection processes—specificity of enzyme or microbial reactions and of the selective electrode.

Measurements for two electrochemical modes, amperometric and potentiometric, are made as follows: In the potentiometric mode the log of the concentration of the detected species is a linear function of the measured electrode potential (Nernst equation). In the amperometric mode the concentration of the detected species is proportional to the electrode current. The potential of the amperometric electrode chosen corresponds to the redox potential of the detected species. Through the stoichiometry of the enzyme or bacterial reaction, the concentration of the analyte is easily calculated from the concentration of the detected species.

However, the compatibility between conditions for enzymatic and microbial action and the optimal electrode sensing environmenta in the form of pH, solvent, ionic strength, temperature, etc. must be taken into account. At times the compromises made in the conditions do not serve well the measuring objective of the enzyme or microbial electrode ensemble. This point will be illustrated.

(i) Enzyme electrodes[45,54,56]

Enzymes are immobilized in several ways, e.g., absorption on a porous inorganic structure or polymer gel membrane or copolymerization with a compatible monomer to form a thin membrane. The immobilized enzyme film is viable for from about two to four weeks. The modular construction of the electrode permits easy replacement of the immobilized enzyme membrane.

(x) Potentiometric type

A potentiometric enzyme electrode may be formed from a gas-sensing electrode assembly containing an ion- or molecular-sensitive electrode. The immobilized enzyme membrane is inserted in the space allotted for the thin film of internal solution (see Figure 23). An example of this electrode is the measurement of urea where reaction with the enzyme urease is illustrated as follows:

$$\text{urea} + H_2O + \text{urease} \rightarrow CO_2 + 2NH_4^+. \qquad (28)$$

At an alkaline pH the forms NH_3 which is detected by an ammonia, gas-sensing electrode. Alternatively, a pH/glass electrode can be used to determine the change in pH due to the hydrolysis of the NH^4_+ ion. Potentiometric enzyme electrodes are also available for the analysis of L-lysine and L-tryptophane.

Incompatibility of enzyme or bacteria with the selective electrode can occur because of the differences in pH for optimal enzyme, microbial, and selective electrode activity. For example in the determination of urea, the enzyme, urease, converts urea to ammonium ion, NH^4_+, and bicarbonate ion, HCO_3^-. This reaction optimally occurs at a pH of about 7. An ammonia gas-sensing electrode is the electrode used and the NH^4_+ ion, enzymatically formed, requires a pH of 8 or more to change NH^4_+ to ammonia, NH_3, which is sensed by the electrode. Thus none of the components are operable, optimally, at each other's best pH. An alternative selective electrode in this enzyme electrode is a glass electrode which detects NH^4_+. However, Na^+ and K^+, are also sensed thereby obviating some of its selectivity.

An automatic analyzer is available for the analysis of urea that addresses the problem of optimal pH conditions (see Part Two Section 5,*b,(3),*(*c*),(*iii*)).

(y) Amperometric type

The glucose electrode consists of an amperometric probe covered with immobilized glucose oxidase. The enzymatic reaction is as follows:

$$\beta\text{-D-glucose} + O_2 + H_2O + \text{glucose oxidase} \rightarrow H_2O_2 + \text{D-glucono-}\Delta\text{-lactone}. \qquad (29)$$

Either oxygen or peroxide may be detected as a measure of the glucose content. The decrease in oxygen or the increase in peroxide is proportional to the glucose concentration. Therefore, an oxygen or peroxide amperometric electrode can be used. Each electrode has a specific advantage; the oxygen-based electrode doesn't respond to other reaction substituents but the peroxide does respond to other oxidizable components of low molecular weight. However, the oxygen electrode has a lower sensitivity than the peroxide probe, since it has a high background signal.

The oxygen electrode (see Section III,B,*2,*b,*(2),*(a)) is used in a number of enzyme electrodes because of its selectivity.[56] Amperometric enzyme electrodes are also available for the analysis of alcohols, L-amino acids, ascorbate, L-glutamate, lactate, lactose/galactose, oxalate, salicylate, sucrose, and uric acid.[56]

Enzyme electrodes have been incorporated into an automatic or semi-automatic analyzer (see Part Two Section 5,*b,(3),*(*c*),(*iii*)).

(ii) Microbial electrodes[52,53]

Microbial electrodes are similar in construction and operation to enzyme electrodes. In the microbial electrodes a polymeric membrane containing immobilized organisms is placed between the electrode and the analyte solution. The nature of the analyte dictates the species of organism. Several examples of analytes, immobilized organisms and electrodes that comprise a number of microbial electrodes are listed in Table 9.

(x) Potentiometric type

Glutamic acid and glutamate can be detected by a microbial electrode utilizing a CO_2, gas-sensing electrode.[57,58] The

TABLE 9

Microbial electrodes[a]

[b] Amp.—amperometric; GS—gas sensing; FC—fuel cell.

immobilized Escherichia coli, having glutamate decarboxylase enzymic activity, participate in the following reaction:

$$\text{Glutamic acid}+\text{enzyme}\rightleftharpoons\text{CO2}+\text{g-aminobutyric acid.} \quad (30)$$

The sample solution is at pH 4.4, low enough to assure the presence of CO_2 (pK = 6.34) instead of HCO_3^- (see equation 24). This electrode responded very slightly to some other amino acids.

A linear dynamic range is obtained in the following terms: a linear relationship exits between the log of the concentration range, 100–800 mg/L, vs. the potential of the CO_2 electrode. The standard deviation, sd, is 1.2 mg/L. Measurement time is 5 minutes. The sensor functioned consistently for more than three weeks and 1,500 determinations.

(y) Amperometric type

An example of a microbial electrode of use in wastewater analysis is the ammonia electrode illustrated in Figure 24. The nitrifying reactions are as follows:

$$NH_3+1.5O_2+\text{Nitrosomonas sp}\rightarrow NO_2^-+H_2O+H^+ \quad (31)$$

$$NO_2^- + 0.5O_2 + \text{Nitrobacter sp} \rightarrow NO_3^-. \quad (32)$$

Oxygen concentration is detected, amperometrically, by the Pt electrode. The current decrease is linearly related to the NH_3 concentration when the NH_3 concentration is below 42 mg/L; the minimum detectable NH_3 concentration is 0.1 mg/L. This sensor has about a 4 min. response time.

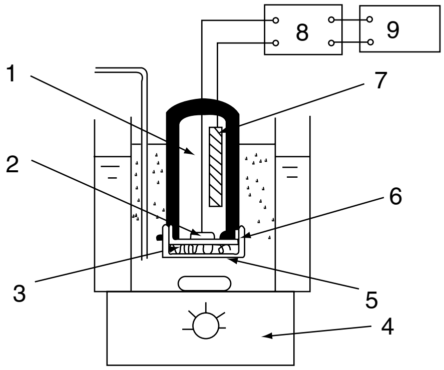

FIGURE 24 The microbial sensor system for ammonia. 1. Electrolyte (NaOH); 2. Cathode (Pt), 3. Immobilized cells of nitrifying bacteria; 4. Magnetic stirrer; 5. Gas permeable Teflon membrane; 6. Karube uses a bacterial electrode employing Trichosporon cutaneum to measure biochemical oxygen demand in wastewater treatement. The difference between the steady state and initial electrode current was correlated to 5-day BOD, BOD_5.[71] A BOD_5 measuring system[52] utilizing a different microbial electrode is described in Section 5,*b,(3)*,(*c*),(*ii*).

b. Voltammetric and amperometric procedures

Voltammetry and amperometry are used to determine the concentration of an electroactive analyte through current measurement under various potential regimes. In voltammetric procedures the current is measured as a function of the potential scanned between two potential values. Amperometric methods measure current at a fixed potential.

Amperometric methods apply to electrochemical sensors which are used directly or in a variety of titrimetric methods. Voltammetry can be divided into two categories:

In polarography the dropping mercury electrode, DME, is utilized and other voltammetric methods employ a variety of solid and paste electrodes. Polarography includes linear-scan (classic), current-sampled, and normal- and differential-pulse, and alternating-current techniques. Other voltammetric methods comprise fast linear-sweep, cyclic, and stripping voltammetry.

As described in Section III,B,*2*,a, the working electrode is the sensor in these electrochemical methods. The cell may consist of two or three electrodes. There are two basic types of cells, electrolytic and galvanic. In an electrolytic cell the redox reaction occurs due to the imposition of a potential from an outside source. The galvanic cell is based on a spontaneous reaction occurring through the proper choice of anode and cathode materials and the electroactive analyte. Electrolytic and galvanic cells are used in amperometry, while electrolytic cells are employed in voltammetry.

Voltammetric and amperometric currents are measured using working microelectrodes (surface areas of a few square millimeters) under conditions leading to polarization of the working electrode. The condition of polarization of an electrode exists when a change of potential of the electrode will not result in a change in the current generated.

Polarization occurs when the analyte is impeded in its electrochemical reaction with the electrode surface. The analyte–electrode reaction rate is dependent on the rates of a number of rate processes giving rise to several types of polarization. These are as follows: Concentration polarization is the limited access of the analyte to the electrode surface due to the rate of mass transfer of analyte by diffusion. Charge or electron transfer polarization arises through the slow, heterogeneous transfer of electrons between the analyte and the electrode surface. Physical or surface polarization occurs when adsorption, desorption, or crystallization (electrodeposition) processes occur. Reaction polarization takes place when the analyte or intermediates undergo chemical reactions before or after electron transfer.

(1) Voltammetry[50,75]

(a) Polarography[76,77,78]

Polarography is a voltammetric method where the dropping mercury electrode, DME, is the indicating electrode. The DME is a length of capillary tube connected by tubing to a mercury reservoir situated above the capillary. The polarographic cell contains the DME and a reference electrode for a two electrode system and a third electrode, usually a platinum wire, in a three electrode system (see Figure 25). Drops

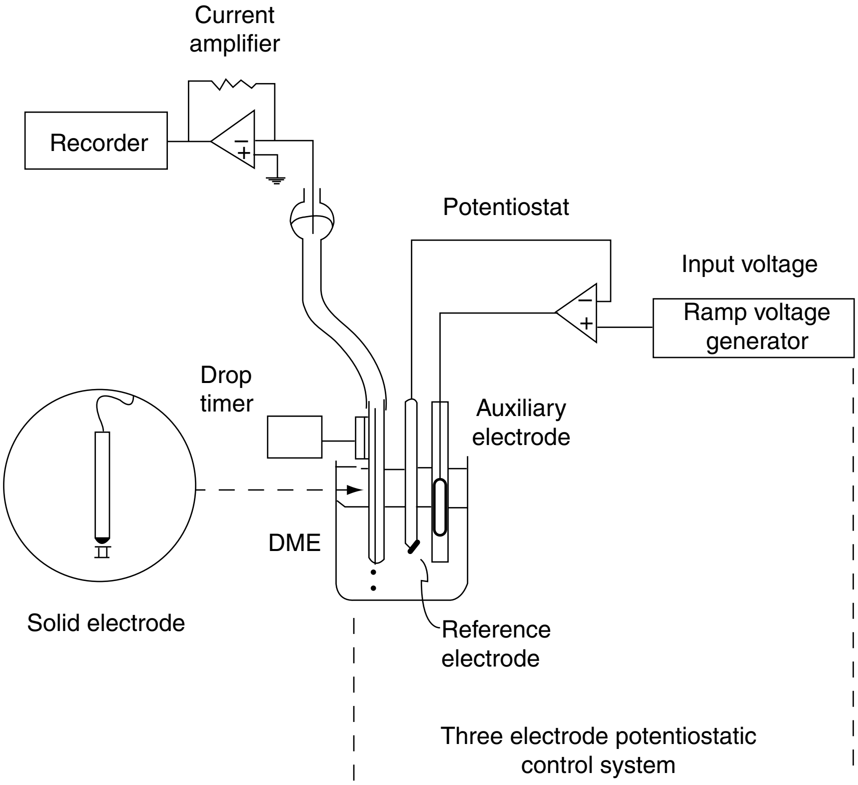

FIGURE 25 Three-electrode polarographic and voltammetric analyzer. A DME equipped with a drop timer or solid electrodes (gold, platinum, glassy carbon, wax impregnated carbon, etc.) are employed for polarographic or voltammetric analysis, respectively.

issue constantly from the DME. The rate of mercury flow, *m,* is 1 to 3 mg/second and is dependent on the lumen and length of the capillary and the height of the mercury column (the applied pressure) in classical (linear scan) polarography. Drop diameters are between 0.1 and 1 mm. The large excursions seen in Figure 26A on the plateau of the curve are due to the growth of the mercury drop. In current-sampled, and normal- and differential-pulse polarography drop time, t, is controlled by a mechanical or electrical device causing dislodgement of the drop at chosen drop times of 1 to 5 sec. The excursions on the curve are diminished because drops times are decreased as compared to classical polarography (see Figure 26A). The DME provides a renewable surface electrode that prevents the anomalous surface effects experienced, at times, with solid electrodes.

The polarographic cell solution containing the analyte and an indifferent electrolyte are purged with pure nitrogen to remove all dissolved oxygen. (A reduction wave for oxygen occurs and interferes with the analyte wave.) The indifferent electrolyte, e.g., potassium chloride, removes the possible condition of electrostatic attraction or repulsion of a charged analyte resulting in a migration current, i_m. This then allows the analyte to approach the electrode by the process of diffusion leading to a diffusion current, i_d, solely. The voltage is scanned with a linearly increasing d.c. ramp of 1 to 5 mv/sec (mv, millivolts). In the voltage scanning process, before reduction or oxidation of the analyte takes place, impurities in the solution contribute to a small current known as the residual current, i_r, resulting in a baseline of slowly increasing current as a function of potential (see Figure 27). The electrochemical redox reaction of the analyte begins at the decomposition potential in a heterogeneous transfer of electrons between the analyte in solution and the electrode surface. The current increases, sharply, until the limiting current, i_L, is reached where it remains constant due to concentration polarization. Concentration polarization is a necessary condition in some types of voltammetry. Figure 27 shows a polarogram and the measurement of the diffusion current of a polarographic wave for a substance i_d.

A number of scanning and measuring modes, i.e., linear scan (classic), current-sampled (tast), normal and differential pulse, and fast-linear sweep, are available. Figure 26A and B illustrates the various polarographic curves for each of these scanning modes. The classical "S" shaped curve is obtained with linear (classic), current-sampled (tast), normal pulse techniques. The fast linear scan gives a distorted "S," while the differential pulse produces a differential curve. The height of the wave, the diffusion current,

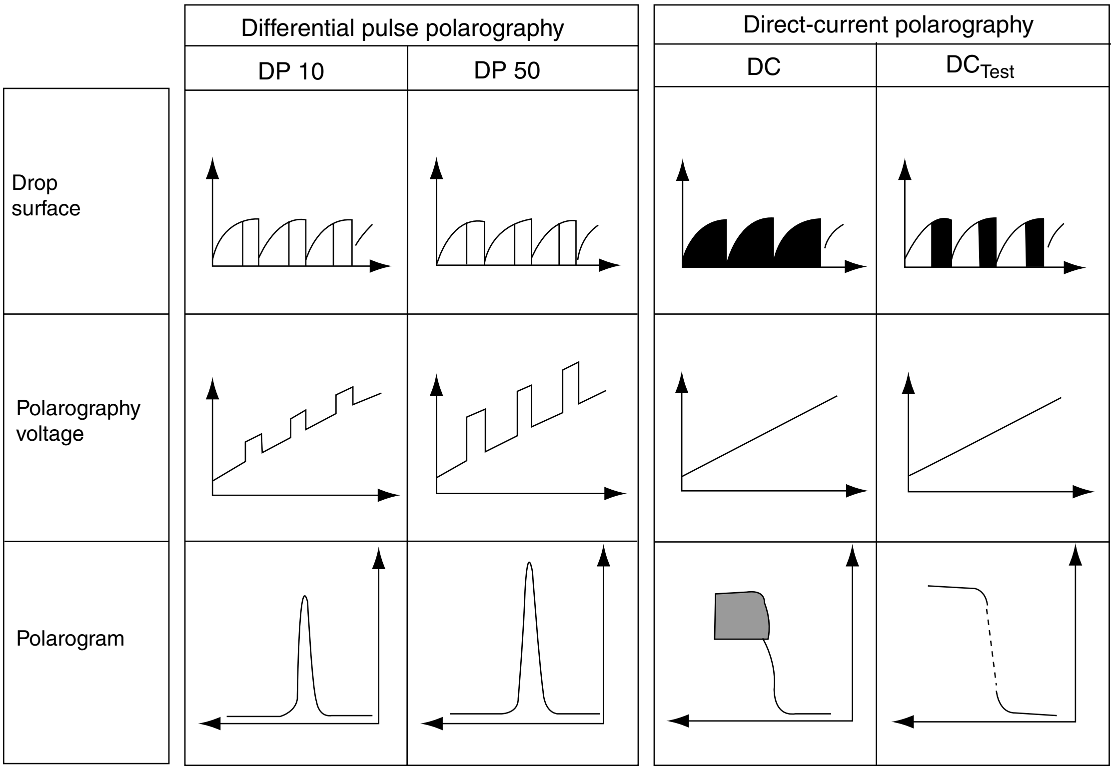

FIGURE 26A Direct-current, DC, and differential pulse, DP, polarographic methods. (Last and current-sampled polarography are synonymous.) The following are detection limits and $E_{1/2}$ resolution values i.e., 2×10^{-6} M and 0.2 V, 1×10^{-6} M and 0.2 V, and 1×10^{-7} M and 0.05 V for DC, DC tast, and DP polarography, respectively. (Courtesy of Brinkmann Instruments, Inc.)

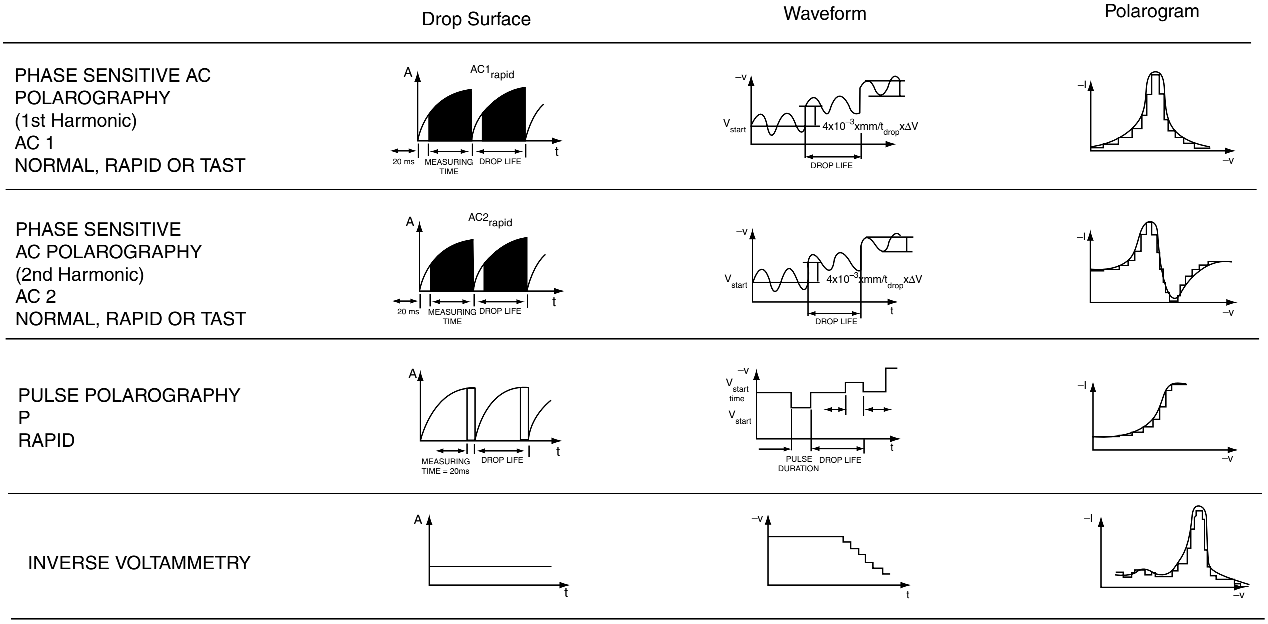

FIGURE 26B Other polarographic and voltammetric methods. (Pulse polarography refers to normal pulse as differentiated from differential pulse polarography. Inverse and stripping voltammetry are synonymous.) The following are detection limits and $E_{1/2}$ resolution values i.e., 5×10^{-7} M and 0.05 V, 5×10^{-7} M and 0.2 V, and 10^{-9} M and 0.1 V for AC and normal pulse polarography, and stripping voltammetry, respectively. (Courtesy of Brinkmann Instruments, Inc.)

i_d, is proportional to the concentration of the electroactive analyte, while the half wave potential, $E_{1/2}$ in volts, is the qualitative factor identifying the analyte (see Figure 27). For the differential pulse curve, the height of the peak, i_p, is proportional to the concentration of the analyte and the peak potential, E_p, is almost equal to the $E_{1/2}$. The standard reduction potential, E^0, and the $E_{1/2}$ value are approximately equal (see equation 11). The Ilkovic equation relates the i_d, in amperes, with the diffusion coefficient of species S, D_s in cm^2/seconds; the concentration of the analyte, C in moles/L; the number of electrons transferred in the redox reaction, n; the flow rate of mercury, m in mg/seconds; and the drop time, t in seconds as follows:

$$i_d = 708nD_s^{1/2}\,Cm^{2/3}\,t^{1/6}. \qquad (33)$$

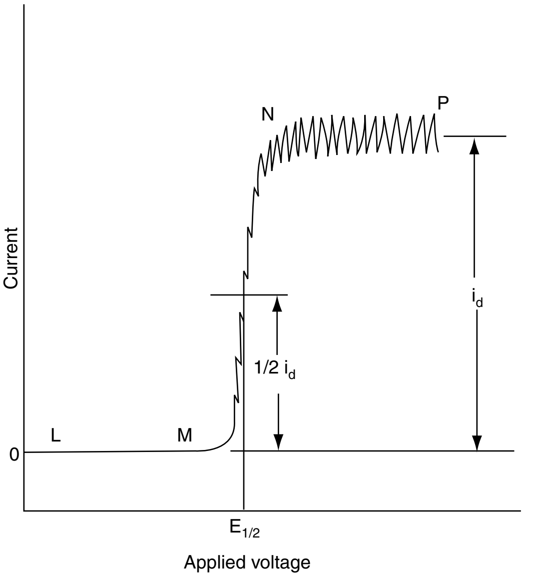

FIGURE 27 Typical polarogram. The line LM represents the residual current, i_r and i_d the diffusion current. (Reprinted from Ref. (176), p. 394 by permission of Prentice-Hall, Inc., Englewood Cliffs, NJ.)

In linear scan or classic polarography an impediment to low level detection is the changing non-faradaic charging current that electrostatically charges the mercury drop. (Consider the drop as a condenser.) As the area of the mercury drop increases with time, the rate of area increase decreases with time. Thus, the non-faradaic charging current decreases with time and is quite low at the end of the drop time. The total polarographic current is a sum of the diffusion current, i_d, the charging current and the residual current, i_r. (The i_r, due to electroactive contaminants, is rather small and invariant with time.) Since the charging current is an unknown quantity the signal can not be amplified to increase the sensitivity of the method without introducing a considerable but variable error. To obviate the charging current problem, normal-and differential-pulse[79] and current-sampled modes were developed (see Figure 26). In each of these modes the current is measured during the last 5 to 20 msec of each drop before the drop is dislodged. At that point the charging current is at a very low level and doesn't cause much error on amplification to increase sensitivity.

In the normal pulse technique, an increasing d.c. pulse is imposed on the linearly increasing d.c. ramp on each successive drop. A 20-to-100 mv pulse is imposed on each mercury drop in the differential pulse mode. The voltage pulse leads to an increased surge in current by the electroacive species undergoing reaction at the electrode surface due to the change in voltage. This enhanced current occurs in both normal- and differential-pulse. There is also a decrease in non-faradaic charging current because the measurement is made at the end of the drop life-time about 40 msec after the pulse is applied to allow for the exponential decay of the capacitive current. In the normal pulse technique the current is measured as in the current-sampled method, in the last 5–20 msec; whereas in the differential pulse mode the current is the difference between the diffusion current before the pulse and the current at the end of the pulse on each drop. The enhancement of the polarographic current in normal and differential pulse techniques is due to two effects, enhancement of the faradaic current and a decrease in the nonfaradaic charging current. The differential method is less sensitive than the normal pulse method, however its resolution is higher. The pulse techniques are more sensitive than classical polarography (see Figures 26A and B).

Fast linear sweep, LS, polarography carries out a fast sweep of the voltage range on one drop of mercury.[12] A differential curve is obtained whose summit or peak current is composed of the surge in current previously mentioned in pulse techniques and the i_d. The peak current, i_p, is given by the equation

$$i_p = (2.69)\left(105\mathrm{n}^{3/2}\ \mathrm{ArD}_s^{1/2}\ \mathrm{Cv}^{1/2}\right). \tag{34}$$

Here Ar is the area of the electrode, v is the voltage scan rate in volts/sec, and the remaining terms are those given in equation 33. E_p for a reversible reaction is written

$$E_p = E_{1/2} - 0.065/\mathrm{n}. \tag{35}$$

This procedure has the advantage of good resolution as in the pulse methods, speed, and increased sensitivity (see the discussion in the following paragraph on LSV and Figures 26A and B).

Alternating current polarography employs 1 to 35 millivolts of a.c. of 10 to 60 Hz superimposed on a d.c. ramp of 5 mv/sec used in the previous methods. The a.c. faradaic current responsible for the redox reactions of the analyte is recorded as a function of the d.c. ramp voltage and provides a maximum peak voltage, E_p, similar to the $E_{1/2}$ of the analyte. The concentration of the analyte is proportional to the a.c. faradaic current. Species undergoing reversible redox reactions are sensitive to the a.c. technique. The detection limit is quite low and the a.c. peak accords high resolution when several analytes are present. Therefore, a low concentration of a reducible species can be detected in the presence of a high concentration of a less easily reducible species. This method responds to a kinetic factor. Very slow reactions do not give peaks but intermediate ones give a.c. currents limited by the reaction rate. A.c. polarography finds advantageous use in analysis and the study of electrode kinetics.

(b) Other votammetric methods[50,75,80,81]

A number of procedures use electrodes other than the DME employing stripping, and linear sweep, LSV, and cyclic, CV, voltammetry. These electrodes include stationary hanging mercury drop, HMDE, and mercury film electrodes, solid electrodes of noble metals such as platinum, palladium, silver, and gold in the form of cylindrical (wires) or flat surfaces, and various types of carbon electrodes, such as treated spectroscopic amorphous carbon, glassy carbon, and carbon paste.[81] These electrodes can be used in the quiescent solution or as a rapidly rotating wire or disk electrode. The wide variety of electrodes offer unique advantages for dealing with different analytes, concentration ranges, and interferences present in sample solutions.

Linear sweep and cyclic voltammetry are related. For LSV a rapid scan at rates of several mv/sec to several hundred mv/sec is used. However, in cyclic voltammetry a triangular (cyclic) voltage scan is impressed on the electrode amounting to two linear sweeps, forward and reverse. The process allows the selective reduction of the analyte followed by the oxidation of the reduced analyte, if the redox process is reversible. However, the order of the scan can be reversed, oxidation followed by reduction. The cyclic voltammagram permits one to interpret redox reaction mechanisms for complicated electrode reactions. The HMDE and solid electrodes, referred to previously, are used in quiescent solutions in this techniques.

Stripping analysis[82] is a method that concentrates the analyte on or near the electrode (HMDE or solid) surface in a deposition (redox electrolytic) step. The voltammagram is obtained by the oxidation or reduction of the electrolytic product by a fast linear sweep scan in the stripping step. Stripping analysis is of two kinds: Anodic (ASV) and cathodic (CSV) stripping voltammetry where cation and anion analysis occurs, respectively.

For ASV in the deposition step a stirred dilute cupric ion solution ($>10^{-9}$ M) is subjected to electrolysis at an electrode for a predetermined time while stirring the solution. (The lower the concentration of the analyte, the longer the deposition time.) The fixed plating voltage is more positive than the reduction potential of the ion. For example, the cupric ion is reduced to copper metal and the metal forms an amalgam on the surface of the HMDE or a film on a solid electrode. At the end of the electrolysis step the stirring is ended. In the stripping step a fast linear voltage sweep in the negative direction causes the copper to be oxidized. The recorded voltammagram of this oxidation yields a peak whose height is proportional to the concentration of analyte cation (see Figure 26B). In CSV halides are deposited on the mercury anode as the mercury(I) halides. The remainder of the procedure is similar to ASV.

There is an on-line instrument for laboratory and field use to carry out ASV.[83] In the cell a glassy carbon electrode is automatically coated with a thin film of mercury. (When the replating of the electrode is necessary it is carried out automatically.) A pump and a set of five solenoid stream-switching valves direct sample and reagents to the cell. By means of a microprocessor and keyboard all steps and analytical parameters can be facilitated. The detection limits are 1 ppb for bismuth, cadmium, copper, lead, thallium and zinc that plate on mercury and 50 ppb for gold and silver that do not plate on mercury and mercury itself.

A.c. voltammetry employs a variety of electrodes with similar operations and response described in the polarography section above.

Figures 26A and B give information relating to the detection limits in terms of the molarity of the analyte and the resolution between peaks or waves expressed as volts. Therefore, comparisons can be made among the techniques illustrated.

(2) Amperometry

(a) Dissolved oxygen electrode

Dissolved oxygen, DO, in water is determined by DO probes using galvanic or electrolytic type cells. These DO probes have their electrodes protected by an oxygen permeable membrane and are referred to as membrane electrode systems. These systems contain a cathode working electrode and a Ag/AgCl reference electrode and an electrolyte of 1M KCl.

In an electrolytic probe the working electrode may be a platinum (Clark electrode[84]), gold, carbon, or silver microelectrode (see Figure 28). Gold seems to give the best service. A membrane electrode system using a gold electrode, an Ag/AgCl reference electrode with a KCl gel electrolyte, and a polarizing voltage of −0.80 is commercially available.[85] The cell reactions are as follows:

Gold cathode

$$O_2 + H_2O + 4e \rightarrow 4OH^- \qquad (36)$$

silver anode (Cl^-,a = 1)

$$4Ag + 4Cl^- \rightarrow 4AgCl + 4e. \qquad (37)$$

The design, based on the Clark electrode, is commonly used by a number of manufacturers.[85,86,87]

A DO probe operating on the galvanic principle is one developed by Mancy *et al.*[88] In this cell a spontaneous electrochemical reactions occurs as follows:

Pb anode

$$2Pb + 60H^- \rightarrow 2PbOOH^- + 2H_2O + 4e \qquad (38)$$

Ag cathode

$$O_2 + 2H_2O + 4e \rightarrow 4OH^-. \qquad (39)$$

The electrolyte, 1 M KOH, is used since hydroxide, OH^-, ion is formed during the reduction of the oxygen. For higher sensitivities a saturated potassium bicarbonate electrolyte solution is employed because of the insolubility of the lead salt formed. A 1 mil, polyethylene membrane separates the cell from the analyte sample. Several galvanic electrode systems are available.[89,90,91]

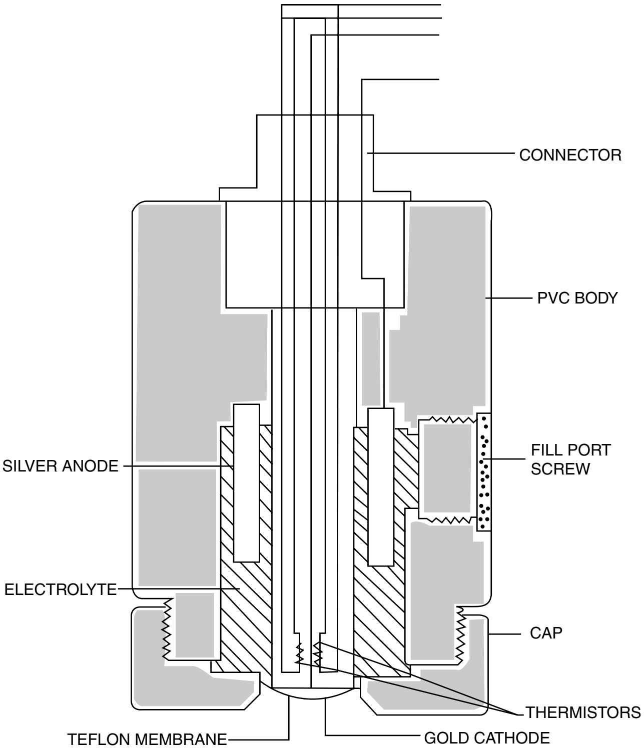

FIGURE 28 Clark DO membrane probe. (Courtesy of Rosemount Analytical, Inc., La Habra, CA.)

The DO probe output current, from both types of cells, is sensitive to temperature changes. To compensate for this effect, thermisters are placed in series with the load circuit[92] or in a bridge circuit.[93]

(c) Potentiometric, amperometric and conductometric titrations

Electrochemical means are used in potentiometric, amperometric and conductometric titrations to determine the endpoint of a titration. These titrations are so named to indicate the mechanism of endpoint determination. The electrodes used in the potentiometric and amperometric methods are sensitive to analyte and/or titrant redox species; whereas in conductometric titrations total ion content is detected. In amperometric titrations the magnitude of current flow is determined as a function of the volume of titrant. The electrode potentials are measured as a function of the titrant volume in potentiometric titrations. Conductance measurements are used in conjunction with titrant volumes in this third method.

(1) Potentiometric titrations[94]

The electrodes discussed in the previous section on potentiometric instruments may be used in potentiomeric titrations. A reference and the appropriate indicating electrode allows the measurement of the potential for each volume of titrant added. The potential changes in response to the changes in the ratio of concentrations of oxidized to reduced species. The Nernst equation can be used to calculate the magnitude of these changes. A common classical example of a potentiometric titration is an acid-base titration using pH/reference electrode pair. The pH electrode indicates the hydrogen ion concentration in terms of pH as a function of volume. The titration apparatus and the resulting "S" shaped curve is shown in Figure 29. Another example concerns the complexometric titration of calcium ion with the titrant, EDTA (the sodium salt of ethylene diamine tetraacetic acid). A calcium ion selective and reference electrode are employed. The titration curve, is similar in shape to the curve in Figure 29. The pCa value is measured by the calcium electrode as a function of volume of EDTA titrant.

Automatic titrators allow the analyst to carry out a variety of potentiometric titrations without the consumption of a great deal of time and effort. However the reaction must not be too slow and the concentrations of the analyte between 0.1 and 0.001N. Two types of automatic titrators are available—recording and non-recording. Many commercial titrators have the following features: A delivery system consisting of a buret with a solenoid operated delivery valve or a calibrated syringe whose plunger is motor-driven by a micrometer screw. The potential from the indicator-reference electrode pair is compared to a set end point potential by an anticipator, null-sensing amplifier circuit yielding an amplified error signal. The error signal controls the buret delivery. Anticipation of the endpoint prevents over titrating the endpoint (see Figure 29).

Recording titrators plot the titration curve and are completely automatic accepting a number of samples for titration in a serial manner. Some titrators contain microprocessors providing computational ability and processing of a number of samples. The error signal is used to drive the recorder pen and control buret delivery. Advantageously, unknown systems may be titrated yielding a curve that can be interpreted by the analyst.

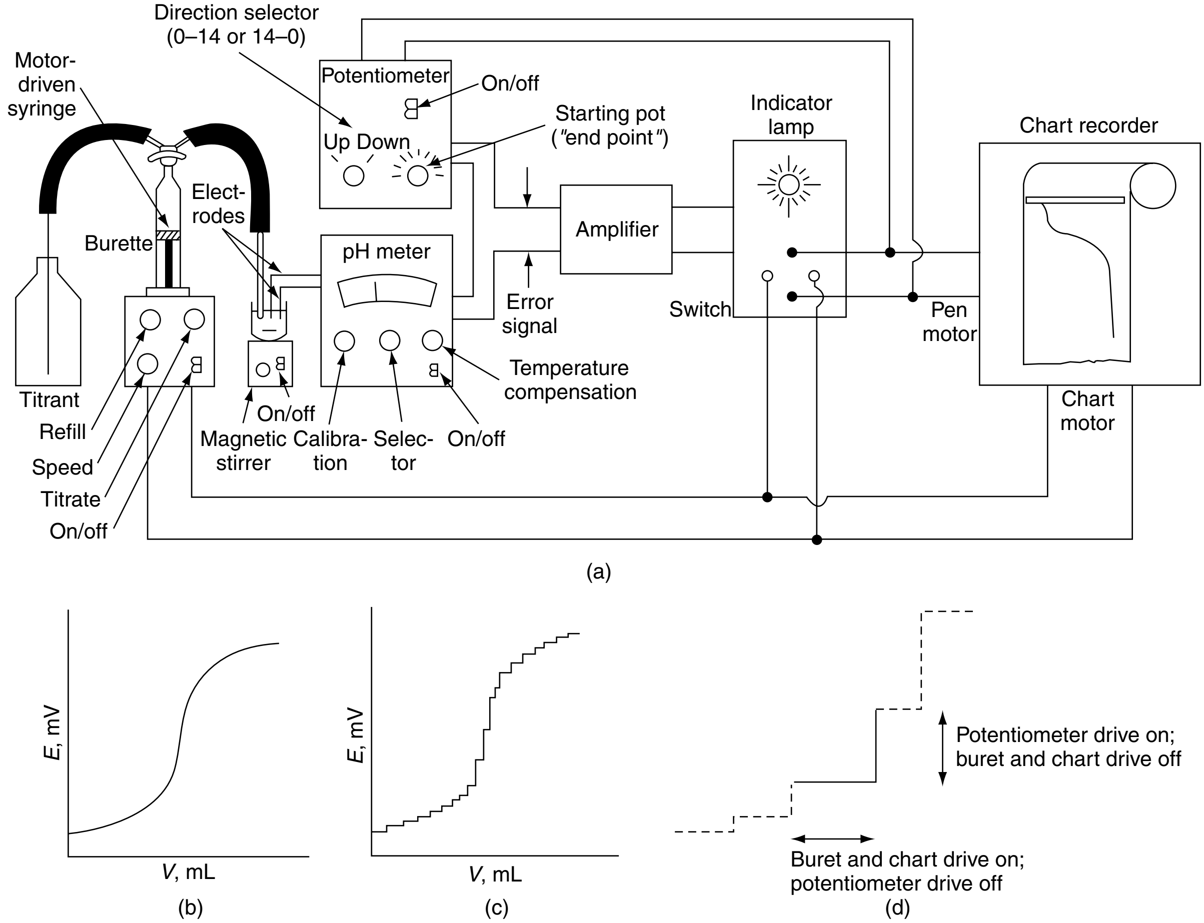

FIGURE 29 (a) An automated, curve-recording titrator. (b) Theoretical titration curve. (c) Recorded curve with endpoint anticipation. (d) Enlarge portion of (c) with explanation. (From G. Svehla, Automatic Potentiomeric Titrations, p. 176, Pergamon Press. Copyright © 1978 by Prof. G. Svehla. Reprinted with permission.)

The accuracy of automatic titrators depends on the concentration of the analyte and the sensitivity of their electrode sensing systems. Accuracies are 0.1% for a 10^{-2} N solution and 1% for the limiting concentration of 10^{-3} N.

Titrimetric methods are given in Standard Methods[2] for the following parameters—carbon dioxide, cyanide, COD, sulfite, and ammonia.

(2) Amperometric titrations[50]

Amperometric titrations may utilize one or two polarizable micro electrodes configured differently, electrically. These several electrode systems will lead to differently shaped titration curves. Titration curves show the current flow as a function of the volume of titrant.

A single polarized electrode may be a DME, a solid-state electrode of carbon, platinum or other noble metal or a rotating noble metal electrode. The potential imposed on the indicating electrode is such that the limiting current, i_L, is obtained. As in voltammetry, the current obtained is proportional to the concentration of the electroactive species. Therefore as the titration proceeds, the diffusion current, i_d, changes. The shape of the titration curve depends on the electroactivity of the titrant and the analyte as seen in Figure 30. In general two straight lines are obtained and their interpolated intersection indicates the endpoint.

Two polarized microelectrodes result in titration curves whose shapes depend on the reversibility of the electrode reactions of the titrant and the analyte. When there is a reversible reaction for the analyte, (I_3^-/I^-), and an irreversible one for the titrant, ($S_2O_0^-/S_4O_6^{—}$), the result is a "deadstop" endpoint where the current ceases to flow. When analyte and titrant show reversible electrode behavior, e.g., Fe^{2+}/Fe^{3+} and Ce^{3+}/Ce^{4+}, respectively, the titration curve shows no current flow at the endpoint. There is current flow on either side of the endpoint.

(3) Conductometric titrations[95]

The instrumental apparatus and conductance cells for conductometric titrations are given in Figures 31 and 32. In Figure 33 a precipitation and several acid–base titration curves are illustrated. Since ions are detected by the electrodes, any change in ionic concentration in the analyte solution during the titration is the basis for a conductometric titration. In a neutralization reaction two ions, hydronium, H_3O^+ and hydroxide, OH^-, are removed to form unionized water, H_2O. Two ions, silver, Ag^+ and chloride, Cl^-, form a precipitate of silver chloride, thereby decreasing the conductivity of the solution in the course of the titration. Analogously, the formation of an unionized complex can be the basis for a conductometric titration.

(d) Conductometric methods[96]

Conductometric methods detect ionic species in solution. The conductivitivity of a solution indicates the presence of ionic species and can, under certain conditions, be used to estimate the concentration of the dissolved electrolyte. Conductance is also used in conductometric titrations (see the previous section III,B,*2*,c,*(3)*). Solutions containing electrolytes conduct electricity and obey Ohm's law. Electrical resistance or conductance is measured by placing the solution between two electrodes and using a Wheatstone bridge to carry out the measurement.

Conductivity, C_n, is reciprocally related to resistance, Rs, so that $C_n = 1/Rs$. Units for Rs and C_n are ohms and mhos (ohms^{-1}), respectively. (The IS unit for C_n is siemans, S.) Resistance and conductivity of a solution are sensitive to the dimensions of the volume of solution included between the plate electrodes (see Figure 32). Conductivity is proportional to the area of the electrodes and reciprocally related to the distance between them.

By normalizing conductivity to a given dimension, a cube that is one centimeter on its edge, and designating a new parameter, specific conductance, C_{sp} in mhos/cm, the following calculation can be made,

$$C_{sp} = (1/R_m)(d/ar) = (1/R_m)(k_c) \text{ mhos/cm} \qquad (40)$$

where R_m is the measured solution resistance in the conductivity cell, d and ar are the distance between and the area of the

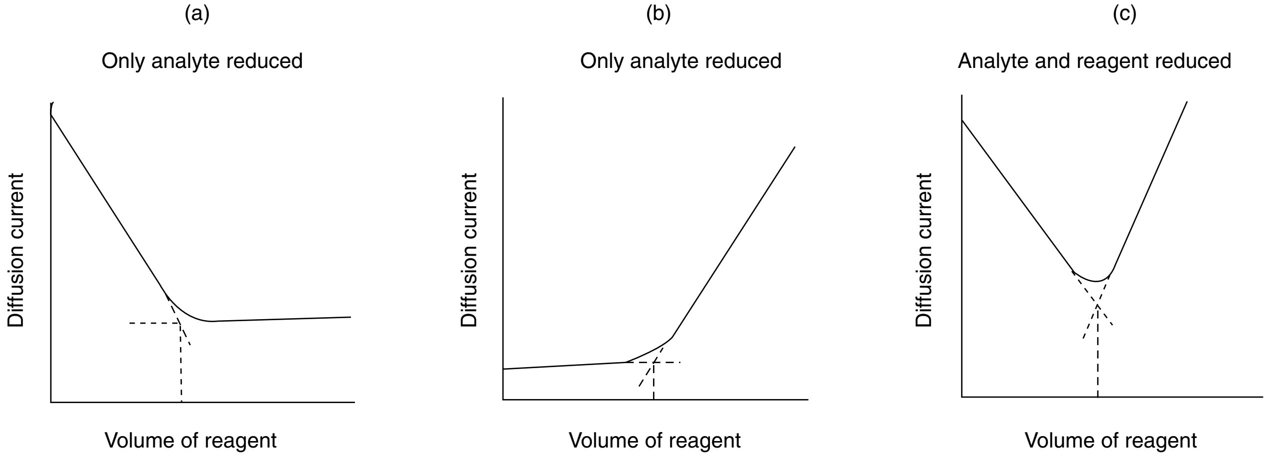

FIGURE 30 Amperometric titration curve.

electrodes, respectively. The cell constant is $k_c = d/ar\ cm^{-1}$. In analytical determinations of solution conductivities, C_{sp} is usually calculated as micromhos per centimeter (μmhos/cm) or in SI units of millisemens per meter (mS/m).

Temperature control during measurements is necessary, since the temperature coefficient for conductance measurements is about 0.5 to 3% per °C. Conductance data is usually obtained at 25°C. Temperature corrections can be made, however the further the data temperature is from 25°C, the greater the uncertainty.

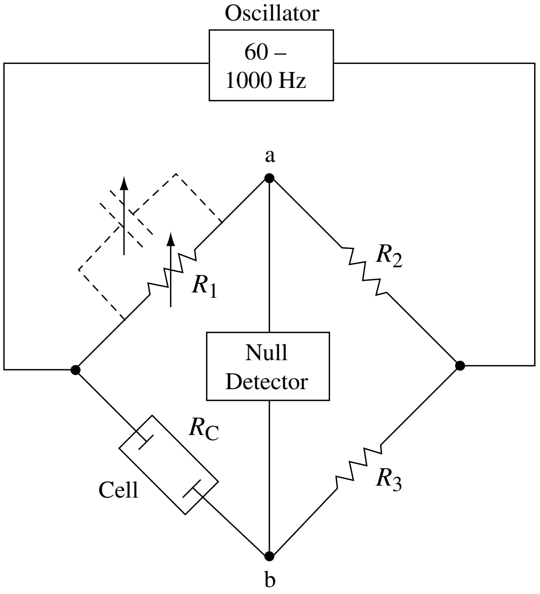

FIGURE 31 Basic Wheatstone ac bridge circuit for measuring conductance. (From Gary D. Christian and James E. O'Reilly, Instrumental Analysis, 2nd edition. Copyright © 1986 by Allyn and Bacon. Reprinted with permission.)

The measurement of solution resistance requires a conductance cell to contain the solution and a Wheatstone bridge for measurement. The Wheatstone bridge, shown in Figure 31, has an alternating current source of 6 to 10 volts with a frequency of 60 to 1000 Hz. R_2 and R_3 are fixed resistors of known values, R_1 is a variable resistor with up to 4 decades of resistance, and R_c is the resistance of the analyte solution. The null detector may be a headphone used with 1000 Hz, a cathode-ray tube or a micrometer. A variable capacitor is connected across R_1 and adjusted to balance out any phase shift in the a.c. signal caused by the capacitance of the electrode surfaces. This adjustment is made to provide the sharpest minimum in the null signal.

A conductivity cell essentially consists of two square plates of platinum of the same area, ar and platinized with platinum black to prevent polarization (see Figure 32). The plates are arranged parallel to each other at a fixed distance, d. (Other durable metals such as stainless steel and nickel are used in field and continuous monitoring operations.) The cell constant is not easily nor accurately obtained by measurement of the area and distance. A standard procedure is to fill the cell with a potassium chloride solution of known molarity and specific conductivity, C_{sp}. The measured resistance, R_m, along with C_{sp}, when substituted in equation 40, will give the cell constant, k_c. Standard Methods gives an excellently, detailed description of the measurement of conductivity.[2]

The measurement of specific conductances has a number of uses in water analysis: i) Ascertaining the mineral content of water in order to determine the effect of total ionic content on corrosion rates, physiological effects on animals and plants and the effects on chemical equilibria. ii) Appraising daily and seasonal variations in the mineral content in raw waste and natural waters. iii) Estimating the mineral content of high purity (distilled and deionized) water. iv) Checking the results of chemical analysis and estimating sample size. v) Determining the endpoint in conductometric titrations. vi) Estimating the total dissolved solids content by multiplying the specific

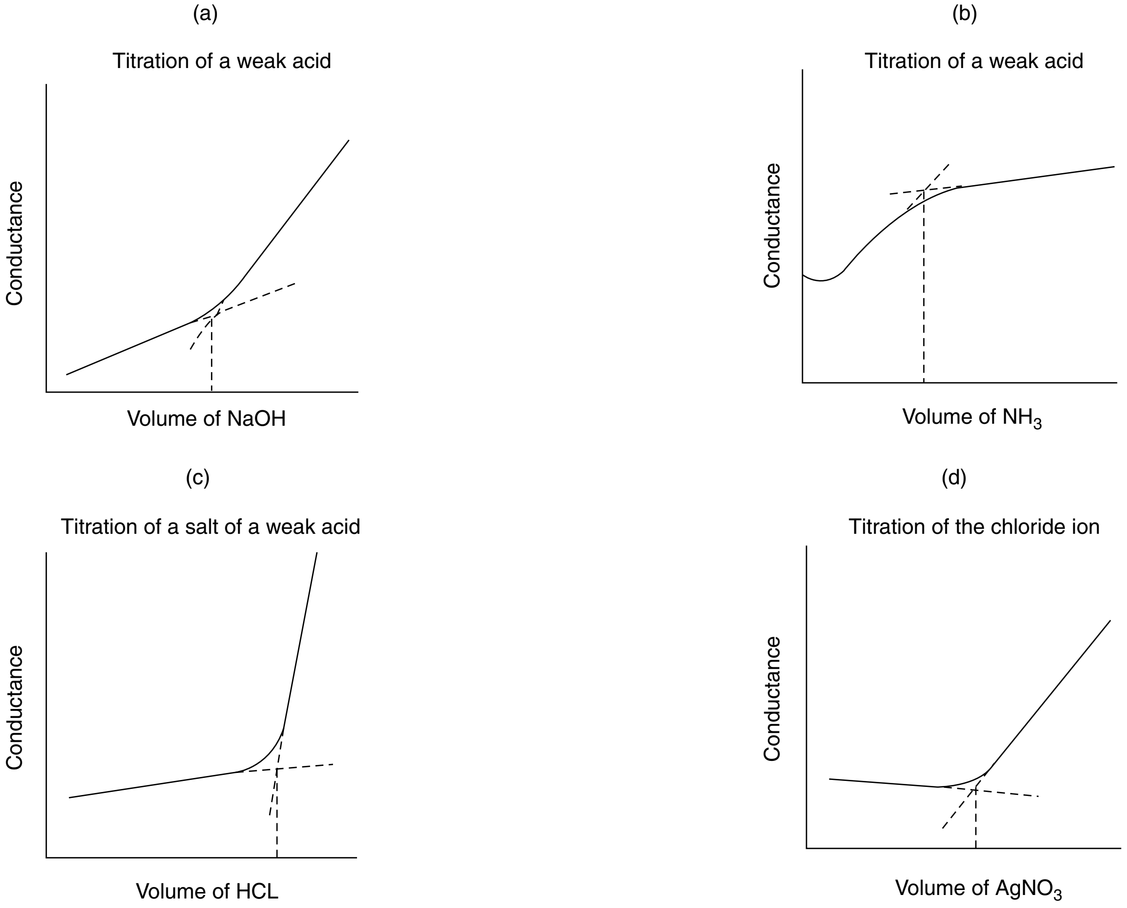

FIGURE 33 Examples of conductometric titration curves. The first three curves *a, b,* and *c* represent acid/base titrations and curve *d* a precipitation titration.

conductance by developed empirical factors.[2] Conductivity is also used to control plant processes, such as fluoride additions to drinking water and coagulant dosage control.[97]

(e) Coulometric methods[98]

Coulometry embraces three methods coulometric titrations of constant-current (amperostatic) coulometry, constant-potential (potentiostatic) coulometry, and electrogravimetry. In these methods the oxidation or reduction of an analyte to a new species or the reaction of an analyte with an electrolytically generated substance takes place. In the two coulometric methods the number of coulombs, necessary to directly or indirectly affect and electrochemical change of the analyte or a species that reacts with the analyte, is determined. In electrogravimetry the analyte undergoes an electrolytic reaction and the new species is deposited on an electrode and measured gravimetrically. The analyte concentration is calculated from a knowledge of the chemical composition of the deposit.

(1) Electrogravimetry

The analyte, metallic cations, halide ions, etc., are completely removed from the solution by plating on an inert electrode, usually platinum, in electrogravimetry. The increase in electrode weight is due to a species containing the reduced or oxidized form of the analyte. Electrolytic deposits can be pure metals on the cathode or compounds such as lead peroxide, thallium oxide and manganese dioxide on an anode, and silver halide salts on a silver anode. Complete removal of the analyte by electrolytic deposition from solution requires an unpolarized process where large electrodes and vigorous stirring are used. Two conditions are necessary concerning the electrolytic deposit: The deposit must adhere well to the electrode so that an accurate weight of the plated substance can be obtained, and a predictable, constant chemical composition of the deposit is required. The composition of the electrolyte solution does have, at times, a dramatic effect on the nature of the deposit. Substances are added to the electrolysis solution to improve the adherence of the plated substance to the electrode. Electrolysis in electrogravimetry can be achieved under two conditions—constant current through the cell or at a controlled working electrode potential.

Constant-current electrolysis has the advantage of a constant rate of reaction and is faster than the controlled-potential method. The limitation is an uncontrolled, working electrode potential. As the reaction progresses, the voltage must be increased to provide a constant current because of polarization effects. This can lead to the deposition of other species. However, this method is advantageously applicable when the species is alone in the solution, more readily reduced than hydrogen ion, and therefore, not requiring a controlled working electrode potential. Some of the cations amenable to this technique are cadmium(II), cobalt(II), copper(II), iron(III), lead(II), nickel(II), silver(I), tin(II), and zinc(II). If interfering ions are present they may be complexed in order to prevent electrodeposition or removed by prior chemical precipitation. Another application of this technique is the removal of a species which would interfere in a subsequent analytical operation. A mercury electrode is frequently used in this last application.

Controlled, working electrode potential electrolysis has the greatest applicability to mixtures of analytes. The control of the working electrode permits selective deposition of metals with standard potentials that differ by several tenths of a volt. A schematic diagram in Figure 34 embodies the elements of the apparatus. One example is the analysis of a sample containing copper, bismuth, lead, cadmium, zinc, and tin. The first three metallic ions are deposited at selective potentials; tin is held in solution as the tartrate complex. Cadmium and zinc are selectively deposited from ammoniacal solutions. Finally, the solution is acidified to decompose the tin-tartrate complex and tin is deposited.[99] Table 10 lists analyses amenable to this technique.[100] Controlled, working electrode potential electrolysis is a slower process than the constant current method, since the current flow tends to decrease in the controlled-potential technique due to polarization and other effects.

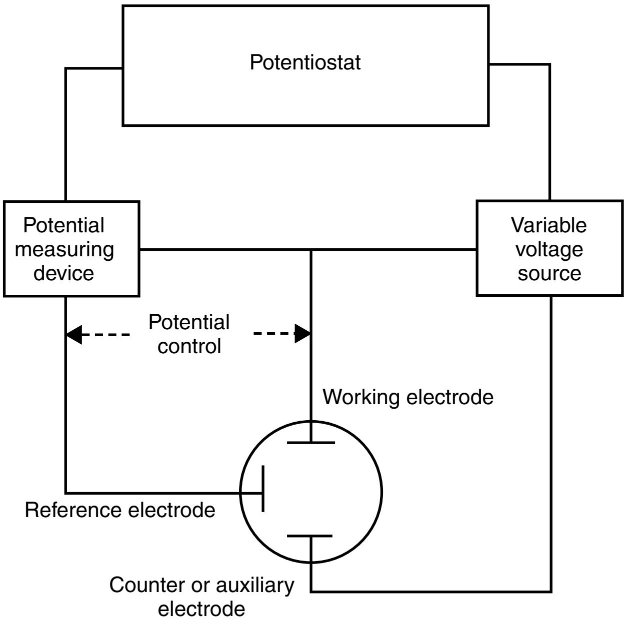

FIGURE 34 Schematic for a controlled-potential electrolysis apparatus.

(2) Coulometry

In coulometry one measures the quantity of electricity (number of coulombs) that is required to carry out a redox reaction of the analyte or generate a reagent that reacts with the analyte. Two general methods are used in coulometry, namely controlled-potential (potentiostatic) and controlled-current (amperostatic), commonly known as coulometric titrations. All the current must be used, solely, either directly or indirectly, for the reaction concerned with the analyte, that is, the current efficiency must be 100% for a quantitatively accurate, analytical result. In these methods standards are not needed; the proportionality constant (Faraday's constant) relating the number of coulombs and the amount of the analyte is derivable from known physical constants. In the cell the effects of polarization are decreased by using electrodes with large surface areas and by vigorous stirring of the solution during electrolysis.

Faraday's law relates the amount of electricity in coulombs to the number of equivalents of reactant in a redox reaction. Faradays's constant, 96,487 coulombs/equivalent, is the stoichiometric factor relating electrical charge passing in an electrolysis and the equivalence of substance reduced or oxidized. Since one ampere is the rate of flow of one coulomb per second, the time integrated flow of the current during a redox reaction will yield the number of coulombs, Q. When the current varies over the reaction time period an integration is necessary. With constant current the number of coulombs can be calculated by the equation,

$$it = Q = 96{,}487\ W/ew. \tag{41}$$

The quantities are i, amperes; t, seconds; W, sample weight in grams, and ew, equivalent weight in grams per equivalent. The equivalent weight is the atomic weight, aw, or formula weight, fw, divided by the number of electrons in the redox or half cell reaction. For example in the reactions,

$$Fe^{3+} + e = Fe^{2+} \tag{42}$$

TABLE 10
Controlled-potential electrolysis for metal separation and determination

Metal Separated	Metal Matrix
Sb	Pb, Sn
Bi	Sb, Cd, Cu, Pb, Sn, Zn
Cd	Zn
Cu	Sb, Bi, Cd, Pb, Ni, Sn, Zn
Pb	Al, Cd, Fe, Mn, Ni, Sn, Zn
Ni	Al, Fe, Zn
Ag	Cu and more active metals

and

$$MnO_4^- + 8H^+ + 5e = Mn^{2+} + 4H_2O \qquad (43)$$

the ew of Fe^{3+} is the aw/1 and ew of MnO_4^- or $KMnO_4$ is the fw/5. The number of equivalence is represented by the fraction. W/ew, in equation 41.

(a) Potentiostatic coulometry

The working electrode is maintained at a constant, present potential in potentiostatic coulometry. In this process the analyte changes oxidation state reacting quantitatively with the current: i.e., at 100% current efficiency. Redox reactions with less reactive species in the analyte solution are precluded. Maintenance of 100% current efficiency allows the amount of analyte present to be determined unambiguously by the quantity of coulombs consumed application of Faraday's law (see equation 41). As the redox reaction proceeds, the current and, therefore, the reaction rate decreases because of increases in polarization effects, changes in solution resistance, etc. Nevertheless the working electrode potential is maintained restricting the rate of the redox reaction of the analyte. The amount of current consumed usually decreases with time and is measured by an integrating device: namely, an electronic, chemical or electromechanical coulometer. An electronic controlled-potential coulometric titrator developed by Kelley *et al.*[101] includeds a potentiostat, which provides and maintains a constant potential, a d.c. current source, an electrolytic cell, and an integrating coulometer providing the readout in coulombs. This device has a range of 10 microamperes to 10 milliamperes, an accuracy of 0.01%, and a response time of 10 milliseconds.

An application of this method is the analysis of a mixture of antimony(III) and antimony(IV) accomplishable in two steps.[102] From the voltammetric data, the centered plateau reduction voltages for the following reactions are as follows:

$$Sb^{5+} + 2e = Sb^{3+}, -0.21 \text{ V vs SCE} \qquad (44)$$

and

$$Sb^{3+} + 3e = Sb^0, -0.35 \text{ V vs SCE.} \qquad (45)$$

The supporting electrolyte (6M hydrochloric acid plus 4M tartaric acid) is reduced at −0.35 V, before addition of the sample to remove impurities. Upon addition of the sample of antimony species, the solution is deaerated with nitrogen. The potentiostat described previously[101] is set at −0.21 V and the experimental voltage rises slowly to that value during the reduction of Sb^{5+}. The current starts to decrease when the set voltage is reached because of the decreasing concentration of Sb^{5+}, other polarization effects, etc. When all the Sb^{5+} has been reduced to Sb^{3+}, the current will decrease to a negligible value signaling the end to the first analytical step. The second reduction is carried out by setting the potentiostat at −0.35 V and repeating the process. In calculating the Sb^{3+} content of the sample a correctin for the Sb^{3+} generated in the first reduction must be made. When interfering substances are present, e.g., the analysis of plutonium in the presence of iron, an indirect approach can be used.[103]

Potentiostatic coulometry has the same advantages of controlled-potential electrogravimetry. In employing this method rather than electrogravimetry, the attendant problems of poorly adhering electrolytic deposits are eliminated. In addition analytes that do not yield electrolytic deposits, but are amenable to coulometric analysis can be analyzed. This technique requires a longer analysis time compared to amperostatic coulometry because of the decrease in current flow as the reaction proceeds.

(b) Coulometric titrations

Coulometric titrations (amperostatic or controlled current coulometry) are carried out at constant current (see Figure 35). At the working electrode a reagent is generated that reacts with the analyte in one of several types of reactions namely, oxidation/reduction, acid/base, complexation or precipitation (see Figure 36). When all the analyte has reacted with the generated reagent, the endpoint or completion of the reaction may be detected by potentiometry, indicator color changes, amperometry, or conductance. In some coulometric titrations, however, part of the current arises from direct reduction or oxidation of the analyte at the electrode and the remainder through the generation of the reagent. Subsequent reaction of the reagent and the remaining unreacted analyte ends the titration and 100% current efficiency is maintained. The measured quantity for a coulometric titration is the number of coulombs necessary to generate the reagent; it is comparable to the volume of titrant in a classical titration. (A current efficiency of 100% is, therefore, required.) Classical and coulometric titrations are comparable in a number of ways; these two methods have similar endpoint detection methods and stoichiometric reactions between titrant and analyte must be rapid, complete, and free of side reactions. Since constant current is used in this technique, an accurate timer is used in the coulometric titrator in Figure 35. The product of time and current (see equation 41) will give the number of coulombs. An integrator is not needed, as in potentiostatic coulometry, where the current can change with time.

The generation of reagents can be internal, in the cell containing the analyte, or external to the cell. Outside generation of reagents is often convenient for several reasons: Electrolytic interference of substances in the sample solution and incompatibility in conditions fostering efficient generation of the reagent can occur in internal generation.

(x) Internal generation

Two modes of internal generation are utilized and are referred to as primary and secondary coulometric titrations. In the primary mode the analyte reacts directly with a species generated from the electrode material. Therefore, no other species should be present which will react electrolytically with the working electrode within about 0.5 V of the

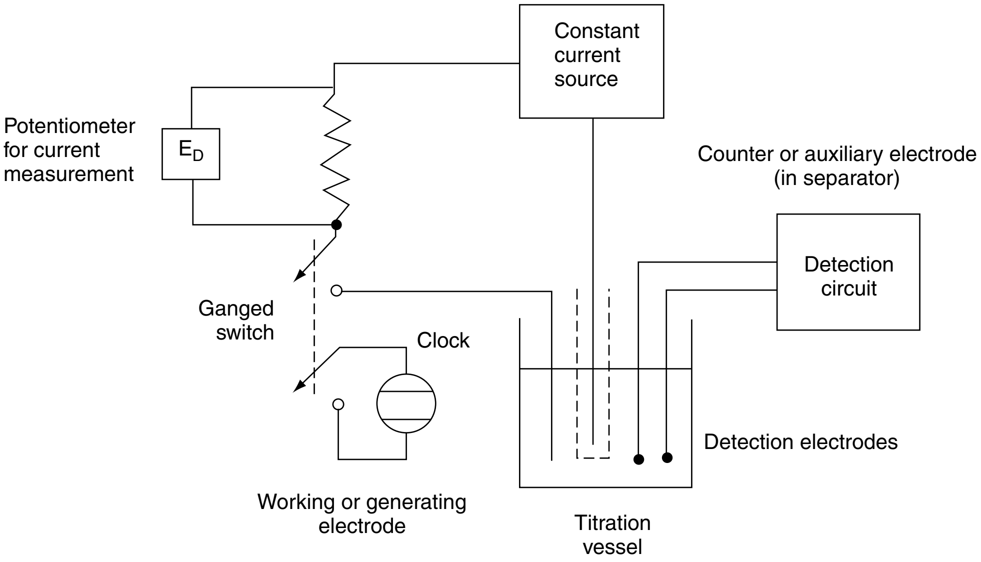

FIGURE 35 Coulometric titration apparatus.

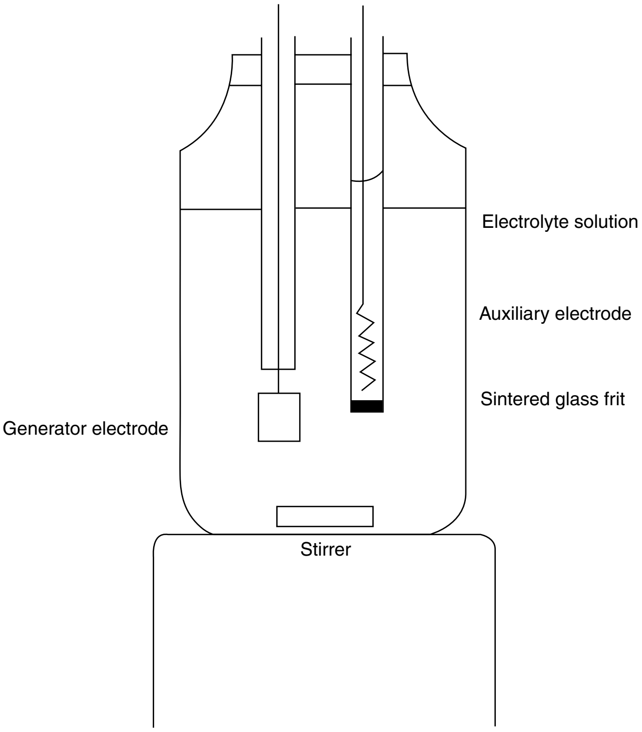

FIGURE 36 Coulometric titration cell.

potential of the analyte reactivity. An example of this mode is the reaction of ionic halide ions, mercaptans, or sulfhydryl groups with electrolytically generated silver ion from a silver working electrode. The endpoint may be determined amperometrically.

In the secondary mode an active intermediate is generated which reacts directly with the analyte. The intermediate is generated at a potential between that of the potential of the analyte redox reaction and the potential of an interfering, unwanted reaction. The interfering reaction can be due to electrolysis of the supporting electrolyte or another electroactive substance in the sample. An illustration of a secondary titration is as follows: The coulometric titration of ferrous ion uses the Ce^{3+}/Ce^{4+} system as the intermediate reactant. At the onset of the titration the ferrous ion is directly oxidized at the platinum working electrode. Since the current is constant, the potential increases as the concentration of ferrous decreases. At the oxidation potential of cerous ion and ceric ion is generated and in turn oxidizes the ferrous ion. The summation of number of coulombs consumed by each electrolytic reaction, direct and ceric oxidation, is that needed to titrate the ferrous ion present. The endpoint chosen is the presence of excess ceric ion indicating the complete oxidation of ferrous ion. The ceric ion can be detected photometrically or amperometrically. Since an excess of cerous ion is present, the working electrode is maintained at the unique potential of the cerous/ceric couple. The potential of the working electrode is prevented from increasing to a value where the interfering substances would be electrolyzed.

In secondary coulometric titrations reagents can be generated that are inconvenient to use in classical titrimetry. Some examples are the generation of hydroxide ion free of contamination by carbonate and the reactive titrants bromine, chlorine and titanous. More on this subject is given in the section on external generation of titrants.

(y) External generation

External generation of reagents can be necessary because of the presence of interfering substances in the sample. In Figure 37 a double-arm apparatus for the outside generation of reagents is shown.[104] Specifically the equations for the generation of acid (hydrogen ion) or base (hydroxide ion)

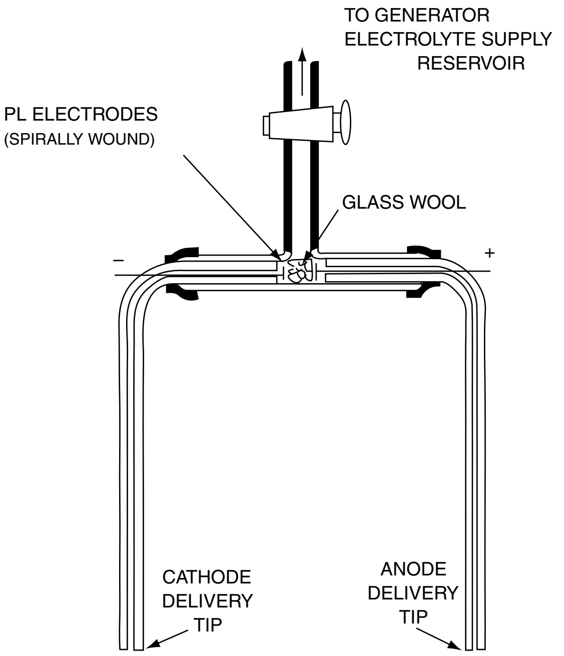

FIGURE 37 Generator cell for external production of titrants for coulometric titrantions. (Adapted with permission for reference 104. Copyright 1931 American Chemical Society.) For example in acid/base titrimetry: (a) generation of OH^- at the cathode: $2H_2O + 2e \rightarrow H_2 + 2OH^-$ (b) generation of H^+ at the anode: $H_2O \rightarrow 1/2O_2 + 2H^- + 2e$.

are illustrated. A single arm electrolytic cell is also available.[105] Unstable reagents, namely, bromine, dipositive silver, titanium(III), chlorine, etc., can be conveniently generated and utilized in this technique. In Table 11 a number of applications are listed. The ability to utilize these unstable reagents expands the horizon of tritrimetry and analytical methodology.

(3) Measurement of radioactivity[106–8]

a. Introduction

Radioactive species in water and wastewater samples arise from natural and anthropogenic sources. The radiation emitted from radioisotopes is deleterious to all life forms and has led to the development of a number of radiochemical methods. Standard Methods[2] includes procedures for the detection of tritium, radium, and radioactive species of cesium, iodine, strontium, and uranium, as well as, the general measurement of the amount of ionizing radiation.

Several kinds of ionizing radiation emanate from radioisotopes. They include gamma and x-rays, beta rays (electrons and positrons), and alpha rays (helium nuclei). Ionizing radiation, when penetrating matter, causes the formation of ions that are dangerous to life forms leading to cancer in people and animals. Gamma and x-rays are at the high frequency ($>10^6$ Hz) end of the electromagnetic spectrum. The former arise from decay events occurring in the nucleus and are more energetic higher frequency than x-rays that arise from rearrangement of electrons surrounding the decaying nucleus. Both kinds of radiation are highly penetrating due to their high energy, and therefore are quite dangerous. Gamma and x-rays are emitted as continuous spectra.

Beta particles are of two types; negatively charged electrons or negatrons and positively charged positrons. They arise from decay processes in nuclei. A positron has a very short life time and is annihilated on collision with an electron to form two gamma photons. Beta particles have a greater penetrating ability than alpha particles and are poorer at ionizing matter. Since beta particles are scattered in air, their range is difficult to assess. Beta particles, emitted during nuclear decay, yield a continuous spectrum of particle energies.

Alpha particles are the nuclei of helium atoms and have a positive charge of two. They are the product of the decay of natural isotopes, such as uranium, radium, and others. Alpha particles have high energies and, therefore, high ionizing power. Their penetrability, however, is low, about 5–7 cm in air. Alpha particles emitted from radioisotopes do not yield continuous spectra. The particles are monoenergetic or have a group of several discrete energies.

b. Instrumentation

Ionizing radiation interacting or colliding with matter causes the production of charged particles or energetic species; measurement of these entities is the basis of radiation detectors. Two phenomena are utilized in detecting ionizing radiation: namely, ionization of gases and solids to yield an ion current pulse and the excitation of crystals to provide a luminescence pulse. The ionization of gases is used in ionization chambers, proportional counters, and GM (Geiger Muller) tubes. Semiconductor radiation devices produce electron–hole pairs on the impingement of ionizing radiation. Crystal and liquid scintillation detectors are employed for insoluble and soluble samples, respectively. An instrument for radiation measurement consists of several modules: namely, the detector responding to the radiation, circuits that count pulses, and pulse height analysis circuits that discriminate between the energies of the pulses.

The nature of the pulse must be understood. In a number of detectors the pulse height of the radiation event is proportional to the energy of the particle or radiation and independent of the applied potential, whereas in other detectors the pulse height is independent of energy. The pulse of photoelectrons or luminescence has a pulse width due to the random nature of the collision process. This fact leads to small statistical differences in the pulse heights for a series of radiation events with the same energy. The smaller the pulse width the greater the resolution of the detector.

Radiation detectors operate under two modes, pulse and mean level. Of interest here is the pulse type that detects the interaction of radiation with the detector as a unique event. These pulses are counted and measured in counts per unit time, usually, counts per minute, cpm. The type of radiation (beta, gamma, etc.), the frequency or wavelength and the intensity of the radiation can also be determined.

TABLE 11

Typical electrogenerated titrants and substances determined by coulometric titration*

Electrogenerated Titrant	Generating Electrode and Solution	Typical Substances Determined
Bromine	Pt/NaBr	As(III), U(IV), NH_3, olefins, phenols, SO_2, H_2S, Fe(II)
Iodine	Pt/KI	H_2S, SO_2, As(III), water (Karl Fischer), Sb(III)
Chlorine	Pt/NaCl	As(III), Fe(II), various organics
Cerium(IV)	$Pt/Ce_2(SO_4)_3$	U(IV), Fe(II), Ti(III), I^-
Manganese(III)	$Pt/MnSO_4$	Fe(II), H_2O_2, Sb(III)
Silver(II)	$Pt/AgNO_3$	Ce(III), V(IV), $H_2C_2O_4$
Iron(II)	$Pt/Fe_2(SO_4)_3$	Mn(III), Cr(VI), V(V), Ce(IV), U(VI), Mo(VI)
Titanium(III)	$Pt/TiCl_4$	Fe(III), V(V, VI), U(VI), Re(VIII), Ru(IV), Mo(VI)
Tin(II)	$Au/SnBr_4(NaBr)$	I_2, Br_2, Pt(IV), Se(IV)
Copper(I)	Pt/Cu(II)(HCl)	Fe(III), Ir(IV), Au(III), Cr(VI), IO_3^-
Uranium(V), (IV)	Pt/UO_2SO_4	Cr(VI), Fe(III)
Chromium(II)	$Hg/CrCl_3(CaCl_2)$	O_2, Cu(II)
Silver(I)	$Ag/HclO_4$	Halide ions, S^{2-}, mercaptans
Mercury(I)	$Hg/NaClO_4$	Halide ions, xanthate
EDTA	$Hg/HgNH_3Y^{2-}$[a]	Metal ions
Cynaide	$Pt/Ag(CN)_2^-$	Ni(II), Au(III, I), Ag(I)
Hydroxide ion	$Pt(-)/Na_2SO_4$	Acids, CO_2
Hydrogen ion	$Pt(+)/Na_2So_4$	Bases, CO_3^{2-}, NH_3

[a] Y^{4-} is ethylenediamine-tetra-acetate anion.

(1) Detectors

Radiation detectors operate on two principles; ionization of a gas or solid to generate a small ion current and excitation of a substance to cause a short term luminescence in a crystal or a solution. Ionization detectors are of two varieties; those that use gas as the ionization medium, i.e., gas-filled detectors and those that use a crystal, i.e., semiconductor detectors. Measurements of luminescence due to radiation are made in crystal and liquid scintillation counters.

(a) Ionization and detectors

(i) Gas-filled detectors

Gas-filled detectors respond to ionizing radiation by the formation of ion pairs, a photoelectron and a positive ion (cation) by the gas molecules. The gas in the detector tube may be a mixture: e.g., argon and a low concentration of an organic substance or methane. In Figure 38 the gas-filled detector is shown with a central electrode (anode) to which is applied a voltage. The pulse of photoelectrons migrate to the electrode due to the electric field, are collected, and produce a small ion current. The current represents the radiation event or particles deposited in the detector. Several types of gas-filled detectors are available and are operated in a number of voltage ranges leading to different kinds of detector responses; the operation potentials of these detectors are illustrated in Figure 39.

In the saturation (ionization) chamber region a radiation event of given energy gives rise to a number of photoelectrons independent of the applied potential. They are collected on the electrode yielding an ion current or pulse height proportional to the energy of the radiation event. The pulse of photoelectrons, however, has a pulse width due to the random nature of the collision process. This situation leads to a statistical variation in pulse heights for the same energy source defining the resolution of the detector. An ionization chamber in combination with a pulse height analyzer can operate as an alpha particle spectrometer.

When the applied voltage is increased, producing a field greater than 200 V/cm, the electrons formed in ion pair formation are accelerated. These accelerated electrons collide with gas molecules causing increased ionization leading to an increase in the collected electrons. This effect is called gas amplification and is present in the proportional counter and GM tube regions.

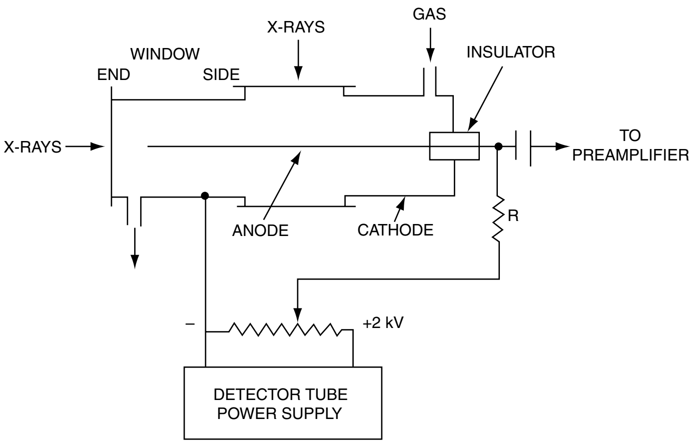

FIGURE 38 Structure of the gas-filled x-ray detector (proportional and Geiger counters, and ionization chamber). The detector is shown to have both end and side windows for illustration only.

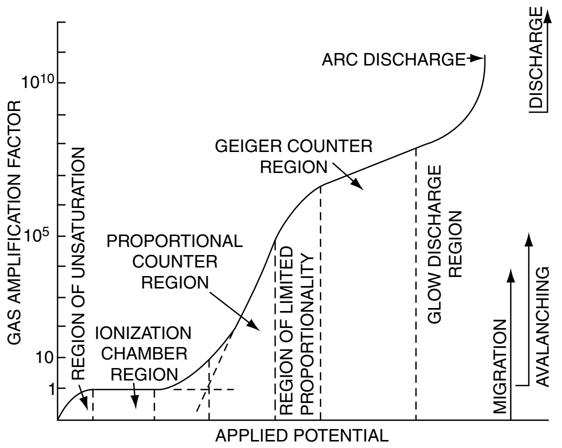

FIGURE 39 Gas-amplification factor as a function of applied potential for the gas-filled detector.

The proportional counter region yields a pulse height that is proportional to the energy of the radiation or particle. The amplification factor is 500 to 10,000 and the detector has a dead or non-conducting time of 0.5 μsec. Alpha and beta particles can be measured separately by using two different voltages and a pure alpha emitter in a proportional counter. The limited proportional region is not useable because the presence of secondary charges hinders the gas amplification process.

In the GM tube region the amplification factor is 10^9 and the pulse height is independent of the energy and type of radiation. Therefore pulse height analysis can not be performed using the GM tube but it can be used for general counting. The plateau is 300 V in length and the counting rate increases less than 3% for a 100 V increase in applied voltage. The positive space charge formed in the detector causes a non-conducting or dead time of 250 microseconds leading to a loss in radiation events. Serious rate errors are experienced when counting rates are larger than 10^4 cpm. A correction to the rate may be calculated using the resolving time. This detector is useful for the analysis of separated radionuclides.

(ii) Semiconductor detectors

There are several types of semiconductor detectors, namely the surface barrier and p-n junction detectors and the lithium drifted silicon or germanium detectors. They all function, generally, according to the following model.

Semiconductor detectors are analogous to gas-filled detectors in their principle of operation. In the semi-conductor detector a radiation event leads to an ion pair formation of an electron–hole pair, whereas in the gas-filled detector electron–cation pair are formed. A model of a semiconductor detector, a lithium drifted detector, is given in Figure 40. A central zone of ultrapure intrinsic semiconductor is flanked by thin layers of p and n type semiconductor material. A bias voltage is imposed across the ensemble to form a high field. The radiation event causes the formation in the central zone of a highly energetic photoelectron which gives rise to a large number of electron–hole pairs. The large number of highly mobile electrons are raised to the conduction band due to the transfer of kinetic energy from the photoelectron. The electrons and holes "move" to the p and layers, respectively, and are collected under the effect of the high field giving a current pulse. The size of the current pulse is proportional to the energy of the radiation event as in the proportional counter and has a pulse width due to the randomness of the process as discussed previously.

In the lithium-drifted detectors lithium, an n-type substance, is used to form the ultrapure intrinsic semiconductor from p-type silicon or germanium. Ultimately lithium becomes the doppant for the n-type semiconductor after several involved processes. These detectors function more efficiently if the detector and preamplifier are kept at liquid

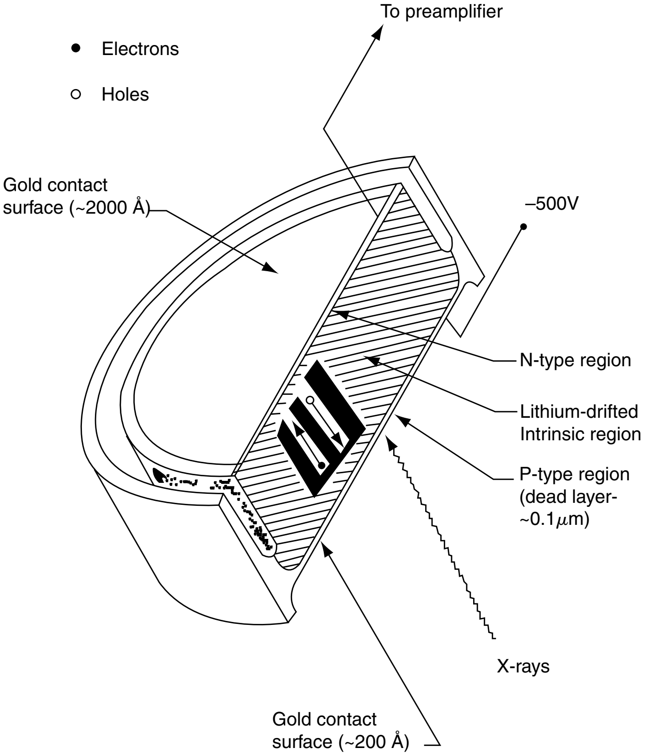

FIGURE 40 Cross-section of a typical lithium-drifted silicon, Si(Li), detector, x-rays create electron-hole pairs in the intrinsic region of the semiconductor; these charge carriers then migrate to the electrodes under the influence of an applied bias voltage. (Courtesy of the Kevex Instruments, Inc.)

nitrogen temperature, -196°C. At this low temperature thermal electronic noise is reduced and the lithium is prevented from diffusing into the central zone of intrinsic semiconductor material affording increased resolution capabilities. The energy required for an electron-hole pair generation for several radiation detectors are as follows: 2.9 eV (eV, electron volt) for germanium, 30 eV for a gas ionization chamber and 500 eV to produce a photoelectron in a NaI(T1) scintillation detector. Thus the germanium detector produces 170 times the number of ion pairs than the scintillation detector per unit of eV and the resolution is better by 13 times. Different pulse widths from each type of detector caused by the randomness of the process lead to the differences in energy resolution. For electrons, x-rays, and photons the energy resolution in the germanium detector is 3.8, 0.6 and 20 keV, respectively. The line widths for the germanium and scintillation detectors are 3.3 and 46 keV (keV, 1000 ev), respectively. The germanium detector in conjunction with a pulse height analyzer can be used to measure x- and gamma rays in energy dispersive spectrometers. In these systems radiation with a spectrum of energies can be resolved, since the germanium detector produces a current pulse proportional to the energy of the radiation. One disadvantage of this system is that radiation with a wave-length above one Angstrom is better resolved in a crystal spectrometer. Energy dispersive systems have excellent resolution for wavelengths below one Angstrom but demonstrate poor resolution for wavelengths above 1 Å.

(b) Scintillation counters

Some inorganic crystals and organic crystals or molecules emit a pulse of light on interaction with ionizing radiation. The energy of the radiation causes ionization or activation of the scintillating substance; it relaxes emitting a fluorescent or phosphorescent light pulse with life times of about 10^{-8} and 10^{-4} seconds, respectively, in the visible or near uv region. The number of photons emitted in each light pulse is proportional to the energy of the radiation event. Some crystals, namely sodium iodide, are doped with an activator to shift the light pulse to a longer wavelength.

(i) Crystal scintillation counters

Scintillation counters utilize a crystal optically coupled to a photomultiplier tube that converts the light pulse to a current pulse (see Section III,B,1,b,*(4)*,(*a*),(iii)). Further coupling to a pulse height analyzer results in an energy dispersive spectrometer. Inorganic scintillation crystals of alkali halides doped with thallium, lead or europium as activators, are commonly used. Potassium halides containing the natural radioisotope, ^{40}K, which radiates electrons, positrons, and γ rays, are not used in scintillation detectors.

A sodium iodide crystal doped with 0.1 to 1% of thallium (I) iodide, NaI(T1), is most widely used. The NaI has a high density that absorbs gamma radiation and the iodide ion provides an efficient conversion of radiation to light. The radiation event first activates the iodide ion that emits a light pulse in the uv region. The uv pulse excites the thallous ion that on relaxation emits fluorescent light at about 410 nm. It is compatible to the photomultiplier tube. Since NaI is hygroscopic, the crystal must be sealed well. For most efficient counting a "well type" detector is frequently used. Isotopes emitting x-, gamma, beta, and alpha radiation are detected by NaI(T1), and in particular x- and gamma radiation are most beneficially measured. Energy dispersive spectrometers using this detector are employed in x- and gamma-ray spectrometers.

(ii) Liquid scientillation counters

Liquid scintillation counting is a convenient and efficient means of detecting low levels of radiation from small amounts of samples. The liquid scientillation solution consists of a primary, or a primary and secondary scintillator or phosphor dissolved in an organic solvent. The radioactive sample is dissolved in the scintillation solution. The radiation excites the organic solvent molecules, such as toluene, xylene, terphenyl, etc. The excited molecules transfer their energy, mainly non-radiatively, to the primary scintillator causing emission of a fluorescent light pulse detected by the photomultiplier tube.

The newer models of liquid scintillation counters contain photomultiplier tubes that respond to the emissions of a primary scintillator. PPO (2,5-diphenyloxazole), a primary scintillator, emits light pulses in the range 330 to 400 nm. Blue sensitive photomultiplier tubes employed in older model counters necessitated the use of a secondary phosphor which absorbed the light pulse of the primary phosphor and emitted a light in the blue wavelength region. POPOP, the 2^0 scintillator, 2,2′p-phenylenebis(4-methyl-5-phenyl-oxazole), absorbs at about 360 nm and emits fluorescence light at 410 to 420 nm. Therefore, PPO and POPOP are a good pair to provide an effective liquid scintillator for the older blue sensitive photomultiplier tubes. A diagram of a scintillation counter is shown in Figure 41.

(2) Signal processors and readout

Radiation detection instruments are able to measure two characteristics; the number of particles or radiation events occurring in a unit time and the energy of each particle or event.

The counting of events is carried out in electronic countering devices. Counting circuits convert voltage pulses to square waves, scale or reduce the number of input pulses, and count the frequencies of pulses using binary digital circuits. A scaling circuit decreases the frequency of pulses arriving from the detector by a known fraction in order to accommodate the counting devices detection rate. Binary digital circuits containing JK flip-flops accomplish this reduction. A binary counter with four JK flip-flops produces one output pulse for every sixteen input pulses. Arrangement of the binary circuits to provide a decade counting unit provides a decimal readout.

In ionization chambers, proportional counters, semiconductor detectors, and scintillation counters the size or height of the pulse is proportional to the energy of the radiation event. Pulse height analyzers are coupled to the output of these detectors in order to form an energy dispersive instrument. Pulse height analyzers employed to separate radiation of differing energies are equivalent to monochrometers used to disperse uv, vis, and ir radiation. Instruments are also available that carry out wavelength dispersion. The radiation is dispersed using a crystal for x- and gamma rays.

A description of the operation of a pulse height analyzer is as follows: the radiation event is converted to a signal by the detector and amplified resulting in pulses as large as 10 volts. A pulse height selector provides a narrow voltage window by rejecting voltage pulses between minimum and maximum values using electronic discriminator circuits. This window can have a voltage range of 0.1 to 0.5 volts. A pulse height analyzer can consist of one or several pulse height selectors. One pulse height selector comprises a single channel pulse height analyzer. The voltage range of 10 volts can be scanned, automatically or by hand, using a window of 0.1 volt yielding an energy dispersion spectrum. Two to hundreds of channels comprise a multichannel analyzer. Each channel with its own counting circuit is set for a specific voltage window. Therefore, the total spectrum can be simultaneously counted and recorded.

Readout of counting rates can be displayed on solid state devices, printers, etc. Spectra display on a potentiometric recorder or storage in a computer with subsequent printout is available.

(3) Applications

Liquid scintillation counting is used for a variety of tasks: namely; measurement of the low energy beta emitters ^{3}H, ^{14}C, ^{32}P and ^{35}S; gamma and x-ray energy dispersive spectrometry; and beta-gamma coincidence scintillation counting for ^{131}I.

Standard Methods[2] has procedures for the analysis of cesium-134 and 137, and iodine-129 through 135, total radioactive strontium (^{89}Sr and ^{90}Sr) and ^{90}Sr alone, tritium, radon-222, uranium-234, 235 and 238, and total radium, radium-226, radium-228, and total alpha and beta content of water.

LEGAL ASPECTS OF THE ENVIRONMENT

The environment has become a concern of the law and Environmental Law is now a recognized and established legal discipline.

The body of Environmental Law is growing in response to the felt needs of society which is beginning to acknowledge that the technological advances of this generation are destroying the legacy of the past and the capital assets of the future.

Historic forces forged common law doctrines suited to a world of endless frontiers, where ruthless exploitation of natural resources was a manifestation of the desperate need to subdue all nature as the means of survival in the wilderness of a new world. Such survival techniques are no longer appropriate on an earth whose life support systems are as fragile as those in a space capsule.

As natural resources are being utilized at rates unprecedented in the history of civilization, and the quality of environment deteriorates, there is increasing public demand for legal aid to the environment. Attorneys are being called upon to act as public defenders of the environment and the law is being asked to restore the quality of life.

Environment and the law interface in three significant areas: Legislation, Administration and Executive action, and Judicial determination.

There already exists a substantial body of statutory law at the federal, state and local levels dealing with matters of environmental concern, and there has been a perceptible evolution of ecologically sophisticated, environmentally responsible, socially relevant and politically feasible legislation at all operative levels of government.

Administrative agencies characterized by a combination of delegated legislative, executive and judicial powers, functions, and responsibilities affect the environment in the furtherance of their statutory mission.

The administrative agencies are legislative creations. In theory, they exist to effect policy established by the elected legislative representatives of the people. To accomplish this the legislature ceded rule-making power from its legislative mandate under the Constitution, the executive ceded a certain amount of administrative power, and the judiciary ceded certain judicial functions, in particular fact-finding and preliminary hearing. As a result of this tripartite grant of power, administrative agencies represent not a fourth branch of government as some seem to think, but the foundation of all practical government operations: Administrative agencies provide the substantial bulk of bureaucracy.

The judiciary of the United States and that of the several states furnish the forum for environmental litigation. Such litigation involves the interpretation of statutes and the adjudication of liabilities for damages resulting from nuisance, negligence, trespass and other traditional common law torts; as well as general actions seeking declaration of the rights of the people (in the form of class actions for declaratory judgment) and equitable relief (injunction, reparations) based on such ancient common law equitable principles as the Trust Doctrine and the maxim *sic utere to alienam non laedas*—so use your own property as not to injure that of another. Following the trail blazed by the American Labor Movement and retracing many of the judicial steps of the Civil Rights struggle, while seeking judicial vindication of a fundamental human right, to a salubrious environment, as one of those rights "so basic and important to our society that it would be inconceivable that it is not protected from unwarranted interference" and is a right retained by the people of the United States under the Ninth Amendment of the Constitution of the United States and protected from disparagement by the actions of the federal government by operation of the *due process* and *equal protection* clauses of the Fifth Amendment of the Constitution and protected from disparagement by the actions of any of the several states by operation of the *privileges* or *immunities, due process* and *equal protection* clauses of the Fourteenth Amendment of the Constitution.

Environmental Law and Environmental Litigation became recognized elements of the Anglo-American legal system in the Spring of 1966 when a suburban housewife brought an action on behalf of all the citizens of Suffolk County, New York seeking equitable relief from a toxic insult to the community ecosystem; challenging not merely the local mosquito control commission still routinely using DDT in an increasingly futile attempt to control a mosquito population that had long since become resistant to that pesticide, but the broad spectrum, persistent chemical biocide, 1,1,1-trichloro-2, 2-bis parachlorophenyl) ethane: DDT itself.

The New York State Supreme Court issued a temporary injunction restraining the County of Suffolk from using DDT for mosquito control on August 15, 1966 and continued this "temporary" injunction until December 6, 1967, finally holding that:

> DDT has, by its inherent chemical stability, become a continuing factor in some ecological life cycles so as to profoundly alter them and the environmental equilibrium. Thus, it is reasonably apparent that DDT is capable of and actually has to some extent caused extraordinary damage to the resources of this country. If in no other way, the chemical by its very stability has introduced an element of instability in the general ecosystem. For instance, by reducing a food source of some of the larger wildlife and so reducing the overall large wildlife population, lesser elements multiply more quickly. These lower forms are presumably more of a nuisance, assuming they in turn survive. Furthermore, DDT affects wildlife directly. Its ingestion, from whatever source has the capability, it seems, to disrupt reproductive processes or even more simply act as a poison. It is fairly apparent then that the application of DDT in Suffolk County has and is continuing to have a demonstrable effect on local wildlife, reducing it slowly but surely, either directly across the board or indirectly from the top down, but reducing it nevertheless.
>
> We have a situation where plaintiff has at least minimally sustained a massive effort to validiate the allegation that DDT does in fact do biological harm [*Yannacone v. Dennison et al.* (1967) 55 Misc 2d 468, 471–472, 285 NYS 2d 476].

ENVIRONMENTAL LEGISLATION

National Environmental Policy Act of 1969

The principal national legislative statement on the environment is the National Environmental Policy Act of 1969 (National Environment Policy Act) the purpose of which is:

> To declare a national harmony which will encourage productive and enjoyable harmony between man and his environment; to promote efforts which will prevent or eliminate damage to the environment and biosphere and stimulate the health and welfare of man; to enrich the understanding of the ecological systems and natural resources important to the Nation; and to establish a Council on Environmental Quality.

The National Environmental Policy Act (NEPA) is a synthesis by a Conference Committee of bills introduced in the Senate by Senator Jackson and in the House by Congressman Dingell.

The declaration of a national environmental policy contained in section 101 of the act speaks for itself.

> Sec. 101. (a) The Congress, recognizing the profound impact of man's activity on the interrelations of all components of the natural environment, particularly the profound influences of population growth, high-density urbanization, industrial expansion, resource exploitation, and new and expanding technological advances and recognizing further the critical importance of restoring and maintaining environmental quality to the overall welfare and development of man, declares that it is the continuing policy of the Federal Government, in cooperation with State and local governments, and other concerned public and private organizations to use all practicable means and measures, including financial and technical assistance, in a manner calculated to foster and promote the general welfare, to create and maintain conditions under which man and nature can exist in productive harmony, and fulfill the social, economic, and other requirements of present and future generations of Americans.
>
> (b) In order to carry out the policy set forth in this Act, it is the continuing responsibility of the Federal Government to use all practicable means, consistent with other essential considerations of national policy, to improve and coordinate Federal plans, functions, programs, and resources to the end that the Nation may
>
> 1) fulfill the responsibilities of each generation as trustee of the environment for succeeding generations:
> 2) assure for all Americans safe, healthful, productive, and esthetically and culturally pleasing surroundings:
> 3) attain the widest range of beneficial uses of the environment without degradation, risk to health or safety, or other undesirable and unintended consequences:
> 4) preserve important historic, cultural, and natural aspects of our natural heritage, and maintain, wherever possible, an environment which supports diversity and variety of individual choice;
> 5) achieve a balance between population and resource use which will permit high standards of living and a wide sharing of life's amenities; and
> 6) enhance the quality of renewable resources and approach the maximum attainable recycling of depletable resources.
>
> (c) The Congress recognizes that each person should enjoy a healthful environment and that each person has a responsibility to contribute to the preservation and enhancement of the environment.

Sec. 101 (b) (95) is recognition by Congress that uncontrolled magnitude and distribution of population underlies many of this nation's environmental and resource problems. To insure that a high standard of living is made available to all citizens and that all citizens have the opportunity for aesthetic enjoyment from a quality environment, the intent of NEPA is that the Federal Government must strive to maintain the magnitude and distribution capacity to provide such benefits. By section 101 (b) (5) Congress has thus implied that the rights of underprivileged citizens to a high standard of living are not to be sacrificed as a result of the national environmental policy to protect and environment.

The provision of NEPA most debated by the members of Congress was section 102.

Sec. 102. The Congress authorizes and directs that, to the fullest extent possible; (1) the policies, regulations, and public laws of the United States shall be interpreted and administered in accordance with the policies set forth in this Act, and (2) all agencies of the Federal Government shall—

A) utilize a systematic, interdisciplinary approach which will insure the integrated use of the natural and social sciences and the environmental design arts in planning and in decision making which may have an impact on man's environment;

B) identify and develop methods and procedures, in consultation with the Council on Environmental Quality established by title II of this Act, which will insure that presently unquantified environmental amenities and values may be given appropriate consideration in decision making along with economic and technical considerations;

C) include in every recommendation or report on proposals for legislation and other major Federal actions significantly affecting the quality of the human environment, a detailed statement by the responsible official on—

    i) the environmental impact of the proposed action,

    ii) any adverse environmental effects which cannot be avoided should the proposal be implemented,

    iii) alternatives to the proposed action,

    iv) the relationship between local short-term uses of man's environment and the maintenance and enhancement of long-term productivity, and

    v) any reversible and irretrievable commitments of resources which would be involved in the proposed action should it be implemented.

    Prior to making any detailed statement, the responsible Federal official shall consult with and obtain the comments of any Federal agency which has jurisdiction by law or special expertise with respect to any environmental impact involved. Copies of such statement and the comments and views of the appropriate Federal, State, and local agencies, which are authorized to develop and enforce environmental standards, shall be made available to the President, the Council on Environmental Quality and to the public as provided by section 552 of title 5, United States Code, and shall accompany the proposal through the existing agency review processes;

D) study, develop, and describe appropriate alternatives to recommend courses of action in any proposal which involves unresolved conflicts concerning alternative uses of available resources;

E) recognize the worldwide and long-range character of environmental problems and, where consistent with the foreign policy of the United States, lend appropriate support to initiatives, resolutions, and programs, designed to maximize international cooperation in anticipating and preventing a decline in the quality of mankind's world environment;

F) make available to States, counties, municipalities, institutions, and individuals, advice and information useful in restoring, maintaining, and enhancing the quality of the environment;

G) initiate and utilize ecological information in the planning and development of resource-oriented projects; and

H) assist the Council on Environmental Quality established by title II of this Act.

NEPA strengthened the right of public access under the Freedom of Information to records and information of Federal agencies Act. In addition, Congress has required all Federal agencies, to the fullest extent possible, to "make available to States, Counties, municipalities, institutions and individuals, advice and information useful in rest and maintaining, and enhancing the quality of the environment . . ."

These provisions enable citizens, under the Freedom of Information Act, to gain access to those records of Federal agencies that are relevant to environmental protection in addition to the environmental impact statements required to be filed under Section 102.

NEPA requires all Federal agencies and officials to consider environmental values in reaching decisions or in planning agency action.

Though Congress has enacted numerous laws over the past years that constitute Congressional mandates on various aspects on environmental policy, areas of Federal policy and action exist which have no environmental goals or policies and in which the conflicting operational necessities of different agencies complicate and often frustrate attainment of environmental quality objectives which are in the interest of the entire country. Many of the older operating agencies of the Federal Government, for example, do not, at present, have a mandate within the body of their enabling laws permitting them to give adequate attention to environmental values. In other agencies, especially when the expenditure of funds are involved, the latitude of a public official to deviate from the most economical alternative to reach an environmental goal may be strictly circumscribed by Congressional authorizations which have overlooked existing or potential environmental problems. There is also reason for serious concern over the activities of those agencies which do not feel they have sufficient authority to undertake needed research and action to enhance, preserve, and maintain the quality of the environment in connection with development activities.

The National Environmental Policy Act reemphasizes the importance of existing statutory programs relating to the environment. Prior to the passage of the National Environmental Policy Act of 1969, existing legislation involving certain areas of Federal activity did not provide "clear authority for the consideration of environmental factors which conflict with other objectives," and many Federal agencies had not given substantial and consistent consideration to environmental factors during decision making in certain areas of their responsibility.

Section 102 (1) remedies these shortcomings in the statutory foundations of existing agency programs by incorporating the policy and goals set forth in section 101 into the actions and programs of all Federal agencies. Section 102 (2) establishes procedures which will help to insure that the policies enunciated in sections 101 are implemented.

Prior to the passage of the National Environmental Policy Act of 1969, planning and decision-making that might have an effect on the quality of the environment was too often the exclusive province of the engineer and cost analyst. The National Environmental Policy Act requires Federal agencies to consider all relevant points of view and draw upon the broadest possible range of social and natural scientific knowledge and design arts in planning and decision making. In the past, Federal agencies have all too frequently ignored environmental factors in planning and decision making or omitted them from consideration during the early stages of planning because of the difficulty in evaluating such factors as compared with the ease of evaluating economic and technological factors. Under NEPA, Federal agencies and officials are now required to develop the methodology and techniques necessary to determine the total environmental impact and full course of actions by the Federal government.

One of the most frequent sources of environment litigation involves the construction and application of the National Environmental Policy Act of 1969 and the sufficiency of environmental impact statements prepared pursuant to section 102 (2) (C). Although the initial determination of environmental impact is made by the agency itself, should the agency find that the proposed activity will have a significant effect on the environment, the agency report of recommendation supporting the proposal must make findings with respect to the environmental factors set forth in section 102 (2) (C) (i)–(v). If adverse environmental effects cannot be avoided by reasonable alternative actions the agency must demonstrate that such adverse environmental effects are justified by other considerations of national policy, which must be stated in detail. The use of local, short-term resources must be found to be consistent with the maintenance and enhancement of the long-term productivity of the environment. Proposals involving significant commitments of resources that will be irreversible and irretrievable under conditions of known technology and reasonable economics must be found necessary.

The National Environmental Policy Act supplements the statutory authority of most Federal agencies and requires them to follow the policies, goals and procedures of the Act, unless the existing law governing such agency's operations expressly prohibits full compliance, however section 103 provides that no Federal agency is to interpret its existing statutory authority in such a way as to avoid compliance with the directives of NEPA. If the agency finds a clear conflict between its existing statutory mandate and the Act, the agency is required to propose to the President of the United States such measures as will be necessary to bring the statutory authority and mandate of the agency into conformity with the provisions of the National Environmental Policy Act.

The National Environmental Policy Act is a relevant statute within the meaning of the Administrative Procedure Act, thus conferring standing upon representatives of the general public seeking judicial review of actions and decisions by federal agencies which may have failed to follow the policies, goals and procedures of the Act, where such action or decision of the agency threatens to have adverse effects upon the ecological system an individual may reside in or use for recreation. Section 101 (C) of the National Environmental Policy Act recognizes that "each person should enjoy a healthful environment and that each person has a responsibility to contribute to the preservation and the enhancement of the environment," indicating that Congress intends to recognize the interests of individual citizens in the protection of the ecosystem they may reside in or use for recreation.

Such an individual citizen is within the class of persons which the National Environmental Policy Act was meant to protect, and is thus a person adversely affected or aggrieved within the meaning of the Administrative Procedure Act and as such a person is entitled to judicial review of the agency action.

The national goal and policies for the protections, establishment and enhancement of this Nation's environment established by the National Environmental Policy Act are in the words of its Senate sponsor, Senator Jackson.

More than the statement of what we believe as a people and as a nation, it establishes priorities and gives expressions to our National goals and aspirations. It provides a statutory foundation to which administrators may refer...for guidance in making decisions which find environmental values in conflict with other values.

What is involved is a congressional declaration, that we do not intend, as a government or as a people, to initiate actions which endanger the continued existence or the health of mankind: that we will not intentionally initiate actions which will do irreparable damage to the air, land, and water which support life on earth.

An environmental policy is a policy for people. Its primary concern is with man and his future. The basic principle of the policy is that we must strive in all that we do to achieve a standard of excellence in man's relationship to his physical surroundings. If there are to be departures from this standard of excellence, they should be exceptions to the rule and policy.

Administrative Procedure Act

The Administrative Procedure Act provides both an independent source of federal jurisdiction and a grant of standing to conservation organizations and aggrieved persons seeking to challenge decisions of, or actions by, Federal agencies which may result in environmental degradation.

Senator McCarren, the author of the bill which ultimately became the Administrative Procedure Act, explained that it conferred no administrative powers, but provided definitions of, and limitations upon, administrative action, to be interpreted and applied by the agencies in the first instance, but to be reviewed by the courts in the final analysis.

The scope of judicial review of agency action is governed by the language of the Administrative Procedure Act:

To the extent necessary to decision, and when presented the reviewing court shall decide all relevant questions of law, interpret constitutional and statutory provisions, and determine the meaning or applicability of the terms of an agency action. The reviewing court shall . . .

2) hold unlawful and set aside agency action, findings and conclusions found to be—
    A) Arbitrary, capricious, an abuse of discretion, or otherwise not in accordance with the law;
    B) Contrary to constitutional right, power, privilege or immunity;
    C) In excess of statutory jurisdiction, authority, or limitations, or short of statutory rights; . . .
    F) Unwarranted by the facts to the extent that the facts are subject to trial *de novo* by the reviewing court . . . (5 United States Code § 706).

Under the Administrative Procedure Act any person "suffering legal wrong because of agency action or adversely affected or aggrieved by agency action within the meaning of a relevant statute" may seek judicial review.

Agency action made reviewable by statute and final agency action for which there is no other adequate remedy in a court are subject to judicial review. A preliminary, procedural, or intermediate agency action of ruling not directly reviewable is subject to review on the review of the final agency action. Except as otherwise expressly required by statute, agency action otherwise final is final for the purposes of [the Administrative Procedure Act] whether or not there has been presented or determined an application for a declaratory order, for any form of reconsideration, or, unless the agency otherwise requires by rule and provides that the action meanwhile is inoperative, for an appeal to a superior agency or authority. (5 United States Code § 104).

The "legal wrong" contemplated by the Administrative Procedure Act is something more than the mere personal damage normally contemplated in the law of torts. The damage necessary to constitute legal wrong under the provisions of the Administrative Procedure Act must produce some illegal effect and be demonstrably contrary to law in either substance or procedure. However, the law considered relevant upon judicial review of agency action under the Administrative Procedure Act is not only the statutory law directly involved with the agency action, but general constitutional law as well. The legal wrong necessary to confer jurisdiction on the court and standing to the party complaining can be the invasion of any legally protected right.

Jurisdiction can also be obtained over agents and officers of the United States Government such as contractors of the Atomic Energy Commission, the Secretary of Agriculture, the Secretary of Interior, and divisions and departments of Federal agencies such as the Division of Wildlife Services, the Bureau of Sport Fisheries and Wildlife, and the Bureau of Land Management of the United States Department of the Interior, the Corps of Engineers of the United States Army of the Department of Defense, and the Federal Aviation Administration and the Bureau of Public Roads of the Department of Transportation.

There is a basic presumption in the law favoring judicial review of agency or administrative action even where the statute prescribing agency action does not on its face provide for judicial review. For the right of judicial review to be denied, the agency must produce clear and convincing evidence of legislative intent to foreclose judicial review. The Supreme Court of the United States [*Association of Data Processing Service Organizations, Inc. v. Camp* (1970) 397 US 150, 25 h Edzd 184, 90 SCt 827] has reemphasized the presumption of judicial review of agency action in recent litigation which construed the Administrative Procedure Act not grudgingly but as serving a broadly remedial purpose holding that "the mere failure to provide specially by statute tor judicial review is certainly no evidence of intent to withhold review."

No presumption in favor of "administrative absolutism" and against judicial review exists. A congressional purpose to preclude judicial review of agency action must be "fairly discernable in the statutory scheme," since the right to judicial review is ordinarily inferred where congressional intent to protect the interests of the class of which the complainant is a member can be found.

Administrative action is not immune from judicial review because it may be committed to agency discretion or simply because the statute authorizes a public official to "prescribe such regulations as he may deem proper to carry out the provisions of [the legislation]."

The right to judicial review of agency action is all that stands between the citizen and government by administrative fiat not subject to correction by the elective process. Although a court usually will not substitute its judgement for that of an administrative agency, it can compel the proper exercise of statutory authority by the agency, since it is not for the administrative agency to finally determine the limits of its own power. That is a judicial function.

Where a party aggrieved has no other adequate remedy following administrative action there is certainly the right, upon proper application, to judicial review of agency action. Some confusion existed in the Federal Courts for a number of years after the passage of the Administrative Procedure Act because the provisions for judicial review apply, "According to the provisions thereof, except to the extent that agency action is committed to agency discretion by law" (5 United States Code § 701).

Some Federal Courts held that agency action involving the exercise of discretion could not be reviewed for any reason under the Administrative Procedure Act, however, the majority of Federal Courts have adopted the rule that any agency action, even that involving the exercise of discretion and dependent upon the special technical and scientific expertise of the agency, is subject to judicial review to the extent provided by the Administrative Procedure Act. The mere fact that the acts of some administrative official, even a cabinet-level Secretary, require the exercise of discretion and judgment does not preclude judicial review of official action. Any contrary decision would lead to establishment of a shadow government by administrative officials not subject to popular election or judicial review and therefore totally outside the systems of checks and balances so carefully developed during the Constitutional Convention. The rights and the public must receive active and affirmative protection at the hands of the administrative agencies.

Much environmental litigation has involved the standing of parties to bring suit against administrative agencies, their officials, employees and agents. Recent decisions have established the right of public benefit organizations whose purposes include protection of the environment, or protection the lives, health, and property of human beings or animals, as well as individuals seeking to proceed in the public interest as "private attorneys general," to bring actions to persons "adversely affected" or "parties aggrieved" without the meaning of the Administrative Procedure Act.

Neither economic injury nor a specific individual legal right are necessary adjuncts to standing. A complainant need only demonstrate that it is an appropriate person (corporate or human) to question the alleged failure of an agency to protect those values recognized by law as in the public interest.

Environmental Protection Agency

By virtue of the executive authority to reorganize Federal agencies, President Nixon created an Environmental Protection Agency to which was transferred, effective December 2, 1970, significant environmental responsibilities formerly scattered throughout the several executive and administrative branches of government.

> Sec. 2 *Transfers to Environmental Protection Agency.* (a) There are hereby transferred to the Administrator [of the Environmental Protection Agency].
>
> 1) All functions vested by law in the Secretary of the Interior and the Department of the Interior which are administered through the Federal Water Quality Administration, all functions which were transferred to the Secretary of the Interior by Reorganization Plan No. 2 of 1966 (80 Stat. 1608), and all functions vested in the Secretary of the Interior or the Department of the Interior by the Federal Water Pollution Control Act or by provisions of law amendatory or supplementary thereof.
> 2) (i) The functions vested in the Secretary of the Interior by . . . 16 USC 742d-1 (being an Act relating to studies on the effects of insecticides herbicides, fungicides, and pesticides upon the fish and wildlife resources of the United States), and (ii) the functions vested by law in the Secretary of the Interior and the Department of the Interior which are administered by the Gulf Breeze Biological Laboratory of the Bureau of Commercial Fisheries at Gulf Breeze, Florida.
> 3) The functions vested by law in the Secretary of Health, Education, and Welfare or in the Department of Health, Education, and Welfare which are administered through the Environmental Health Service, including the functions exercised by the following components thereof:
>   i) The National Air Pollution Control Administration,
>   ii) The Environmental Control Administration;
>   A) Bureau of Solid Waste Management,
>   B) Bureau of Water Hygiene,
>   C) Bureau of Radiological Health,
>
> except that functions carried out by the following components of the Environmental Control Administration of the Environmental Health Service are not transferred: (i) Bureau of Community Environmental Management, (ii) Bureau of Occupational Safety and Health, and (iii) Bureau of Radiological Health, insofar as the functions carried out by the latter Bureau pertain to (A) regulation of radiation from consumer products, including electronic product radiation, (B) radiation as used in the healing arts, (C) occupational exposures to radiation, and (D) research, technical assistance, and training related to clauses (A), (B), and (C).
>
> 4) The functions vested in the Secretary of Health, Education, and Welfare of establishing tolerances for pesticide chemicals under the Federal Food, Drug and Cosmetic Art, as amended, 21 USC 346, 346a, and 348, together with authority, in connection with the functions transferred, (i) to monitor compliance with the tolerances and the effectiveness of surveillance and enforcement, and (ii) to provide technical assistance to the States and conduct research under the Federal Food, Drug, and Cosmetic Act, as amended and the Public Health Service Act, as amended.

5) So much of the functions of the Council on Environmental Quality under section 204(5) of the National Environmental Policy Act of 1969 . . . as pertains to ecological systems.

6) The functions of the Atomic Energy Commission under the Atomic Energy Act of 1954, as amended, administered through its Division of Radiation Protection Standards, to the extent that such functions of the Commission consist of establishing generally applicable environmental standards for the protection of the general environment from radioactive exposures or levels, or concentrations of quantities of radioactive material, in the general environment outside the boundaries of locations under the control of persons possessing or using radioactive material.

7) All functions of the Federal Radiation Council (42 USC 2021 (h)).

8) (i) The functions of the Secretary of Agriculture and the Department of Agriculture under the Federal Insecticide, Fungicide, and Rodenticide Act, as amended (7 USC 135–135k), (ii) the functions of the Secretary of Agriculture and the Department of Agriculture under section 408(1) of the Federal Food, Drug and Cosmetic Act, as amended (21 USC 346a(1)), and (iii) the functions vested by law in the Secretary of Agriculture and the Department of Agriculture which are administered through the Environmental Quality Branch of the Plant Protection Division of the Agricultural Research Service.

9) So much of the functions of the transfer of officers and agencies referred to in or affected by the foregoing provisions of this section as in incidental to for necessary of the performance by or under the Administrator of the functions transferred by those provisions or relates primarily to those functions. The transfers to the Administrator made by this section shall be deemed to include the transfer of (1) authority, provided by law, to prescribe regulations relating primarily to the transferred functions, and (2) the functions vested in the Secretary of the Interior and the Secretary of Health, Education, and Welfare by section 169(d)(1)(B) and (3) of the Internal Revenue Code of 1954 (as enacted by section 704 of the Tax Reform Act of 1969, . . .); but shall be deemed to exclude the transfer of the functions of the Bureau of Reclamation under section 3(b)(1) of the Water Pollution Control Act (33 USC 446a(b)(1)).

b) There are hereby transferred to the Agency:

1) From the Department of the Interior, (i) the Water Pollution Control Advisory Board (33 USC 466t), together with its functions, and (ii) the hearing boards provided for in sections 10(c)(4) and 10(f) of the Federal Water Pollution Control Act, as amended (33 USC 446g(c)(4); 446g(f)). The functions of the Secretary of the Interior with respect to being or designating the Chairman of the Water Pollution Control Advisory Board are hereby transferred to the Administrator.

2) From the Department of Health, Education, and Welfare, the Air Quality Advisory Board (42 USC 1857c), together with its functions. The functions of the Secretary of Health, Education and Welfare with respect to being a member of the Chairman of that Board are hereby transferred to the Administrator.

Sec 6. *Abolitions* (a) Subject to the provisions of this reorganization plan, the following, exclusive of any functions, are hereby abolished:

1) The Federal Water Quality Administration in the Department of the Interior (33 USC 446–1).

2) The Federal Radiation Council (. . ., 42 USC 2021(h)).

Among the procedural landmark established in the Project Rulison litigation was the right of the plaintiff COSCC to take the depositions of experts prior to the determination of the defendants motion for summary judgment to dismiss the complaint. COSCC argued that the motion for summary judgment could not be decided without considering the relevant testimony of certain experts under the control of the defendants and the Court directed the defendants to produce those experts for pre-trial oral examination. The information obtained in those pre-trial examinations established the need for a full hearing on the merits as a condition precedent to determination of any AEC motion for summary judgment dismissing the complaint.

Sovereign Immunity and Popular Sovereignty

Throughout the relatively short history of environmental litigation involving agencies of government, sovereign immunity has been raised as a defense by the government agency asserting that the action is a suit against the sovereign United States of America brought without the consent of congress and that the relief sought would invade the powers of officers of the executive branch of the Federal Government to whom the actions complained of had been delegated. This defense is usually buttressed by an appeal for judicial restraint under the doctrine of Separation of Powers.

The general doctrine of the immunity of the United States from suit without consent of Congress is a rule propounded in a diction by United States Supreme Court Chief Justice John Marshall in the case of *Cohens v. Virginia* [19 US (6 Wheat)

264, 411–412 (1821)]. However, in the earliest discussion of sovereignty by the United States Supreme Court [*Chisholm v. Georgia* (1973) 2 US 419], the court stated,

> . . . the term sovereign has for its correlative, subject. In this sense, the term can receive no application; for it has no object in the Constitution of the United States. Under the Constitution, there are citizens but no subjects.
>
> . . . the people of the United States . . . have reserved the supreme power in their own hands; and on that supreme power have made these [governments] dependent, instead of being sovereign . . .
>
> Even in almost every nation which has been denominated free the state has assumed a supercilious preeminence above the people who have formed it; hence the haughty notions of State independence, State sovereignty, and State supremacy. In despotic governments, the government has usurped in a similar manner both upon the state and the people: hence all the arbitrary doctrines and pretensions concerning the supreme, absolute and incontrollable, power of government. In each, man is degraded from the prime rank which he ought to hold in human affairs . . .

Another instance, equally strong, but still more astonishing is drawn from the British Government as described by Sir William Blackstone and his followers. As described by him and them, the British is a despotic Government. It is a Government without a people. In that Government, as so described, the sovereignty is possessed by the Parliament: In the Parliament, therefore, the supreme and absolute authority is vested: In the Parliament resides that incontrollable and despotic power, which, in all Governments, must reside somewhere. The constituent parts of the Parliament are the King's Majesty, the Lord's Spiritual, the Lord's Temporal, and the Commons. The King and these three Estates together form the great corporation of body politic of the Kingdom. All these sentiments are found; the last expressions are found verbatim, in the *Commentaries Upon the Laws of England.* The Parliament forms the great body politic of England. What then, or where, are the people? Nothing! No where! They are not so much as even the "baseless fabric of a vision!" From legal contemplation they totally disappear! Am I not warranted in saying, that, if this is a just description; a Government, so and justly so described, is a despotic Government?

Chief Justice Jay also recognized the people of the United States, not the Federal Government, as the sovereign:

> From the crown of Great Britain, the sovereignty of their country passed to the people of it . . . [T]he people, in their collective and national capacity, established the present Constitution. It is remarkable that in establishing it, the people exercised their own visits, and their own proper sovereignty, and conscious of the plenitude of it, they declared with becoming dignity. "We the people of the United States, do ordain and establish this Constitution." Here we see the people acting as sovereigns of the whole country . . . [T]he sovereignty of the nation as [in] the people of the nation . . .
>
> Chief Justice Jay noted that in England the doctrine of sovereignty was based on feudal principles that considered the prince as sovereign and the people as his subjects. These feudal principals contemplated the sovereign.
>
> As being the fountain of honor and authority; and from his grace and grant derives all franchises, immunities and privileges; it is easy to perceive that such a sovereign could not be amenable to a Court of Justice, or subjected to judicial control and actual constraint. It was of necessity, therefore, that suability, became incompatible with such sovereignty. Besides, the Prince having all the Executive powers, the judgment of the Courts would, in fact, be only monitory, not mandatory to him, and a capacity to be advised, is a distinct thing from a capacity to be sued. The same feudal ideas run through all their jurisprudence, and constantly remind us of the distinction between the Prince and the subject. No such ideas obtain here. At the Revolution, the sovereignty devolved on the people and they are truly the sovereigns of the country, but they are sovereigns without subjects . . . and have none to govern but themselves, the citizens of America are equal as fellow citizens, and as joint tenants in the sovereignty.
>
> . . . Sovereignty is the right to government; a nation or State-sovereign is the person or persons in whom that resides. In Europe the sovereignty is generally ascribed to the Prince; here it resides with the people . . . Their Princes have personal powers, dignities, and pre-eminences, our rulers have none but official; nor do they partake in the sovereignty otherwise, or in any other capacity, than as private citizens.

A majority of the Supreme Court of the United States, just five years after the adoption of the Constitution of the United States, rejected the idea of the United States as sovereign—and necessarily the rule of sovereign immunity from suit because "suability became incompatible with such sovereignty." The people of the United States are the sovereign, not the United States government.

In 1882, the Supreme Court of the United States further said,

> Under our system the *people,* who are there [in England] called *subjects,* are the sovereign. Their rights, whether collective or individual, are not bound to give way to a sentiment of loyalty to the person of a monarch. The citizen here knows no person, however near to those in power, or however powerful himself, to whom he need yield the rights which the law secures to him when it is well administered. When he, in one of the courts of competent jurisdiction, has established his right to property, there is no reason why deference to any person, natural or artificial, not even the United States, should prevent him from using the means which the law gives him for the protection and enforcement of that right [*United States v. Lee* (1882), 106 US 196, 205 to 209].

Land Use and Resource Management

Throughout history, land and natural resources have been considered the property of the sovereign to be used, abused, given or taken at the sovereign whim. The history of civilization, to a certain extent, can be considered a chronicle of wars and revolutions fought over the ownership and utilization of land and natural resources.

The Constitution of the United States provides that the rights not explicitly given by the people of the United States to the federal government are retained by the people of the United States, individually, and as collectively assembled in the several states.

The enumeration of the Constitution, of certain rights, shall not be constructed to deny or disparage others retained by the people (*United States Constitution,* Ninth Amendment).

The powers not delegated to the United States by the Constitution, nor prohibited by it to the States, are reserved to the States respectively, or to the people. (*United States Constitution,* Tenth Amendment).

As the individual state constitutions were formulated, the rights of individual property owners were strengthened, but at no time did the sovereign people of the United States relinquish the ultimate right to determine the highest and best use of the land and natural resources subject to the jurisdiction of the United States. The justification for any legal restriction on the private use of land or natural resources is rooted in this concept of sovereignty in the people.

According to the report commissioned by the Council on Environmental Quality as a preparation for consideration of a National Land Use Policy Act,

> This country is in the midst of a revolution in the way we regulate the use of our land. It is a peaceful revolution . . . a quiet revolution . . .
>
> The *ancien regime* being overthrown is the feudal system under which the entire pattern of land development has been controlled by thousands of individual local governments, each seeking to maximize its tax base and minimize its social problems, and caring less what happens to all the others.

And if we are to live in harmony with that which has been given to us from preceding generations, and from the earth before mankind appeared, we must make certain assumptions with respect to every accessible parcel of real property and every natural resource capable of exploitation.

1) The area of resource is vulnerable.
2) Development, exploitation or utilization of some kind is inevitable.
3) The highest and best use of the land or resource as an element of human ecology must be accommodated.
4) Development must be consistent with natural ecological constraints.
5) Planned achievement of the highest and best use of land and resources is more profitable to mankind than unplanned development.
6) The police power of the state, the ultimate sovereignty of the people, and the maintenance of private property concepts are compatible and can result in the harmonious, beneficial development of land and resources.

Recognizing the limited availability of land itself and the place of land as the basic capital asset of civilization, land use historically has been limited by executive, legislative and judicial process.

An early example of land use legislation—zoning—has been upheld by the courts on the grounds that it represents action by an individual community to assure the highest and best use of limited resources for the greatest number of people without undue infringement upon the rights of individuals.

Zoning is not just an expansion of the common law of nuisance. It seeks to achieve much more than the removal of obnoxious gases and unsightly uses. Underlying the entire concept of zoning is the assumption that zoning can be a vital tool for maintaining a civilized form of existence only if we employ the insights and the learning of the philosopher, the city planner, the economist, the sociologist, the public health expert and also the other professions concerned with urban problems . . .

This fundamental conception of zoning has been present from its inception. The almost universal, statutory requirement that zoning conform to a "well-considered plan" or "comprehensive plan" is a reflection of that view. [See Standard State Zoning Enabling Act, US Dept of Commerce (1926).] The thought behind the requirement is that consideration must be given to needs of the community as a whole. In exercising their zoning powers, the local authorities must act for the benefit of the community as a whole following a common, deliberate consideration of the alternatives, and not because of the whims of either an articulate minority or even majority in the community . . . Rather, the comprehensive plan is the essence of zoning. Without it, there can be no rational allocation of land use. It is the insurance that the public welfare is being served and that zoning does not become nothing more than just a Gallup poll [*Udell v. Hass* (1968), 21 NY2d 463, NE2d 897, 288 NYS2d 888].

The key to successful land use and resource utilization legislation is the community determination of the highest and best use of land and resources in terms of intrinsic suitability and naturally imposed constraints. Of necessity this must be done by a team of individuals trained in the several disciplines necessary to define the environmental parameters of a Regional Ecological System. The community itself, particularly its people, constitute elements of that regional ecological system just as surely as topography, hydrology, and climate. One of the most significant contributions of environmental litigation to the development of Anglo-American jurisprudence has been the broadening of the concept of "expert witness" to include an individual member of a multidiscipline scientific team testifying about the work of the entire team even though the individual scientist may not have performed the work testified about personally. Environmental litigation, particularly that involving such environmental toxicants as DDT and radionuclides has led to legal acceptance of the "environmental scientist" who is permitted to testify generally, upon a showing, to the satisfaction of the Court, of demonstrated competence in some recognized scientific discipline together with regular collaboration with other scientists of diverse disciplines upon general problems of environmental concern.

The adequate determination of the highest and best use of the limited natural resources of any regional ecological system mandates a systems approach supported by modern computer technology in order to determine the relevant boundary conditions and elemental optimizations of the complex, non-linear dynamic relationships that describe a natural system as it actually exists. Courts increasingly are accepting evidence in environmental litigation, and the techniques of general systems analysis have become key factors in the resolution of environmental controversy such as that concerning the continued use of DDT, the distribution of radionuclides from peaceful applications of nuclear energy, and the Cross-Florida Barge Canal.

The acceptance of systems methods in ecology by the courts now means that any land use or resource utilization law which does not fully reflect the system characteristics of the Regional Ecological System in which it will operate is fatally defective in the legal sense. It cannot be sustained in the face of sophisticated legal challenge; while any such law which does, in fact, reflect the system characteristics of the region can be sustained in the public interest, even where such a law appears to limit the rights incident to private property ownership.

The current litigation involving the adequacy of statements prepared under the mandate of section 102 of the National Environmental Policy Act (environmental impact statements) demonstrates that any failure to consider the ecological integrity of a region and fully determine the interrelationships among each element of the land, landscape and natural processes diminishes the legal value of the effort; while a full evaluation of any environmentally significant action with respect to its effect upon the overall ecological integrity of the region and the interrelationships among each element of land, landscape, and natural processes of the region can form the basis for legal restraints upon land use and resource exploitation, even where such restraints appear to infringe upon private property rights or government agency prerogatives.

ENVIRONMENTAL LITIGATION

Environmental litigation includes almost all the actions brought before the courts of the United States, the several states, and the various administrative agencies exercising quasi-judicial powers which involve a determination which may affect natural processes, resources or the environment.

The Scenic Hudson Preservation Case

One of the landmark cases in environmental law is *Scenic Hudson Preservation Conference* v. *Federal Power Commission* [354 F2d. 608 (1965, CA2), *certiorari denied* 384 US 941, 16 LEd 2d 540, 86 SCt 1462], which established the right of conservation organizations and other public interest groups to challenge the extent of consideration given to historic, scenic, aesthetic, conservation and recreational aspects of power development by the Federal Power Commission. The holding of that case has been extended to permit similar organizations to challenge the consideration of such values by the Secretary of Transportation (in approving federal-aid highways) and the Secretary of the Army and Chief of Corps of Engineers (in licensing and granting permits for projects on navigable waterways).

The *Scenic Hudson* saga began on January 29, 1963 with Consolidated Edison of New York (the major electric power utility servicing the City of New York) filing an application with the Federal Power Commission (FPC) for a license to construct a pumped-storage hydroelectric facility on the west wide of the Hudson River at Storm King Mountain. As information concerning the project spread, the Federal Power Commission directed that a public hearing on the project be held February 25, 1964. The Scenic Hudson Preservation Conference was hastily formed and filed a petition on February 6, 1964 seeking to intervene in the proceeding. The petition was granted on February 14, 1964; intervention was permitted; hearings were held in Washington, DC; and the hearing examiner made an initial determination approving the license application on July 31, 1964 subject to review by the entire Federal Power Commission which eventually licensed the project on March 9, 1965.

The pumped-storage plant proposed by Consolidated Edison would generate electric power for use during peak load periods in New York City using hydroelectric units driven by water from a reservoir. The project consisted of three major components—a storage reservoir, a powerhouse, and transmission lines. The reservoir would be located over the power house which was to be located on the shores of the Hudson River at the foot of Storm King Mountain, a mountain of striking aspect rising over 1,360 feet above the river. The reservoir would be connected to the powerhouse by a tunnel 40 feet in diameter. During slack periods of demand for electrical power in New York City, Consolidated Edison's steam generating plants in New York City would provide electric power for the pumps at Storm King to force water through the tunnel and up the mountain into the reservoir. The water would be stored in the reservoir until periods of peak demand for electrical power in New York City at which time the water would be released from the reservoir to rush down the mountain through the tunnel to power the generators. The project was to have a capacity of two gigawatts (billion watts, or million kilowatts), but would be capable of expansion to three gigawatts. At that time, the Storm King Project was to be the world's largest pumped storage electric generating facility and was estimated to cost an estimated $162,000,000.

Subsequently the United States Court of Appeals for the Second Circuit reviewed the determination of the Federal Power Commission holding, that

> if the Commission is properly to discharge its duty in this regard [approve those projects best adapted to a comprehensive plan for improving or developing a waterway], the record on which it bases its determination must be complete. The petitioners and the public at large have a right to

> demand this completeness. It is our view, and we find, that the Commission has failed to compile a record which is sufficient to support its decision. The commission has ignored certain relevant factors and failed to make a thorough study of possible alternatives to the Storm King Project.

The court found that the Commission must take into consideration the unique beauty and important historical significant of the Hudson River noting that the Federal Power Act sought to "promote the comprehensive development of the Nation's water resources."

The court directed the Federal Power Commission to reexamine all the issues that the court found had not been properly considered.

The commission's renewed proceedings must include as a basic concern the preservation of natural beauty and of national and historic shrines, keeping in mind, that, in our affluent society, the cost of a project is only one of several factors to be considered. The record as it comes to us fails markedly to make out a case for the Storm King Project on, among other matters, cost, public convenience and necessity, and absence of reasonable alternatives. Of course the Commission should make every effort to expedite the new proceedings.

Following the hearings on remand, the hearing examiner made an initial determination on August 6, 1968 recommending that the license be issued. New York City then petitioned to intervene prior to a decision by the Commission in order to introduce evidence of the effects project construction activities might have upon the safety of the Catskill Aqueduct which supplies a substantial part of the water for New York City. The proceedings were reopened and on December 23, 1969 a supplemental decision was issued by the hearing examiner recommending that the licence be granted with some modifications.

On August 17, 1970, the Federal Power Commission issued the license for construction of a pumped-storage plant by Consolidated Edison at Storm King Mountain. In a lengthy opinion, the Commission paid close attention to the decision of the Second Circuit Court of Appeals, giving detailed consideration to areas in which the court had found that the previous decision had been deficient, including alternative sources for the needed power, alternative sties for the project, fish protective devices, underground transmission lines, and the scenic, aesthetic, and historical values that would be affected by the project. The Commission found the project to be compatible with the natural environment, and not to have an adverse effect upon the ecology of the area, the water quality of the Hudson River, or the fishery resources of the Hudson River. The area would be replanted after construction; the power house would be totally underground and the Commission found that the project, as modified and as licensed, represented no real impairment to the environment and scenic aspects of the highlands and the natural beauty of the area. The Commission recognized man's already awesome impact on this section of the Hudson River shoreline, by stating that,

> . . . it should not be inferred that previous and existing environmental detriment permits additional detriment which would otherwise not be permitted but for existing conditions, pointing out that Consolidated Edison would rehabilitate the waterfront area in the vicinity of the project site, an area which the Commission euphemistically described as "blighted."

Although the hearings had been conducted prior to the passage of the National Environmental Policy Act, the Commission found that full and careful consideration had been given to all the concerns which the Act embodies and that the licensing of the facility complied with the requirements of that Act.

All parties appealed to the Second Circuit Court of Appeals which affirmed the Commission's issuance of the license. The majority of the Court found that the decision of the Federal Power Commission was supported by substantial evidence and had been based on a consideration of all relevant factors, and had in fact complied with the requirements of the Federal Power Act and the National Environmental Policy Act.

After 8 years of litigation, at enormous cost to the Scenic Hudson Preservation Conference, its supporters, and Consolidated Edison, not to mention the inconvenience and cost to the electric power-hungry people of the City of New York, the project would be constructed, little modified from the initial proposal.

The first decision of the Court of Appeals in the Scenic Hudson Preservation case represented a crucial selection event in the evolution of Environmental Law. If the conservationists were willing to submit the controversy to the Federal Power Commission, then, according to the Court, the Federal Power Commission should hear and consider evidence on natural values and environmental impacts in addition to evidence on the economics of electric power generation and distribution. The alternative choice open to the conservationists was to remain before the court and challenge the inherent suitability of the Federal Power Commission as a body capable of resolving environmental conflict. The Scenic Hudson Preservation Conference, a coalition of preservationists and aesthetically concerned conservationists, chose to yield to the Federal Power Commission the authority to make an ecological judgment binding upon generations yet unborn, cloaking the Federal Power Commission with a mantle of ecological competence. Since the Scenic Hudson Preservation Conference chose to take its "day in court" before an administrative agency rather than a court of equity, the findings of fact made by the Commission were binding upon the conservationists in subsequent review by the Courts.

Fortunately, the principles set forth by the Court of Appeals in its initial review of the *Scenic Hudson* case mandating consideration of all relevant issues including environmental issues, and requiring affirmative action by the Agency to protect the public interest are not limited in application to the Federal Power Commission. Other agencies, including the Corps of Engineers of the United States Army, the Atomic Energy Commission, the Department of Transportation, the Department of the Interior and the

Department of Agriculture, must also consider all relevant issues, including environmental issues and take affirmative action to protect the public interest.

The Defense of Florissant

The Florissant fossils, located a short distance west of Colorado Springs, Colorado, are found in more than 6,000 acres of an ancient lake bed where seeds, leaves, plants and insects from the Oligocene period (34 million years ago) are remarkably preserved in paper-thin layers of volcanic shale which disintegrate when left exposed to weather unless properly protected. A number of bills had been introduced over the years in Congress to protect the Florissant fossil bed but they did not receive extensive consideration until the United States National Park Service promulgated a master plan detailing the paleontological and palynogical values of Florissant.

At the time the Florissant Fossil Beds National Monument Bill passed the Senate, Park Land Company, a Colorado Springs real estate group had already contracted to purchase 1,800 acres of the ancient lake bed. While the House of Representatives was deliberating its version of the National Monument bill, Park Land Company announced it would bulldoze a road through a portion of the proposed national monument to open the area for development and immediate sale to anyone interested in recreational housing. A group of Colorado conservationists met with the principles of the Park Land Company in an attempt to persuade them to withhold excavation in the area to be included within the Florissant Fossil Beds National Monument at least until the House of Representatives acted on the bill. This request was refused as was a similar request to confine development activities to the area lying outside the ancient lake bed. The only alternative offered the conservationists was the opportunity to purchase the land—for cash immediately—at a price considerably in excess of any appraised value based on recent land sales in the area.

Faced with the irreparable loss of a substantial portion of these unique and irreplaceable fossil beds, a small group of concerned citizens formed a non-profit, public benefit corporation called the Defenders of Florissant and commenced an action for declaratory judgment and an injunctive against the Park Land Company and all the other land owners and contract vendees in the area to be included within the proposed National Monument.

The United States District Court for the District of Colorado heard the Defenders of Florissant application for a temporary restraining order on July 9, 1969, and although the plaintiffs' proof that the proposed excavations for roads and culverts would result in the destruction of some of the most valuable fossil areas in the proposed national monument was uncontradicted and unchallenged the District Court held that there was nothing in the United States Constitution preventing the owners from using their property in any way not prohibited by law. The District Court denied the application for a temporary restraining order and a subsequent application for a stay pending appeal, but did, however, note the importance of preserving the fossil beds.

Following the District Court decision, representatives of the plaintiffs' held an informal conference in the Courtroom with two of the partners in the Park Land Company who agreed to postpone excavation until Monday, July 14, if the plaintiffs gave some assurance of raising the purchase price by that day. Refusing to accept an offer they felt was a form of community blackmail, the Defenders of Florissant appealed to the Tenth Circuit Court of Appeals the following morning, July 10. At the hearing before three judges of that Court in the afternoon, the Court questioned whether it had authority to issue a restraining order in the absence of any statute protecting the fossils. . . .

Admitting that Congress ". . . in its infinite wisdom, has not seen fit to pass legislation protecting fossil beds in general," plaintiffs argued: ". . . if someone had found the original Constitution of the United States buried on his land and then wanted to use it to mop a stain on the floor, is there any doubt . . . they could be restrained?"

Legally, plaintiffs claimed that the right to preservation of the unique and irreplaceable Florissant fossils, a national, natural, resource treasure, was one of the unenumerated rights retained by the people of the United States under the Ninth Amendment of the Constitution and protected by the *due process* and *equal protection* clauses of the Fifth Amendment, and the *privileges or immunities, due process* and *equal protection* clauses of the Fourteenth Amendment. Plaintiffs also asserted that the Florissant fossil beds were subject to judicial protection under the Trust Doctrine and while the defendants could profit from their nominal title to the land and make reasonable use of the area, they were under a duty to maintain that portion of the property vested with the public interest—the 34-million-year-old fossil shales. Procedurally, the Defenders invoked the federal equity jurisdiction relying on the fundamental equitable maxim, "there shall be no wrong without a remedy."

> In summation, counsel for the Defenders of Florissant picked up a fossil palm leaf that had been uncovered at Florissant, and holding it up to the Court, pleaded:
>
> The Florissant fossils are to geology, paleontology, paleobotony, palynology and evoluton what the Rosetta Stone was to Egyptology. To sacrifice this 34 million year old record, a record you might say written by the mighty hand of God, for 30 year mortgages and the basements of the A-frame ghettos of the seventies is like wrapping fish with the Dead Sea Scrolls.
>
> After a short recess, the Court issued an order restraining the defendants from disturbing the soil, subsoil or geological formation of the Florissant fossil beds by any physical or mechanical means. . . .

After a trial on July 29, 1969, the District Court denied the Defenders application for a preliminary injunction for the same reasons it had previously denied the application of a temporary restraining order, and the Park Land Company announced that its bulldozer would begin excavation that afternoon. Several hours later, the Plaintiffs filed a motion for an emergency stay with the Tenth Circuit Court of Appeals, citing defendants threat, and the Court of Appeals for the Tenth Circuit dramatically issued an order extending the restraining order of July 10 indefinitely until further order.

On July 31, 1969, the House Interior and Insular Affairs Committee, through its Subcommittee on Parks and Recreation favorably reported an amended version of the Florissant Fossil Beds National Monument Bill, and floor action by the House of Representatives was scheduled for August 4.

During the argument of the appeal before the Tenth Circuit Court of Appeals, the plaintiffs amplified their legal position, asserting that the Federal Courts had a duty to cooperate with Congress, and that by issuing a preliminary injunction, pending the final deliberation of the Congress of the United States the court was thereby aiding the orderly operations of the Legislative and Executive branches of government. Plaintiffs pursued their original theory that the Trust Doctrine protected the fossil beds, arguing that the land had acquired a public character due to the actions of Congress on the bills pending to dedicate the land as a national monument. The Court reserved decision at the close of the arguments and continued the temporary restraining order. That afternoon the House of Representatives passed its version of the bill as a number of concerned Congressmen from all over the country turned out to suspend the rules and consider the bill out of the regular order because of the pending threat to the fossils. The Senate agreed to the House version of the bill on August 7, and the President signed the bill on August 14, 1969. The preliminary restraining order issued by the Tenth Circuit Court of Appeals remaining in effect while the United States of America instituted suit to acquire the Park Land Company land by condemnation.

The court order prohibiting excavation of the fossil beds may have deprived the landowners of the most profitable use of their land, but did not prohibit all uses of the land consistent with the protection of the fossil beds. The landowners were free to develop the land for tourism, scientific research, or other uses compatible with maintenance of the paleontological integriryt of the area. Such uses, while perhaps not the most profitable use of the land, would still return a reasonable yield on the defendants' speculative investment.

The mere fact that the landowners might not wish to use the land for this purpose does not make the restraint on the land development an unreasonable taking where the public interest in the land was so great.

Certainly where a natural resource is as unique as the Florissant fossil beds were, the value to the public of protecting such a resource is so substantial as to justify the resultant burden upon the private property interests involved, even if it could have been shown that there was no reasonable expectation of profitable use of the property from tourism or other ancillary commercial development.

The message of the Florissant litigation is that judicial protection of a unique, national, natural resource treasure such as the 34-million-year-old Florissant fossil beds warrants restraint upon the rights of private property ownership, particularly during the period of due deliberation by Congress or other legislative body representative of the people.

The mere fact that Congress could not move as fast as the developers' bulldozer does not prevent a federal court of equity from acting to protect a national, natural resource treasures threatened with irreparable damage.

Project Rulison

Project Rulison provided the first direct confrontation among the several theories currently urged in support of citizen action to protect the environment from federal agency operations. Three separate suits were filed concerned with the AEC-Austral Oil Co. experiment seeking to stimulate production of natural gas by underground nuclear explosion. The first action was supported by the American Civil Liberties Union and relied on conventional theories to establish standing: Individual plaintiffs alleged direct, personal, private injury and special damage, seeking injunctive relief to protect their own property rights. The ACLU. application sought to restrain detonation of the underground nuclear device as its principle request for relief, and had already been denied when the second action was filed by the Colorado Open Space Coordinating Council. The title of that action in itself indicates the contrasting theories.

Colorado Open Space Coordinating Council, on behalf of all those entitled to the protection of their health and safety and of the health and safety of those generations yet unborn, from the hazards of ionizing radiation resulting from the distribution of radioactive materials through the permanent biogeochemical cycles of the Biosphere as a result of the defendants conduct of *Project Rulison,* and on behalf of all those entitled to the full benefit, use and enjoyment of the national, natural resource treasures of the State of Colorado without degradation resulting from contamination with radioactive material released as a result of the defendants conduct of *Project Rulison,* and all others similarly situated,

Plaintiffs

—against—
AUSTRAL OIL COMPANY, INCORPORATED
and
CER GEONUCLEAR CORPORATION,
Defendants
US ATOMIC ENERGY COMMISSION,
BUREAU OF MINES, US DEPARTMENT
OF INTERIOR, and
LOS ALAMOS SCIENTIFIC LABORATORY,
as their several interests may appear.

The shift in emphasis in the COSCC action from an emotional outcry against the underground nuclear blast itself to a reasoned demand for care in the release of radionuclides to the environment led to a Court order restraining the "flaring" of the radioactive natural gas following the blast until the hearing and determination of the action brought by COSCC.

By amending their complaint, ACLU, on behalf of the other individuals concerned personally with the blast, remained in the action. Subsequently, the District Attorney of the Ninth Judicial District of the state of Colorado attempted to bring an action in the state court on public nuisance theory, but that action was summarily transferred to the US district Court the consolidated with the COSCC and ACLU actions at the request of the Atomic Energy Commission.

EQUITY

The truly unique element of the Anglo-American is the concept of equity. Equity jurisprudence as a system of remedial law evolved from a number of common sources. It can be found in the Talmud and the earliest writings of the Roman law. It can be found today, though it is somewhat less than obvious, in the current system of civil jurisprudence derived from the Code Napoleon and used throughout most of Europe.

In its most elementary form, the fundamental principle of equity jurisprudence is the command: to use your own property as not to injure that of another. And the law, in order to give effect to this right provides for appeal to the ultimate power of society, be it king, parliament, state, or people, with a corollary maxim: equity permits no wrong to be without a remedy! The effective assertion of equitable rights by an individual or group of individuals is limited only by the rule that a party seeking equitable relief must come forward with "clean hands"—the party must be morally right as well as legally justified. There is an additional rule of restraint self-imposed by courts of equity: the relief granted must be commensurate with the injury suffered by the party seeking relief and tempered by the needs of society.

The Origin of Jurisdiction in Equity

Aristotle asserted that all law is universal and thereby cannot admit of exceptions, yet laws promulgated to cover a broad range of human action frequently cause injustice to some innocent individual because a particular case does not appear to be covered by the application of the universal law. Aristotle reasoned that when lawmakers make a law, they make it for the good of the community, therefore some legal remedy must be available to the individual treated unjustly by the particularly application of a general law.

In order to determine whether the individual was indeed being treated unfairly by the law, one must look to the intent of the lawmaker and the operation of the law. The remedy for the individual unjustly treated in a particular case by application of a general law was termed by Aristotle *Epicheia,* which translates loosely as "There should be an exception." It was left up to the judge deciding each particular case to determine whether a general or universal law was applicable, and if not, to make the appropriate exception in order to preserve the intention of the lawmaker, which was to ensure the good of the community.

The early Roman lawgivers accepted this concept, named it equity, and used it as a cornerstone for the development of what we now call the Roman Law. The intention of the Roman lawgivers was that one person should not benefit by a law while another person was injured by that law unintentionally and unnecessarily.

During the Middle Ages the heir apparent to the Roman legal system, the Christian church, developed the concept of equity even further, establishing the principle that "for every injury there must be some legal remedy," on the philosophical grounds that if the lawmaker did not provide some remedy for injury to an innocent individual, the law would allow certain injustices to go unpunished while others were punished, and this would be unjust. Since it was then an accepted principle that lawmakers were just, they could not have intended an injustice to follow from their laws, therefore, they intended to provide the legal remedy and the court would simply serve as the means to provide that which they intended to provide all along. Although such circumlocution might have found favor with medieval philosophers, there was, nevertheless, a singular practical reason for development of he principle. For if there was no procedure for individual relief from the unintended application of a general law, and sufficient individuals were oppressed by the unintended application of that law, then the individuals would tend to look with disfavor on the lawmakers and, in spite of the repression inherent in the feudal system, there might be civil unrest, a condition not conductive to the maintenance of the tenuous existence of the feudal estates which represented civilization in western Europe during the Middle Ages.

Equity jurisprudence developed throughout the ecclesiastical courts following the decline and fall of the Roman Empire, but it was to see its most dramatic development in England following the Norman conquest.

The common law, as distinguished from the customary law of the popular courts, originated in the establishment by Henry II of a national court administering a law for the entire nation, and by the end of the reign of Henry II, we find established a *Curia Regis,* a court of the King, which was a true court of law in the modern sense, administering a national law, common to the entire country, and which had largely displaced the customary laws of the different parts of the country. This continued during the thirteenth century, so that by its close, the common law was definitely established as the law of the nation, displacing the customary law and the local courts which were limited to local petty maters. The law of the *Curia Regis,* which had been the law of the very great, extended and adapted to the needs of the people so as to become the common law of a nation.

So long as the common law remained a flexible system with its field undefined, its power of inclusion unlimited, and its organs undifferentiated, there was no reason for distinguishing between the common law and equity. But soon the common law became so fixed as inflexible and its practitioners so absorbed in nice questions of form and pleading, there was no longer room for equity. By the early fourteenth century, the common law, which had supplanted the ancient customary law, had now, in its turn, become the regular system of remedial justice, but with gaps and defects where sufficient remedies were not provided, and resort was necessary to the ancient power of the king as the fountain of all justice.

Equity did not directly contest the existence of settled legal right. Rather, after recognizing those rights, equity went on to insist that the holder of such legal rights if they were acquired or retained unconscionably, or if they were being used in an unconscionable attempt to interfere with the fundamental rights of others, should be subject to the jurisdiction the "Chancellor" or the "Keeper of the Conscience of the King" as the source of all legal rights.

Equitable Relief

It is a fundamental principle essential to the very existence of organized society, and civilization as we know it, that every person, in exercising personal rights and in the use of personal property shall respect the rights and properties of others. Every person must so conduct themselves in the enjoyment of the rights and privileges which they may enjoy as individual members of society in such a way that they shall prejudice no one in their possession and enjoyment of their personal rights or the rights they hold in common as members of society. When there is an invasion of the rights or privileges of the public or the rights and privileges of any individual held in common by reason of the existence of civilized society, the absence of exact precedent and the fact that commentators on the law do not discuss the subject is of no material importance in awarding equitable relief.

That the exercise of the preventive powers of a court of equity is demanded in a novel case is not a fatal objection. In social evolution, with the march of the arts and sciences, and in the resultant effects upon organized society, it is quite intelligible that new conditions must arise in personal relations, which the rules of the common law, cast in the rigid mold of an earlier status, were not designed to meet. It would be a reproach to equitable jurisprudence, if equity were powerless to extend the application of the principles of common law, or of natural justice, in remedying a wrong, which in the progress of civilization, has been made possible as the result of new social or commercial conditions.

Equity is the agency by which law is brought into harmony with society. It is one of the factors which operate in judicial evolution. It succeeds legal fictions—those judicial assumptions through which a rule of law is modified in its operation—and it precedes legislation.

Equity has neither fixed boundaries, nor logical subdivisions, and its origin, both in Rome and in England, was that there was a wrong for which there was no remedy at law. As Lord Chancellor Cottenham observed:

It is the duty of this court, [equity], to adopt its practice and course of proceeding to the existing state of society and not, by a strict adherence to forms and rule, under different circumstances, to decline to administer justice and enforce rights for which there is no other remedy . . . If it were necessary to go much further than it is, in order to open the doors of this court to those who could not obtain [justice] elsewhere, I should not shirk form the responsibility of doing so.[†]

A distinguishing feature of equity jurisdiction is that it will apply settled rules to unusual conditions, and mold its decrees so as to do justice between the parties.

Peculiar and extraordinary cases will arise in the complex and diversified affairs of men, which perhaps, cannot be classed under any of he distinct heads of equity jurisdiction, but which must be acknowledged, nevertheless, to come within the legitimate powers of a court of equity because complete justice cannot otherwise be done between the parties. Therefore, when no remedy exists at law, courts of equity, to prevent injustice and in many cases on principles of general policy, will go far in granting relief.

Such was the law of equity at the start of the eighteenth century. If that rule of law had been developed with vigor much of the human and environmental degradation of he Industrial Revolution might have been avoided.

Since that time, two anomalous rules have evolved, interfering with the principle that for every wrong there is a remedy. The first of these anomalies concerns the artificial distinction between public and private nuisance and the second is the doctrine of "sovereign immunity." Both of these doctrines can be attributed to the meddling of Sir William Blackstone (1723–1780).

Public and Private Nuisance

Until Blackstone there was no distinction made between public and private nuisance. The rule had been well established that any individual could apply to a court of equity to abate a nuisance. But during the later part of the eighteenth century, Blackstone created a new rule of law that was to represent a classic manifestation of the obfuscation of simple legal principles by "self-proclaimed" legal scholars. This new rule of law proclaimed by Blackstone was to contribute substantially to the environmental and social crises of today and represents the kind of antisocial perversion of the law that made the common law of England during the seventeenth, eighteenth, and nineteenth centuries such an inviting target for the diverse talents of William Shakespeare, Jonathan Swift, Charles Dickens, and W.S. Gilbert.

Blackstone created a difference between public and private nuisance, and the significance of that difference is to be fond in the criteria for abatement of the public nuisance: (1) only a public nuisance may be made the basis for a criminal prosecution, and (2) only the public, through he proper officer, may sue to enjoin or abate a public nuisance, in the absence of special damage to a particular private individual—damage which is substantially greater than that suffered by other individual members of society—a public nuisance is subject to correction only at the hands of public authority. The mischief done and the disastrous consequence of Blackstone's whim are still evident.

In 1965, an action was brought on behalf of the people of the Town of Brookhaven, in the County of Suffolk,

---

[†] *Wallworth* v. *Holt* 4 Myl & C619, 41 Eng. Rep. 238 (1984).

New York, by a group of citizens, to restrain the Long Island duck industry form discharging raw, untreated sewage equivalent to that of a city of one million people into the waters of Great South Bay, which was once one of the finest shellfishing and marine recreation areas on the east coast of the United States. The duck industry defended the action by admitting that the eight million ducklings grown along the estuaries of he Great South Bay did in fact deliver the raw sewage effluent equivalent of a city of one million people into the Bay, but that the Court should dismiss the action on the grounds that such an affront to the public waters was so great that it was a "public nuisance" not a "private nuisance" and as a "public nuisance" it could only be attacked by the Attorney General of the State of New York, not by any private citizens, unless of course those private citizens could establish "special damages" different from the damages sustained by the public at large.

A New York Supreme Court, the same court that less than a year later in a dramatic reversal of precedent would issue that first injunction against the use of DDT ever granted by a Court, dismissed the case against the duck industry, accepting without question the argument that a public nuisance could not be abated by a private citizen or group of citizens.

How could this strange concept have crept into the law equity? What is the justification for this strange anomaly in that body of law that holds no wrong may exist without a remedy? In 1858, the Court of Appeals of the State of New York identified the source and expounded the justification for this onerous rule.

A contrary rule would be productive of very great inconveniences . . . No private person or number of persons can assume to be the champions of the community and in its behalf, challenge the public officers to meet them in the courts of justice to defend their official acts.

The court continued and discussed the theory of the decision,

> The general rule is that for wrongs against the public, whether actually committed or only apprehended, the remedy, whether civil or criminal, is by a prosecution instituted by the state in its political character, or by some officer authorized by law to act in its behalf. . . .

The principle is further exemplified in questions respecting nuisances. Common or public nuisances, which are such as are inconvenient or injurious to the whole community in general, are, as all are aware, indictable [the People of State can take action in a criminal proceedings] only, and the not actionable [any citizen can sue]; for as Blackstone [*Blackstone's Commentaries,* Book 4, p. 167] says, "it would be unreasonable to multiply suits by giving every man a separate right of action for what damnifies him in common only with the rest of his fellow-citizens.

Just who was Sir William Blackstone that he should exert such a restraint on the general application of equitable principles? Referring to the eleventh edition of the *Encyclopaedia Britannica,* published in 1911 and drawing on continual revisions from the first English edition in 1771, the following information may be elicited under the entry, "Blackstone, Sir William [1723–1780]:

> . . . In 1746 he was called to the bar. Though but little known or distinguished as a pleader, he was actively employed during his occasional residences at the university (Oxford), in taking part in the internal management of his college. In May 1749, as a small reward for his services, and to give him further opportunity of advancing the interests of the college, Blackstone was appointed steward of its manors. In the same year, on the resignation of his uncle, he was elected recorder for the Borough of Wallingford. . . . He accepted a seat on the bench, and on the death of Sir Joseph (Yates) succeeded him (in the court of common pleas). He died on the 14th of February, 1780. . . .

Blackstone was by no means what would now be called a scientific jurist. He had only the vaguest possible grasp of the elementary conceptions of law. Austin, who accused him of following slavishly the method of Hale's Analysis of the Law, declares that he "blindly adopts the mistakes of his rude and compendious model; missing invariably, with a nice and surprising infelicity, the pregnant but obscure suggestions which it proffered to his attention, and which would have guided a discerning and inventive writer to an arrangement comparatively just."

From the small place which equity jurisprudence occupies in his arrangement, he would scarcely seem to have realized its true position in the law of England.

Bentham accuses him of being the enemy of all reform, and the unscrupulous champion of every form of professional chicanery. Austin says that he truckled to the sinister influences and mischievous prejudices of power, and that he flattered the overweening conceit of the English in their own institutions. "He displays much ingenuity in giving a plausible form to common prejudices and fallacies. . . ."

For more than a century the opinion of that one man has stood in the way of a proper disciplined application of a fundamental principle of equity jurisprudence, "equity will not suffer a wrong without a remedy."

Just what happened at the time of Blackstone? It was obvious that Blackstone set himself to the task of codifying the laws of England, but in the process of attempting to build a logical and consistent body of legal principles he lost the basic insight of the Anglo-American system of jurisprudence, the common law.

The common law grew with civilization and the practices and customs of society. As the oppressed peasants obtained certain remedies during the Middle Ages, these remedies became a part of the common law. That is why the Anglo-American legal system depends on case law or precedent rather than elaborate codes promulgated by a legislature or king. A system of administering justice based on precedent rather than stature is inherently more flexible and capable of meeting the needs of society because the court is free to interpret the law with reference to, and by analogy with, part cases of similar import, though not precisely identical.

There is no doubt that Blackstone did a reasonable job of tidying-up the law, but in his attempt to make of law an axiomatic science little different from geometry, he lost the essential elements of equity jurisprudence, particularly the rule that for every injury there must be a legal remedy.

Blackstone's justification for striking the principle that for every injury there must be a legal remedy from the law of England arose from his belief that the King could do no wrong. Reasoning that failure to provide an adequate legal remedy for an injury was wrong, and that the King could do no wrong, it was obvious that there was no need for a rule of law providing a remedy for every wrong, because the King had obviously provided the remedy, since the King could do no wrong and failure to provide a remedy for an injury would be wrong. This perfectly circular argument has been exposed by many legal scholars, yet it still appears in decisions of courts that should know better.

Consider for a moment the ideological basis for establishing American independence. The founding fathers of this country were asserting the fundamental equitable principle that no wrong should exist without an adequate legal remedy. They did not deny the right of George III to tax his American colonies, they asserted that certain taxes were the wrong taxes, at the wrong time and for the wrong purposes. Taxation without representation was wrong. In other words, the King could, in fact, under certain circumstances, do wrong, and the equitable rule of law that no wrong should exist without a legal remedy was a fundamental human right.

Environmental Law is a mixture of the new and the old. Affirming the timeless principles of equity jurisprudence and asserting the unenumerated rights reserved to the people by the Ninth Amendment of the Constitution and protected by the *equal protection* and *due process* clauses of the Fifth Amendment and the *privileges or immunities, due process* and *equal protection* clauses of the Fourteenth Amendment of the Constitution, the law is newly applying these established principles and traditional legal procedures directly to the environmental crises threatening the Biosphere.

The basic element of environmental jurisprudence is recognition by our courts that the people have an absolute right to a salubrious environment as one of the "fundamental and inherent rights with which all humans are endowed even though no specific mention is made of them in either the national or state constitutions. . . ." The inherent human freedoms with which mankind is endowed are "antecedent to all earthly governments' rights that cannot be repealed or restrained by human laws, rights derived from the Great Legislator of the Universe."

[*Colorado Anti-Discrimination Com. v. Case*, 151 Colo. 235, 380 P. 2d 34 (1962).]

The words of Lord Atkin in an English case are compelling: "When those ghosts of the past stand in the path of justice, clanking their medieval chains, the proper course for the judge is to pass through them undeterred. . . . The common law does not go on the theory that a case of first impression presents a problem of legislative as opposed to judicial power."

[*United Australia, Ltd. v. Barclay Bank, Ltd.* (1940) 4 All En. 20, (1941) A C 1, 29.]

"The law will protect a flower or a vine as well as an oak . . . ; [Such] damages are irreparable too, because the trees and vines cannot be replaced."

[*Campbell v. Seaman*, 63 NY 568 (1978).]

The above historical treatment presented an overview of the fundamental arguments of Environmental Law. Some examples of recent legislative activity are discussed below by the editors.

The Clean Air Act Amendments of 1990 were the latest of a series which also include those of 1970 and 1977. They deal with the broad reduction of emissions from acid rain precursors (i.e., reductions of 10 million tons/yr and 2 million tons/yr in SO_x and NO_x emissions, respectively within 10 years) and air toxic emissions from industrial sources including over 170 species not previously listed. The American Electric Power Company said of the CAA amendments, "probably the most complex piece of legislation we've seen in the last 40 years."

Pursuant to the 1990 CAA requirements, Maximum Achievable Control Technology (MACT) regulations for many sources emitting hazardous air pollutants (HAP's) have been promulgated and are being enforced. Also new NAAQS limits have been established for particulate matter less than 2.5 micron diameter. These regulations and their enforcement are discussed in the article by C.V Mathai and Elliott, E.D., **EM**, pp. 25–34, May 2002. The U.S. Supreme court may be called upon to settle some lawsuits brought forth by a coalition of states, local governments and environmental groups in the enforcement of EPA regulations, such as New Source Review (NSR) provisions—Smith, D.C.," US Climate Change Legislation," Refocus, pp. 16–19, Apr/May (2004) and Barcott, Bruce, "Changing all the Rules", *New York Times Magazine*, pp. 38–78, Apr. 4, 2004. Also in the global arena, an administration's failure to confront climate change by its rejection of the Kyoto agreement, may be the subject of a lawsuit before an international tribunal (Strauss, A., The legal Option: Suing the United States in International Forums for Global Warming Emissions," Environmental Law Reporter, **33**, 108185 (2002). David Grossman argues that there may be good reason to shift the costs of damages caused by fossil fuel companies that have received economic benefits of activities that negatively impact the environment (Grosssman, David A., "Warming up to a not so radical idea: Tort-based climate change litigation," *Columbia Journal of Environmental Law* **28**, 1 (2003).

LEGAL ASPECTS: see also ENVIRONMENTAL LAW

LIMNOLOGY

INTRODUCTION

Limnology is the scientific study of the physical, chemical, and biological factors that affect aquatic productivity and water quality in lakes. Lakes are important resources—much more than places for groundwater, surface water, and precipitation to collect. They control flooding, provide water for domestic and agricultural uses, and provide recreational opportunities such as swimming, fishing, boating, and waterskiing. Lakes also provide habitat for insects, fish, and wildlife such as frogs, turtles, waterfowl, and shorebirds. Lakes' commercial value in food supply, tourism, and transportation is worth many billions of dollars each year. Lakes also offer opportunities for relaxation and appreciation of natural beauty. According to the North American Lake Management Society, this quality is not a minor asset; over 60 percent of Wisconsin lake property owners who were asked what they valued in lakes rated aesthetics as especially important. (U.S. EPA, 1990).

However, a lake cannot be all things to all people. Desirable uses, even obtainable ones, can conflict. For example, swimmers may want no plants but some plants are needed in order to provide fish habitat. Lakeside property owners and lake associations often want their lake to do everything; they want aesthetic pleasure, great fishing, clean water, sandy shorelines and bottoms, and a healthy wildlife population—without insects or weeds. No lake can meet all of these demands.

This article will provide an overview of the physical, chemical, and biological components of lake ecosystems. An ecosystem is a system of interrelated organisms and their physical–chemical environment. It is impossible to alter one characteristic of a lake ecosystem without affecting some other characteristic of the ecosystem. The article will also explain how lake ecosystems get out of balance, and what can be also done to restore the balance.

LAKE WATERSHEDS AND ZONES

Lakes are receiving bodies—constantly receiving water, dissolved materials, and particulates from their watersheds and from the atmosphere, and energy from the sun and wind. A watershed is the area which drains to a lake. Watersheds come in all sizes. For example, the watershed that drains to Beaver Lake in western Washington near Seattle is less than two square miles in area, whereas the Lake Washington watershed is 350 square miles. Lakes are sensitive to existing conditions in the surrounding watershed and atmosphere.

Each lake has a unique watershed, size, and shape. The size and shape are often determined by the origin of the lake basin and, in turn, influence the lake's productivity, water quality, habitat, and lifespan.

The most common origin of lake basins in North America has been glacial activity such as the erosion of bedrock and deepening of valleys by expansion and recession of glaciers. Glacial lakes of Canada and the upper midwestern United States were formed about 8,000 to 12,000 years ago. For example, the Finger Lakes of upper New York State were formed when deep depressions left by receding glaciers filled with meltwater (U.S. EPA, 1990).

The depressions left by melting ice blocks form kettle or "pothole" lakes. This type of lake is common throughout the upper midwestern United States, the eastern portion of the state of Washington, and large portions of Canada. Kettle lakes and their watersheds are popular home sites and recreational areas. The size and shape of kettle lake basins reflect the size of the original ice block and how deeply it was buried in the glacial debris (U.S. EPA, 1990).

Some lakes are formed by volcanic activity; i.e., a volcano erupts creating a huge depression or caldera which then fills with water. Crater Lake in Oregon is an example of a volcanic lake. Movements of large segments of the earth's crust created Reelfoot Lake in Tennessee, Lake Tahoe in California and Nevada, and many other lakes (U.S. EPA, 1990).

Solution lakes are formed where groundwater has dissolved limestone; this is the case for many Florida lakes. Other lakes originate from shifting of river channels. For example, oxbow lakes are stranded segments of meandering rivers. The persistence of dam-building beavers can also create lakes (U.S. EPA, 1990).

A lake has four zones, each with different plants and animals (Figure 1). The littoral zone is the portion of the lake that extends from the shoreline lakeward to the greatest depth occupied by rooted plants. By contrast, the pelagic zone is the open area of a lake from the edge of the littoral zone to the center of the lake. The benthic or profundal zone refers to the deep waters at the bottom of a lake where photosynthesis does not occur because light does not penetrate. The marginal zone refers to the margins of the lake on the lake shoreline (U.S. EPA, 1990).

Shallow lakes tend to be more biologically productive than deep lakes because of the large area of bottom sediments

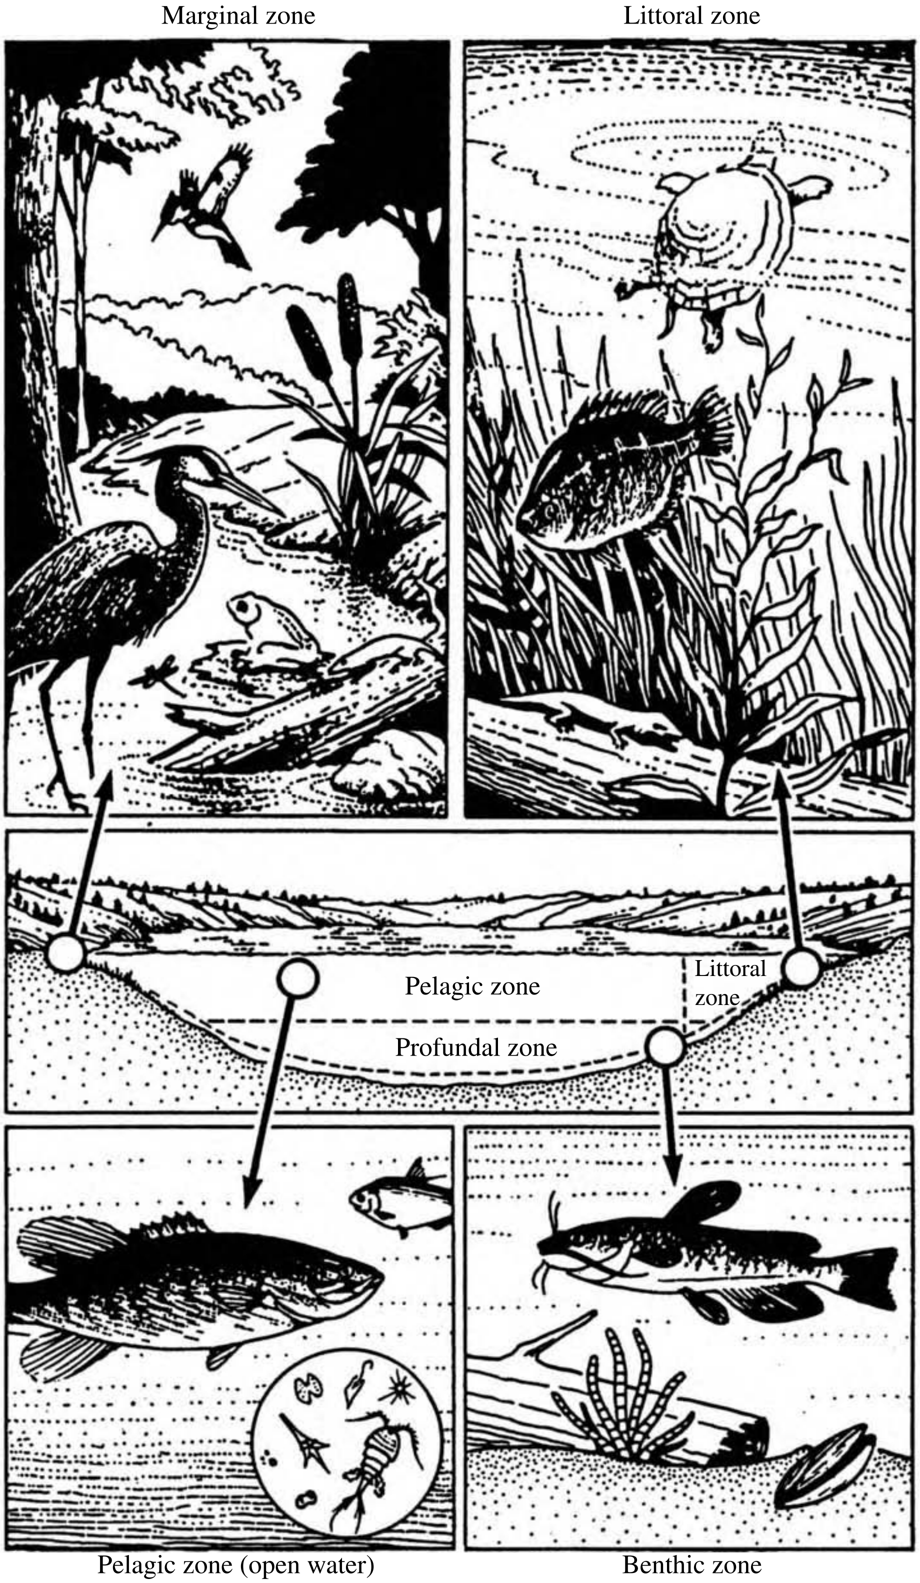

FIGURE 1 The location and nature of typical lake communities, habitats, and organisms. In addition to the lake's watershed, all of these components are part of the lake ecosystem. (U.S. EPA, 1990)

relative to the volume of water, more complete wind mixing of the lake water, and the large littoral zone along the lake perimeter that can be colonized by plants. Shallow lakes often have most of their plants in littoral areas and have little pelagic habitat. On the other hand, deep lakes have fewer areas that receive enough light for rooted aquatic plants to grow, and therefore have a high proportion of pelagic habitat and less littoral habitat.

HYDROLOGIC CYCLE AND WATER BUDGET

Since precipitation and surface water runoff have direct influences on lake ecosystems, understanding the hydrologic cycle and water budget are key concepts in limnology. The hydrologic (water) cycle refers to the circulation of water between the Earth's surface and the atmosphere. This is powered by the sun. Water falls to Earth as precipitation. About 75 percent of the precipitation is returned to the atmosphere as vapor through direct evaporation and transpiration from both terrestrial and aquatic plants during photosynthesis. The remaining 25 percent of the precipitation is stored in ice caps, drains directly off the land into lakes, streams, wetlands, rivers, and oceans, or infiltrates the soil and underlying rock layers and enters the groundwater system. Groundwater enters lakes and streams through underwater seeps, springs, or surface channels (Cooke *et al.*, 1986; U.S. EPA, 1990; Wetzel, 1983).

Drainage lakes are formed primarily by inflowing rivers and streams. Therefore, their water levels vary with the surface water runoff from their watersheds. On the other hand, seepage lakes form where groundwater intersects with the land surface. Since seepage lakes are maintained primarily by groundwater inflow, their water levels fluctuate with seasonal variations in the local water table. For both drainage and seepage lakes, the balance between water inputs and outputs influences the supply of plant nutrients (nitrogen and phosphorus) to the lake and the lake's hydraulic (water) residence time, thereby influencing the lake's water quality and biological productivity (U.S. EPA, 1990).

The hydraulic (water) residence time is the amount of time that water entering a lake will remain in it or the average amount of time required to completely renew a lake's water volume. The amount of water entering a lake from its watershed controls the volume of the lake. The hydraulic residence time is calculated by dividing the water volume of a lake by its flow rate, and varies greatly among lakes. For example, if a lake has a volume of 500 acre-feet and the outflow rate is 10 acre-feet per day, then the hydraulic residence time would be 50 days. If the hydraulic residence time of a lake is 100 days to several years, this means that plant nutrients and pollutants remain in the water column long enough to degrade water quality and to allow plants to accumulate (U.S. EPA, 1990; Wetzel, 1983).

Each lake has a water balance, in which water input = water output + the change in the amount of water stored in the lake. If inputs are greater than outputs, lake levels rise as water is stored in the lake. When outputs are greater than inputs, lake levels fall. This happens during summer droughts.

A related concept is the lake water budget, which is a measure of the sources of water entering and flowing out of a lake over the course of a year. A lake's water budget is affected by the hydrologic cycle, and the quantity and timing of water entering and leaving the lake. Types of data used in calculating a water budget include precipitation, stream flow into and out of the lake, and lake surface elevation (water level). Sources of water input or inflow include the lake inlet(s), precipitation, surface water runoff, point source discharges, and groundwater. Sources of water output or outflow include the lake outlet(s), evaporation, transpiration from lake plants, groundwater seepage, and water withdrawals for domestic, agricultural, and industrial purposes. The change in storage accounts for changes in surface elevation over the year. This change is positive if lake volume increases over the year, negative if lake volume decreases (U.S. EPA, 1990; Wetzel, 1983).

Land use and geology of the surrounding watershed affect the water budget. For example, lakes in areas with permeable soils receive inflowing groundwater throughout the year. Lakes in areas with impervious surfaces can receive large volumes of stormwater runoff.

PHOSPHORUS BUDGET AND LOADING

Another important characteristic of lakes is the phosphorus budget, a measure of the sources of phosphorus entering and leaving the lake over the course of a year. Phosphorus is a nutrient that is essential in plant growth. The amount of phosphorus in a lake directly influences biological productivity. The phosphorus budget will indicate if the phosphorus in the lake is coming from within the lake, from sources in the watershed, or from both internal and external sources.

For a given lake, phosphorus inputs (inflow loading) –phosphorus outputs (outflow loading) + net sedimentation + change in storage. This means that phosphorus inputs to the lake equal phosphorus losses from the lake plus or minus the change in the total amount of phosphorus stored in the lake. Change in phosphorus storage within the lake equals the amount of phosphorus entering the lake minus the amount of phosphorus leaving the lake minus the net loss of phosphorus to the lake sediments. Sources of phosphorus inputs to a lake are the lake inlet(s), point sources discharging directly to the lake, precipitation, surface water runoff, leachate from malfunctioning shoreline septic tanks, other groundwater inputs, and migrant waterfowl wastes. Sources of phosphorus outputs from a lake are the lake outlet(s), groundwater seepage, and water withdrawals for domestic, agricultural, and industrial purposes (Cooke *et al.*, 1993b; U.S. EPA, 1990; Wetzel, 1983). Figure 2 illustrates the phosphorus budget for Cottage Lake, near Seattle, Washington. As indicated in the figure, most of the phosphorus in the lake comes from the Daniels Creek inlet and from the lake sediments. Most of the phosphorus that leaves the lake does so via the lake outlet (KCM, 1994; Solomon *et al.*, 1996).

Net sedimentation refers to the amount of phosphorous accumulated in lake bottom sediments, i.e., the difference in the amount of phosphorus that binds to the sediments and

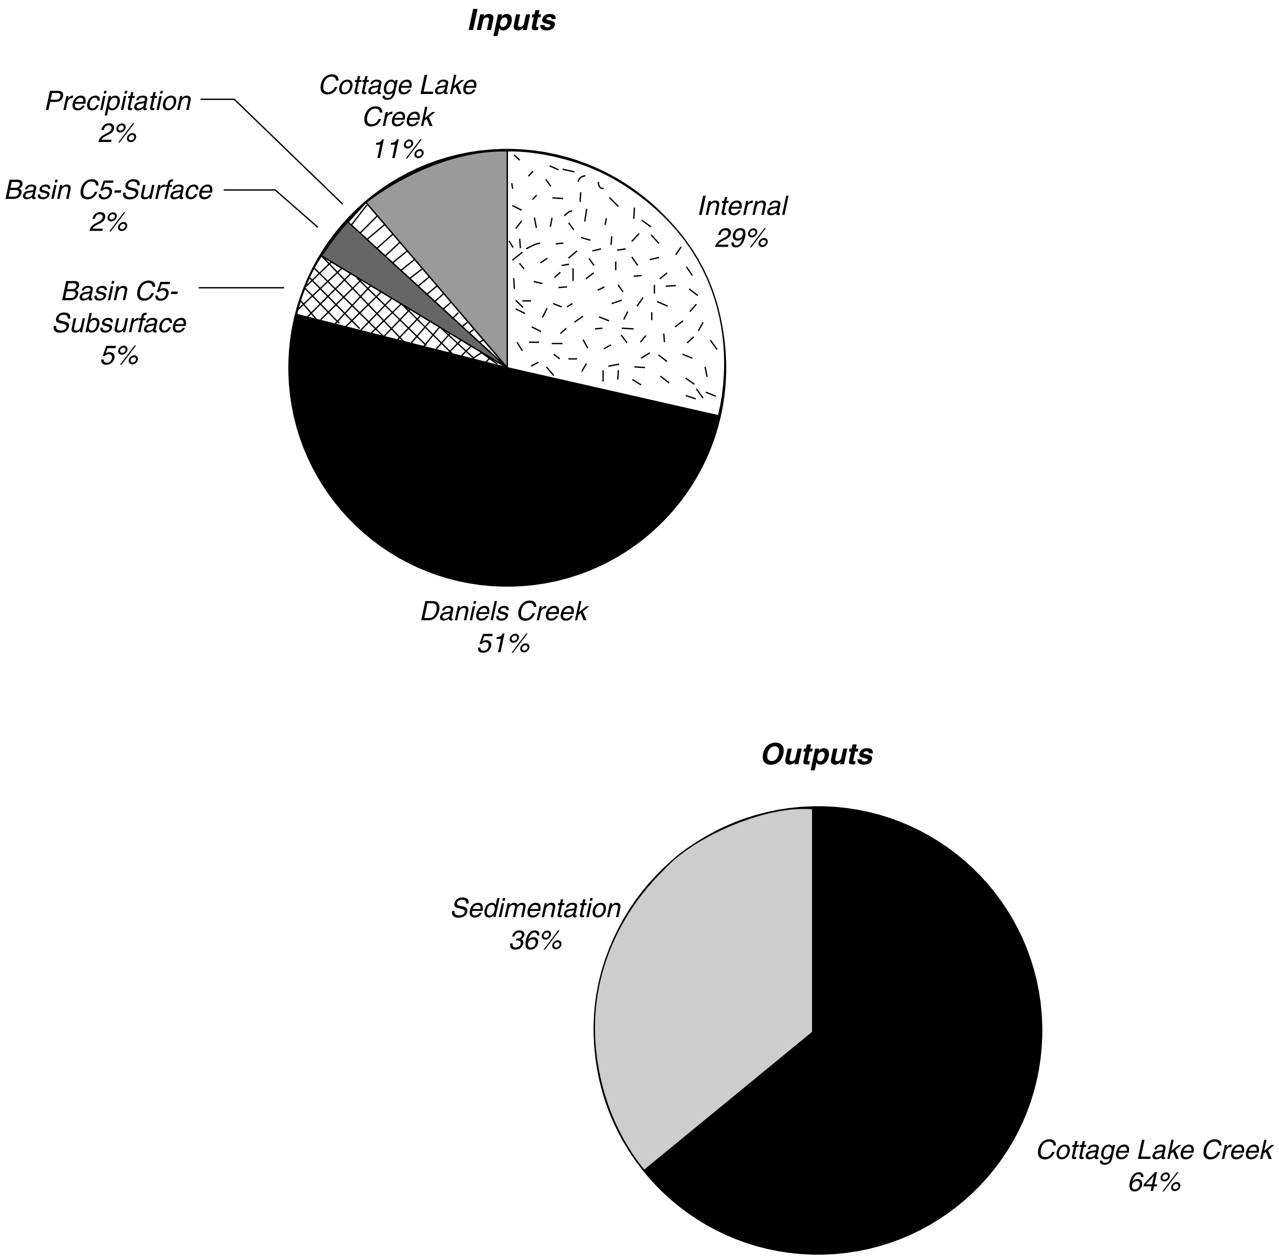

FIGURE 2 Cottage Lake total phosphorus inputs and outputs.

the amount of phosphorus released from the sediments to the water column. In general, lake water quality will improve as the magnitude of sedimentation increases because higher sedimentation means there is less phosphorus in the water column to stimulate overgrowth of aquatic plants (for more details, see section on eutrophication). The change in storage accounts for changes in the total amount of phosphorus in the lake water column between the beginning and end of the year.

Phosphorus concentration differs from phosphorus loading. Phosphorus loading to a lake is calculated on the basis of the water budget for the lake and measured phosphorus concentrations in the lake, its inlets, its outlets, precipitation, surface water runoff, and groundwater. Loadings are based on concentrations and flow rates and most accurately express the relative impacts of various watershed sources on lake water quality. For example, a stream that is an inlet to a lake may have a high concentration of phosphorus. This does not necessarily mean that the stream is a major contributor to the lake phosphorus budget. If the stream has a low flow, it will contribute a relatively low annual phosphorus loading.

The concept of phosphorus loading can be illustrated with an analogy to a grocery bill as shown in Table 1. For each grocery item, the cost is determined by multiplying the unit cost and the number of items purchased. The total grocery bill is the sum of the costs of all items. Likewise, for each source of phosphorus input to a lake, the phosphorus loading is determined by multiplying the flow rate for the source (lake inlet, groundwater, etc.) and its phosphorus concentration over annual and seasonal periods. The total "phosphorus bill" (total phosphorus loading from all sources) is the sum of the loadings from each source.

TABLE 1
Phosphorus Loading Concept (U.S. EPA, 1990)

Grocery Bill	Phosphorus Loading
Item	Source
Quantity	Flow
Unit Cost	Concentration
Cost of Item	Loading from Source
Total Cost of All Items	*Total Loading from All Sources*

Phosphorus loadings change in response to season, storm events, upstream point sources, and land use changes. For example, converting an acre of forest into residential or commercial land typically increases the phosphorus loading to a lake in that watershed fivefold to twentyfold. This is because there will be increases in both water flow (runoff from the newly created impervious surfaces) and phosphorus concentration (deposition of phosphorus on impervious surfaces). An evaluation of phosphorus loadings provides a basis for predicting lake responses to changes in land use.

STRATIFICATION

Many swimmers notice that when they dive into a lake during the summer, the deeper waters of the lake are much colder than the surface waters. This is due to stratification, an interesting temperature-related characteristic of most temperate climate lakes.

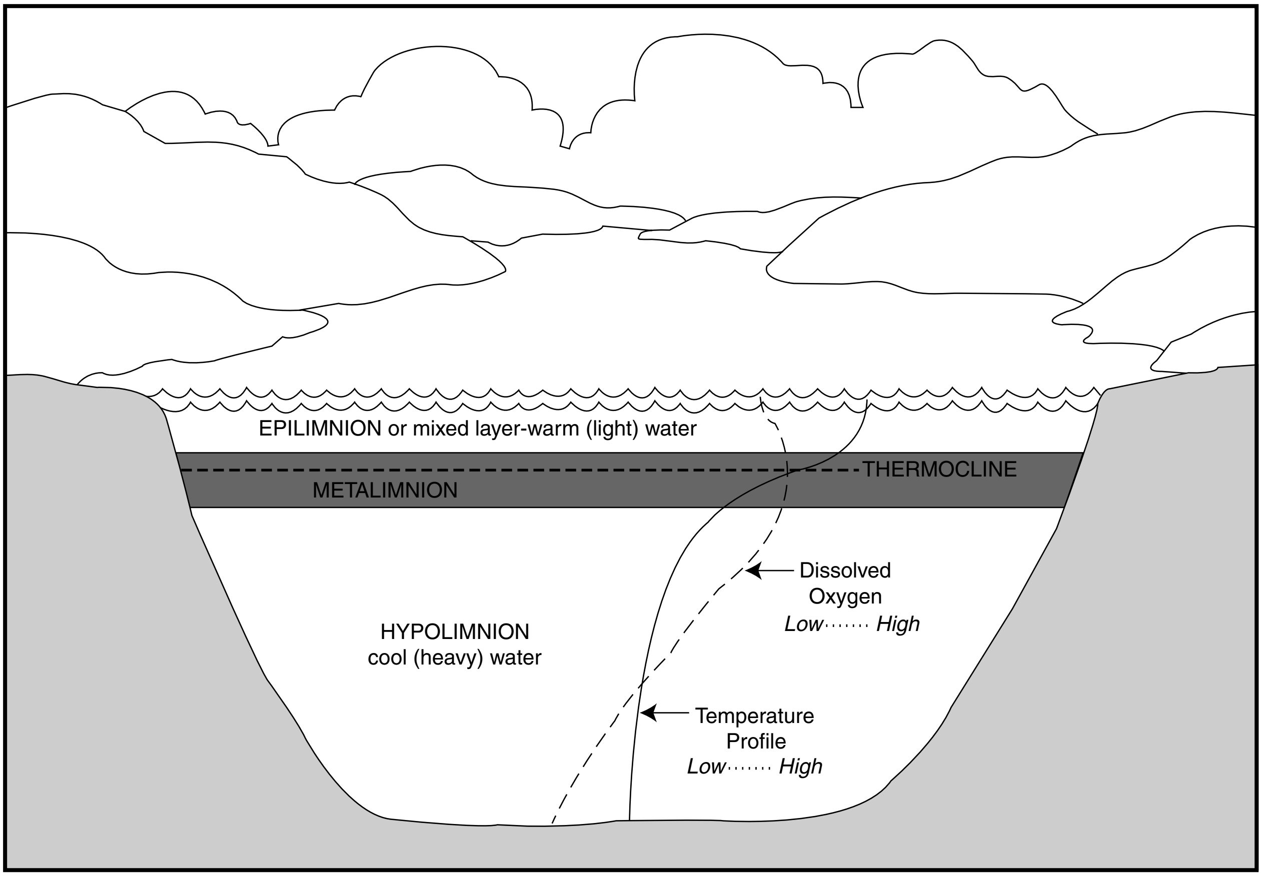

FIGURE 3 Thermal stratification.

Temperature-related characteristics of water have a large effect on the water quality and ecology of lakes. Water is at its densest at 4°C or 39°F, then expands (becomes less dense) until it freezes at 0°C (32°F). This anomalous expansion of water allows ice to float and form at the surface of lakes at 0°C (32°F) or less, and thermal stratification to occur during the warmer, summer weather. During spring and early summer, energy from the sun heats the upper water layer. The warmer, less-dense surface waters float on top of the cooler, denser bottom waters. This results in the upper layer, or epilimnion, becoming isolated from the lower layer, or hypolimnion (Figure 3). The two layers are separated by the middle layer, or metalimnion, where large temperature changes occur with changes in depth. The thermocline, which is located within the metalimnion, is a horizontal plane of water across the lake through the point of the greatest temperature change. The metalimnion presents a physical barrier to the mixing of the epilimnion and hypolimnion. Since there is little or no exchange of water between the epilimnion and the hypolimnion, water quality can be quite different in each layer.

In the temperate regions of the world where there are not strong contrasts in seasonal conditions (e.g., mild winters and summers), this type of thermal stratification is common during the summer and early fall. After the summer, the epilimnion tends to cool, and by late fall or early winter the temperature difference between the two water layers is small enough that the winds will mix the water throughout the lake, which will then remain fully mixed until the onset of stratification in late spring. Lakes that undergo this type of seasonal pattern (i.e., they stratify once and re-mix or turn over once each year) are called monomictic lakes. These include lakes in mountainous regions of the temperate zones, warm regions of the temperate zones, many coastal regions of North America and Europe, and mountainous areas of subtropical latitudes (U.S. EPA, 1990; Wetzel, 1983).

By contrast, in the temperate regions of the world with strong contrasts in seasonal conditions (e.g., very cold winters and very hot summers), lakes undergo complete turnover in the spring and fall separated by thermal stratification in the summer (i.e., warmer surface waters float on top of cooler bottom waters) and inverse thermal stratification in the winter. Ice cover forms and floats on the surface of such lakes under clam, cold conditions. Inverse stratification of water temperatures occurs under the ice, in which colder, less-dense water overlies warmer, more-dense water near the temperature of maximum density at 4°C. Some gradual heating of the water occurs during the winter under ice cover. When the ice cover melts in the spring, the water column is nearly uniform in temperature. If the lake receives sufficient wind energy, as is usually the case, then the lake circulates completely and undergoes spring turnover. Stratification occurs during the warmer days of summer, with another complete turnover in fall. Lakes that undergo this type of seasonal pattern (i.e., they stratify twice and re-mix twice each year) are called dimictic lakes and include most lakes of the cool temperate regions of the world (U.S. EPA, 1990; Wetzel, 1983).

LAKE BIOTA

The types of organisms found in a lake may include phytoplankton (algae), zooplankton, benthic infauna, fish, amphibia (such as tadpoles, frogs, and salamanders), reptiles (such as turtles and water snakes), and birds (waterfowl and shorebirds). Lake plants and animals are interrelated via a food chain.

Algae are microscopic plants found in the lake water column. Algal species may occur in many different forms including filamentous, colonial, and single-celled. Algae are easily carried by wind-generated currents and will often accumulate in windward areas of the lake, forming surface scums. When algae populations increase rapidly, the algae can become a nuisance by forming high concentrations in the water column, or even surface accumulations, called algal blooms.

Several different algal species can usually be found in a lake at any time of the year. A variety of environmental factors including light, temperature, and nutrient levels, affect phytoplankton production and the occurrence of algal blooms. Diatoms are algae that are golden in color and contain silica. They predominate in the spring and autumn due to their ability to reproduce and grow in cooler temperatures and less light. During the summer, increased water temperatures and available light create conditions that favor green algae or blue-green algae. Blue-green algae can form nuisance blooms; they are particularly problematic because they will float to the surface, forming scums that affect the recreational uses and aesthetic qualities of a lake. In some lakes with high biological productivity, blue-greens dominate in spring, summer, and fall.

In addition to algae, large vascular plants (plants with roots, stems, and leaves) or macrophytes are found in lakes. Macrophytes are classified as emergent, floating, or submersed. Emergent plants grow on the shoreline and include cattails, irises, and purple loosestrife. Floating plants are plants that float on the surface of the lake. They can be rooted in the lake bottom such as water lilies or watershield or free-floating such as duckweed. Submersed plants are rooted plants that live below the lake surface and include pondweed and water weed (*Elodea*). Figure 4 illustrates the community types and common examples of plants associated with each type (Washington State Department of Ecology, 1994).

Some macrophytes are native to the particular lake and geographic region; others, called exotics, have been imported or are transported to the lake from other lakes. For example, native macrophytes in lakes of the Pacific Northwest region of the United States include cattails, yellow water lilies, and pondweed. Exotic or non-native plants in Pacific Northwest lakes include purple loosestrife, white water lilies, and Eurasian watermilfoil. Some non-native plants are invasive, crowding out native plants and not providing useful habitat for fish and wildlife.

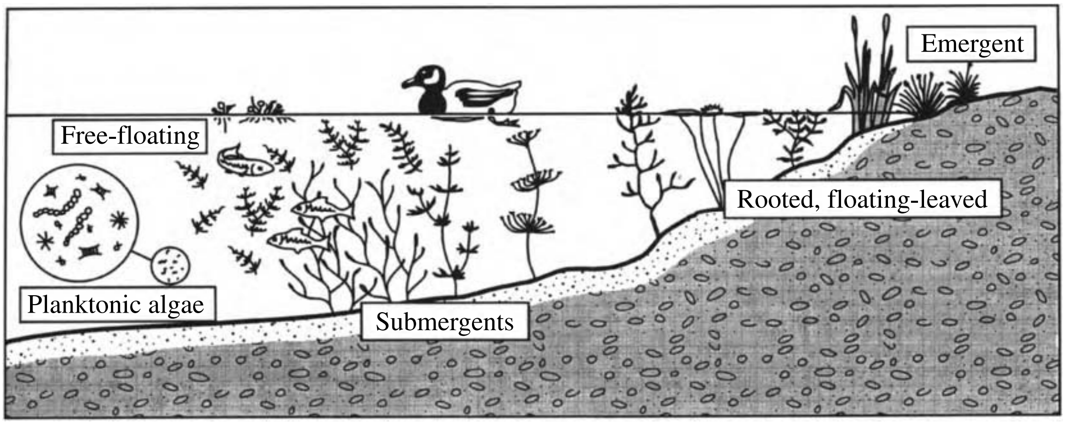

FIGURE 4 Macrophyte community types.

Aquatic plants provide many benefits, including sediment and shoreline stabilization; food source and habitat for benthic invertebrates, fish, and wildlife; oxygenation of the water column; and aesthetics. Most rooted macrophytes obtain their nutrients from lake sediments rather than the water column, and take up phosphorus that would otherwise have been available for algal growth, thus preventing the overgrowth of algae.

However, when there are too many aquatic plants, particularly non-native plants, the advantages turn into disadvantages. When a lake is shallow and nutrient-enriched, then there can be too many macrophytes. Too many aquatic plants can decrease the quality of fish and wildlife habitat, interfere with beneficial uses of a lake such as swimming and boating, and even create safety problems, i.e., swimmers can become entangled in milfoil and other plants. When the plants decay, they deplete the lake waters of oxygen and release nutrients into the water column which can promote algal growth. Too many macrophytes can make a lake look unsightly. The advantages and disadvantages of aquatic plants are opposite sides of the same coin; it's a matter of degree and balance.

Many types of animals are found in lakes. Zooplankton are microscopic animals found in the lake water column. Examples are rotifers and water fleas, e.g., *Daphnia.* They are visible to the naked eye on close inspection of a glass of lake water. Zooplankton are important in the food web of a lake because they eat algae and, in turn, are eaten by planktivorous fish. The types and number of zooplankton present are also indicative of lake water quality. Generally, large grazing species improve water quality by eating algae. On the other hand, a general decrease in the size of zooplankton species, with their reduced capacity to graze the phytoplankton, is a response to the greater availability of bacterial detritus resulting from the relatively ungrazed algae (Welch, 1992). Therefore, the presence of larger zooplankton in a lake usually indicates good water quality, while the presence of smaller zooplankton generally indicates more nutrient-rich waters.

Benthic infauna are small invertebrate animals such as molluscs, worms, and midges that live in the bottom sediments of lakes. They feed on detritus in the sediments and recycle nutrients to the water. The species of benthic animals found in a given area are usually indicative of the surrounding water quality. Some invertebrates, such as mayflies, are intolerant of low dissolved oxygen conditions; their presence in large numbers in lake ecosystems indicates good water quality. Other invertebrates, such as oligochaetes and chironomids, are more tolerant of low dissolved oxygen conditions; their presence in large numbers in a lake may indicate the presence of pollutants or degraded water quality.

The greatest density and diversity of benthic invertebrates is usually found in the littoral zone of a lake, where ample vegetation and oxygen are present. The benthic communities, in turn, provide food for larger invertebrates, fish, amphibians, and birds.

The types of fish found in a lake are influenced by water temperature and dissolved oxygen levels. Fish such as perch, bass, and smelt are warmwater fish and thrive in lakes where the summer water temperature exceeds 65°F. The dissolved oxygen level needs to be at least five parts per million (ppm) in order for the fish to remain healthy. Coldwater fish such as salmon and trout are found in lakes where the summer water temperature is less than 65°F. The dissolved oxygen level needs to be at least seven ppm for these fish. If the summer water temperature is too high, the dissolved oxygen level is often too low to support healthy fish populations.

Each organism in a lake is dependent on other organisms for its food. Each lake has a natural food chain. Algae are eaten by zooplankton. In some lakes, the efficient grazing of zooplankton by algae can help to maintain water clarity. Zooplankton are eaten by planktivorous fish such as longfin smelt and perch. Planktivorous fish are eaten by larger, piscivorous fish such as northern squawfish and largemouth bass. The larger fish are eaten by birds and by mammals, including humans. Figure 5 illustrates the aquatic food chain found in many lakes.

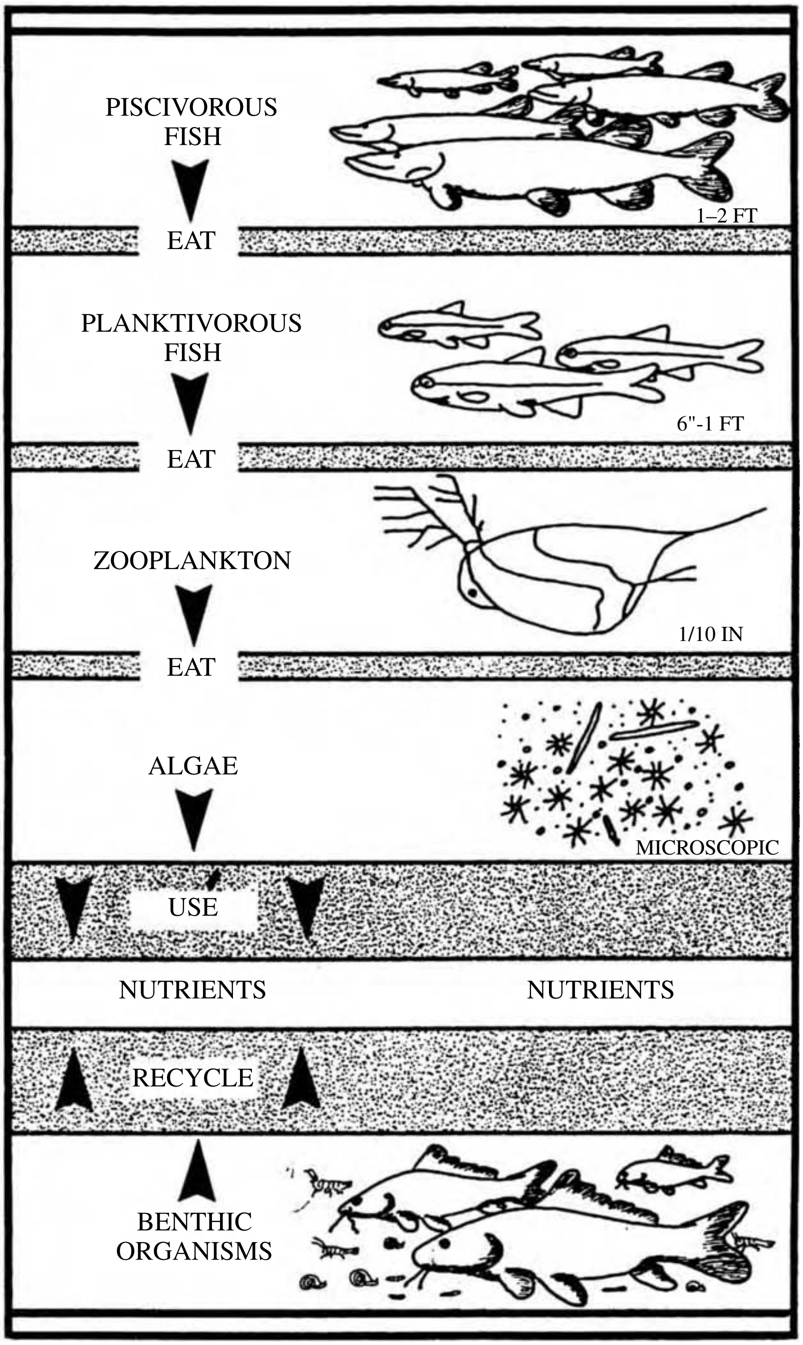

FIGURE 5 Aquatic food chain (U.S. EPA, 1990).

The food chain concept involves the flow of energy among the lake organisms and the recycling of nutrients. Each trophic level (food chain level) transfers only 10 to 20 percent of the energy received up the chain to the next trophic level (Kozlovsky, 1968; Gulland, 1970). This means that a few large piscivorous fish depend on a large supply of smaller planktivorous fish which depend on a very large supply of zooplankton which depend on a successively much larger base of photosynthetic production by phytoplankton and other aquatic plants. By constantly producing wastes and eventually dying, all of these organisms provide nourishment to detritus-eating organisms in the sediments, which obtain their energy by decomposing organic matter. Organic matter decomposition results in the recycling of nutrients that are required for further plant production (U.S. EPA, 1990).

When one level of the food chain of a lake is altered, it affects all other levels, sometimes positively and sometimes adversely. For example, in Lake Washington, *Daphnia* populations increased in the 1970s.Why? The longfin smelt population increased in the 1960s when flood control activities in the main inlet stopped and spawning beds were no longer damaged. Longfin smelt feed on a large crustacean called *Neomysis* which feeds on *Daphnia.* Predation on *Daphnia* was thereby reduced. This had a positive effect on Lake Washington because *Daphnia* grazed on the algae, resulting in improved water clarity in the lake.

Another example of food chain manipulation is stocking a lake with piscivorous fish. When the fish are removed by anglers, there will be more planktivorous fish which will result in a decreased zooplankton population. Fewer zooplankton will mean more algae in the lake, which could have adverse effects on water clarity in the lake. In sum, altering one part of a lake's ecosystem has repercussions throughout the ecosystem.

TROPHIC STATUS/EUTROPHICATION

Lakes are characterized according to their level of biological productivity, or trophic status. The trophic status of a lake depends on the concentration of chlorophyll *a* (the pigment found in green plants that traps energy from the sun to enable the plants to produce their own food by the process of photosynthesis), frequency of algal blooms, the concentrations of nutrients, particularly phosphorus, and water clarity (transparency). The phosphorus concentration determines how many algae and other plants will grow in the lake. The clarity of the water is influenced by a variety of factors including algae, turbidity from sediments or other suspended particles, and the natural color of the water in the lake. Water clarity is measured with the use of a Secchi disk, a 20-centimeter plastic or metal disk that is divided into alternating black and white quadrants. The disk is lowered into the water until the observer can no longer see it. The distance between the lake surface and the point at which the disk disappears from view is called the "Secchi transparency" or "Secchi depth" of the lake.

Three trophic classifications are commonly used for lakes. An oligotrophic lake is one in which there is clear water, low levels of chlorophyll *a* and nutrients, and hence little aquatic life. Oligotrophic lakes tend to be found in alpine and other wilderness areas. The lakes are beautiful to look at and are fine swimming and boating lakes, but are not good fishing lakes unless they are stocked with fish. There are few naturally occurring fish in oligotrophic lakes because there are few plants or insects for fish to eat.

At the other end of the scale are eutrophic lakes. A eutrophic lake has murky water, high levels of chlorophyll *a* and nutrients, and is full of aquatic life. Many lakes in urban and suburban areas are eutrophic, as evidenced by algal blooms. A mesotrophic lake is in between, i.e., is moderately transparent, with moderate levels of chlorophyll *a* and nutrients, and some aquatic life.

Transparency, chlorophyll *a* and total phosphorus (both organic and inorganic forms of phosphorus) are most frequently used to assign trophic status to lakes. The general relationship between these lake water quality parameters and trophic status index (TSI) is summarized in Table 2.

A lake's natural level of productivity is determined by a combination of factors, including the geology and size of the watershed, depth of the lake, climate, and water sources entering and leaving the lake. Some lakes are naturally eutrophic based on their inherent physical attributes and watershed characteristics.

Increases in a lake's natural productivity over time, a process called eutrophication, occurs naturally in some lakes, and may be accelerated in others by human activities. For many small lakes, natural eutrophication typically occurs over hundreds or thousands of years, and is hence not observable in a single lifetime. What is observable in a single lifetime is the human-induced, or cultural eutrophication of lakes. Our land-based activities, including home-building, agriculture, forestry, resource extraction, landscaping, gardening, and animal husbandry, all contribute nutrients and sediments to surface waters, which in turn contribute to increasing a lake's biological productivity. Land erosion and forest clearcutting contribute sediments to lakes. Surface water runoff from impervious surfaces such as construction sites, parking lots, and pavement contributes nutrients and pollutants to lakes. Agricultural practices such as horses grazing near lakes, cows wandering in streams, and extensive pesticide use contribute nutrients and toxic pollutants to lakes. If oil or other toxic chemicals are poured down storm drains, these end up in the nearby lake, stream, or bay. Gardening chemicals such as fertilizers and household toxic chemicals can end up in storm

TABLE 2

Trophic status and associated values (Carlson, 1977; Cooke *et al.*, 1993b; Porecella *et al.*, 1980)

Trophic Status	Transparency (meters)	Chl. a (μg/L)	Total Phosphorus (μg/L)	TSI (average)
Oligotrophic	>4	<3	<4	<40
Mesotrophic	2–4	3–9	14–25	40–50
Eutrophic	<2	>9	>25	>50

μg/L = micrograms per liter (parts per billion).

drains and thus in lakes. Failing septic systems can discharge nutrients from raw sewage to lakes.

The result of all these inputs of phosphorus, nitrogen, sediment, and organic matter in large algal blooms which are unsightly and can severely restrict lake beneficial uses including swimming, fishing, boating, and aesthetic appreciation. Beneficial uses of a lake may also be degraded by other water quality problems related to eutrophic conditions, including low dissolved oxygen levels, fish kills, algal toxicity, and excessive aquatic macrophyte growth.

The level of dissolved oxygen in lakes is one determinant of the habitat available to aquatic organisms. Oxygen is added to a lake from exposure to the air, and by the contribution or aquatic plants through photosynthesis. Oxygen is removed from a lake by the respiration of aquatic organisms and plants, and the bacterial decomposition of organic matter in the water and sediments. Eutrophic lakes with large algal blooms are characterized by high phosphorus concentrations and low dissolved oxygen concentrations in the lake hypolimnion in the summer. This happens because decaying algae and other plants fall to the bottom of the lake where they contribute phosphorus and remove oxygen. Photosynthesis does not take place in the hypolimnion of a eutrophic lake because light does not penetrate to that depth; hence, the oxygen that is being depleted is not replaced. Anoxic (lack of oxygen) conditions at the water—sediment interface on the lake bottom usually increase the potential for nutrient release by converting iron phosphate in the sediments from a water-insoluble to a water-soluble form.

The very low dissolved oxygen levels in the hypolimnion of eutrophic lakes during the summer months may be too low to support coldwater fish such as salmon and trout. The salmon and trout would then move to the lake epilimnion, but the water temperatures may be too high for them in the surface waters. Eutrophic conditions in lakes often lead to decreased quantity and quality of fish habitat and stressed fish populations.

RESTORING BALANCE TO LAKE ECOSYSTEMS

Management of Eutrophic Lakes

When a lake is eutrophic with unsightly algal blooms, water quality problems, and impaired beneficial uses, its ecosystem is out of balance. Lake restoration involves reducing the impact of human activities on lake water quality, with the goal of decreasing biological productivity and improving water quality and associated beneficial uses of the lake. Several methods are available to accomplish this goal. Each method has its advantages and drawbacks.

In order to determine the most effective method(s) to use in a given lake, it is first necessary to be knowledgeable about the physical, chemical, and biological components of the lake's ecosystem. This can be accomplished through one or two years of monitoring parameters such as transparency, lake temperature, acidity, alkalinity, dissolved oxygen, lake level, amount of precipitation, nutrient levels, chlorophyll *a,* fecal coliform bacteria (a group of bacteria associated with human, other mammal, and bird wastes), algae, zooplankton, benthic infauna, an fish. Once monitoring data are obtained, they need to be summarized and pollution sources prioritized for control.

Most lake water quality problems are associated with an overabundance of nutrients, which results in excessive plant growth. In managing such water quality problems, it is important to assess what nutrient limits plant growth. In eutrophic lakes, phosphorus is often the limiting nutrient; this means that the amount of phosphorus in the lake will determine the amount of plant growth. Therefore, most lake management strategies focus on reducing phosphorus loading.

If the lake's phosphorus budget shows that most of the phosphorus is coming from within the lake, in-lake restoration techniques should help to reduce phosphorus levels and make the lake less eutrophic. On the other hand, if most of the phosphorus is coming from the watershed (this is often true of small lakes with very large watersheds), then the focus should be on watershed best management practices (BMPs) to control sources of nutrients. In some lakes, phosphorus comes from within the lake and the watershed, so both types of actions are needed.

Watershed Best Management Practices Implementation of watershed best management practices (BMPs) improves water quality by reducing the quantity of pollutants entering the lake. Most pollutants within a watershed result from human activities. Pollutants originating on each parcel of land within a watershed can collectively become a serious threat to the receiving water quality. BMPs are structural and nonstructural methods, including common sense "housekeeping measures," used to prevent or reduce pollution by controlling erosion, surface water runoff, sources of nutrients, and sources of toxic chemicals. Watershed BMPs can be basin-wide or can target management of developed property. These measures can include native plant revegetation of lake shorelines, retention/detention ponds and biofiltration swales for stormwater treatment, and homeowner/business owner BMPs to enhance water quality through better landscaping methods, alternative household and gardening practices, better animal-keeping practices, drainage controls, and septic system maintenance and repairs. Local and state agencies can work in partnership with lake associations and other citizen groups in a watershed to educate residents and business owners about BMPs that are inexpensive, easy to implement, and make a difference in protecting lake water quality and aquatic biota. Ideally, this environmental education should include hands-on water quality activities (e.g., storm drain stenciling, lakeshore revegetation) and habitat monitoring activities for community volunteers including schoolchildren because these activities impart a sense of lake stewardship to people who live on or upstream of a lake. Following is a discussion of each type of BMP.

Many lakes have no native plants growing on the shoreline; houses may have manicured lawns leading to the water's edge. Where shoreline vegetation is absent, surface water runoff enters the lake directly, degrading lake water quality.

Ducks and geese may also graze on the shoreline and affect lake water quality via the nutrients and fecal coliform bacteria in their wastes. Native plantings along lake shorelines and streambanks of creeks that are tributary to lakes serve multiple functions: improving wildlife habitat; acting as a physical barrier to intrusion by ducks and geese; increasing shoreline soil stability thereby preventing erosion; and moderating impacts of surface water runoff by filtering out suspended solids, nutrients, and toxic chemicals.

Alternatives to standard lawn maintenance and landscaping practices include minimal use of fertilizers, reduction in lawn size, regular thatching and aeration, incorporation of native plants in new landscaping, soil enhancement through mulching and composting rather than chemical fertilizers, and integrated pest management techniques rather than chemical pesticides.

Household hazardous wastes should be properly disposed of at collection sites and never in storm drains. Homeowners should be educated about non-toxic alternatives to common household cleaning products.

When cars are washed near storm drains, wash water carries oils, greases, nutrients, heavy metals, suspended solids, and soaps to local water bodies including lakes and their tributaries. Residents of a lake watershed should be encouraged to wash their cars at commercial car wash facilities, which discharge wash water to the sanitary sewer system. People who do wash their cars at home should be informed about draining wash water to vegetated areas such as lawns, using a high pressure nozzle with trigger to minimize water usage, and using commercial products that clean vehicles without water.

The feeding of waterfowl by lakeside residents should be discouraged. Pet and domestic animal waste should be properly disposed of away from a lake and surface water pathways that reach a lake.

Business owners should be educated about BMPs, such as proper storage of toxic chemicals and proper maintenance and repair of oil-water separators in order to prevent the discharge of petroleum hydrocarbons, metals, and other toxics to lakes and their tributaries. Many local and state agencies provide technical assistance to businesses in preventing or reducing the discharge of pollutants to lakes and streams.

State and local agencies such as conservation districts should also educate agricultural landowners about agricultural BMPs to improve pastures, maintain healthy livestock, dispose of or recycle livestock water, restrict livestock access to lakes and their tributaries (e.g., building fences around streams which are inlets to lakes), and prevent discharge of pollutants from livestock waste and farm operations to lakes and tributaries. Cost-sharing incentives and technical assistance increase the success rate of these measures.

Maintaining on-site wastewater treatment systems (septic systems) in good working order is another way to reduce phosphorus loading to a lake. Lakeside and watershed residents and business owners should know about septic system operation and maintenance practices, such as using no- or low-phosphate detergents, composting organic wastes rather than using garbage disposals, selecting and maintaining optimal vegetative cover over drainfields, and inspecting and cleaning the system on a regular basis to ensure proper system functioning. This can be accomplished through articles in lake association newsletters, through brochures, and through workshops conducted by local and state agencies.

In-Lake Restoration Techniques In-lake restoration techniques that can be used to control internal phosphorus loading are phosphorus inactivation and precipitation (e.g., aluminum sulfate treatment), removing sediments from the lake bottom (dredging), hypolimnetic aeration, hypolimnetic withdrawal, dilution, and artificial circulation. Following is a discussion of the principles, advantages and disadvantages of each technique.

Adding aluminum sulfate (alum) to a lake reduces the lake's phosphorus content by precipitating phosphorus and retarding its release from the sediments (Cooke *et al.*, 1993a). When alum is added to the water column, a polymer forms that binds phosphorus and organic matter. The aluminum phosphate-hydroxide compound (commonly called alum floc) is insoluble and settles to the lake bottom. Dramatic increases in water clarity typically occur immediately following an alum treatment, as suspended and colloidal particles are removed from the water column by the floc.

Alum has been used extensively in the United States, with general success in controlling phosphorus release from lake sediments for several years (Cooke *et al.*, 1993a; Garrison and Knauer, 1984). If external sources of phosphorus are not controlled, the effectiveness of alum will decrease with time as the alum layer on the sediments becomes covered by nutrient-rich silt and organic material. The lake may therefore need to be treated again. Regular long-term monitoring is required in an alum-treated lake to evaluate the effectiveness of the treatment.

The alum dose should be based on the pH and alkalinity of the lake, and the potential toxicity of aluminum to the lake (Cooke *et al.*, 1986, 1993a; Kennedy and Cooke, 1982). As alum is added to a lake, pH and alkalinity decrease and dissolved aluminum concentrations increase; alkaline lakes can tolerate higher alum doses than can softwater lakes. Adding alum to a lake with low to moderate alkalinity requires careful planning to ensure that pH and alkalinity are not lowered to levels that would stress aquatic biota. The use of sodium aluminate as a buffer permits a greater alum dose to be used. Such buffering agents have been applied with alum in several northeastern lakes and high success in maintaining normal lake pH and alkalinity levels (Cobbossee Watershed District, 1988; Dominie, 1978). The use of sodium carbonate in the alum treatment of Long Lake in western Washington was also highly successful in maintaining safe pH and alkalinity levels, as well as in improving lake water quality (KCM, 1994).

Alum is a promising technique for reducing algae through physical settling and removal during the application and through the long-term control of internal nutrient loading. The treatment does not kill the algae instantaneously in the water column, but settles them on the lake bottom, where they die over a period of up to two weeks. This longer time period and the location at the lake bottom greatly reduce the hazard from toxins that might be released by the dying algal cells. Alum can provide long-term reduction in the occurrence of algal toxicity if internal phosphorus loading is reduced. Alum has also been found to reduce the sediment-to-water migration of blue-green algae in Green Lake in Seattle (KCM, 1994).

The use of alum salts may cause toxic conditions. Alum causes zooplankton to flocculate and settle out of the water column, along with sediment and phytoplankton, which can stress the food chain of a lake. To date, alum treatments have not resulted in adverse effects on fish and have not damaged invertebrate populations in well-buffered lakes (Cooke *et al.*, 1993a; Narf, 1990). Invertebrate populations may, however, be more sensitive to alum application in softwater lakes. For example, the alum/sodium aluminate treatment of Lake Morey in Vermont (alkalinity = 30 to 50 milligrams of calcium carbonate per liter) resulted in a short-term decrease in density and species diversity of benthic invertebrates (Smelzer, 1990).

Although most case studies of alum treatments demonstrate multiple-year success, failures have also occurred. These have been attributed to insufficient dose, lake mixing, inadequate reduction in external nutrient inputs, and a high coverage of macrophytes.

Other nutrient inactivation techniques have been used with less success than alum. Calcium hydroxide (lime) has recently been used in hardwater Alberta, Canada lakes to control nutrient supply and algal growth (Murphy *et al.*, 1990; Kenefick *et al.*, 1992). However, lime would not offer the same phosphorus-binding benefit in softwater lakes (Cooke *et al.*, 1993a).

The release of nutrients from lake sediments can also be controlled by removing the layer of the most highly enriched materials. This may result in significantly lower in-lake nutrient concentrations and less algal production. Several types of dredging equipment can be used to remove sediments from lakes; a hydraulic dredge equipped with a cutterhead is the most common choice. The cutter loosens sediments that are then transported as a slurry of 80 to 90 percent water through a pipeline that traverses the lake from the dredging site to a remote disposal area. In the United States, a permit from the U.S. Army Corps of Engineers is normally required before sediments can be dredged from a lake (Cooke *et al.*, 1993b; U.S. EPA, 1990).

Sediment removal to retard nutrient release can be highly effective. For example, in Lake Trummen (Sweden), the upper, nutrient-rich layer of sediments was removed, increasing the lake depth from 3.6 feet to 5.8 feet. The sediment was disposed of in diked-off bays and upland ponds. Return flow from the ponds was treated with alum to remove phosphorus. The total phosphorus concentration in the lake dropped sharply (U.S. EPA, 1990).

However, sediment removal has high potential for serious negative impacts on the treated lake and its surrounding watershed. The disposal area must be sufficiently large to handle the high volume of turbid, nutrient-rich water that accompanies the sediments. Unless the sediment-water slurry can be retained long enough for settling to occur. The turbid, nutrient-rich runoff water will enter the lake outlet and end up in a tributary stream or another lake downstream of the treated lake. Turbidity, algal blooms, and dissolved oxygen depletion may result in the receiving waters (Cooke *et al.*, 1993b; U.S. EPA, 1990).

Prior to dredging, the lake sediments must be analyzed for heavy metals (especially copper and arsenic, which have been extensively used as herbicides), chlorinated hydrocarbons (which have been used in pesticides), and other potentially toxic chemicals. Special precautions will be required if these substances are present in high concentrations (Cooke *et al.*, 1993b; U.S. EPA, 1990).

Another technique for preventing the release of phosphorus from lake sediments to the water column is hypolimnetic aeration. This technique involves oxygenating the bottom waters of a lake without causing destratification. Air is used to raise cold hyplimnetic water in a tube to the surface of deep lakes, where the water is aerated through contact with the atmosphere, loses gases such as carbon dioxide and methane, and is then returned to the hypolimnion. Phosphorus release from the sediments is limited by hypolimnetic aeration if there is sufficient iron in solution to bind phosphorus in the re-oxygenated waters. Aeration oxidizes the soluble ferrous phosphate to insoluble ferric phosphate, which would then precipitate out into the sediments and remain there. In addition, hypolimnetic aeration increases habitat and food supply for coldwater fish species. The technique has been used with varying levels of success. Unsuccessful treatments have been attributed to inadequate oxygen supplies, disruption of lake stratification, or lack of sufficient iron (Cooke *et al.*, 1993b; KCM, 1994; U.S. EPA, 1990).

It is important that hypolimnetic aeration not destratify the water column. Premature destratification (e.g., before fall turnover of the lake) can be stressful and become toxic to aquatic life when bottom waters with little dissolved oxygen, low pH, and high concentrations of toxic gases mix with surface waters. Destratification can also stimulate algal growth by supplying hypolimnetic nutrients to surface waters and mixing algae throughout the water column. In shallow lakes, destratification could occur due to wind mixing (KCM, 1994).

An alternative to aerating the hypolimnion is to remove this nutrient-rich, anoxic water layer either through a deep outlet in a dam or by a siphon, thereby accelerating a lake's phosphorus loss and perhaps producing a decrease in phosphorus concentration in surface waters. There are few documented case histories of hypolimnetic withdrawal (Cooke *et al.*, 1993b; Nurnberg, 1987; U.S. EPA, 1990).

There are major disadvantages to hypolimnetic withdrawal. The hypolimnion water that is discharged may be of poor quality and therefore may require aeration or other treatment. Federal, state or local regulatory agencies may require a permit to discharge this water. Hypolimnetic withdrawal could destratify the water column, thereby introducing nutrient-rich, oxygen-poor water to the surface of the lake and triggering on algal bloom (Cooke *et al.*, 1993b; Nurnberg, 1987; U.S. EPA, 1990).

Another approach to reducing the phosphorus concentration in eutrophic lakes is to dilute the lake water with sufficient quantities of another water source that is low in phosphorus; algal cells will be flushed out of the lake at the same time. When water low in phosphorus is added to the inflow, the actual phosphorus loading will increase, but the mean phosphorus concentration will decrease, depending upon initial flushing rate and inflow concentration. Concentration will also be affected by the degree to which loss of phosphorus to sediments decreases and counters the dilution. Lakes with low initial flushing rates are poor candidates for this technique because in-lake concentration could increase unless the dilution water is essentially devoid of phosphorus. Internal phosphorus release could further complicate the effort (Cooke *et al.*, 1993b; U.S. EPA, 1990).

Flushing can control algal biomass by cell washout; however, the flushing rate must be near the cell growth rate to be effective. Flushing rates of 10 to 15 percent of the lake volume per day are believed to be sufficient (U.S. EPA, 1990).

There are very few documented case histories of dilution of flushing because additional water is seldom available, especially water that is low in nutrients. One successful example is Moses Lake in eastern Washington. Low-nutrient Columbia River water was diverted through the lake. Daily water exchange rates of 10 to 20 percent were achieved in this eutrophic lake. Lake transparency dramatically increased and algal blooms dramatically decreased (Welch and Patmont, 1980).

For dilution and flushing to be successful, lake outlet structures must be capable of handling the added discharge. The increased volume of water released downstream could have negative effects. Water used for dilution or flushing must be tested to ensure that no toxics are present before the water is introduced into the eutorphic lake.

Another in-lake restoration technique is artificial circulation. This eliminates or prevents thermal stratification, through the injection of compressed air into lake water from a pipe or ceramic diffuser at the lake's bottom. The artificial circulation structure must be designed properly to ensure an air flow of about 1/3 cubic foot per minute per acre of lake surface; this is required to maintain oxygen within the lake. Algal blooms may be controlled through one or more of the following processes. First mixing of algae to the lake's bottom will decrease their time in full light, leading to reduced net photosynthesis. Introduction of dissolved oxygen to the bottom of a lake may inhibit phosphorus release from the sediments (i.e., have the same impact as hypolimnetic aeration), hence curtailing internal phosphorus loading. A third possible process is that rapid circulation and contact of lake water with the air, as well as the introduction of carbon dioxide-rich bottom water during the initial period of mixing, can increase the water's carbon dioxide content and lower the pH, leading to a shift from blue-green algae to less noxious green algae. Finally, when zooplankton are mixed to the lake's bottom, they are less vulnerable to planktivorous fish. If more of the zooplankton survive, then they may eat more algae (Cooke *et al.*, 1993b; U.S. EPA, 1990).

Results of artificial circulation have been highly variable. In about half the lakes where this technique has been attempted and where temperature differences are small between surface and bottom waters during the summer, algal blooms have been reduced. In other cases, phosphorus and turbidity have increased and water transparency has decreased (U.S. EPA, 1990).

Management of Aquatic Macrophytes

The watershed BMPs outlined above for reducing the quantity of algae in a lake are also effective in reducing the quantity of aquatic macrophytes in a lake. Watershed BMPs involve voluntary changes in behavior and are easy and inexpensive to implement. Any reduction in nutrient loading to a lake as a result of BMPs can maintain or extend the effectiveness of in-lake methods for managing aquatic macrophytes. The disadvantage of watershed BMPs is that they will not result in immediate, substantial reduction in nuisance aquatic plant growth because habitat has already been created in the lake that supports aquatic plant growth. Therefore, watershed BMPs usually must be combined with other methods to reduce aquatic plant growth.

There are physical, chemical, and biological methods for reducing aquatic plant growth in lakes and restoring balance to the lake ecosystem so that the aquatic plants are beneficial rather than harmful. Following is a description of examples, principles, advantages, and disadvantages of each method, summarized from *Aquatic Plant Control* (Washington State Department of Ecology, 1994), *A Citizens' Manual for Developing Integrated Aquatic Vegetation Management Plans* (Gibbons, Gibbons, and Systma, 1994), and *Crary WeedRoller Pilot Project Report* (Cooke, 1996).

Physical Methods Physical methods of reducing the amount of aquatic plants in a lake include hand-pulling, hand and mechanical cutting, mechanical harvesting, bottom barriers (sediment covers), water level drawdown, water column dyes, rotovating, diver-operated suction dredging, and weed rolling.

Hand-pulling aquatic plants is similar to pulling weeds out of a garden. This method involves digging out the entire plant with a spade or long knife and disposing of the residue onshore. In waters deeper than three feet, hand removal can best be accomplished by snorkelers or scuba divers carrying collection bags for plant disposal. The technique results in immediate clearing of the water column of nuisance plants and is most appropriate for small-area, low-plant density treatment, e.g., clearing pondweed from areas around docks and beaches.

Hand and mechanical cutting differ from hand-pulling in that plants are cut below the water surface (roots are usually not removed) with scythes, rakes or other specialized devices that can be pulled through the weed beds by boat or people. Rakes can be equipped with floats to allow easier plant and fragment collection. Mechanical cutters can be battery-operated and hand-held, portable and mounted on boats, or specialized underwater cutters using a sickle to cut weeds in water as shallow as ten inches and as deep as five feet. Cutting results in immediate removal of nuisance submerged plants.

Hand-pulling, hand-cutting, and mechanical cutting are inexpensive, easy to implement around docks and swimming areas, environmentally safe, and allow removal of undesirable aquatic plants while leaving desirable plants. On the other hand, these methods are labor-intensive, time-consuming, and may need to be repeated several times each summer. It may be difficult for the laborer to see and dig out all plant roots. Some plants, such as water lilies, are difficult to cut or pull. Visibility may become obscured by turbidity generated by cutting activities. All plant fragments must be removed from the lake to prevent them from rerooting or drifting onshore. This is particularly important in the case of invasive, non-native plants such as Eurasian watermilfoil. Environmental impacts of hand-pulling and cutting include short-term, localized increases in water turbidity and some disruption of benthic infauna.

Mechanical harvesting is a short-term technique to temporarily remove plants that interfere with recreational uses or aesthetic enjoyment of a lake. Mechanical harvesters are large machines which cut plants below the water surface and collect the plants and plant fragments for disposal. Harvested plants are removed from the water by a conveyor belt system and stored on the harvester until disposal. A barge stationed near the harvesting site for temporary plant storage in an efficient disposal method. Alternatively, the harvester can carry cut weeds to shore for disposal in landfills or for use as compost. Harvesting is usually performed in late spring, summer, and early fall when submersed and floating-leafed plants have reached or are close to the surface of the lake. Harvesters can cut and collect several acres per day depending on plant type, plant density, and the storage capacity of the equipment. Depending on the equipment used, the plants are cut from 5 to 10 feet below the water's surface in a swatch that is 6 to 20 feet wide. Harvesting is most appropriately used for large, open areas with few surface obstructions.

Like mechanical cutting, harvesting results in immediate open areas of water and can be targeted to specific locations. The lake can continue to be used for recreational purposes while harvesting is underway. Another advantage of mechanical harvesting is that removing plants from the water also eliminates a possible source of nutrients often released during fill dieback and decay. Furthermore, harvesting can reduce sediment accumulation by removing organic matter that normally decays and adds to the bottom sediments. Harvested vegetation can often be easily composted and used to enrich soil.

Mechanical harvesters share the previously mentioned disadvantages of creating plant fragments and requiring repeated application. Several disadvantages are unique to mechanical harvesting. Off-loading sites and disposal areas for cut plants must be available. On heavily developed shorelines, suitable off-loading sites may be few and require long trips by the harvester. Some large harvesters are not easily maneuverable in shallow water or around docks or other obstructions. Furthermore, harvesting can be detrimental to non-target plants, insects, and small fish; these are often removed from the lake along with target plants.

The use of bottom barriers (sediment covers) is an effective physical method of plant control. Barrier material is placed like a blanket over the lake bottom to prevent plants from growing. Applications of bottom barriers can be made up to any depth, with divers often utilized for deeper water placement. Readily available materials such as burlap, plastics, synthetic rubber, polypropylene, perforated black mylar, fiberglass screens, woven polyester, and nylon film can all be used as bottom barriers. There are also commercial bottom barriers which are specifically designed for aquatic plant control. These include Texel, a heavy, felt-like polyester material, and Aquascreen, a polyvinylchloride-coated fiberglass mesh which resembles a window screen.

The ideal bottom barrier should be durable, reduce or block light, prevent plants from growing into and under the fabric, be easy to install and maintain, and should readily allow gases produced by rotting weeds to escape without "ballooning" the fabric upwards. Even the most porous materials, such as window screen, will billow due to gas buildup. Therefore, it is very important to anchor the bottom barrier securely to the bottom of the lake. Unsecured barriers can create safety hazards for swimmers and boaters.

The duration of plant control depends on the type of material used, application techniques, sediment composition (bottom barriers are difficult to place on deep muck sediments), the rate that plants can grow through or on top of the bottom barrier, and the rate that new sediment is deposited on the barrier. Installation of bottom barriers is easiest in winter or early spring when plants have died back. In summer, plants should be hand-pulled or cut first in order to facilitate bottom barrier installation. Bottom barriers may also be attached to frames rather than placed directly onto the sediment. The frames may then be moved for control of a larger area.

Bottom barriers can provide immediate removal of nuisance plant conditions upon placement. It is easy to install bottom barriers in small, confined areas such as around docks, moorages or beaches. Other advantages of bottom barriers are that they are hidden from view, do not interfere with shoreline use, and do not result in significant production of plant fragments.

Disadvantages of bottom barriers include high cost of some materials, suitability only for localized plant control, possible regrowth of plants from above or below the barrier, and the need for regular inspection and maintenance to remove accumulations of sediment and any rooting plant fragments. Bottom barriers can also cause localized decreases in the populations of benthic infauna such as aquatic insects.

A fifth type of physical plant control is water level drawdown. This involves exposing plants and root systems to prolonged freezing and drying or hot, dry conditions to kill the plants. Drawdown is usually performed during the winter and is more common in management of aquatic macrophytes in reservoirs and ponds than in natural lakes. Accurate identification of target plant species is important because aquatic plants vary greatly in terms of susceptibility to drawdown.

In addition to controlling aquatic plant biomass, drawing down the water level makes it possible to use several other lake restoration or improvement procedures. For example, water level drawdown can be used for fish management to repair structures such as docks or dams, to facilitate localized dredging or bottom barrier placement, or to remove stumps or debris. This technique can result in compaction of certain types of sediments, such as mucky substrates and thus improve shoreline use. Drawdown can reduce nearshore vegetation, thereby reducing potential inputs of nutrients to the water from seasonal dieback of aquatic plants. Drawdown can also be used to attract waterfowl by enhancing growth of emergent plants such as cattails and bulrushes.

A disadvantage of water level drawdown is that it is not species-selective; hence beneficial plants may be removed along with nuisance plants. Wetlands adjacent to the lake can be exposed with adverse impacts on their plant and associated animal communities. Prolonged freezing and drying can kill benthic infauna that are important food sources for planktivorous fish. Lowering the water level in a lake may result in decreased levels of dissolved oxygen, with resulting negative impacts on fish and other aquatic biota. During the period of drawdown, recreational use of the lake may be limited or unavailable.

A sixth physical plant-control method is the application of dark-colored dyes to reduce the amount of light reaching the submersed plants, thereby shading the plants from the sunlight needed for photosynthesis. Several commercial dye products are available; they impart a blue color to the water. Best results are obtained when the dye is used early in the growing season.

Advantages of using water column dyes for aquatic plant control are that no special equipment is needed for application (the dye can be poured into the water by hand from shoreline or boat) and the dyes are non-toxic to aquatic organisms, livestock, and humans. However, there are several drawbacks. Water column dyes can be used only in shallow water bodies with no outlet and are less effective when aquatic plant growth is within two feet of the lake surface. Repeat dye treatments may be necessary throughout the plant-growing season. Water column dyes should not be applied to lakes used for drinking water.

Another method for reducing aquatic plant biomass in a lake is rotovation (bottom derooting or underwater bottom tillage). Rotovators use underwater rototiller-like blades to uproot aquatic plants. The rotating blades turn seven to nine inches deep into the lake bottom to dislodge plant roots. Plants and roots may then be removed from the water using a weed rake attachment to the rototiller head, a harvester or manual collection. This technique is most suitable for use in larger lakes because of the larger size and high costs of the equipment.

Rotovation can be used year-round but is most effective in the winter and early spring when plants have died back. Depending on plant density and sediment type, two to three acres per day can be rotovated. Rotovation is particularly effective in controlling Eurasian watermilfoil and can produce a high level of milfoil control for two to three growing seasons.

Advantages of rotovation are that it can remove the entire plant, can decrease density of undesirable plants, and may stimulate the growth of some desirable native plants. Rotovated areas in the state of Washington and the province of British Columbia have shown increases in species diversity of native plants, with resulting benefits to fisheries. Fish are not removed through rototilling as they are by mechanical harvesters. Since rotovating takes place during winter and early spring, there is no interference with peak summertime lake recreational activities.

On the other hand, rotovation is limited to areas with few bottom obstructions and should not be used where water intakes are located. Bottom sediments are disturbed which can result in short-term impacts on water quality and benthic infauna. Plant nutrients or toxic chemicals in the sediments may be released into the water. Since rotovation is not species-selective, beneficial plants may inadvertently be removed. Rotovation may also interfere with fish spawning or migration. Some rotovators are difficult to maneuver around docks and in shallow water. Plant fragmentation resulting from rotovation may increase the spread of invasive weeds like milfoil.

Another physical method for controlling aquatic plant growth in lakes is diver-operated suction dredging. This method was used in the late 1970s in British Columbia as an improvement to hand removal of sparse colonies of Eurasian watermilfoil. Scuba divers operate portable dredges with suction heads to uproot and remove individual plants from the lake sediment. After the divers physically remove the plants with sharp tools, the plant/sediment slurry is then suctioned up and carried back to a barge through hoses operated by the diver. Plants parts are sieved out on the barge and retained for later off-site disposal. The water-sediment slurry can be discharged back to the water or piped off-site for upland disposal.

Efficiency of plant removal is dependent on sediment condition, density of aquatic plants, and underwater visibility. Diver-operated suction dredging is best used for localized infestations of low plant density where plant fragmentation must be minimized. Therefore, this technique has great potential for milfoil control and can remove 85 to 97 percent of milfoil from a lake.

Advantages of diver-operated suction dredging are that it is species-selective and site-specific. Disruption of sediments and plant fragmentation are both minimized. The method can be used to cover areas larger than practicable for hand pulling or cutting, and can be conducted in tight places or around obstacles that would preclude use of larger machinery.

Drawbacks to this method are that it is labor-intensive and expensive. The usefulness of this method may be reduced in dense plant beds. Returning the water-sediment slurry directly to the lake may result in some loss of plant fragments. If the dredged slurry is disposed of upland, more specialized equipment and materials are required and the process is much more costly. Short-term environmental impacts include localized increases in turbidity and release of nutrients and other contaminants from the sediments. Some sediments, benthic infauna, and non-target plants may also be inadvertently removed during this process.

A new mechanical method of controlling aquatic plant growth is weed rolling. The method uses a commercially available, low-voltage power unit that drives an up-to-25-foot long roller set on the lake bottom through an adjustable arc of up-to 270°. A vertical drive head mounts to a dock. A reversing action built into the drive automatically brings the roller back to complete the cycle. The 25 feet of roller includes flexible couplers to follow the contour of the lake bottom. The device operates on the principle of the "well-worn path." Whole plants or plant stems and leaves can be removed. Fins on the rollers detach some plants from the soil, while the rollers force other plants flat, gradually inhibiting growth. Detached plants and plant fragments need to be removed from the water with a rake or net.

Once plants are cleared from the area, the weed rolling device can be used weekly or less often to prevent regrowth. The device requires little maintenance, lasts for at least five years, and can be moved from dock to dock which allows sharing by a lake association.

A weed rolling device was tested on three lakes in King County, Washington, during the summer of 1995 and was found to be easy to operate and effective in reducing the density of both milfoil and water lilies. Weed rolling has also been effective in removing unwanted aquatic plants from many Midwestern lakes.

Advantages of weed rolling are that it creates and maintains areas of open water adjacent to docks, installation is simple, operating costs are low (similar to the costs of using a 75 watt lightbulb), and the treatment area can be modified by varying the number of roller tube sections used and adjusting the roller tube travel arc.

There are several disadvantages. Although it is easy to operate a weed rolling device, collection of the resulting plant fragments is labor-intensive. If the plant fragments are not collected, invasive plants may be spread from one area of the lake to the other. Weed rolling may disturb some bottom-dwelling animals and may interfere with fish spawning. There are also some safety considerations. People cannot be allowed in the water near where the weed rolling device is operating. After each use, the rollers must be unplugged from the power source, moved, and stored under or alongside a dock.

Chemical Methods Chemical control of aquatic plants in lakes is accomplished through the use of aquatic herbicides. Systemic herbicides are absorbed by and translocated throughout the entire plant, and kill the entire plant. Contact herbicides kill the parts of the plant with which they come in contact, leaving roots alive and capable of regrowth. To be most effective, herbicides must be applied to plants during the period when they are growing most rapidly. Because of environmental risks from improper application, aquatic herbicide use is regulated. Some expertise in using herbicides is necessary in order to be successful and avoid unwanted impacts. Generally, applicators must be licensed by and obtain permits from a local, state or federal agency. A certain percentage of all aquatic plants in each lake must usually remain untreated in order to provide food and habitat for fish and wildlife.

Some aquatic herbicides that are registered with the U.S. Environmental Protection Agency include glyphosate, fluridone, endothall, and copper compounds. Glyphosate (commercial name Rodeo) is a non-selective, broad-spectrum herbicide used to control floating-leafed plants like water lilies and emergent plants like purple loosestrife and cattails. It is generally sprayed or painted in liquid form on plant leaves. Symptoms of herbicidal activity are apparent after seven days and include wilting and yellowing of plants, followed by complete browning and death. Since glyphosate is a systemic herbicide, it is effective in long-term plant control. It dissipates quickly from natural waters, is low in toxicity to benthic infauna, fish, birds, and mammals, and does not prohibit use of a lake for swimming, fishing, and irrigation while treatment of plants is underway. The major drawback of glyphosate is that it can affect non-target plant species. Careful application to prevent drift will minimize this possibility.

Fluridone (commercial name Sonar) is a slow-acting systemic herbicide used to control Eurasian watermilfoil and other submersed plants. Applied to the lake water as either a liquid or pellet, this chemical begins to show effects 7–10 days after application, with full control of target plants often requiring 6–12 weeks. Fluridone acts by damaging plant chlorophyll and preventing photo-synthesis; hence dying plants exhibit retarded growth and bleached out leaves before falling to the lake sediments and decomposing. The best time for fluridone application is early in the growing season for the target plant, usually spring or early summer, because of the amount of time required for full plant control.

As is the case with glyphosate, long-term plant control can be achieved with the use of fluridone. Fluridone has a very low order of toxicity of aquatic animals and humans. Disadvantages of its use are that it is very slow-acting and therefore not effective in flowing water. Fluridone can drift out of the treatment zone, thereby affecting non-target plants. Consequently, it is most suitable for whole-lake treatments, not for treating a defined area within a large, open lake. As the affected plants decay, they may consume dissolved oxygen from and release nutrients to the water column. Furthermore, fluridone-treated water may result in injury to irrigated vegetation. Therefore, use of lake water for irrigation is delayed following treatment. To protect drinking water sources, fluridone should not be applied within 1/4 mile of a lake water intake.

Endothall (commercial name Aquathol) is a fast-acting contact herbicide which is applied in either a granular or liquid form and destroys the plant stems and leaves but does not kill the roots. It is used for short-term control of aquatic plants, i.e., a few weeks to a few months, with no carryover to the next growth season. Advantages of endothall are that plant death occurs in one to two weeks and there is little or no drift impact from proper application of this chemical. On the other hand, non-target plant impacts are possible because many aquatic plants are susceptible to endothall. Following treatment, there is often a period of time when lake waters cannot be used for swimming, fishing, or crop irrigation.

Copper sulfate and chelated copper compounds are generally used to control algal blooms. Copper is an essential element, required in small amounts, for plant growth. High concentrations of this metal can lead to inhibition of photosynthesis and to plant death. The effectiveness of copper chelates is enhanced by warm temperatures and sunlight, conditions that stimulate copper uptake by sensitive plants. The effect of copper treatment can be observed within 10 days, with full effects manifested in four to six weeks. Several treatments may be needed each season. An advantage of using copper compounds for aquatic plant control is that there are no restrictions in lake uses following treatment; copper compounds can even be used in lakes that are drinking water supplies. However, copper compounds must be used with extreme care because copper is persistent in the environment. Yearly application of copper to lakes can result in elevated copper concentrations in sediments, where the copper can then be taken up by benthic infauna and fish. The toxicity of copper to fish is higher in soft than in hard water.

Biological Methods The development and use of biological methods of aquatic plant control is in its infancy. Interest in biological control agents was stimulated by a desire to find more "natural" means of long-term control of nuisance aquatic plants as well as reduce the use of expensive equipment or chemicals. The biological control method that is used in many states is stocking the lake with sterile grass carp (white amur), a vegetarian fish native to large rivers of China and Russia. The fish are sterile because they are triploid, i.e., they have an extra set of chromosomes. Grass carp were first introduced into the United States in 1963 by the state of Arkansas and are now legal in most states. The objective of grass carp use is to end up with a lake that has 20 to 40 percent plant cover, not a lake that is totally devoid of plants.

Grass carp are rapidly growing fish that live for at least 10 years. In general, they reach at least 10 pounds in weight and have been known to reach 40 pounds in the southern U.S. They feed from the top of the plant down and therefore do not stir up lake sediments. They are most appropriately used for lakewide, low-intensity control of submersed plants such as water weed, water celery, and certain pondweeds. Milfoil is less preferred and water lilies and watershield are not eaten at all. Grass carp are dormant during the winter and start intensive feeding when water temperatures reach 68°F.

The appropriate stocking rate is usually determined by the fisheries department of the particular state in which the lake is located and will depend on the amount and type of plants in the lake as well as spring and summer water temperatures. Survival rates of the fish will vary depending on fish disease and presence of predators such as ospreys and otters.

Grass carp are inexpensive compared to some other aquatic plant control methods and offer long-term control. However, there are numerous disadvantages to their use. There is no control over how much the grass carp will eat. Overstocking of grass carp could result in eradication of beneficial as well as nuisance plants or eradication of all plants in the lake. Removing excess fish is difficult and expensive. If native plants are not growing in a lake, other plants such as invasive, non-native plants or algae will move in to fill the void. Furthermore, the grass carp will add nutrients to the lake through their wastes and through the decay of their bodies when they die; this will contribute to the growth of other plants in the lake.

In addition to no control over how much the grass carp will eat, there is no control over where they will graze. The fish may avoid areas of the lake experiencing heavy recreational use (e.g., swimming docks), resulting in less plant removal than desired for those areas. Substantial removal of vegetation by grass carp may not become apparent until three to five years after introduction. Furthermore, all inlets and outlets to the lake must be screened to prevent grass carp from migrating out of the lake into streams, rivers, and other lakes with potential impacts on downstream, non-target plants.

MANAGEMENT OF RADIOACTIVE WASTES

RADIOACTIVE WASTE

Radioactive waste may be defined as solid, liquid, or gaseous material of negligible economic value containing radionuclides in excess of threshold quantities. High level wastes (HLW) are produced in the first cycle of reprocessing spent nuclear material and are strongly radioactive. Intermediate level wastes (ILW) can be divided into short lived, with half lives of twenty years or less, and long lived, in which the half lives of some constituents may be thousands of years. Low level wastes (LLW) contain less than 4 GBq/ton of alpha emitters and less than 12 GBq/ton of beta and gamma emitters. Very low level waste (VLLW) contains activity concentrations less than 0.4 MBq/ton.

ACTIVITY AND EXPOSURE

The Becquerel (Bq) is the activity of one radionuclide having one spontaneous disintegration per second. One Curie (Ci) is defined as 3.7×10^{10} disintegrations per second. The Becquerel is the more commonly used unit. The unit of ionizing radiation which corresponds to energy absorption of 100 ergs per gram is the rad (roentgen-absorption-dose). The newer unit is the Gray (Gy), which is equal to 100 rads. The amount of radiation which produces energy dissipation in the human body equivalent to one roentgen of X-rays is the rem (roentgen-equivalent-man). One Sievert is equal to 100 rems and is the commonly accepted unit.

Philosophy

The group of people engaged in management of radioactive wastes has evolved from a small body of operators who, originally with little or no expert knowledge, were engaged in day-to-day solution of unpleasant problems. They now form a recognized profession, extending from whole-time research scientists to field workers who in some countries are conducting a profit-making industry.

The members of the profession came mainly from Health Physics and brought with them the caution and "conservative" attitude to radiation hazards characteristic of Health Physicists. They regard their mission as being to ensure that members of the public, as well as workers in the field of nuclear energy, will not be harmed by the radioactive material for which they are responsible. With their Health Physics background this sometimes leads to an attitude which industry regards as overrestrictive, although recent controversies have tended to cast them ironically in the role of particularly dangerous polluters of the environment.

It is clear that any human activity that involves conversion of something into something different must produce waste. Conversion of energy from one from to another is no exception. It is sometimes possible for an industry to recycle its waste products and to convert part of them to a useful form, but there is always some minimal residue which cannot be retained within the system. This must find some place within the environment. Usually the cheapest procedure is to discharge it in some way that will ensure a sufficient dilution to make it innocuous. If this is impracticable for technical or political reasons it must be confined, but usually the more effective the confinement, the higher the cost. To say that a process must be conducted with now waste is equivalent to saying that the process may not be conducted at all, and to demand a certain level of confinement or restriction of wastes implies an acceptance of the cost of the waste management system as a necessary part of the cost of the process.

Discharge of potentially noxious materials into the environment involves some risk, which may or may not be measurable. Within very broad limits research in nuclear hazards enables us to forecast the effects of exposure of large groups of people, for extended periods, to low doses of radiation. We can also estimate, with less accuracy, the probability that an individual will suffer some harm from such exposure, and we can say with much greater confidence what will happen if an individual is exposed to larger doses—say 50 rem and upwards—in a single dose. The nuclear industry, then, can provide some information on the probable consequences of environmental contamination extended over a lifetime, and better information on the probable consequences of a major nuclear accident which leads to high radiation exposure. In other words we can, within rather broad limits, estimate the risks.

The situation is different in most other industries. The consequences of acute doses of cyanide, lead, fluoride or carbon tetrachloride are well known, and there is some evidence for the effects from low doses received over a lifetime, but who knows what effect to expect in humans from benzpyrene or nitrous oxide emitted from smoke stacks or from the low levels of polychlorodiphenyls and mercury compounds that are liberated into the environment? They affect every age group in the population and are a potential lifelong hazard. But nothing is known about the probability that they will eventually do harm, and it is difficult to see how such knowledge could be obtained in a human population.

Every human activity is associated with some risk, however small. Normally we do not solemnly calculate the risk, weigh it against the benefit we expect to obtain, and then decide for or against the activity. Yet to decide to do something—such as driving a car, getting up in the morning, or going mountain climbing—must involve some sort of conscious or unconscious weighing of risk against benefit.

In deciding upon a particular waste management system, or in deciding to license a particular kind of nuclear power station, a much more deliberate weighing of cost vs. benefit must be undertaken. There is, however, a fundamental difficulty which up to now has made it impossible to express such a judgment in numbers. It is characteristic of a ratio that the numerator and the denominator must be in the same units. It should be possible to express most of the benefits of nuclear power, for example, in dollars, but if we regard part of the cost of nuclear power as an increase in the probability that people will develop cancer or that they will experience a shortened lifetime, how can that be expressed in dollars?

One benefit of nuclear power is the difference between death and injury among uranium miners and processors and the corresponding figure for equivalent energy production by the coal mining industry. This, again, cannot be expressed in dollars. To work out a true COST/BENEFIT ratio is thus little better than a dream, and the people responsible for approving a waste management system or a new power station are therefore faced in the last analysis with a value judgment, which is at least to some extent subjective. It is not a scientific decision. In the broadest sense, the decision is political.

Controls

The responsibility for making decisions on matters related to "dealing in"—i.e. having anything to do with—radioactive materials, machines capable of producing electromagnetic radiation (expect for medical purposes) and certain scheduled materials such as heavy water, usually rests with a national atomic energy authority. Typically, regulations are issued by the authority that have the force of law. Assistance is given to the authority in assessing hazards of reactors and other installations—including waste management systems—by an independent advisory committee which can call on the services of an expert staff.

In most countries regulations lay down the maximum permissible exposure to radiation for workers in nuclear industry and also for the general population. Maximum permissible doses (MPDs) have been recommended by the International Commission on Radiological Protection (ICRP), which have received worldwide acceptance as the fundamental basis for national regulations. The ICRP has derived from the MPDs a list of maximum permissible concentrations (MPCs) in air and water on the basis that if workers were to breathe air, or drink water, at the MPC for any particular radionuclide over a lifetime they would not suffer any unacceptable harm.

"Unacceptable" means "detectable", in the sense that it could reasonably be regarded as caused by the radiation. The ICRP has also laid down rules for calculating the MPC for mixtures of more than one radionuclide.

The MPDs are constantly under review by the ICRP, which consists of people who have devoted their professional lives to assessment of radiation hazards. They drawn upon the work of large numbers of scientists throughout the world, many of whom are actively engaged in research on somatic and genetic effects of radiation. Changes have been made from time to time in details of the ICRP recommendations but it is remarkable that in such a rapidly developing field the necessary changes have been so few.

The ICRP has consistently emphasized that the MPD and its associated MPs are *maximum permissible* figures. The Commission has made another recommendation equal in force and status to those on maximum permissible doses. This states that exposure to radiation must always be held down to the lowest PRACTICABLE dose. The world "practicable" was carefully chosen, after considerable debate. If "possible" had been used it could have been claimed that a single contaminated rat must be buried in a platinum box. It is our mission to see that all practicable steps are taken to protect mankind from exposure to radiation, and we can do that very effectively.

SOURCES OF WASTES

Uranium Mining and Milling

Apart from the normal hazards associated with hard-rock mining, the workers in uranium mines are exposed to radon and the decay products which arise from the radium content of the ore. These hazards can be controlled by sealing old workings and general "good house-keeping", but more particularly by installation of an efficient ventilation system and, where necessary, the use of respirators. The ventilation air contains radioactive material and dust, some of which can be removed if necessary by filtration, but the radon remains. The large volume of air used for mine ventilation is ejected at high velocity from a stack, which ensures adequate dilution into the atmosphere.

The end products of the mill are uranium oxide and "tailings". The tailings, together with mine drainage water, contain most of the radium originally present in the ore. Radium is

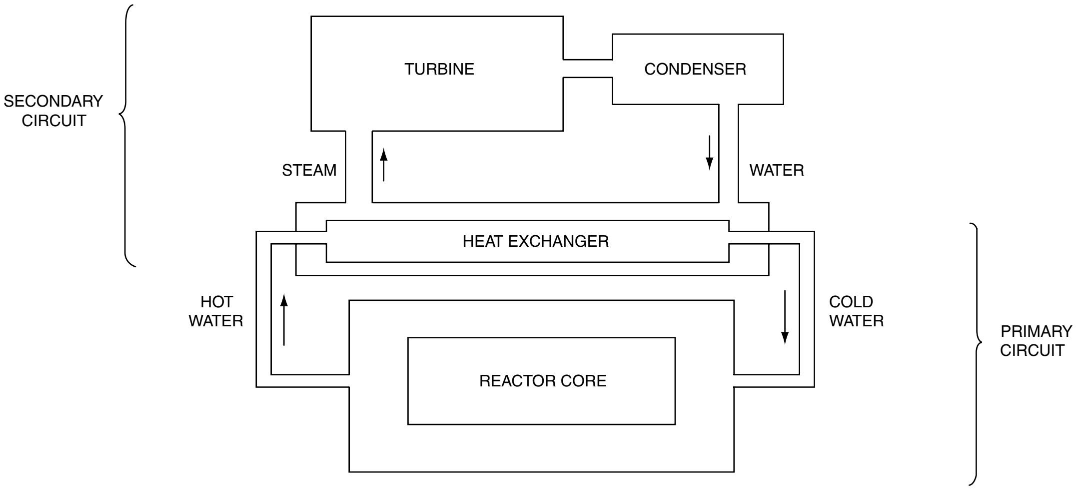

FIGURE 1 Schematic diagram of processes in nuclear power station. Nearly all radioactivity remains inside the fuel, which is inside the core, which is inside the primary circuit.

one of the most toxic of all radionuclides and presents a serious potential hazard. Various methods of treatment, such as co-precipitation with barium, render most of the radium insoluble. But the water draining from tailings ponds often contains more radium than is permissible in drinking water.

Proper design of outfalls into suitable bodies of water can ensure adequate dilution, but vigilance is necessary to prevent rupture of the tailings ponds or improper practices that will nullify or bypass the treatment system. A monitoring system for analysis of downstream water and fish is common today, but in the early days of the industry the dangers were little understood or ignored, with the result that lakes and streams in uranium mining areas became contaminated.

In Canada the existence of a problem was recognized in time to avert a public hazard, but the Report of a Deputy Minister's Committee showed that action was necessary to protect the environment in the Elliott Lake and Bancroft areas. This was particularly urgent as greatly increased activity in uranium mining was anticipated within a few years.

The size of the problem can be judged from the fact that a Congressional Hearing was told that 12,000,000 gallons of water containing nearly 10 g of radium was discharged daily to the tailings ponds of American uranium mills.

Processing of Uranium Oxide

The crude (70%) U_3O_8 produced by the mills may be converted to metal, to UO_2 or to UF_6. The hexafluoride is used in separation of ^{235}U from ^{238}U. A serious waste problem would result from nuclear fission if a critically large amount of ^{235}U were to accumulate accidentally in one place. This is a rare event, but is not impossible. Otherwise, the wastes consist of uranium chips and fines, contaminated clothing and respirators and dust accumulated in air-cleaning systems. The uranium at this stage is practically free from radium so it is hardly a radioactive hazard. The toxicity of natural uranium or ^{238}U is that of a toxic metal rather than of a radionuclide.

Uranium metal is produced by converting the dioxide to tetrafluoride which is then reduced to the metal at high temperature with magnesium. The waste form this process—magnesium fluoride slag and uranium metal fines from trimming the ingots—is a normal slag disposal problem since it is sparingly soluble in water.

Fuel Fabrication

There are many different kinds of fuel elements, but their manufacture produces little waste beyond dust and faulty pellets or fuel pins. This material is usually recycled, particularly if it contains added ^{235}U.

Reactor Wastes

An operating reactor contains a very large inventory of fission products. A 500 MW (thermal) reactor, after operating for 180 days, contains four hundred million curies for fission products, measured one day after shutdown. This is equivalent to the activity of about 400 metric tons of radium. The fission products decay rapidly at first, leaving 80 million curies at the end of a week, and more slowly later. After a month, the inventory is reduced to about 8 million curies.

Nuclear power stations rated at 1000 MW (electrical)—i.e. 3000 to 5000 MW thermal—are not unusual. At first sight it would seem that these plants would be enormous potential sources of radioactive wastes, but in practice this is not the case (Figure 1). In an operating power reactor the fuel is contained within a non-corrodible cladding—usually zirconium or stainless steel—and the fission products cannot get out unless the cladding is ruptured.

It is possible to operate the reactor with defects in a few fuel elements, but these sources of leakage make the primary cooling circuit radioactive. It is impracticable to operate a station in the presence of high radiation fields, so the primary coolant is continually purified by ion exchangers. Again, it is a practical necessity to renew the ion exchangers after they have developed a certain level of radiation. The net result of these considerations is that for reasons of operator safety and economics the presence of more than a small proportion of ruptured fuel in a reactor will require its removal.

Fuel removed from the reactor is normally stored on site for a considerable time to permit decay of shortlived radioactivity. Storage facilities are usually deep tanks filled with water, which acts simultaneously as coolant and radiation shield. If defective fuel is present the water will rapidly become contaminated, but even if there are no defects in the cladding the water in cooling ponds does not remain free from radioactive material. This is because the cladding and the reactor structure contribute neutron activation products (or corrosion products) to the cooling water and the cladding itself always contains minute traces of uranium, which undergoes fission in the reactor. Hence, the pond water must be purified, usually by resin ion exchangers, so these resins also become a waste.

If resins are regenerated, the regenerants (acids, alkalis, or salts) will appear as a liquid waste for disposal. Otherwise, the resin will be handled within its original container or as a powder or slurry.

The radioactive content of gaseous effluents from reactors depends upon the design of the reactor. If air passes through the core very large amounts of argon-41 may be emitted from the stack. Although ^{41}Ar is a hard gamma emitter it has a short half-life (about two hours) so its effects are only noticeable within or very near to the plant. Radioactive isotopes of nitrogen and oxygen decay so rapidly that they do not reach the stack in appreciable amount and the long-lived carbon-14 is not produced in sufficient amount to be hazardous at the present scale of nuclear power generation. Some concern has, however, been expressed that by the end of this century the buildup of ^{14}C in the atmosphere might become a significant source of radiation within the biosphere.

More concern attaches to radioactive krypton, ^{85}Kr, with a half-life of 10.4 years. This, in contrast with ^{41}Ar and ^{14}C, is a fission product. It is liberated via fuel defects and by diffusion through fuel cladding. It is not a hazard from any single plant, but with increasing numbers of nuclear power stations it might become an ubiquitous source of low-level radiation, though the source of most of the ^{85}Kr would be spent fuel processing plants rather than power stations.

Similar concern has been expressed regarding tritium, the radioactive isotope of hydrogen, which is produced within the fuel and by neutron activation of the heavy hydrogen in ordinary water or the D_2O coolant and moderator of heavy-water reactors. It is also formed by neutron activation of lithium, sometimes used as a neutralising agent in reactor coolants, or of boron which functions as a "poison" in some reactor control systems.

Sometimes the significance of a "source" of radioactive waste depends on whether one is considering the safety of people within the plant, or the public outside. For example, ruptured fuel elements or ordinary day-to-day type mechanical failures can produce air-borne radioactive iodines and other fission products which are a nuisance to operators because they have to work in plastic suits and respirators. The ventilation filtration system and the high dispersion capability of the atmosphere combine to make sources of this kind insignificant beyond the boundary of the exclusion area. However, they may reduce efficiency and disrupt work schedules within the station very seriously, and give rise to significant disposals in the form of clean-up solutions, contaminated clothing, mopheads and metal scrap.

A noteworthy source of this nature is the tritium which builds up in the coolant and moderator of heavy-water reactors. In a 1000 MW (electrical) power station the equilibrium tritium concentration in the moderator is about 50 Ci/litre. This leads to stack discharges which are quite negligible, but any leaks in pump seals, valves or pipe joints within the station would produce operating problems for those responsible for the radiation safety of the staff. On the other hand, material sent for waste disposal would be no problem, partly because heavy water is recovered for economic reasons and partly because the maximum permissible concentrations of tritium in air and water are much higher than those of most other radionuclides.

In summary, in spite of the enormous potential source of radionuclides within an operating power station the amount of waste generated is small compared with that arising from a research and development establishment, and minute in comparison with a plant fuel processing plant. This statement covers normal operation, including the ordinary accidents and malfunctions expected in any well-designed plant. It does not include the consequences of the "Maximum Credible Accident" which is, in fact, so improbable that designers of waste management systems do not normally make provision for it.

However, the accident at the Chernobyl Nuclear Power Station in 1986 was particularly sensational. A reactor exploded and caught fire, releasing an estimated 30 million Curies. Half of the resulting fallout was within 30 kilometers of the plant. The remainder spread over much of Europe. There was great economic loss and many cancer deaths were attributed to the incident.

Spent Fuel Processing

Wastes arising from processing of spent fuel account for more than 99.9% of the "waste disposal problem". Fuel which has been enriched with ^{235}U must be treated for recovery of unburned ^{235}U because the fission product load of spent fuel reduces its efficiency as a source of energy. It ceases to be economic as fuel long before the expensive ^{235}U is exhausted.

After removal from the reactor, and storage for sufficient time for decay of short-lived fission products, the fuel is de-sheathed and dissolved, usually in strong nitric acid (Figure 2).Uranium and plutonium are extracted into an organic solvent, and the acid solution of fission products left behind forms the high level or primary waste. Washing of the organic extractant produces Medium Level wastes, whereas Low Level waste consists of further washings, cooling water, scrubber water and liquids from other sources too numerous to catalogue.

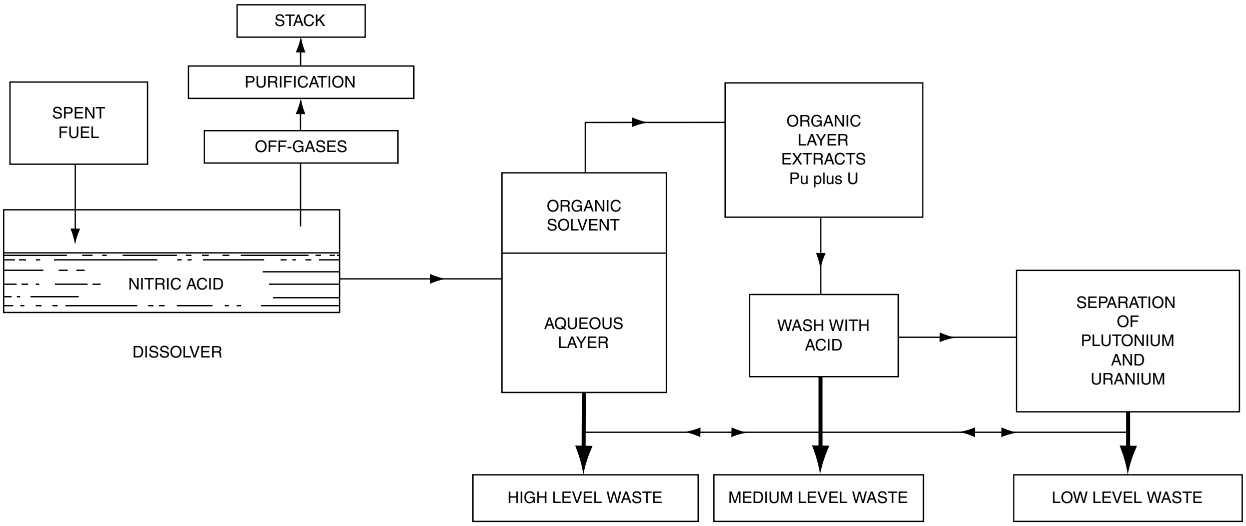

FIGURE 2 Schematic diagram of fuel processing plant. Showing origins of main waste streams. Reactor fuel contains over 99.95% of the total radionuclides eventually disposed of as waste.

As long ago as 1959 fifty million gallons of High Level wastes were stored in stainless steel tanks at Hanford (USA) alone. The radionuclides in solution generate so much decay heat that many of the tanks boil, making the provision of elaborate off-gas cleaning systems necessary. Some high level waste tanks have ruptured, but since they are constructed on a cup-and-saucer principle, with adequate monitoring for spills, and spare tankage is kept available, no unexpected contamination problems have arisen.

Gases from the dissolvers and storage tanks contain tritium, bromides, iodines, xenon, krypton and smaller amounts of less volatile elements such as ruthenium and cesium. After storage for decay, scrubbing and filtration, off-gases can be liberated from a tall stack. As mentioned in the section on reactors, proliferation of fuel processing plants in the future might conceivably lead to local or even eventual world-wide atmospheric contamination if improved containment is not provided in time at spent fuel processing sites.

Solid waste may include glasses or ceramics, used as a means for fixing the activity in high-level liquid wastes, and bitumen or concrete blocks containing less active material. Products of waste processing such as sludges, evaporator bottoms, incinerator ash, absorbers, filters and scrap fuel cladding are usually in the medium level category. Worn and failed equipment such as pipes, tanks and valves, unserviceable protective clothing, cleanup material and even whole buildings may have a variety of levels of contamination, by numerous different radionuclides, which defies quantitative assessment. This is not a serious difficulty, except for administrative and recording purposes when quantitative reports have to be made, because most of these wastes have to be contained in some way and none of them are dumped into the environment.

The most difficult problem for the fuel processing industry is not high or medium level waste, offgases or heterogeneous contaminated scrap. The real problem is very low level liquid waste, because it arises in such enormous volume. Coming from numerous different sources—e.g. cooling and final wash waters, laundry and decontamination center effluents, floor drainage from cleanup operations, personnel shower drainage and effluent from the final stages of liquid waste purification plants—low level and “essentially uncontaminated but suspect” waste adds up to billions of gallons per year. Although some countries (Sweden and Japan, for example) evaporate such effluents on a large scale they are usually discharged by some route into the environment.

Research and Development

A wide variety of wastes arises in such research establishments as Brookhaven (USA), Chalk River (Canada) or Harwell (UK) and the include many of the types mentioned under the heading of fuel processing. In addition the research reactors usually produce very large quantities of radioisotopes which may be processed onsite. However, the quantities involved are very much lower, especially in the high level category, and elaborate waste processing systems are seldom needed even at large research centers unless they are situated in built-up areas or immediately over important aquifers.

Hospitals and Biological Laboratories

Organic material and excreta makes wastes from these institutions difficult to handle. The radioactive content is usually small, and limited to a restricted list of radionuclides. Those used as sealed sources seldom appear as waste, and the rest are practically confined to ^{131}I, ^{32}P, ^{59}Fe, ^{51}Cr, ^{35}S and ^{24}Na. Other nuclides may be used in small amounts for special purposes such as specific location in certain organs. The nature and amount of radionuclides used in these institutions are such that a high proportion of the waste can be handled safely by the municipal sewage and garbage systems.

Sealed sources are, however, a very difficult matter. While they remain sealed they are usually within heavy shielding in teletherapy machines, which are only operated by competent people, or they are in the form of needles and plaques for implantation, or instrumental standard sources used by specialists. However, the time comes when such sources have decayed to the point where they are no longer useful. Sufficient activity remains for them to be highly dangerous to the unwary, so they are dealt with in special ways, usually after return to the supplier.

Isotope Production Plants

These facilities are often associated with large reactors, and wastes are similar to those generated in Research and Development plants. Processing of very large sources of volatile elements such as iodine and tellurium necessitates an elaborate ventilation cleaning system. Manufacture of large sources of ^{90}Sr, ^{137}Cs or the trans-uranic elements as power sources may call for sophisticated remote handling equipment in heavily shielded cells. But the waste problems are difficult only in scale from those encountered in an *R* and *D* plant.

Some people have considered the separation of ^{90}Sr and ^{137}Cs from fuel processing wastes as a helpful step in their management. Removal of these nuclides leaves a mixture which, during 20 years' storage, would decrease in activity by a factor of about 30,000. However, an industry handling the fission products from 50 tons of ^{235}U burned in one year would have to deal with 500,000,000 Curies of separated ^{90}Sr and about the same amount of ^{137}Cs. It might be difficult to find a market for sources of this scale unless they were cheap, and it must be remembered that they would eventually come back as "waste."

Industrial Applications

Use of radioisotopes in industry is not a significant source of wastes. Most industrial sources are sealed, and nearly all unsealed sources are short-lived.

Transportation

Ships are the only form of transportation using nuclear reactors as a source of power. They include naval ships, ice breakers and merchant vessels. They contain large amounts of fission products within the reactors, but as a source of waste they are not important, except possibly in some harbours and inshore waters.

During start-up of the reactor the secondary coolant expands and the limited space in submarines necessitates the dumping of this expansion water. In common with landbased reactor coolant it contains radioactive corrosion products and tritium. The coolant is maintained at a low level of activity by means of ion exchangers, which become waste eventually. Normally this material is disposed of on land, although it has been shown by the Brynielsson Panel of the International Atomic Energy Agency that resin from a fleet of as many as 300 nuclear ships could be dumped safely if this were done only on the high seas.

Apart from these sources wastes from nuclear shipping consist of clean-up solutions, laboratory wastes, laundry effluent and other minor sources common to all reactor operations. Except in submarines, practically all wastes can if necessary be retained on board for disposal ashore.

DISPOSAL PRINCIPLES

There are two main procedures available for disposal—Concentration and Confinement: or Dilution and Dispersion.

a) If wastes are truly confined, in the sense that in no credible circumstances could they be liberated into the environment, then the only additional requirement is "perpetual custody" to ensure that the confinement is never broken. This is easier said than done. In the field of high level wastes when we say "perpetual" we are speaking in terms of thousands of years. Few private firms go back for 100 years, political regimes have seldom lasted for as long as 500 years, and there are few civilizations that have survived for 2000 years. In our own day forecasters tend to regard dates beyond 2000 AD as being in the distant future. What, then, can we do about "perpetual custody" of wastes containing, for example, plutonium with a half-life of 24,000 years?

This is not a fanciful dilemma. A story from Chalk River will illustrate the point. When the Canadians decided to concentrate on natural uranium heavy water reactors for power production it became apparent that processing of spent fuel would be uneconomic until the price of uranium or plutonium rose considerably. Processing was therefore stopped, but the wastes accumulated during the pilot plant operation had to be disposed of. A considerable volume of medium level waste was mixed with cement in steel drums and enclosed within solid concrete monoliths below ground in the waste management area (Figure 3).The question then arose "What if some archeologist digs this structure up 1000 years from now and thinks it is an ancient temple or tomb?" Eventually someone suggested that its true nature should be inlaid in non-corrodible metal on the top of the monolith. Dr. A. J. Cipriani, who had listened to the debate in silence, then asked "In what language?"

The implications of this question are profound. Some of the wastes for which we are responsible will still be radioactive after our present civilization has disappeared and perhaps been forgotten. So far as we know there is no practicable solution to the problem. The best we can do is ensure that the nature, amount and location of all major disposals

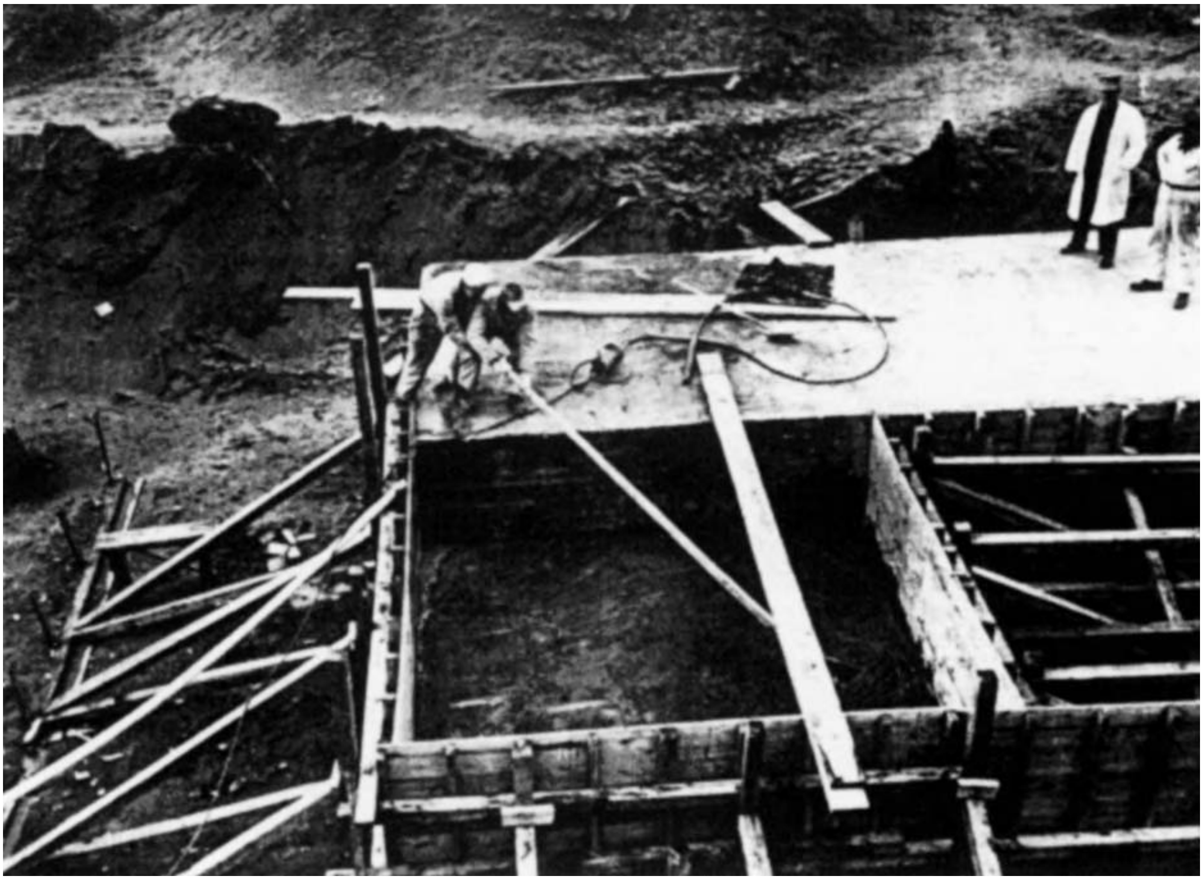

FIGURE 3 Pouring a concrete monolith. Steel drums filled with waste, solidified by mixing with cement, were stacked on concrete slabs surrounded with forms. The forms were filled with concrete. The monoliths were about 2 m below ground level.

are recorded in the nearest approximation we have to a perpetual repository of archives—a government department. Beyond that we can only rely on folk memory. After all, farmers in Europe have been ploughing around Neolithic tumuli and prehistoric roads for thousands of years for no good reason known to them, except that it was accepted to be the right thing to do.

b) Dilution and dispersion is the traditional method that men have always used for dealing with their wastes. Until recently it seemed to work fairly well unless populations became very concentrated, but it is now becoming clear that there are so many people that the system is showing signs of breaking down. It depends upon the capacity of the environment to dilute or detoxify the wastes to a level that is innocuous to man and to organisms of interest to man. We are still a very long way from contaminating our environment with radioactivity to a point where radiation effects are observable, even in close proximity to nuclear enterprises, but we must maintain vigilance to ensure that slow and subtle changes do not occur which escape our notice until it is too late.

Safety in discharge to the environment depends upon three factors—(1) Dispersion by such means as atmospheric dilution, mixing into big bodies of water, or spreading through large volumes of soil. (2) Fixation of radionuclides on soil minerals and organic detritus. (3) Decay of radionuclides, dispersed or fixed, before they are able to affect man.

The principle of dispersion has one logical trap into which regulatory bodies have sometimes fallen. In some countries the discharge of liquid and gaseous wastes is limited by the concentration in the effluent pipe or the concentration at the stack mouth. This is based upon the assumption that if the concentration is limited to the maximum permissible value, all will be well. However, the “dilution capacity” of a river is a function of the number of Curies per day put into the river, divided by the daily flow of water. If an operator wishes to dispose of double the amount of waste, and he is limited only by the concentration in the effluent pipe, he need simply double the amount of water flowing in the pipe. But the downstream effect will be a doubling in the concentration, unless he has doubled the flow in the river.

> For this reason, limitations must be made in Curies per unit time, not in micro-curies per millilitre, and account must be taken of volume of river flow if this is seasonally variable. Regulations set on the basis of concentration at the point of discharge only protect people close to the discharge point.

DISPOSAL PRACTICES

Gases

Radioactive gases arise mainly in reactors, spent fuel processing, isotope production, and research and development facilities. The general principles are the same for all procedures that depend upon dispersion into the atmosphere.

If we have a stack that is emitting Q Curies/sec., the concentration C at a given distance downwind will be KQ. The parameter K is a very complex function which depends upon wind speed and direction, weather conditions, stack height, topographical features, variability of temperature with height, velocity and buoyancy of the effluent and other conditions. Values of K for a range of conditions can be calculated from equations proposed by Sutton (1947), Pasquill (1961) and Holland (1953). These equations have been used to calculate the permissible emissions from stacks by inserting appropriate numbers and parameters applying to unfavourable weather conditions likely to obtain at the site. The permissible emission rate has been set at a value which would ensure that populations downwind would not be exposed to more than an agreed maximum radiation dose rate.

The classical equations have been based on statistical theory with empirical values for the diffusion parameters being obtained from experimental work which has sometimes had little relation to real emissions from actual stacks.

Returning to the superficially simple equation $C = KQ$, it is apparent that if we could observe, over a long period of time, the maximum value of C ever attained per unit emission rate, we could define a figure $K_{\max}$ which was not likely to be exceeded. With a sufficient number of observations of C and Q, extended over a sufficient variety of weather conditions, we could estimate the probability that our value $K_{\max}$ could ever be exceeded.

When a maximum permissible concentration is set for a noxious substance the decision really depends upon a belief that the probability of damage is so low that it is acceptable. If, then, C is set at the *MPC* at a given distance from the stack, and $K_{\max}$ is known for that distance, then Q_p, the maximum permissible release rate, is determined.

It has been shown by Barry that $K_{\max}$ is not very dependent upon topography or climate, because it depends mainly on rather large-scale behaviour of the atmosphere, and the frequency of most adverse conditions normally experienced do not vary grossly from one place to another.

The maximum permissible emission rate—or in some cases the *MPC* at the stack mouth—is given in the regulations governing the plant or laboratory. It is then the responsibility of the operator to ensure that emissions are kept as far below the permissible level as may be practicable. Numerous methods are available, other than variation of stack height, for achieving this end (Figure 4).

Filtration It is advisable to filter contaminated air near to the source of the activity. This reduces the amount of air to be filtered and also cuts down the "plating-out" of radionuclides on the duct-work, which can be a source of radiation fields with the plant.

Filters must be suitable for the job they are supposed to do. They should be made of non-flammable material such as glass or other fibre and should be tested before and after installation. If fine (e.g. "Absolute") filters are used it is often necessary to precede them with a coarse filter to avoid rapid clogging with dust.

Filters must be very efficient to be adequate for fuel processing plants and incinerators burning highly active waste. For example, a sand filter at Hanford capable of passing 10,000 m^3/min had an efficiency of more than 99.5%, but this was inadequate. The necessary efficiency of 99.99% was attained with a bed of glass fibers 100 cm thick.

Electrostatic Precipitators Small airborne particles are usually electrically charged. The charge can be increased by passing the air through a corona discharge, or through a charged fabric screen. The particles are attracted to a surface carrying the opposite charge, from which they can be removed mechanically. It is possible to use the same principle by imposing a charge on filters.

Steam Ejector Nozzles The most efficient air cleaning device other than "Absolute" filters consists of a nozzle in which the air is mixed with steam and expelled into an expansion chamber where the steam condenses on the particles. After passing through a second construction into another expansion chamber, where the air is scrubbed with water jets, removal efficiency for 0.3 micron particles is 99.9%.

Incinerator Off-gases The hot gas from an incinerator carriers with it fly ash, tars and water vapour as well as particles. Tars may be removed and the gases cooled by water scrubbing devices. Water droplets must then be eliminated by reheating or passage through a "cyclone". This is a cylinder with a conical bottom. Gas injected tangentially at the top sets up a vortex which causes deposition of particles on the sides.

In smaller incinerators the gases are cooled and some fly ash is removed by passage through a cooling chamber fitted with baffles. After this stage a roughing or "bag" filter is used, followed if necessary by Absolute or charcoal filters.

Processing Plant Gases The devices required for cleaning gaseous effluent depend on the nature of the process. Off-gas from boiling high level wastes must be passed through condensers and scrubbers to recover nitric acid as well as to remove volatile radionuclides. However, these and other air cleaning equipment previously mentioned will not remove gases such as ^{85}Kr, nor hold back all of the radioactive halogens.

Radioactive iodine in molecular form is fairly easily absorbed by alkaline scrubbers and copper or silver mesh filters, but in the form of methyl iodine it can only be arrested by an activated charcoal filter. These filters have to be kept cool, not only to remove the decay-heat of adsorbed halogens

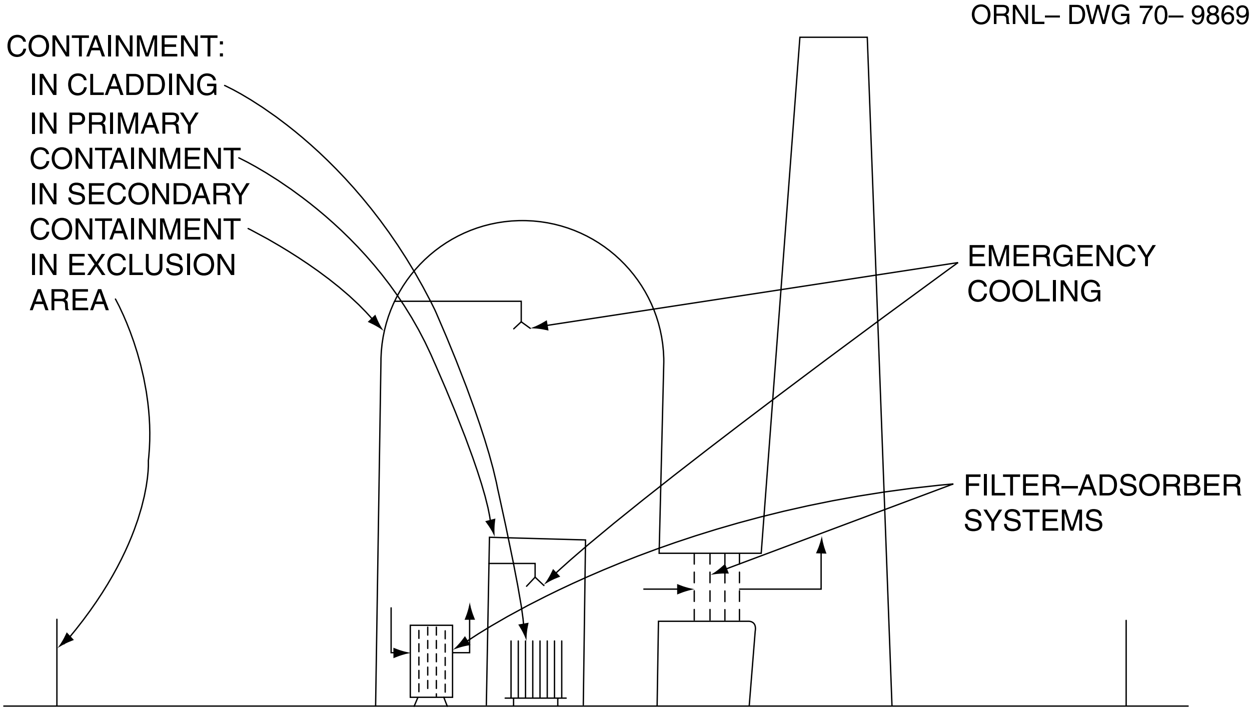

FIGURE 4 Reactor containment system. Any leakage from fuel must pass through the cladding, the primary containment, and either the secondary containment or the stack filters. Contamination within the building can be removed by sprays and/or filters.

but also because ^{85}Kr is absorbed much more powerfully by cold charcoal. This is the only practical means we have for removal of radioactive noble gases.

The very large dispersive capacity of a high stack usually makes it unnecessary to remove ^{14}C (as $^{14}CO_2$) or tritium (mainly $^3H^1HO$) because their toxicity is very low. However, the coolant CO_2 in a gas-graphite reactor does contain enough ^{14}C to require alkaline scrubbing, which removes radioiodine as well.

Liquids

Storage The necessity for long-term storage of very large quantities (many millions of gallons) of high level, strongly acid waste has led to the development of tankage and pipeline systems which have stood up to severe conditions for many years. Failures have occurred, but good design and carefully selected materials have prevented environmental contamination.

Tanks are constructed from material, often stainless steel, which will not be corroded by the solutions to be stored. Secondary containment is provided by catch tanks or drip trays and sufficient spare tankage is kept available for rapid emptying of a ruptured tank. Leakage is detected by a monitoring system which alarms immediately if radioactive liquid appears in the catch tank (Figure 5). Movement of active liquid is effected by pumping rather than by gravity to ensure that it is the result of deliberate action rather than accident.

Evaporation The most straight-forward and apparently the simplest method of treatment for radioactive liquid wastes is evaporation. In a carefully designed evaporator with an efficient droplet de-entrainment system the radionuclide content of the distillate can be about one millionth of that in the pot. There is little about the design that is specifically related to radioactivity except that shielding may have to be provided for the operator, and off-gases must be monitored and possibly treated in some way. Unfortunately, evaporation is expensive because it consumes a large amount of energy and the end product—the concentrate—is still a radioactive liquid waste. Evaporation to dryness or to the point of crystallization has been practised, by the residue is so soluble in water that without further processing it is not suitable for disposal.

Where discharge of a large volume of low-level waste into the environment is unacceptable the cost of evaporation may be justified by its many advantages. Practically all liquid wastes are treated by evaporation in Denmark and Sweden, and it is also widely used in Japan.

Residues from evaporation may be mixed with cement, fused with glass frit or various ceramic mixtures, or incorporated with melted bitumen. The product is then handled as a solid waste.

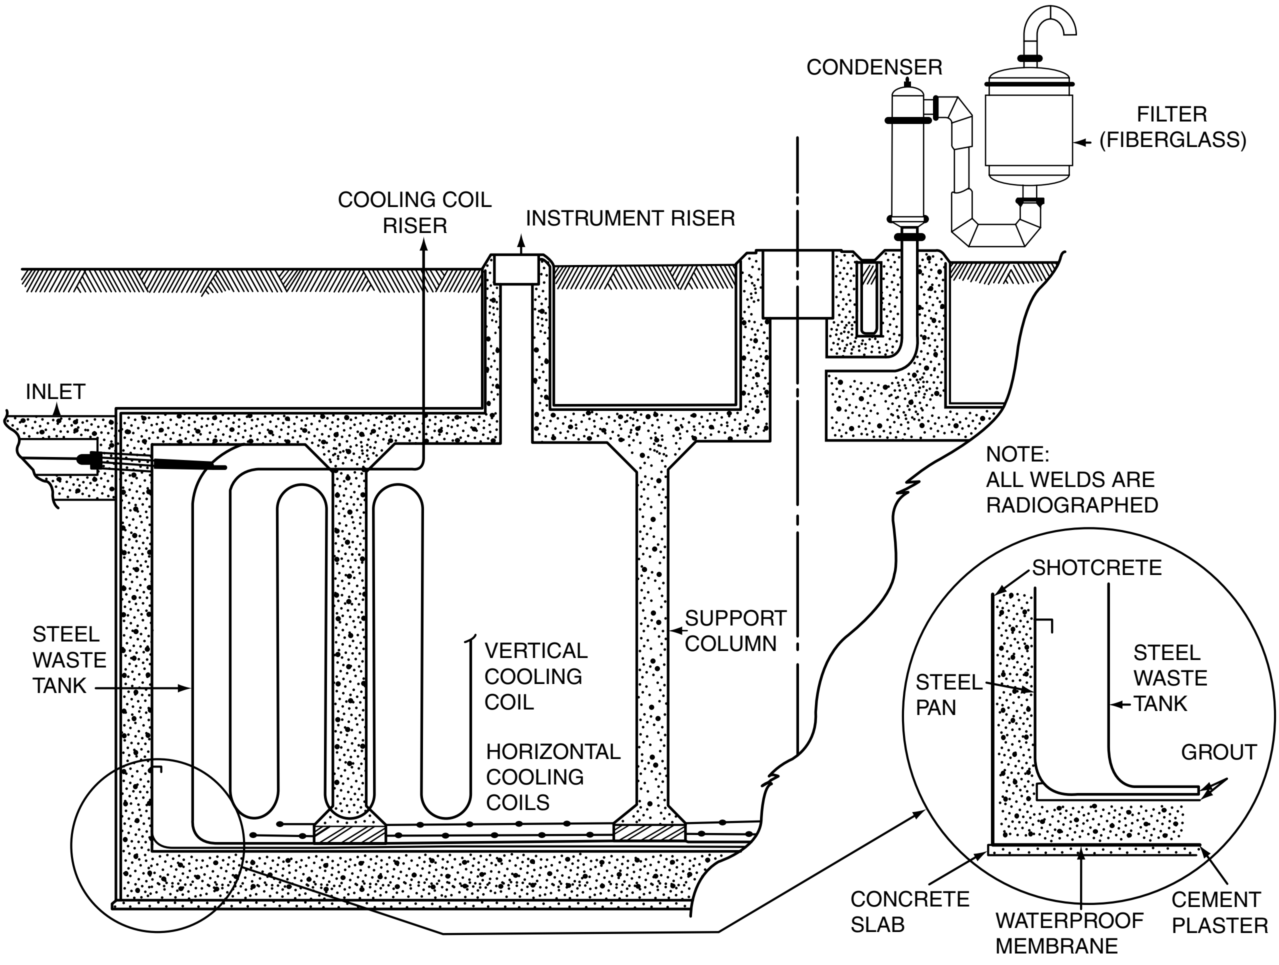

FIGURE 5 Structure of high level waste tank at Savannah River.

Flocculation and Precipitation The cheapest and simplest process for treatment of radioactive liquids is removal of the activity on some kind of precipitate, either as an integral part of the precipitated material, or adsorbed on its surface.

In most waste tanks a sludge settles out which may contain up to 90% of the activity, and a copious precipitate of metallic hydroxides is formed on neutralization which may carry down up to 90% of the remainder. Further purification of the clear effluent after separation of these sludges can be achieved by addition of lime and sodium carbonate. Up to 99% of the remaining activity can sometimes be removed by this treatment. Treatment with lime and sodium phosphate is also very effective (Figure 6).

The treatment used depends upon the particular radionuclides present in the waste, and also its gross composition for example, the pH and salt content of the solution. In some cases ferric chloride, clay or other additives are introduced at carefully chosen points in the process. The selection of the process, and modifications introduced as the composition of the waste changes, require constant analysis and control by specialized chemists.

One problem common to all flocculation processes is how to deal with the sludge. The floc settles very slowly and after it has been drained through filters or separated by centrifugation it is in the form of a thick cheese-like solid which, in spite of its appearance, still contains 80 to 90% of water. In a successful British process the sludge is repeatedly frozen and thawed. The separation of pure ice crystals leaves behind a concentrated salt solution which coagulates the small particles of floc into a form which settles more rapidly and is less likely to clog vacuum filters.

Ion Exchange The effluent from a flocculation process may still contain too much activity for discharge to public waters. It can then be passed through ion exchangers, which are expensive but very efficient. They cannot be used economically on a solution with a high salt content because their ion-exchange capacity would rapidly be exhausted by absorbing the dissolved salts.

The effluent from a well-controlled flocculation process has a low total-solids content and after filtration to remove traces of floc it can be passed through a cation exchanger or mixed-bed resin suitable for removal of the radioactive

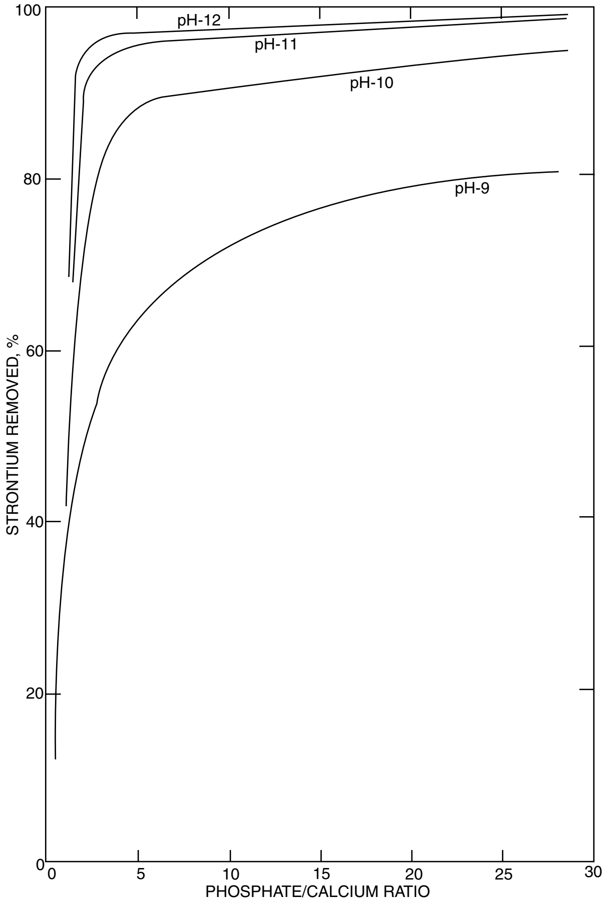

FIGURE 6 Decontamination with lime and phosphate—effect of pH and lime/phosphate ratio on removal of strontium-90.

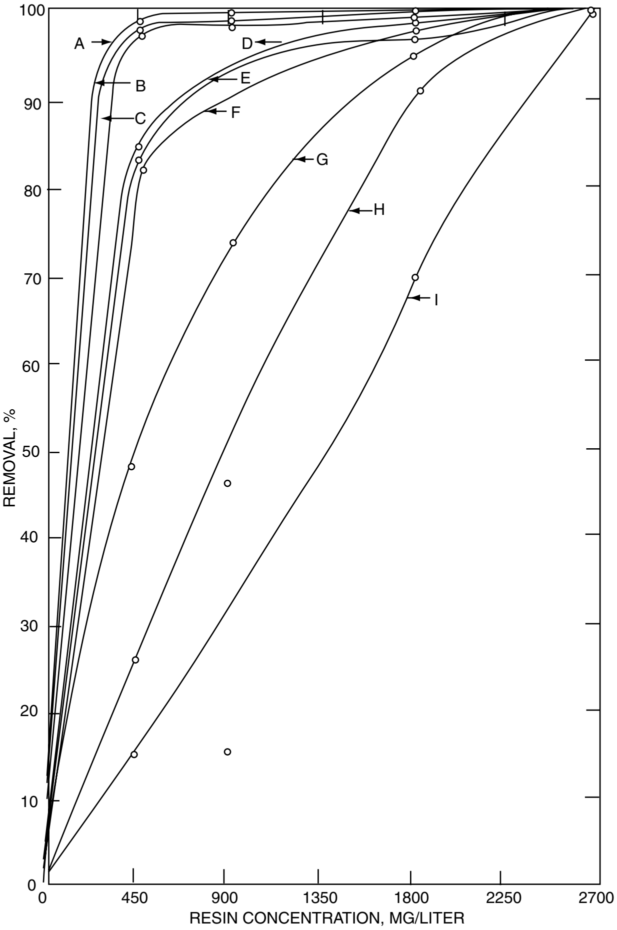

FIGURE 7 Decontamination with ion exchange resin—efficiency for various radionuclides; A, ^{182}Ta; B, ^{144}Ce$-^{144}$Pr; C, ^{95}Cr$-^{95}$Nb; D, ^{140}Ba$-^{140}$La; E, ^{131}I; F, fission product mixture; G, ^{32}P; H, ^{115}Cd; I, ^{137}Cs$-^{137}$Ba.

contaminants. If properly chosen such a resin will remove 99.9% of most radionuclides (Figure 7). Certain minerals—clinoptilolite, greensand and vermiculite are examples—are also efficient ion-exchangers. They are much cheaper than synthetic resins but they require longer contact times for maximum effectiveness.

Glass The very high-level "self heating" wastes—the primary wastes held in stainless steel tanks—are too active to be treated by flocculation or ion exchange. Storage in liquid form is seldom regarded as a permanent solution—somehow these wastes must be fixed in a nonleachable solid form which can be stored safely without danger of leakage or constant maintenance costs. One of the most promising ways to fix high level waste is to incorporate it into a glass.

Glass is a leach-resistant material which can be made from simple ingredients. Its quality varies with composition but it is not usually sensitive to changes in minor constituents. Its low melting point makes it convenient for casting in various shapes and sizes for different disposal procedures. Glasses are supercooled, very viscous, liquid solutions of silicates. Soda glass is made by melting together silica, calcium carbonate and sodium carbonate. Other varieties contain potassium or potassium plus lead instead of sodium, and phosphate or borate in place of part of the carbonate. Metallic oxides are incorporated to form coloured glasses. Such a mixture might well be suitable for fixing the radioactive metallic oxides which form the major proportion of "mixed fission products", after the nitric acid has been removed and the residue ignited.

Successful fixation of radionuclides in glass has been reported from the USA, UK and Canada. British and American practice has concentrated on borate and silicate glasses, or fusing the waste oxides with glass frit, whereas the Canadians have used a natural silicate, nepheline syenate, instead of a glass mix (Figure 8).

Glass fixation is now being done on quite a large scale at the Pacific Northwest Laboratory (Hanford) Washington, USA. By the end of July 1970 nineteen million Curies had been solidified, representing waste from about ten tons of irradiated fuel.

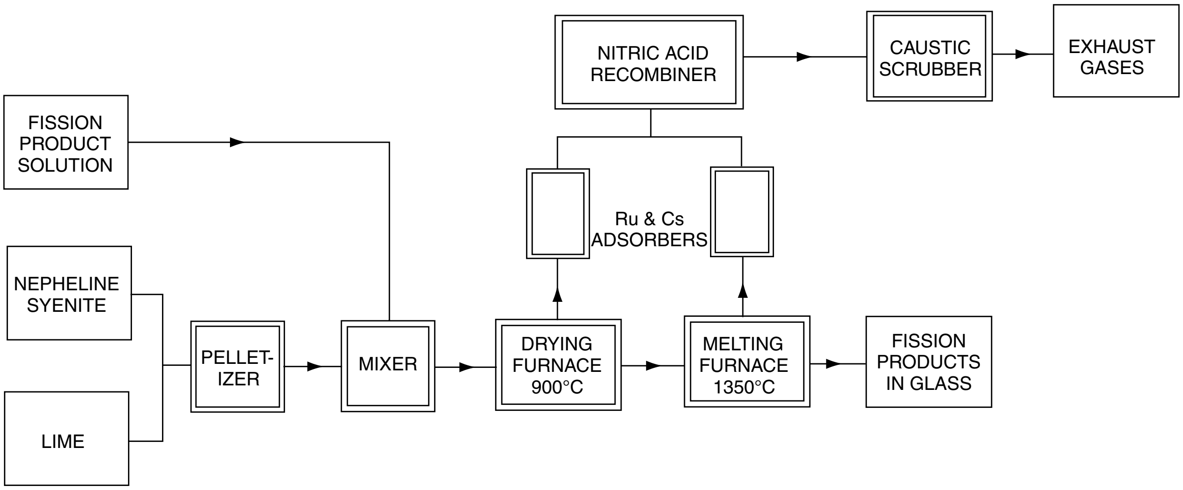

FIGURE 8 Fixation of fission products in glass. Fission product solution is added to pelletized nepheline syenite + lime, dried and melted at 1350°C.

In Canada nepheline syenite glass containing 1100 Ci mixed fission products has been buried in a swamp, below the water table, since 1960. Careful studies of leaching, by sampling of the soil and ground water downstream from the disposal, have shown that fusion products equivalent to the dissolving of 10^{-10} g of glass per cm^2 per day are being removed from the disposal. Less than 1 mCi has been dissolved in ten years from 1100 Ci. This suggests that burial of active glass in dry soil, or even disposal into a big body of water, would be acceptable for quite large quantities of wastes.

Calcination Several methods have been developed for evaporation and subsequent calcination of wastes. Oxides are often soluble in water, so materials are usually added that will bind the oxides into soluble complexes. The calcination process is done in a heated steel container, a fluidized bed or a spray calciner.

The pot calciner is essentially an expendable piece of steel pipe heated in an electric furnace. The waste, mixed with flass-forming fluxes such as borax or lead oxide, is heated to about 9000°C.

The spray calciner is a heated steel cylinder with a nozzle at the top through which the waste is sprayed. At a temperature of 875°C a fine powder is produced which must be stored in a dry place as it is leachable by water.

It is characteristic of all waste fixation methods involving evaporation, sintering and fusion that elaborate off-gas treatment systems are required to prevent environmental contamination by dust and volatile radionuclides. The concentrating equipment itself is essentially simple and often not expensive to build, but the glass purification plant is always sophisticated, complex and expensive. However, it is also very effective.

Rock Fracturing The oil industry has developed methods for creating fissures in rock in order to encourage movement of oil to gas through a formation towards a well. This process has been adapted to disposal of medium-level wastes.

A horizontally bedded formation—shale has been used up to now—is drilled to several thousand feet. A high pressure jet of sand and water cuts through the well casing and penetrates between the strata near the bottom of the hole. The well is then sealed and water forced down under very high pressure, splitting the rock between the bedding planes. The water is followed up by the waste, mixed with cement, sugar and other additives. The mixture spreads out in a thin horizontal sheet, which solidifies after several hours. Typically the sheet is about a half inch thick.

The method has been used for disposal of a very large volume of waste at Oak Ridge, Tennessee. The equipment, including large bins for ingredients of the cement mix, mixing apparatus, a drilling rig and a very powerful pump is expensive, but the method is suitable for large-scale operation because successive sheets can be injected at intervals of a few feet through the depth of the bedded rock formation.

Salt Mines The hazard that must be met by most radioactive waste management systems is contamination of public waters leading directly or indirectly to intake of radionuclides by man. An ideal situation for disposal would therefore be one where public access was impossible and contact with water incredible. The nearest approach to these conditions is found in a deep salt mine. The presence of the salt guarantees that water has been absent for millions of years, and geological study can produce assurance that water is not rapidly penetrating into the salt bed. The excavated galleries of salt mines are large and stable tunnels, suitable for storage and roomy enough for safe work with active loads.

Major disposals of “solidified” waste are being made in a salt mine in Kansas, where detailed investigation has shown that eventually the creep characteristics of the salt will seal the disposal sites of heat-producing wastes. Work on disposal of liquids into cavities cut in the salt suggests that hot liquid waste could also be placed in such a site.

Solids

As with liquid wastes, the most intractable problem is the safe management of the high-volume, low activity waste. The high activity waste is at first sight more dangerous, but although safe custody may be expensive it is not technically difficult.

Low-level waste consists mainly of "garbage"—contaminated clothing, equipment and structural material; broken glassware, cleanup materials such as cloths and mops; and a large amount of "potentially contaminated" material such as packing and paper which must be treated as active simply because it originates in an active area.

Much of this material can be reduced in volume by incineration or baling under high pressure. Fumes and smoke from incinerators and the dusty air from baling plants are cleaned up by methods dealt with under Gases (pp. 717–718), but the ash and baled waste remain to be dealt with.

In some countries geographical or legal circumstances restrict the possibility of burial of radioactive material in the ground. Elsewhere, ground burial is regarded favourably. In the latter case bales and non-combustible waste are likely to be buried in sparsely populated regions. Where land is cheap, low-level wastes may be buried without any volume reducing process.

Conditioning Pre-treatment of waste before final disposal is called "conditioning". The aim is usually immobilization of radionuclides together with, if possible, volume reduction. There is very wide variation in practice from one country to another. For example, in France quite low level solid wastes are put into concrete containers which are then filled with cement mixture so that the end product is a large concrete block. These blocks are stored, under a roof, on a concrete floor. In Canada, on the other hand, similar wastes are put into open trenches at Chalk River and covered with the local sandy soil. Practical measurements seem to show that both procedures are equally safe in the local circumstances.

A very effective conditioning process is fixation in bitumen or asphalt. Bitumen is very resistant to radiation, has a low melting point, is impermeable to water and has some mechanical flexibility. Radionuclides enclosed in, or even mixed with, bitumen leach very slowly into water. Sludges are dewatered when mixed with melted bitumen, which helps considerably in restricting the volume of the disposals. In general, bitumen is beginning to be favoured over concrete as the method of choice for "fixing" otherwise mobile waste radionuclides.

Ground Disposal In some countries direct burial of contaminated material in the ground is forbidden at any level, whereas in others the amount and nature of ground disposals is left to the discretion of the operator.

Nearly all cations move through soil more slowly than the ground water although some anions—ruthenate and iodide for example—are retarded very little. In the case of the average "mixed fission products" usually of concern in waste management the fastest moving radionuclide is ruthenium, usually followed by Sr, Cs and Ce in that order. Relative rates of movement are affected by the nature and pH of the soil and the ground water, but even in acidic sandy soil ^{90}Sr moves through the soil at only 1/25 to 1/100 of the rate of movement of the ground water.

If the site of the waste management area is selected with care in relation to potable water supplies, so that the time of transit between the point of disposal and the point of human consumption is prolonged in relation to the half-life of the critical radionuclides, direct ground disposal of low level waste is effective and safe. There are a great many places where knowledge of the rate and direction of movement of the ground water, together with the distribution coefficients of radionuclides between water and soil, make it apparent that no significant discharge into the environment would be credible as a result of direct disposal into the ground.

When simple burial is unacceptable, disposal trenches and areas can be drained, with processing of the drainwater, or the area can be covered with asphalt and protected from encroachment of ground water by circumferential drainage.

A further step in the direction of safety is the "engineered enclosure." This is a structure built like a concrete house basement. It usually takes the form of a long concrete-lined trench divided into sections by concrete cross-walls. The section in use is covered by a temporary roof (Figure 9). The object of the structure is to prevent the ingress of water, so joints in

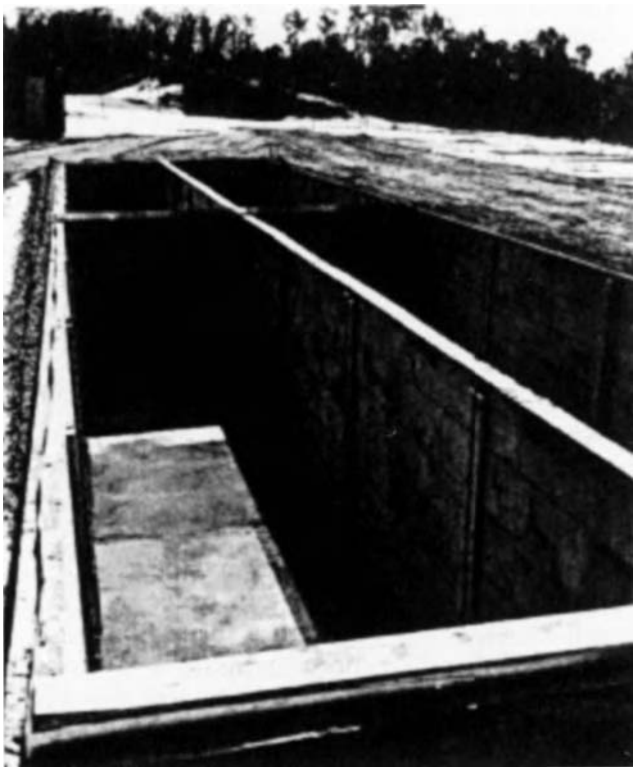

FIGURE 9 Concrete trench. Double trench, for medium-level solid wastes, is covered with a light roof when in use. The filled trench is levelled with sand and a concrete roof is poured. Note galvanized steel seals for joint.

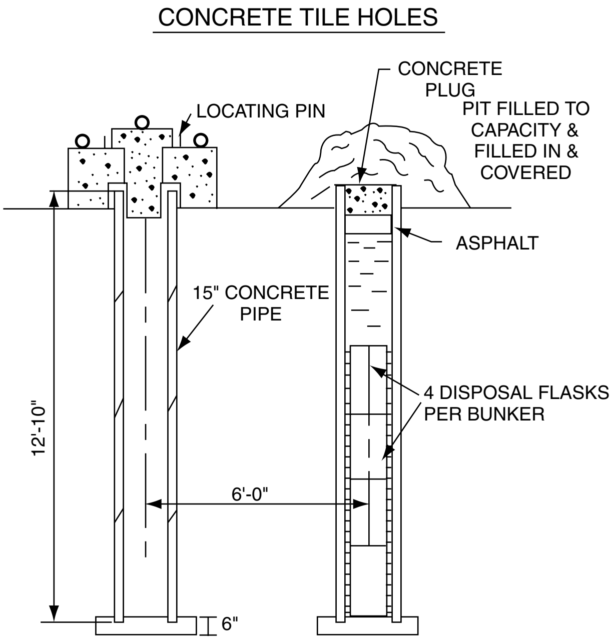

FIGURE 10 Concrete Holes, constructed from drain pipe painted with bitumen, provide will-shielded receptacles for high-level solid waste.

the concrete are water-sealed and the base of the work is laid well above the maximum height of the water table. Since the facility will be used for reception of quite high-level waste the approaches must be suitable for trucks and mobile cranes.

Concrete trenches are unsuitable for reception of small, intensely radioactive objects such as spent teletherapy sources because of the inconvenience of scattered radiation fields. They can be accommodated on concrete-lined holes fitted with removable shielding plugs. Canadian practice is to construct these from sections of concrete drain pipe, painted on the outside with bitumen, which is also used to seal joints between sections (Figure 10).

There are many different versions of the types of disposal facility just described. Some are in the open, some within buildings, but all are designed to prevent access of water to the contents.

It is often convenient to delay the passage of radionuclides contained in high volume low-level wastes before discharge into the environment in order to take advantage of radioactive decay. If the local soil and ground water regime are suitable this can often be done by discharge into seepage. In 1969 the Hanford (USA) laboratories discharged 5000 million gallons of low-level waste into the ground, containing nearly 4000 Ci of radionuclides. More than 99.9% of this activity is held on the sediments immediately below the disposal facilities.

METHODS FOR "SMALL USERS"

The International Atomic Energy Agency has issued a code of practice on management of radioactive wastes by hospitals, research institutes and industry when no special facilities are available on the site. It gives a review of the scope and nature of the necessary control, particularly in the establishment of permissible limits for discharge into the environment. These institutions rely heavily upon the public sewers and garbage disposal systems, depending upon the fact that in practice there are levels of radioactivity below which things are not regarded as radioactive. Sometimes this is the level at which measurement becomes practical and sometimes legal limits exist.

The ICRP and the IAEA both recognize 10^{-4} μCi/ml as the concentration in the sewer of an institution below which no restrictive action is required, irrespective of the nature of the radionuclide. This assumes that since large dilutions will occur before ingestion by the public, the individual at risk is the sewer worker. Plumbers can also encounter hazards in traps and filters, and they must be made aware of the situation. Similarly, although very low-level discharges to public disposal areas are usually acceptable, the waste management authorities must know of the practice so that they can warn their staff or undertake special procedures such as tip-and-fill operations. It is particularly important that scavenging should be prevented, because a very small source, normally innocuous, can be hazardous if carried for a long time in a pocket.

Apart from the use of public facilities, radioactive waste disposal for the "small user" does not differ in principle from the methods available to the larger producer of waste. A good deal of common sense and sense of proportion are required in dealing with the problem, aided by technical advice such as that in the IAEA report. It is also useful to remember that an ordinary illuminated wristwatch gives a count of several thousand per minute on a Geiger counter from the face side and almost zero from the back.

SEA DISPOSAL

In 1983 the London Dumping Convention passed a non-binding resolution which imposed an international moratorium on sea dumping of radioactive wastes. In 1993 a binding resolution against sea disposal of these wastes was passed by the LDC. A scientific evaluation of this ban will be conducted about the year 2019.

THE FUTURE

The accidents at Three Mile Island and Chernobyl have focused public attention on the potential for disaster. After the Chernobyl incident the WHO (World Health Organization) European Office set up a Working Group to consider harmonization of response to any similar incident which might occur in the future. The accident has proved conclusively that some nuclear accidents will have consequences for removed from the accident sites. Thus, it makes little sense for one nation to take measures in isolation. The report produced by the WHO European Office sets forth not only the effects of Chernobyl but also presents an excellent discussion of the foundations for international cooperation in case of a future accident.

With the reduction of tensions between the major nuclear powers the questions of nuclear weapons destruction and clearup of weapons producing plants have become the dominant issues. The technology for accomplishing these tasks is available. However, the massive sums necessary are not readily available. Nevertheless, these sums must be expended.

MANAGEMENT OF SOLID WASTE

INTEGRATED WASTE MANAGEMENT

The most recent comprehensive document produced by the federal government characterizes the materials commonly referred to as "municipal solid waste" ("MSW") as follows:

" … residential solid waste, with some contribution from commercial, institutional and industrial sources. In some areas, nonresidential wastes are managed separately, largely because industrial and some commercial sources produce relatively uniform waste in large quantities, which makes them more suitable for alternate disposal techniques or recycling. Hazardous wastes, as defined by Federal and State regulation, generally are managed outside the municipal solid waste stream. Exceptions are household hazardous wastes and hazardous wastes generated in very small quantities, which are often placed in the municipal solid waste stream by the generator."[1]

One of the most significant developments in municipal solid waste is the growing acceptance by citizens, all levels of government, and industries of a new overall philosophy concerning the management options available to address the problem of increased waste generation in the face of ever-decreasing land disposal sites. This philosophy is commonly known as "integrated waste management" and involves the reliance upon a hierarchy of options from most desirable to least desirable. The options are as follows:

Source reduction, limitation of the amount and/or toxicity of waste produced
Recycling, reuse of materials
Incineration, thermal reduction
Sanitary landfill, land disposal

While this hierarchy is little more than a common sense approach to municipal solid waste problems and the unit operations represented are not new, emphasis on the source reduction and recycling options as preferred represents a profound shift in attitudes toward municipal waste management. The traditional perspective that generators could produce discards without limit and depend on technological approaches to mitigate such wastes and any associated effects of treatment is no longer acceptable. This approach is not unique to the solid waste area but is a part of federal and state "pollution prevention" strategies, which emphasize avoidance of all types of pollution as preferable to "end of pipe" and other traditional methods of environmental regulation.

LEGISLATION

In 1984, amendments were made to the Resource Conservation and Recovery Act of 1976 ("RCRA"), the existing federal legislation covering solid waste management. Although the majority of these amendments were concerned with the regulation of hazardous waste as were the original RCRA mandates, some changes and additions were made to those provisions which were directed at nonhazardous waste.

The U.S. Environmental Protection Agency ("EPA") was directed to determine whether the existing criteria for land disposal of waste previously promulgated pursuant to Sections 1008(a) and 4004 of RCRA are adequate to protect human health and the environment from groundwater contamination and whether additional authorities are needed to enforce them. In addition, EPA must revise the criteria for those facilities which may receive hazardous household or small quantity generator waste. Furthermore, States were given three years to develop a program to ensure that municipal facilities met the existing criteria and the revised criteria when they are promulgated. Although enforcement is still largely a state matter, EPA is empowered, though not required, to enforce the criteria if states fail to comply with their obligations. As of this writing, revised criteria have been proposed but not yet adopted.[2]

Perhaps the most significant aspects of the federal law and its implementation involve initiatives with legislative roots in the original RCRA legislation which had historically received less attention than the Act's mandate to establish a hazardous waste management regulatory system. EPA has begun pursuing a number of activities such as conservation of virgin materials through guidelines establishing revised product specifications and similar initiatives.

State legislation has also witnessed a marked shift toward more conservation-oriented management schemes as well as stricter standards for processing and land disposal facilities. For example, at least twenty-four states have laws mandating the use of recovered materials in procurement processes. As of this writing, nine states had legislation requiring deposits on beverage containers and four states had mandatory recycling laws covering a wide range of materials. The scope of these new legislative initiatives and the myriad of options and alternatives they entail is beyond the purview of this analysis. What is apparent, however, is that source reduction and recycling represent an important part of modern waste management systems.

INTRODUCTION

Any discussion of solid waste neatly divides into three categories:

1) Source and composition,
2) Collection,
3) Disposal (or, hopefully, reuse).

Another natural division, resulting in part from the current regulatory states, is between hazardous and nonhazardous wastes. This section will deal primarily with nonhazardous wastes; specifically, with their source and composition and disposal. However, a brief discussion of hazardous wastes is included because of their importance in understanding the management of urban waste. More detailed discussion of hazardous waste is found in another section. The important problem of collection is also left to a special section on that subject.

Solid waste used to be considered any solid matter which was discarded as no longer being useful in the economy. During the last decade, this definition has been considerably broadened. For regulatory, and usually disposal purposes, solid waste is now defined as "any garbage or refuse, sludge from a waste treatment plant, water supply treatment plant, or air pollution control facility, and other discarded material, including solid, liquid, semi-solid, or contained gaseous material resulting from industrial, commercial, mining, and agricultural operations, and from community activities, but does not include solid or dissolved materials in domestic sewage, or solid or dissolved materials in irrigation return flows or industrial discharges which are point sources."[3] This definition is important because it indicates that all matter which is disposed of onto the land in any form is considered "solid waste." In addition that material which causes or significantly contributes to an increase in mortality or serious illness or poses a substantial hazard to human health or the environment, is considered a "hazardous waste." Hazardous wastes have been further defined by rulemaking to a limited set of materials and criteria such as toxicity, flammability, reactivity, or corrosivity.[4] The handling of hazardous waste requires special care and special permitting. Contrary to the management of normal refuse or solid waste, the generators, transporters, and disposers of hazardous wastes must meet stringent federal and state criteria and have considerable potential liability exposure. The disposers of solid waste which is not hazardous must meet state criteria that are not nearly as stringent as those for hazardous materials. Thus, while hazardous material in the past has been often disposed of along with all other refuse, today this is no longer the case. Industrial waste generators segregate their hazardous from their industrial waste so as to minimize their problems.

Solid wastes are one of the three major interacting *waste* vectors; the others are air and water pollutants. Solid wastes, if improperly handled, can be a source of land, air and water pollution. They are, also, at this writing, one of the most volatile public issues and a problem which is presenting many communities with significant institutional challenges.

Significant progress has been made in regulating the disposal of solid waste over the last decade. Open dumps which presented aesthetic as well as environmental challenges are for the most part closed. Regulations are in place for managing solid wastes in an acceptable manner. However, dumping into the ocean, which can create "dead" zones, hopefully will be eliminated. Nor have we eliminated the potential problems of leachate from landfills. Perhaps the most significant problem is the one of locating new landfills or substituting resource recovery, reuse and recycling capacity for landfill disposal. The technologies are available, but the economics still favor land disposal. In the early '70s there was great hope for massive resource recovery and recycle projects. Some of those, discussed later in this section, have not come to fruition because of economic and institutional barriers. Others have succeeded but the technology has not been spread, primarily because of economic barriers. Individual and community action to reduce the amount of wastes generated and collected has, in many areas of the country, been successful. For example, solid waste contains significant amounts of valuable material; 40% to 50% of urban waste is paper and, if recycled, can replace virgin stock equivalent to about 9 trees per person per year. In addition, the community and thus the taxpayer also saves in terms of lower collection and disposal costs. However, this is still of limited application because it is usually limited to newspapers, aluminum cans and perhaps glass. Both technology and institutional methodologies for recycling solid waste are still in their infancy and must gain momentum if we are to meet the challenge of solid waste management in the years to come.

REGULATION OF SOLID WASTE MANAGEMENT

Regulation of solid waste management has been scattered. The federal government, contrary to its prior policies in air and water, did not take a strong posture in solid waste management. It left regulatory initiative to the states and localities. These dealt with the solid waste management primarily through the licensing of collectors, through the "Utility Commissions" and adding to zoning ordinances regarding local landfills. Public health regulations also played a role with respect to reduction of rodents and pests at landfills. Air emissions from incinerators were regulated as were wastewater discharges. In the last several years a number of states have enacted and implemented legislation to regulate landfills. Probably the earliest and still among the most comprehensive is the regulatory effort of the State of California which has classified landfills which respect to underlying geological conditions in terms of what a landfill can and cannot accept.

A comprehensive solid waste law at the federal level was passed in 1976 as the "Resource Conservation and Recovery Act of 1976."[5] This act provides for federal assistance to states and regions developing and encouraging environmental sound disposal of solid waste and the maximum utilization of resources. It calls for state and regional plans and for federal assistance to develop these plans. It requires that each plan shall prohibit the establishment of open dumps and provides for the upgrading of open dumps that are currently in use. It also requires that criteria for sanitary landfills be established. However, it leaves enforcement to the states. At the same time, the Act under Subtitle C provides for federal regulation of the management of Hazardous Wastes. Many of these regulations have been issued but the critical ones covering treatment, storage and disposal facilities are still under review.

SOURCES OF WASTE

Solid waste differs from air and water pollutants in that it comes in discrete quanta and is very heterogeneous in nature. Both composition and rate vary significantly from day to day and from season to season as well as from otherwise similar sources.

The solid waste production in the United States is in excess of four billion tons/year and was expected to increase to five billion tons by 1980.[6] Table 1 breaks this down for the year 1967 by major source. However, waste generation appears to have stabilized despite increased loads from air and water pollution control facilities. How long this will last remains to be seen, if and when significant conversions to "coal as fuel" and more stringent air and water pollution control take place.

Urban Waste

Urban waste collected is between 4 and 8 lbs per person per day, with typical values lying between 4.5 and 5.5 lbs per day. This differs from the amount generated because of self and private disposal. The major wastes included in this category are tabulated in Table 2, which includes a summary of disposal trends. One should be careful in the terminology because often domestic and municipal are used interchangeably to indicate the total refuse picked up from residential (domestic), institutional, small business and light industrial sources.

Some further definition of terms may be useful at this point. In general usage many of the terms have been used interchangeably. However, an effort to standardize the terminology was made by the Institute for Solid Waste of the American Public Works Association and the Office of Solid Waste Management of the Environmental Protection Agency.[7] The standard usage of terms detailed by these groups is summarized here:

Refuse All solid waste matter.
Garbage The animal and vegetable waste resulting from the preparation of food.
Rubbish The waste from homes, small businesses, and so on excluding garbage.
Trash Used equivalent to rubbish.
Litter Street refuse.
Industrial Waste Specialized refuse from manufacturing plants, and usually excludes rubbish.

TABLE 1
Major sources of waste matter United States 1967[5]

	Solids generated	
Source	lab/cap/day	Million tons/yr

Mineral	30.8	1126
Federal	1.2	43
Total	100.0	3650

Domestic waste composition will vary seasonally, as well as with locale and economic status. Typical analyses for domestic plus municipal refuse are shown in Table 3. As can be seen in a comparison of the data, the composition has not changed drastically with time except for a significant reduction in ash because of the change from coal as a home heating fuel. Location variations noted are as great or greater. A study of seasonal variations made in 1939 for New York City also showed greater variations: the ranges were garbage, 44 to 3.5%; and metal, 11.6 to 3.1%.[8] Base data have been difficult to obtain because of the many variabilities in the base. The most significant variables include the economic level of the area, the ratio of commercial to residential property, the type of commercial establishments and the housing density and age. The entire picture on obtaining accurate data on urban and/or domestic refuse is further complicated by the sampling problem. A discussion of this problem is beyond the scope of this work; the reader is referred to some basic work in this area by Carruth.[9] An excellent review of sampling and testing has been prepared by the Institute of Solid Wastes.[10] Further work is being done in this area by ASTM's D-34 Committee.

The ultimate chemical composition of municipal refuse has been examined by a number of investigators. Table 4 gives the range of values to be expected. Recently 0.3 to 0.5% chloride has been found in refuse independent of the presence of polyvinyl chloride; this is due to the presence of salt primarily.[11]

Density of municipal refuse varies with the load applied to it. Typically household refuse has a density of 350–400 pounds per cubic yard. Transfer stations and/or landfill operations can compact it to between 500 and 800 lbs per cubic yard depending upon the material and conditions. The effect of compression on density for the Chandler, Arizona refuse is shown in Figure 1. High pressure compaction (see Compaction) can increase the density to 1200 to 1400 lbs per cubic yard.

Industrial Wastes

Industrial wastes amount to about 115 million tons annually. They include any discarded solid materials resulting from an

TABLE 2
Composition of wastes from urban sources[6]

Urban sources	Waste	Composition	Disposal, present
Domestic	Garbage	Wastes from preparation, handling and sale of food	
	Rubbish, trash	Paper, wool, excelsior, rags, yard trimmings, metals, dirt, glass, crockery, minerals	Landfill
	Ashes	Residue from fuel and combustion of solid wastes	Incineration
	Bulky wastes	Furniture, appliances, rubber tires	Dumping
Commercial	Garbage	Same as domestic	Landfill
Institutional	Rubbish, trash	Same as domestic	Incineration
	Ashes	Same as domestic	
	Demolition wastes, urban renewal, expressway	Lumber, pipes, brick masonry, asphaltic material and other construction materials	Dumping Landfill
	Construction wastes	Scrap lumber, pipe, concrete, other construction materials	Dumping Landfill Open burning
	Special wastes	Hazardous solids and semiliquids, explosives, pathological wastes, radioactive wastes	Burial, incineration Special
Municipal streets, incinerators, sewage treatment plants, septic tanks	Street refuse	Sweepings, dirt, leaves	Fill
	Dead animals	Cats, dogs, horses, etc.	Bury or incinerate
	Abandoned vehicles	Unwanted cars and trucks	Reclaim
	Fly ash, incinerator residue, boiler slag	Boiler house cinders, metal scarps, shavings, minerals	Landfill or dump Landfill
	Sewage treatment residue	Solids and sludge	—

industrial operation or establishment with the exception of dissolved or suspended solids in domestic or industrial waste waters. The composition and quantity of industrial solid wastes vary significantly from location to location, as well as between industries and within a given industry. Table 5 lists the type of wastes to be expected from the various SIC Industrial Groups. A large fraction of the wastes are generally common to most industries and are listed on Table 6.

Data on the amounts of waste generated by or collected from various industries is very limited. Industry, quite naturally, has considered this type of data confidential in that it often reveals significant process and economic information. Average data, even if available, are of limited value because wide variations can result from process differences, process efficiencies and direct recycle, as shown in a study based on detailed interviews. The results of this study giving total waste by industry are summarized in Table 7. Industry waste production on a unit per employee basis vary widely and are summarized for large and small companies in Tables 8 and 9.

Increased efficiency as well as new uses for present industrial waste streams will alter both the quantity and composition of the material for disposal in the next decade. For example, saw mill waste is being reprocessed into composition board and this utilization could essentially eliminate this waste stream. Only limited projections can and have been made and these show only a reduction in saw mill wastes.[12] Conversely, enforcement of air pollution statutes will increase the amount of potential solid wastes significantly. Greater purification of industrial wastewater will also affect the solid waste load.

Agricultural Wastes

Agricultural wastes are principally organic as indicated in Table 10. The exceptions are chemicals used in various facets of farming such as pesticides, containers, and small amounts

of miscellaneous waste matter resulting from maintenance and general housekeeping.

Most crop waste is either plowed back into the soil or composted. Some open burning takes place. In some special cases such as bagasse (sugar cane stalks) industries have been established to utilize the waste material. Essentially none of this material finds it way into the usual disposal facilities.

Animal wastes pose a different problem because much is produced in very concentrated areas such as feed lots or poultry farms. The disposal of these wastes is posing a greater problem than crop waste, but may be more easily solved because it is concentrated and therefore susceptible to processing without collection. Average waste yields for a variety of domestic animals are summarized on Table 11.

Mineral Wastes

Mineral wastes including solids generated in mining, milling and processing industries are expected to reach between two and four billion tons per year in 1990. In 1965 this waste amounted to 1.4 billion tons, as summarized in Table 12.

Hazardous Wastes

Hazardous wastes as defined by the federal government and in many cases similarly by the states, must be receiving special handling. These wastes generally include materials that are injurious to human health, toxic, can cause irreversible environmental damage, such as high concentrations of pesticides, are corrosive, reactive (form toxic gases), or highly inflammable. These wastes are defined in Federal Regulations (40CFR261). They require special management from generation through treatment and disposal as defined again by Federal Regulations. A detailed discussion of Hazardous Waste Management is covered in a section on Hazardous Waste.

Processing Methods

A variety of processing methods, as summarized in Table 13, are available at present for handling solid wastes. Most have been in use in some modification for at least the last 50 years. The choice of processing method will depend not only on the type of waste but also on location, sources, quantity of waste, method of collection, public opinion, and ultimately economics.

Solid waste management was a 4.5 billion dollar industry in 1968. It is only in recent years that the public has begun to worry about disposal of solids. Prior to that it was "out-of-sight, out-of-mind." With ever growing amounts of solid waste as detailed in the discussion on sources, and concerns about pollution of ground and drinking water as well as release of hazardous materials, public pressure is becoming a major factor in any decision on waste management.

The major disposal methods in use are landfill and incineration. Of potential interest in the United States are high pressure compaction and reclamation by recycling. Recycling is being used, but requires solution of institutional and technological barriers before becoming a major factor. Compaction is utilized in at least one major facility in the Meadowlands in New Jersey. Composting is practiced in Europe, but also has not been successfully applied in the United States although it does have potential. There are new processes and techniques appearing for waste disposal and for the first time an organized research and development effort was mounted in the early '70s to look at solid waste disposal; it has slowed down but there is ample opportunity for further progress.

Disposal methods could be discussed from the point of view of source: a brief summary of the most used methods for a variety of sources may be found in Table 14. This discussion will instead focus on the disposal methods most commonly in use today, landfill and incineration, followed by discussion of compaction, composting, and some of the newer disposal techniques.

The oldest method of disposal is dumping either on land or sea. Here dumping in distinguished from Sanitary Landfill (see below). Dumping costs between $6 and $10 per ton and has been used for all waste materials. It is totally unsatisfactory for putrescible materials such as food wastes and unsatisfactory from a public health as well as aesthetic and land use viewpoint, even for inert material such as demolition waste.

Open burning is often used for demolition waste, tree branches and stumps, and similar items; it is unacceptable because of the air pollution it creates. Neither dumping nor open burning have a place in the modern waste disposal scheme and are illegal.

Sanitary Landfill

Landfill is the most widely used method of waste disposal. There are 8900 authorized sites (about half publicly operated) used by the 6300 communities surveyed in 1968.[14] There appeared to be an equal number of unauthorized dumps. Unfortunately only 6% of the sites were considered to be "truly" sanitary. The remainder fell either into Category B or C on the US Public Health Service Classification Scale, summarized in

TABLE 5
Sources and types of industrial wastes

SIC group classification	Waste generating process	Expected specific wastes
Plumbing, heating, air conditioning Special trade contractors	Manufacture and installation in homes, buildings, and factories	Scrap metal from piping and duct work; rubber, paper, and insulating materials, miscellaneous construction and demolition debris
Ordnance and accessories	Manufacturing and assembling	Metals, plastic, rubber, paper, wood, cloth, and chemical residues
Food and kindred products	Processing, packaging, and shipping	Meats, fats, oils, bones, offal, vegetables, nuts and shells, and cereals
Textile mill products	Weaving, processing, dyeing, and shipping	Cloth and fiber residues
Apparel and other finished products	Cutting, sewing, sizing, and pressing	Cloth and fibers, metals, plastics, and rubber
Lumber and wood products	Sawmills, mill work plants, wooden container, miscellaneous wood products, manufacturing	Scrap wood, shavings, sawdust; in some instances metals, plastics, fibers, glues, sealers, paints, and solvents
Furniture, wood	Manufacture of household and office furniture, partitions, office and store fixtures, and mattresses	Those listed under Code 24, and in addition cloth and padding residues
Furniture, metal	Manufacture of household and office furniture, lockers, bedsprings, and frames	Metals, plastics, resins, glass, wood, rubber, adhesives, cloth, and paper
Paper and allied products	Paper manufacture, conversion of paper and paperboard, manufacture of paperboard boxes and containers	Paper and fiber residues, chemicals, paper coatings and fillers, inks, glues, and fasteners
Printing and publishing	Newspaper publishing, printing, lithography, engraving, and bookbinding	Paper, newsprint, cardboard, metals, chemicals, cloth, inks, and glues
Chemicals and related products	Manufacture and preparation of organic chemicals (ranges from drugs and soups to paints and varnishes, and explosives)	Organic and inorganic chemicals, metals, plastics, rubber, glass, oils, paints, solvents and pigments
Petroleum refining and related industries	Manufacture of paving and roofing materials	Asphalt and tars, felts, asbestos, paper, cloth, and fiber
Rubber and miscellaneous plastic products	Manufacture of fabricated rubber and plastic products	Scrap rubber and plastics, lampblack, curing compounds, and dyes
Leather and leather products	Leather tanning and finishing: manufacture of leather belting and packing	Scrap leather, thread, dyes, oils, processing and curing compounds
Electrical	Manufacture of electric equipment, appliances, and communication apparatus, machining, drawing, forming, welding, stamping, winding, painting, plating, baking, and firing operations	Metal scrap, carbon, glass, exotic metals, rubber, plastics, resins, fibers, cloth residues
Transportation equipment	Manufacture of motor vehicles, truck and bus bodies, motor vehicle parts and accessories, aircraft and parts, ship and boat building and repairing, motorcycles and bicycles and parts, etc.	Metal scrap, glass, fiber, wood, rubber, plastics, cloth, paints, solvents, petroleum products
Professional, scientific controlling instruments	Manufacture of engineering, laboratory, and research instruments and associated equipment	Metals, plastics, resins, glass, wood, rubber, fibers, and abrasives
Miscellaneous manufacturing	Manufacture of jewelry, silverware, plated ware, toys, amusement, sporting and athletic goods, costume novelties, buttons, brooms, brushes, signs, and advertising displays	Metals, glass, plastics, resins, leather, rubber, composition, bone, cloth, straw, adhesives, paints, solvent
Stone, clay, and glass products	Manufacture of flat glass, fabrication or forming of glass: manufacturer of concrete, gypsum, and plaster products; forming and processing of stone and stone products, abrasives, asbestos,and miscellaneous nonmineral products.	Glass, cement, clay, ceramics, gypsum, asbestos, stone, paper, and abrasives
Primary metal industries	Melting, casting, forging, drawing, rolling, forming, and extruding operations	Ferrous and nonferrous metals scrap, slag, cores, patterns, bonding agents
Fabricated metal products	Manufacture of metal cans, hand tools, general hardware, nonelectric heating apparatus, plumbing fixtures, fabricated structural products, wire, farm machinery and equipment, coating and engraving of metal	Metals, ceramics, sand, slag, scale, coatings, solvents, lubricants, pickling liquors
Machinery (except electrical)	Manufacture of equipment for construction, mining, elevators, moving stairways, conveyors, industrial trucks, trailers, stackers, machine tools, etc.	Slag, sand, cores, metal scrap, wood, plastics, resins, rubber, cloth, paint solvents, petroleum products

Table 15. There are additional classifications with respect to use in force in California and suggested in the new Federal Regulations.[15] There is an increase in "Sanitary Fills" and an elimination of "Dumps."

Sanitary landfill is an acceptable method of disposal of solids and provides for the ultimate disposal of many types of waste; exceptions are non-degradable materials such as plastic or aluminum which are placed in landfills. Other items material, toxic chemicals, and hazardous materials, are not allowed in landfills for safety. Where land is plentiful, or marginal areas are available for reclamation, sanitary landfills offer a number of advantages over other disposal methods including low initial and operating costs. Other advantages and disadvantages are summarized in Table 16. Sanitary landfill is basically the dumping of wastes followed by compaction and the daily application of an earth cover. This situation has improved in the last decade and by the mid-1980s—all landfills will be sanitary. Several techniques are available, some of which are depicted in Figure 2, depending on the type of site available. The one constant in all operations is the daily earth cover, preferably a sandy loam, amounting to, usually, one part earth for every four parts refuse. Another, which is being required in new landfills, is leachate collection and treatment. In addition these types of waste disposal are limited to "non-hazardous" materials unless the landfill is especially constructed, licensed and managed.

Proper site selection is as critical to a satisfactory landfill as is sound operation. Selection criteria include proper ground and surface water drainage and isolation as well as leachate collection and treatment, to prevent pollution of the ground water table. Location in a drainage basin near streams or lakes and in or close to the ground water table present special problems and should be avoided, where possible. Placement in the 100 year flood plain is prohibited. Accessibility of cover material is an important consideration. The use of tidal areas and marshes is prohibited. Dry pits, abandoned quarries and certain types of canyons of depressions are often satisfactory landfill sites.

The size of landfills is often restricted by the amount of land available. The capacity can be estimated with a fair degree of accuracy. Refuse on arrival may vary in density from 300 to 800 pounds per cubic yard, depending on the delivery method. Typically the density in the "fill," of the initial compaction with a typical crawler tractor will be 1000 lbs/yd for a single lift (layer) with a depth of 20 feet of less. For multiple lifts the initial density can reach 1250 lbs/yd. This initial loading increases by as much as 50% over a period of time as further compaction and decomposition takes place.[16]

Much of the material in the sanitary landfill decomposes over a period of between three and ten years depending on climate, permeability of the cover, composition of the refuse and degree of compaction. The decomposition in sanitary landfills is anaerobic as compared to aerobic degradation often found in other types of fill. Temperatures typically reach 120°F in the fill as a result of the degradation. The principal gas products are carbon dioxide and methane. The greatest gas production takes place in the first two years, according to a study made at the University of Washington. Ammonia and hydrogen sulfide are not problems in sanitary landfills although small amounts of these gases are produced. Odors resulting from the decomposition of putrescible material can be controlled by observing good operating practice; that is, covering the fill continuously and sealing surface cracks. Fire hazard and insects and vermin are not a problem, as compared to dumps, in a properly operated sanitary landfill although chemical control of the latter two is sometimes required.

Completed landfills are suitable for use as recreational facilities, airfields and parking areas; light industrial buildings may be erected on landfill. Building of residential structures on fill requires special precautions because of the potential hazards associated with the evolution of methane and other decomposition gases.

The cost of operating a sanitary landfill makes it an attractive means of disposal where land is available. Costs for a

[d] For Canning and Preserving (SIC 203), no individual firm data were available. The industry total developed for the county as a whole was divided by the total employment in the industry (specially tabulated) to arrive at the multiplier. See text for further explanation.
[e] Data not available.

sanitary fill will vary between $3 and $10 per ton, depending on location and size of the fill. Small fills, handling less than 50,000 tons per year, will have a unit cost of $5 to $10 per ton. A large urban fill more typically shows costs of $3 to $6 per ton. The wide variation is a result of location differences, which include differences in land acquisition costs, labor costs and operating differences due to local surface conditions and requirements.

The use of landfill will continue; however, its future, particularly in densely populated urban areas, is in doubt. Land is at a premium for this type of application close to urban centers. What land is available must be preserved for non-combustible material and ashes. For examples, one urban county in New Jersey has less than three years landfill capacity available and in portions of Long Island no more land for landfill is available. Hauling costs too, as well as public resistance in more rural areas is making landfill less attractive for urban areas such as metropolitan New York. Finally, landfill does not provide for maximizing the value of refuse as a source of raw materials.

Recent studies to find alternatives to traditional landfill practices include a demonstration of shredding prior to filling. Only domestic refuse was shredded; the product was a superior fill compared to “raw” refuse. It could be left uncovered with satisfactory sanitary and aesthetic results and was easier to dump and compact. Flies and rats did not breed on the shredded refuse.

The compacted, uncovered fill also had better weathering and load bearing characteristics. This can be achieved at a cost of about $5.00 per ton in a 65,000 ton per year operation.[17] The method has some attractive features, and some commercial facilities including one in Monmouth Country, NJ, which incorporates some recycle, use this principle. However, operating and investment costs do appear to be higher than the more traditional method of filling “raw,” as collected, refuse.

Baling of refuse may be particularly attractive where landfill sites are not locally available. A feasibility study was carried out in Chicago which showed that this method overcomes many of the present objections to landfill. The

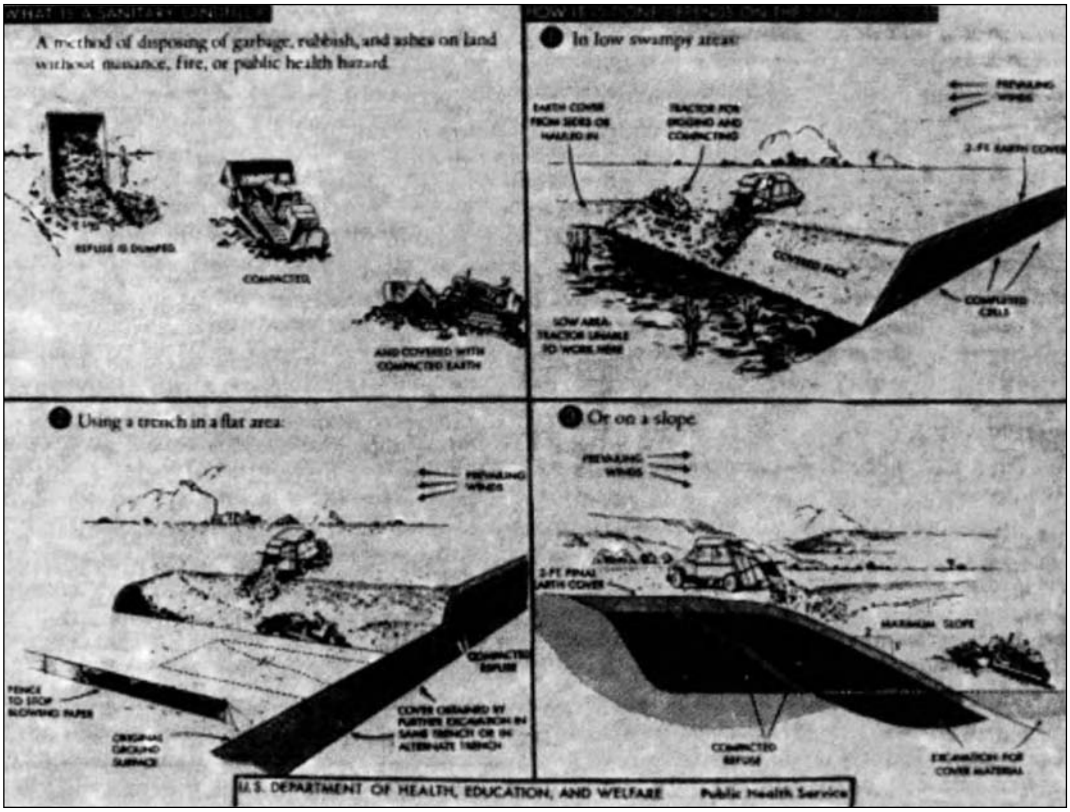

FIGURE 2 Sanitary land fill operations: Credit: US Public Health Service.

Japanese have been leaders in this area using high pressure presses to provide solid cubes suitable for use in building new land in tidal areas. A facility is being successfully operated in New Jersey. More details may be found in the discussion of compaction.

Incineration

Incineration is essentially a method for reducing waste volume and at the same time producing an inert, essentially inorganic, solid effluent from material which is largely organic. Typical feed analyses are shown in Table 4. In addition to the solid product a gas is produced consisting mainly of CO_2, H_2, O_2 and N_2 but containing other gaseous components in tract quantities depending on the type of material burned and the operating conditions. Incineration is not an ultimate disposal method in that the solid residue which is primarily an ash containing some metal must still be disposed of, usually as landfill. The primary advantage is that it reduces the volume to be disposed of and results in a "clean" inert fill. For every 100 tons of material fed to the incinerator approximately 20 tons of residue result. The volume reduction is even more significant, often resulting in a 90% lower solids volume for organic materials.

The theory of incinerator operation is very simple. A unit is designed to expose combustible material to sufficient air at high temperature to achieve complete combustion. Combustion is usually carried out in fuel beds to ensure good contact of air and refuse. Several types of configurations are used to achieve contact; these include concurrent flow of fuel and air-underfire, countercurrent flow of fuel and air-overfire, flow of fuel and air at an angle to each other—crossfeed; and combinations of these. The combustion is basically the same for all methods in that at the ignition front oxygen is rapidly consumed in the reaction $O_2 + C \rightarrow CO_2$ and if oxygen is depleted $CO_2 + C \rightarrow 2CO$. Therefore, sufficient oxygen must be available to obtain complete combustion; usually this is provided by adding additional air in the chamber above the fuel. Incinerators are typically operated with about 50 to 150% excess air in order that the gas temperatures do not drop below that required for good odor-free combustion; this is usually in the 1700–2300°F range. Recent trends have been to go to the higher part of this range while old units often operate at 1600°F or below. The effect of excess air on gas composition is summarized in Table 17 for a typical refuse. A detailed discussion of typical air requirements and their effect on the thermal balance may be found in Principles and Practices of Incineration.[18]

Trace components in the incinerator-start gas include some SO_2 and NO_x. The former depends on the sulfur in the refuse and is typically around 0.01 to 0.02%. Nitrogen oxide is generally formed in combustion processes and depends on the amount of excess air and to some degree the operating temperature of the incinerator. Typical values of two pounds of equivalent NO_2 per ton of refuse have been reported.[19,20]

TABLE 10[12]

Agricultural waste (1966)

Waste	Composition	Amount (million tons/yr)
Crop residue	Corn stalks, grain stubble, cull, fruit and vegetable, vines, rice hulls, bagasse, tree prunings, etc.	552
Animal manure (paunch manure)	Organic matter, protein, fat, carbohydrates, nitrogen, phosphorus etc.	1.532[a]
Poultry manure	Same as animal manure	30[b]
Animal carcasses	—	—
Forest operations	—	25
Pesticides, insecticides, etc. residue and containers	Chlorinated hydrocarbons, organophosphorus compounds, other organics and inorganics, e.g. sulfur, lead arsenate, etc.	—

This is equivalent to 500 to 1000 ppm of NO^x in the off-gas depending on the refuse composition and the amount of excess air. Other trace components can be found in the off-gas and air summarized in Table 18. Their presence or absence is very much dependent on the type of refuse incinerated and the operating conditions.

Particulate matter is also present in the stack gas and is removed by the usual techniques discussed in the section on Air Pollution. Particulate loadings of 3 to 25 pounds per tonne of refuse burned have been reported.[21,22] Typically, particles range from 5 to 350 microns in size with 30% by weight under 10 microns and 75% less than 200 microns in size.

Solids residue from incinerators will vary widely with the type of feed and incinerator operating conditions. Typical residues have been examined by the Bureau of Mines. The results of this work are summarized in Table 19. A typical ash and slag chemical analysis may be found in Table 20. This residue can be utilized in road fill or separated (see Reclamation).

Incineration can effectively be divided into local, onsite and central methods. The basic principles are the same but the applications vary considerably. Central incineration facilities handle refuse from many sources and a wide variety of feeds. Local incinerators handle either special feeds, onsite, such as industrial or hospital wastes, or serve a particular small location such as an apartment house. Size is not necessarily a criterion although generally central incineration facilities have capacities in excess of 100 tons per day.

At the present time there are about 200 central incineration facilities in use (making this type of waste reduction facility the most prevalent one). Central incineration handled about 15 million tons of waste annually and is concentrated in the northeastern part of the United States. It is also widely practiced in Europe. The practice of incineration of wastes was growing as land for fill, particularly in urban areas, becomes scarcer and technological improvements provide more efficient and cleaner systems.

A typical incineration facility will have a capacity ranging from 100 to 1200 tons per day with individual furnaces usually limited to a 300 ton per day rating. Most large incinerators today are continuous-feed rather than batch design because operation is more controlled and easier. In addition the absence of the heating and cooling cycle results in lower maintenance and a higher capacity per investment dollar. Air pollution control is improved significantly in continuous-feed incinerators are compared to batch plants.

A large central incineration facility is schematically shown in Figure 3. It can be divided into five areas: (1) the receiving section which includes the weight station, storage hopper and bucket crane; (2) the furnace—which includes the charging hopper, stokers, furnace chamber and air feed system; (3) the effluent gas treating facilities; (4) the ash handling system; and (5) the cooling water system. The particular system shown does not have provision for waste-heat recovery; only a few systems incorporate this at present.

For mixed refuse, a typical refractory-wall incinerator will have 12.7 cubic feet in the primary furnace chamber and 18.5 cubic feet in the secondary chamber per ton of refuse per 24 hours with a grate loading of 77 pounds per square foot per hour. Volume and loading requirements will vary with the type of feed as well as furnace configuration. Typically the values quoted correspond to a 12,500 Btu per hour per cubic foot heat release. A detailed discussion of furnace design is

TABLE 13
Solid waste management methods

Type	Present usage	Relative cost	Items disposed of	Principal benefits
Sanitary landfill	Most used (80%) decreasing[9]	Low[b]	All except hazardous materials	Low initial cost, takes all items may reclaim land
Central incineration	Increasing second largest method (4%)	High	All burnable except special items and over-sized items	Reduces volume, clean product can produce by-product items
Open burning	Illegal	Low	Construction wastes, leaves, agricultural waste	
Compaction, high pressure	Two plants in operation	Medium-high	All except hazardous materials	Produces dense, essentially inert blocks for fill
Composting	Very few	Medium-high	Organic only. No tires, large pieces	Provides soil conditioner
Garbage grinding	Large number home units	High	Organic only	Reduces domestic collections
Dumping	Not legal	Lowest	Non-putrescibles	
Recycling	Only for selected materials and areas, increasing	High	Selected. Depends on process	Reduces quantity for ultimate disposal

[a] Many landfills are not sanitary but are included in this classification.

[b] Low under \$10/ton; Medium \$10 to \$30/ton; High \$30 + ton.

beyond the scope of this work and the reader is referred to an excellent work by Richard C. Corey.[22]

Incineration in the past has received a bad reputation because of poor control of gaseous effluents and sloppy handling of solid and liquid effluents. With proper design and operation an incinerator can meet or exceed requirements on all effluent discharges. A modern central incinerator is a more complex operation than a large commercial steam boiler. It therefore requires skilled operating, maintenance and supervisory personnel to ensure efficient operation.

At the present time control of particulate matter in the effluent gas is the most critical problem in incinerator design

TABLE 14
Waste source and disposal methods

and operation. A typical modern facility will include either a wet scrubber or a spray chamber followed by solid separation in a baghouse filter or electrostatic precipitator. These methods can achieve up to 99% removal of particulate matter, which will meet the code requirement of 0.0 pound 0.03 grams per DSCF particulate in flue gas at 50% excess air in almost all cases. The costs for this required cleanup are significant and can be as high as $2000 per daily ton of refuse capacity (see Air Pollution Control). Odor control is achieved by providing adequate time (0.5 sec) in the combustion chamber at temperatures above 1500°F. As incineration temperatures in modern units are between 1800 and 2200°F this poses no problem.

Waste heat recovery has been practiced to only a very limited degree in the United States. Less than 10% of the incinerators surveyed in 1966 had waste heat recovery facilities. Presently, there are six major resource recovery mass burning units in the United States and about a dozen are in the design or construction stage. This is in contrast to the practice in Europe where waste heat recovery is practiced in a large number of units. Those US plants that do recovery of heat incorporate the water wall principle used in furnaces; in contrast, a few refuse-derived fuel units have been built modifying existing boilers previously used as suspension units; again this compares to the European practice where water wall incinerators are common.

One water-wall incinerator (600T/D) has been in operation since 1967 at the US Navy Base, Norfolk, Va.[23] Several reasons have been advanced for the lack of heat recovery in the United States. These included adverse economics. In addition corrosion problems and much slagging of the walls (due apparently to differences in waste composition) seems to have held back the use of water walls. With new technology, and a tighter fuel picture, waste heat recovery in incinerators will become commonplace in the next decade. In general municipal service, a 1200 per day ton facility in Montreal went on stream in 1970 and produces 100,000 pounds of steam per hour and a 1600 ton per day facility in Chicago started up in 1971. Cogeneration facilities that generate steam and electricity are now being designed.

The investment and operating costs for incinerators are high and to date have been one of the major deterrents to wider use. Typical installations of the 600 to 1000 ton per day range require an investment of $20,000 per ton or installed daily capacity depending in part on the air pollution control devices which can account for 20% of the total cost as well as size. Water-wall installations typically will run more than refractory lined incinerators; the 1600 ton per day Northwest Chicago plant cost about $16,000 per ton. Present costs are about $40–45,000 per installed ton.

Operating costs including amortization of the investment will vary between $50 and $200 per ton. Actual values for generated steam have not been published but estimates indicate

TABLE 15
U.S. Public health service landfill classification

A: *Sanitary*
Landfill operated without public nuisance or public health hazard; covered daily and adequately, no deliberate burning practiced.

B: Operated without public nuisance or public health hazard, but location permits modification of "A" such as burning of certain types of waste at site, or covering of fill only three times weekly.

C: Operating techniques permit development of public nuisance and potential health hazards, such as fly breeding, rodent substance, and odors.

TABLE 16
Sanitary landfill—advantages and disadvantages

Advantages

1) Most economical method when land is available.
2) Low initial investment.
3) Complete and final disposal.
4) Short period of time from need to full operation.
5) Flexible daily capacity with same working force.
6) Reclamation of marginal land for recreational and other uses.
7) All types of waste are acceptable.

Disadvantages

1) Lack of close-by suitable land in urban areas may make uneconomical.
2) Public opposition in, or near, residential areas.
3) Settling after completion means continued maintenance.
4) Public nuisance and health hazard is not properly operated.
5) Products of decomposition, methane and other gases, may create hazard.
6) Require special practices for construction on completed fill.

TABLE 18
Incinerator stack gas contaminants

Component	Amounts reported
Organic Acids	
Formic	25–133 ppm (31)
Palmitic	0.6 lbs/ton of refuse (32)
Acetic (all organics)	40–600 mg m^3 (33)
Esters	
Methyl acetate	5–137 ppm (32)
Ethyl acetate	—
Aldehydes	
Acetaldehyde	2.8×10^{-4} (33)
Formaldehyde	1.1 lbs/ton refuse (32)
Hydrocarbons	4 μgm/gm of particulate (29[a])
Halogenated Hydrocarbons	
(depends on plastics and aerosols)	6–120 mg m^3 (33)
	0.44–10 ppm (31)
	0.3 lbs/ton refuse (32)
Ammonia	0.15–1.5 ppm (31)
Nitrogen Dioxide	0.15–5 mg m^3 (33)
Nitrogen Trioxide	4–100 mg/m^3 (33)
HCl	300–1200 mg/kg refuse (33)
	30–350 mg/m^3 (33)
SO_2	0.25–1.2 ppm (31)
	1.9 lbs/ton refuse (32)

[a] When burning rubber.

a potential recovery of $10 to $15 per ton or refuse for the steam sold.

In addition to the installation of units with waste heat recovery facilities the trend will be to longer installations to take advantage of the economics of size. However, small skid-mounted units with capacities in the range of 20 ton to 50 tons per day are available at a cost which will make central incineration for smaller communities economical possible. The first of these units that met most air pollution codes was marketed by Combustion Engineering in the late ’60s. It was ahead of its time and did not enjoy success. However, similar size units with energy recovery are now finding a good acceptability. Another development will be the installation of more combined sewage sludge-refuse incineration facilities using the Nichols multiple earth rotating grid or similar installations.

Rotary kiln incinerators have been successfully utilized in handling mixed wastes, often predominantly industrial wastes. They are particularly useful where long residence times are required to insure complete combustion. Their disadvantages center primarily around high maintenance costs. One of these incinerators has been in operation at Dow Chemical, Midland, Michigan for almost 30 years.

Incineration in fluidized beds was demonstrated by Black and Clawson in a facility in Franklin, Ohio, as well as by Combustion Power Co. which combined a fluid bed combustor with a gas-turbine generator to produce power from 400 tons per day of refuse. The latter demonstrations had technical difficulties and fluidized bed technology has not been commercialized.

Numerous on-site incinerators are operated with satisfactory results for the reduction of industrial wastes. These facilities are usually specially designed to handle one type of refuse. Typical materials that are incinerated include plastics, rubber, wood scrap and paper. The economics of waste recovery are changing so that often these materials are no longer burned. For example wood chips and sawdust at sawmills are often sent to paper-mills or composition board producers as feed, where formerly they were burned. Insulated copper wire and automobiles are incinerated to remove the organic components prior to recovery of the metal. Special liquid

$Fe2O_3$	8%	P_2O_5	2%
TiO_2	3%	BaO	0.6%
CaO	10%	SO_3	0.3%
MgO	3%	ZnO	0.5%

wastes such as water containing organics are incinerated. The special applications are numerous, including the incineration of radioactively contaminated wastes.

In addition to the more traditional incinerators, whether rectangular or cylindrical, special designs are employed in industrial waste disposal. For example shredded plastic[24] as well as “white water” from paper-mills[25] is incinerated in a fluidized-bed combustion chamber. Industrial sludge is being burned in a rotary kiln[26] by Kodak. Dow Chemical has had a rotary kiln on line for over 20 years handling a mix of refuse and industrial waste. Solid cyanide waste in automobile plants is put into solution and then burned while aluminum chloride sludge from a petrochemical operation can be burned to produce HCl and alumina.

Although hauling to landfill sites is the present disposal method for many industries, on-site incineration of industrial wastes will receive wider use for waste disposal where recycle is not possible and volume is sufficient, in excess of 500 lb/day, to justify an installation.

Hospital wastes are now commonly being disposed of in onsite incinerators. To eliminate the possibility of spreading infection, wastes should be promptly incinerated. This is best done in an onsite facility. The average load for hospital incinerators is about 20 pounds per day per patient with a very high fraction of garbage and paper and plastic throw-away products.[27] Provision must also be made to handle pathological wastes, therefore combustion temperatures should be in excess of 2000°F and adequate residence time for the gases at 1500°F should be provided.

Refuse-Derived Fuel

In the past there has been some objection to direct firing of refuse. Partly these are aesthetic in nature and partly they result from the high variability of raw refuse. At one time, it was thought that firing of coal and refuse might overcome a number of these problems. Indeed it did, but not the institutional problems of handling raw refuse. As a result several processes were developed to produce refuse-derived fuel (RDF). These processes have been in development for the past ten years and have not found, to date, wide commercial application. Essentially, raw refuse is separated into the organic and paper portion, and the recoverable, recyclable components, such as ferrous metal, aluminum, glass. This separation is carried out after shredding, as discussed under the section on Reclamation, Reuse and Conversion. The shredded material can then be fed as is; and that form is the lowest grade of RDF. Some cases it is palletized, and fired as pellets. Palletizing reduces handling problems and increases storability at the expense of an additional processing step. RDF has been successfully co-fired with coal and it is anticipated that over the next ten years a number of RDF fired power boilers will be installed either for steam generation or electric power generation.

Compaction

The reduction of waste volume is receiving considerable attention in an effort to reduce collection costs; compaction is one of the favored methods to achieve this reduction. High pressure compaction has been developed by Tezuka Kosan of Japan to provide a high density product suitable as an essentially inert fill or even as a building material.[28] Using this product as a base covered with a minimal earth over, the Japanese have reclaimed land from tidal areas having a water depth of 10 feet.[29]

The Japanese process shown in Figure 4 collects refuse and subjects it to three stages of compression with the final main press exerting 3000 psi on the refuse. The resulting bale is usually wrapped in chicken wire and coated with asphalt for ease of handling and to prevent crumbling and/or leakage. The bales have a density of between 1900 and 2300 pounds per cubic yard and result in a volume reduction of about 90%. This compares to densities of about 1200 to 1500 pounds per cubic yard achieved in lower pressure compaction. The product bale is inert and such bales have survived exposure in Tokyo Bay for three years to date without visible signs of degradation.

Studies by the Japanese indicate that the high pressure squeezing and resultant elevated temperatures decrease the BOD from 6000 in the raw refuse to 200 in the product. Similarly the COD of 8000 (which compares to about 14,000 in US refuse) was reduced to about 150. Inspection of the interior of the bale shows a homogenous, plastic like mass. The bale will not support vermin, rodents, or insects and is essentially odor free even if it is not protected by an asphalt coating. The only other product of the compaction is waste liquor, which amounts to 5% of the feed in Japan and will probably be about 3% with US refuse because of its lower moisture content.

Composting

Composting is the biochemical degradation of organic material (see: COMPOSTING) to yield a sanitary soil supplement. Anaerobic composting has been practiced in Asia and is the process by which sanitary landfills degrade refuse. Modern composting has been practiced in Europe for over 50 years using aerobic microorganisms. The practice has been attempted on a commercial scale in the United States but with very limited success. The unattractiveness of composting is primarily the result of American agriculture's orientation to chemical fertilizers. This has made the large scale marketing of compost difficult. Composting, while not economical now, could prove more attractive as public opinion moves toward an attitude which requires that wastes returned to the earth be compatible with the environment.

Composting has one overriding advantage; it is the only process which provides for recycling of organic residue. The process can handle garbage and other organic refuse (but not plastics) as well as sewage sludge and industrial waste from certain operations such as saw and paper mills. The primary disadvantages are cost, the need for fairly large areas for final outdoor curing, a slight odor associated with a composting plant, and lack of a market for the product.

Composting is practiced in several forms. Traditionally rows of refuse, shredded or ground, four to six feet high, are exposed to the environment and turned regularly. This is known as the "windrow" method and is still used. Complete composting can be achieved in 10 to 14 days, if seeding with compost is employed, but often four to six weeks.

Mechanically aided aerobic composting is carried out in a number of processes. Among the more prevalent are the Dano process, the Earp-Thomas Multi-Bactor compost tower, and a number of cell-type stated tower systems. Decomposition takes place under aerobic conditions with the microorganisms supplied by seed compost. Typical operating temperatures reach 130 to 140°F. Material is held in the unit from one to six days depending on the process. This is usually followed by an open air curing. A new plant at Sehweinfurt, Germany, using the Caspari-Brikollare process, produces briquettes in which from the compost is stored until it is to be used.

Raw materials suitable for aerobic composting will be finely ground (coarse for windrowing) and have a maximum carbon to nitrogen ratio of 50 to 1. It is important that good dispersion of air can be achieved and that the moisture level be maintained between 50 and 60%. Recycling of between 1 and 10% of active compost enhances the composting process by minimizing the time required for sufficient microorganisms to develop. The yield from composting is about one volume for every three volumes of feed; the weight yield is between 30 and 40%.

In Europe compost is utilized as an organic soil conditioner in luxury agriculture such as vineyards, hotbed vegetable farming, flower and seed production, fruit farming and the improvement of recreational land. It has found little or no use in basic agriculture, nor is it used for erosion control. In Germany less than 1% of the domestic refuse is composted and in Holland only about 15% is so treated. There appears to be no increase in composting operations because of a lack of additional marketing opportunities.

The investment for a composting facility varies widely depending on size and process. Investments of between \$7500 and \$12,000 per daily ton of capacity have been reported; no valid average figures can be reported because there are so few operational plants. Operating costs, including the cost of capital, will vary between \$8 and \$12 per ton of refuse (assuming labor at \$15,000 per man year) on a US basis. European investments appear to be as low as \$1000 per daily ton and operating costs in 1964 were between \$3.20 and \$6.60 per ton, with an average of \$4.50 per ton of refuse.[30] Part of this cost was recovered by sale of salvage (16¢ per ton) and compost; the average recovery amounted to \$1.17 per ton resulting in a net average cost of \$3.38.[31]

The Economics of Waste Disposal

Economic considerations have and will, of course, continue to play a significant role in the choice of waste management method. Table 21 summarizes both operating and investment costs for principal waste processing methods. It must be realized that values can vary widely depending on local conditions. Technological improvements can also alter the price structure. Most important, however, is the fact that long range implications of waste management, environment and resource considerations cannot readily be reduced to a quantitative cost, and these factors should weigh heavily in the choice of a waste processing method.

Reclamation, Reuse and Conversion

There has been a salvage industry as long as there has been waste. The intensity of this effort has been limited however and varies very much with location as well as the economic situation at the time. No concentrated effort, except perhaps in wartime, has ever been made to recover and recycle a high percentage of waste. True landfill can be considered a form of reclamation but it is a very low grade use of refuse. This is not to say that the salvage industry is small: the latest figures indicate that it has sales in excess of \$10 billion per year.

TABLE 21
Waste processing investment and operating costs (1980 basis)

Method	Investment $/ton daily capacity	Operating costs[a] $/ton
Sanitary landfill	5–20	10–40
Hazardous landfill	10–40	30–100
Central incineration		
No waste heat recovery	40,000	30–50
Waste heat recovery	10,000–80,000	40–80[b]
Composting	12,000	8–12[c]

[a] Per ton of capacity, based on 2–20 foot lifts.

[b] No allowance for value of steam, which will be between $1.00 and $2.00 per ton.

[c] 3 shift operation 450 tons/day.

TABLE 22
Value of reclaimed waste, average 1980 prices

	$/ton
Paper	
Newsprint	3–25
Other sorted	Up to 50[a]
Glass	3–90
Cotton	4–20
Metals	
Iron and steel	10–60
Copper and brass	270–800
Aluminum	160–250
Lead	70–160

[a] Depends on type, color, etc.

In certain areas such as paper, with 11 million tons recycled in 1968 (25% of consumption), aluminum with 700,000 tons recycled (30% of production), copper with 1.5 million tons recovered, and iron and steel salvage are an important source of raw materials. Unit salvage values are summarized in Table 22. Automobiles are regularly recovered; it is economically a break-even operation once the auto body is delivered to the salvage operation.

Mixed waste such as municipal refuse has not been a major source of this salvage and contains large amounts of additional metals as well as other potentially valuable materials. However it is only recently that essentially total recovery has been considered. That is, "waste" is being looked at as a potential "natural resource." As an example, one company, Industrial Services of America, operated a separations plant for industrial solid wastes where odor is no problem and manual separation is feasible in the late '40s.

One of the major problems of recycle and reuse has been separation. Most ferrous metal is easily separated by magnetic means, but other waste separation requires hand picking, which is very costly. This method can also create public nuisance in that the odors from such operations can be significant and have resulted in the closure of several such operations. Studies in the late '60s by the Bureau of Mines, Stanford Research Institute and others provide potential alternates for waste separation, but these have not found wide commercial application.

The work at SRI is particularly interesting because it is intended as a total separation process; waste is shredded and then classified into components by density in an air classifier.[32] While the process has not achieved separation of materials with densities that are close together (and much refuse is in the situation) the concept as illustrated in Figure 4 is in the right direction and should lead to promising results.

Similar work has been piloted using a hydrapulper to separate organic, glass and cellulose from metal. Hydrapulping as developed by Black Clawson Company costs about $6 per ton of feed.[33] A demonstration unit (Figure 6) with a 70 T/day capacity was operating in Franklin, Ohio, using the Hydraposal system (of which Hydrapulping is a part). Installed costs were about $14,000/ daily ton for a 300 T/day plant with net operating cost of about $4.5/ton. About 400 pounds/ton of Fiber are reclaimed along with glass cullet, metals and steam. A material balance is shown in Figure 5. However a dry separation such as that proposed by SRI may have significant advantages over wet separation because the removal of water from cellulose is a very costly operation. The fiber from Black Clawson was fed to a roofing paper mill.

The aluminum industry, for example, as shown in Figure 6, has suggested a process for taking municipal refuse and separating it into aluminum, other nonferrous metals, ferrous metals, glass and other waste. Dr. James Etzel of Purdue piloted a process, based on hydrapulping, which handles sewage and solid waste and yields metals and a slurry containing fine particles of glass and organics which can be further treated or used as a soil supplement. Such techniques require considerable additional development and refining but will be one of the key waste management tools of the future.

Pyrolysis, once thought to be a promising process, has not yet found wide acceptance. However, it remains technically feasible. Pyrolysis is the thermochemical degradation of complex organic molecules into low molecular weight

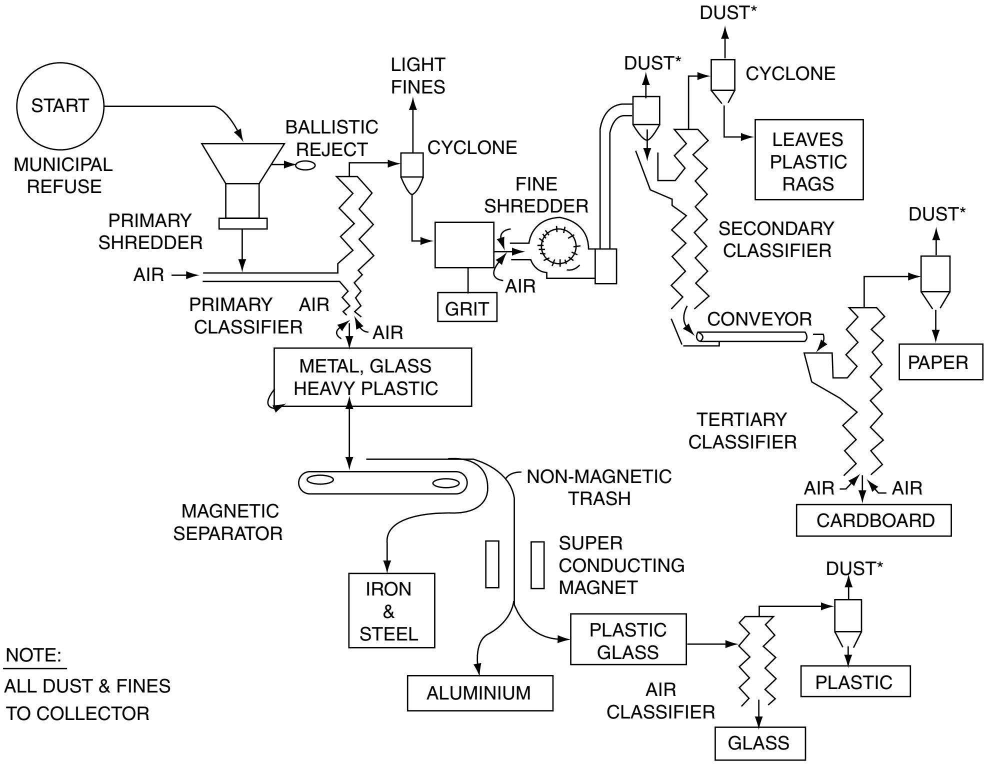

FIGURE 4 Proposed waste separation system, using SRI Air Classifier.

molecules. The process is carried out in the absence of added oxygen (or with very limited oxygen), and with the addition of heat, at temperatures in the range of 900–1700°F. The process will produce a fuel gas, oil and carbon. A study in San Diego indicated that about 50% of the refuse is susceptible to pyrolysis.[34] This study yielded low BTU gas, char and oxygenated hydrocarbons. Cities Services has evaluated a similar process and believed it to be potentially economic in plants with capacities of 5000 tons per day which are subsidized at the rate of \$2 to \$8/ton.[35] Pilot plant studies by the Bureau of Mines indicate that both industrial and municipal refuse yield large amounts of gas and solid, as shown in Table 23.

A process using pyrolysis has been piloted for tires, which present some particularly difficult disposal problems in incineration and landfill.[37] Similar processes can be effective in recovering chemicals from plastics but have not been developed because of separation problems.[51]

The US Bureau of Mines has also piloted a high pressure process where refuse free of glass and metal is reacted in the presence of water and carbon monoxide (hydro-oxynation) at 1400 psig and 500 to 700°F to yield oil, gas and carbon.[37] This process appears to have very favorable oil yields. Process variable studies have shown that conversions as high as 90% can be obtained with a 40% yield of oil; typical yield is shown in Table 24. These yields indicate a potential oil production rate of 2×10^8 tons annually as compared to US crude production of 5×10^8 tons per year. Similar studies using hydrogen showed lower yields and conversions. The use of CO does present some significant operating problems as well as economic debits.

Several systems using pyrolysis were ready for commercialization. Hercules in Delaware planned a unit to pyrolyze industrial waste. Monsanto Environchem built a pyrolysis unit using the LANDGARD process (Figure 7). This process emphasized waste reduction (with recovery of ferrous metal), rather than recovery of variable byproducts; it has been piloted in a 35 T/day semiworks facility. The process reduces the solid waste, typically, by 90%; a typical stack gas analysis is given in Table 25 and indicates the very low particulate matter in the effluent. Unfortunately the unit did not operate successfully at full scale because particulate removal did not meet expectations and costs became prohibitive.

In contrast to the Landgard system, a pyrolysis process emphasizing recovery of valuable products was developed by Garrett Research and Development Co. This process was piloted at a 4 T/day level. It consisted of shredding, air classification, pyrolysis and pyrolysis product separation steps. (A full scale unit was built in San Diego, but never operated a full capacity because of mechanical problems). Product recovery was similar to that obtained by the Bureau of Mines.

One may ask why solid refuse should be subjected to complex processes such as hydropulping or pyrolysis. Where actual wastes such as paper or cellulose fiber can be recovered, hydropulping is certainly attractive; on the other

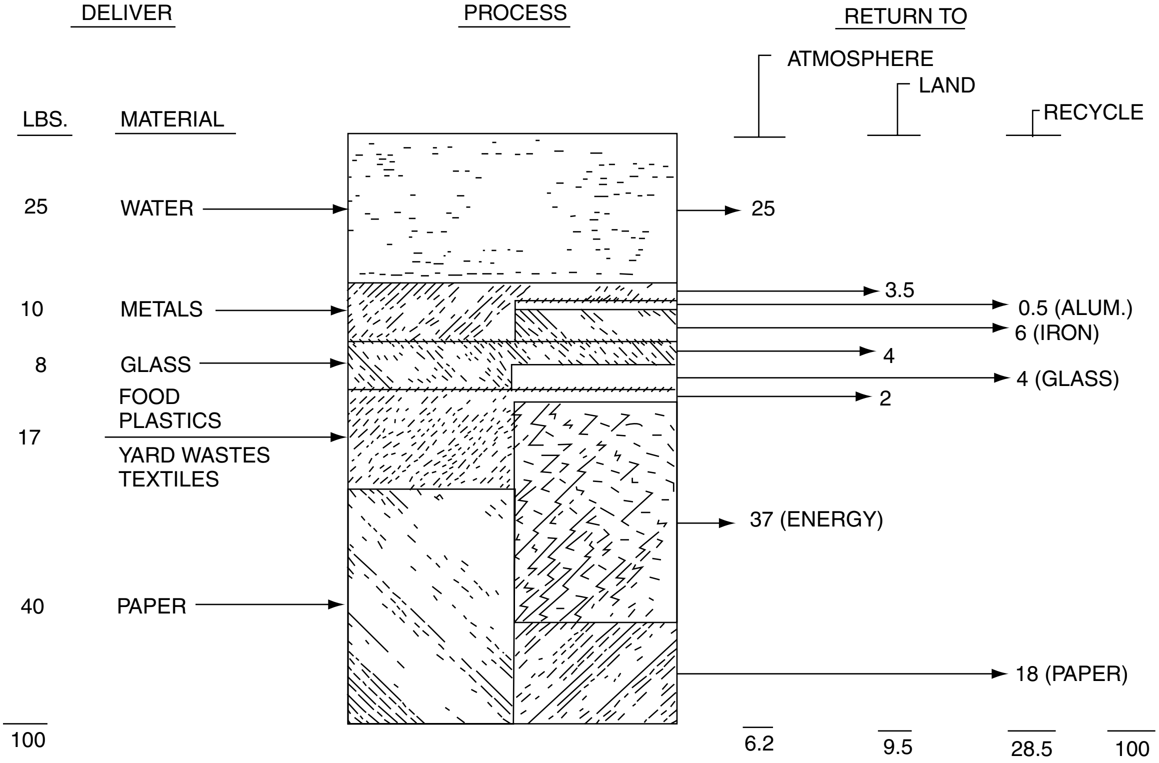

FIGURE 5 Black Clawson Hydraposal-Fiberclaim. Material balance. Credit: Black Clawson Co.

hand where waste is utilized as fuel the possibility of using it directly rather than converting it to fuel oil (Bureau of Mines process) must be considered. Pyrolysis, hydro-oxydation or similar processes should be competitive with direct fire waste-heat recovery incineration where clean fuel is desired or fuel is to be used at locations other than where the refuse is available. The recovery of chemical raw materials from refuse using these processes may also become attractive as the process technology is refined.

The recovery of valuable products from incinerator effluent is not, however, being neglected. The Bureau of Mines has demonstrated technology to recover metals and glass from incinerator residues using high-intensity magnetic sorting as well as chemical techniques at a cost of about $4 per ton.

ITT Research Institute has shown that refuse may be selectively separated into a ceramic and metal slag when incinerated at temperatures between 2800 and 3200°F. While technically feasible, this separation incurs some severe economic costs; it does yield some interesting products including tiles, pipe and structural shapes. In addition to the newer methods being studied, the use of incinerator fly ash and even slag for road fill and concrete aggregate appears to be attractive in some situations.

Specific process to convert refuse fractions are also receiving attention and will be utilized in limited situations where the economics are attractive. An engineering study has shown that the organic portion of raw refuse can be economically converted to sugar by acid hydrolysis. This can then be a raw material for alcohol production. One of the limitations to this and similar processes is a limited market for the product, and competition with other sugar sources as well as other sources of alcohol; for example conversion of 3% of the refuse to ethanol would saturate the normal market.

Though fuel use of alcohols is possible, only limited amounts of refuse can be converted using these processes unless major shifts occur in our economy. Process development to convert citrus waste to citric acid is being conducted at the University of Florida. Other conversion studies are being carried out, but all face the difficulties inherent in processing a heterogeneous, complex, often variable, mixture.

Of more than passing interest are studies being carried out of the University of Maryland to obtain a protein concentrate for human and animal consumption from food processing wastes. Similar studies at Louisiana State University, in the pilot plant stage, has shown that agricultural cellulose wastes can be broken down by selected microorganisms to yield a low cost, high protein food. Yeast can also be produced from cellulose wastes.

The use of waste as a "resource material" is still in its infancy. It is gathering momentum quickly and in the next decade should see significant changes in waste management.

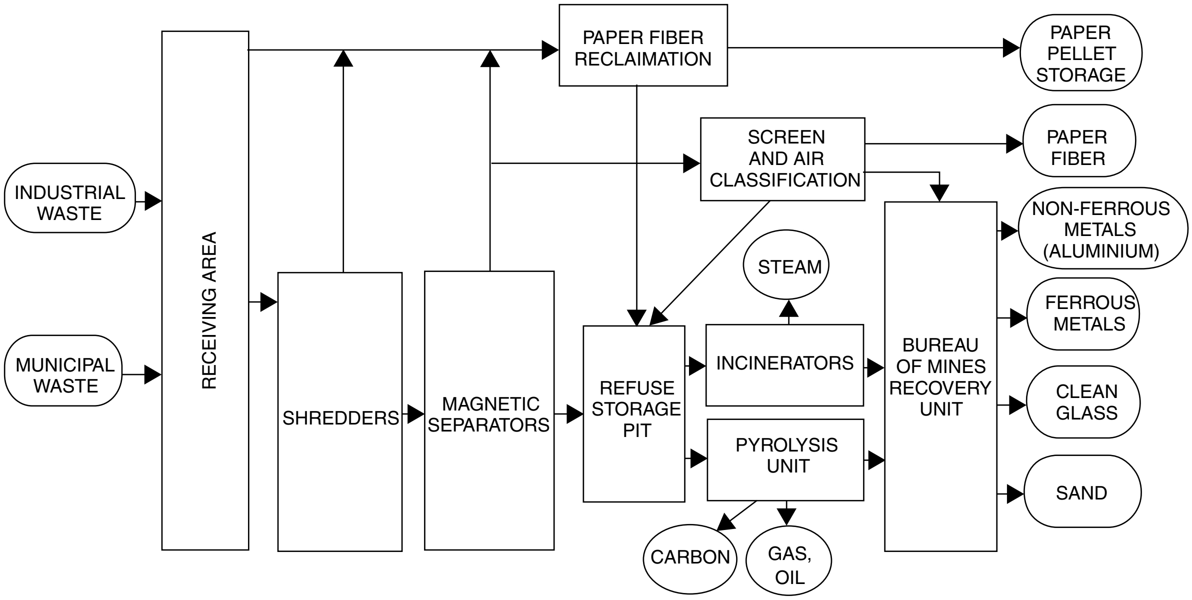

FIGURE 6 Refuse recycling plant. (Aluminum Association of America).

SOURCE REDUCTION

By way of background, it is important to identify the universe of municipal solid waste, or the “source” from which the volume of waste may be reduced. The total volume waste generated in the United States in 1986 was approximately 160 million tons.[40]

Source reduction, while related to recycling in some respects, is nonetheless unique as a waste management option which occurs “before the fact”. It has been said that “an ounce of prevention is worth a pound of cure”. In the area of solid waste management, a reduction of a single ounce in the current per capital generation rate of 3.5 pounds per person per day represents a decrease in annual volumes produced of almost 3 million tons! The importance of source reduction becomes at once apparent.

As noted above, source reduction involves a decrease in waste volume or toxicity. It is appropriate to offer some additional analysis of the nature of these two alternatives and the specific areas which provide the greatest opportunity for change and thus measurable progress in source reduction.

TABLE 23
Pyrolysis of refuse typical yields[36]

	Source	
	Raw material	Heil milled industrial

Heating Value		
Gas btu/ft^3	447	498
Residue, btu/lb	5,260	2,180

Perhaps the greatest concern among solid waste management officials is the great number of single use or disposable products. Disposables are ubiquitous, from beverage containers to disposable diapers to food service containers and utensils. Furthermore, manufacturing technology has advanced to the point where even products which traditionally were never considered single use items may now be purchased at prices which make their use and replacement competitive with reliance on a far less frequent purchase of their durable antecedents. The availability of disposable razors and blades and such commonplace items as pens is not surprising. However, widespread marketing of disposable flashlights, electronic watches, and even cameras must be viewed as unexpected by all but the most optimistic technologists. Absent product bans which are unlikely at the federal level

Particulates	0.06 grains per SCF dry gas corrected to 12% CO_2

except in the case of palpable threat to human health and/or the environment, avoidance of these types of items is largely a mater of consumer choice. Nevertheless, some local governments have begun restricting the use of certain types of plastic, nondegradable or other materials.

Beverage container deposit legislation, mentioned above, is a good example of an issue which straddles the areas of source reduction and recycling. If a mandate to use only *refillable* containers is utilized, certainly waste generation will be decreased. This is clearly source reduction. However, the mandate that deposits be utilized to encourage the return of used containers is a recycling initiative, since the returned bottles and cans will be used as secondary materials rather than being refilled on a unit basis.

Disposable products may also be manufactured using less raw materials as another alternative to achieve measurable source reduction gains. Obviously the limiting factor here is the production of a product which contains less raw material but still serves its intended use.

Extending the useful life of non-disposable products is another legitimate source reduction alternative. The use of alkaline rather than lead acid batteries is a good example. The use of rechargeable batteries rather than disposable batteries is an even better example. As another example, consider the use of automobile tires which have a longer useful life. Tires are currently produced (and disposed) at a rate of 220 million unit per year. Any tangible extension of useful life for individual tires would decrease this generation rate and avoid any increase in the current estimated 2 to 3 billion discarded tires currently stockpiled.

The reduction in the toxicity of wastes is another important source reduction measure. Among the materials of greatest concern are lead and cadmium. The presence of these and other heavy metals in incinerator ash often results in the classification of such ash as a hazardous waste. Hence the desire to identify the likely sources of lead and cadmium and ultimately, to find ways to eliminate or replace these elements in the products which contain them.

The most current data available indicate a total of 213,652 tons of lead and 1,788 tons of cadmium in the municipal solid waste generated in 1986. The figure for lead does not include the lead present in the lead acid batteries which were recycled which amounts to some 80% of the batteries produced. The primary sources of lead entering municipal waste stream (again not including that contained in the batteries which are recycled) is as follows:

- 65% lead acid batteries (primarily car batteries)
- 27% consumer electronics
- 4% glass and ceramics
- 2% plastics

The primary sources of cadmium in the municipal waste stream (after recycling) are as follows:

- 54% household batteries
- 28% plastics
- 9% consumer electronics
- 5% appliances
- 4% pigments

To the extent that the lead and cadmium in the products listed above can be eliminated or replaced, substantial source reduction may be achieved.[41]

Recycling is the next preferred alternative in the hierarchy of integrated waste management options. As noted above, it generally involves the reuse of secondary materials as a supplement to or wholly in place of virgin materials in the production of various goods. Whether or not the material is used to produce the same goods which were recycled depends on a number of technical, economic, and aesthetic considerations. For example, plastics such as polyethylene tetraphthalate (or "PET") are currently being recycled from large relatively uncontaminated one and two liter beverage containers. They are not, however, used to produce new plastic containers which will be used in contact with food. This limitation is not a constraint where other types of beverage containers made from aluminum or glass are concerned. Aside from composting, which is addressed below, recycling generally takes place as an in-plant practice or after certain consumer products are used.

Recycling of process waste from a variety of industrial and/or manufacturing operations has been practiced for some time on a discretionary basis. The decision to use or dispose of the byproduct of a given process often involves technical considerations such as chemical or physical differences between the raw materials otherwise used and the scrap material available. Assuming that no technical impediments exist, the decision about whether to recycle is one of economics. There is no question that the higher disposal costs currently being experienced have driven more industries to recycle as a business decision. However, the types and amounts of materials and the number of industries potentially involved are beyond the scope of this document.

The recovery of materials from municipal waste streams or so called "post consumer" recycling has experienced substantial gains over the past several years due to diminishing disposal capacity and dramatic increases in tipping fees. At least 18 states have recycling goals established in legislation including the four mentioned above where recycling is mandatory. The materials most commonly recycled include newspapers, glass, aluminum cans and to a lesser extent, corrugated cardboard, various ferrous and non-ferrous scrap metals, and plastics. These materials are typically accumulated by private citizens and businesses and either collected curbside separately from the remainder of solid waste destined for disposal or brought to centralized collection facilities. As a matter of convenience and to maximize citizen participation, many systems collect commingled glass and cans or commingled glass, cans, and newspapers in a single container.

The value of the materials described has varied widely, depending on the quantity of material available, expected levels of contamination, and transportation distance to end markets. Furthermore, the rush to recycle by more and more communities has resulted in erratic markets for certain materials. For example, newspaper, which would demand approximately $60 per ton as recently as 1987, is now worth $20 per ton in some cases and is taken for no compensation in other cases. Projections by some waste newspaper exporters indicate a probable net cost of $25 per ton by 1990. While markets for other materials have been less volatile than this, considerable variations have occurred. As of this writing, typical values per ton for other recycled commodities are as follows:

- aluminum $800
- Plastic PET bottles $120
- glass $40
- steel cans $10

Composting of vegetative waste is also a form of recycling. It has become more widespread as landfill disposal costs have risen. Leaves and other yard waste are amenable to this process, which has proven more troublesome for grass clippings due to the anaerobic odors often associated with grass not mixed adequately to limit the development of such conditions.

Incineration of municipal solid waste has become more widespread with new plants almost always incorporating steam generation and electrical power production. Waterwall, or mass-burn incineration has become the technology of choice among those communities whose overall management strategies include large scale volume reduction processes after source reduction and recycling operations have been utilized to maximum advantage and prior to sanitary landfilling of residuals or noncombustible materials. Currently, 126 such facilities operate in 37 states. The average design capacity of these facilities is 814 tons per day. Total design capacity for all these facilities is 68,399 tons per day. This latter figure is projected to reach 107,832 tons per day by 1992 when all facilities currently under construction are completed and operational. The largest incinerators currently operating are a 3,300 tons per day plant in Michigan and a 3,000 tons per day plant in Florida. There are also 124 modular plants currently in operation. These modular plants are similar to mass burn plants but generally smaller and sold as prefabricated units. The average modular plant burns 124 tons per day.[42]

While the process description of incineration remains as described in the full text, significant design improvements and air pollution control methodologies have been applied to new facilities. The designs are all based on facilities established in Europe and are marketed by a number of United States companies. American ReFuel (Browning Ferris), Blount, Ogden Martin, and Waste Management currently hold the largest market share in terms of facilities operational and/or under construction.

Air pollution controls utilized include electrostatic precipitators or baghouses (sometimes both) as well as acid gas scrubbers where removal of HCl emissions is required. The newest plants will also incorporate thermal treatment to limit nitrous oxide emissions. The specific air pollution control equipment employed at individual facilities depends upon the requirements of the regulatory/permitting agencies (generally states with federal oversight) and the ambient air classification of the region in which the plant operates/will operate.

Nine plants continue to produce refuse derived fuel ("RDF") which supplements fossil fuel or is fired alone in dedicated boilers. The average RDF plant processes 953 tons per day of incoming solid waste.

Virtually all of the technology demonstration projects originally funded by the federal government have ceased to operate due to technical and or economic reasons. The only exception is the Delaware Solid Waste Authority facility in Wilmington, Delaware. This plant, originally designed and built by Raytheon, continues to operate as part of an integrated waste management system operated by the Authority. The writer is unaware of any proposed new installations of this particular technology.

A number of other *alternative technologies* have been offered to communities by private entrepreneurs. They are generally materials separation processes and a few more highly technical approaches such as laser destruction of raw waste and/or incinerator ash. These processes claim some success at laboratory or bench scale demonstrations for mixed municipal waste with some larger applications handling specific homogeneous waste streams. To the extent that larger operations (on the order of at least several hundred tons per day throughput) are built and evaluated over a number of years on mixed municipal waste streams, their viability may be determined.

Environmental controls required at *sanitary landfills* have become substantially more stringent over the past several years as states have revised regulations due at least in part to serious ground and surface water pollution problems arising from older sites without such controls. As a result of these stricter regulations many environmentally deficient sites were forced to close. This has resulted in a disposal capacity shortfall in many areas, particularly in the urbanized areas of Northeastern states.[43] Those sites which remain as well as the limited number of new sites being built must incorporate a variety of specialized controls which a few years ago were not even required for hazardous waste facilities. While it is impractical to list the many variations in individual state regulations, an overview of the proposed revised federal criteria for land disposal mentioned above will serve to provide a good indication of the minimum standards which will apply nationally if the final regulation is adopted as proposed. Obviously, there is no assurance that this will be the case but the proposal certainly reflects the federal government's best analysis of the degree of control necessary. As such it is worthy of some brief analysis. The discussion below highlights only the technical aspects of the proposed criteria and not the administrative concern such as facility registration and similar issues.

Location Restrictions: Areas of Special Concern

- landfills within 10,000 feet of an airport would be required to operate in a manner that precludes birds attracted by solid waste from creating a hazard to aviation
- landfills located in 100-year floodplain would be prohibited from restricting the flow of the 100-year flood, reducing the temporary water storage capacity of the floodplain, or resulting in the washout of solid waste so as to pose a threat to human health and the environment
- new landfills may not be sited in wetlands absent a demonstration that there is no practical alternative, no significant adverse environmental impacts, and that relevant discharge standards will be met.
- new landfills may not be sited within 200 feet of faults which have had displacement during Holocene time (i.e., within 11,000 years)
- new landfills in seismic impact areas would be required to be designed to resist ground motion from earthquakes
- landfills in unstable areas such as Karst terrain would be required to incorporate engineering safety design measures

Operating Criteria: Minimum Requirements

- procedures for excluding the receipt of hazardous waste
- application of daily cover material
- control of disease vectors
- monitoring and control of explosive gases
- prohibition of open burning
- limitation of site access
- control of storm water run-on and run-off
- limitation of surface water discharges
- prohibition of bulk liquids
- record keeping

In addition to the above requirements, the proposed criteria call for site closure and post-closure care criteria including a minimum of 30 year maintenance and monitoring, establishment of financial security to ensure that these activities are carried out. Finally there is a requirement that corrective actions be taken in the event of identification of groundwater contamination.[44,45]

One area of note is increasing interest in landfill mining as a source of combustible fuel, cover material for current landfills, and the creation of new fill capacity in the airspace vacated by the mined sections of a site. One such project was conducted in Naples (Collier County), Florida. In addition, several sites in New York State are being evaluated for possible research into this technology.

Some Special Problems

Radioactive solid wastes create special problems and are discussed elsewhere in a section on Radioactive Wastes.

Industrial wastes, as mentioned previously, has been dumped as a general rule. Because of the high specialized nature of industrial wastes, it is impossible to discuss them in a general way. Total recycling of many industrial wastes will become a more frequent practice. Mine tailings will find their way into construction material, fill, or may be recycled into the mines. Slag from steel mills should become less of a problem as different processes are used but will still remain a significant contributor; slag can be used in special concrete and efforts in this area will continue.

Sewage sludge (see: SEWAGE) presents some special problems. To date it has generally been dumped. Composting (see: COMPOSTING) should be a major process for handling sewage sludges. Several attempts to sell composted sludge have only been marginal because of the lack of markets; however this should change in the future. Material that, for economic reasons, cannot be composted, can be burned to recover waste heat in specially designed incinerators.

More of a problem will be spent solids from water treatment facilities. These solids are high in carbonates and often have a foul odor due to entrained organic material. They are now being filled and this practice will have to continue unless chemical recovery methods which produce a useful product are found; this is not likely as carbonates are in oversupply.

The management of solid wastes will undergo dramatic changes in the next decade. From a "cottage industry" it will emerge as a major process industry recovering many vital materials and converting others into valuable products. Landfill and incineration will continue to play a role with the former decreasing in importance and the latter coming into greater prominence. However new process technology, only some of which is now in development, will play an ever more important role in total solid waste resource management.

MARINE SPILLAGE—SOURCES AND HAZARDS

INTRODUCTION

Scope

Pollution of navigable waterways resulting from operation of commercial and naval vessels may be a consequence of normal service or from casualties such as collisions and groundings. Propulsion system fuel oil and liquid cargoes may be involved in any case and will be considered in this chapter. Waste disposal from shipping is of comparatively small magnitude compared to waterway pollution from shoreside sources and will not be considered. Emphasis will be on description of the pollution problem and on means for prevention. The subject of spill collection and disposal is considered elsewhere in this text.

Problem Definition

Normal operations A decade ago, the primary source of pollution of the world's waterways was the intentional discharge of oily ballast water during routine operations. At that time, for virtually all seagoing operations ballast water was taken aboard for a portion of the voyage in order to obtain sufficient draft and trim for propeller immersion, adequate steering ability, acceptable conditions of seaworthiness; and to satisfy mandated operational and regulatory requirements for intact and damaged stability. If assigned ballast tank capacity was inadequate to meet these requirements, it was the general practice to ballast empty fuel oil tanks, or empty liquid cargo tanks in the case of tank vessels. This procedure resulted in the necessity for pumping overboard large quantities of contaminated ballast water before taking on fuel oil or liquid cargoes. These procedures have been largely outlawed by international agreements developed by the International Maritime Organization (IMO) of the United Nations, and enforced by the national regulatory agencies of the member countries.

Casualties Spills resulting from casualties generally receive more attention in the world press than incidents involving operational discharges. Spills may occur from operational mishaps in the pumping of fuel oil bunkers and liquid cargoes. Incidents of spills that occur from collisions and groundings are accompanied by associated dangers to personnel and the environment and are likely to involve the largest quantities of pollutant discharged in a single incident. The magnitude of such spills is clearly far greater in the case of a loaded tank vessel than the grounding and rupture of the double bottom fuel tanks of a dry cargo vessel.

SHIP CLASSIFICATION AND DESCRIPTION

The arrangements and general characteristics of the various merchant ship types are well described in such standard texts as Reference (1) and in the technical literature, including the comprehensive discussion in Reference (2) covering U.S. shipbuilding during the 1936−1976 period. Accordingly, the following discussion will be restricted to characteristics pertinent to the pollution problem, for example, arrangement of tank spaces.

The following standard abbreviations have been used throughout for convenience:

DWT = deadweight = total displacement − light weight
= cargo + consumables
mld. = molded
fbd. = freeboard
B.P. = between perpendiculars

Break Bulk Vessels

The greatest variety of seagoing vessels are in this category which includes the ordinary general cargo vessels carrying a great variety of dry products in raw material as well as finished and packaged form. An outline sketch of the cross-section through a typical cargo hold, showing hatchway, tween decks and fuel oil or ballast spaces, is shown in Figure 1. Fuel oil is commonly carried in the double bottoms, as indicated, but may also be carried in deep tanks, particularly outboard of shafting and in the vicinity of the machinery spaces. Except for settling and daily service tanks, all bunker spaces are normally piped for fuel oil or ballast. The availability of cubic capacity for tankage assigned only to ballast service is limited in such vessels and frequent use of fuel tanks for ballasting is likely in most operations.

Unitized Cargo Carriers

Ships in this category are usually designed for the exclusive transport of standard containers or wheeled trailer vans, and, to a lesser extent as hybrid carriers to handle container, wheeled vehicles and general break-bulk cargo. In the case of container ships, as illustrated in the typical hold section, Figure 2. the cellular nature of the cargo stowage requires some "squaring off" of the hold spaces, with the result that considerable wing space is available for ballast tanks. As a

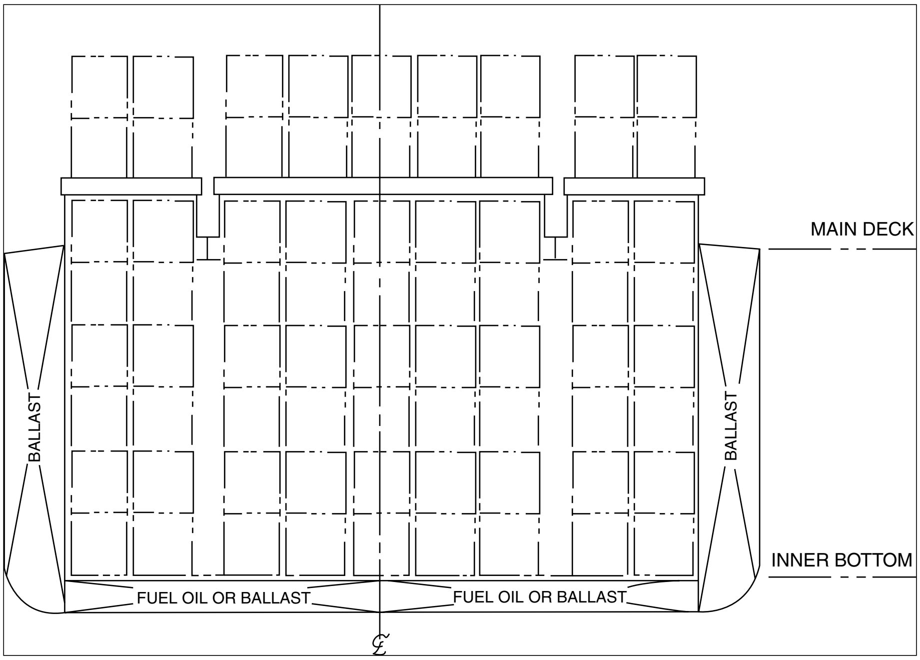

FIGURE 2 Outline midship section through container hold, typical container ship.

result such vessels are able to operate with clean ballast only and no ballasting of fuel tankage is normally required.

Roll-on/roll-off or trailer ships are similarly "squared off" internally and, in addition, may have extensive deep tank spaces available below the lowest vehicle deck. As with the container ships, tankage is likely to be available in sufficient quantity to permit full clean ballast operations.

Dry Bulk Carriers

Dry bulk carriers are engaged primarily in the transport of such commodities as coal, grain and ores. Two general configurations exist, as shown in Figure 3. For light weight, high cubic cargoes, such as coal and grains, the hold configuration is such that water ballast capacity, in the amount of 35 per cent to 40 per cent of cargo deadweight, is available for clean ballast service, as shown in Figure 3a and 3b. Fuel oil bunkers are generally confined to deep tanks within the machinery spaces or to portions of the wing and double bottom tanks adjacent to the machinery spaces. Clean ballast operation is generally feasible.

Vessels designed specifically for heavier cargoes such as ores are generally arranged with comparatively small cargo holds and large surrounding tank spaces as shown in Figure 3c. Clean ballast operation is readily accomplished under all loading conditions.

Liquid Bulk Tank Vessels

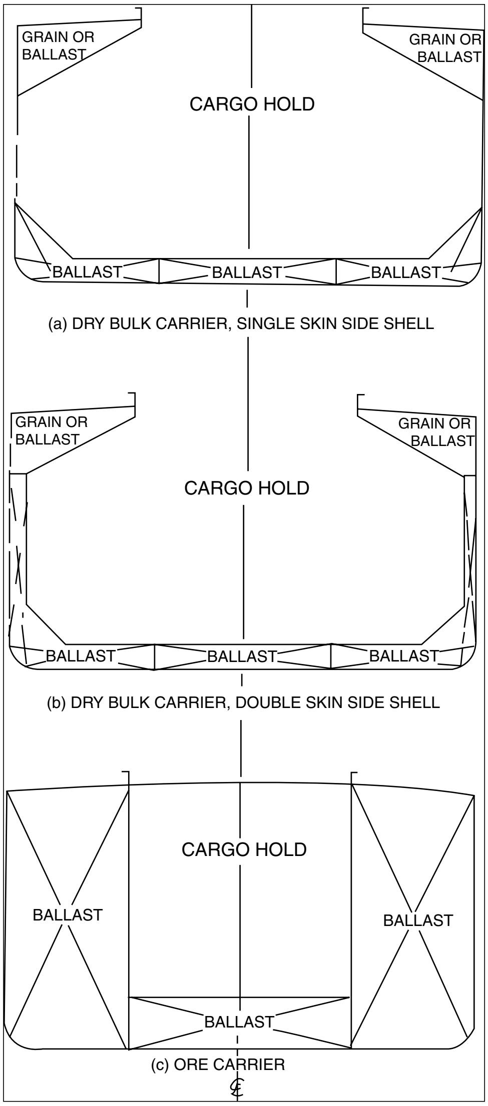
The modern tank vessel has evolved from the standard 16,000 deadweight ton (DWT) "T2" tanker of World War II to modern tank vessels exceeding 500,000 DWT capacity. The transport of liquid cargoes, predominantly petroleum crudes and refined petroleum products is the single largest category of waterborne commerce and represents the greatest potential pollution hazard with respect to normal operations as well as casualties. Accordingly, characteristics of vessels in the liquid bulk trades will be considered in somewhat greater detail than other ship types.

Petroleum Crude and Products Carriers With the exception of the steam turbo-electric main propulsion machinery and electric drive cargo pumps, the World War II T2 tanker is, in general arrangement, a parent of the tanker designs developed during the early post-war years. Typical characteristics of these vessels include:

1) Cargo section divided by a pair of longitudinal bulkheads into port, center and starboard tanks.
2) Relatively short cargo tanks independent of ship size.
3) Poop, bridge and forecastle superstructures with navigating bridge located amidships.
4) Forward and after fuel bunkers.
5) Forward and after pump rooms.
6) Relatively long, single screw, main propulsion machinery, with separate boiler and engine rooms.

From the late 1950s until the present, tanker design evolved through the following changes, all directly related to reduced cost of construction and operation:

1) Increase in size to over 500,000 DWT capacity, with corresponding increases in dimensions and operating drafts.



(a) DRY BULK CARRIER, SINGLE SKIN SIDE SHELL

(b) DRY BULK CARRIER, DOUBLE SKIN SIDE SHELL

(c) ORE CARRIER

FIGURE 3 Outline midship sections through cargo holds, typical dry bulk carriers.

2) Simplification of arrangement, particularly by reduction in number and increased size of cargo tanks. Typical modern crude oil tankers are arranged with as few as five center tanks and ten wing tanks. Secondary arrangement changes have included elimination of superstructure and houses amidships, location of all accommodation and navigation spaces aft and elimination of forward pump room and fuel bunkers.
3) Speed has remained within the 14 to 16 knot range.
4) Crew size has been reduced substantially, averaging as low as 19 men on U.S. flag as well as foreign tankers.
5) Propulsion system power levels have increased with size, approaching 40,000 SHP on a single screw. Centralized pilot house control of all propulsion machinery is a state-of-the-art development available to operators of diesel and steam turbine machinery.
6) Cargo pumping systems are generally similar to those of the post World War II period, except for increase in pumping rate with ship size. Elimination of pump rooms and fitting of deep well pumps in each cargo tank is a recent trend, following the arrangements of special products carriers.

Regulatory effects on tanker design, imposed since the 1973 MARPOL Convention for the Prevention of Pollution from Ships, have been significant. These regulations, imposed progressively from 1973 through 1985, include the following requirements and constraints:

1) Limitation on maximum cargo tank size to 30,000 cubic meters.
2) Segregated ballast tanks (SBT) on all new tankers larger than 20,000 DWT capacity. SBT capacity must be sufficient to obtain the following conditions:

    - Capacity to obtain minimum mean ballast draft of 0.02L + 2 meters, where L = length between perpendiculars
    - Trim by the stern no greater than 0.015L
    - Draft at the stern sufficient to submerge the propeller
    - SBT located to so as to protect 30% to 40% of the side shell in way of the cargo tanks. (Actual requirements vary with ship size and geometry.)

Since the segregated ballast tanks are restricted to clean ballast service only, the net effect of these requirements has been to increase the ship dimensions to accommodate the required SBT volume. As a result, modern tankers that meet the SBT requirements are volume rather than weight limited, and will only load to the assigned draft marks when carrying very dense cargoes.

The SBT capacity requirements are considerable, amounting to about 25% to 40% of the deadweight. The optimum SBT and cargo tank arrangements, for minimum ship acquisition cost, vary with ship size and proportions. A common arrangement is to assign two pairs of wing tanks within the cargo tank section to SBT service. In some cases the preferred arrangement is the concentration of segregated ballast in double bottom tanks extending under the entire length of the cargo tank section of the ship.

Table 1 include a summary of principal characteristics of U.S. flag tank vessels built since 1977. All meet the MARPOL SBT requirements. The SBT arrangements are reviewed later in connection with protection from collision and grounding.

Special Products A great variety of liquid products are carried in specially constructed tankers. While the quantities carried are small compared to the volume of petroleum

crudes and refined products, transport of these commodities may involve unique containment problems and associated hazards.

Special products carriers may be classified in the following manner, according to nature of cargo:

1) Liquefied natural gasses (LNG) and liquefied petroleum gasses (LPG).

    (a) Low temperature—ambient pressure containment—The most exacting containment requirements are in this category, with cargo carried at about −260°F for liquefied natural gas (LNG). The largest LNG carriers at this time have capacities of about 130,000 cubic meters.

    LPG transport includes the carriage of such gasses as propane, butane and ethylene, with propane, carried at about −50°F, the most common.

    In a typical LNG or LPG carrier, cargo is carried in an independent, insulated tank or membrane liner. Double bottom and wing tank spaces are normally assigned to salt water ballast and fuel oil is carried in a relatively small portion of the double bottom and in deep tanks within the machinery spaces. Geometry is similar to that of a container ship and clean ballast operation is accomplished with no difficulty.

    (b) High pressure—ambient temperature—LPG may be carried in pressure vessels, designed to the A.S.M.E. Code for Unfired Pressure Vessels. While this mode of containment has been generally superceded by low temperature transport for international trade, a considerable amount of LPG and similar cargoes is carried in this manner on the inland waterways of the United States and Europe and in smaller coastwise vessels and barges. The limiting design condition is usually for propane, in cylindrical tanks designed for 250 psig. In general, vessels carrying cargoes in pressure vessels have sufficient cubic capacity to permit clean ballast operation.

2) Miscellaneous liquefied gasses—Anhydrous ammonia is carried in significant quantities in U.S. inland and coastal waters. This commodity may be carried at low temperature or under pressure, in containment designed for the transport of propane.

    Chlorine gas is commonly transported by barges in U.S. waters, primarily in pressure vessel containment. Other commodities of importance are primarily petro-chemicals, including butadiene, ethane, ethyl chloride, prophylene and vinyl chloride.

3) High temperature commodities—The transport of molten sulfur at about 275°F in heated independent insulated tanks has become the most common high

temperature commodity carried on international and inland waters. Internal hull geometry resembles that of the low temperature LPG or LNG vessel, with double bottom and wing tank spaces available for clean ballast.

The transport of asphalt and bitumen in the molten state is less exacting than the case of molten sulfur transport and cargo is normally carried in conventional integrated tanks.

Sulfur and bitumen cargoes are relatively dense and clean ballast operation should be expected. The use of cargo tanks for ballast services is not feasible, except for emergency situations.

4) Toxic and corrosive chemicals—A great variety of hazardous cargoes are carried in relatively small quantities in a variety of containment systems. References (3) and (4) contain a hazardous cargo classification and data for specific commodities, with particular respect to marine transportation.

Virtually all hazardous cargo carriers will be built with sufficient ballast tank capacity, in the form of integral double bottom or wing tanks. It is unlikely that the use of cargo tanks for salt water ballast would be permitted, except for emergency conditions.

Combination Bulk Carriers

In order to improve the overall utilization of conventional dry or liquid bulk carriers, combination bulk carriers have been developed to permit transporting dry and liquid cargoes within the same cargo hold spaces. A typical voyage, for example, would involve carrying crude oil from the Persian Gulf to Maine, ballast from Maine to Hampton Roads, coal from Hampton Roads to Japan, Japan to Persian Gulf in ballast, etc. Cargo operations of this type involve unique cargo handling and hold cleaning problems, with associated potential pollution problems.

Two general configurations exist, the ore-oil carrier and the more common ore-bulk-oil (OBO) carrier. These are analogous in function and similar in geometry to ore carriers and general bulk carriers, respectively, illustrated in this section sketches in Figure 3. A common modification in the latter case is the provision of a double skin side shell to facilitate hold cleaning.

Referring to Figure 3, the ore-oil carrier is equipped to carry cargo oil in the wing tanks as well as the center cargo hold. The double bottom space is normally reserved for clean ballast. The degree to which an ore-oil carrier can maintain a clean ballast operation, when operating as a tanker, will depend on the relation of cargo density to cargo volume available. The OBO will be operated with dry and liquid cargoes restricted to the main hold spaces, hence such vessels will normally operate with clean ballast, as a conventional bulk carrier. In both cases, however, hold cleaning between cargoes is a major operational problem that will be considered in later discussions.

The largest dry bulk carrier in existence is believed to be the 365,000 DWT ore carrier BERGE STAHL, delivered in 1986. The largest combination carrier is the 280,000 DWT ore/oil carrier SVEALAND, delivered in 1972.

Miscellaneous Commercial Vessels

The great variety of miscellaneous and floating craft that could be sources of pollution are too numerous to consider here. In general, all can be considered, with respect to pollution, in one of the categories considered earlier. One particular case, of current interest, however, is the development of large, unmanned seagoing barges for the ocean transport of dry and liquid bulk commodities. Tank barges of 50,000 DWT are in service. The geometry of a tank barge resembles that of an austere crude oil tanker of comparable deadweight, with five center tanks and 10 wing tanks. Operational as well as casualty pollution hazards are comparable to those of a self-propelled tanker, with the added complication that no personnel are aboard when the vessel is underway.

POLLUTION FROM NORMAL OPERATIONS

Ballasting and Tank Cleaning

Break Bulk Vessels The major source of pollution from break bulk general cargo vessels is in the intentional discharge of dirty ballast. As consumables, primarily fuel, are expended, displacement, draft and stability changes and may reach the condition that the addition of water ballast may be required. Some tankage may be available for clean ballast, but, in general, ballasting of fuel tanks will probably become necessary at some point beyond the expenditure of one half the consumables on board.

Since the imposition of the MARPOL regulations, the use of clean segregated ballast tanks has been mandatory and the disposition of oily ballast at sea should no longer be a major problem.

Tank Vessels, Crude and Refined Petroleum Products Until the MARPOL agreements came into effect, the greatest source of intentional discharge of contaminated ballast into the sea was from the operation of tank vessels transporting petroleum crudes and products. Tankers are normally one way product carriers and return voyages to the cargo source are in ballasted condition. MARPOL segregated ballast requirements for tank vessels were summarized earlier in Section 2.4. The arrangement of the ballast tanks to meet operating requirements and to provide some collision and grounding protection is discussed later.

Tank Vessels, Special Products Carriers The special products carriers described in earlier discussions are predominantly clean ballast vessels. Sea water will rarely be pumped into cargo tanks and sufficient tankage is normally provided, in the form of double bottoms and wing tanks, to serve as cargo tank protection as well as clean ballast tankage.

Dry Bulk Carriers The typical dry bulk carrier operates in ballast over a significant portion of the operating life. Many trade conditions exist in which return cargoes are not available and ballasting is required for adequate propeller immersion and seaworthiness. Bulk carriers are inherently stable and ballasting is not required for this purpose. As discussed earlier, sufficient cubic capacity is normally available in the wing and double bottom spaces to permit clean ballast operation.

Combination Carriers The most common of the combination carriers, the OBO, has the same general configuration as the dry bulk carrier and, accordingly, is generally capable of clean ballast operation. When in petroleum crude or product service, the OBO operates as a tank vessel and must comply with all relevant regulations. Hold cleaning between voyages with incompatible cargoes, however, is an additional source of pollution. In the example given in earlier discussions, the OBO discharges crude oil at Portland, Maine, proceeds in ballast from Maine to Hampton Roads and takes on coal at Hampton Roads for delivery to Japan. During the ballast voyage from Maine to Hampton Roads, the holds are cleaned by conventional means and the dirty oil washings discharged into slop tanks located in a pair of wings immediately aft of the cargo holds. A more complex situation arises for the ballast voyage from Japan to the Persian Gulf, after discharging coal. Several days of manual labor are required to remove coal residue, followed by Butterworth cleaning to remove the fine coal powder remaining. The solids and wash water are discharged at sea in unrestricted zones, unless prohibited by environmental regulations.

In general, combination carriers can be changed over from liquid to solid cargoes in a comparatively short time, say a period of 18 hours to two days. The reverse procedure may require more time consuming cleanup procedures. Operators, accordingly, will tend to prefer maintaining a given ship in a single cargo trade for seasonal periods, if permitted by the economics of the trade. Operational pollution problems are reduced in complexity when the occasions for cleaning between incompatible cargoes are minimized.

Cargo Transfer, Loading and Unloading

Liquid Cargoes Some pollution inevitably occurs as a result of fuel and cargo oil transfer between ship and terminal or between ship and lighter alongside. The majority of such incidents results, directly or indirectly, from human failure. Typical incidents include overflow through tank vents and hose failures. In most cases, proper monitoring or automatic control of cargo transfer and fueling operations will minimize the probability of oil spillage. Normal inspection routines should permit anticipating most equipment failures.

The rapid development of the large crude oil tankers has been accompanied by the parallel development of offshore terminals to accommodate the deep draft vessels. The tankers moor to large "monobuoy" single point mooring buoys which are anchored permanently to the sea floor. Oil pipelines are led to the underside of the monobuoy along the sea floor, from the shore tanks. Flexible hoses are led from the buoy to the midship pumping station on the tanker, usually by a tending launch. Means for mooring the tanker and connecting up to the oil hoses are under constant development and are reaching a high level of reliability. It is not expected that operations of the offshore terminals, under proper control, will represent a major source of pollution.

The lightering of petroleum crude from deep draft tankers offshore to draft-limited ports is a major activity at U.S. coastal ports. The majority of the existing shuttle tankers are relatively small 40,000 DWT to 50,000 DWT vessels. Shuttle tankers operate between transit vessels and terminals over one-way distances generally less than 100 miles. In some cases the service is limited to a lightening operation to reduce the transit tanker draft to the allowable terminal draft.

It is anticipated that pending U.S. legislation will address the lightering issue by allowing existing single skin transit tankers to be served by double hull shuttle tankers discharging to U.S. coastal terminals. It is understood that the minimum allowable standoff distance between transit tanker and coastal terminal will be 60 miles.

Shuttle tankers operate on short voyages, with frequent encounters with large transit tankers and terminals, through heavily travelled shipping channels. It is anticipated that requirements for environmental protection for this class of tankers will be demanding, considering the nature of the service and proximity to environmentally sensitive coastal areas.

Dry Bulk Cargoes Earlier discussions of combination operations included mention of solids pollution from hold washings when converting from dry bulk to liquid bulk operations. Of far greater importance is the harbor pollution occurring at dockside from the simple transfer, by grabs or similar mechanical devices, of dry bulk products between ship and shore storage facility. Over a long period of time, dry bulks spilled between ship and pier accumulate and become a local, but significant cause of harbor pollution. While many of the commodities are inert, others, including coal and some ores have an adverse effect on the ecology. The cargoes involved are of low value and command low freight rates, hence there is little incentive to control spillage of small, but accumulative, quantities into harbor waters.

POLLUTION FROM CASUALTIES

The magnitude of a particular oil spill, or other pollution casualty, is a function of ship type, ship size and nature of the incident. Tank vessel collisions or groundings involve the greatest magnitude of pollution resulting from individual casualties and, accordingly, will be considered in some depth in these discussions. Other vessel types are considered briefly.

Break Bulk Vessels

Pollution resulting from rupture of fuel tanks, as a result of collision or grounding, is the only significant casualty of this class of shipping likely to result in pollution. Less important is the potential rupture of deep tanks carrying various special cargo oils, primarily edible oils. Figure 1, showing a typical section through a cargo hold, indicates that double bottom tanks are normally assigned to fuel oil or ballast service. The largest general cargo vessel operating under the U.S. flag has a maximum fuel oil capacity, including all double bottoms, deep tanks and settling tanks, of about 3700 tons. About 83 per cent of this tankage, or about 3000 tons, is in the double bottoms. In general, the operator will tend to carry a minimum weight of fuel oil in order to maximize cargo deadweight, hence somewhat less than the 3700 tons of fuel oil is likely to be aboard.

The largest double bottom fuel tank in this particular vessel holds about 280 tons. A one-compartment damage collision, assuming damage from the side to the centerline, could expose 465 tons of fuel oil to the sea. Two-compartment damage, again from the side of the centerline, could expose about 900 tons of fuel capacity to the sea. A grounding incident, in which the bottom shell is opened to the sea for a considerable portion of the ship's length, could expose as much as 2/3 the double bottom fuel capacity, or about 2000 tons, to the sea. These values represent the maximum quantities likely to be exposed following a casualty. A considerable portion of the fuel would be released to the sea in any of these incidents. Magnitudes of such spills are significant but small relative to the catastrophic effects of a comparable tank vessel incident.

Unitized Cargo

Container, roll-on/roll-off and unitized cargo combination vessels in liner service are larger and higher powered than the break-bulk vessels, hence carry greater quantities of fuel oil. Arrangements of fuel, ballast and cargo oil tanks are varied and fuel oil may be located in bottom, wing or deep tanks. In general, the mode of release of fuel oil to the sea would be as discussed for break bulk vessels, with the quantities somewhat greater. A considerable portion of the wing and bottom tankage of unitized cargo vessels is piped only for ballast, thus lessening the probability that only fuel tanks would be breached in the event of a collision or grounding.

Tank Vessels

Fuel tanks are of relatively minor importance in the case of tank vessels involved in casualties. Fuel is generally confined to two or three deep tanks and settling tanks and represents a small portion of total tankage exposed to the sea following a casualty.

The evolution of tanker design since the early 1950's, with respect to pollution from collision and grounding, was considered briefly in earlier discussions.

Collision and Grounding Protection The cargo section of a modern tank vessel is arranged with the minimum number of tank divisions to meet loading, trim and safety requirements. Crude oil tankers may have as few as five tanks along the cargo length, divided into port, center and starboard tanks by a pair of longitudinal oiltight bulkheads, resulting in a 3 × 5 matrix of cargo tanks. A sixth pair of wing tanks, designated "slop tanks", may be located immediately forward of the machinery spaces, to accommodate cargo oil or cargo tank washings. A typical cargo tank arrangement is shown in the outline arrangement, Figure 4, illustrating the tank arrangement of the EXXON VALDEZ, Table 1. This design meets the MARPOL requirements for segregated ballast and limitations on cargo tank volume prevailing at the time of the construction contract in 1984. Wing tanks numbers 2 and 4 are designated as segregated ballast tanks within the cargo spaces.

A great variety of segregated ballast tank arrangements have been adopted to meet the mandated protection of 30% to 40% of the shell in way of the cargo tanks. The most common arrangement consists of two pairs of wing tanks, as in the EXXON VALDEZ, Figure 4. A less common alternative is to provide a continuous double bottom in way of the cargo tanks to carry most of the ballast, while providing significant grounding protection. This arrangement, typical of tankers carrying refined products or chemicals, is illustrated in Figure 5.

By the time of this writing in the spring of 1990, a series of major casualties had occurred during the 1989–1990 period. These events were followed by a period of intense investigation and legislative activity directed to development of improved means of minimizing the consequences of collisions and groundings. The widely publicized grounding of the EXXON VALDEZ in Prince William Sound, with an estimated outflow of 11 million gallons of crude oil, resulted in extensive environmental damage and massive cleanup efforts by EXXON and state and federal agencies. Figure 6 shows, diagrammatically, the extent of damage, involving eight of the 11 cargo tanks. It is estimated that 60% or more of the cargo outflow would have been retained had the EXXON VALDEZ been designed and built with a continuous double bottom. It is ironic to note that the EXXON VALDEZ design was based in part on the earlier design of the 188,700 DWT B.T. SAN DIEGO class of tankers which were built with double bottoms.

The recently enacted Oil Pollution Act of 1990, discussed further in Section 5, establishes requirements for double hulls for tank vessels operating in U.S. waters. Requirements include specific minimum values for depth and breadth of double bottoms and wing tanks, respectively. In anticipation of these requirements, designers and builders have developed designs of "environmental" tankers and a significant number of building contracts have been let for construction of these vessels.

A variety of cargo tank configurations have been developed for double hull tank vessel designs. The most widely proposed is a variation of the conventional arrangement, Figure 4, wherein the longitudinal bulkheads are located well outboard to form relatively narrow segregated ballast wing tanks, in association with a continuous double bottom. Two innovative concepts recently developed are the Japanese EPOCH design, Figure 7, and the Danish product tanker design, Figure 8. The latter evolved from a successful series of bulk carrier designs.

It should be noted that double hull design to meet anticipated regulatory safety requirements does not require new

technology. As noted earlier, LNG, LPG and a variety of special products carriers have all been built with double hulls, as mandated by regulatory requirements.

Special Hazards in Tanker Operations In addition to collision and grounding, the following hazards to tank vessel operation should be considered as potential sources of pollution:

a) Fire—Of the many possible disasters which may occur to a tank vessel in petroleum trades, fire is among the most common. Should rupture of a tank occur incidental to the fire, the cargo may be burned, thus preventing extensive pollution. However, gross structural failures may occur as a consequence of fire damage, resulting in uncontrolled release of cargo that may not be consumed by the fire.
b) Explosion—Despite the many regulations and operational precautions, explosions occur when an obscure source of ignition takes place in the gaseous atmosphere above the liquid cargo level. Some of the most disastrous incidents have taken place when tankers in ballast with empty tanks not gas-free have been involved in minor collisions.

It should be noted that the MARPOL requirements include the installation of inert gas systems (IGS) on all tank vessels of 20,000 DWT or greater. IGS systems consist of means for pumping flue gas or treated gas from an inert gas generator into the cargo tanks to displace air with a combustible oxygen content.

Special Products Carriers Casualties to the special products carriers described in earlier discussions involve unusual hazards and pollution problems. The responsible regulatory agencies were active in studying and regulating various special hazardous cargoes long before oil pollution was recognized as a major hazard. Accordingly, safety codes and regulations have been formulated and effectively enforced for a long period of time. Regulations of the U.S. Coast Guard, for example, which apply to various hazardous cargoes, as well as liquefied petroleum and natural gasses, are covered in References (9), (10) and (11).

Hazardous cargo transportation is given special treatment by the designer and the cognizant regulatory agencies by consideration of the following:

a) Materials—Where indicated by the corrosive or otherwise restrictive nature of the cargo, special materials, subject to rigorous testing requirements, are specified. Liquefied gas containment, for example, requires special steels or other materials to avoid brittle fracture at low temperature. Similar restrictions hold for piping and cargo pumps.
b) Containment—As noted earlier, in all cases where special hazards exist, it has generally been the practice to require transport of cargoes inboard of shell plating, that is, cargo is contained within an inner hull formed by an inner bottom and longitudinal bulkheads. Further restrictions in some cases require that the cargo containment be structurally independent of the ship's main hull structure. This is the case with pressure vessels and rectangular tanks for carrying liquefied gasses at low temperature and molten sulfur at high temperature. The requirement for secondary containment, that is, the ability to contain the cargo for indefinite periods of time in the event of rupture of the primary tank, has long been established as a basic requirement for the transport of liquefied gases at low temperature.
c) Cargo handling—Elaborate safety precautions to avoid spillage and sources of ignition are inherent in established design practices and regulatory requirements.

The above brief discussion indicates a comparatively high level of design for safety in the case of hazardous cargoes. In the event of a low energy collision or stranding there is a reasonable probability that the primary containment system will remain intact.

For the liquefied gasses, the greatest tonnage category of special hazardous cargoes, pollution hazards are limited, or at least of short duration, since the cargoes are volatile and would be dissipated in a short period of time in the event of primary tank rupture. For the other cargoes, toxic materials in particular, the pollution hazard remains. Cargoes are shipped in relatively small quantities, however, and effective containment is readily achieved with modern construction methods.

Dry Bulk Carriers

Fuel oil is likely to be carried primarily in deep tanks, and, to a lesser extent, in selected double bottom and wing tanks. Accordingly, fuel bunkers comprise a relatively small portion of total tank space and do not represent an unusual in the event of collision or grounding.

Combination Bulk Carriers

When transporting oil cargoes, combination carriers function as tankers. The internal arrangement of ore/oil tankers, Figure 3, resembles the arrangement of a tanker, with respect to location of longitudinal bulkheads at least 20% of the breadth from the side shell. Accordingly, the extent of cargo oil pollution from side collision is comparable to the case of the tanker, assuming comparable compartment lengths.

The ore/bulk/oil, or OBO, carrier, however, is designed with high capacity cargo holds in order to transport low density dry bulk cargoes as well as oil. As a result, the boundary of the center holds is well outboard the 20% breadth penetration line, for either the single skin or smooth skin side shell arrangement. In the event of a side collision in way of a single compartment of a nine-hold vessel about 1/9 the oil cargo will be exposed to the sea, compared to about 1/20 the total cargo in the case of a modern crude tanker. In the case of a low energy collision, the OBO with double skin side shell will offer a somewhat greater resistance to penetration than the more common single skin arrangement.

The double bottom arrangement of combination carries does provide for some grounding protection, particularly in way of the center holds. The lower outboard sloping wing tanks of some vessels, however, are regularly used as cargo oil tanks.

PREVENTION

Improvements in maritime safety standards have historically followed some major disaster at sea. This was the case with respect to loss of the TITANIC, the 1960 SOLAS convention with respect to the sinking of the ANDREA DORIA, and now the accelerated IMO activity in the wake of the 1988−1989 casualties.

It must be emphasized that economic incentives are the fundamental basis for the increased potential for pollution due to collision and stranding. The trend to larger tank vessels and toward simplification of the ship design, all directed to substantial economies in construction and operation, are not easily reversed. Yet this trend necessarily increases the pollution hazard occurring from an individual incident. In the light of the overwhelming short term economic incentives, it is clear that all improvements must necessarily come from the imposition of requirements from outside the industry; that is, from the deliberations of regulatory bodies at an international level and perhaps just as effectively, from the pressures of the insurance industry.

Some suggested directions for study in improvement of design and operation are included in the following discussion.

Operational Measures

Dirty Ballast This source of pollution should be largely eliminated with the imposition of MARPOL regulations requiring segregated ballast and the general prohibition against discharging oily waste at sea.

Fuel and Cargo Oil Transfer Fuel and cargo transfer operations are, to a large extent, under control of shore personnel. The ship's crew is responsible for tank loading sequences and monitoring the loading operation to avoid overflow through tank vents. The general adoption of cargo automation systems involving existing and developmental hardware should minimize this source of pollution.

Ship Design, Arrangement and Structure

The recently enacted Oil Pollution Act of 1990, Reference (12), mandates that all tank vessels of 5000 gross tons or larger, operating in waters subject to jurisdiction of the United States, must be of double hull construction by the year 2015. The law includes explicit phase-out time tables for retiring existing tank vessels, depending upon year of delivery and type of cargo tank arrangement, that is, single skin, double bottom, or double side configuration. The law also mandates the establishment of a research and development program, directed to improvements in ship design and operations. For example, the following are among the structural design measures which warrant study:

a) Structural design to increase collision protection. Wing tanks could be designed to absorb collision energy and limit penetration. Techniques are available to study various arrangements empirically. See References (5) and (6).
b) Structural design to improve grounding resistance. Double bottom structural systems could be optimized to enhance grounding protection. Empirical and analytical approaches to this design objective are reported in References (7), (8), and (9).
c) Mandatory installation of stress measuring instrumentation at strategic locations in the hull structure, with indicators located on the bridge. The objective here is to monitor cargo, fuel and seaway loading effects that may cause unacceptable stresses.

Ship Design, Performance and Maneuverability

Maneuverability is a primary means for avoiding collision and grounding in emergency conditions. Accordingly, the following observations and studies are pertinent to the overall problem.

Backing Power The conventional crash stop maneuver for the 550,000 DWT twin screw, twin rudder tanker BATILLUS, Reference (10), required 34 minutes to stop in 22 ship lengths. With both rudders turned outward, these values were reduced to 28 minutes and 16 ship lengths, respectively. Data given in Reference (11) demonstrates that steam turbine propelled single screw U.S. flag tankers, with displacement ranging from 25,000 to 77,000 tons, can be expected to stop in 8½ to 9 ship lengths from the full ahead condition and periods of 5½ to 9 minutes will be required to execute this maneuver from the time the crash stop order is given.

The geared steam turbines installed in the above ships are fitted with astern elements with a capability of about 80 per cent full ahead torque and 50 per cent full ahead RPM, i.e., about 40 per cent full ahead power. The time required to obtain full astern revolutions, from the full ahead condition, is on the order of one minute. Crash stop characteristics of the diesel ship may be somewhat better, because full astern power is available.

It has been shown that tanker sizes have grown at a far greater rate than the installed power, hence, the stopping ability has been reduced significantly, with the obvious reduction in ship maneuverability.

Steering and Directional Control Turning circles of conventional single screw tankers, expressed as turning circle diameter/LBP, vary from 3 to 4. Current U.S. Coast Guard regulations require the posting of turning circle and crash stop trial data on the bridges of ships over 1600 gross tons. While no minimum standards are included in international or federal regulations at this time, it is understood that establishment of such standards is under active consideration.

Miscellaneous Safety Considerations

Regulatory agencies such as the U.S. Coast Guard regularly upgrade national shipping regulations in compliance with changes in international regulations, and in response to changes in the nature of particular transportation systems. Current examples (mid 1990) include upgrading of safety standards for coastal passenger vessels, and the comprehensive Oil Pollution Act of 1990. Other current design and operational trends that are being addressed by regulatory agencies and classification societies include the following:

a) Manpower reduction and automation—Crew sizes on large oceangoing tank vessels average about 19 to 21 persons. Trends to further reductions to 12 to 15 persons within the next few years are conservatively anticipated. These crew reductions must be supported by integrated command and control systems and condition monitoring of main and auxillary machinery systems and components.
b) Maintenance reduction—To maintain a safe operating condition, inspection and maintenance procedures must be maintained at acceptable levels, while recognizing the constraints of reduced crew size.

c) Enhanced navigation systems—Long term objectives include the integration of satellite and terrestrial navigational aids, electronic updating of charts, and automatic position plotting. Safety objectives include installation of grounding and collision avoidance systems and "dead man" alarms. Problem areas to be addressed include international standardization of data format and transfer, and barriers to electronic data transfer inherent in chart copyright status. Research and development is required in all areas noted above, to attain a "user friendly" state of development and to reach the degree of reliability necessary to satisfy regulatory requirements.

Detailed discussions of potential improvements to tank vessel design, construction and operation are included in Reference (13).

MICROBIOLOGY

INTRODUCTION

Microbiology is the study of organisms which are small enough to require the aid of a microscope to be seen. In a few cases, organisms are included in this group which can be seen by the unaided eye because these organisms are clearly related to the smaller ones. Microorganisms include viruses, bacteria including rickettsia, mycoplasma, fungi (yeast and molds), most algae, protozoa and, if one interprets “micro” broadly, certain tiny multicellular plants and animals. The study of cells and tissues from higher plants and animals (*tissue culture*) uses techniques common to the microbiologist and is frequently considered part of modern microbiology.

Cells in general vary greatly in size but have many similarities in internal organization. Among the most primitive type of cells, it is impossible to clearly distinguish whether they are distinctly “plants” or “animals” since they may have some of the properties of each type. Viruses, on the other hand, are *not cells* at all. Instead of arguing endlessly about whether a microorganisms is more plant-like or more animal-like and worrying how to assign viruses, many scientists have divided organisms in general into those which have (1) only animal characteristics, (2) only plant characteristics and (3) the *Protista* (Table 1), which have some characteristics of both plants and animals. Some protists, viruses, may have characteristics not shared by either plants or animals, that is, crystallizability and ability to reproduce only by infecting some cell and using the cell’s manufacturing machinery.

PHYSICAL CHARACTERISTICS OF MICROORGANISMS

Protists vary greatly in size, shape and internal architecture. Protists are subdivided into *prokaryotes,* and *eukaryotes. Prokaryotes* do not have their genetic material (chromosomes) separated from the rest of the cell by a membrane whereas eukaryotes have a true nucleus (*eu*—true, *karyo*—nucleus) separated from the rest of the cell by a nuclear membrane. Viruses (virions) are usually included among the prokaryotes. There are 9 types of prokaryotes.

Prokaryotes

1) *Viruses* are the *smallest protists.* They range in size from about 30–300 nm. The smallest viruses can only be visualized with an electron microscope while the largest can be seen with a light microscope. Viruses are composed of two general molecular types (1) *only one* nucleic acid, either *ribonucleic acid* (RNA) or *deoxyribonucleic acid* (DNA), and (2) a group of proteins also called *protein subunits* or *capsomeres,* which surround the

TABLE 1
Characteristics of the Protista

Virion (virus)	30–300 nm	icosahedron, hollow cylinder icosahedral head + tail	RNA, DNA	requires participation of host machinery
Mycoplasma	100–300 nm	pleomorphic prokaryotes	DNA	fission
True bacteria	250–3000 nm	spherical, rod, spiral rods, prokaryotes	DNA	fission
Higher bacteria	500–5000 nm	spherical, rod, spiral rods, filamentous, prokaryotes	DNA	fission, budding
Prokaryotic algae	500–5000 nm	spherical, rods in chains, spiral rods in chains	DNA	fission, internal septation, gonidia
Eukaryotic algae	500 nm to macroscopic	unicellular or multicellular, filamentous, leafy	DNA in nucleus, chloroplasts, mitochondria	asexual or sexual simple fission to complex life cycles
Protozoa	500–500,000 nm	unicellular or colonial various forms	DNA in nucleus, mitochondria	asexual or sexual simple fission to complex life cycles

nucleic acid and form a protective coat or *capsid.* The smallest viruses appear spherical but magnification in the order of 150,000–700,000 × reveals that they are *icosahedrons* (20 triangular faces and 12 corners) for example, wart virus. Other viruses, for example, tobacco mosaic virus (TMV), the first virus crystallized in 1935 by Wendell Stanley, is grossly rodlike. Tobacco mosaic virus is composed of a central, spirally-attached RNA to which capsomeres are attached to form the outside of a cylinder. The center of the RNA spiral of TMV is hollow. Structurally, the most complicated viruses are some which attack bacteria and blue-green algae.

These complicated viruses are composed of an icosahedral head, containing DNA, a protenaceous tail and sometimes accessory tail structures which are important for the attachment of the virus to its host cell.

2) *Mycoplasma* are prokaryotes which overlap viruses in size. They range from 100–300 nm in size. They are highly *pleomorphic:* they do not have one typical shape but rather can appear coccoid, filamentous, or highly branched. Unlike most other prokaryotes, they do not have cell walls external to their cell membranes. Their cell membranes usually contain sterols, which are thought to lend strength to these cell-limiting membranes (see also Table 2).
3) The *true bacteria* or *Eubacteriales* are prokaryotes which are built on three general geometric forms: spheres or cocci, *rods,* and *spirals* (including spiral helices). All true bacteria have rigid cell walls. They are either permanently immotile or move by means of one to many flagella. They may be aerobes or anaerobes. Some of the anaerobes are photosynthetic. Their sizes and shapes are usually constant except among the rods, in which rapidly-multiplying cells may be somewhat smaller than usual. When the cells divide, they often remain attached to each other and form characteristic, multicellular clusters. The shape of the cluster is determined by the number of division planes.

When *cocci* divide in only one plane, they form chains which may be as much as 20 cells long. *Diplococcus pneumoniae* forms chains only two cells long while *Streptococcus* is an example of the long-chain forming type. On the other hand, cocci which divide along two planes, at right angles to each other, form sheets of cells, and cocci which divide in three planes form cube-shaped packets. If there is no regular pattern of the orientation of successive division planes, a randomly-shaped cluster is formed. *Staphylococcus* is an example of a coccus which forms random clusters. A typical coccus is in the size range of 0.15–1.5 μm in diameter.

Rods always divide in only one plane. They may appear as single cells or groups of only two when they separate rapidly. The common intestinal bacterium *Escherichia coli* (size 0.5 × 2.0 μm) is an example of this type. Frequently rods form long chains or *streptobacilli. Bacillus megaterium* (size 1.35 × 3.0 μm), the organism responsible for the "bloody bread" of ancient times, is an example of a chain forming rod. Some basically rodshaped bacteria are either curved or helical rods. Their sizes range from almost as small as the smallest straight rod shaped form to close to twice the length of the largest straight rod.

True bacteria always divide by binary fission after their single circular chromosome replicates in a semiconservative fashion.

Some true bacteria have complicated life cycles which includes *spore-formation.* Spore-formers are all rods but belong to diverse genera. They are ecologically related in that they are found primarily in soil. Since that natural

TABLE 2
Some characteristics of prokaryotic and eukaryotic cells

Structure	Prokaryote	Eukaryote
Weight Chromosome	0.001–1.0 pg one, single circular DNA double helix not complexed with histones	10–10,000 pg several linear DNA double helices (several chromosomes usually complex with histones)
Nucleus	No true nucleus. Chromosomes not separated from cytoplasm by a membrane	True nucleus. Chromosomes enclosed in a nuclear membrane
Reproduction	Usually asexual, conjugation takes place rarely, no mitosis or meiosis	Asexually by mitosis or sexually after meiosis
Membranes	Only cell limiting membrane present. Usually lacks sterols (except for mycoplasma)	Cell limiting membrane plus membrane limited organelles present. Composition includes sterols
Organelles	None	Many including mitochondria, chloroplasts (plants only), Golgi apparatus, lysosomes, etc.
Apparatus for protein synthesis	Ribosomes, 70 S type usually not associated with membranes	Ribosomes, 80 S type in cytoplasm associated with endoplasmic reticulum. 70 S type in mitochondria and chloroplasts not associated with membranes

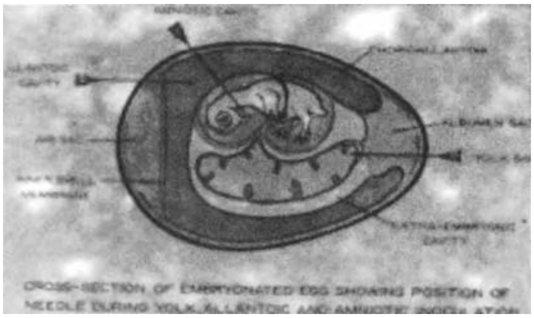

FIGURE 1 Animal viruses are often grown in embryonated eggs. The position of the hypodermic needles indicates three common inoculation places.

environment is rather variable in that it can range from very hot to very cold and from very wet to very dry, the heat- and cold-resistant dormant spores offer the bacteria a means of surviving adverse environmental conditions for months or even years. Many important pathogens and commercially important organisms are spore formers, e.g. *Bacillus anthracis* which causes anthrax, *Clostridium tetani* which causes tetanus and *Clostridium acetobutylicum* which can ferment corn or potato mash into acetone, ethanol and butanol.

Corynebacteria are also rod-shaped bacteria but they are *pleomorphic* and often look club-shaped. One of the best known members of the genus is *C. diphtheriae*, which causes diphtheria. Other members of the genus are commercially important as producers of the vitamin folic acid.

Arthrobacter species are found widely in soil and water. Depending upon the nutrients supplied, they can appear as cocci or pleomorphic rods.

4) *Spirochetes* are NOT true bacteria though they resemble Eubacteriales in that they are spirally curved, unicellular and multiply by binary fission. They differ from eubacteria by the *absence of a rigid cell wall* which allows them to be quite flexible. They are all motile by means of *axial filaments* attached at the cell poles and spirally wrapped around the cell. The smallest spirochete is 0.1 × 5 nm while the largest is 3.0 × 120 μm. One of the most important spirochetes is *Treponema pallidum*, which causes syphilis.
5) *Actinomycetes* are NOT true bacteria. Rather, they are naturally-branching, filamentous, spore-forming organisms which have a *mycelial structure* similar to that of filamentous fungi. Many actinomycetes, especially those from the genus *Streptomyces,* are commercially important sources of antibiotics.
6) *Mycobacteria* are rods which can form a rudimentary mycelium which resembles actinomycetes, but they differ in that their cell walls are particularly rich in waxes, which allows them to retain stain imparted by such dyes as basic fuchsin even after treatment with dilute acid. This property, called *acid fastness,* is characteristic of mycobacteria. Many species occur in soil but the best known are the human pathogens *M. tuberculosis* and *M. leprae*, which cause tuberculosis and leprosy respectively.
7) *Budding bacteria* are NOT true bacteria. They possess a complicated life cycle which includes *multiplication by budding* rather than binary fission. Their type of budding can be readily distinguished from that of true fungi such as yeast. The budding bacterium *Hyphomicrobium* exists for part of its life cycle as a flagellated, slightly curved rod. For multiplication, the flagellum is lost, the chromosome replicates, and one chromosome migrates to one end of the cell where a hypha-like lengthening takes place. When the hyphal extension ceases, it becomes a rounded bud which contains the chromosome. The bud grows in length and diameter until it reaches the size of the mother cell, grows a new flagellum, and separates from the hyphal extension.
8) *Gliding bacteria* are diverse group of prokaryotes which are motile without having flagella. They have very close affinities to blue-green algae although gliding bacteria are not themselves photosynthetic. They may be unicellular rods, helical or spiral-helical, or filamentous.
9) *Blue-green algae* or *Cyanophyta* are the only prokaryotic algae. They are a diverse group that include both unicellular and filamentous forms. They have cell walls that resemble Gram-negative bacteria but their photosynthesis more closely resembles that of eukaryotes in that it is aerobic rather than anaerobic (as in photosynthetic bacteria). They are among the most complex prokaryotes. Even though they lack defined organelles, e.g. they lack *chloroplasts,* many species have complex membranous or vesicular substructures which are continuous with the cell membrane.

Some filamentous forms contain specialized structures such as *gas vacuoles, heterocysts,* or *resting spores* (*akinetes*). Gas vacuoles are frequently found in *planktonic species,* i.e. those which live in open water. These vacuoles are thought to provide the algae with a means of floating and sinking to the depth most appropriate to support photosynthesis. *Heterocysts* arise from vegetative cells and are thought to function in N_2 fixation. Some blue-green algae show gliding motility. None are flagellated. They are very widely distributed either in terrestrial or aquatic habitats from the arctic to the tropics. Some forms are found in hot springs. Other *Cyanophyta* are *symbionts* in a variety of plants and animals. For example a species of *Anabaena* fixes N_2 for its host the water fern, *Azolla.* Many blue-green algae form especially luxuriant mats of growth called *blooms* which clog waterways and limit their use for navigation, etc.

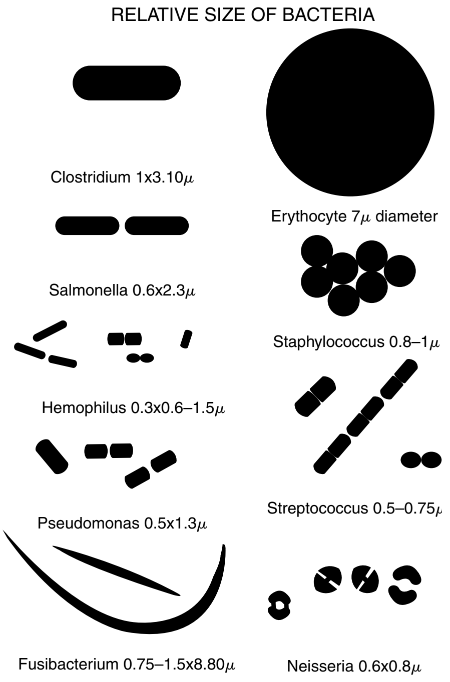

FIGURE 2 Relative sizes of bacteria.

The prokaryotic blue-green algae, *Cyanophyta,* are usually divided into 5 groups:

Chooccocales are unicellular. They sometimes occur in irregular packets or colonies. Cells multiply by binary fission.

Chamaesiphonales are unicellular, filamentous, or colonial epiphytes or lithophytes. Cells show distinct polarity from apex to base. The base usually has a holdfast which permits attachment to the substrate. Cells multiply by internal septation or by formation of spherical cells (*gonidia*) at the ends of filaments.

Pleurocapsales are filamentous with differentiation into aerial and nonaerial elements. Cells multiply by crosswall formation or by internal septation.

Nostocales are filamentous without differentiation into aerial and nonaerial elements. They are unbranched or falsely branched and frequently have pale, empty-looking cells called *heterocysts* and resting spores (*akinetes*). Reproduction is by liberation of a short filament only a few cells long, called a *hormogonium,* which then elongates.

a) *Nostacaceae* are unbranched and produce heterocysts. They frequently produce akinetes.
b) *Rivulariaceae* are unbranched or falsely branched. Filaments taper from base to tip. Heterocysts are usually present at the base. There is some akinete formation.
c) *Scytonemataceae* are false branched. Heterocysts are frequently found at branch points.
d) *Stigonematalis* are filamentous with aerial and nonaerial differentiation. Hormogonia and heterocysts are present. They often show true branching and have pit connections between cells. Akinetes are rare.

Eukaryotes

Eukaryotic microorganisms include all the algae (except the *Cyanophyta*), all the protozoa, and most fungi. All are microscopic in size.

The eukaryotic algae are separated into nine *divisions* based upon their pigment and carbohydrate reserves (Table 3). They are all photosynthetic and, like higher plants, evolve oxygen during photosynthesis. Many algae are *obligate phototrophs.* That is, they are completely dependent upon photosynthesis: they can not use exogenously supplied organic compounds for growth in either the dark or light. Some algae are *facultative phototrophs;* they are able to utilize organic compounds for growth in the dark but fix carbon dioxide photosynthetically in the light.

Occasionally algae, especially unicellular forms, permanently lose their chloroplasts by exposure to any one of several adverse conditions, e.g. heat or chemicals. If the organism had been a facultative phototroph, before the loss of the chloroplasts, it has the enzymatic machinery necessary to survive except that now, in its chloroplastless state, it is indistinguishable from certain other unicellular organisms more commonly called protozoa. The ease with which an organism at this primitive level of evolution may be interchanged between groups containing a preponderance of plant-like or animal-like attributes underlines the need for the term *protist* rather than plant or animal to describe them. Indeed both botanists and zoologists claim the protists. Some algae e.g. *Euglena* spp., normally only form chloroplasts when they grow in the light while others e.g. *Chlorella* spp. form chloroplasts regardless of the presence of absence of light. There is great diversity in size, shape, presence or absence of life cycles, type of multiplication, motility, cell wall chemistry, and chloroplast structure. Although these parameters are of great assistance in defining affinities among algae, there are still groups whose proper place is debated.

Many algae are important as sources of food, chemical intermediates of industrial and medical importance, and research tools. Others are nuisances which clog waterways or poison other aquatic life with their potent toxins.

Eukaryotic Algal Groups

The eight groups are:

1) *Chlorophyta* (green algae) are either marine or freshwater forms. This large and diverse group includes forms which are either unicellular, colonial, filamentous, *tetrasporal* (cells separated but held together in groups of four in a mucilaginous material), *coenobial* (cells more or less attached to each other in an aggregate), or *siphonaceous* (simple, nonseptate filaments). They frequently have life cycles which

include motile, flagellated stages. Both asexual and sexual reproduction occurs.

2) *Euglenophyta* differ from the other algae by possessing a rather flexible cell wall which allows considerable plasticity of form. They are either fresh water or marine forms. They all have two flagella but in some genera the second flagellum is often rudimentary. Many forms are *phagotrophic* (can ingest particles). Chloroplastless forms are fairly common. Multiplication is only by asexual means.
3) *Xanthophyta* are mostly freshwater forms. They may be unicellular, colonial, filamentous or siphonaceous. Some forms have life cycles which include both asexual and sexual reproduction. Motile anteriorly flagellated cells are found.
4) *Chrysophyta* are mainly freshwater forms but important marine forms are known. Most genera are unicellular but there are some colonial forms. Cell walls are often composed of siliceous or calcareous plates. Some form siliceous cysts. They are mainly found in fresh water but some important marine forms exist. Reproduction is asexual.
5) *Phaeophyta* (diatoms) are unicellular or colonial forms with distinctly patterned siliceous cell walls. Both asexual and sexual multiplication is found. Freshwater, marine, soil and aerial forms exist.
6) *Pyrrophyta* are unicellular flagellates with cellulose cell walls which are sometimes formed in plates. Reproduction is asexual. Sexual reproduction is rare.
7) *Cryptophyta* are unicellular, usually flagellated forms which produce asexually.
8) *Rhodophyta* (red algae) are unicellular, filamentous or leafy forms with complex sexual cycles. Most are marine but there are a few freshwater forms.

Fungi

The "true" fungi or *Eumycota* are eukaryotes which are related to both protozoa and algae. They are divided between

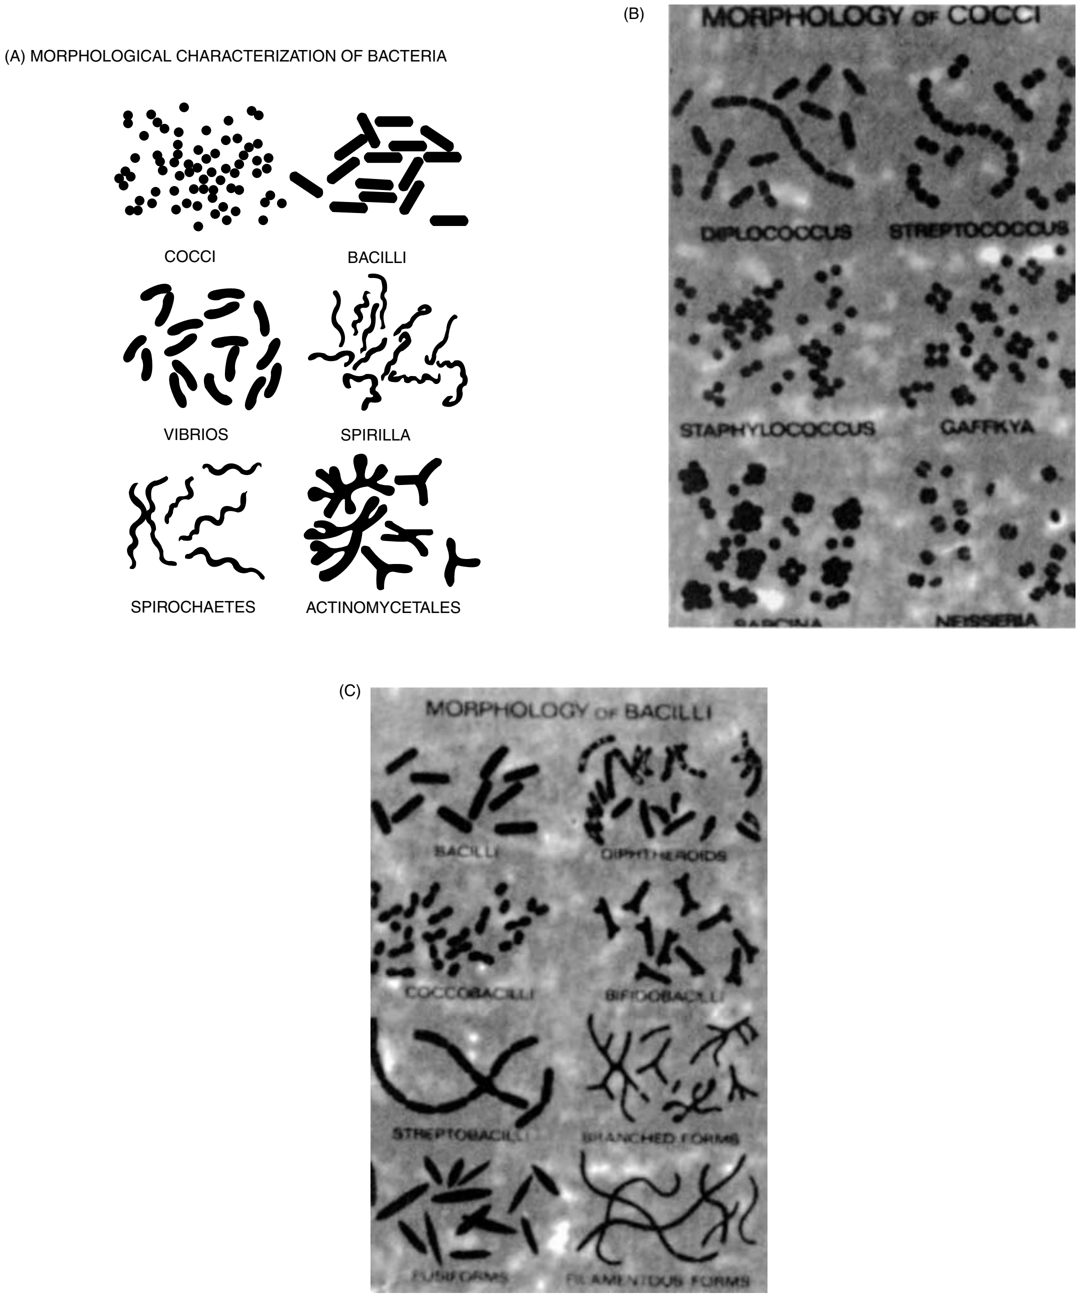

FIGURE 3 A. General morphological characteristics of bacteria; B. Variety of morphological types among the cocci; C. Variety of morphological types among the bacilli (rods).

microscopic and macroscopic and macroscopic groups. In general, they have rigid cell walls, lack chlorophyll, and are usually immotile. Most fungi reproduce asexually or sexually by means of spores though important budding groups such as yeasts are well known. Since fungi are classified by the pattern of their sexual structures, fungi whose sexual stages are unknown are placed into a group called *Fungi Imperfecti* and assigned genera on the basis of their asexual structures. They are further subdivided into the so-called lower and higher fungi. The lower fungi, *Phycomycetes,* are also called water molds but not all are aquatic (e.g. black bread molds). Some species multiply by means of flagellated gametes or flagellated spores i.e. more like certain green algae than other fungi; Most, but not all, Phycomycetes have

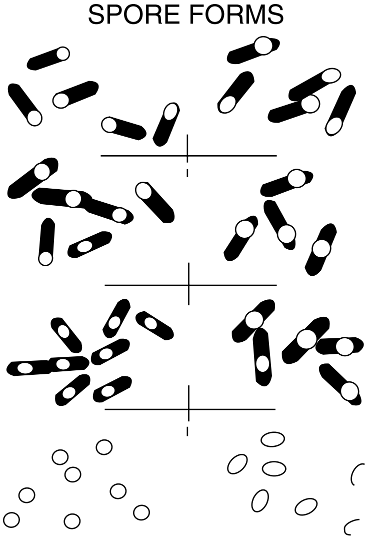

FIGURE 4 Diagrammatic representation of spores (clear areas) inside rod-shaped bacteria. Note (bottom row) that free spores may be ball or egg-shaped.

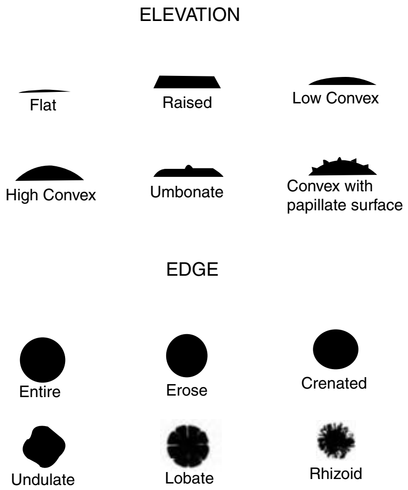

FIGURE 5 Diagrammatic representation of types of bacterial colonies. These shapes are specific for individual types and are therefore quite useful as a step in the process of identification of unknown organisms.

hyphae, microscopic cytoplasm-filled tube-like branches (lacking crosswalls), which together make a felty mat called a *mycelium.* Individual hyphae are microscopic but the mycelium, equivalent to a bacterial colony, is macroscopic. Growth takes place by extension of the hyphae. Specialized spore-containing bodies called *sporangia* can form at the ends of some hyphae. Sexual reproduction requires fusion of hyphae from two different mycelia to form a specialized *zygospore.*

It is more common now to discard the term Phycomyetes and instead subdivide the group into 4 classes in which affinities are much clearer. However, at present, the literature is divided in its use of the older and newer terminology. As with bacteria, chemical analyses of structures and metabolic pathways followed are important in defining the classes. These four classes are:

1) *Chytridiomycetes* lack true mycelia. They are aquatic, have posteriorly uniflagellated zoospores and cell walls composed of chitin.
2) *Hyphochytridiomycetes* have true mycelia. They are aquatic, have anteriorly uniflagellated zoospores and cell walls composed of chitin.
3) *Oomycetes* have true well developed mycelia and cell walls composed of cellulose.

   a) *Saprolegniales* are generally aquatic and have asexual spores on specialized mycelear structures. Only male gametes are motile.
   b) *Peronosporales* are generally terrestrial. Sporangia either produce asexual zoospores or may germinate directly to form hyphae. Both gametes are nonmotile.

4) *Zygomycetes* are terrestrial and have large and well developed mycelia and nonmotile spores. Asexual spores are produced in sporangia. Cell walls are made of chitosan or chitin.

There are two classes included in the higher fungi.

1) The *Ascomycetes* are the best known and largest class of fungi. Ascomycetes have hyphae divided by porous crosswalls. Each of these hyphal compartments usually contains a separate nucleus. Asexual spores called *conidia,* form singly or in chains at the tip of a specialized hypha. The sexual structure called *ascus,* is formed at the enlarged end of a specialized fruiting structure and usually contains eight *ascospores.* Some important microscopic members of this group include yeasts, mildews, the common red bread mold and many species which produce antibiotics. On the other hand macroscopic forms include *Morchella esculenta* or morels which are highly regarded as a delicacy by gourmets.
2) The *Basidiomycetes* are entirely macroscopic and are commonly known as mushrooms and toadstools.

Slime Molds

The slime molds, *Myxomycetes,* are at times classified with either true fungi or protozoa or, as here, treated separately. They produce vegetative structures which look like ameboid

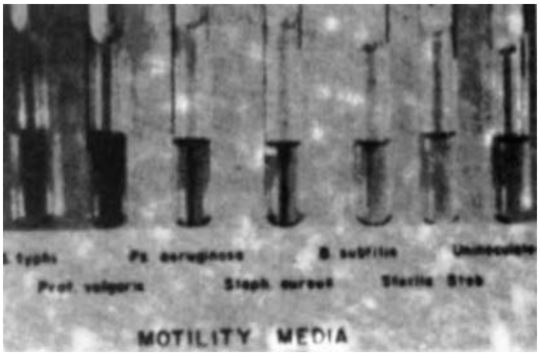

FIGURE 6 Bacterial motility. Motility is tested by stabbing an inoculated needle into a tube of very viscous growth medium. The motile organisms (*S. typhi* and *P. vulgaris*) grow away from the stab mark.

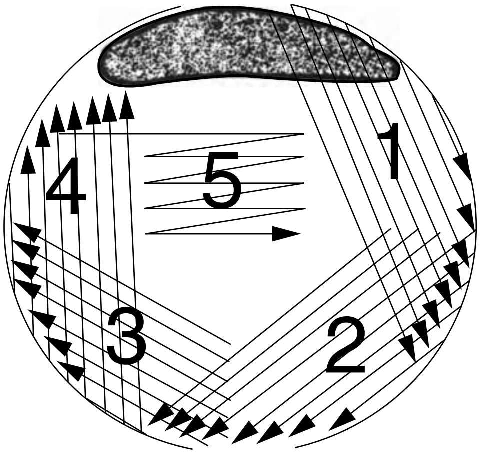

FIGURE 7 Isolation of single bacterial colonies on agar plates by dilution streaking. A diagrammatic representation of method of streaking inoculated needle across nutrient-containing plate. Stippled area is the primary inoculation. The inoculation needle is then flamed to sterilize and is then drawn across the stippled areas as indicated for area 1. The needle is then resterilized and drawn across area 2, etc.

protozoa and fruiting bodies which produce spores with cell walls like fungi. There are two major subdivisions (a) Cellular and (b) Acellular. They both primarily live on decaying plant material and can ingest other microorganisms, such as bacteria, phagocytically. Both have life cycles, but that of the acellular slime molds is more complicated.

Cellular slime molds have vegetative forms composed of single ameboid cells. Cyclically, ameboid cells aggregate to form a slug-shaped *pseudoplasmodium* that begins to form *fruiting bodies* when the slug becomes immotile. Spores are finally produced by the fruiting bodies.

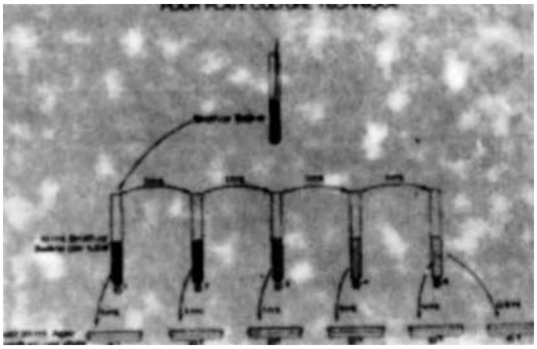

FIGURE 8 Isolation of single colonies by pour plate technique.

Acellular slime molds have vegetative forms called *plasmodia* which are composed of naked masses of protoplasm of indefinite size and shape and which travel by ameboid movement (protoplasmic streaming). Two kinds of nesting structures are produced: *fruiting bodies* (part of the sexual cycle) and *sclerolia.*

Protozoa

The last major group of microorganisms are the protozoa. As already stated, it is very hard to distinguish plants from animals at this primitive stage in evolution where organisms have some attributes of each. Most workers therefore are less interested in whether protozoa should be claimed by botanists or zoologists as they are in studying the group as the root of a phylogenetic tree which gave rise to clearly separable plants and animals. Protozoa range in size from that of large bacteria to just visible without a microscope. They have a variety of shapes, multiplication methods and associations which range from single cells to specialized colonies. They are variously found in fresh water, marine, terrestrial, and occasionally, aerial habitats. Both freeliving and parasitic forms are included. Most are motile but there are also important nonmotile forms. The protozoa are divided into four subphyla (I–IV).

I. *Sarcomastigophora* include forms which have either flagella, pseudopodia or both. Usually a single-type of nucleus (though opalinids contain multiples of this one type) is present except in development stages of a few forms. Asexual reproduction by binary fission is common. One whole class contains chloroplasts and are claimed by both protozoologists and algologists (they are considered here in detail with the eukaryotic algae). Many important parasites of diverse animal and some plant groups are found here. Sexual reproduction is present in a few forms.

The Sarcomastigophora are divided into three superclasses.

A. Mastigophora (*flagellates*) Are further sub-divided into *Phytomastigophorea* or plant-like flagellates (see eukaryotic algae) and *Zoomastigophorea* or animal-like flagellates which are divided into nine orders.

1) *Choanoflagellida* have a single anterior flagellum surrounded posteriorly by a collar. Some forms are attached to substrates. They are solitary or colonial and are all free-living.
2) *Bicosoecida* have 2 flagella (one free, the other attached to the posterior of the organism). They are free-living.
3) *Rhizomastigida* have pseudopodia and 1–4 or more flagella. Most species are free-living.
4) *Kinetoplastida* have 1–4 flagella and all have a kinetoplast (specialized mitochondrion). Many important pathogens (e.g. trypanosomes) and some free-living genera are included.
5) *Retortamonadida* have 2–4 flagella. The cytostome is fibril-bordered. All are parasitic.
6) *Diplomonadida* have 2 karyomastigonts, each with 4 flagella and sets of accessory organelles. Most species are parasitic.
7) *Oxymonadida* have one or more karyomastigonts, each with 4 flagella. All species are parasitic.
8) *Trichomonadida* have mastigont systems with 4–6 flagella. Some have undulated membranes. Many important pathogens (e.g. *Trichomonas*) are included.
9) *Hypermastigida* have mastigont systems with numerous flagella and multiple parabasal apparatus. All are parasitic. Some forms reproduce sexually.

B. Opalinata Are an intermediary group related to both ciliates and flagellates and are entirely parasitic. Opalinics have many cilia-like organelles arranged in oblique rows over their entire body surface. They lack cytosomes (oral openings). They have multiple nuclei (ranging from 2 to many) which divide acentrically. The whole organism divides by binary fission. Life cycles are complex.

C. Sarcodina Or ameboid organisms have Pseudopodia which are typically present but flagella may be present during certain restricted developmental stages. Some forms have external or internal *tests* or skeletons which vary widely in type and chemical composition. All reproduce asexually by fission but some also reproduce asexually. Most species are free-living (in both aquatic and terrestrial habitats) but some are important pathogens; for example, *Entameba histolytica*, which causes amebic dysentary. The sarcodinids are further divided into three classes.

1) *Rhizopodae,* a free-living, mostly particle-eating (phagotrophic) group which includes both naked and shelled species. The specialized pseudopodia are called lobopodia, filopodia, or reticulopodia.
2) *Piroplasmea.* These parasitic small, piriform, round, rod-shaped or ameboid organisms do not form spores, flagella or cilia. Locomotion is by body-flexing or gliding. They reproduce by binary fission or schizogony.
3) *Actinopodea* are free-living, spherical, typically floating forms with typically delicate and radiose pseudopodia. Forms may be naked or have membraneous, clutenoid, or silicated tests. Both asexual and sexual reproduction occurs. Gametes are usually flagellated.

II. *Sporozoa* typically form spores without polar filaments and lack flagella or cilia. Both asexual and sexual reproduction takes place. All species are parasitic. Some have rather complicated life cycles.
The Sporozoa are divided into three classes:

A. Telesporea Can reproduce sexually or asexually, have spores, move by body flexion or gliding and generally do not have pseudopodia.
B. Toxoplasmea Reproduce asexually, lack spores, pseudopodia or flagella, and move by body flexion or gliding.
C. Haplosporea Reproduce asexually and lack flagella. They have spores and may have pseudopodia.

III. *Cnidospora* have spores with one or more polar filaments and one or more sporoplasms. All species are parasitic. There are two classes.
IV. *Ciliophora* have simple cilia or compound ciliary organelles in at least one stage of their life cycle. They usually have two types of nucleus. Reproduction is asexually by fission or sexually by various means. Most species are free-living but parasitic forms are known.

ENERGY AND CARBON METABOLISM

All cells require a source of chemical energy and of carbon for building protoplasm. Regardless of whether the cell type is prokaryote or eukaryote or whether it is more plant-like or more animal-like, this basic requirement is the same. The most basic division relates to the source of *carbon* used to build protoplasm. Organisms which can manufacture all their carbon-containing compounds from originally ingested inorganic carbon (CO_2) are called *autotrophs* while those which require ingestion of one or several organic compounds for use in the manufacture of cellular carbon compounds are called *heterotrophs.* Some organisms are nutritionally versatile and may operate either as autotrophs or heterotrophs and are therefore referred to as *facultative-autotrophs* or *facultative-heterotrophs* (depending upon which mode of nutrition usually predominates).

Autotrophs are further divided according to the manner in which they obtain energy. *Chemoautotrophs* (also called chemotrophs or *chemolithotrophs* oxidize various inorganic compounds to obtain energy while *photoautotrophs* (also called phototrophs or *photolithotrophs*) convert light to chemical energy *via* the absorption of light energy by special pigments (chlorophylls and carotenoids). In both cases, chemical energy is stored in the form of chemical bond energy in the compound adenosine triphosphate (ATP).

When bonds of ATP indicated by ~ are broken, a considerable amount of energy is released. This ~ bond cleavage energy operates the biological engines: it is the universal chemical power which operates in all cells, autotroph or heterotroph.

Chemolithotrophic nutrition is only used by certain true bacteria. These bacteria are of ecological importance in that they are used to convert one form of nitrogen to another (i.e. in the nitrogen cycle) or industrially to oxidize low grade metallic or non-metallic ores. There are six bacterial groups which are chemolithotrophic.

1) The ammonia oxidizers such as *Nitrosomonas*, *Nitrosococcus*, *Nitrosocystis*, *Nitrosogloea* and *Nitrosospira*.
   One scheme for ammonia oxidation had hydroxylamine as an obligate intermediate and has been proposed for *Nitrosomonas.*
2) The nitrite oxidizers such as *Nitrobacter* and *Nitrocystis.* One proposed scheme for nitrite oxidation for *Nitrobacter* is:

$$NO_2^- \xrightarrow[\text{reductase}]{\text{cytochrome}} \text{cytochrome C} \xrightarrow[\text{oxidase}]{\text{cytochrome}} O_2$$

ATP ADP

3) Hydrogen oxidizers *Hydrogenomonas.* One proposed hydrogen oxidation scheme is:

   $H_2 \rightarrow 2H^+ + 2e \rightarrow$unknown$\rightarrow$flavor protein compound

   $\rightarrow$ubiquinone$\rightarrow O_2$
   cytochrome
   b compex

   Nicotinamide adenine$\rightarrow$menadione

   $\rightarrow$cytochrome C$\rightarrow$cytochrome a
   $\rightarrow O_2$ dinucleotide (NAD)
4) Ferrous compound oxidizing bacteria such as *Ferrobacillus* and *Thiobacillus ferroxidans.*

   One proposed ferrous oxidizing scheme for

   F. ferrooxidans is:

   $4FeCO_3 + O_2 + 6H_2O \rightarrow 4Fe(OH)_3 + 4CO_2$

5) Methane oxidizers such as *Methanomonas methanooxidans* and *Pseudomonas methanica* are common in the upper layers of marine sediments and soil.

   Methane is oxidized in the following manner:

   $CH_4 \rightarrow CH_3OH \rightarrow HCHO \rightarrow HCOOH \rightarrow CO_2$

6) The sulfur-compound oxidizing bacteria *Thiobacillus.*

Four pathways for oxidation of thiosulfate ($S_2O_3^{+2}$) by different *Thiobacillus* species are known. These are:

a) $6Na_2S_2O_3 + SO_2 \rightarrow 4Na_2SO_4 + 2Na_2S_4O_6$
   $2Na_2S_4O_6 + 6H_2O + 7O_2 \rightarrow 2Na_2SO_4 + 6H_2SO_4$
b) $Na_2S_2O_3 + 2O_2 + H_2O \rightarrow Na_2SO_4 + H_2SO_4$
c) $5Na_2S_2O_3 + H_2O + 4O_2$
   $\rightarrow 5Na_2SO_2 + H_2SO_4 + 4S$
   $2S + 3O_2 + 2H_2O \rightarrow 2H_2SO_4$
d) $2Na_2S_2O_3 + H_2O + 1/2O_2 \rightarrow Na_2S_4O_6 + 2NaOH$

Photolithotrophic nutrition is used by photosynthetic bacteria, blue green algae and eukaryotic algae. The general reaction in which both utilization of CO_2 (carbon dioxide fixation) and energy generation is summarized is:

$$CO_2 + H_2A \xrightarrow{nv} (CH_2O) + 2A + H_2O$$

Where A is either oxygen for all eukaryotic algae and the prokaryotic blue-green algae ($H_2A = H_2O$), or sulfur for green sulfur bacteria, *Chlorobacteriaceae,* and purple sulfur bacteria, *Thiorhodaceae* ($H_2A = H_2S$) or any one of several organic compounds for nonsulfur purple bacteria, *Athiorhodaceao* ($H_2A = H_2$-organic compound which is oxidizable).

Both green and purple sulfur bacteria are obligate anaerobes whereas the non-sulfur purple bacteria are facultative anaerobes (they are anaerobic when growing heterotrophically). In all cases, photosynthetic organisms operate by the initial transduction of light to chemical energy. In this transduction, chlorophyll + light quanta $Ch1^+$ (excited chlorophyll) + e^- (electron driven off of Ch1). Many such events take place simultaneously and electrons released during these reactions migrate through the photosynthetic unit to the reaction center and transfer energy to a special *reaction-center chlorophyll.* At the reaction center, a charge separation of the oxidant and reductant occurs. Electron flow after this event differs in photosynthetic bacteria as compared with algae and higher plants (Figures 9 and 10). In addition, differences in photosynthetic ability exist among organisms based upon the absorption maxima of their light-transducing pigments (primarily chlorophylls). The combination of light intensity, wavelength of available light, wavelength of operation of principal energy transducing pigment, degree of aerobiasis, and availability of oxidizable compound (H_2O, H_2S, or H_2-organic compound) all influence the efficiency of photosynthesis. These factors should be borne in mind when one looks for the ecological niche occupied by these various organisms.

Ecology of Microorganisms

One should understand the physiological requirements of microorganisms *before* investigating the effects of environmental changes on the distribution and activity of diverse

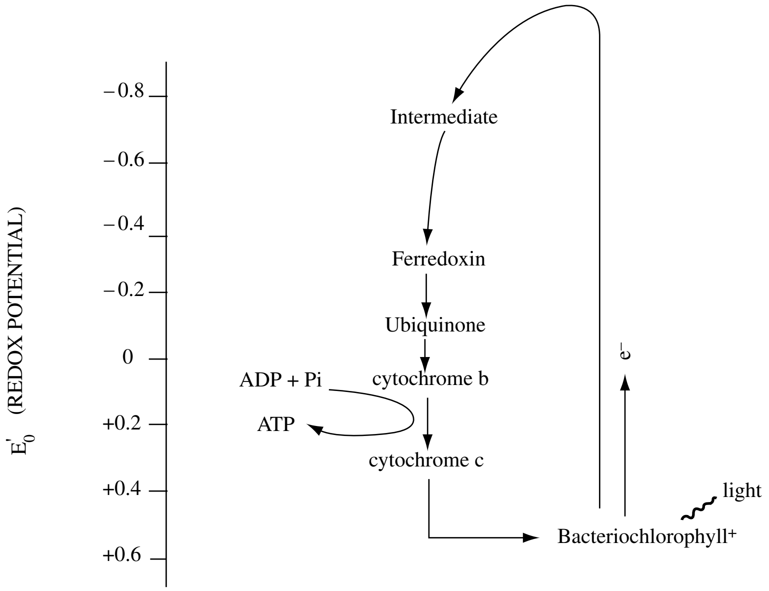

FIGURE 9 Electron flow in bacterial photosynthesis.

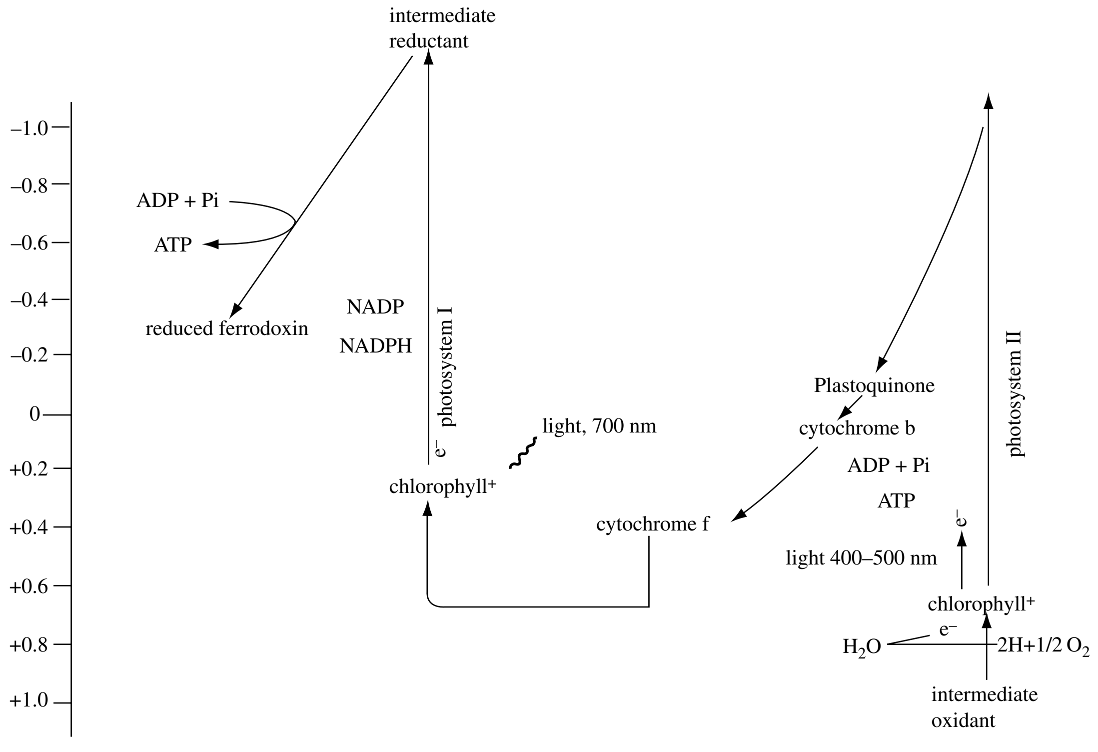

FIGURE 10 Electron flow in algal and higher plant photo-synthesis.

microbial types, their interactions and their relationships to higher plants and animals. It is important to note that the "natural" balance may be undesirable. Thus studied efforts to change these bal ances would be quite desirable. The most important precaution to observe relates to the ancillary consequences of these changes, i.e. do the changes produce side effects which may be as unappetizing as the original condition.

The development of techniques which form the bases for studying microbial ecology comprise an important chapter in

classical microbiology. These laboratory methods, pioneered by Winogradsky (1856–1953) and Beijerinck (1851–1931) and refined by others, utilize specialized, restrictive, physical and chemical conditions to select and cause to predominate one or few types of organisms from a highly diverse mixture. Hence this method is termed *selective enrichment culture.* Once one understands how to manipulate these laboratory systems, it is easier to analyze field observations in which specific conditions which result in microbial changes can be recognized and, if necessary, altered. We will first explain the principles of selective enrichment techniques and then look at the natural distribution of microorganisms and their relationship to higher plants and animals. Highlights of microbial characteristics which are useful taxonomically have been described in the various sections listed under *Physical Characteristics of Microorganisms.*

Selective Enrichment Methods

To determine whether a given sample of soil, water, or air contains microorganisms capable of living under a particular set of conditions, one prepares a growth medium which is selective for a property peculiar to those conditions. For example, if organisms which can fix atmospheric nitrogen are sought, all non-atmospheric sources of nitrogen (such as nitrites, nitrates, ammonia, amino acids) are eliminated from the growth medium. If organisms which obligately fix carbon dioxide are required, all nonatmospheric (organic) sources of carbon are eliminated from the growth medium and, frequently, additional CO_2 is bubbled through the medium.

On the other hand, it might be of particular interest to determine if a certain weed-killer is *biodegradable* before it is used under field conditions. Many different approaches to this important problem are possible. Thus more than one mode of attack is described. The approach which is closest to the general principle of revealing (selectively enriching for) a minor population of desired microbial type among a multitude of undesirable organisms makes use of an enrichment medium in which the weed-killer is used as either (a) the only source of organic carbon and nitrogen, (b) the only source of organic carbon though other sources of nitrogen are present, or (c) the only source of nitrogen though other sources of organic carbon are present. Subsequent microbial growth indicates biodegradability. The organisms may be isolated and used as seed cultures for a percolation system which is fed by the aqueous runoff from a field which was treated with the weed-killer. Thus the more public waterways fed by aqueous effluents from treated fields would not be polluted by potentially-toxic agricultural chemicals.

In order to prepare selective enrichment media, one needs to provide the microorganisms with all their nutritional requirements in proper proportions. Insufficient quantities will not support growth and excesses are frequently toxic. In addition conditions must be biased in some way to insure that most of the undesired organisms will not grow at all or will grow appreciably slower than the desired organisms. It should be recognized that it is rare for any single enrichment to select out only one microbial species. Thus further purification steps are required if one wishes to isolate only one species uncontaminated with other living things. An uncontaminated, single membered culture is called a *pure* or *axenic* (a = absence of, xenos = strangers) culture. The common nutritional requirements of microorganisms, the quantities in which they must be supplied, and the biological uses of each substance are shown in Table 5. The selective enrichment techniques to be described are most frequently used for the isolation of bacteria, yeast, and certain prokaryotic algae. An outline of selecting properties is given in Table 6.

A demonstration of factors involved during the natural selection which takes place under field conditions is shown in Figure 11. These models are called *Winogradsky columns*. The variety of microbial life which develops over a period of 2–10 days is determined by (a) the degree of acidity or alkalinity of these natural growth media, (b) the nutrients contained in the liquid and solid phases, and, of course, (c) the initial populations of microorganisms. In the examples shown, light is provided to ensure growth of photosynthetic organisms.

If the basic principles of the Winogradsky column are to be used to reveal the microbial population in a particular soil or water sample, then the column and all its components are first sterilized and then inoculated with a *nonsterile* soil or water sample. The microbial population of the sample will develop in the portions of the column which provide the proper physical and chemical conditions.

An important application of Winogradsky columns can be made for testing various chemicals for potential ecological changes. The chemical agent is percolated through a soil column or is simply added to a predominantly liquid column either when the column is started or after its microbial population has developed. Significant changes in the column's normal population (diversity or population density) is indicative of toxicity to one or more types of microorganisms. The profound changes in populations of higher plants and animals due to disruption of the balance of microbial life can be readily appreciated when the cyclic nature of nitrogen and sulfur dissimilation is considered (Figures 12 and 13). These interdependences emphasize the key role played by microorganisms in maintaining the balance of soil nutrients.

Use of the Winogradsky Column for Testing Biodegradability Capacity of a Natural Soil or Water Body

In the last section, an example was given in which one of these bodies with little capacity for biodegradation of a weed-killer can be controlled so that the body in question does not spread the potential pollutant to a bordering body. We now consider a method for pretesting the biodegradation test. One would hope that this or a parallel test would become standard before new agricultural chemicals are marketed. That is, chemicals which are not decomposed *before* they leave the immediate land or water body in which they are used would not be marketed or would only be marketed *after* controls against accumulation of the chemical had been worked out.

The Winogradsky column test for ability of a potential soil or water body to degrade a potenlially dangerous chemical such as a weed-killer consists of (a) preparing a standard column composed of soil or water from the body in question, and (b) after the column has been allowed to develop its natural population (c) an isotopically labelled version of the weed-killer can be added in the concentration (and 10 × the concentration that the weed-killer is to be used). After a time equivalent to that in which the weed-killer is expected to remain in the natural body (i.e. account for flushing time from rain or water currents), the column is tapped by elution with water or buffer, and the effluent is analyzed for per cent undergraded weed-killer as well as *the nature of the degradation products.* The latter point is particularly important

TABLE 5

Nutritional requirements of typical heterotrophic microorganisms with limited synthetic capacity

Type compound	Example	Quantity in typical medium (%)
Energy source	Glucose, sucrose, glutamic acid, succinic acid	0.1−2.0% 0.1−0.5%
Synthesis of protein and fat	sodium acetate	0.01−0.1%
	Lecithin amino acids	0.001−0.005% 0.002−0.1%
Synthesis of nucleic acids	purines and pyrimidines	0.0005−0.002%
Coenzymes	Vitamins	0.0001−0.005%
Major inorganic requirements	PO_4, Mn^{++}, Mg^{++}, Na^+, K^+	0.01−0.05%
Minor inorganic requirements	Ca^{++}, Co^{++}, Zn^{++}, Fe^{+++},Cu^{++}, Cl^- NH_4^+ or NO_3^-	0.001−0.01%
Water	All the above are prepared in aqueous solution

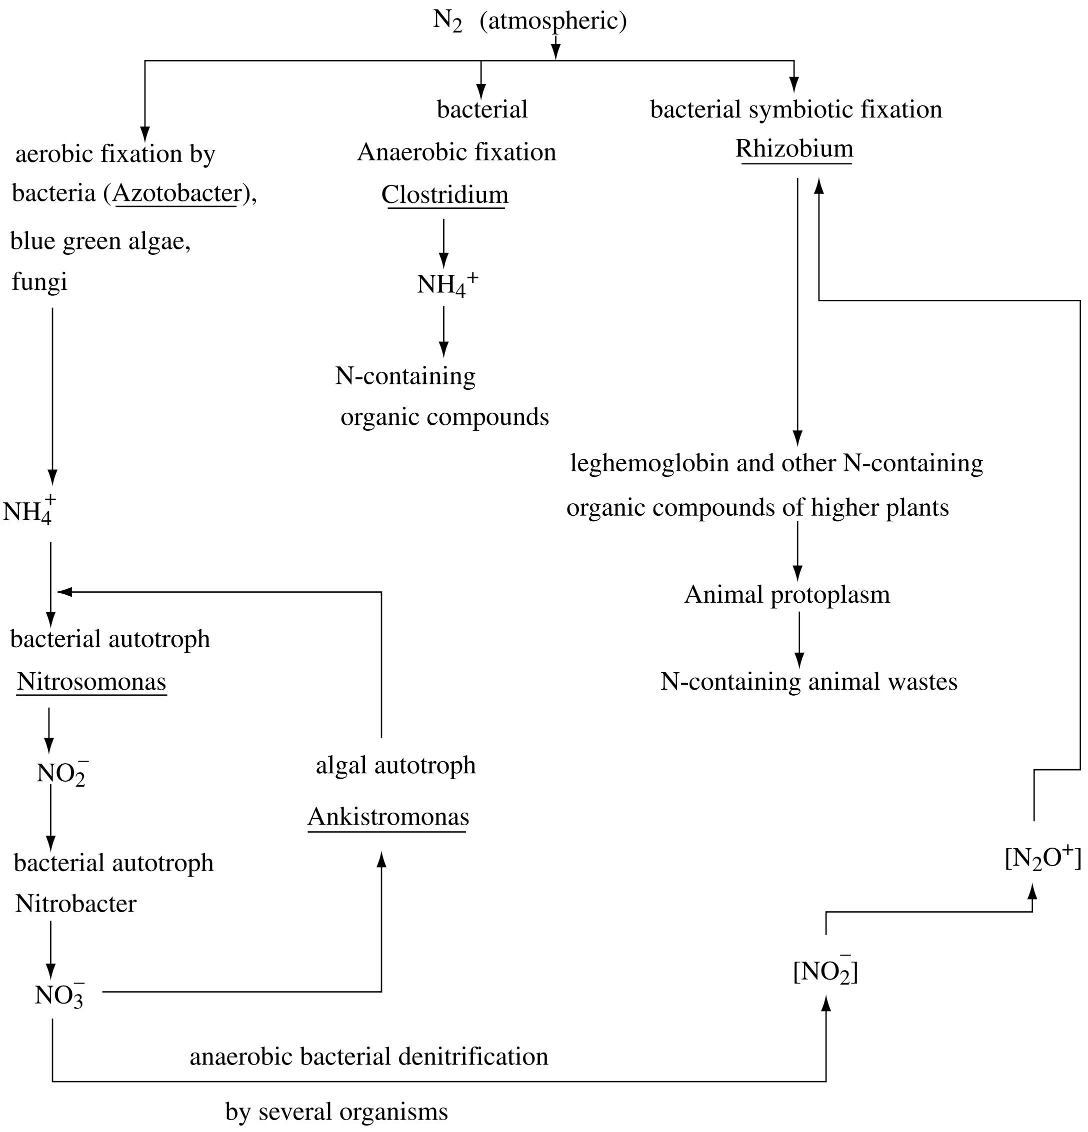

FIGURE 12 The nitrogen cycle presented in a generalized way so that the role of various microorganisms are indicated as well as the relationship to higher plants and animals. The precise arrangement will vary according to several physical parameters of the natural environment.

since the degradation products may themselves be noxious. Thus, the only degradation products which are acceptable are those which may enter normal metabolism or are labile enough to be further degraded to metabolizable compounds by the physical conditions in the body in question.

Determination of Gross Populations of Microorganisms

Quantitative sampling techniques are required for the determination of the microbial population in air, water, or soil samples. The method used for sample collection must ensure against (a) loss of more than a trivial number of microorganisms and (b) cross-contamination from other sources during sample transport and laboratory manipulation. Once the sample has arrived in the laboratory, selective enrichment techniques can be used to reveal the diversity of microorganisms or mixed populations can be counted by using some variation of the pour plate technique (see Figure 8).

A. *Air sampling techniques* Non-spore forming organisms are rarely found in air samples because they are too delicate to survive for long in the generally dehydrating conditions of atmospheric transport. A convenient sampler consists of a sterile membrane filter connected to a metering vacuum pump. At the beginning of the sampling period, the

    2. NO_2^- is N source, *Nitrobacter* (bacterium)
    3. NH_4^+ plus special atmosphere composed of 85% H_2; 10% O_2; 5% CO_2 at pH 7 Hydrogen bacteria
    4. NH_4^+ plus $S_2O_3^=$ at pH 7. Certain *Thiobacillus* spp. (bacteria)
  - Light present and sulfide absent
    - N_2 can serve as sole nitrogen source: Blue-green algae
    - Nitrogen must be present in combined form: Green algae

6B *Selecting Factors for Heterotrophic Organisms*

- Anaerobiasis
  - Light present, neutral pH: Non-sulfur purple bacteria
  - Light absent
    1. Acid pH, fermentable sugar present Yeast spp.
    2. Neutral pH
       - fermentable sugar
         - N_2 as sole nitrogen source *Clostridium* species (bacteria)
         - Presence of combined nitrogen source. Numerous microbial types.
       - non-fermentable substrate, electron acceptor is 1, 2 or 3
         1. NO_3 Denitrifying bacteria
         2. CO_2 Methane bacteria
         3. $SO_4^=$ *Desulfovibrio* (bacterium)
- Aerobiasis (see below)

- Aerobiasis
  - Light present Many algae will grow here, pH aids in further differentiation as does the precise selection of organic components
  - Light absent
    - N_2 is sole nitrogen source *Azotobacter* (bacterium)
    - Presence of combined nitrogen source. Depending upon the complexity of the medium and pH, most aerobic bacteria yeast, protozoa and some algae could grow. Specific texts should be consulted for further details.

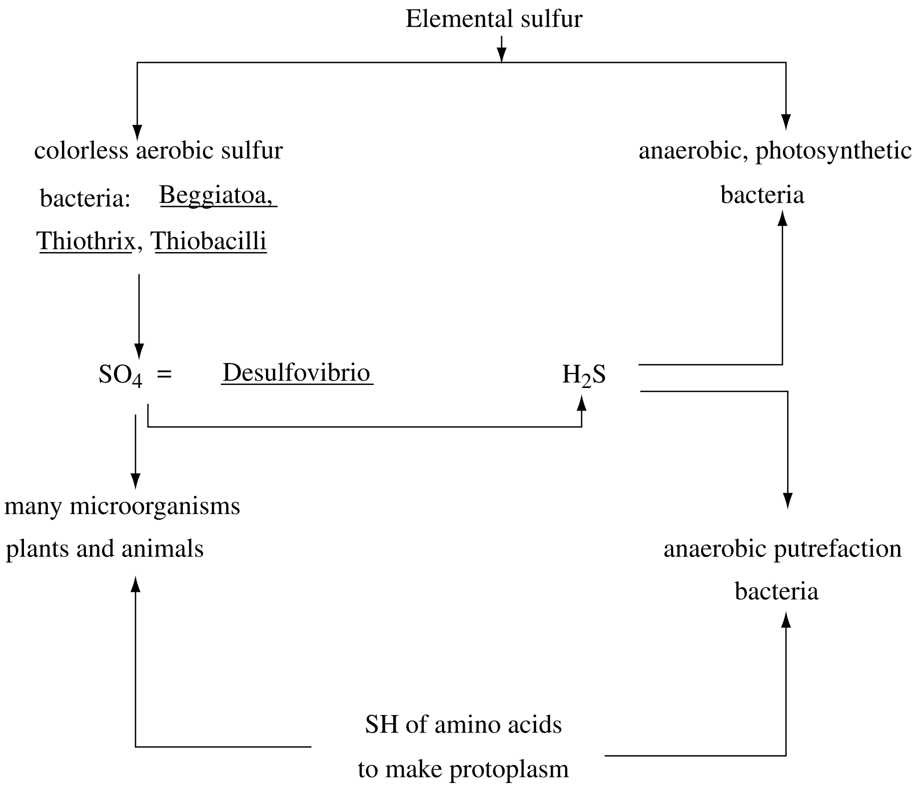

FIGURE 13 The sulfur cycle. Microorganisms are becoming increasingly useful for processing low-grade sulfur-containing ores. Sometimes overlooked is the natural cyclic distribution of sulfur-containing compounds in which microorganisms play principle roles.

membrane is exposed and the desired amount of air passed through it. Air-borne microorganisms are trapped on or in the membrane. Some discrimination among organisms can be made during sampling by using membranes with graded porosities. In this way organisms are segregated according to their cross-sectional dimensions. To reveal the organisms impinged upon the membrane, the membrane is treated as inoculum for the various selecting media.

B. *Water sampling techniques* Any container which can be sterilized and can be opened and closed by remote signal can be used. It should be recognized that pressure changes after retrieval may influence viability of organisms collected at great depths.

C. *Soil sampling techniques* A sterilized coring device is usually used to ensure against contamination with airborne organisms. The soil samples are handled aseptically and weighed amounts are tested for their microbial population.

MINE DRAINAGE: see POLLUTION FROM MINE DRAINAGE

MOBILE SOURCE POLLUTION

Mobile sources, alternatively called transportation or vehicular sources, include cars, trucks, buses, ships and various aircraft. Air pollutants emitted will vary, depending on the fuel being combusted or reacted (in the case of fuel cells or batteries) and the engine design of each vehicle.

THE AUTOMOBILE

The automobile's discovery appears to satisfactorily combine a human desire for rapid transportation with the desire for independence and flexibility. However, the increasing vehicle population poses a series of threats to continued physical and psychological well-being and to the future of our environment.

As the automotive industry expands, other auxiliary industries such as petroleum production and concrete and tire manufacturing also grow, with additional potential for pollution problems. Additional roads also have to be built, with a negative impact on both ecology and landscape. A balance must be made between the right of an individual to use his own car when and where he drives and the harm brought upon society as a whole by his doing so. If it is accepted that society needs to be protected, a number of legislative and economic measures can be initiated to discourage automotive usage.

Legislation has been enacted to limit the emission of HC (hydrocarbons), NO_x (oxides of nitrogen), CO (carbon monoxide) and particulate matter including lead compounds. However, other waste materials such as tires and the automobile itself (including the repugnant abandoned cars) must be disposed of.

The broad approach to automotive pollution control is to encourage alternative means of transportation. This would include improvements in mass transit such as high-speed trains, moving sidewalks, increased links and modernization. In the city, bicycle riding and walking are low pollution, high exercise alternatives; in rural areas car pools might be formed.

Cars have been built using different energy concepts (ex. battery, turbine engine, sterling engine) and to run on different fuels (ex. natural gas, alcohol). Special control devices (ex. catalytic reactors, afterburners) placed at the exhaust of internal combustion engines are the primary means of reducing emissions of various materials. The total solution to the problem will probably combine technical and strategic methods.

The US EPA and US DOE produce the Fuel Economy Guide to help car buyers choose from the best fuel gallons per mile (mpg) ratings for both city and highway traffic modes. A pdf version may be found at http://www.epa.gov/cgibin/epaprintonly.cgi[1]

In the present discussion, we shall concentrate on the major moving source of pollutants, the internal combustion engine. In the automobile, evaporative losses of pollutants occur from the fuel tank and carburetor (ca. 5%), fumes from the crankcase (ca. 20%) and the exhaust system (ca. 75%). The major offenders are unburned hydrocarbons, carbon monoxide, nitrogen oxides and HC oxidants. Positive Crankcase Ventilation (PCV) on all modern cars reduces the emissions by pulling air and fumes into the engine by maintaining a vacuum at the engine. Of course a highly efficient combustion process will eliminate the partially oxidized substances. One reason for incomplete combustion is that as the "flame front" generated from the spark moves toward the relatively cool cylinder walls, a quenching action takes place preventing further reaction, the kinetics of which are very temperature sensitive. Other factors influencing incomplete combustion are improper dilution by poor cycle timing and less than the proper excess of oxygen admitted at the carburetor. Standard engine cycles have been developed so that pollutant guidelines might be drawn. The Federal Driving Cycle initiated in 1972 in considered the standard of vehicle testing. A federal short cycle Table 1 has been used for convenience in some instances. Measured emission values averaged for various test sites in representative US cities are presented in Table 2 for steady state at various miles per hour (mph) and for the short cycle. Carbon monoxide and NO_x levels increase as the mph level increases. The federal 1975 proposed standards for CO, hydrocarbons and NO_x are 11, 0.5 and 0.9 grams per mile, respectively, and 0.5%, 40 ppm and 225 ppm, respectively. Their extent of enforcement is increasing as of the early 1990s.

The CO standard is based primarily on tests which have shown that the capacity of blood to carry oxygen is hampered by CO absorption.[2] Brain function is retarded after an exposure of 10 to 15 ppm CO for several hours. The HC and NO_x levels are mainly based on their role in photochemical smog using ambient levels. Shy *et al.*[3] found in their Chattanooga study that "NO_2 alone and exposure to suspended particulate matter alone appear to be the most probable explanation for the observed excess in respiratory illness rates." The data are not completely convincing as pointed out by automobile industry researchers.[4] However, the U.S. government took the initiative for the welfare of the public in not waiting for all the details to be perfectly established. Certainly there are those among us (aged, with heart conditions, etc.) who will be more severely affected than the average by typical ambient pollutant concentrations and will need protection.

At least two approaches to the removal of internal combustion engine pollutants have come into wide acceptance. One is the improvement of the combustion process itself. This includes reducing manifold vacuum (and hence dilution of charge) between exhaust and intake steps; increasing the cylinder wall temperature; and designing for less maximum horsepower by minimizing the surface to volume ratio.

The other approach is controlling exhaust emissions by further reaction, either after-burning or catalytic. After-burning can be accomplished slightly downstream from the exhaust valve by additional oxygen injection converting HC and CO to CO_2 and water vapor. The after-burner has the disadvantage of not being able to remove NO_x. In fact, because of its high temperature, still more NO_x is formed. The catalytic approach is to find a catalyst or set of catalysts and temperature or set of temperatures which will completely oxidize both CO and HC, but also will reduce the NO_x. These two approaches will be discussed in detail below.

Meteorological and vehicle persistence factors have been developed for estimation of 1 hour carbon monoxide concentrations defined as worst-case total persistence factors.[33]

IMPROVEMENT OF THE COMBUSTION PROCESS

As mentioned above the explosion of fuel accounts for chemical pollutant formation. In the Rankine cycle engines, liquids may continually be vaporized and recondensed, and in the Sterling cycle engines a gas is repeatedly heated and cooled. Both cycles are accomplished in a sealed container and the heat used for the process comes from an open flame external to the engine. Very little pollution is generated in such a controlled rather than explosive flame.

Exhaust gas recirculation (EGR) is used on American Motors, Chevrolet and Chrysler automobiles. This includes a diaphragm-actuated flow control valve located between the exhaust and intake manifolds. The valve is operated by ported vacuum directed through hoses and a coolant temperature override. Permitting metered amounts of exhaust gases to enter the intake manifold, which are mixed with incoming fuel mixtures, lowers the combustion temperatures within the cylinders. Reducing maximum cylinder combustion temperatures minimizes the creation of Oxide of Nitrogen (NO_x). EGR operation does not take place until engine operating temperature has reached a preset level and engine load is sufficient to permit proper EGR operation.

Almost all autos now contain a PVC system which directs filtered air into the crankcase and channels vapors but toward the manifold leading to the combustion chamber. Fuel tank vapors are also concentrated by charcoal canisters in American Motors vehicles for recycled combustion.

An H.E.W. report[5] discusses engine modification systems, "Features shared by essentially all versions of the engine modification system include calibrated carburetors that provide (a) relatively lean air–fuel mixtures for idle and cruise operation and (b) higher engine idle speeds. Refined control of spark timing is also used, and, in some cases, regarded spark timing at idle is employed. In addition, many engines are fitted with special air cleaners and ducting designed to supply heated air at nearly constant temperature to the carburetor, to permit even leaner mixture settings. Most versions also incorporate high-temperature radiator thermostats to raise coolant temperatures, and thus improve mixture distribution and promote complete combustion. In some cases, higher capacity cooling systems are used to handle the additional cooling load at idle that results from wider throttle openings and retarded ignition timing during this operating condition. In addition, combustion chamber design attempts to avoid flame quenching zones where combustion might otherwise be incomplete, and result in high hydrocarbon emissions."

Hydrocarbon and CO emissions are reduced by adjusting the carburetor to a fuel-lean mixture during part throttle

TABLE 1
Federal short cycle

Mode					
No.	Type	Speed range	Time in mode (sec)	Average speed (mph)	Average acceleration rate (mph/sec)
1	Accel	0–16	6.0	8.00	2.67
2	Accel	16–29	23.0	22.50	0.57
3	Cruise	29	10.0	29.00	0.00
4	Accel	29–37	18.0	33.00	0.44
5	Accel	37–42	4.5	39.50	1.11
6	Decel	42–37	2.5	39.50	2.00
7	Decel	37–20	32.0	28.50	-0.53
8	Decel	20–0	7.5	10.00	-2.67
9	Idle	0	21.5	0.00	0.00

and idle operation. “Lean surge during cruise has been largely overcome through improvement in manifolding (better mixture distribution), better carburetor fuel-metering characteristics, higher coolant temperatures, increased heating of the air–fuel mixture, and, in some cases, provision for heating the incoming air to the carburetor.

Exhaust emissions of CO and HC are particularly difficult to control during engine idle and closed-throttle operation (deceleration). Considerable effort has gone into designing carburetor idle systems that will provide a lean air–fuel mixture and minimize emissions during these periods. To ensure that idle air–fuel mixture cannot be adjusted to be too rich (which would tend to increase CO and HC emissions appreciably), some means of limiting idle-mixture adjustment is used on most carburetors. Such devices allow idle mixture to be adjusted leaner than a predetermined value, but not richer.”

The effects of charge dilution on the exhaust emission of nitric oxide (NO) from a single-cylinder engine were evaluated over a range of engine design and operating parameters.[6] Nitric oxide emission decreased as much as 70% as charge dilution fraction was increased from 0.0065 to 0.164 due to increased valve overlap, external exhaust recirculation, and reduced compression ratio. NO emission was strongly dependent on charge dilution fraction, but was independent of the specific method used to change charge dilution. The combined effects of increased charge dilution and 10 degree spark retard reduced NO emission 90%. However, definite limits of operation were observed on the single-cylinder engine with high charge dilution.

The Ford Motor Company uses a system which reduces the hydrocarbon and carbon monoxide content of exhaust gases by continuing the combustion of unburned gases after they leave the combustion chamber. This is achieved by injecting fresh air into the hot exhaust stream leaving the exhaust ports. At this point, the fresh air mixes with hot exhaust gases to promote further oxidation of both the hydrocarbons and carbon monoxide, thereby reducing their concentration and converting some of them to carbon dioxide and water.

TABLE 2

Summary of results, steady state tests and federal short cycle vehicle exhaust emissions in grams per vehicle mile[a]

City	Effluent	Idle	15 mph	30 mph	45 mph	60 mph	FSC[b]
Los Angeles	HC	1.45	5.28	3.09	2.91	2.60	5.69

EMISSION CONTROL DEVICES

Additional Combustion

An afterburner is an additional baffled tubular reactor in which the gases are reignited and burned to completion. An air pump provides the necessary oxygen-rich mixture and the heat of reaction maintains a high temperature to speed its completion.

It is not necessary in all cases to have a separate afterburner. The aforementioned report[5] states, "An injection systems decrease exhaust CO and HC emissions by injecting air at a controlled rate and at low pressure into each exhaust port. Here, the oxygen in the air reacts with the hot exhaust gases, resulting in further combustion of the unburned hydrocarbons and CO that would otherwise be exhausted to the atmosphere. Optimum reduction of emissions by this method depends on proper air injection rates over a wide range of engine operating conditions, carefully tailored air-fuel mixture ratios and spark advance characteristics, and in some cases the use of heated carburetor air. Some engines also provide for retarded ignition timing during closed-throttle operation.

All air injection systems use essentially the same basic air pump, a positive displacement rotary-vane type.

To guard against excessive temperature and back pressure in the exhaust system resulting from high air delivery rates at full throttle and high speeds, a pressure-relief valve is installed in the pump housing. The valve opens to bleed off some of the pump flow at a predetermined pressure setting.

Output from the air pump is directed through hoses and an air distribution manifold (or two manifolds—one for each bank on V-8 engines) to the air injection tubes located in each exhaust port. A check valve between the air distribution manifold and the air pump prevents reverse flow of hot exhaust gases in the event that pump output is interrupted.

A vacuum-controlled antibackfire valve is used to prevent flow of air to the exhaust ports during the initial stage of closed-throttle acceleration. The high vacuum that occurs during deceleration causes rapid evaporation of liquid fuel from the intake manifold walls. The resulting rich mixture creates a potentially explosive vapor in the exhaust manifold if injected air is present.

As with engine modification systems, most air injection systems also employ spark retard during idle or idle and deceleration through use of 'ported' vacuum sources of dual-diaphragm distributor-vacuum-advance mechanisms."

Besides residual gas dilution and wall quenching, engine variables have the most effect on the amount of hydrocarbons in exhaust gases. Over sixty privately owned and operated automobiles fueled with commercial leaded gasoline have been tested and seven main engine variables were found which changed the hydrocarbon concentration in the exhaust gases. These results can be briefly summarized as:

1) Air-fuel ratio: Low value for gas mixture results in higher hydrocarbon concentration in exhaust gases.
2) Ignition timing.
3) Speed: Increase in speed of engine decreases the amount of hydrocarbon.
4) Air-flow rate: The effect of air-flow rate on the total hydrocarbon concentration depends on the air-flow ratio, ignition timing combination.
5) Compressor-ratio: Increasing the compression ratio, by decreasing head-to-piston distance, increases the total hydrocarbon concentration.
6) Exhaust Back Pressure: The amount of hydrocarbon in exhaust decreases with increasing exhaust pressure.
7) Coolant Temperature: Increasing the coolant temperature decreases the hydrocarbon concentration.

Catalytic Reactions

The engine exhaust gases may be passed through a cylindrical shaped canister packed with catalytic particles. Although this method has great potential, two problems may arise. The long term stability of the catalyst (50,000 miles) is difficult to maintain since lead and other chemicals in trace amounts poison the catalyst. The catalyst structural stability is difficult to maintain under the influence of varying gas flow rates and fairly high temperature. Also, removing three or four pollutants simultaneously can prove difficult for any single type of catalyst. The removal of NO_x, for instance, requires a reduction catalyst, whereas CO requires an oxidation catalyst. For this reason dual stage catalytic reactors have been proposed. The technical problems for this method are greater but the potential advantages are even greater.

Nitric Oxide Removal A review of some chemical reaction data which might be useful in automobile pollution control work has been presented by Shelef and Kummer.[7]

One approach to solving the stability problems has been to avoid leaded fuel in automobiles containing converters. The catalytic approach to conversion for American Motor cars is to use a pellet-type of catalyst with a monolithic-type warm-up feature for California and high altitude cars. The warm-up converter is separately mounted ahead of the catalytic converter. Chrysler Corporation and Chevrolet use a catalyst support coated with platinum, palladium and rhodium. Hydrocarbons, CO and NO_x are all reduced by this three component catalyst. An extensive literature exists on more economical active phases[11,13,16,22] which are not as effective converters. The air to exhaust ratio in catalytic converters is computer controlled in American Motor cars.

For this reason, reactions which involve combination with rather than decomposition of NO_2 are being studied very carefully. The equilibrium constants in terms of partial pressure are given in Table 3 for NO combination with hydrogen, CO and methane at various exhaust temperatures. The thermodynamic conditions (large K_p values) are generally favorable for conversion (reduction). A Monel (nickel–copper alloy) catalyst has been found reasonably successful for removing NO by combining it with residual CO in the exhaust stream. The Monel dissociates the oxygen from NO and then oxides CO to the harmless dioxide.

TABLE 3

The equilibrium constants for some reduction reactions of nitric oxide[17]

Reactions	log *Kp*				
	600	700	800	900	1000K
$NO + 5H_2 \rightarrow 2NH_3 + 2H_2O$	49.0	48.1	32.13	26.44	21.8
$NO + 2H_2 \rightarrow N_2 + 2H_2O$	51.7	43.4	37.1	32.2	28.3
$NO + CO \rightarrow ½N_2 + CO_2$	27.3	22.6	19.7	16.46	14.29
$NO + CH_4 \rightarrow ½N_2 + 2H_2$	19.59	18.1	17.6	16.2	15.5
NO + Hat → HNO	12.4	9.77	7.79	6.24	5.0
$NO + ½ H_2 \rightarrow HNO$	−3.7	−3.6	−3.52	−3.46	−3.42

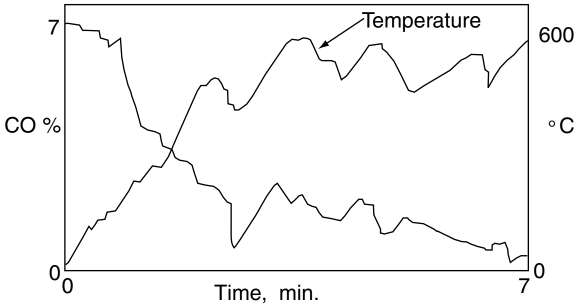

FIGURE 1

In this system, when the engine operation is too rich (too little oxygen) nitrogen oxide reduction is found to be excellent, but carbon monoxide conversion poor. The nitrogen oxide will readily combine with Monel, forming Monel oxide and nitrogen since there is little oxygen to compete with the nitrogen oxide for active sites on the Monel. However, since the CO:NO ratio is so large, there will be insufficient Monel oxide formed to give up its oxygen to the carbon monoxide.

On the other hand, if the engine operation is too lean, NO reduction will be poor and CO conversion excellent since the reaction becomes significant and oxygen will compete with the nitrogen oxide for sites on the Monel.

Some typical conversion data[1] at space velocities of 50,000 v/vhr indicated that conversion of NO in synthetic gas mixture (2% CO, 1000 ppm NO) was over 95% if the temperature was above 700°C, but fell off sharply at temperature below 650°C. Problems associated with this technique are the formation of NH_3 if any residual H_2 is present and back pressure buildups with the current catalyst structure. In addition, dusts form which are emitted as particulates. It is essential for efficient performance of this catalyst that it warms up to operating temperatures very rapidly. Lead in the fuel reduces the chemical activity and ultimately increased the rate of deterioration of the catalyst.

Another catalyst which showed promise for the same reaction but at lower temperature (200 to 350°C) has also been mentioned.[18] Despite the fact that conversions of better than 90% were reported equal amounts of CO and NO were used. Automotive exhaust have about 16 times more CO than NO. Activated carbon has been used[19] successfully with H_2 gas at 600°C. However, activated carbon lost a considerable portion of its activity after only 7 hours service.

CO and Hydrocarbon Removal Major automotive and petroleum companies have combined efforts in the development of an inexpensive multi-thousand mile catalytic package for reducing CO and HC exit concentrations. Since the input of gasoline and hence the effluent gases are rarely at steady state, any study of a catalytic reactor must consider the dynamic situation. To give some idea of magnitude, the exhaust gas flow in standard cubic feet per minute (SCFM) is roughly twice the miles per hour equivalent of an automobile and the temperatures of the exhaust gas change from that of the ambient to well over 600°C. Figure 1 shows typical CO and temperature levels in the exhaust stream after engine startup in a Federal cycle.

For balancing pollution problems with no catalytic or afterburner control an air–fuel ratio of about 16 is recommended. Above this level the NO_x level increases markedly and below it the amount of unburned HC and CO substantially increases. With catalytic devices this ratio may no longer be optimum, since the catalyst selectivity may be greater towards removal of one of the pollutants than any of the others.

Wei[20] has noted that the kinetics of CO oxidation over an egg-shell catalyst turn out to be first order for CO and 0.2 order for O_2 in the range of 1 to 9% oxygen. The curvature in the Arrhenius plot (Figure 2) is believed to be caused by a pore diffusional phenomena. As the catalyst ages and activity falls the reaction rate becomes controlling and the Arrhenius plot becomes a straight line. The catalyst of the figure is best above 350°C, but a lower operating temperature may be preferred for longer catalyst life. Wei[20] found that, "As the catalyst lost 90% of its activity, the emission rose by only 30%; but the last 10% of activity loss would result in a precipitous rise of carbon monoxide emission. A catalyst with 50% reduction in heat capacity performs much better; a reactor with 50% reduction in volume performs better when the catalyst is fresh and worse then it is aged." His philosophy is, "It is our engineering goal to produce a low-cost and convenient solution. However, any solution requires some inconvenience and cost from everyone. Quick warm-up is no problem if we are willing to sit and wait in the car for 2 min for an auxiliary heater to warm up the catalyst bed before the car moves. We have ninety million cars on the road, and a $100 device will cost us nine billion dollars. How much are we willing to pay for 90% cleaner air? These decisions belong to the public, not the engineers. For the sake of everyone we hope to be able to present to the public an economical and convenient solution in the near future."

Stein *et al.*[21] have evaluated the effectiveness of possible catalysts by a microcatalytic technique based on gas chromatography. The technique which is described in detail allows a large variety of hydrocarbons and catalysts to be rapidly tested over a wide range of temperatures (100–600°C). In general oxides of cobalt, chromium, iron, manganese, and nickel are the most effective catalysts. The higher molecular weight hydrocarbons are more easily oxidized than the lower

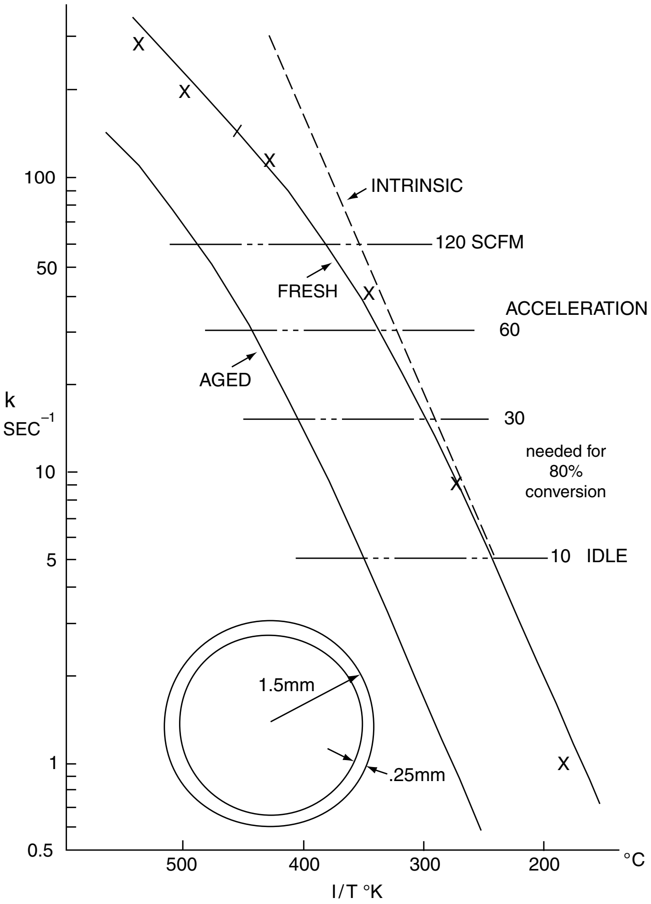

FIGURE 2 Carbon monoxide activity of an eggshell catalyst.

and hydrocarbons of a given carbon number increased in reactivity according to the series: aromatic < branched paraffin or alicyclic < normal paraffin < olefinic < acetylenic. The olefinic hydrocarbons, generally considered the most undesirable, are relatively easy to remove. Other results could be summarized in the following manner:

1) With most of the catalysts tested, some cracking occurs during the oxidation of hydrocarbons. Oxidation without CH_4 formation was possible with the oxides of Co, Cr, Cu, Mn and Ag only. Zirconium oxides are unique in that they produce only cracking products, mainly methane and smaller amounts of intermediate hydrocarbons.
2) Complete removal of all hydrocarbons was not attained with some of the catalyst, even at 600°C.

The oxidation is not a simple function of temperature.

The potential of copper oxide-alumina catalyst for air pollution control has been studied by Sourirajan and Accomazzo.[22] They stated that, "the simultaneous removal of hydrocarbons and carbon monoxide present in the auto exhaust gases has been tested making use of a six-cylinder Chevrolet engine run on leaded gasoline fuel. The hydrocarbon and carbon monoxide concentrations encountered in these studies varied in the range 170–17,000 ppm and 1–7%, respectively. It was found that the minimum initial temperature of the catalyst bed required for the complete removal of both hydrocarbons and carbon monoxide, simultaneously, was 226°C under no load condition, 342°C, under an engine load of 2.5hp, 400°C, under an engine load of 5.1hp or higher, and 236°C under deceleration conditions. The catalyst showed no deterioration in performance even after 100 hours of continuous service in conjunction with the above auto exhaust gases. The extent of removal of hydrocarbons from the exhaust gases was found to depend on the initial temperature of the catalyst bed and the engine load condition.

It is realized that a successful 100 hour run does not constitute a life test on the catalyst, but it does indicate the potential applicability of the catalyst in air pollution control devices. The engineering design of the suitable converter for any particular practical application of the catalyst should naturally take into account the heat liberated during oxidation. Instantaneous catalyst temperatures of the order of 900°C have been encountered in this work with no deleterious effect on the subsequent effectiveness of the catalyst . . . the heat liberated during the reaction can be advantageously used to maintain the full effectiveness of the catalyst under all conditions of engine operation encountered in normal practice."

When contaminants are passed through a Hopcalite (unsupported coprecipitate of copper and manganese oxides) catalyst burner, the results vary from almost complete oxidation of some organics to very slight oxidation of the lower molecular weight aliphatic hydrocarbons[23] at some 300°C. Nitrogen compounds form N_2O when oxidized and halogenated compounds indicate a strong acid reaction when the reactor effluent is tested with detector paper.

An interesting example of the use of exhaust gas recycle and catalysts has been presented by the Esso Research Group. In Figure 3, typical hot cycle traces of CO, O_2 and NO are presented for cases before the catalyst, after Monel catalyst and after a 2nd stage Platinum-alumina catalyst, for instance, with and without recycle. The major beneficial effect of recycle is on the NO concentration.

The combustion of gasoline is more or less incomplete regardless of the quantity of excess air used. About 1% of the exhaust gas is composed of harmful products chiefly carbon monoxide (CO), oxides of nitrogen (NO_x) and hydrocarbons (HC). A significant variable affecting each of these pollutant concentrations is the air to fuel ratio (ATFR). The stoichiometric value, $(ATFR)_{STO}$ is about 14.7:1.0 on a weight basis.

Using a catalytic three way converter, more than 90% of the pollutants can be converted to harmless substances. To avoid catalyst contamination lead free gasoline must be used. In the closed loop electro-mechanical control of $(ATFR)_{STO}$ described by Robert Bosch,[34] 1985, an oxygen sensor in the exhaust gas transmits a signal which is used to correct ATFR deviations. This control method is particularly effective on fuel injection engines because they do not have the additional delay times of carburetor engines. For catalytic converter operation, the optimum ATFR range is

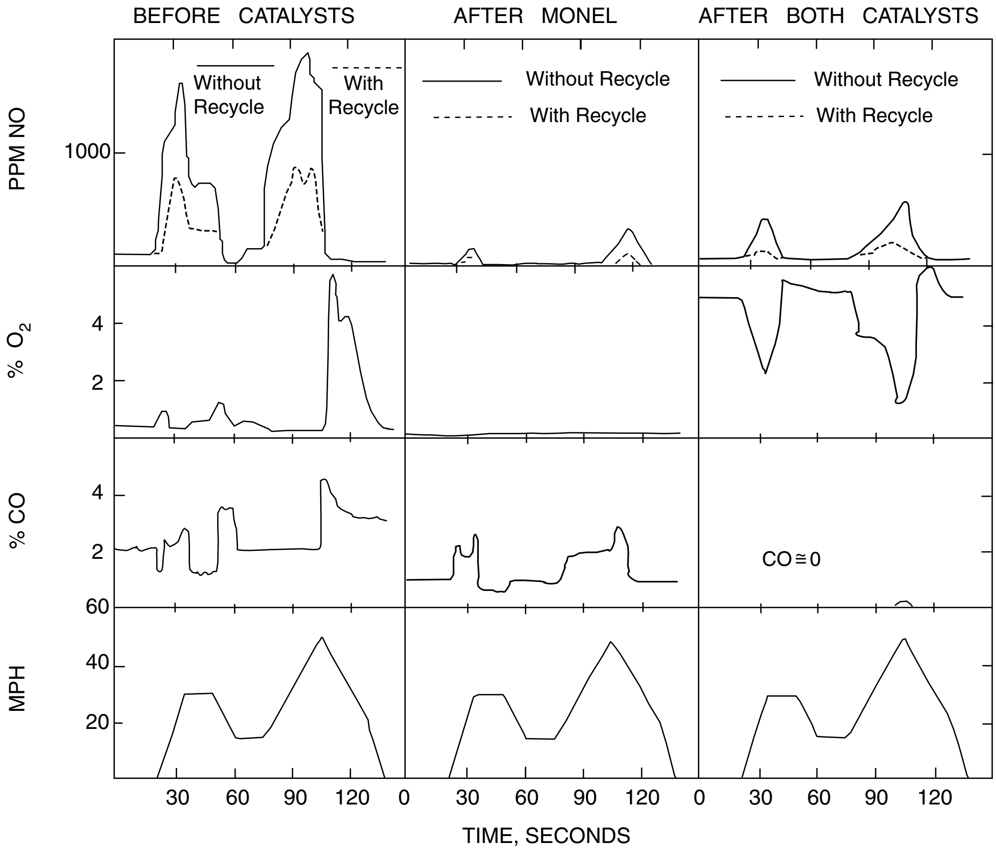

FIGURE 3

between 99 and 100% of $(\text{ATFR})_{\text{STO.}}$ Above this range NO_x levels increase markedly as ATFR is increased; below this range CO and HC levels increase as ATFR is decreased.

Electric vehicles (EV's) operated by high energy high powered batteries are making great strides toward commercialization. The near term goal is to provide over 100 miles per recharge at accelerations capable of matching the internal combustion engine. The California Air Resources Board has issued a technical document in December of 1995 supporting the concept of such vehicles. The key performance parameter for EV's is its specific energy (or energy density), measured in watthours per kilogram, with a near term goal of 80–100 wh/kg, suggested by the US Advanced Battery Consortium (USABC).[38] Another important measure of performance is the peak specific power (or power density), which gives us an idea of an EV's acceleration. It is measured in units of watts per kg with an USABC near term goal of 150 w/kg that can be sustained for 30 seconds during discharge down to 80% depth of discharge. A comparison of different chemical system performance parameters is presented in Figure 4. All of the batteries are expected to achieve the USABC's midterm goals for these EV parameters, which coincide with lasting about five years (-600 cycles) and costing no more than $150 per kwhr of battery capacity. Hybrid power electric-diesel engines became available in 1995. They alternate between diesel power operation at 2000–2600 RPM where its efficiency is best to battery power at other RPM.

RELATED TRANSPORTATION PROBLEMS

Diesel Exhaust Odors

Diesel engines are found in buses, trucks, off-road vehicles and power applicators and increasingly in automobiles. Public reaction to diesel-engine exhaust odors provides the impetus for controlling effluents of that type of fuel combustion.[24] A list of oily kerosene and smokyburnt odor compound identified by A.D. Little, Inc. is included in Table 4. Exhaust odor and smoke from diesel engines are more objectionable than those from spark ignition. CO emissions are generally less serious but NO_x is troublesome (4 to 10 g/mile). Improved fuel injection and afterburners are considered to be the most promising of the existing control methods. The injection differs from the internal combustion engine in that fuel does not enter the cylinder as a mixture with air, but is injected under high pressure into the chamber in exact quantities through low tolerance nozzles. For NO_x removal the basic approaches

Gas Turbines

The exhaust of gas turbines contains perhaps less pollutants than that of any other internal combustion process. The high airport traffic density makes the problem a real one, however. Sulfur dioxide emissions are low, but the smoke and odor producing compound levels are high. For automobile use, the total mass of gas turbine exhaust is many times greater than that for the gasoline engine of equivalent power. Hydrocarbon and CO mass emissions are known to be low and difficult to reduce. A greater deal of the pollution control work underway is in the engine modification area. In aircraft the turbofan engine is largely replacing the turbojet. Turbofans bypass some of the air past the engine and rejoin it with the burner gases at the exhaust tailpipe. Modern dry NO_x combustion systems can obtain emissions of 25 ppm at 15% O_2.[36,37]

The airplane is a much more efficient carrier (pollution wise) than the automobile, on a people × miles basis. Aircraft engine research has been concerned primarily with smoke reduction. Fuel type, fuel additives and combustion chamber design have been the primary variables studied.

PARTICULATE EMISSIONS

The particulate matter emitted from automobiles has been characterized[25] as consisting of "lead salts, alkaline earth compounds, iron oxides, soot carbonaceous material, and tars. This material ranges in size from large flakes to submicron particles and varies in consistency from hard and brittle particulate to oil mists. Some of the particulate material is generated in the engine combustion chamber and nucleated and agglomerated in the vehicle exhaust system before it passes out the tail pipe. On the other hand, a large portion of the particulate material generated in the engine subsequently deposits on various surfaces of the exhaust system. At some later time, this deposited material flakes off and becomes reentrained in the exhaust gas to be emitted from the vehicle. Obviously, opportunities exist for various types of chemical and physical processes to take place and, as a result, the overall particulate emission process for a vehicle is quite complex and difficult to define."

TABLE 5
Lead particulate emissions as a function of size and mileage[25]

Average mileage	Average lead salt emissions, g/mile		
	>9 microns	<1.0 microns	<0.3 microns
5,000	0.04	0.07	0.05
16,000	0.06	0.05	0.04
21,000	0.06	0.05	0.03
28,000	0.10	0.03	0.02

Much of the particulate is in the form of polynuclear aromatic (PNA) hydrocarbons and tars. As for gaseous products, standard federal cycles have been designed to test for particulate emissions.

Lead particulate matter is emitted at a rate of about 0.16g/mile. The average particle size emitted is slightly less than a micron, but sizes are substantially distributed over the 0.10–10 micron range. In Table 5, the effect of mileage on particle distribution may be observed. As the number of miles driven increases, the segment of particles greater than 9 microns also increases, probably because of deposition buildup on exhaust pipes.

Using 500 microns as a divider, about 30% of the lead burned over the lifetime of a car is in the form of fines 40% in the form of coarse particulate.

Research studies[27] showed that a relationship exists between traffic volume, proximity to the highway engine acceleration vs. constant speed, wind direction and the amount of lead in the air. Lead values can be expressed as a quadratic function of time and a linear function of traffic volume. Ter Haar[28] and coworkers found that for Federal 7-mode cycle conditions (Z) cars vary widely in the amounts and composition of their particulate emissions; (2) cold cycle operation gives 2–8 times more particulate than hot engine operation; (3) lead compounds represent less than one-third of total particulates, the remainder being carbon compounds along with ammonium and nitrate ions and unknown materials; (4) carbon emission for stabilized cars using leaded gasoline varies widely but averages about 35% of the total; (5) suspended particulate emissions are nearly equal with new cars whether or not lead is present; (6) exhausted lead varies with the condition of the exhaust system and ranges between 7 and 30% of the lead consumed by the engine; (7) fuel additives affect the amount of emitted particulates; (8) probe sampling techniques underestimate by a large factor of amount of particulates emitted by vehicles; and (9) trapping systems offer potential for greatly reducing the emission of suspended total particulates. Nonleaded-fuel cars were found to exhaust 0.165g of particulate per mile while leaded-fuel cars exhausted 0.152g/mile. The reason for this is that nonleaded fuel is more aromatic in nature and that the percentage emission for aromatic hydrocarbons is considerably greater than that for paraffinic material. An increase in the volume of aromatics in the fuel from 10 to 70% doubles the amount of carbon particulates emitted. It has been claimed[29] that a reduction of 80–90% of the lead emitted is possible by trapping systems.

Two simple traps have been compared for particulate removal and the results presented in Table 6.

More complex traps are likely to be very successful in reducing both lead and total particulate matter.

A more detailed chemical analysis of particulates has been described under Federal emission test conditions.[30] This investigation found that a decrease in the total mass of particulates especially particles of very small size, occurred when using nonleaded fuel. The discrepancy with the aforementioned work[28] may be a result of differences in exhaust deposition for the two systems. Particles emitted in the vehicle exhaust varied in size from 0.01 to 5000 microns, the latter for such products as rust scale. Typical chemical compositions for the particulate exhausts are presented in Figure 5.

The ratio of Pb to Br is relatively constant 2.1:1. The ratio on impactor plates was somewhat lower, indicating that the chemical composition of lead salts may be related to particle size. Considering some of the differences in the findings for different particulate matter studies it is critical that such investigations be perfected and intensified. An interesting additional discussion of the characterization of particulate lead in vehicle exhaust may be found in the work of Habibi[31] and Mueller.[32]

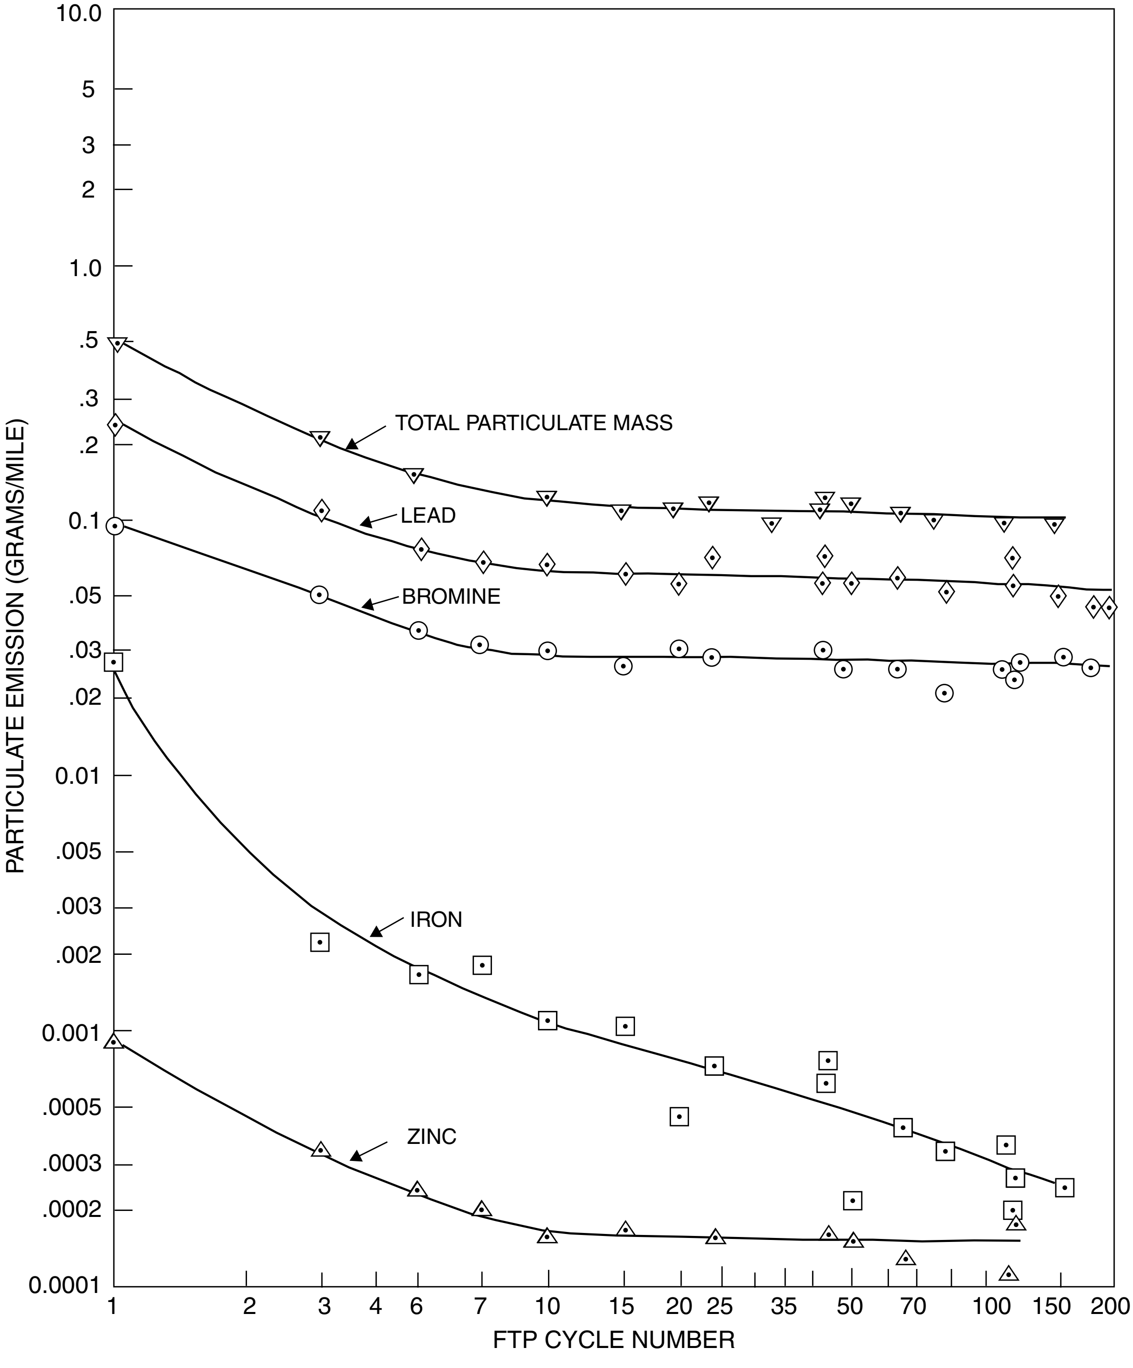

FIGURE 5: Particulate mass emissions from car operating on Indolene-30, as measured by the *Total Volume System,* versus FTP driving cycle number.[30]

In addition to the fuel and exhaust line, additional sources of particulates are to be found in catalysts for gaseous pollutant removal and from the disintegration of tires. The monel catalyst, described previously[1] for NO*x* and Co removal, deteriorates with time at about 0.019 g/mile. The presence of lead in the fuel substantially increases the rate of Monel deterioration.

Sheih[35] estimated that the increase in diesel emissions concentration in the Chicago area would be predominantly for particles having diameters smaller than one micron. At diameters in the vicinity of 0.2 microns the concentration would increase 10 fold.

One other source of vehicle particulate emissions which might be mentioned is that from jet aircraft. By weight, more

than fifty per cent of the total particulate matter emitted from aircraft engines appears to be due to unburned and partially oxidized fuels. More detailed analysis of this constituent must await development of improved measurement techniques. About 90 per cent of the non-hydrocarbon material present is elemental carbon (i.e., smoke), while the remainder is material eroded from the engine, fuel contaminants, or dust ingested by the engine. Fuel additives containing metallic compounds are seldom used for normal aircraft operations. The emission of such metallic particles does not appear to constitute a problem.

It has been demonstrated that fuel-rich pockets in the primary combustion zone of the burner were the source of the smoke-producing carbon particles and that the smoke could be reduced by "leaning out" the fuel-rich areas. Redesign of the burner is believed to be the most effective approach to smoke reduction.

The author wishes to acknowledge the assistance of Mr. George Musser, Exxon Research and Engineering Company, for his discussion on particulate matter emissions, of Dr. William Peterson, formerly of the Polytechnic, for supplying test procedure information, and of Mr. John Pinto of the New York City Department of Environmental Protection for his review.

The particulate problem most often cited for diesel engines in PM-2.5 emissions.[39] The 2.5 refers to the particle aerodynamic diameter, d, in microns, μm and the PM refers to the concentration in $\mu m/m^3$ of particulate matter of $d \leq 2.5$ μm. An Environment Defense report estimated that in New York Harbor alone, ferries, tugboats, container ships and other commercial vessels produce as much smog-forming contamination over the course of a year as do 300,000 automobiles.[40] These sources were largely unregulated as of 2005. It has been noted by the International Maritime Organization (IMO) that in terms of emission intensity—emissions per ton of cargo transported—marine shipping is one of the most environmentally efficient methods of shipping. According to the IMO, between 85–90% of all commodities are transported by ships, and diesel engines power the majority of these vessels.[41] The diesel engines have become more efficient in recent years. New air pollution rules expected to be in effect will require diesel and gasoline engine emission level equivalence by 2010.

MODELING OF ESTUARINE WATER QUALITY

INTRODUCTION

Estuarine water quality is a term used to describe the quality of characteristics of the water in estuaries. Although the term implies quality in a physical-chemical sense, its use has been extended to include also the acceptability of water in a socioeconomic sense. The term "water quality," like environmental quality and air quality, has to do with the quality of the water or the environment wherever it is found and wherever it is used or encountered. The high chemical and bacteriological quality of the water supplies has become an almost matter-of-fact part of any American's life, but the quality of waters in which man recreates has become of greater concern with man's awareness of degradation of the quality of the waters around him.

Estuarine water quality has become a major focus of the U.S. Environmental Protection Agency with passage of the Water Quality Act of 1987 establishing the National Estuary Program with the goal of identifying nationally significant estuaries, protecting and improving their water quality, and enhancing their living resources. The original four estuaries selected in 1985 for study were Narragansett Bay in Rhode Island, Long Island Sound in New York and Connecticut, Buzzards Bay in Massachusetts, and Puget Sound in Washington. Within a year, Albemarle-Pamlico Sounds in North Carolina and the San Francisco Bay/Sacramento-San Jacinto Delta system in California were added, and most recently Galveston Bay in Texas, among others, has been added.

A thoroughly technical description of water quality would require several volumes to cover the physical, chemical, and biological characteristics of water and how these characteristics change in different environments, how they interact, and how they influence the many ways water is used by plants, animals, and especially man. This would be true even though this article is limited to estuaries, which are among the most complex natural systems known and which feel the impact of man perhaps more than any other natural aquatic system. Suffice it to say that estuarine water quality will be examined in a broad way only, and the reader is referred to the books and articles cited in the bibliography for further discussions on the topics covered herein.

Use Context for Water Quality

Quality of water may be discussed most usefully in the context of water use. That is, for certain uses of water, whether they be recreation, drinking, navigation, or some other use, some level of water quality is required or desired for that particular use. Some uses, such as drinking, will require a much higher level of water quality than will another use such as swimming, and swimming may require a higher quality of water than navigation. The important point is that for desired uses of bodies or areas of water, certain levels of water quality are desired, and if the quality of the water desired or needed to support that use is not present, the use may not be sustained. The concept of use applies not only to man's direct uses of the water, but applies also to biological uses of bodies of water such as fish spawning grounds, shrimp nursery areas, and so forth. Indeed, the history of setting levels of desired water quality for particular uses has shown that following the setting of levels for water quality for drinking and swimming, levels of water quality were set for protecting and enhancing the survival of fish and other organisms in streams. Levels of dissolved oxygen in streams, which are in state and federal water quality standards, are there to protect fish in those streams.

As uses for bodies of water become more numerous, a competition for use of the water begins to develop. Uses such as navigation, swimming, recreational fishing, fish and shellfish nursery areas, and other uses are not uncommon competing uses for a body of water. The quality of water required to support each of these uses is different as noted above, and because of this, some uses may or may not be sustained, depending on which use is the most "beneficial" of that particular body of water.

The Federal Water Quality Act of 1965 stated that water quality standards were to be adopted by all the states by June, 1967, and in preparation of these standard public hearings were to be held to determine the desired uses of all the waters of the state which were under federal jurisdiction. Although many states had already determined uses of their waters, particularly for streams, this was the first time that a nation-wide effort was made to determine desired uses of waters and to set water quality standards for them. The hearings, the water quality standards developed, and the subsequent implementation and enforcement of the standards showed the very real problems which arise when competing uses of the water resource become very strong and intense. One or two particular uses become dominant, and the water quality for a particular use is set to meet that use. Other uses which require a higher level of water quality may or may not be sustained, while levels of water quality required for other uses may be more than adequately met.

This use context has been supported in subsequent legislation, particularly the 1972 Water Pollution Control Act, which required that water quality criteria be updated periodically by the U.S. Environmental Protection Agency as well as by the states.

Estuaries

The estuary is one of those bodies of water which is the focus of intense competing uses. Estuaries comprise one of the most important resources of any country for the support of such uses as navigation, recreation, nursery and resting grounds for waterfowl and wildlife, nursery and spawning areas for fish and shellfish, and particularly sites for urban growth and the consequences or byproducts of urban growth. It is estimated that about 75% of the entire population of the U.S. lives within 50 miles of the nation's coasts (USEPA 1987), and such a large urban population presents heavy use pressures on coastal areas, particularly estuaries.

Estuaries are semi-enclosed coastal bodies of water having a free connection with the open sea and within which the sea water is measurably diluted with fresh water derived from land drainage (Pritchard, 1967). Along the coasts of the United States alone some 45,832 square miles of estuarine waters exist. Of this total, 17,058 square miles are found along the Atlantic Coast, while along the Pacific Coast south of Alaska but including the Pacific Islands some 14,353 square miles exist, 2760 square miles are found along the Coast of Alaska, and 11,661 square miles are found in the Gulf of Mexico and Caribbean Islands (National Estuarine Study, 1971). Of the total, less than 30% is water less than six feet deep, vulnerable to filling, as well as especially productive of fish, shellfish and wildlife. At least 6.8% of the latter have been obliterated through filling, most in the last 50 years (Stroud, 1971).

Development of estuary shorelines indicate some of the uses of the estuaries. Of the 89,571 statute miles of tidal shoreline in the United States estuaries, some 17,853 miles can be described as recreation shoreline, that is, accessible and useful for recreational pursuits. Of this shoreline, 16,559 miles are privately owned and 1,294 miles are publicly owned; however, only 770 miles may be considered recreation areas. Marine transportation terminal facilities are users of a portion of the shoreline estuaries. In 1966, there were 1,626 marine terminals providing deep water berths in 132 ports on the Atlantic, Gulf, and Pacific Coasts. Industries use estuarine waters for cooling and return a heated effluent. Industries and cities use estuaries as disposal sites for their wastes. With a third of the United States population located in the estuarine zone, the impact of man on estuaries must necessarily be quite high (National Estuarine Study, 1971).

Biological uses of estuaries are also quite high. It has been estimated that nearly 63% of the commercial catch on the Atlantic Coast is made up of species of fish believed to be estuarine dependent. Assuming that this applies equally to the combined catches by foreign nationals as to the US domestic catch, the fisheries yield to the US Atlantic continental shelf and present levels of development of the fishery is equivalent to about 535 pounds per acre of estuaries (McHugh, 1966). Similar but somewhat smaller estimates have been made for the Gulf of Mexico estuaries based on commercial catches in the Gulf of Mexico and for the Chesapeake Bay estuary based on catches within the estuary itself (McHugh, 1967).

Factors Influencing Estuarine Water Quality

What are the factors that control the quality of waters in estuaries? The predominant factors are the hydraulic (transport) characteristics of the estuary, the inputs or sources of materials which make up elements of the quality of the water, and the sinks present in estuaries—those physical, chemical and biological phenomena which cause materials in the water to change in concentration or to be altered chemically to a different form than when originally introduced.

The hydraulic regime of an estuary is dependent upon three particular factors: the physiography of the bay—its size, area in relation to volume, depth, and shoreline development; the amount and seasonability of river inflow to the estuary; and the wind and tidal mixing which takes place in the estuary on each tidal excursion. The latter factor is dependent upon the tidal range, the configuration of the entrance to the estuary, the volume of the river inflow and the periodicity of the tides. The impact of sources of material to an estuary are dependent upon the character and amount of the material and the location in the estuary where the material enters. Materials which enter with the river inflow will very likely reach broad areas in the estuary due to mixing within the estuary and the fact that the material will pass through the estuary on its way to the ocean. On the other hand, material discharged near the mouth of the estuary will travel only a short distance into the estuary and most likely be transported out of the estuary rather quickly. This generalization does not apply to all estuaries, particularly those which are strongly stratified. This type of estuary will be discussed in more detail later on. The size of the sinks for materials in estuaries is dependent on the conservative or non-conservative nature of the material, that is, whether the material can be broken down into by-products or whether it remains in essentially the same form throughout its history within the estuary. Conservative and nonconservative materials may both be removed from the water column due to flocculation or sedimentation within the estuary, in which case materials may become part of the bottom sediments and lost from the water column unless the sediments are disturbed.

Because of the intimate tie between water quality and estuarine hydraulics, they will be examined below as well as the sources and sinks for materials within estuaries, both natural and man-made materials, before discussing water quality-estuarine use interactions.

ESTUARINE HYDRAULICS

A spectrum of hydraulic types may occur or exist in an estuary. These may range from the situation in an estuary in which the river flow dominates to the estuary in which the river flow is negligible and the hydraulic regime is dependent on the tidal mixing. Naturally, in a river flow dominated estuary, the water quality in the estuary is most similar to that of the river, whereas in the tidal mixing dominated estuary, its water quality is more like that of the off-shore waters. The other factor greatly influencing the hydraulic regime in an estuary is the physiography of the estuary which is very greatly dependent on the origin of the estuary and the subsequent natural events which have taken place in geologic time and man-made events in contemporary time to modify the original shape of the estuary.

Origins of Estuaries

From a geomorphological standpoint, there are four primary subdivisions of estuaries: (1) drowned river valleys; (2) fjord type estuaries; (3) bar-built estuaries; and (4) estuaries produced by tectonic processes (Pritchard, 1967). Each of these types of estuaries is characterized by the fact that at some point in geologic time, it has been inundated with ocean water due to the rise in the sea level. During the last glacial stage, sea level was about 450 feet below its present level, and the shorelines of the continent were at or near the present continental slopes. Within the last 50,000 years, the sea level has risen from that stage to the present with the last changes in sea level occurring about 3,000 years ago (Russell, 1967).

As the name implies, drowned river valley estuaries are river valleys found along a coastline with a relatively wide coastal plain, which were inundated with ocean water as the sea level rose. The Chesapeake Bay is a prime example of this type of estuary. During the last glacial period, the Susquehanna River reached the ocean about 180 kilometers seaward of the present shoreline; the York River and the other rivers now entering the bay to the north of the York were then tributaries of the Susquehanna River. The rise in sea level flooded the valleys of these rivers to form the present Chesapeake Bay system. The drowned river valleys, or as they are more commonly called, coastal plain estuaries, extend up river to a point approximately where the floor of the river rises above sea level. This is also the point at which a major change in water quality occurs from the ocean and estuary type water quality to that of the river. This geographical point may be downstream from parts of the river which are still influenced by the oscillation of the tidal currents.

The fjord type estuary is that formed by glaciers. These estuaries are generally U-shaped in cross section, and they frequently have a shallow sill formed by terminal glacial deposits at their mouths. The basins inside these sills are often quite deep, reaching depths of some 300 or 400 meters. Most fjords have rivers entering at the head and exhibit estuary features in the upper water layers. The sill depths in Norwegian fjords are often so shallow that the estuarine features develop from the surface to the sill depth while the deeper basin waters remain stagnant for prolonged periods.

Bar-built estuaries are those formed in an offshore area where sand is deposited as a sand island and sand pit built above sea level, and they extend between the headlands in a chain broken by one or more inlets. Such bays often occur in areas where the land is emerging geologically. The area enclosed by the barrier beaches is generally parallel to the coast line. Frequently, more than one river enters the estuary, though the total drainage area feeding a bar-built estuary is seldom large. The lower valleys of such rivers have frequently been drowned by the rising sea level, and hence the bar-built estuary might be considered as a composite system, part being an outer embayment partially enclosed by the barrier beaches, and part being a drowned river valley or valleys. Tidal action is usually considerably reduced in such estuaries. These systems are usually shallow, and the wind provides the important mixing mechanism (Pritchard, 1967). Several of the North Carolina estuaries and most of those along the Texas Gulf Coast are examples of this type of estuary.

Estuaries produced by tectonic processes are those formed by faulting or by local subsidence, and they usually have an excess supply of freshwater inflow. San Francisco Bay is an example of such an estuary.

Circulation in Estuaries

Other than the physiography of estuaries, the dominant physical processes associated with movement of water and mixing in an estuary are the wind, tides, and the inflow of river water. Extensive analysis of these processes has been presented in Fischer *et al.* (1979), Fisher (1981), Thomann and Mueller (1987), and others. The composite actions of these processes produce a variable interaction or interfacing of fresh water from the river and salt water from the ocean. Because these two sources of water have very different densities, the less dense fresh river water will tend to float on top of the dense salt water, and the extent that the two types of water mix is dependent on the strength of the mixing mechanisms. In an estuary with no tides or wind and a steady river inflow, the fresh water inflow would ride on top of the salt water from sea level in the estuary or river bed to the ocean. Because in a real system friction is present, the fresh water will force sea water some distance downstream from the sea level point in the river and the interface between the salt and fresh water layers will tilt downward in the upstream direction in a wedge shape. The friction between the layers will also cause an exchange of water from one layer to another, generally from the salt water, or "salt wedge," to the fresh water. The amount of exchange depends strongly on the mixing mechanisms, wind, tides, and river inflow.

In a wind dominated estuary, wind provides most of the energy for moving and mixing the water. In a tide dominated estuary, turbulence associates with the tidal currents results in mixing between the salt and fresh water, which in turn produces the density gradients associated with the non-tidal circulation pattern. In a river dominated estuary, such as the Mississippi River estuary, water movement is predominantly related to riverflow and mixing is caused mostly by the breaking of unstable interfacial waves at the upper boundary between the fresh river water and the salt water from the ocean.

In an estuary in which a salt wedge occurs distinctly the river flow completely dominates the circulation. The salt water extends as a wedge into the river and the interface between the fresh and salt water slopes slightly downward in the upstream direction. The steep density gradient at the interface, amounting to a discontinuity, reduces the turbulence and mixing to a very low level. The effect of the Coriolis force causes the interface to slope downward to the right in the northern hemisphere looking toward the sea. In the moderately stratified estuary, the dominant mixing agent is turbulence caused by tidal action, rather than velocity shear at the interface between the salt water and overlying fresh water layer as in the previous case. With a tide of moderate amplitude, random water movements at all depths occur and turbulent eddies transport fresh water downward and carry salt water upward, in contrast to the dominantly upward advection of salt across the interface which constitutes the vertical flux of salt in the river dominated estuary. The result of this two way mixing is that the salt content of both the upper and lower layers increases toward the sea. At any given point the bottom layer is always higher in salt content than the lower layer. The boundary between the seaward flowing upward layer and the counter flowing lower layer occurs with a mid-depth region of relatively rapid increase in salt content with depth, compared to the vertical gradient in either the upper or lower layers. This type of mixing contributes a greater volume of salt water to the upper, seaward flowing layer than in the salt wedge estuary. The rate of flow in the upper layer of the moderately stratified estuary is therefore much greater in volume than in the highly stratified estuary, necessitating a correspondingly larger compensating up estuary flow in the lower layer.

When tidal mixing is sufficiently vigorous, the vertical salinity stratification breaks down, and the estuary approaches true vertical homogeneity. The type of circulation which exists in a vertically homogeneous system depends upon the amount of lateral homogeneity. Owing to the Coriolis force in the northern hemisphere, the water on the right of an observer looking seaward may be lower in salinity than the water to his left. A cyclonic circulation pattern is developed, with fresher, seaward flowing water concentrated to the right of center and a compensating up estuary flow of higher salinity water to the left of center. Although a vertical salinity gradient is absent in a vertically homogeneous estuary, vertical transfer of salt is not lacking. There is also a strong lateral transfer of salt which represents the dominant circulation pattern in this type of estuary.

Certain vertically homogeneous estuaries, particularly those which are relatively deep and narrow, do not exhibit these cyclonic circulation patterns. The direction of water movement is symmetrical about the longitudinal axis, and fluctuations in velocity are related to the tides and the net flow averaged over several tidal cycles is directed seaward at all depths. There is a tendency for salt to be driven out of the estuary by the action of the advective process. There must be a compensating non-advective longitudinal flux of salt directed toward the head of the estuary (Pritchard, 1967).

It is very important to note that the quality or character of the water at any point in the stratified, partially stratified, or vertically homogeneous estuary will be strongly correlated with the salinity content of the water. For example, the high salinity, bottom water in a stratified estuary will have a quality much like that of the offshore ocean water. The water at the geographical midpoint of a vertically homogeneous estuary will be a mixture of river and ocean waters. Also, materials introduced into an estuary will be influenced at any point in time or space by the circulation patterns in the estuary. Estuaries which have not felt man's influence either in the estuarine zone or the fresh waters which flow into them have biological systems adapted to whatever water quality patterns exist. Since these water quality patterns are strongly influenced by the circulation patterns and/or introduction or removal of materials, they will have a beneficial or deleterious effect on the biota of the estuary depending on the extent of the change or the nature of the material introduction or removal. Thus, it is important to examine the circulation patterns of estuaries as well as the material introduced or removed to understand the water quality and biota of the estuary and the uses which may be made of the estuary.

Estuarine Circulation Models

Numerous attempts have been made to model the hydraulic processes which occur in estuaries. Originally, these models were developed to determine circulation modifications which might occur because of physical modifications to the estuary. These models have been extended in recent years to include constituents of water and the prediction of their transport and fate in estuaries.

One of the first type of models developed for estuaries was the hydraulic model. This type of model is a physical representation of an estuary on a small scale. Such models are usually distorted in the vertical direction so that water depth may be represented on a larger scale than a lateral dimension. For example, if an estuary were modeled on a scale of 1:100, the width of the estuary, if it were 10 miles, would be 0.1 miles in the model, but the depth of the water, if it were 10 feet, would be 0.01 feet which would be not much more than a film of water in the model. To avoid this situation which would make the model unusable, the vertical scale is reduced to a lesser extent than the horizontal scale such that the 10 foot depth of water mentioned above would be about 1 foot. While the hydraulic models are capable of representing tidal currents, momentum entrainment, and gravitational circulation, they are not able to represent local currents and turbulent eddies. For this reason, there is considerable distortion of diffusive processes in the physical model that makes its utility in quantitative concentration distribution studies dubious (Ward and Especy, 1971). From a qualitative standpoint, the physical model possesses an excellent demonstration capability for the visualization of flow patterns in resultant concentration distributions, and this capability should not be under-rated.

The other types of models developed for estuaries are mathematical models which may be intended to model tidal currents, net advective movement, or tidal stage in an estuary, or they may be intended to model the transport of salt in the water or other chemical forms. Such models may be three dimensional to represent transport of material down the estuary as well as laterally and vertically, or they may be two dimensional to represent transport of material down the estuary and laterally or vertically, or they may be one dimensional to represent transport of material down the estuary. Because the complexity of developing and solving mathematical models decreases as the number of dimensions included are decreased, the one dimensional model has received the widest attention in terms of development and use. This type of model is most advantageously applied to linear type estuaries, that is, estuaries which have little or limited variation in cross sectional area and depth with distance down the estuary. Examples of such models include the model of the Thames River in England, the Delaware River in New Jersey, the Potomac River in Maryland, and the Hudson in New York (see Thomann and Mueller 1987 for an excellent introduction to such models).

Water quality models are usually derived from the following basic three dimensional continuity equation:

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x}\left(E_x \frac{\partial C}{\partial x}\right) + \frac{\partial}{\partial y}\left(E_y \frac{\partial C}{\partial y}\right) + \frac{\partial}{\partial z}\left(E_z \frac{\partial C}{\partial z}\right) - \frac{\partial}{\partial x}(uC) - \frac{\partial}{\partial y}(vC) - \frac{\partial}{\partial z}(wc) \pm \sum S$$

where

E = dispersion coefficient along each of the three axes x, y, and z
u,v,w = velocity in x, y, or z direction respectively
S = source or sink for material
C = concentration of material.

This equation expresses a relationship between the flux of mass caused by circulation and mixing in the estuary and the sources and sinks of mass. In the one-dimensional form in which the assumptions have been made that concentrations of some material are of homogeneous concentration laterally and vertically (the y and z directions, respectively) and that the net transport of the material through the estuary is of concern, then the following equation has been used (O'Connor and Thomann, 1971; Thomann and Mueller 1987):

$$\frac{\partial C}{\partial t} = \frac{1}{A}\frac{\partial}{\partial x}\left(EA\frac{\partial}{\partial x}\right) - \frac{1}{A}\frac{\partial}{\partial x}QC \pm S$$

where

A = cross sectional area of estuary
Q = freshwater inflow
E = dispersion coefficient in x direction

and other terms are the same as above. Such models may be used to determine changes in material concentration with time for materials whose rate of entry to the estuary and/or loss from the estuary in a sink are steady or only slightly variable. A further assumption is to select the steady state situation, the condition in which the concentration of the material does not change with time. For this condition $\partial C/\partial t$ in the above equation is to set to zero and the equation solved.

Recently two dimensional models have been developed. These models often assume that vertical stratification does not occur in the water column and that lateral stratification does occur. Such models are most appropriately applied to estuaries with large surface areas and shallow waters. Such models have been developed for many estuarine systems. Feigner and Harris (1970) describe a link-node model developed specifically for the Francisco Bay-Delta Estuary, but applicable elsewhere. It models the two-dimensional flow and dispersion characteristics of any estuary where stratification is absent or negligible. Hydrological parameters of tidal flow and stage are computed at time intervals ranging from 0.5 to 5.0 mins and at distance intervals ranging from several hundred to several thousand feet. Predictions of quality levels are computed on the same space scale, but on an expanded time scale, ranging from 15 to 60 mins. The model is thus truly dynamic in character. It predicts fluctuating tidal flows and computes tidally varying concentrations of constituents, in contrast to a non-tidal model based on the net flow through the estuary such as that developed for the Delaware estuary. It can also accommodate both conservative and non-conservative constituents.

First, the hydraulic behavior of the estuary is modeled. Having established channel directions both in the actual prototype channels and (artificially) in the bay areas, the authors use one dimensional equations based on the following assumptions:

a) Acceleration normal to the x-axis is negligible.
b) Coriolis and wind forces are negligible.
c) The channel is straight.
d) The channel cross-section is uniform throughout its length.
e) The wave length of the propagated tidal wave is at least twice the channel depth.
f) The bottom of the channel is level.

Equations of motion and continuity are, respectively

$$\frac{\partial u}{\partial t} = -u\frac{\partial u}{\partial x} = Ku|u| - g\frac{\partial H}{\partial x}$$

and

$$\frac{\partial H}{\partial t} = -\frac{1}{b}\frac{\partial}{\partial x}(uA)$$

where

u = velocity along the x-axis
x = distance along the x-axis
H = water surface elevation

g = acceleration of gravity
K = frictional resistance coefficient
t = time
b = mean channel width
A = cross-sectional area of the channel.

The terms on the right hand side of the equation of motion are, in sequence, the rate of momentum change by mass transfer, the frictional resistance (with the absolute value sign to assure that the resistance always opposes the direction of flow), and the potential difference between the ends of the channel element. In the continuity equation the right hand side represents the change in storage over the channel length per unit channel width. To minimize computation, the equation of motion is applied to the channel elements and the continuity equation to the junctions.

Both equations are rendered into partial difference form and solved for each channel element and junction, using a modified Runge-Kutta procedure. The results comprise the predicted channel velocities, flows, and cross-sectional areas and the predicted water surface elevations at each junction for each time interval. These data are then input to the water quality component of the model. The equations are put into finite difference form and solved to give the concentration of the substance at each junction.

Ward and Espey (1971) and Masch and Brandes (1971) describe a segmented hydrodynamic and water quality model which has been applied to Texas estuaries. Each segment is a square one nautical mile on each side, and the estuary is divided into these segments. Hydrodynamic transport across segment boundaries is represented much as the equations given above and occurs in response to forcing flows from river inflow at the head of the estuary and tidal exchange at the lower end. The model is able to simulate water stage change within each segment and flows between segments with change in tides, and the averages of the flows are used in conjunction with the water quality portion of the model to forecast concentrations of conservative and nonconservative constituents.

A third type of two-dimensional model is that of Leendertse (1970) who developed a water-quality simulation model for well-mixed estuaries and coastal seas (i.e., no stratification) and applied it in Jamaica Bay, New York. Leendertse and Gritton, 1971, have extended the model to include the transport of several dissolved waste constituents in the water, including any interactions among them. The changing tide level influences the location of the land-water boundaries in the shallow areas of coastal waters. To simulate this process, procedures were developed in the model to allow for time-dependent boundary changes. Large amounts of numerical data are generated by the computer program developed from the simulation model. To assist the investigator in extracting important and meaningful results from these data, machine-made drawings were used to graphically present the results of the computation.

The basic mass-balance equation for 2-dimensional transport of waste constituents in a well mixed estuary (uniform concentration in the vertical directions) is given in Leendertse (1970) as:

$$\frac{\partial}{\partial t}(HP) + \frac{\partial}{\partial x}(HUP) + \frac{\partial}{\partial y}(HVP) - \frac{\partial}{\partial x}\left(HD_x \frac{\partial P}{\partial x}\right) - \frac{\partial}{\partial y}\left(HD_y \frac{\partial P}{\partial y}\right) - HS_A = 0$$

where

P = integrated average over the vertical of the waste constituents mass concentration
U and V = vertically averaged fluid velocity (components in the x (eastward) and y (northward) directions respectively)
S_A = source function
D_x and D_y = dispersion coefficients
H = instantaneous depth at a point.

The generalized mass-balance equation for n constituents is written in matrix notation as

$$\frac{\partial}{\partial t}(H\bar{P}) + \frac{\partial}{\partial x}(HU\bar{P}) + \frac{\partial}{\partial y}(HV\bar{P}) - \frac{\partial}{\partial x}\left(HD_x \frac{\partial \bar{P}}{\partial x}\right) - \frac{\partial}{\partial y}\left(HD_y \frac{\partial \bar{P}}{\partial y}\right) + [K]H\bar{P} + H\bar{S} = D$$

where

$\bar{P}$ = mass-concentration vector with n elements
$[K]$ = reaction matrix
$\bar{S}$ = source and sink vector.

The reaction matrix $[K]$ in its most general form can give rise to a non-linear transport equation. This occurs because the individual elements of the matrix can be defined as functions of their own concentration, or that of other constituents or both. Since the elements of $[K]$ are multiplied by the elements of the concentration vector, such non-linear terms imply kinetics of an order higher than first.

Point sources, such as occur at the location of sewage discharges into the estuary, are simulated by adding delta-function source terms to the source vector.

For two-dimensional flow in a well-mixed estuary, vertical integration of the momentum and continuity equations yields the following basic equations for the flow model

$$\frac{\partial U}{\partial t} + U\frac{\partial U}{\partial x} + V\frac{\partial u}{\partial y} - fV + g\frac{\partial \zeta}{\partial x} + g\frac{U(U^2+V^2)^{1/2}}{C^2H} - \frac{1}{\rho H}\tau_x^s = 0$$

$$\frac{\partial V}{\partial t} + U\frac{\partial V}{\partial x} + V\frac{\partial V}{\partial y} + fU + g\frac{\partial \zeta}{\partial y} + g\frac{V(U^2+V^2)^{1/2}}{C^2H} - \frac{1}{\rho H}\tau_y^s = 0$$

$$\frac{\partial \zeta}{\partial t} + \frac{\partial}{\partial x}(HU) + \frac{\partial}{\partial y}(HV) = 0$$

where

f = Coriolis parameter

g = Acceleration of gravity

C = Chezy coefficient

τ_x^s = Component of the wind stress in the x direction

τ_y^s = Component of the wind stress in the y direction

ρ = Water density

ζ = water level elevation relative to the reference plane.

The wind stress components are given by

$$\tau_x^s = \theta \rho_a W^2 \sin\varphi$$
$$\tau_y^s = \theta \rho_a W^2 \cos\varphi$$

where

θ = wind stress coefficient ≈ 0.0026

ρ_a = atmospheric density

W = wind velocity

φ = angle between the wind direction and the y axis.

In the finite difference approximations of these equations, the discrete values of the variables are described on a space-staggered grid. The position and time coordinates (x, y, t) are represented on the finite grid by (jΔx, kΔy, nΔt), for j, k, n = 0, ±1/2, ±1, ±3/2, K.

Water levels and pollutant concentrations are computed at integer values of j and k (x and y directions). Water depths, obtained from a field survey, are given at half-integer values of j and k. The velocity component U (x directed) is computed at half integer values of j and integer values of k, and the velocity component V (y directed) is computed at integer values of j and half-integer values of k.

The set of finite different equations used to approximate the momentum and mass-balance equations are then presented at two adjacent time levels, n and (n + 1/2). Numerical computation of the reaction matrix terms in the mass-balance equations is accomplished by a sequential use of forward and backward information. If M constituents are transported, then for constituent i(1 < i < M), in the first operation at time level n (going from t to t + 1/2Δt), information is used in the reaction matrix terms on the level (t + Δt) for all constituents for which the sequence numbers m is smaller than i. Information at the level t is used for which m > i. In this step, the constituents are computed is ascending order, from 1 to M.

In the second operation, at time level n + 1/2 (going from t + 1/2 Δt to t + Δt), the constituents are computed in descending order, M to 1. Information on the level t + 1/2Δt is used for all constituents whose m < i, and information on the level t + 1/2Δt is used for all constituents whose m > i. This procedure centers the reaction matrix information of the mass-balance equations within the time interval t to t + Δt. The reaction matrix terms which involve the ith constituent itself are taken centered over each half time step.

The sequential use of finite-difference approximations for the continuity equations at n and n + 1/2 results in alternating forward and backward differences. This means that over a full time step the terms are either central in time or averaged over the time interval. In the first operation at time level n (going from t to t + 1/2Δt), the momentum and continuity equations are solved first for the water levels and x-directed velocities at time level n + 1/2. The information generated is then used in the mass balance equations to obtain the constituent concentrations at time level n + 1/2.

The results of this first operation are then used at time level n + 1/2 to determine the unknowns in the second half timestep, going from t + 1/2Δt to t + Δt. Again, the momentum and continuity equations are solved first, but this time the water levels and y-directed velocities at time level n + 1 are obtained. This new information is then used in the mass balance equation to obtain pollutant concentrations at time level n + 1.

This procedure is then repeated for each succeeding full time step. The model can be used to investigate the influence of wind on low and circulation in the area covered, together with its effect on water levels and distribution of pollutants. This was the first time that real wind effects were investigated in detail.

The need for three dimensional models has been recognized for salt wedge type and moderately stratified estuaries, and three dimensional mathematical models of real estuaries have been developed. Leedertse and Liu (1975) developed a three dimensional code for water movements, salinity, and temperature which was applied to San Francisco and Chesapeake Bays and later to the Bering Sea, Chukchi Sea, the Beaufort Sea, and the Gulf of Alaska (Liu and Leendertse 1987). Other three dimensional models include that of Oey (1985) who modeled the Hudson-Raritan estuary.

SOURCES AND SINKS

In addition to the hydraulic regime of an estuary, the other factors which have great influence on the water quality of estuaries are the sources and sinks of the materials. The circulation patterns and water movement in estuaries will dictate the distribution of fresh and salt water in the estuary. Superimposed on this distribution is another pattern made up of materials introduced by sources and lost to sinks.

In all these equations, the source and sink terms become zero for conservative substances. For non-conservative substances, reactions that take place may usually be represented by first-order kinetics, i.e., the rate of reaction is proportional to the concentration of the material. In some cases the reaction term defines the fundamental reaction mechanism, whereas in other uses it is an empirical approximation to the phenomenon.

While as a general rule the modeling of the hydrodynamic transport of a constituent in an estuary is much further advanced than the modeling of its reaction kinetics, the most commonly unsatisfactory aspect of present water quality models is the specification of the source and sink terms. Many of the physical-chemical processes affecting the concentration of parameters lack adequate formulation. These include sedimentation and deposits of particulate matter, non-linear reaction kinetics, surface exchange of gaseous constituents, and chemical and biological reactions. Modeling of the relation of water quality and estuarine biota is not well advanced. Models of phytoplankton production, of nitrogen cycling, and of gross ecological parameters have been attempted with limited success.

Sources

Sources for the materials which are found in the waters of estuaries include two major sources, river inflow and ocean water inflow. The concentrations (or ranges) of selected chemical constituents of fresh and ocean waters are given in Table 1. Fresh waters may have large ranges of concentrations of the lands which they drain. These ranges are quite different from those of oceanic waters. In fresh waters, calcium is usually the most abundant cation and sulfate is the most abundant anion although carbonate may also be quite high in concentration. In sea water, on the other hand, chloride is the most abundant constituent and anion followed by sulfate and bicarbonate. Sodium and magnesium constitute the majority of the cations. Depending on the relative balance of river inflow and the incursion of seawater brought in by tidal action, the quality of the water in the estuary assumes a composition in proportion to the two sources. However, the location of constituents from the various sources either laterally in the estuary or vertically in the water column is highly dependent on the circulation patterns existing in the estuary which were discussed earlier.

Although in relation to river and tidal flows, direct precipitation is a small hydraulic input to an estuary, its water quality cannot be ignored. In shallow bays with little river inflow and a restricted opening to the ocean such as bar-built estuaries, rainfall directly on the estuary may be an important source of fresh water.

Waste discharges may exert a dominant influence on the water quality of estuaries depending on the amount of material discharged and its character. Because urbanization typically occurs around estuaries, waste discharges are usually directed to the estuaries since they are the most convenient waste disposal site. Domestic wastes, wastes derived from municipalities and ultimately humans, contains large amounts of organic and nutrient (nitrogen, phosphorus, trace) materials. Some typical concentration values are given in Table 2. The relative amounts of material discharged to estuaries or other bodies of water may be estimated by knowing the population served by a sewerage system and mass discharge coefficients. These coefficients indicate the amount of material discharged per person per day. Such coefficients are also given in Table 2.

TABLE 1
Quality of fresh and ocean water
(Concentration units are mg/L)

Constituent	Fresh	Ocean
Chloride	1.0–1,000	18,980
Sodium	1.0–1,000	10,560
Sulfate	1.0–1,000	2,560
Magnesium	1.0–1,000	1,272
Calcium	1.0–1,000	400
Potassium	0.01–10.0	—
Bicarbonate	1.0–1,000	142
Carbonate	0.01–10.0	—
Bromide	0.0001–0.1	65
Strontium	0.01–10.0	65
Boron	0.01–10.0	4.6
Fluoride	0.01–10.0	1.4
Aluminum	0.0001–0.1	0.16–1.9
Iodide	0.0001–0.1	0.05
Silicate	1.0–1,000	0.04–8.6
Nitrogen	0.01–10.0	0.03–0.9
Zinc	0.0001–0.10	0.005–0.014
Lead	0.0001–0.1	0.004–0.005
Iron	0.01–10.0	0.002–0.02
Phosphorus	0.0001–0.1	0.001–0.10
Mercury	—	0.0003

Industrial wastes also reach estuaries either as a direct discharge to the estuary, as spills from vessels carrying materials to or from the industries, as the result of dredging activities, as the discharge of heated effluents from power plants and heated effluents from nuclear power plants which also carry radioactive materials, and in other forms. Most industrial activities involve the use of and/or the disposal of water. Such waters usually contain the by-products of the industrial process and are characteristic of the process. For example in manufacturing steel, a certain amount of water is required for cooling and washing purposes. The amount of water used to produce a ton of steel by a given process is fairly consistent and the quality of the water resulting from the process is also fairly consistent. Table 3 lists various types of industrial activities, the amount of water used in the activity, and the pounds of oxygen required to oxidize the organic material in the wastewater as well as the pounds of suspended solids produced in making some unit amount of product.

Another source of waste material is urban and rural runoff. Urban runoff may consist of storm water runoff from the streets and gutters which is routed to the nearest waterway by storm water pipes, or it may consist of a mixture of storm water runoff and sanitary sewage in what is called a combined sewer system. Such systems are typical of older cities in the United States and other countries which built one pipe to carry both sanitary wastes and storm water wastes.

TABLE 2
Quality of domestic wastes (Concentration units are mg/L)

Constituent	Strong	Medium	Weak	Mass discharge coefficients (9 lbs/person/day)
Solids, Total	1,000	500	200	—
Volatile	700	350	120	—
Fixed	300	150	80	—
Suspended, Total	500	300	100	0.23
Volatile	400	250	70	—
Fixed	100	50	30	—
Dissolved, Total	500	200	100	—
Volatile	300	100	50	—
Fixed	200	200	50	—
BOD (5-Day 20°C)	300	200	100	0.2
Dissolved Oxygen	0	0	0	—
Nitrogen, Total	86	50	25	0.06
Organic	35	20	10	0.035

Because of economics the pipe could be built just so big, and at the size it could carry all the domestic wastes during dry weather but only a portion of the wastes during wet weather. During a large storm, the pipe would fill to capacity and the flow would have to be diverted to a waterway to insure that backups did not occur in the sewage system. For such drainage systems, each large rainfall results in a certain amount of material being washed into the nearest waterway. The amount of material produced is highly dependent on the drainage system itself, on the use of land in the drainage area, and for some systems on the stage of the tide when the overflow occurs. The quality of such wastewater is given in Table 4 as well as some mass discharge coefficients. A more detailed discussion of this type of wastewater is given in another part of this Encyclopedia (see *Urban Runoff*).

Rural runoff, though less innocuous than urban runoff, cannot be disregarded as a wastewater source. Mass discharge coefficients relating to quality of the runoff water to the land use and amount of rainfall are given in Table 5. Miscellaneous waste discharges occur into estuaries which cannot be quantified in the way done for other types of waste discharges. These include such waste as oil spills, spills of toxic or hazardous materials waste from houseboats or larger vessels with quarters for crew for living purposes, dredging spoils, heat from power or nuclear plants, and other sources.

Another source of material in estuaries is biological recycling. Although biological recycling may also be considered as a sink and will be discussed as such later, recycling of material is extremely important in transforming waste materials from man-made waste discharges (or waste discharges from other lower animals or even dead organisms) to a chemical form in which it may be used again by the biological system. For example, organic material in a domestic waste discharge is oxidized at least partially by bacteria to carbon dioxide and water. Carbon dioxide is a necessary constituent for the growth of plants in conjunction with light. The process of photosynthesis using light reduces carbon dioxide in an organic material which is incorporated in the tissues of the plant. Since plants comprise the basic food stuff for all organisms, the recycling of carbon from the organic form to the inorganic form as carbon dioxide is vitally important. Similarly, nitrogen, which may be in an organic form in a waste discharge, is oxidized by plants for growth. In both cases the organic form acts as a sink while concurrently the inorganic form becomes the source.

Sinks

There are several types of water quality sinks in estuaries. Water withdrawal from an estuary is one type of sink; withdrawals may be made for industrial uses such as salt production or for cooling purposes. In the latter case, some water may be returned to the estuary in a heated condition, but the water withdrawn which is lost in the cooling process as evaporation is lost to the estuary. Sedimentation becomes another sink as molecules of material which were in the water column sorb into the particulate matter which settles out and becomes part of the bottom sediment. Unless the bottom sediment is disturbed, eroded or dredged, this material is essentially lost to the water column. Precipitation may also occur to tie up several minerals which then settle out on the bottom and as with sedimentation are lost from the water column. Precipitation quite commonly occurs in estuaries which have little fresh water inflow but a high evaporation rate. These estuaries are known as hypersaline estuaries because the salinity content rises to levels above that of normal sea water. In the Laguna Madre Bay of Texas, salinity levels reach two or three times that of normal sea water. In this bay, crystals of gypsum are found on the shores.

Another type of sink which is tied intimately to the biological system of the estuary is the degradation of materials, that is, the change from one chemical form to another by biological action. Above, the process of oxidation of organic material was mentioned. This is one form of oxidation in which organic material is oxidized to smaller molecular material, which is further oxidized to carbon dioxide and water as the ultimate inorganic products. Oxygen is consumed in the process and is lost to the water. Another oxidation process is nitrification. In this process, nitrogen in the organic form is oxidized to ammonia which is then further oxidized by the bacterium, *Nitrosomonus* to nitrite and further to nitrate by the bacterium, *Nitrobacter.* Under low oxygen or anaerobic conditions, the nitrate or nitrite may be reduced by bacteria to elemental nitrogen gas which may then be removed from the system according to the solubility of the nitrogen gas.

QUALITY NEEDED FOR ESTUARY USE SUSTENANCE

Now that some of the hydraulic, biological, and man-made mechanisms which influence water quality in estuaries have been described, the use concept for estuaries and the water quality needed to sustain uses should be considered.

As an example, the San Francisco Bay-Delta Study Report (1969) listed some of the uses which can be made of estuaries, and these are given in Table 6. These uses are quite varied and in some cases would be competing uses if applied to the same part of an estuary. For combinations of uses for a given area in an estuary, usually one use will require a water quality higher than the other uses, and this use will dictate the water quality needed in that particular area. Some of the uses listed are not really dependent on water quality such as shipping, unless the quality is particularly adverse (very acid water or large floating material).

The general philosophy of estuary use in particular or resource use in general is that a range of uses may exist bounded by two extreme views. These views are: (1) a resource may be used indiscriminately without regard to the consequences (e.g., total consumption, contamination, etc.) of that use; and (2) a resource should be preserved with no interaction with man. Both views, despite being held by some are recognized as incompatible, and the concept of sustained use, the designation of some use or uses for a resource area and management of the system to support that use best, is favored. As mentioned at the beginning of this article, the designation of uses for estuarine areas in all states through public hearings was a recognition of the sustained use concept. However, subsequent attempts to manage waste inputs to estuarine systems and the estuarine systems themselves have shown how difficult management is. The difficulties lie in the technical aspects of management (the interrelatedness of water quality with estuarine circulation and sources and sinks), the economic aspects (the cost of management systems directly and indirectly),

and the socio-political-legal aspects (the interrelatedness of social desires and political decisions and the lack of adequate pollution control laws).

For each of the uses listed in Table 6, a list of physical, chemical and/or biological properties or constituents may be compiled. This list would indicate the levels of the properties or constituents which have to be provided or cannot be exceeded if that use is to be sustained. These constituent lists have changed as they have been found to be unimportant or found to be needed, and as the levels have changed new knowledge has been gained about how the levels more specifically affect the desired use. The extension of water quality criteria to toxic materials in recent years (U.S. Environmental Protection Agency 1976, 1986) indicates how emphasis has shifted from one set of criteria for which waste discharge problems have been solved essentially to another set which is comprised of substances of major concern today.

Unfortunately at this time, very little is known about the bases for many levels set. For example, good epidemiological evidence relating fecal or total coliform organism concentrations in swimming areas to disease is still lacking. A larger gap, however, is the criteria list for the fish and wildlife of estuaries and the organisms they feed on. For these organisms the best information available pertains to temperature, dissolved oxygen, pH and salinity. Beyond these criteria, the levels set for other materials such as toxic substances are being developed (U.S. Environmental Protection Agency 1986).

The reader may obtain more specific information about water quality in general and estuarine water quality in particular by referring to the bibliography references and to other related material. Of special interest might be the reports of studies on major estuaries such as San Francisco Bay, Galveston Bay, Delaware Bay, and Jamaica Bay. The studies include not only the theory of water quality but the practical techniques for and applications of its management.

MONITORING OF STACK EFFLUENTS: see STACK SAMPLING

MUNICIPAL WASTEWATER

Sewage is the spent water supply of a community. Because of infiltration of groundwater into loose sewer pipe joints, the quantity of groundwater is frequently greater than the quantity of water initially consumed. Sewage is about 99.95% water and 0.05% waste material.

A weaker (more dilute) sewage results from greater per capital water consumption. Industrial wastes will contribute to sewage strength. Sewage flow varies with time of day and will be higher during daylight hours. Larger cities will exhibit less variation with time than smaller cities. Many small communities will have a flow in the late night hours that is due almost entirely to infiltration.

Per capita production will vary from less than 100 gallons per day for a strictly residential community to about 300 gallons per day for a highly industrialized area. The concept of "population equivalent" is frequently applied in evaluating industrial waste contributions to sewage flow and planning for hydraulic, solids, and biochemical oxygen demand loadings.

Wastewater treatment facilities have high initial capital costs due to the need for large tanks, equipment and land area. The designed life of a treatment plant is normally equal to the life of the bonded indebtedness of the project. It is expected that capacity will be just reached at the end of this period. In a community with combined sanitary and storm sewers it is often found necessary to bypass wastewater flows during periods of heavy rain or, in low lying areas, during high tides. Excess water may be held in detention basins until normal flow resumes and then treated in the plant. Bypassed flow can be screened and chlorinated before discharge. This subject is receiving increasingly close attention.

Strength of sewage is usually expressed in terms of the following parameters: total solids (sometimes called volatile suspended solids, VSS), filterable solids, and biochemical oxygen demand (BOD). Many methods are available for determination of the foregoing. However, in order that operating and research data reported by workers in widely separated areas be comparable, it is necessary to have analytical methods which are simple, give consistent results and are widely accepted. This need is filled by Standard Methods for the Examination of Water and Wastewater. Contained in each edition are methods for analysis of water and wastewater which have been accepted by committees of experts in various fields. Standard Methods is revised about every five years.

Analysis of a typical American sewage is given below:

Total solids	600 mg/l
a) suspended solids	200 mg/l
1) settleable solids	120 mg/l
2) colloidal solids	80 mg/l
organic	60 mg/l
mineral	20 mg/l
b) Filterable solids	400 mg/l
1) colloidal solids	40 mg/l
organic	30 mg/l
mineral	10 mg/l
2) dissolved solids	360 mg/l
organic	100 mg/l
mineral	260 mg/l
c) BOD (5 days 20°C)	
1) suspended	42 gms/cap. × day
settleable	19 gms/cap. × day
non-settleable	23 gms/cap. × day
2) dissolved	12 gms/cap. × day
	Total 54 gms/cap. × day

Assuming an average daily flow of 100 gallons per capita, 54 gms/cap. × day = 0.12# BOD/cap. × day. This is a strictly domestic sewage. Per capita BOD values can vary from about 0.10#/day to above 0.25#/day. A commonly accepted value used for estimation is 0.17#/cap. × day.

In the above analysis, the determination of solids, mineral and organic, gives an indication of the loadings to be placed on the plant. Volatile solids give the organic loading and mineral solids are those which must be accommodated by sedimentation equipment.

BOD is a measure of the loadings placed on the oxygen resources of the receiving waters. Several methods have been used over the years for determination of the amount of oxygen necessary for stabilization of the waste. Permanganate and other oxidizing agents were formerly used. One method still finding application, but only as a general indication, is the putrescibility, or methylene blue, test. Methylene blue, a dye, decolorizes in the absence of dissolved oxygen. This test is only quasiquantitative, but finds use in day to day operation control of wastewater treatment plants. The method used today is an incubation and dilution method. Dissolved oxygen is determined at the beginning and end of a 5 day period by the Alsteberg azide modification of the Winkler method.

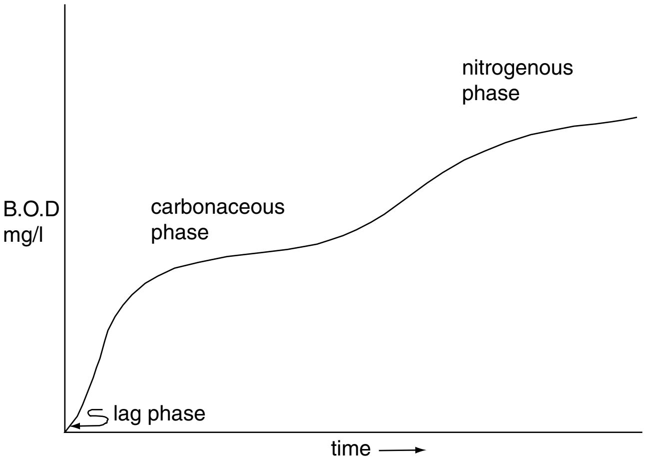

FIGURE 1

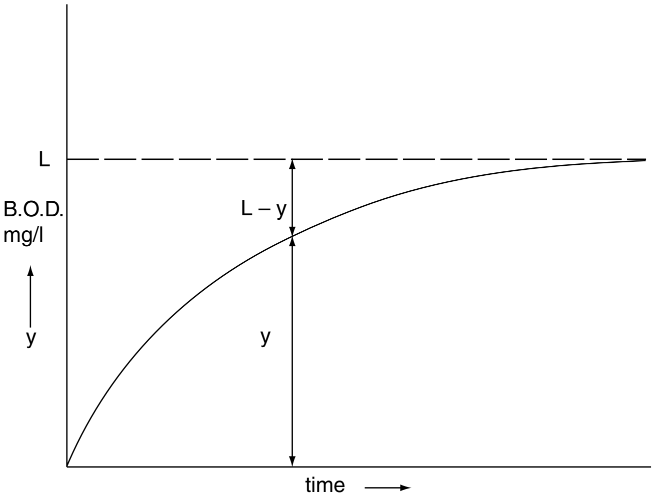

FIGURE 2

Water can hold about 10 mg/l dissolved oxygen. Since BOD values can vary from less than 1 mg/l for a clean stream to many thousands of milligrams per liter for some industrial wastes, it is necessary to dilute stronger wastes.

The dissolved oxygen concentration of a seeded nutrient dilution water is determined. A measured quantity of waste is then added to a known volume of dilution water. Total sample volume is usually about three hundred milliliters. The mixture is then incubated at 20°C for five days. At the end of this period the dissolved oxygen concentration of the mixture is again measured. BOD is then equal to the reduction in dissolved oxygen divided by the dilution factor.

Figure 1 shows the exertion of BOD over an extended period (more than 50 days). The trajectory displayed is one which might be followed when waste is added to a relatively clean stream and the watercourse acts as an incubation bottle. Such a complex reaction is of little utility for day to day control. In order to make the concept of BOD more useful, a simplified model is developed. The path followed in the idealized model is displayed in Figure 2.

The lag phase is eliminated by use of seeded dilution water. In this phase, microorganisms which utilize the waste material for food are becoming acclimatized and assuming dominance in the system. In the carbonaceous phase the dominant organisms are feeding upon the more easily degraded compounds. The nitrogenous phase, in which the character of the food and the microbial population change, does not usually begin for at least ten days. This portion is of interest in research on kinetics but can be ignored in the following. It is hypothesized that a simple monomolecular rate constant can describe the carbonaceous phase and the reaction is asymptotic to a limiting value L at infinite time. L is known as the ultimate BOD and is a mathematical artifact. The rate of reaction is assumed proportional to the BOD still remaining,

$$\frac{dy}{dt} = k_1'(L - y).$$

Integration and taking of proper limits gives

$$y = L(1 - e^{-k_1' t}) = L(1 - 10^{-k_1' t}).$$

Phelps' relation for decolorization of methylene blue with time

$$\frac{y}{L} = 1 - 0.794^t$$

is equivalent to the model equation when k_1 equals 0.10/day.

In practice, the 5 day 20°C BOD is used to describe the strength of a waste. Simple enumeration of the BOD value tells nothing about the path by which the number was reached since L and k_1 are not specified. Sewers and treatment plants are not isothermal entities but it is necessary that a common basis be established. One of the reasons advanced for the choice of the five day period is the fact that almost all rivers in England are within five days flow of the sea. Waste once discharged to the infinite ocean is no longer of interest. Times have changed and there is great concerns for effects of waste on the "infinite ocean."

In the literature reference to BOD means 5 day 20°C BOD (BOD_5) unless specifically stated otherwise. Recently, some popular writers have erroneously used the term "biological oxygen demand." There is no such parameter.

The reaction rate constant k_1 actually describes a series of complex microbiological reactions. In the initial stages of biological stabilization of sewage, carbonaceous material is oxidized to carbon dioxide and nitrogenous material is oxidized first to nitrite and then nitrate. One of the measures of degree of stabilization of organic matter in an effluent is the nitrate concentration. However, recent theories concerning eutrophication have raised serious questions concerning the desirability of high effluent nitrate concentrations.

Sewage contains the waste of a city and its inhabitants. It is possible to find almost any microorganism in sewage. In fact, in the sewer system can be found quite unexpected creatures. About 1960, sewer workers in New York City found a number of live and exceedingly unfriendly alligators in that city's sewers. These animals, gifts to city residents, had been disposed of through household toilets. The warm, wet environment of the sewers, rich in food, was excellent for rapid growth.

Traditionally, public health practice applied to water sanitation has placed major emphasis on prevention of typhoid fever, the causative organism of which is S. typhosa. This disease is spread by the pathway of anus to mouth. S. typhosa is a fairly delicate organism and is usually not found in high concentrations. It is felt that if pollution arising from human intestinal discharges is removed to a high degree, then S. typhosa will also be removed. As BOD is used as an indicator of pollutional loading on oxygen resources, so is the indicator organism E. coli used as an indication of pollutional loading due to human intestinal waste. E. coli is a normal inhabitant of the human intestinal tract. It is excreted in huge numbers and the presence of this organism in receiving waters may be evaluated quantitatively. The lactose broth-brilliant green bile test is commonly used to determine the presence of E. coli. A common soil organism, A. aerogenes, gives a false positive test and further confirmatory tests are necessary. Serial dilutions of the water being tested are prepared and, on the assumption that one organism is responsible for a positive test, the Most Probable Number (MPN) of organisms is determined. The MPN is based on statistical reasoning. Work by Kupchick, using the enzyme urease to determine the presence of uric acid, has shown a high degree of correlation between the concentration of this acid in wastewater and the MPN.

Most pathogenic organisms are not hardy and do not compete well for food. The use of E. coli as an indicator organism is in the way of a margin of safety. This is consistent with Phelps' concept of multiple barriers.

Microorganisms form the basis of secondary, or biological, wastewater treatment. Stated briefly, microorganisms establish themselves on trickling filter slime or in activated sludge liquor and feed on waste material in the sewage.

Large particles are removed in the primary settling portion of treatment. The larger particles, grease, etc. are in some ways not as objectionable as the colloidal or truly dissolved materials. The larger particles are, of course, objectionable from an aesthetic point of view, but the smaller particles place more of an immediate load upon the receiving waters. In almost all areas of environmental engineering surface area is one of the controlling parameters. Microorganisms, in carrying out their vital processes, utilize the waste as food and the smaller particles offer greater surface area per unit volume. Microbial activity is correspondingly greater and the oxygen required is also greater.

Microorganisms require a readily available source of oxygen. Aerobic conditions are said to exist when the oxygen is in the form of dissolved molecular oxygen or nitrates. At the point of exhaustion of nitrates and nitrites the system is in the anaerobic state and the oxygen sources are then sulfates, phosphates, borates, etc. Reduction of sulfates to give mercaptans (HS^-) carriers with it characteristic vile odors. Secondary treatment is an essentially aerobic process while conventional sludge digestion is an anaerobic process.

In the trickling filter an activated sludge processes microorganisms extract their food from the flowing wastewater. By means of extracellular enzymes large molecules are broken down so that they may pass through the microbial cell wall by diffusion. The food is further broken down for cell synthesis and energy by means of intracellular enzymes. End products are largely carbon dioxide and water. The waste material, now part of the cell mass, is removed in the final stage of treatment.

The primary reason for treating any waste is the need for avoiding nuisance and dangerous conditions in the environment. It is necessary to remove some of the waste so that the remaining can be discharged to the surroundings. This is, in effect, disposal by dilution. Discharge standards are usually based on concentration and total quantity.

Sewage purification works were formerly constructed for reasons based primarily on public health. More modern thinking has expanded the original rationale to include protection of oxygen resources of the receiving waters. If the second criterion is satisfied, the first will almost always be also satisfied. Demand for clean waters is increasing even more rapidly than population. Water will be used many times in its passage to the sea. Lakes are essentially a closed system. Leisure time is increasing and the question of water pollution has reached the point where aesthetics is now a significant parameter in planning. It is no longer possible to treat a watercourse as a separate entity. The approach now finding wider and wider application is that of basin management. This is the systems approach. An excellent example of this is the Ohio River Sanitation Commission. Here it has been possible to rise above local jealousies and self interest. The results are most gratifying and should serve as an example to other areas. It is unfortunate, but true, that one heavy pollution source can undo the efforts of many groups with social responsibility and foresight.

Because objectives in waste management can change drastically at political boundaries, it has occasionally been necessary for intervention by representatives of larger political entities when pollution problems effect, for example, several states. Federal agencies in the Unites States and other countries have come to play an increasingly larger role in waste management, particularly when problems do not respect political boundaries. The discussion presented here involves primarily technology of wastewater treatment and the underlying philosophy will not be extensively covered.

It has been mentioned that larger particles in wastewater can be removed by physical means. Removal of colloidal and dissolved components requires other methods and this must be accomplished economically. Treatment is classified as primary if it is without biological basis. Secondary treatment is generally accepted as biological treatment. A few regulatory authorities have endeavored to classify treatment degree on the basis of degree of removal. This relegates some biological treatment to primary status. Many experts do not agree with this change in definition. A widely accepted definition of tertiary treatment is the use of any process, in addition to conventional secondary treatment, for the purpose of further removals. From the foregoing it should be noted that chemical treatment, popular in the past, is a primary treatment process.

Water carriage of waste was practised in the Minoan civilization of Crete. It may be said that sanitation practices reflect the level of a civilization. Certainly, sanitary practices of the Middle Ages were of a rather low order. Methodical control of waterborne diseases was not attained until the 19th century. It is of historical interest to note that knowledge of the use of creosote for odor control at the Carlisle, England sewage purification works gave inspiration to Joseph Lister for the birth of asepsis in surgery.

The process by which wastewater is purified can best be understood by following the waste from its source through the collection system and treatment plant. Organic material discharged to a watercourse will eventually undergo stabilization. This is accomplished by natural processes (unit operations) and a wastewater treatment plant basically sets up, under controlled conditions, the processes which act in the river. Indeed, it has often been said that a sewage treatment plant is a river in miniature. In the river heavy particles settle out and lighter particles float to the surface. Biological decomposition takes place. Oxygen present is used by organisms that accomplish decomposition. Some of the settled material will be resuspended, increasing the organic loading. While oxygen is being withdrawn by BOD this resource is being replenished at a rate proportional to the deficit. The oxygen deficit is the difference between the amount that can be held at saturation (about 10 mg/l) and the amount actually present.

Stated mathematically, the oxygen concentration in a river as a function of time is

$$\frac{\mathrm{d}D}{\mathrm{d}t} = k_1' y - k_2' D.$$

This expression considers only the effects of BOD and atmospheric reaeration. A more complete equation can be written but effects of oxygen production by algae and oxygen reduction by benthal (bottom) deposits are not of major significance here. Solving the above gives

$$D_t = \frac{k_1 L}{k - k_1}\left\{10^{-k_1' t} - 10^{-k_1 t}\right\} + D_0 \times 10^{-k_2 t}.$$

This expression is commonly known as the oxygen sag equation and is displayed in Figure 3. It is of interest here because it illustrates the rationale underlying waste treatment requirements. Waste is treated so that undesirable conditions do not develop in the receiving waters. In effect, a limit has been placed on the allowable oxygen deficit.

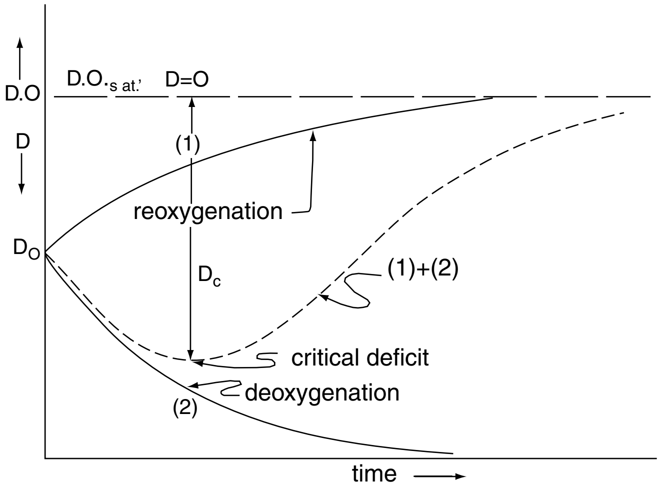

FIGURE 3

Regulatory authorities usually require that a minimum dissolved oxygen level be maintained. Normally, this will be stated as a percentage of dissolved oxygen saturation. This is the largest permissible critical deficit. Game fish may require a minimum of 5 mg/l D.O. while scavengers can survive in a much lower quality water.

The critical deficit is given by

$$D_c = \frac{k_1 L \times 10^{-k_1 t_c}}{k_2}.$$

Once the maximum deficit is specified, the BOD loading on the stream can be immediately estimated. The allowable BOD loading will be that impressed on the watercourse by the wastewater treatment plant effluent. It is of interest to observe the effect of the condition of the river at the point of discharge. A river in poor condition will have a large initial deficit, D_0. This can raise the treatment requirements. It can be seen that it is necessary to integrate the efforts on a basin wide basis. Parameters other than just dissolved oxygen must be controlled by the treatment processes. This is accomplished in some, or all, of the following steps.

Decomposition of the waste begins in the collection system. Ease, or difficulty, of treatment depends to a large degree on the condition of the sewage when it reaches the plant. Some substances are not permitted in the sewage system. Gasoline and other flammable substances, oil, hexavalent chromium are examples of prohibited substances. These can damage either the collection system or the treatment plant and processes. The legal vehicle by which such materials are excluded is known as a sewer ordinance.

It is most economical to collect sewage by gravity flow. If topography does not permit, pumping will be necessary in order to cross high points and to avoid excessively low flow velocities and deposition of waste material in the pipes.

A combined system will, at times, exceed the hydraulic capacity of the treatment plant and flow must be either bypasses or held in detention tanks until heavy flow has subsided.

Multiple treatment units are provided and treatment is not interrupted during periods of maintenance or repairs. Protection must be provided for pumps against large objects, such as floating pieces of wood. Coarse racks, with clear openings of more than 2 inches, may be placed at the entrance to the plant. Racks to be placed in advance of grit chambers and settling tanks will have clear openings of 1 to 2 inches. In smaller plants racks are cleaned by hand while larger plants have mechanically cleaned racks. Disposal is by burial, incineration or digestion with sewage sludge. Mechanically cleaned racks have smaller clear openings because head losses are lower with continuous cleaning. Racks with clear openings of 1 to 2 inches can be expected to give from 20 to 100 ft^3 of solids per 1000 people annually. Comminutors macerate floating material into sizes sufficiently small to be easily handled by centrifugal pumps. Racks and screens with very small openings have been almost completely replaced by comminutors.

Rate of flow into the plant will vary over a wide range during any 24 hour period with smaller plants exhibiting greater variation. Flow is measured by Parshall flume, Venturi meter or Sutro (keyhole) weir. The Parshall flume, sometimes called the open channel venturi, is most commonly used. The device operates on the principle of critical flow and measurement of water depth upstream of the flume throat. The governing equation is of the form $Q = cWH^{3/2}$, where Q is the discharge per unit time, W is the throat width, H is the water depth, and c is a constant. While c changes with throat width, it is closely constant for a constant throat width. Flume liners of reinforced fiberglass are all but replacing steel and concrete liners. Ease of fabrication, close tolerance, and corrosion resistance are advantages cited. The true Venturi operates on closed pipe (pressure) flow and is usually found in larger plants. The Sutro, or keyhole, weir is shaped as its name suggests. Its principal advantage is maintenance of a constant upstream velocity over a wide flow range, but it does have a high energy loss and metering is lost when the opening is submerged.

It is necessary to remove grit in order to protect pumps against excessive wear and to maintain capacity of sludge digesters. It has been found that digesters in plants serving low lying sandy areas can, if grit removal is not efficient, lose up to a third of capacity in but a few years. Grit chambers must operate in a fairly narrow velocity range of from 0.75 to 1.25 ft/sec. Above this range deposited material is scoured back into suspension and below the lower value organic material settles out. The resulting material, called detritus, is unsuitable for landfill uses due to its highly putrescible nature. Grit chambers are usually designed to remove particles with a specific gravity of 2.65 and a mean diameter of 0.02 cm. Because flow variation with depth follows a parabolic function, $Q = cWH \cdot H^{1/2}$, the grit chamber is often given an approximately parabolic shape and better velocity control is attained. The amount of grit collected per million gallons flow is found to vary from 1 to 12 cubic feet. Grit is removed manually in small plants and continuously by mechanical means in larger plants.

Settling tanks are provided for removal of larger, heavier organic particles, oil, and grease. Oil, grease, and other materials lighter than water are skimmed continuously from the surface and led to digestion. Both circular and rectangular surface configurations are used. Rectangular tanks of the flow through variety have length to width ratios of 4/1 to 6/1. Circular tank size is usually limited by structural requirements of trusses carrying skimming devices. Tank depths vary from 7 to 15 feet. Bottoms are sloped about 1% in rectangular tanks and about 8% in circular tanks to facilitate sludge removal.

Design is on the basis of hydraulic loading. A commonly used figure is 1000 gal/day × ft^2 surface area. It can be expected that a BOD removal of 30% will be achieved in a well operated primary sedimentation unit.

If treatment includes only screening, sedimentation, and chlorination of effluent, the treatment is classed as primary. Primary treatment, while inadequate for most areas, is better than no treatment. The adequacy of secondary treatment is now being seriously questioned. Nonetheless, it fits the economics of the situation. Only in the 1960's did wastewater treatment become of interest to any but a small number of people. Sanitary engineers were wont to say "It may be sewage to you but it is bread and butter to me." Theirs was not a profession to which much glamour was attached. Financing bodies were reluctant to invest adequate sums in waste treatment facilities. Hopefully, this has now changed.

There are two main processes utilized for biological (secondary) treatment. These are (1) the trickling filter and (2) activated sludge.

The trickling filter is not a true filter. It can best be described as a pile of stones, or other coarse material, over which sewage flows. This is the most widely used biological treatment process. Present day biological treatment technology is a logical development from sewage farms (irrigation areas) to intermittent sand filters to contact (fill and draw) beds to trickling filters and activated sludge units. Numerous modifications of the basic processes have evolved but the underlying principles remain unchanged. In biological treatment a suitable environment is provided so that microorganisms may thrive under controlled conditions. The suitable environment is one rich in food and maintained in the aerobic state. The zoogleal mass remains fixed on the filter media in the trickling filter while the sewage flows past. In the activated sludge process the sewage and organisms flow together. In both cases the microorganisms come from the sewage itself. Traditional secondary treatment plants operate in the declining growth phase.

Irrigation by sewage provides water return and some waste stabilization but this means of sewage disposal is in conflict with sound public health practice and ought not be used where there is a possibility that sewage can pass with little change into the groundwater table. Irrigation is best applied in arid regions. When it is utilized for food growing areas, care must be taken so that edible plants and fruit are not contaminated. Odors are a problem and removals decline markedly in cold weather.

Intermittent sand filters are much like the slow sand filters used for potable water production. The sewage is applied to a sandy area and allowed to percolate downward. Raw sewage may be applied at rates as high as 80,000 gal/acre × day and secondary effluents at rates as high as 800,000 gal/acre × day. Application of the secondary effluent would be considered tertiary treatment. Biological films that form on the sand grains undergo continuous stabilization. It is necessary to rest the bed between dosings so that objectional conditions do not develop. Surface accumulations of solids must be periodically removed. This method is not recommended for areas underlain by fissured limestone.

Fill and draw beds operate as the name indicates. A tank, packed with coarse material, is filled with sewage and allowed to stand full. It is then drained and allowed to rest. Air is drawn into the bed during filling and emptying. Loadings are about 200,000 gal/acre × ft × day. There is little application of this method today in treatment of municipal wastewater but it does find use in industrial waste treatment. Fill and draw beds are a batch operation and the trickling filter is a continuous operation.

Sewage is distributed over a trickling filter by slowly revolving arms equipped with nozzles and deflectors. Some earlier plants had fixed nozzles but this is no longer done. Revolving arms are driven by hydraulic head. Sewage discharged is allowed to flow slowly downward through the bed. Air is down into the bed by temperature differential, thus maintaining a supply of oxygen for the process. Filter media is usually stone. Sizes are in the range of 1 to 4 inches. Packing of this size permits air to be drawn into the bed and the bed is not clogged by biological slime. There appears to be a trend toward more use of plastic filter media. Filter depths range from 3 to 14 feet. A common depth is 6 feet. After passage through the filter the sewage is collected in tile underdrains. These underdrains serve two purposes: (1) collection of filter effluent and (2) circulation of air into the filter. The underdrains discharge to a main collection channel which, in turn, discharges to the final settling (humus) tank. The importance of the function of the final settling tank can be seen by an examination of what occurs in the filter itself.

A new filter is "broken in" by applying sewage as in normal operation. After a time the microbial (zoogleal) mass establishes itself on the filter media and carries on the work of waste stabilization. Waste material in the flowing sewage (food) is first absorbed into the zoogleal mass and then assimilated by the microorganisms. Much of the organic waste material has, at this point, been utilized for cell synthesis and energy. There must be continuous removal of filter slime or the process becomes sluggish due to a lower feeding rate of old organisms. Since waste material is now a part of the filter slime there must be a means provided for removal of sloughed off organisms or the waste material, now in different form, would still appear in the plant effluent and little constructive would have been accomplished. The required removal is carried out in the secondary settling tank. A rate of application lower than that of the primary tank is necessary here because of the different character of the material to be removed. Rates in this portion of the system are in the range of 600 gal/ft^2 × day.

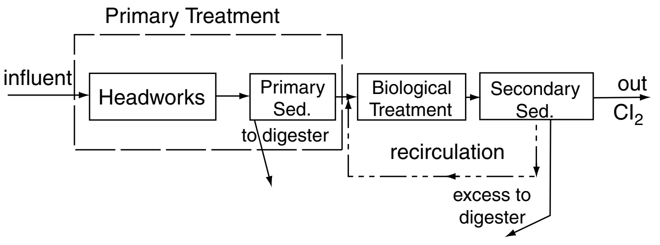

FIGURE 4

A portion of the effluent is recirculated, as shown in Figure 4. This is done in order to (1) smooth out flow, (2) keep the food concentration more constant, (3) lower the film thickness and, thus, control the psychoda fly, and (4) reseed the applied sewage with acclimatized organisms. The psychoda, or filter, fly is a very small insect which breeds in trickling filter slime. It does not bite but can be extremely bothersome because it does get into the nose and mouth. The range of flight is short but the creature can be carried great distances by the wind. Control of the fly in its developmental phase can be achieved by flooding the filter periodically or through chlorination of influent.

Trickling filters can be classified on the basis of (1) hydraulic loading per unit area and (2) applied pounds of BOD per 1000 ft^3 of filter volume.

The low rate trickling filter, with hydraulic loadings of 2 to 4 million gallons per acre per day (mgad) and 10 to 20 pounds BOD per 1000 ft^3, is usually found in use in smaller plants. With proper operation, BOD removals of 80 to 85% can be routinely expected. Raising the applied sewage to 10 mgad produced greater BOD removals per unit filter volume but the effluent organic concentration was found to be high. Influent organic concentration was reduced by greater effluent recirculation and lower effluent organic concentration was realized. Units that operate in the 10 to 40 mgad range are called high rate trickling filters. BOD loadings are up to 90 pounds per 1000 ft^3, but removals to be expected are in the range of 65 to 75%.

In the 4 to 10 mgad range operational difficulties were frequently encountered and this range was avoided for many years. It appears that, in this range, the hydraulic application was inadequate to keep the filter slime from attaining excessive thickness. Many plants had operated well in this range, but other plants had many problems. The solution seems to have been reached with use of relatively large, 2 to 4 inches, filter stones.

Experimental plants using plastics media have recently achieved very high removal efficiencies (97%) at hydraulic loading rates of 100 mgad. Much of the microbial mass is in the recirculated effluent and these plants are, in effect, modifications of the activated sludge process. Organic loadings are in the region of 100 pounds BOD per 1000 ft^3 filter volume.

Filter packing by plastic media is finding wider application. Design criteria, however, call for quite deep filters and this appears to be uneconomical in terms of power requirements.

Modifications of the trickling filter process over the years have dealt with improvements in media, air circulation, and loadings. One of great interest is that proposed by Ingram. Sewage is introduced at various levels in a very deep filter in an attempt to distribute the load more uniformly over the whole filter depth. Hydraulic loadings up to 500 mgad have been successfully achieved.

A new development in trickling filter technology is the Rotating Biological Contractor (RBC). A rotating drum is partially immersed in wastewater. A zoogleal mass develops on the drum surface, functioning in the same manner as trickling filter slime. Such installations may be completely enclosed in plant buildings, thus avoiding any effects of extremes in outside temperature. An excellent example of the application of this process for upgrading the municipal treatment works at North Bergen, New Jersey.

Activated sludge serves the same function as trickling filter slime. The major difference lies in the filter slime being fixed to the filter media while the activated sludge is carried along with the flowing wastewater. Development of the activated sludge process began with attempts to purify sewage by blowing air into it. It was observed that after prolonged aeration, flocs composed of voraciously feeding organisms developed. This floc settled after aeration was stopped. Addition of fresh sewage to tanks containing the settled sludge produced high purification in a practical time. The name activated sludge was assigned this means of waste treatment. At first, this was operated as a fill and draw system. Research showed that continuous operation could be practiced and this is the present means or operation. The process involves:

1) return of activated sludge to the aeration tank influent and discharge of excess sludge to digestion
2) aeration of the sludge-sewage mixture to maintain purification and
3) settling of the aeration tank effluent to remove floc before final discharge.

Step (3) is necessary for the same reason as the comparable portion of the trickling filter process-removal of waste material transferred to the microbial cell mass. Floc is formed in the tank through aerobic growth of unicellular and filamentous bacteria. Protozoa and other organisms will also be found in the floc. This is a strictly aerobic process and air requirements are high. Two aeration systems are used, (1) diffused air units and (2) mechanical aeration. Air diffusers are more commonly used in North America but mechanical aeration systems may be found in plants of less than 1 million gallons per day (mgd) capacity. Both methods of aeration perform three functions, (1) transfer of oxygen to the mixture and maintenance of aerobic conditions, (2) intimate mixing of floc and sewage, and (3) keeping the floc in suspension.

Aeration tanks are normally rectangular in cross section, 10 to 15 feet deep and 30 feet wide. Length to width should be greater than 5 to 1 in order to avoid short circuiting. Detention periods are from 4 to 6 hours. Air is introduced from diffusers in such a way as to set up a spiral flow pattern, thus aiding in mixing of floc and sewage and helping to prevent dead spaces in the tank. It was found that oxygen requirements decreased as the waste proceeded through the tank. The number of diffusers was, therefore, increased at the beginning of the unit and decreased at the effluent end. This is now the common practice and is known as tapered aeration. Mechanical aeration has the same function as air diffusers but is accomplished by rotating paddles or brushes. Peripheral velocity is about 2 ft/sec.

Floc returned to the aeration tank has the purpose as trickling filter slime but floc concentration can be varied as operation needs dictate. Returned sludge varies from about 10 to 30%. Mixed liquor suspended solids (MLSS) will vary from 600 mg/l to 4000 mg/l, on a dry weight basis. An important parameter in routine process control is the ratio of the volume of MLSS to the dry weight of MLSS. This is known as the sludge volume index (SVI) and is in the range of 50 to 100 in well operating plants. When the value approaches 200 operating difficulties can be expected. Factors which promote or inhibit microbiological growth are important and these include pH, temperature, and oxidation-reduction potential (ORP). Hydrogen ion potential, pH, will have a great effect on the dominant species of organisms. Bacteria predominate above pH of 6.5 while fungi assume greater importance below this value. There must be adequate buffering capacity if metabolic products are acidic.

Modifications of the basic activated sludge process have come about for solution to specific operating problems.

The municipal treatment plant at Peoria, Illinois received a waste high in carbohydrates. The resulting nitrogen deficiency caused a light and poorly settling activated sludge floc with attendant poor waste stabilization. Kraus, for whom the modification is named, aerated digester supernatant. This, added to the influent, gave a nitrifying activated sludge. The result was a readily settleable sludge with improved organic removals.

New York City has plants scattered throughout the five boroughs, treating more than 1 billion gallons of sewage per day. A major modification resulting from experimentation with plant operation has come from this city. In conventional plants sewage was added at one end of the aeration tank and allowed to flow through. This gave a high initial microbial food supply and correspondingly high oxygen requirement. The New York City modification involves introduction of sewage at intervals along the tank. This smooths out the food supply and lowers the oxygen requirements. The sewage is added at discrete steps along the unit and the name applied is step aeration.

A low mixed liquor suspended solids concentration of 200 to 500 mg/l is maintained in the high rate process. This gives a high food to microbial mass ratio. This keeps the floc in the active growth phase, but excess food will be discharged in the effluent. BOD removals are only 50 to 60%, but in some areas this is acceptable. New York City applied this method successfully because of a weak sewage and low temperatures. Philadelphia and Los Angeles met with indifferent success because of stronger sewage or higher temperatures.

A process originated simultaneously and independently by Smith and Eckenfelder made use of a phenomenon observed by many researchers but dismissed as experimental error. When activated sludge and raw sewage are mixed together in an aeration vessel there is a noted reduction in BOD, followed by a rise and then another reduction. The first decrease had been ignored by most research workers. Smith and Eckenfelder found that this was due to adsorption of waste material onto the activated sludge floc. This came from material desorbed from colloidal particles. Plants at Austin, Texas, and Bergen County, New Jersey were converted from overloaded to underloaded by changing to the biosorption process.

A recent activated sludge process modification is the Deep Shaft Process. As its name suggests, two concentric deep shafts (120–150 m) are sunk into the ground. Wastewater is injected into one of the concentric shafts and the effluent is withdrawn from the other. A constant ambient temperature is maintained due to the surrounding geological formations. Compressed air is injected at the bottom, giving high dissolved oxygen concentrations and provided intimate mixing. Waste sludge is removed in clarifiers as in conventional activated sludge plants.

Putrescible material collected from the primary settling tanks and excess sludge from humus tanks must be disposed of cheaply and efficiently. This material is highly unstable and a potential nuisance source. Because it is putrescible it can be stabilized by biological means, serving as food and energy sources for microorganisms naturally found in the sludge.

Raw sludge is about 95% water, but the water is not easily removed. As the sludge is broken down the water content is lessened, and the volume is markedly reduced. A rough rule is that sludge volume is reduced by half when water is lowered from 95 to 90%, and by two thirds when reduced from 95 to 85%. Fresh sludge has a gray color and can be easily pumped. Its odor is most disagreeable, being due principally to mercaptans. Digested sludge is black in color, granular and has a slight tarry odor.

Sludge digestion is carried out in order to reduce the volume of sludge to be handled, and reduce the number of pathogens. Sludge is usually withdrawn at regular intervals from primary and secondary tanks and led by gravity to a sludge well. It is then pumped to the digester.

Mixing is very important for efficient sludge digestion. Temperature is equally important.

Since destruction of sludge is carried on by microorganisms, kinetics of their life processes will be temperature dependent. It has been found that sludge temperature of about 95°F will give acceptably short detention times. Even shorter detention times for the same quality of digested sludge can be achieved with temperatures of about 125–130°F, but this temperature range is not widely used for reasons of economics. Above 95°F an increase in detention time is noted, up to 110°F, and then again a decrease. The reason for this is the changing character of the predominant organisms.

Heating of sludge for efficient digestion is carried out in one of two ways. The older installations have hot water coils in the periphery of the tank, and heat is transmitted to the digesting sludge. Mixing was felt to be adequately effected by turbulence due to gas generation. Mechanical mixers have been used. It was found, however, that mixing was not sufficient. In addition, heating of entire tank contents was not achieved due to "baking" of sludge in the vicinity of the heating coils. A second method of sludge heating and mixing was developed, involving the use of external heat exchangers. Sludge is pumped from the digestion tank through a heat exchanger and returned to the tank. Two objectives are accomplished (1) efficient mixing of sludge, thereby reducing the amount of inadequately digested sludge, (2) more uniform temperature throughout the tank, thus reducing digestion time. The use of external heat exchangers has almost completely supplanted heating coils and internal mixers in new plant design.

Sludge gas generated during digestion is approximately 72% methane and 28% carbon dioxide. Hydrogen and H_2S are present in trace amounts. Gas thus generated has a calorific content of about 600 BTU/ft^3. About 10 ft^3 of gas are produced per cubic foot of raw sludge digested. Generally, the amount of sludge gas produced is sufficient to provide heat used in maintaining digesting sludge at the required temperature, heating plant buildings, provide hot water and incineration of digested sludge, when practiced, and fuel and generators.

Volatile acids, reported as acetic acid, are perhaps the most important parameters in control of sludge digestion. Volatile acids below 1000 mg/l occur in a healthy digestion process. Volatile acids of 6000 mg/l indicate a malfunctioning process. pH values of 6.8 to 7.2 are optimum. Values less than 6.8 usually are due to excessive volatile acid production. In the past liming of malfunctioning tank contents was practiced in an effort to adjust pH to about 7.0. However, the change in volatile acids production was due to changing dominant process microorganisms. The lowered pH and high volatile acids concentrations were a sign of a sick process, rather than the cause.

Digested sludge is reasonably inert but it must be further dewatered and the question of final disposal of raw and digested sludge is one of the most pressing with which environmental engineers must deal today.

Sludge can be dewatered on open or covered drying beds. Open beds are exposed to the air and drying is accomplished by drainage and evaporation. Covered beds resemble a greenhouse. Temperatures are rather high and this aids evaporation. In both cases sludge is allowed to flow over sand beds and let stand for a suitable period. The dried sludge is then scraped from the beds.

Sludge can be dewatered by vacuum filtration. Filter drums rotate slowly, picking up wet sludge at the bottom. A slight vacuum is applied and the water drawn off is returned to the plant stream. At the end of the cycle the dewatered sludge is removed by a scraper.

Dried sludge can be incinerated, taken to a landfill disposal site, composed or subjected to superoxidation. Some coastal cities barged sludge to sea. This was to have ceased in 1981 but was permitted to continue for ten years. It is not allowed after 1991. Incineration of sludge has the potential for air pollution problems and often there is local opposition to installation of an incinerator. Incinerators are expensive to build and operate. Land disposal is expensive and disposal sites frequently are considerable distances from the generating wastewater treatment plants. Groundwater pollution can occur. Landfills which can accept digested sludge are in short supply. Transportation costs are a quite significant part of total disposal costs. Composting has been suggested as a possible ultimate solution. The requirement of relatively large land areas and odor production are problems.

A promising approach involves superoxidation. Here the sludge is treated with a strong oxidizing agent. Volume is reduced greatly and the end product is stable and inoffensive. Transportation costs are thus reduced.

It is common practice to chlorinate effluent for bacterial control. Regulations vary from state to state, but most regulations require chlorination to a specified residual. Requirements usually vary from season to season, the most stringent rules governing the swimming season.

A phenomena not yet fully understood is that of aftergrowth, wherein bacterial count is fairly low immediately after effluent discharge but then suddenly rises to a high figure.

In some plants chlorination of the influent is practiced for the purpose of odor control.

Chlorination of storm water overflow is commonly practiced. In some cases storm water overflow is subjected to simple sedimentation and/or screening, storage and chlorination, then discharged after cessation of the storm.

One commonly used definition of tertiary treatment is any treatment in addition to secondary (biological) treatment.

Tertiary treatment is practiced when an effluent of much higher quality is required than is attainable with conventional biological treatment. They type process used will depend on the final effluent quality necessary and the economics of the total process.

Commonly used tertiary treatment processes are listed below:

1) Sand filtration
2) Microstrainers
3) Oxidation ponds
4) Foam separation
5) Activated carbon adsorption
6) Chemical clarification and precipitation
7) Ion exchange

Disposal of human and kitchen wastes in areas not served by sewers and wastewater treatment plants presents unique problems.

Disposal must be in the immediate vicinity of the source of the wastes. In adequate controls are not exercised a closed system may results. An example is Suffolk County (Long Island), New York. Septic tanks are widely used, and there is strong local opposition to the considerable expense of installing sewers. Effluent from the septic tanks found its way into the ground water which is the supply for much of the county. Eventually, the problem was graphically pointed up by the appearance of foaming detergents in water issuing from the tap.

In more primitive societies waste disposal is a matter of convenience. A “cat hole” or communal straddle trench is utilized and covered when capacity is reached. This is the same as the practice with privies and cesspools.

Privies, as the name implies, are simply open pits with a structure to provide privacy. Human excreta is deposited into the pit and is slowly stabilized. Stabilization is slow, due principally to the presence of urine. Pits may be open earth or concrete vault. Drawbacks for both types are odors and fly problems. For the unlined pit there is the additional problem of ground water pollution. Older privy construction allowed access to flies around the edge of the pit. For proper protection against flies there must be a tight seal around the edge of the pit and adequate screening of openings in the privy structure itself.

In the 1930s a large number of the older privies were replaced by concrete vault types. Today, such methods of waste disposal are found only in the smaller rural communities where there is no municipal collection system.

Cesspools are simply pits into which waste is allowed to flow. The term leaching pit is sometimes used. Water seeps into the ground, leaving solid matter in the pit. Construction is of two types. A pit may be unlined, or it may be lined with sewer pipe laid on end. Almost nowhere in the United States are cesspools permitted by health authorities.

Septic tanks are widely used in smaller towns and outlying suburbs of larger cities. They are a combination sedimentation tank and anaerobic digester. Sanitary and kitchen wastes flow into the tank and grease and light material rise to the top. Heavier particles settle to the bottom where anaerobic stabilization occurs. Deflector plates are provided at inlet and outlet in order to minimize short circuiting. Effluent flows to a tile field where disposal is into the earth. The tile field is composed of perforated field tile fed by a manifold. The tile is underlain with granular material, usually gravel. Care must be taken that the earth does not become clogged by material carried over from the septic tank. Septic tanks are being replaced as more and more areas are served by municipal systems. Health authorities do not look with favor on septic tanks. Capacity will be a function basically of the number of persons or units served. Some experts feel that, in no case, should capacity be less than 1500 gallons. Lesser volumes are permitted in many codes and the thought that 1500 gallons ought to be the minimum permitted arouses home builders and land developers. Periodically it is necessary to employ a scavenger service for emptying the tank of accumulated solids. Solids thus collected may be discharged to a convenient treatment system or directly to a wastewater treatment plant.

The Imhoff Tank has not been discussed earlier because it is similar in many respects to the septic tank. Use is generally confined to small communities and isolated installations. Operation is a combination of sedimentation and anaerobic digestion. This tank was invented by Karl Imhoff, who first used them in the Essen District in Germany in 1907. The tank is composed of two chambers, one above the other. Surface configuration may be circular, square or rectangular. Depth is 25′ to 35′.

Sewage flows through the upper chamber, at a low velocity (about 1 fps). Solids settle out and slide through a slot into the bottom chamber. Detention period is about 2 hours.

Solids accumulating in the bottom, or digestion, chamber have an initial water content of 85 to 95%. After proper digestion of about 60 days the water content is reduced to about 50% and the volume is greatly reduced. Gases produced during digestion are vented to the atmosphere by gas vents located at the tank sides. Solids buoyed up by gas are prevented from escaping to the upper tank by deflector plates.

Attempts were made to hasten digestion by heating the lower compartment but were of limited success due to overturning of the tank contents.

Some rectangular tanks are arranged so that the direction of flow can be reversed, with outlets becoming inlets and vice versa.

In recent years manufacturers of waste treatment equipment have endeavoured to supply complete treatment plants for small communities or developments and isolated installations. Basically, these plants, called package plants, supply primary treatment and sometimes some biological treatment on a small scale without requiring extensive operating supervision. It is felt that such treatment is to be preferred to septic tanks or only primary treatment (Imhoff Tanks, for example), but such installations are not the ultimate solution.

NATURAL SYSTEMS FOR WASTEWATER TREATMENT

INTRODUCTION

In the continual search for a simple, reliable, and inexpensive wastewater treatment system, the natural systems are the latest discovery. They provide not only efficient methods of wastewater treatment, but also provide some indirect beneficial uses of the facility such as green space, wildlife habitat, and recreational areas.

In the natural environment, physical, chemical, and biological processes occur when water, soils, plants, microorganisms, and atmosphere interact. To utilize these processes, natural systems are designed. The processes involved in the natural systems include: sedimentation, filtration, gas transfer, adsorption, ion exchange, chemical precipitation, chemical oxidation and reduction, and biological conversions plus other unique processes such as photosynthesis, photooxidation, and aquatic plant uptake.[1] In natural systems, the processes occur at "natural" rates and tend to occur simultaneously in a single "ecosystem reactor" as opposed to mechanical systems in which processes occur sequentially in separate reactors or tanks in accelerated rates as a result of energy input. Generally, a natural system might typically include pumps and piping for wastewater conveyance but would not depend on external energy sources exclusively to maintain the major treatment responses.[2]

In this paper a general overview of natural systems for wastewater treatment is presented. The constructed wetlands are becoming a viable wastewater treatment alternative for small communities, individual homes, and rest areas. Therefore, in this paper, a great deal of information has been presented on site selection, design of physical facilities, performance expectations, hydraulic and organic loading rates, and cost of the constructed wetlands.

TYPES OF NATURAL SYSTEMS

Natural systems for effective wastewater treatment are divided into two major types: terrestrial, and aquatic systems. Both systems depend on physical and chemical responses as well as on the unique biological components.[2] Each of these systems are discussed below.

Terrestrial Treatment Systems

Land application is the sole terrestrial treatment system used to remove various constituents from the wastewater. It utilizes natural physical, chemical, and biological processes within the soil-plant-water matrix. The objectives of the land treatment system includes, irrigation, nutrient reuse, crop production, recharge of ground water and water reclamation for reuse. There are three basic methods of land application: (1) Slow-rate irrigation, (2) Rapid-infiltration–percolation, and (3) Overland flow. Each method can produce renovated water of different quality, can be adapted to different site conditions, and can satisfy different overall objectives.[3,4] Typical design features and performance expectations for the three basic terrestrial concepts are given in Table 1.

Slow-rate irrigation Irrigation is the most widely used form of land treatment systems. It requires presence of vegetation as a major treatment component. The wastewater is applied either by sprinkling or by surface technologies. In this process surface runoff is not allowed. A large portion of water is lost by evapotranspiration whereas some water may reach the groundwater table. Groundwater quality criteria may be a limiting factor for the selection of the system. Some factors that are given consideration in design and selection of irrigation method are (1) availability of suitable site, (2) type of wastewater and pretreatment, (3) climatic conditions and storage needed, (4) soil type, and organic and hydraulic loading rates, (5) crop production, (6) distribution methods, (7) application cycle, and (8) ground and surface water pollution.[2,3,5]

Rapid-infiltration–percolation In rapid-infiltration-percolation the wastewater percolates through the soil and treated effluent reaches the groundwater or underdrain systems. Plants are not used for evapotranspiration as in irrigation system. The objectives of rapid infiltration—percolation are (1) groundwater recharge, (2) natural treatment followed by withdrawal by pumping or under-drain systems for recovery of treated water, (3) natural treatment with groundwater moving vertically and laterally in the soil, and (4) recharging a surface water source.[5]

Overland flow In the overland flow system, the wastewater is applied over the upper reaches of the sloped terraces and allowed to flow overland and is collected at the toe of the slopes. The collected effluent can be either reused or discharged into a receiving water. Biochemical oxidation, sedimentation, filtration and chemical adsorption are the primary mechanisms for removal of the contaminants. Nitrogen removal is achieved through denitrification. Plant uptake of nitrogen and phosphorus are significant if crop harvesting is practiced.[3,5]

Aquatic Treatment Systems

Aquatic system utilize lagoons and ponds, and wetlands. The lagoons and ponds depend on microbial life, and lower plants and animals, while wetlands support the growth of rooted plants. Both pond systems and wetlands are discussed below.

Pond Systems

Within the aquatic systems, pond systems are the most widely accepted ones. Basically pond systems can be of three types based on oxygen requirement. These are aerobic, anaerobic and facultative pond systems. In all cases the major treatment responses are due to the biological components.[2,7] In most of the pond systems both performance and final water quality are dependent on the algae present in the system. Algae are functionally beneficial, providing oxygen to support other biological responses, and the algae-carbonate reactions are the basis for the effective nitrogen removal in the ponds. However, algae can be difficult to remove from the effluent. As a result, the stringent limits for suspended solids in the effluent can not be met. The design features and performance expectations for natural aquatic treatment units are summarized in Table 2.

Aerobic ponds Aerobic ponds, also called high rate aerobic ponds, maintain dissolved oxygen (DO) throughout their entire depth. They are usually 30 to 45 cm deep, allowing light to penetrate to the full depth.[3] Mixing is often provided to expose all algae to sunlight and to avoid deposition. As a result, formation of anaerobic sludge layer can be reduced. Oxygen is provided by photosynthesis and surface reaeration. Because of the presence of sufficient dissolved oxygen, aerobic bacteria can stabilize the waste. Detention time is short, usually 3 to 5 days. Aerobic ponds are limited to warm sunny climate and are used infrequently in the United States.[2,7]

TABLE 1
Design features and expected performance for terrestrial treatment units

				Typical criteria				
Concepts	Treatment goals	Climate needs	Vegetation	Area,[b] ha	Organic loading, kg BOD_5/ha.d	Hydraulic loading, m/year	Effluent characteristics, mg/L	
Slow rate	Secondary, or AWT[a]	Warmer season	Yes	23–280	—	0.5–6	BOD	<2
							TSS	<1
							TN	<3[c]
							TP	<0.1[c]
							FC	0[d]
Rapid infiltration	Secondary, or AWT, or groundwater recharge	None	No	3–23	45–180	6–125	BOD	5
							TSS	2
							TN	10
							TP	<1[e]
							FC	10
Overland flow	Secondary, nitrogen removal	Warmer season	Yes	6–40	<95	3–20	BOD	10
							TSS	10[f]
							TN	<10
							TP	<6

[a] Advanced wastewater treatment.
[b] For design flow of 3800 m^3/d.
[c] Total nitrogen removal depends on type of crop and management.
[d] FC = Fecal coliform, number per 100 ml.
[e] Measured in immediate vicinity of basin, increased removal with longer travel distance.
[f] Total suspended solids depends in part on type of wastewater applied.
Source: Adopted in part from Refs. 2, 3, 5, and 6.

TABLE 2
Design features and expected performance for pond treatment units

Parameter	Aerobic (High Rate)	Aerobic–anaerobic (Facultative)	Anaerobic
Detention time, days	5–20	10–30	20–50
Water depth, m	0.3–1	1–2	2.5–5
BOD_5 loading, kg/ha.d	40–120	15–120	200–500
Soluble BOD_5 removal, percent	90–97	85–95	80–95
Overall BOD_5 removal, percent	40–80	70–90	60–90
Algae concentration, mg/L	100–200	20–80	0–5
Effluent TSS, mg/L	100–250[a]	40–100[a]	70–120[a]

[a] TSS is high because of algae. Effluent quality can be improved significantly if algae is removed.

Source: Adopted in part from Refs. 3, 4 and 8.

Anaerobic ponds Anaerobic ponds receive such a heavy organic loading that there is no aerobic zone. They are usually 2.5 to 5 m in depth and have detention time of 20 to 50 days.[2,3] The principal biological reactions occurring are acid formation and methane production. Anaerobic ponds are usually used for treatment of strong industrial and agricultural wastes, or as a pretreatment step where an industry is a significant contributor to a municipal system. They do not have wide application to the treatment of municipal wastewater.

Facultative ponds It is the most common type of pond unit. These ponds are usually 1.2 to 2.5 m (4 to 8 ft) in depth with an aerobic layer overlaying an anaerobic layer, which often contains sludge deposits. The usual detention time is 5 to 30 days.[2] Anaerobic fermentation occurs in the lower layer, and aerobic stabilization occurs in the upper layer. The key to facultative operation is oxygen production by photosynthetic algae and surface reaeration. The algae cells are necessary for oxygen production, but their presence in the final effluent represents one of the most serious performance problems associated with the facultative ponds.[7]

Wetland Treatment Systems

The wetlands are inundated land areas in which water table is at or above the ground surface (usually 0.6 m or more). This water table stands long enough time each year to maintain saturated soil conditions and also to support the growth of related vegetation. The vegetation provides surface for attachment of bacteria films, and aids in the filtration and adsorption of wastewater constituents. Vegetation also translocate oxygen from leaves to the root systems to support a wide range of aerobic and facultative bacteria and controls the growth of algae by restricting the penetration of sunlight.[9] The unique ability of wetland plants to translocate oxygen to support a wide range of bacteria in the wetlands is shown in Figure 1. Wetlands can be of two types: natural wetlands and constructed wetlands. Both natural and constructed wetlands have been used for wastewater treatment, although the use of natural wetlands is generally limited to the polishing or further treatment of secondary or advanced wastewater treated effluent.[2]

Natural wetlands From a regulatory standpoint, natural wetlands are usually considered as part of the receiving waters. Consequently discharges to natural wetlands, in most cases, must meet applicable regulatory requirements, which typically stipulate secondary or advanced wastewater treatment.[10] Furthermore, the principal objective when discharging to natural wetlands should be enhancement of existing habitat. Modification of existing wetlands to improve treatment capability is often very disruptive to the natural ecosystem and, in general, should not be attempted.[10,11]

Constructed wetlands Constructed wetlands offer all of the treatment capabilities of the natural wetlands but without the constraints associated with discharging to a natural ecosystem. Additionally, the constructed wetland treatment units are not restricted to the special requirements on influent quality. They can ensure much more reliable control over the hydraulic regime in the system and therefore perform more reliably than the natural wetlands.[10] Two types of constructed wetlands have been developed for wastewater treatment (1) free water surface (FWS) systems, and (2) subsurface flow system (SF). The schematic flow diagrams of both types of system have been shown in Figure 2. A general description of both types of systems is provided below. The basic design considerations such as (a) site selection, (b) plants types, (c) physical facilities, (d) hydrologic factors, (e) organic loading factors, and (f) performance expectations, that are presented under a separate section entitled *Basic Design Considerations of Constructed Wetlands.*

Free water surface (FWS) wetlands The free water surface wetlands typically consist of a basin or channels with some type of barrier to prevent seepage, soil to support the root systems

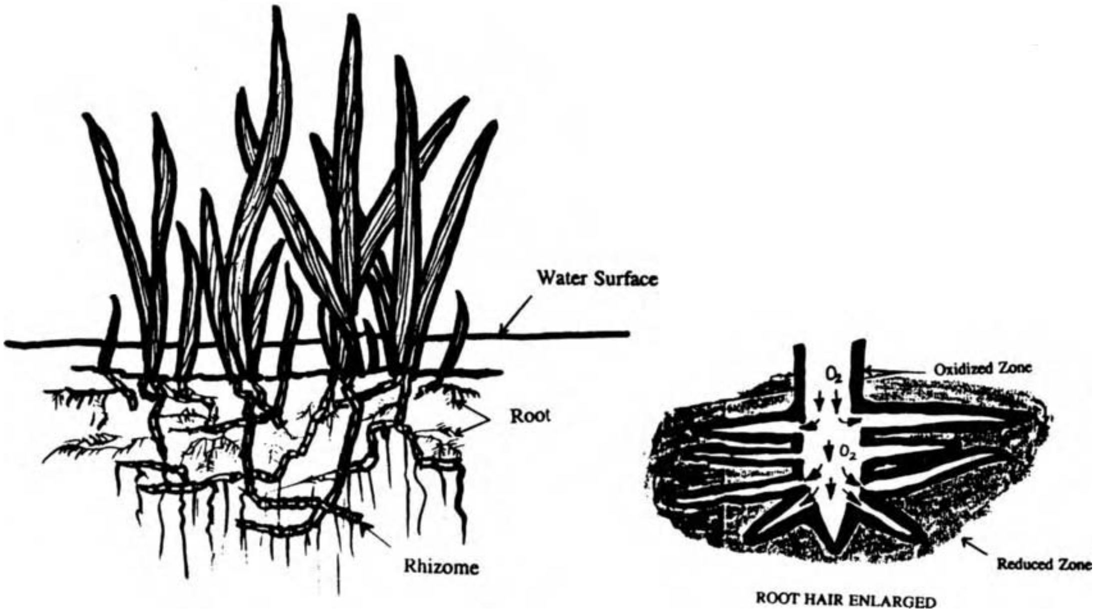

FIGURE 1 An enlarged root hair of wetland plants.

of the emergent vegetations, and water through the system at a relatively shallow depth.[2,9] The water surface in FWS wetlands is exposed to the atmosphere, and the intended flow path through the system is horizontal. Pretreated wastewater is applied continuously to such systems, and treatment occurs as the water flows slowly through the stems and roots of emergent vegetation. Free water surface systems may also be designed with the objective of creating new wildlife habitats or enhancing nearby existing natural wetlands. Figure 2(a) provides a schematic flow diagram of free water surface wetlands.

Subsurface flow (SF) wetlands The subsurface flow wetlands also consist of a basin or channel with a barrier to prevent seepage. The basin or channel is filled to a suitable depth with a porous media. Rock or gravel are the most commonly used media types. The media also supports the root systems of the emergent vegetation. The design of these systems assumes that the water level in the bed will remain below the top of the rock or gravel media. The flow path through the operational systems is usually horizontal.[12] The schematic flow diagram of submerged flow wetlands is provided in Figure 2(b).

Comparing the two types of constructed wetland systems, the SF type of wetlands offer several advantages over FWS type. If the water surface is maintained below the media surface there is little risk of odors, public exposure, or insect vectors. In addition, it is believed that the media provides larger available surface area for attached growth organisms. As a result, the treatment response may be faster, and smaller surface area may be needed for the same wastewater conditions.[2,10] Furthermore, the subsurface position of the water, and the accumulated plant debris on the surface of the SF bed, offer great thermal protection in cold climates as compared to the FWS type.[14] The reported disadvantage of the SF type system however, is clogging of the media possible overflow.

Basic Design Considerations of Constructed Wetlands

Constructed wetlands are relatively recent development, and are gaining popularity for treatment of wastewater from small communities, and residential and commercial areas. In this section the basic design information and economics of constructed wetlands are compared.

Site selection A constructed wetland can be constructed almost anywhere. In selecting a site for a free water surface wetland the underlying soil permeability must be considered. The most desirable soil permeability is 10E-6 to 10E-7 m/s.[10] Sandy clay and silty clay loams can be suitable when compacted. Sandy soils are too permeable to support wetland vegetation unless there is an impermeable restricting layer in the soil profile that result in a perched high ground water table. Highly permeable soils can be used for wastewater flows by forming narrow trenches and lining the trench walls and bottoms with clay or an artificial liner. In heavy clay soils, addition of peat moss or top soil will improve soil permeability and accelerate initial plant growth.

Plants Although natural wetlands typically contain a wide diversity of plant life, there is no need to attempt to reproduce the natural diversity in a constructed wetland. Such attempts in the past have shown that eventually cattails alone or in combination with either reeds or bulrushes will dominate

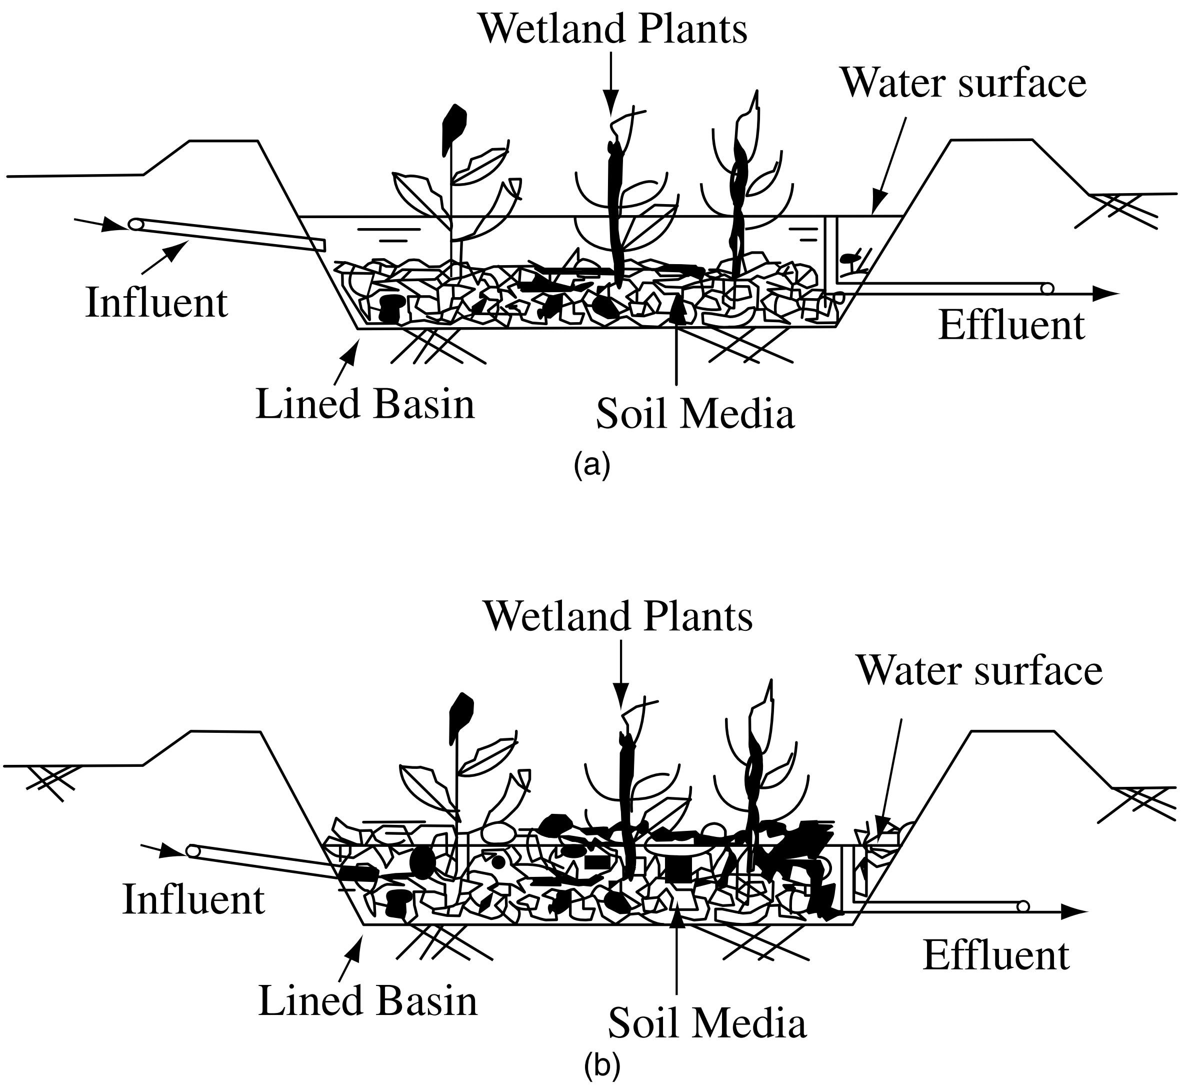

FIGURE 2 Schematic flow diagrams of constructed wetland systems, (a) Free water surface, (b) Subsurface flow.[13]

in a wastewater system owing to the high nutrient levels.[2] The emergent plants most frequently found in the wastewater wetlands include cattails, reeds, rushes, bulrushes and sedges. Some of the major environmental requirements of these plants are given in Table 3.

Physical facilities The constructed wetlands behave typically like a plug flow reactor. Constructed wetlands offer significant potential for optimizing performance through selection of proper system configuration, including aspect ratios, compartmentalization, and location of alternate and multiple discharge sites.

The aspect ratio, defined as the ratio of length to width, typically varies from 4:1 to 10:1. However, based on research data developed on experimental constructed wetlands, the aspect ratios approaching 1:1 may be acceptable.[13] Several alternative flow diagrams and configurations of constructed wetlands are provided in Figure 3.

Hydrologic factors The performance of the constructed wetlands system is dependent on the system hydrology as well as many other factors such as precipitation, infiltration, evapotranspiration, hydraulic loading rate, and water depth. These factors affect the removal of organics, nutrients, and trace elements not only by altering the detention time but also by either concentrating or diluting the wastewater.[9,10] For a constructed wetland, the water balance can be expressed by Eq. (1)

$$[dV/dt] = Q_i - Q_e + P - ET \tag{1}$$

where,

Q_i = influent wastewater flow, m^3/d
Q_e = effluent wastewater flow, m^3/d
P = precipitation, m^3/d
ET = evapotranspiration, m^3/d
$[dV/dt]$ = change in volume of water per unit time, m^3/d
t = time, d

TABLE 3
Emergent aquatic plants for constructed wetlands

Common name (*Scientific name*)	Temperature, °C		Maximum salinity tolerance, ppt[b]	Optimum pH

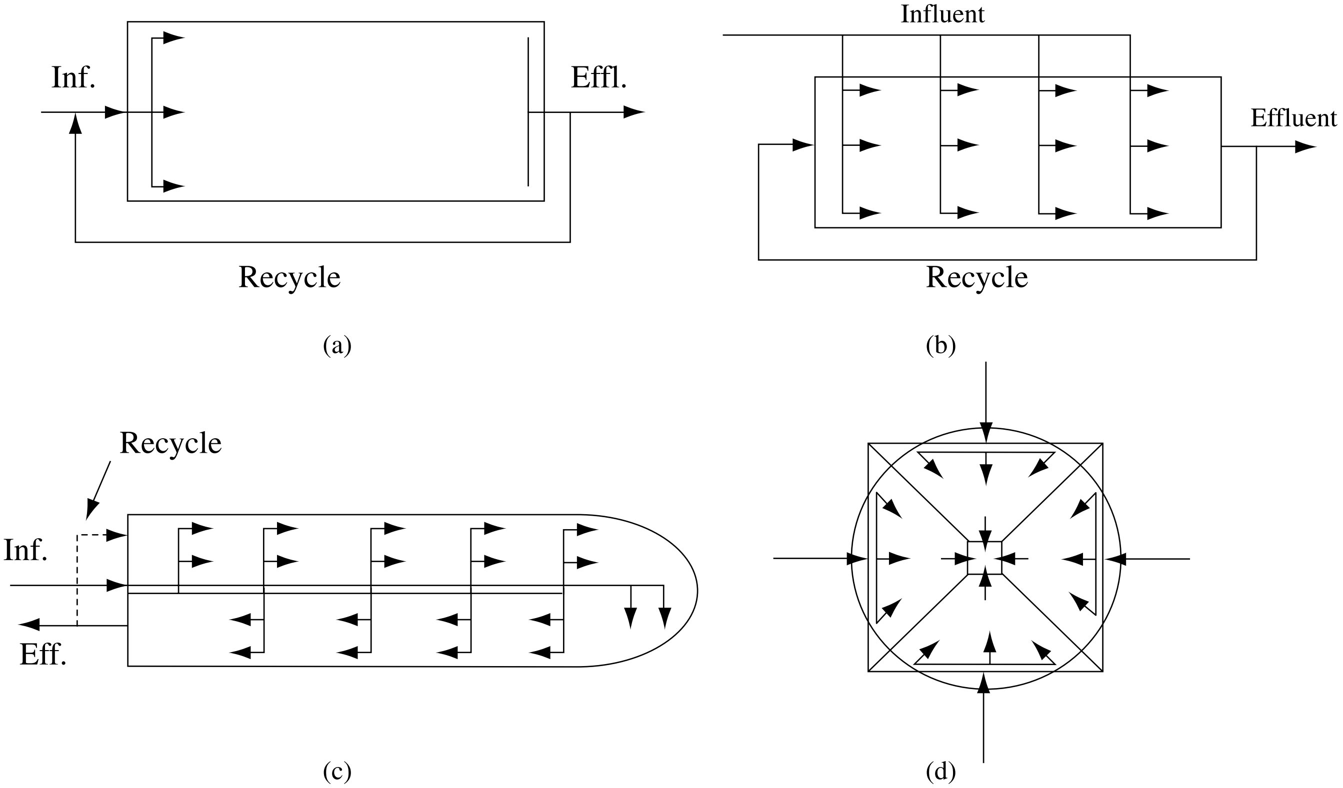

FIGURE 3 Alternate flow diagram and configurations of constructed wetlands: (a) Plug flow with recycle; (b) Step feed with recycle; (c) Step feed in wrap around pond; (d) Peripheral feed with center drawoff.

Hydraulic loading rate for FWS system is closely tied to the hydrologic factors and conditions specific to the site. Typical hydraulic loading rate of 198 m^3/d.ha (21,000 gpd/acre) is considered sufficient for optimum treatment efficiency.

BOD_5 loading rates There are two goals for organic load control in the constructed wetlands. The first is the provision of carbon source for denitrifying bacteria. The second goal is to prevent overloading of the oxygen transfer ability of the emergent plants. High organic loading, if not properly distributed, will cause anaerobic conditions, and plants die off. The maximum organic loading rate for both type of systems (FWS and SF) should not exceed 112 kg BOD_5/ha.d.[2,9,10]

Performance expectations Constructed wetland systems can significantly remove the biochemical oxygen demand (BOD), total suspended solids (TSS), nitrogen and phosphorus, as well as metals, trace organics and pathogens The basic treatment mechanisms include sedimentation, chemical precipitation, adsorption, microbial decomposition, as well as uptake by vegetation. Removal of BOD_5, TSS, nitrogen, phosphorus, heavy metals and toxic organics have been reported.[2,17] The performance of many well known constructed wetlands in terms of BOD_5, TSS, ammonia nitrogen and total phosphorus is summarized in Table 4.

Mosquito control and plant harvesting are the two operational considerations associated with constructed wetlands for wastewater treatment. Mosquito problems may occur when wetland treatment systems are overloaded organically and anaerobic conditions develop. Biological control agents such as mosquitofish (*Gambusia affins*) die either from oxygen starvation or hydrogen sulfide toxicity, allowing mosquito larvae to mature into adults. Strategies used to control mosquito populations include effective pretreatment to reduce total organic loading; stepfeeding of the influent wastewater stream with effective influent distribution and effluent recycle; vegetation management; natural controls, principally mosquitofish, in conjunction with the above techniques; and application of approved and environmentally safe chemical control agents.

The usefulness of plant harvesting in wetland treatment systems depends on several factors, including climate, plant species, and the specific wastewater objectives. Plant harvesting can affect treatment performance of wetlands by altering the effect that plants have on the aquatic environment. Further, because harvesting reduces congestion at the water surface, control of mosquito larvae using fish is enhanced. It has been reported in the literature that a total of 29,000 kg/ha dry weight of harvestable biomass of *Phragmites* shoots can be harvested for single harvesting in a year. Higher yield is achievable with multiple harvesting.

The BOD_5, TSS, nitrogen and phosphorus removal efficiencies of constructed wetlands are discussed below.

BOD_5 Removal in FWS wetlands In the free water surface constructed wetlands the soluble BOD_5 removal is due to microbial growth attached to plant root, stems, and leaf litter that has fallen into the water. BOD_5 removal is generally expressed by a first order reaction kinetic (Eq. 2).[2,3,10]

$$[C_e/C_o] = \exp(-K_T t) \tag{2}$$

where,
C_e = effluent BOD_5, mg/L
C_o = influent BOD_5, mg/L
K_T = reaction rate constant, d^{-1}
t = hydraulic retention time, d.

BOD_5 Removal in SF wetlands The major oxygen source for the subsurface components (soil, gravel, rock, and other media, in trenches or beds) is the oxygen transmitted by the vegetation to the root zone. In most cases, there is very little direct atmospheric reaeration as water surface remains below the surface of the media.[17] Removal of BOD_5 is expressed by Equation (3). This is also a first order equation and can be rearranged to calculate the area required for the subsurface flow system.

$$\log(C_e/C_o) = -[A_s K_t d e]/Q \tag{3}$$

where,
C_e = effluent BOD_5, mg/L
C_o = influent BOD_5, mg/L
K_t = reaction rate constant, d^{-1}
Q = flow rate through the system, m^3/d
d = depth of submergence, m
e = porosity of the bed,
A_s = surface area of the system, m^2.

Suspended solids removal Suspended solids removal is very effective in both types of constructed wetlands. Most of the removal occurs within few meters beyond the inlet. Control dispersion of the inlet flow will enhance removal near the inlet zone. Proper dispersion of solids can be achieved by low inlet velocities, even cross sectional loadings, and uniform flow without stagnation.[10]

Nitrogen removal Nitrogen removal is very effective in both the free water surface and submerged flow constructed wetlands, and the nitrification/denitrification is the major path of nitrogen removal. Total nitrogen removals of up to 79 percent are reported at nitrogen loading rates of (based on elemental N) up to 44 kg/(ha.day) [39 lb/(acre.day)], in a variety of constructed wetlands. If plant harvesting is practiced, a higher rate of nitrogen removal can be expected.[9,20]

Phosphorus removal Phosphorus removal in many wetlands is not very effective because of the limited contact opportunities between the wastewater and the soil. The exceptions are in the submerged bed design when proper soils are selected as the medium for the system.[21] A significant clay content and the presence of iron, and aluminum will enhance the potential for phosphorus removal.[9,20,21]

TABLE 4
Performances of some well known constructed wetlands

Cost Cost is often a significant factor in selecting the type of treatment system for a particular application. Unfortunately, the availability of reliable cost data for wetland treatment systems is limited. The cost of wetland treatment systems varies depending on wastewater characteristics, the type of wetland system, and the type of bottom preparation required. Subsurface flow systems are generally more expensive than free water surface systems. It has been reported that the Tennesee Valley Authority (TVA) wetland construction costs ranged from \$3.58/m^2 to \$32.03/m^2.[22] Estimates are that the construction, operation, and maintenance costs of constructed wetland systems are quite competitive with other wastewater treatment options.

NITROGEN OXIDES REDUCTION

INTRODUCTION

Nitrogen oxides are one of the most persistent categories of globally emitted air pollutants because they are combustion products of both stationary and mobile sources. By far the highest concentration of the oxides formed during combustion are NO and NO_2. Given time, and in the presence of O_2 either in the flue gases or in the atmosphere most of the NO is converted to NO_2.

There are six commonly encountered oxides of nitrogen: (1) nitric oxide (NO); (2) nitrous oxide (N_2O); (3) nitrogen dioxide (NO_2); (4) nitrogen trioxide (N_2O_3); (5) nitrogen tetroxide (N_2O_4); (6) nitrogen pentoxide (N_2O_5). Typically, nitrogen oxides, or NO_x, refers to a collective name for nitric oxide, NO, and nitrogen dioxide NO_2, both of which are formed as a by-product during combustion. Nitric oxide is a colorless, odorless, toxic, nonflammable gas which is slightly soluble in water. Nitrogen dioxide, however, is a reddish-brown gas that is toxic and highly corrosive with a pungent odor. This gas can contribute to highly visible plumes. Emissions of nitrogen oxides are of concern due to their potential role in ozone formation, acid rain deposition, health effects, and formation of toxic air pollutants.

EFFECTS OF NO_X

Human and Animal Health Effects

Of the two compounds, nitrogen dioxide is the most toxic and dangerous to humans. A variety of studies has been performed to observe the effects of NO_2 on humans and animals. Most of these studies have been performed using pure NO_2. Effects of acute NO_2 exposure have been reported as nose and eye irritation, obliterative bronchiolitis, pulmonary congestion and edema, pneumonitis, and death. Most of these reactions, such as pulmonary edema and obliterative bronchiolitis, can occur at extremely high concentrations (150–500 ppm) for short periods of time minutes to an hour. It appears, however, that mixtures of oxides tend to lessen the discomfort and the potential to contract severe disorders. It has also been shown that chronic, intermittent exposure to NO_2 (10–40 ppm) can result in chronic pulmonary fibrosis and emphysema.[1] In animal studies, continuous exposure to NO_2 for 90 days at 5 ppm has resulted in the deaths of 18% of the rats, 13% of the mice and 66% of the rabbits.[1] On the other hand, intermittent exposure for 18 months at the same level (5 ppm) did not result in any deaths. In addition to the chronic and acute effects, it appears that daily exposure to NO_2 concentrations of 5 ppm can lead to slightly accelerated lung tumor formation, but not at a level of any statistical significance.

On the other hand, exposure strictly to nitric oxide has not been reported to result in human poisoning probably due to its relatively low toxicity and its conversion to NO_2. The relative toxicity can be seen in the exposure standards set by NIOSH (National Institute for Occupational Safety and Health) and OSHA (Occupational Safety and Health Administration). For nitric oxide, the threshold limit value (TLV) for an 8-hour time weighted average (TWA) exposure is 25 ppm.[2] For nitrogen dioxide, the TLV is 1 ppm for a short-term exposure limit (STEL). The short-term exposure limit is a 15-minute TWA exposure that should not be exceeded at any time during a workday. Likewise, the immediately dangerous to life or health (IDLH) concentration for nitric oxide is 100 ppm, whereas for nitrogen dioxide, the concentration is 50 ppm.[2] Toxicologists have reported that nitric oxide can be a mild nose, eye and throat irritant. At high concentrations, nitric oxide can lead to a progressive depression of the central nervous system.[1]

Environmental Effects

Not only does NO_x affect the human population, but it also has an adverse effect on the environment, in particular vegetation. Gaseous pollutants damage plants by entering through the stomata during the respiration cycle.[3] The pollutants can disrupt the photosynthesis process and can destroy plant chlorophyll. Experiments have shown that concentrations of NO_2 as low as 0.5 ppm can result in reduced plant growth by as much as 35%. In particular, it appears that plants are more susceptible to nitrogen dioxide effects at night than during the day. Scientists feel that NO_x has played a significant role in the deforestation of central Europe.

Not only does direct exposure to nitrogen oxides result in plant deterioration, but nitrogen oxides combine with certain hydrocarbons to form ozone and peroxyacyl nitrates (PAN's), two compounds that have been found be more toxic towards plants than nitrogen oxides alone. Exposure to these compounds has been shown to result in plant growth suppression, bleaching, glazing and silvering on the lower surface of the leaves.[3]

In addition to vegetative kill, nitrogen dioxide is an extremely corrosive gas that can have deleterious effects on a wide range of materials such as plastics, fabrics, rubber and metals. Studies on Nylon-6 and Kevlar have revealed that the ultimate tensile strengths of these materials are reduced when exposed to a NO_x environment in the range of 0.5–0.8% volume concentration.

Global Warming/Greenhouse Effect

The greenhouse effect occurs due to the buildup of gases which can absorb heat. The earth maintains a constant average temperature by radiating heat to space; thus, greenhouse gases absorb a portion of this heat and radiate it to the lower atmosphere. Scientists believe that the heat is trapped in the lower atmosphere, resulting in global warming, rising sea level and global climatological alterations. There is considerable debate over the global warming issue when viewed from the geologic time scale. In any case, there has been considerable research done in this field and it will continue to be a topic of concern for years to come.

Principally, carbon dioxide is the most important greenhouse gas, contributing to roughly half of the global warming that has been reported. The other half of the global warming has been attributed to approximately 20 other gases, most notably methane, chlorofluorocarbons (CFC-11 and CFC-12), ozone, nitrous oxide, and nitrogen dioxides. Some scientists have estimated that a 50% increase in the current concentration of N_2O will result in a mean global temperature increase of 0.2–0.5°C.[4] Of the nitrous oxide emissions, 25% has been attributed to fossil fuel combustion. If these predictions are accurate, then it becomes even more important to control the emissions of nitrogen oxides from combustion related processes.

Acid Rain Deposition

Acid rain forms when sulfur dioxide and nitrogen oxides mix with water vapor to form sulfuric and nitric acid. In particular, nitrogen oxides are transformed into nitric acid by the following reactions:[5]

$$2NO + O_2 \rightarrow 2NO_2$$

$$NO + O_3 \rightarrow NO_2 + O_2$$

$$2NO_2 + 2H_2O + O_2 \rightarrow 4HNO_3.$$

On an annual basis, nitric acid is responsible for approximately 30% of the acidity of rainfall. This percentage increases to around 50% during the winter. Acid rain is one of the most damaging effects of NO_x emissions. It leads to the destruction of ecosystems in lakes, deforestation, and the stripping of organic material in soils, creating erosion and potentially metal laden soils. In addition, NO_x emissions contribute substantially to the acid pulse in snowmelt, which in turn severely impacts the freshwater ecosystem. Therefore, acid rain is yet another reason for controlling and limiting NO_x emissions to the atmosphere.

Ozone Formation

In addition to being a cause of acid rain, nitrogen oxides are also considered one of two precursors to the formation of primary ozone, O_3. Ozone is thought to be formed from the complex reaction of certain hydrocarbons and nitrogen oxides.

The role of nitrogen oxides in ozone formation is significant because of the health effects associated with elevated levels of ozone. Ozone exposure can lead to coughing and chest discomfort, headaches, upper respiratory illness, reduced pulmonary function, eye irritation, and increased asthma attacks. For ozone, the NIOSH ceiling exposure limit is 0.1 ppm; the OSHA threshold limit value (TLV) for an 8-hour time weighted average (TWA) exposure is 0.1 ppm. The OSHA short-term exposure limit is 0.3 ppm.[2] The immediately dangerous to life or health (IDLH) concentration for ozone is 10 ppm, which is five times less than the IDLH for nitrogen dioxide and nitric oxide, respectively. In addition to human health effects, studies have shown that ozone damages agricultural crops and forest ecosystems.

NO_x REGULATIONS

Stationary Source Regulations

Because of the harmful effects associated with nitrogen oxides, governments around the world have established increasingly stricter regulations over the past few decades to curb and reduce the amount of NO_x emissions. In particular, the United States federal government enacted the Clean Air Act (CAA) to protect the nation's air quality. The CAA was first passed into legislation in 1970, with substantial amendments being added in 1977 and most recently in 1990. The amendments in 1990 greatly increased the scope of the existing CAA. The CAA is divided into seven primary Titles, I–VII. Some of he new major points in these Titles are as follows:[6, 7]

- **Title I**—A new system was established to determine if an area is classified as either an ozone attainment or an ozone nonattainment area. The CAA effectively divides the United States into attainment and nonattainment areas, based on the level of criteria pollutants in the area's ambient air. Because of the formation of ozone from volatile organic compounds (VOC's) and NO_x, Title I requires more stringent requirements for these two classes for compounds.
- **Title II**—Clean fuel requirements and increased restrictions on motor vehicle emissions were introduced in Title II. Under Title II, new vehicle tailpipe emissions of NO_x were to be reduced by 60%, starting with 40% of all new vehicles in the 1994 model year and increasing to 100% by the 1998 model year.
- **Title III**—Emission limitations for 189 hazardous air pollutants (HAP's) are to be set by the

United States Environmental Protection Agency (USEPA). The National Emissions Standards for Hazardous Air Pollutants (NESHAP's) set in earlier versions of the CAA will remain intact, but the USEPA will now be required to use the best demonstrated emissions control practices in a particular industry to regulate sources for that industry. Under standards set by the USEPA, major sources will be required to apply Maximum Available Control Technology (MACT). A major source is defined as one that emits 10 tons/year of a HAP or 25 tons/year of any combination of HAPs.

- **Title IV**—Under Title IV, the USEPA is required to establish a program to reduce the occurrence of acid rain. Because SO_2 and NO_x are the two main contributors to acid rain, facilities that fall under control of Title IV will be forced to meet certain standards and will be required to obtain an acid rain permit.
- **Title V**—A comprehensive operating permit program was established for all significant air emission sources.
- **Title VI**—Under this Title, a new national program was developed to phase out the use of chlorofluorocarbons (CFCs) and similar compounds to protect the stratospheric ozone layer.
- **Title VII**—The USEPA's enforcement ability was greatly enhanced with more criminal and civil powers.

Included in the Title I requirements are the National Ambient Air Quality Standards (NAAQS), which specify the maximum allowable concentrations for six criteria pollutants. These pollutants are: (1) carbon monoxide; (2) lead; (3) nitrogen oxides; (4) ozone; (5) particulates ($\leq$ 10 microns diameter); and (6) sulfur oxides. There are two types of NAAQS, which are defined in the USEPA 40 CFR Part 50 Regulations:

- primary—standards are designed to protect the public health.
- secondary—standards are designed to protect the public from a pollutant's effects on visibility, personal comfort, properly, etc.

If an airshed area exceeds the ambient air concentrations of one of these pollutants, then that area is considered to be in nonattainment. For nitrogen oxides, the primary and secondary National Ambient Air Quality Standards expressed as annual arithmetic mean concentration are 0.053 parts per million (100 $\mu g/m^3$).[8] This limit should not be exceeded, during any 12 consecutive month period, for the annual average of the 24-hour concentrations. Figure 1[9] shows the control technologies required by facilities to meet the NAAQS. The three main categories are BACT, LAER, and RACT. BACT or Best Available Control Technology, is defined by the CAA as " … an emission limitation based on the maximum degree of reduction of each pollutant … which the permitting authority … "[9] considers appropriate. BACT applies to new or modified sources of emissions in attainment areas. LAER or Lowest Achievable Emission Rate applies to new or modified sources in nonattainment areas. It refers to the most stringent emission limitation achieved by a similar facility or a particular source category.[9] RACT or Reasonably

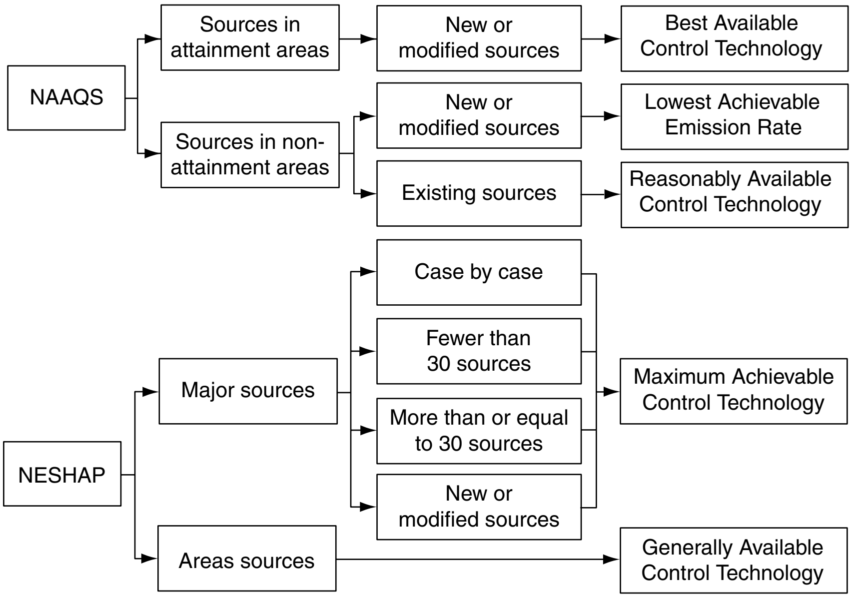

FIGURE 1 Relationships between control technologies and standards.[9]

Available Control Technology applies to existing sources in nonattainment areas. RACT has been defined by the USEPA as "the lowest emission limitation that a particular source is capable of meeting by the application of control technology that is reasonably available considering technological and economic feasibility".[9]

One of the ways the CAA provides for regulation of emissions is through the New Source Performance Standards (NSPS), which is also a component of Title I. The USEPA continually promulgates new standards, under the 40 CFR Part 60's, to regulate the emissions of criteria pollutants from new or substantially modified stationary sources. These new sources may also have to undergo a New Source Review (NSR) permitting process. Under this process, the regulating agency determines whether the facility can begin operation and under what conditions. The following is a list of new source performance standards that pertain to facilities that are regulated for NO_x emissions:[10]

- *Subpart D-Fossil Fuel Fired Steam Generators* (facilities that began construction after 8/17/71) (>250 MBtu/hr)[10]
- The NO_x emission limits are found in Table 1.
- For combinations of fuels, the following proration applies:

$$E_n = \frac{260w + 86x + 130y + 300z}{w + x + y + z}$$

where

E_n = NO_x limit (ng/J heat input)
w = % of total heat input derived from lignite
x = % of total heat input derived from gaseous fossil fuel
y = % of total heat input derived from liquid fossil fuel
z = % of total heat input derived from solid fossil fuel.

- *Subpart Da-Electric Utility Steam Generating Units* (facilities that began construction after 9/18/78) (>250 MBtu/hr)[10]
- The NO_x emission limits are found in Table 2.
- For combinations of fuels, the following proration applies:

$$E_n = \frac{86w + 130x + 210y + 260z + 340v}{100}$$

where

E_n = NO_x limit (ng/J heat input)
w = % of total heat input derived from combustion of fuels subject to the 86 ng/J heat input standard
x = % of total heat input derived from combustion of fuels subject to the 130 ng/J heat input standard
y = % of total heat input derived from combustion of fuels subject to the 210 ng/J heat input standard
z = % of total heat input derived from combustion of fuels subject to the 260 ng/J heat input standard
v = % of total heat input derived from combustion of fuels subject to the 340 ng/J heat input standard.

- *Subpart Db-Industrial-Institutional Steam Generating Units* (facilities that began construction after 6/19/84) (> 100 MBtu/hr)[10]
- The NO_x emission limits are found in Table 3.
- *Subpart Ea-Municipal Waste Combustors* (facilities that began construction after 12/2/89) (>250 tons/day)[10]
- 180 ppm by volume, corrected to 7% O_2 (dry basis).
- *Subpart G-Nitric Acid Plants* (facilities that began construction after 8/17/71)[10]
- 3.0 lb NO_x (as NO_2)/ton of acid produced expressed as 100% nitric acid).
- *Subpart GG-Stationary Gas Turbines* (facilities that began construction after 10/3/77)[10]
- The NO_x emission limits for stationary gas turbines are given by two equations. For units with a heat input at peak load of >107.2 GJ (100 MBtu) per hour, the allowable NO_x emission at 15% O_2, dry is given by the following equation:

$$E_n = 0.0075\,\frac{(14.4)}{Y} + F$$

For units with a heat input peak load of >10.7 GJ (10 MBtu) per hour but <107.2 GJ (100 MBtu) per hour and for units with a base load at ISO conditions of 30 MW or less, the

TABLE 1
USEPA 40 CFR Part 60 Subpart D-Fossil-fuel fired steam generators NO_x emission limits[10]

Fuel type	NO_x emission limits, ng/J(lb/MBtu) (expressed asNO_2) for heat input
(1) Gaseous fossil fuel	86 (0.20)
(2) Liquid fossil fuel	129 (0.30)
(3) Liquid fossil fuel + wood residue	129 (0.30)
(4) Gaseous fossil fuel + wood residue	129 (0.30)
(5) Solid fossil fuel[1]	300 (0.70)
(6) Solid fossil fuel + wood residue[1]	300 (0.70)
(7) Lignite, except (9)	260 (0.60)
(8) Lignite + wood residue, except (9)	260 (0.60)
(9) Lignite mined in North Dakota, South Dakota, or Montana, and which is burned in a cyclone-fired unit	340 (0.80)

[1] Except liginite or a solid fossil fuel containing 25%, by weight, or more coal refuse.

TABLE 2

USEPA 40 CFR Part 60 Subpart Da-electric utility steam generating units NO_x emission limits[10]

Fuel type	Emission limit for heat input ng/J	Emission limit for heat input (lb NO_x/MBtu)
Gaseous fuels		
Coal-derived fuels	210	0.50
All other fuels	86	0.20
Liquid fuels		
Coal-derived fuels	210	0.50
Shale oil	210	0.50
All other fuels	130	0.30
Solid fuels		
Coal-derived fuels	210	0.50
Any fuel containing more than 25%, by weight, coal refuse[1]	([1])	([1])
Any fuel containing more than 25%, by weight, lignite if the lignite is mined in North Dakota, South Dakota, or Montana, and is combusted in a slag tap furnace[2]	340	0.80
Any fuel containing more than 25%, by weight, lignite not subject to the 340 ng/J heat input emissions limit[2]	260	0.60
Subbituminous coal	210	0.50
Bituminous coal	260	0.60
Anthracite coal	260	0.60
All other fuels	260	0.60

[1] Exempt from NO_x standards and NO_x monitoring requirements.

[2] Any fuel containing less than 25%, by weight, lignite is not prorated but its % is added to the % of the predominant fuel.

allowable NO_x emission at 15% O_2, dry is given by the following equations:

$$E_n = 0.0150 \frac{(14.4)}{Y} + F.$$

where

E_n = NO_x limit (% by volume, dry)

Y = mfg.'s rated heat rate at mfg.'s rated peak load or the actual measured heat rate based on lower heating value of fuel as measured at actual peak load for the facility. The value of Y shall not exceed 14.4 kJ per watt hour.

F = defined according to the nitrogen content of the fuel as follows:

Fuel-bound nitrogen (% by weight)	F (NOx % by volume)
$N < 0.015$	0
$0.015 < N < 0.1$	0.04 (N)
$0.1 < N < 0.25$	0.004 + 0.0067 (N-0.1)
$N > 0.25$	0.005

In addition to NSPS and NAAQS, the USEPA is reducing NO_x emissions through Title IV, the Acid Rain Program. The regulations under this program were published as final in the April 13, 1995 *Federal Register* and became effective on May 23, 1995. The regulations are aimed directly at coal fired utility plants in which the combustion of coal on a BTU basis exceeds 50% of its annual heat input. The type of boilers used at these plants has been subdivided into Group 1 and Group 2 boilers. Group 1 boilers include tangentially fired boilers or dry bottom wall-fired boilers. Group 2 boilers include wet bottom wall-fired boilers, cyclone boilers, vertically fired boilers, arch-fired boilers, or utility boilers (i.e. fluidized bed or stoker boilers). In addition, the CAA has set standards based on Phase I and Phase II.

In the acid rain regulations, NO_x emission limits have been established for Phase I coal fired utility units with tangentially fired boilers (95 units) or with dry bottom wall-fired boilers (84 units), which were to be effective January 1, 1996. For tangentially fired boilers, the limit is 0.45 lb/MBtu of heat input on an annual average basis. For dry bottom wall fired boilers, the NO_x limit is 0.50 lb/MBtu of heat input expressed on an annual average basis. The facilities that cannot meet the requirements will be allowed to apply for a less restrictive emission standard or to join an "averaging pool," through which the overall emissions limit average is attained. Phase I standards for Group 2 boilers are scheduled to be set by January 1, 1997 with implementation by January 1, 2000. Phase II standards for Group 1 and 2 boilers are required to be established by 1997.[11]

Similar to the federal government under the Clean Air Act, State governments have the authorization to enact regulations that maintain ambient air quality and to set limits for sources of air pollution. In New York State, the agency charged with

TABLE 3
USEPA 40 CFR Part 60 Subpart
Db-industrial/commercial/institutional steam generating units
NO_x *emission limits*[10]

Fuel/steam generating unit type	NO_x emission limits, ng/J(lb/MBtu) (expressed as NO_2) for heat input
(1) Natural Gas and distillate oil, except (4)	
(i) Low heat release rate	43 (0.10)
(ii) High heat release rate	86 (0.20)
(2) Residual oil	
(i) Low heat release rate	130 (0.30)
(ii) High heat release rate	170 (0.40)
(3) Coal

(ii) Spreader stoker and fluidized bed combustion	260 (0.60)
(iii) Pulverized coal	300 (0.70)
(iv) Lignite, except (v)	260 (0.60)
(v) Lignite mined in North Dakota, South Dakota, or Montana, and is combusted in a slag tap furnace	340 (0.80)
(vi) Coal-derived synthetic fuels	210 (0.50)
(4) Duct burner used in a combined cycle system	
(i) Natural gas and distillate oil	86 (0.20)
(ii) Residual oil	170 (0.40)

enforcing these regulations is the New York State Department of Environmental Conservation (NYSDEC). The USEPA has delegated authority to the NYSDEC to issue permits to construct to sources for the modification or construction of any stationary source subject to federal NSPS, NESHAPS, or PSD (Prevention of Significant Deterioration) requirements, and to implement and enforce the federal standards and PSD requirements where they apply.[12] The NYSDEC requires that any new or modified air emission source acquire a permit to construct and a certificate to operate under the requirements of 6 NYCRR Part 201. Any air contamination source subject to the NSPS, NESHAPS, or PSD requirements must be in compliance with the federal standards as well as any applicable State standards, such as New York State Ambient Air Quality Standards (NYSAAQS) or New York State performance standards. The NYSAAQS for NO_2 is 0.053 ppm (100 $\mu g/m^3$)[13] with the same averaging period as that of the USEPA NAAQS. Recently, the NYSDEC made revisions to the 6 NYCRR Part 200, 201, and 227 air pollution regulations. In particular, these revisions included Subpart 227–2 entitled "Reasonably Available Control Technology (RACT) for Oxides of Nitrogen (NO_x)."[14] This subpart requires operators of existing major stationary sources of NO*x* to use RACT to limit NO_x emissions. A source is classified as a major source if it has the potential to emit 100 tons NO_x per year or if it has the potential to emit 25 tons NO_x per year in a "severe" ozone nonattainment area. The major stationary sources as defined in Subpart 227–2 are:[14]

- Very large boilers—$Q_{MAX} > 250$ MBtu/hr
- Large boilers—100 MBtu/hr $< Q_{MAX} \leq 250$ MBtu/hr
- Mid-size boilers—50 MBtu/hg $< Q_{MAX} \leq 100$ MBtu/hr
- Small boilers—20 MBtu/hr $< Q_{MAX} \leq 50$ MBtu/hr
- Combustion turbines—$Q_{MAX} > 10$ MBtu/hr
- Internal combustion engines—≥225 HP in severe nonattainment areas; >400 HP in all other areas
- Other combustion sources

where, Q_{MAX} is equal to the maximum heat input capacity or rate.

Tables 4–8[14] contain information regarding the NO_x emission limits for the above sources. These limits were to be met by the existing sources by May 31, 1995. Small boiler operators are only required to perform annual tune-ups and to maintain a log book containing process information. Other major combustion sources of NO_x not covered under one of the specific sources above were required to submit a RACT proposal detailing the technology and potential emissions to the NYSDEC by May 31, 1995.

Outside of state and federal regulations, certain cities promulgate their own air pollution control regulations.

The New York City Department of Environmental Protection (NYC DEP) revised their air pollution code in March, 1992. This document contains guidelines for obtaining local permits and certificates as well as standards for air pollutant emissions. In regards to NO_x emissions, the NYC DEP set a limit for boilers with a capacity of >500 MBtu/hr depending on whether the boiler was completed before (150 ppmv NO_x) or after (100 ppmv NO_x) August 20, 1971.[15]

The petrochemical and refinery sectors have been subjected to stringent regulatory requirements in recent years by state

TABLE 4
NYS DEC NO$_x$ RACT emission limits for very larger boilers (lbs NO$_x$/MBtu)[14]

	Boiler configuration			
Primary fuel type	Tangential	Wall	Cyclone	Stokers
Gas only	0.20	0.20	NA	NA
Gas/oil	0.25	0.25	0.43	NA
Coal wet bottom	1.00	1.00	0.60	NA
Coal dry bottom	0.42	0.45	NA	0.30[1]

[1] The limit is 0.33 lbs NOx/MBtu when 25% of other solid fuels, on a Btu basis, are utilized.

TABLE 5
NYS DEC NO$_x$ RACT emission limits for large boilers (lbs NO$_x$/MBtu)[14]

Primary fuel type	Emission limit
Gas only	0.20
Gas/oil	0.30
Pulverized coal	0.50
Coal (overfeed stoker)	0.30[1]

[1] The limit is 0.33 lbs NO$_x$/MBtu when 25% of other solid fuels, on a Btu basis, are utilized.

TABLE 6

[2] Lean burn engine—O$_2$ by volume is greater than or equal to 1.0% in the exhaust.

and federal governments.[33,34,35] NO$_x$ control options have been applied to fired process heaters[34] whose uncontrolled emissions are in the range of 0.10 to 0.53 lb/10^6 Btu. The percentage reductions attained for key control technologies include,

(1) Low NOx burners (25–65%)
(2) Selective Catalytic Reductions (SCR) (65–90%) and
(3) Combined Low NOx and SCR (70–90%)

Additional factors involved in choosing a desired technology include capital, operating and maintenance costs.[35]

Mobile Source Regulations

In addition to stationary combustion, mobile sources, such as passenger cars and trucks, contribute almost 50% of the NO$_x$ produced in the United States. To reduce the emissions from these sources, federal and State governments have implemented standards on tailpipe emissions of NO$_x$. Typically, vehicles are divided into three main weight categories: (1) light duty, (2) medium duty, and (3) heavy duty. Vehicles are further subdivided in each main category; emission limits are applied to these subcategories. Emission limits are expressed two different units: (1) g/mi, grams per mile, or (2) g/bhp-hr, grams per brake horse-power-hour. In the federal and California regulations, standards are expressed in g/mi for light and medium duty vehicles, whereas g/bhp-hr is used for heavy duty vehicles. As a comparison of some of the emission limits, Table 9 shows the federal, California and New York[16,17] standards for passenger and light duty vehicles.

To further reduce air pollutant emissions from vehicles, the federal and State governments have implemented a number of other programs. One such program is the Clean-Fuel Vehicles Fleet Program which is designed to reduce emissions, in highly polluted regions, from vehicles belonging to a fleet. Tailpipe emissions generally account for 60% of the total vehicle emissions.[16] Thus, governments are beginning to focus on the other emission forms associated with vehicles. These include evaporative emissions, CO emissions at cold temperatures, air toxics emissions, emissions testing and procedures, and emissions control diagnostics systems. Regulating emissions is not the only method to curb NO production. The composition of the fuel has also been a target of regulations. Requirements have been promulgated to establish the use of reformulated gasoline, oxygenated gasoline, reduced volatility gasoline, and cleaner diesel fuel.

Thus, the federal and state governments have taken active role in the limiting of NO$_x$ emissions. Depending on the political climate in the United States, these gulations may become less or more stringent over the next few years.

[1] The standard for in-use compliance for passenger cars and light duty trucks certifying to the 0.4 g/mi NO_x standard shall be 0.55 g/mi NO_x for 50,000 miles.

[2] LDTI refers to light duty trucks from 0–3, 750 pounds loaded vehicle weight.

[3] LDT2 refers to light duty trucks from 3,751–5750 pounds loaded vehicle weight, but less than 6,000 pounds gross vehicle weight.

Conversion of Emission Standards

As can be seen from the above regulations, NO_x standards come in various units. Some regulations state NO_x limits in ppm, on a dry volume basis, whereas other regulations may require the emissions in lbs NO_x/MBtu. Figures 2–4 have been developed for converting emission units at different oxygen percents in the flue gas for natural gas, oil, and coal fired units, respectively. Figure 2 is based on a typical gaseous fuel, a US/Texas gas (see Table 10[18,19]). Figures 3 and 4 were based on a number of different liquid and solid fuels (see Tables 11[18,20] and 12[18,21], respectively). Three Lotus spreadsheets were utilized to develop Figure 2. First, a spreadsheet was developed, Table 13, that converts the gas components, on a percent volume basis, to the elemental component mass fractions. In addition, the spreadsheet also calculates the lower and higher heating values of the natural gas based on the components in the natural gas. The lower heating value is compared for accuracy to experimental results. Next, the component mass fractions were read into the second spreadsheet, Table 14, to calculate the flue gas constituents and the pounds of flue gas produced per pound of fuel on a dry weight basis. Using the quantity of flue gas and the higher heating value of the natural gas, a "K" factor was developed for all three figures via:

$$K = \frac{HHV \times V_M}{FG \times MW}$$

where

HHV = heating value of the natural gas, Btu/lb
FG = volume of flue gas per lb of fuel, dscf/lb
MW = molecular weight of NO_2, lb/lbmol
V_M = molar volume, dscf/lbmol

In this equation, V_M is equal to 385.1 dscf/lbmol at 68°F and 29.92 in. Hg. The "K" factors for a new selected fuels are found in Tables 10–12. As can be seen from the tables, the "K" factors do not vary widely for each type of fuel, which implies that Figures 2–4 could be readily applied to a particular fuel type. The exception to the rule are gaseous fuels that have a moderately high carbon dioxide content, such as the natural gas from Germany. Because the carbon dioxide does not play a role in the combustion process, a high carbon dioxide content gas will produce significantly lower flue gas per pound of fuel, thereby increasing the "K" factor. The "K" factor was then read into the third spreadsheet to be used in the following equation to develop the data points for each conversion graph:

$$X = \frac{K \times E \times (20.9 - \%O_2)}{20.9}$$

where

X = NO_x concentration, ppmvd
E = lb NO_x/Mbtu
$\%O_2$ = % oxygen in the flue gas.

In addition to the conversion properties of the graph, some of the pertinent local, state and federal regulations have been included on the graph for quick comparison to the NO*x* levels.

CONTROL OF NO_x

Introduction

As noted earlier, there are numerous ways to control NO_x emissions from combustion systems. Control methods can be broken down into two categories: (1) technologies that reduce emissions during the combustion process; (2) technologies that reduce emissions after combustion has taken place. Technologies used during the combustion process typically utilize different stoichiometric balances or burner configurations to decrease NO_x formation. Post combustion technologies, such as SCR, utilize reactants, with or without catalysts, to break down the NO_x before it is exhausted to the atmosphere. Table 15[22,23] shows some of the control methods used in industry along with the NO_x reductions that can be expected. The following is a detailed description of each of the common processes used in industry today.

Stationary Source Control

Low excess air operation (LEA) NO_x emissions are a function of the amount of available oxygen. Thus, one simple method of reducing NO_x emissions is by reducing the excess air level to the burners. Low excess air operation is effective in reducing fuel NO_x formation, but is limited in decreasing thermal NO_x emissions. Normally, this level is set to some constraint such as flame length, flame stability or carbon monoxide formation. As noted in Table 15, low excess air operation does not result in substantial NO_x reductions.

Off stoichiometric combustion (OS) In off stoichiometric combustion techniques, NO_x reduction is achieved by altering the fuel/air ratio in the primary combustion zone.

Burners-out-of-Service (BOOS) One such technique is known as burners-out-of-service. As the name implies, this operational control method involves taking one or more burners out of service, in a multiburner unit, by terminating fuel supply to the selected burners but leaving the air registers open. NO_x is reduced by lowering the peak flame temperature (PFT) in the remaining operating burners. As the temperature decreases in the combustion zone, the NO_x emissions will also decrease. The temperature decreases as a result of the remaining burners operating in a fuel rich environment, which corresponds to lower oxygen availability; thus, the peak flame temperature is lowered. In addition to the fuel/air ratio, the peak flame temperature is also dependent on the radiative heat effects in the boiler.[24] Each burner is in radiative exchange with adjacent burners; therefore, if the number of burners in-service are reduced, then the radiative effects are reduced along with the peak flame temperature.

Overfire Air (OA) One other method of changing the fuel/air ratio to the burners is by installing overfire air ports above the burner zone. A controlled portion of the combustion air, normally 10–20%, is redirected above; flames to the OFA ports.[25] Effective implementation this control method relies on a number of parameters, most notably adequate mixing of the overfire air with the primary combustion production. In addition, OFA is a function of the location and number of ports, ports spacing and geometry, and on the fan capacity and furnace dimensions. By itself, OFA can yield 15–30% reductions in NO_x emissions. However, there are certain advantages of OFA which have been noted in several cases. Because NO_x reduction requires a separation of the OFA ports from the primary combustion zone, poor temperature distribution in the convective zone and deterioration in carbon burnout has been observed.

One variation of the overfire air control method is called lance air. This method involves the installation of air tubes around the periphery of each burner to supply staged air.[22]

Flue gas recirculation (FGR) One of the most effective methods of reducing NO_x emissions for gas fired units is

through internal or external flue gas recirculation (FGR). In FGR, a portion of the hot inert flue gas (300°F–500°F) is recirculated from the stack back to the burner box. The recirculation rate is normally limited to 15–25%. Figure 5[22] shows the NO_x reductions that can be expected from different amounts of flue gas recirculation. In external FGR, flue gas can be mixed with combustion air or can be injected into the primary combustion zone through the use of a recirculation fan. Internal FGR utilizes the pressure energy of the combustion air, fuel gas or steam or recirculate the flue gas. Although internal FGR eliminates the need for fans and controls, it does necessitate larger burner sizes.

Flue gas recirculation reduces NO_x because the flue gas acts as a diluent. The additional flue gas reduces the peak flame temperature, cutting thermal NO_x formation. In addition, the partial pressure of oxygen is reduced, also limiting NO_x formation. In industrial applications, FGR is typically used in forced draft gas fired units which burn low nitrogen fuels. As noted above, external FGR requires substantial equipment for installation: (1) recirculation

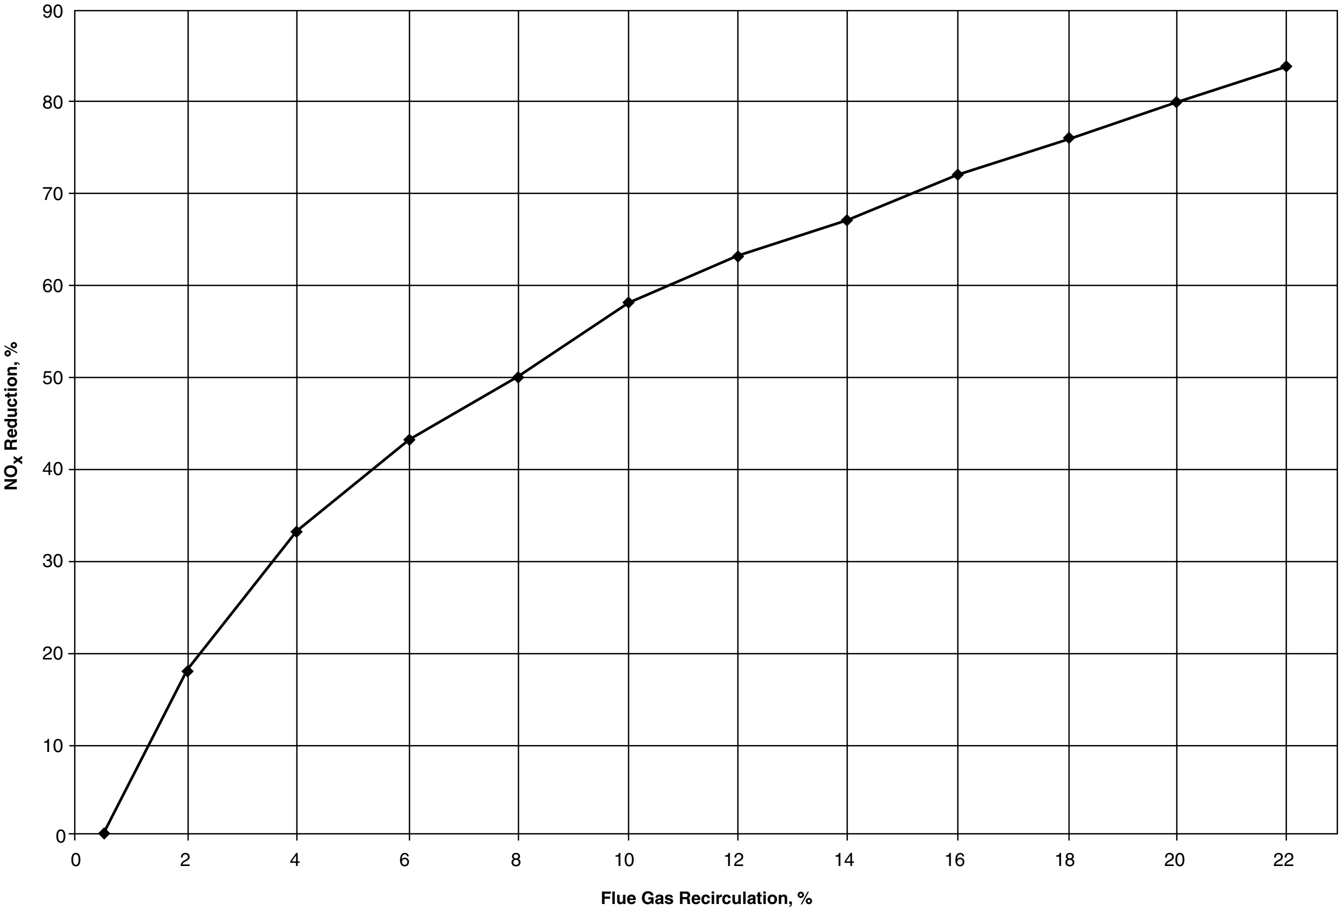

FIGURE 5 NO_x reduction as a function of % flue gas recirculation.[22]

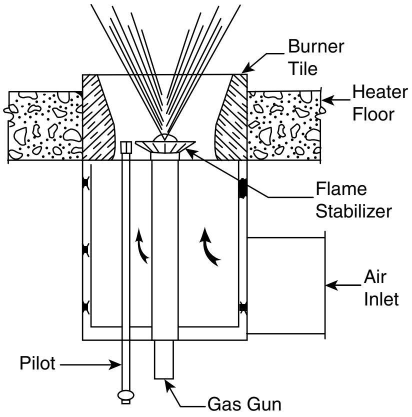
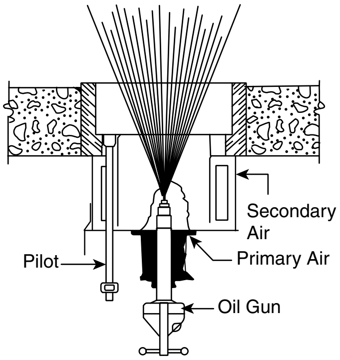
fan, (2) additional ductwork, (3) flow control dampers, and (4) carbon monoxide and oxygen analyzers.[26] The disadvantages of FGR include flame instability and a decrease in net thermal output at high recirculation rates; thus, the reasoning for limiting the recirculation rate.

Low NO_x Burners (LNB) Another way to achieve the staging effects similar to that of OS combustion is to internally design the effect into the burner. A variety of low NO_x burners have been developed to achieve the desired fuel/air ratio required for NO_x reduction in different applications. Figure 6[23] displays some of the burner types used in industry. Table 15 lists some of the burner types and the NO_x reductions that can be expected. Retrofitting a facility with low NO_x burners offers many advantages and include the following: (1) requires no added instrumentation for controlling the fuel/air ratio, (2) needs no additional ductwork or flue gas recirculation fans, as discussed in the previous section, (3) minimal long-term capital investment and maintenance requirements, and (4) cost effective compliance with the regulatory standards.

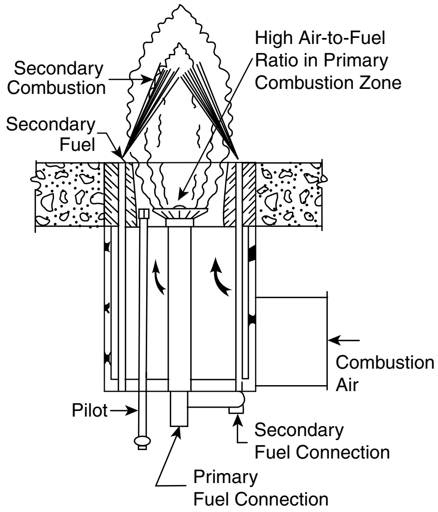
Low Excess Air Burner The first burner type listed in Table 15 is the low excess air burner, which reduces NO_x emissions by combusting the fuel with the lowest amount of excess air possible, usually 5–8%. Typically, boilers operate at 18–30% excess air at full load depending on the fuel. Case studies have shown that a reduction of excess air from 30% to 10% can cut NO_x emissions by 30%. The NO_x is reduced by the same principles as noted in LEA operations. LEA burners are most commonly of a forced-draft design and obviously have the ability to operate at low levels of excess air. Furnaces can operate in two modes: (1) forced draft; (2) natural draft.[27] Forced draft operation involves the pressurization of the air by a fan into the furnace, whereas the natural draft mode requires the stack to draft the combustion



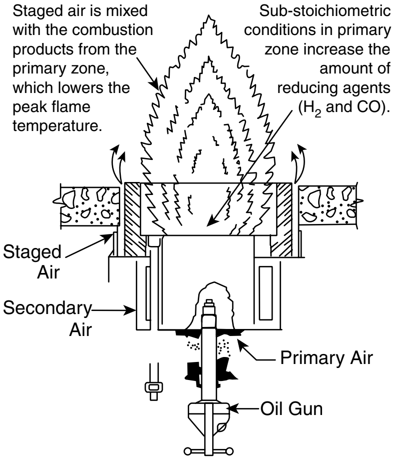
Standard Gas Burner



Standard Oil Burner



Staged Fuel Gas Burner



Staged Air Burner

FIGURE 6 Burner configurations.[23]

air into the furnace. For multiple burner applications, it is imperative that all burners receive equal amounts of air. One burner that receives more excess air will produce more NO$_x$, whereas the resulting burner that receives less excess air will generate more carbon monoxide and unburned carbon.

Staged Air Burner Another type of burner is the staged air burner, which is primarily used in forced draft liquid fuel fired applications, although natural draft applications do exist. The fuels used in this burner are normally such fuels as butane, pentane, diesel, and No. 6 fuel oil. This burner design reduces NO$_x$ by lifting the combustion air into a primary and a secondary zone. Fuel is injected into the throat of the burner and mixed with the primary air. This zone is fuel rich and produces partial combustion. NO$_x$ is minimized in this zone because the nitrogen is converted into reducing agents, which are subsequently oxidized to elemental nitrogen. In addition, because the generated heat in the primary zone is rapidly dissipated, the peak flame temperature is reduced and NO$_x$ formation is also lowered. The fuel lean or secondary zone completes combustion by injecting air through refractory ports, which also stabilizes the flame profile. Although this method can lead to NO$_x$ reductions of 20–35%, staged air burners can lead to long flame profiles, which must be closely monitored and controlled.

Staged Fuel Burner In gas fired applications, staged fuel burners are typically used to lower NO$_x$ emissions. Because liquid fuels can create fouling problems with the secondary gas nozzles, this burner normally is used for firing natural gas and other light fuels. Similar to the staged air burner design, fuel supply is divided into primary and secondary zones. The primary zone involves the mixing of the combustion air with a portion of the fuel gas, resulting in a fuel lean environment. This fuel lean combustion zone reduces peak flame temperature and lowers the formation of thermal NO$_x$. Combustion is completed in the secondary zone where nozzles inject the remaining fuel to create fuel rich conditions. Part of the NO$_x$ formed in the first stage is reduced by hydrogen and carbon monoxide in the secondary zone. Staged fuel burners normally produce a flame that is 50% longer than that of normal standard gas burners.

Ultra Low NO$_x$ Burners The last type of burner design is the ultra low NO$_x$ burner. This burner combines the staged air or staged fuel with internal or external flue gas recirculation to reduce NO$_x$. Typically, internal FGR is utilized. In a staged air internal FGR burner, fuel is mixed with part of the combustion air to create a fuel rich zone. The recirculated flue gas is developed by high pressure atomization of the liquid or gaseous fuel. Combustion is completed by piping the secondary air to the burner block. In a staged fuel internal FGR burner, flue gas is recirculated by the pressure of the fuel gas. The fuel gas creates a fuel lean zone and reduces the partial pressure of the oxygen, thereby reducing NO$_x$ emissions.

Water/steam injection One of the most seldom used methods in controlling NO$_x$ is water/steam injection. Normally, these techniques are applied to gas turbines. These methods have not been used extensively because of the lower thermal efficiency resulting from the absorption of usable energy. Both of these processes accomplish NO$_x$ reduction by lowering the peak flame temperature. The PFT is reduced by directly abstracting heat from the burner flame and by diluting the oxygen concentration near the burner front. Figure 7[22] shows the approximate NO$_x$ reductions that can be expected for different water injection rates.

Although substantial NO$_x$ reductions can be expected from these processes, a number of operational consequences must be considered. At low loads, carbon monoxide and unburned hydrocarbon emissions increase. As noted earlier, usable energy is lost, particularly due to the heat of vaporization of water, which results in an increase in fuel consumption of up to 5%. Further considerations include the additional wear and tear on turbine parts and the additional complexity in controlling and monitoring the process.[28]

Selective Catalytic Reduction (SCR) In lieu of or in addition to changing the air/fuel ratio in the combustion zone, some facilities utilize post combustion techniques to control NO$_x$. There are two basic post combustion control technologies of varying types on the market today: selective catalytic reduction (SCR) and selective noncatalytic reduction (SNCR). These methods have been used extensively on an international scale and have become a common feature on gas-turbine cogeneration and combined cycle systems in the United States. These systems can provide NO$_x$ reductions of up to 90%.

One of the most popular post combustion techniques is selective catalytic reduction. SCR works on the premise of reacting NO$_x$ with ammonia to produce water and elemental nitrogen. The reactions involved in the SCR process are as follows:[29]

$$
\begin{gathered}
4NO + 4NH_3 + O_3 \rightarrow 4N_2 + 6H_2O \\
6NO + 4NH_3 \rightarrow 5N_2 + 6H_2O \\
2NO_2 + 4NH_3 + O_2 \rightarrow 3N_2 + 6H_2O \\
6NO_2 + 8NH_3 \rightarrow 7N_2 + 12H_2O \\
NO + NO_2 + 2NH_3 \rightarrow 2N_2 + 3H_2O.
\end{gathered}
$$

Performance tests indicate that the first reaction is the dominant reaction. An SCR system consists mainly of an ammonia injection grid, catalyst reactor and ductwork.

The first part of the SCR, the ammonia injection grid, involves the mixing of ammonia with the flue gas stream. Two types of ammonia are used in the process: anhydrous and aqueous. A typical anhydrous ammonia injection system involves the following:[29]

- Storage of the anhydrous ammonia in a pressurized tank
- Piping of the anhydrous ammonia to a liquid vaporizer
- Mixing of the ammonia vapor with a predetermined amount of ambient air
- Distribution of the ammonia-air mixture to the grid for injection.

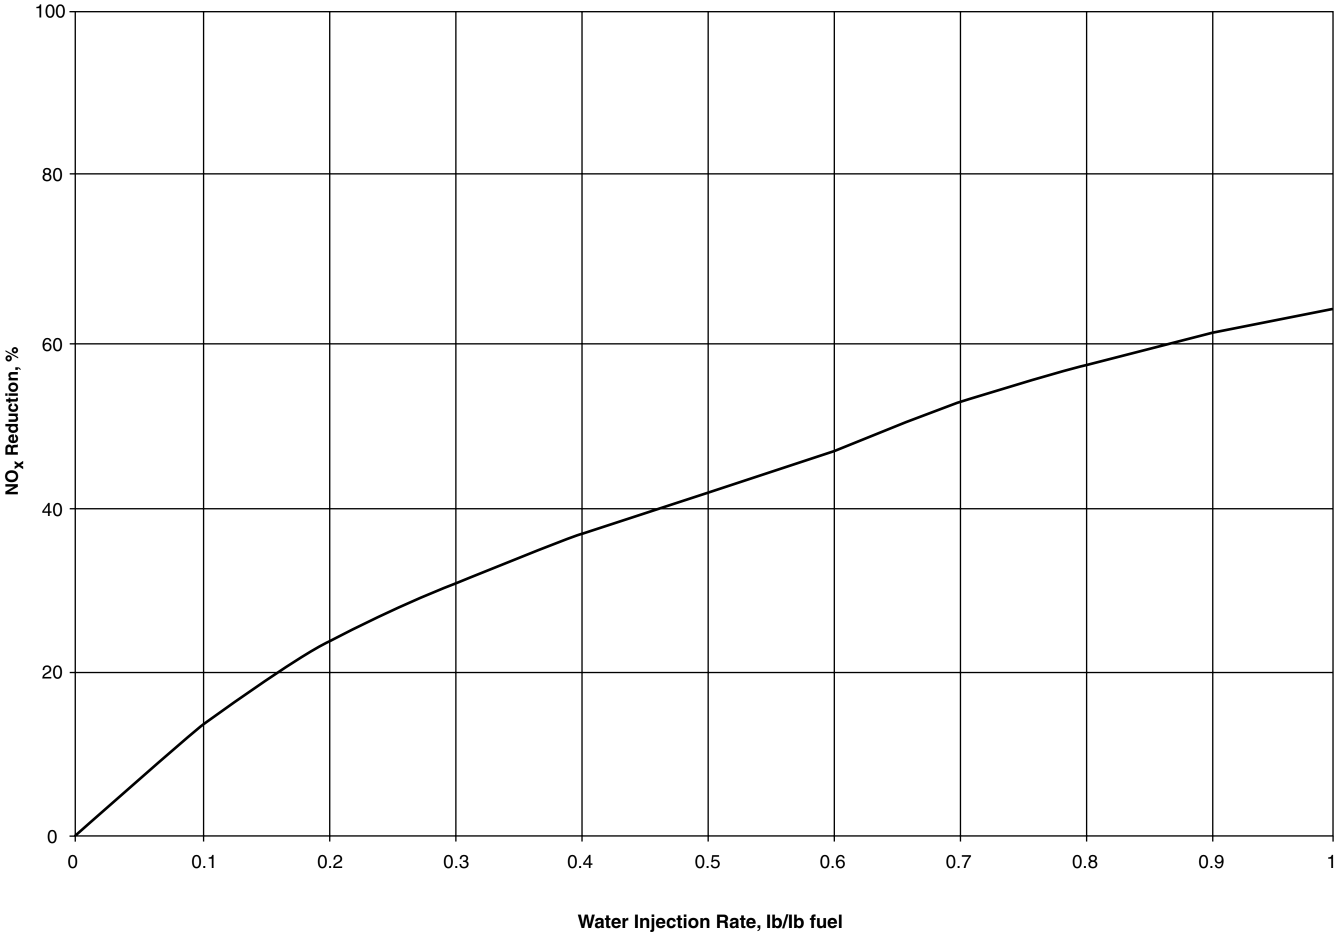


FIGURE 7 NO_x reduction as a function of water injection rate.[22]

One of the drawbacks of using anhydrous ammonia is that the chemical is hazardous and dangerous to handle and transport. Secondly, it requires a double lined steel tank due to its high vapor pressure. The other type of ammonia used for injection is aqueous ammonia, NO_3 H_2O, which typically comes in an industrial grade of 27% NH_3, 73% H_2O by weight. An injection system for aqueous ammonia contains the following:[29]

- Storage of the aqueous ammonia in an ordinary tank
- Vaporizing the ammonia through atomizing nozzles
- Mixing of the ammonia with a predetermined amount of heated ambient air in the vaporizer
- Injection of the ammonia-air mixture into the flue gas stream via a parallel network of pipes containing several orifices.

The advantages of this type of system are that the aqueous ammonia is less hazardous, can be transported on U.S. highways, and can be kept in an ordinary storage tank.

The second part of the SCR system, the catalyst reactor, is the most important. There are a variety of catalysts available on the market today, such as aluminum oxide (Al_2O_3), vanadium pentoxide (V_2O_5), titanium dioxide (TiO_2), tungsten trioxide (WO_3), molybdenum trioxide (MoO_3), and iron oxides.[29,30] In addition to metal catalysts, many SCR systems use zeolites or activated carbon. The use of zeolites has been found to increase catalyst activity, reduce the amount of metals for disposal, and reduce the size and capital cost of the SCR system.

As noted above, SCR's can provide 70–90% reductions in NO_x emissions. The performance of a SCR, however, depends on many parameters, including:[29]

- sulfur content in the fuel
- type and age of catalyst
- residence time of flue gas in the reactor
- oxygen and water vapor concentration in the flue gas
- flue gas temperature
- effective mixing and distribution of ammonia and air in the flue gas stream

- amount of ammonia
- ammonia slip
- catalyst surface area
- dust loading.

Ammonia slip and sulfur content of the fuel are two parameters that are interrelated and must be closely monitored. Theoretically, according to the balanced chemical reactions, only one mole of ammonia is needed to break down one mole of NO_x. Because mixing of the ammonia-air mixture and distribution of the mixture with the flue gas is not ideal, ammonia is normally injected at higher quantities than is theoretically required. This overinjection can lead to residual ammonia escaping into the flue gas, which is called ammonia slip. Although higher values of ammonia slip lead to increased NO_x reductions (to an asymptotic limit), it is environmentally detrimental to allow excess ammonia to the atmosphere. Furthermore, because the sulfur in the fuel leads to SO_2 and SO_3 production, excess ammonia can result in the formation of ammonium sulfate and ammonium bisulfate by the following reactions:[29]

$$SO_3 + 2NH_3 + H_2O \rightarrow (NH_4)_2SO_4$$
$$SO_3 + NH_3 + H_2O \rightarrow NH_4HSO_4.$$

The formation of sulfates can lead to higher particulate concentrations in the flue gas and can lead to catalyst poisoning and equipment deterioration. The formation of sulfates can be mitigated by keeping the temperature of the gas relatively high (>600°F) and by limiting ammonia slip to <10 ppm for low sulfur fuels and to 3–5 ppm for high sulfur fuels.

Oxygen and water vapor concentrations have opposing effects on NO_x reduction. Typically, higher oxygen concentrations result in better catalyst performance leading to improved NO_x reductions, to a certain limit. On the other hand, water vapor decreases the performance of the catalyst as its concentration increases.

Obviously, the type of catalyst is extremely important to the performance of the SCR. As noted earlier, catalysts are available in a variety of materials. In addition, the catalyst shape can vary, including rings, pellets, honeycomb plates and parallel-ridged plates. Although it depends on the particular catalyst, flue gas temperature is critical to the performance of the catalyst. Typically 600°F to 700°F is the optimum range of operation. Below these temperatures, formation of ammonium sulfates becomes more substantial leading to further complications. Figures 8 and 9[30] show the temperature dependence of ammonia slip and NO_x reductions on two catalysts, VNX and ZNX. The VNX catalyst is a low temperature catalyst and is comprised of V_2O_5 and TiO_2. The ZNX catalyst is a high temperature zeolite catalyst. In addition to temperature, the age of the catalyst affects the catalyst performance. Usually, the rate of deterioration is large at the onset of operation, but levels out after the initial settlement. Another important parameter is the specific surface area of the catalyst. The larger the area of the catalyst exposed to the flue gas, the better the SCR performance.

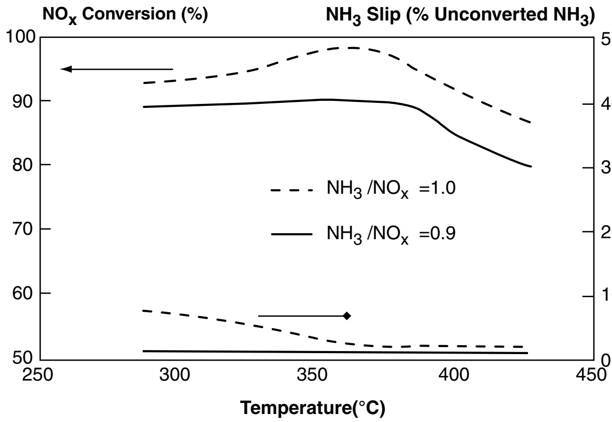

FIGURE 8 NO_x Conversion and NH_3 Slip for VNX™ SCR Catalyst.[30]

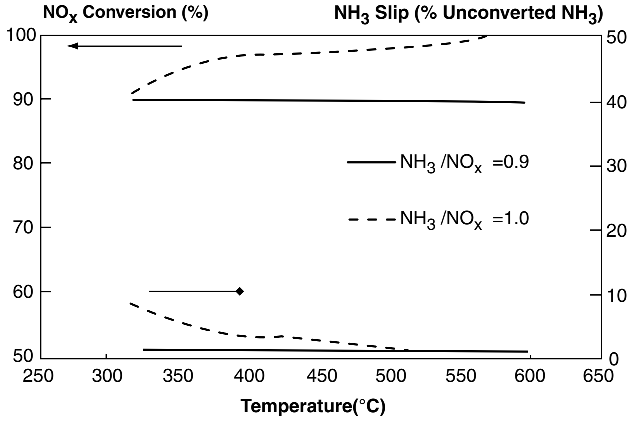

FIGURE 9 NO_x Conversion and NH_3 Slip for ZNX™ SCR Catalyst.[30]

In addition to the surface area of the catalyst, the residence time of the flue gas in the reactor is critical to good performance. Related to the residence time is the space velocity, which is a parameter that is normally used for SCR reactor design. The efficiency of the SCR can be expressed in terms of the space velocity through the following equation:[29]

$$\eta = m(1 - e^{-k/SV})$$

where

η = NO_x removal efficiency
m = molar ratio of ammonia to NO_x
SV = space velocity
k an activity constant that takes into account most of the operating parameters listed earlier.

The molar ratio of ammonia to NO_x is determined by:[29]

$$m = \eta + S/NO_{x,in}$$

where

m = molar ratio of ammino to NO_x
η = NO_x removal efficiency
S = limit of ammonia slip, ppmdv
$NO_{x,in}$ = inlet concentration of NO_x, ppmdv

With the values of m and η know, one can then calculate the space velocity. The volume of catalyst is then determined by dividing the volumetric gas flow by the space velocity.

The last parameter that affects SCR performance is dust loading. This parameter is particularly important when considering coal-fired plants. The dust from the coal pulverization process can accumulate on the SCR catalyst, creating plugging and fouling problems and decreasing performance. Thus, in pulverized coal-fired applications, soot blowers are sometimes installed upstream of the catalyst layers to "dust off" the catalyst surface.

Selective noncatalytic reduction (SNCR) The other major type of post combustion control is selective noncatalytic reduction. SNCR reduces NO_x through the same reactions as SCR. However, SNCR differs from selective catalytic reduction in a number of ways, most notably the lack of catalyst for reaction. Because of the lack of catalyst, NO_x reduction in a SNCR must occur at higher temperatures. Typically, the temperature of the process is in the range of 1,600–2,000°F, with an optimum temperature of approximately 1,750°F.[26] In a SNCR system, a urea based compound can also be used besides ammonia as a reagent. Urea based compounds break down to ammonia and carbon dioxide after injection into the flue gas stream. SNCR does not typically provide the same reductions as SCR, but some studies and tests have shown NO_x reductions using SNCR to be in the range of 60–80%.

As noted, one of the most important operating parameters for SNCR performance is the temperature. Typically, for ammonia injection, the temperatures should be maintained from 1,600°F to 1,750°F. For urea based compounds, 1,000°F to 1,900°F is the optimum temperature range. If the temperature increases above the optimal range, then the reagent will react more with oxygen than with the NO_x, leading to increased NO_x formation. On the other hand, if the temperature falls below the optimal range, then less ammonia will react, creating more ammonia slip.

The disadvantages of using SNCR are the same as that of SCR. Both ammonium sulfate and ammonium bisulfate can form in a SNCR system, creating the fouling and corrosion problems. Ammonium chloride, NH_4Cl can also be formed, resulting in plumes that are more visible. Furthermore, SNCR requires strict control of the temperature and does not provide the same reductions in NO_x as SCR.

The advantages of SNCR over SCR include lower capital and operating costs and safer handling of chemicals when urea based reagents are used. A comparative study of the two processes on a 200 ton/hr oil and gas fired boiler revealed that the SNCR would require a capital cost of \$0.4 million as compared to a capital cost of \$2 million for SCR. The NOx reductions in this study for the SNCR were predicted to be 65–70%.[31]

Fluidized bed combustors or boilers For new power or cogeneration plants, one method of meeting the increasingly stringent air pollutant emission standards is by selecting fluidized bed combustion as the technology for combusting the fuel. There are a number of different fluidized bed technologies available: (1) atmospheric fluidized bed combustion (AFBC); (2) circulating fluidized bed combustion (CFBC); and (3) pressurized fluidized bed combustion (PFBC). Based on the technology selected and on process variations, the FBC technology has an efficiency range of 37–45%. Figure 10[32] is a schematic of a typical PFBC.

The basic principle behind all FBC's is that air is injected upwards through a bed of inert particles (i.e. sand) at a sufficient rate so as to give the bed fluid-like characteristics. The particle bed is normally heated to just above the ignition temperature of the fuel, normally 850°C. Most conventional boilers are operated at 1600°C. Recall that NO_x emissions increase with increasing flame temperature. Thus, one can see that NO_x emissions will be reduced substantially in a FBC because of the reduced combustion temperature. As a matter of fact, almost all NO_x emissions from an FBC can be attributed to fuel NO_x. Combined with other NO_x control techniques, such as staged combustion or SNCR, FBC provides a reasonable alternative to conventional fired boilers for reducing pollutant emissions without sacrificing efficiency.

Mobile Source Control

Spark ignition engines There are a number of methods used to reduce pollutant emissions from spark ignition engines. These methods are based on two different approaches: (1) combustion based; (2) exhaust gas treatment.

Combustion based emission controls for NO_x include spark retard and exhaust gas recirculation (EGR).[18] In spark retard, combustion initiation is delayed to reduce the peak pressure and peak temperature. As noted earlier, reducing the peak temperature of combustion results in lower NO_x emissions. The other type of method, EGR, involves the recirculation of cool combustion products for mixing with the pre-combusted air and fuel mixture. This method reduces the peak temperature through dilution and by increasing the specific heat of the gas due to the addition of water carbon dioxide. Although effective in reducing NO_x emissions, spark retard and EGR must be somewhat limited due to the engine power loss, increased fuel consumption and increased carbon monoxide emissions associated with these control measures.

There are two basic types of exhaust gas treatment: (1) noncatalytic thermal reactors; and (2) catalytic converters[18]. Noncatalytic thermal reactors can reduce hydrocarbon and CO emissions substantially, but is not as efficient in alleviating the NO_x problem. In such a system, NO_x is limited by ammonia reduction. However, the ammonia-NO_x reaction, without catalyst, requires a high and narrow range of temperatures, thereby limiting the application of this technology. On the other hand, catalytic converters have become the standard on most automobiles in the United States. The basic

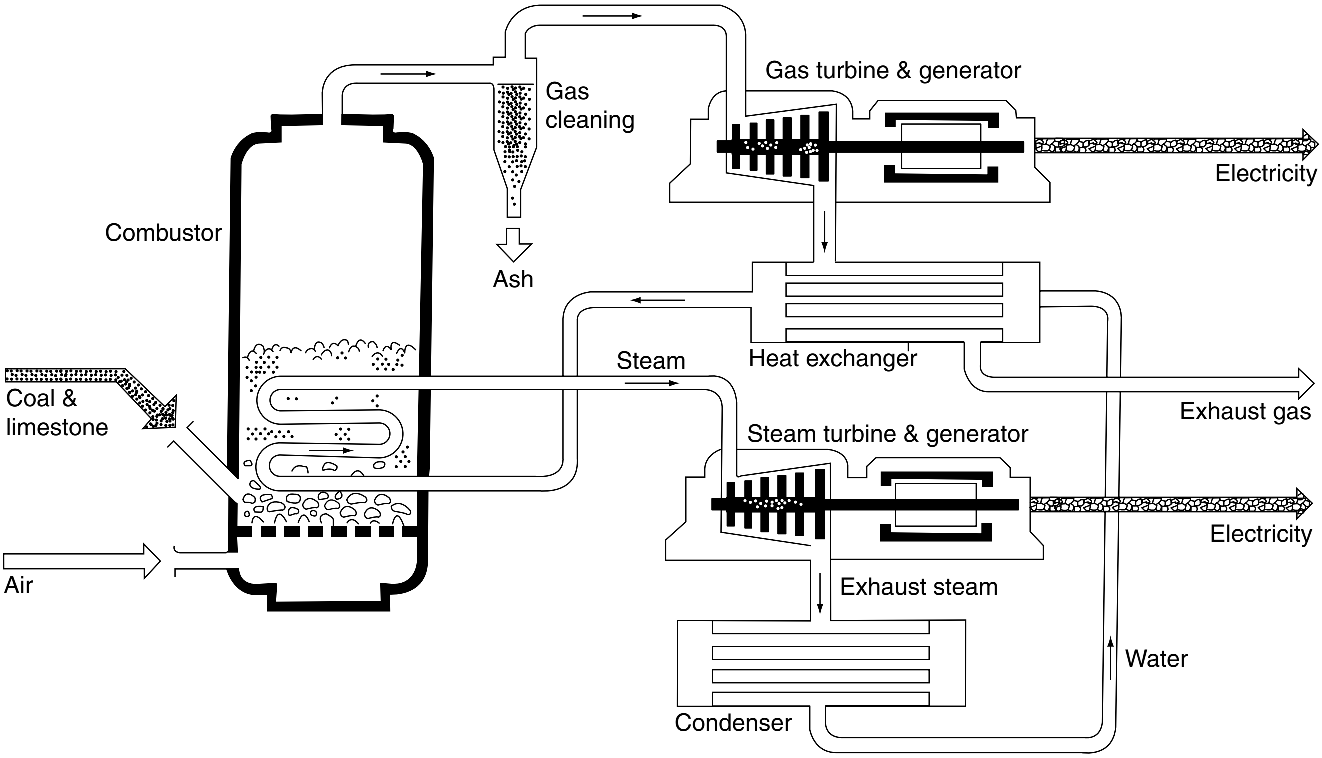

FIGURE 10 Schematic of pressurized fluid bed combustor.[32]

principle behind the catalytic converter is that the exhaust gases are passed through a catalyst bed which effectively lowers the temperatures at which CO and hydrocarbons are oxidized and at which NO_x is reduced.[18] Typical catalysts include alumina, platinum, or metal oxides.

Diesel engines Control measures for diesel engines are similar to those for spark ignition engines. However, because diesel engines generally operate at fuel lean conditions, catalytic reduction of NO_x is not feasible. Therefore, NO_x emissions are reduced from diesel engines through combustion based control measures. These methods include exhaust gas recirculation and injection timing retardation. As with the spark ignition engine, EGR reduces NO_x emissions by lowering the peak combustion temperature through dilution with cool combustion gases. Likewise, retarding the injection timing results in a delay of the heat release in the cycle, thereby lowering the peak flame temperature. As noted above, both of these techniques result in reduced NO_x emissions, but at the potential cost of fuel economy and engine performance.

CONCLUSION

As our knowledge of NO_x advances and as political climates change, NO_x emission regulations will inevitably change, prompting new or modified control technologies to be developed. Although sometimes viewed as cumbersome and costly, regulations are the key to providing a healthy environment for generations to come.

NOISE

Noise and **sound** refer to audible pressure fluctuations in air. Both are characterized by sound level in decibels and frequency content in hertz. Although sound is vital for communication, noise is one of our greatest problems. Intentionally generated acoustic signals including speech and music are usually referred to as *sound. Noise* is a term used to identify unwanted sound, including sound generated as a byproduct of other activities such as transportation and industrial operations. Intrusive sound, including speech and music unwelcome to the hearer, are also considered noise. Thus, the distinction between noise and sound is subjective, and the two terms are often used interchangeably.

When a body moves through a medium or vibrates, some energy is transferred to that surrounding medium in the form of sound waves. Sound is also produced by turbulence in air and other fluids, and by fluids moving past stationary bodies. In general, gases, solids and liquids transmit sound.

Well-documented effects of noise include hearing damage, interference with communication, masking of warning signals, sleep interruption, and annoyance. Noise detracts from the quality of life and the environment; it contributes to anger and frustration and has been implicated as a contributor to psychological and physiological problems.

The National Institute for Occupational Safety and Health (NIOSH) named hearing loss as a priority research area, noting that noise-induced hearing loss is 100% preventable, but once acquired, it is permanent and irreversible. The Occupational Safety and Health Administration (OSHA) noted that hearing loss can result in a serious disability, and put employees at risk of being injured on the job. The World Health Organization (WHO) notes that noise-induced hearing impairment is the most prevalent irreversible occupational hazard, and estimates that 120 million people worldwide have disabling hearing difficulties. In developing countries, not only occupational noise but also environmental noise is an increasing risk factor for hearing impairment.

The European Union (EU) identified environmental noise caused by traffic, industrial and recreational activities as one of the main local environmental problems in Europe and the source of an increasing number of complaints. It is estimated that 20% of the EU population suffer from noise levels that both scientists and health experts consider unacceptable. An additional 43% of the population live in ‘gray areas’ where noise levels cause serious daytime annoyance. Estimates of the cost of noise to society range from 0.2% to 2% of gross domestic product.

Noise control involves reduction of noise at the source, control of noise transmission paths, and protection of the receiver. Source control is preferred. For example, design of transportation systems and machinery for lower noise output may be the most effective means of noise control. But, after trying all feasible noise source reduction, airborne noise and/or solid-borne noise may still be objectionable. Interruption of noise transmission paths by means of vibration isolation, source enclosures, sound absorbing materials, or noise barriers is then considered.

In some industrial situations, excessive noise is still present after all attempts to control noise sources and transmission paths. Administrative controls—the assignment of employees so that noise exposure in reduced—should then be considered. As a last resort, employees may be required to use personal hearing protection devices (muff-type and insert-type hearing protectors). Communities often resort to ordinances that limit noise levels and restrict hours of operation of noise-producing equipment and activities. Community noise control methods also include zoning designed to separate noise sources from residential and other sensitive land uses.

FREQUENCY, WAVELENGTH AND PROPAGATION SPEED

Frequency. Audible sound consists of pressure waves with frequencies ranging from about 20 hertz (Hz) to 20,000 Hz, where 1 Hz = 1 cycle per second. Sound consisting essentially of a single-frequency sinusoidal pressure wave is called a **pure tone.** In most cases, noise consists of sound waves arriving simultaneously from a number of sources, and having a wide range of frequencies. A sound wave which has a frequency below the audible range is called **infrasound** and sound of frequency above the audible range is called **ultrasound.**

Propagation speed. The propagation speed of airborne sound is temperature dependent. It is given by:

$$c = 20.04[T' + 273.16]^{1/2} \qquad (1.1)$$

where c = propagation speed, i.e. the speed of sound, (m/s) T' = air temperature (°C).

At an air temperature of $T' = 20°\text{C}$ (68°F), the propagation speed is $c = 343$ m/s (approx). Sound waves propagate at a different speed in solids and liquids. The propagation speed for axial waves in a steel rod is about 5140 m/s. Note that

c is a wave a propagation speed; it does not represent particle velocity within the medium.

Wavelength. If a pure-tone pressure wave could be observed at a given instant, the length of one cycle of the wave in the propagation directly could be identified as the wavelength. Thus,

$$\lambda = c/f \tag{1.2}$$

where λ = wavelength (m), c = propagation speed (m/s) and f = frequency (Hz). The effectiveness of noise barriers and sound-absorbing materials is dependent on the sound wavelength (thus, effectiveness is frequency-dependent).

SOUND PRESSURE AND SOUND PRESSURE LEVEL

One standard atmosphere is defined as a pressure of 1.01325×10^5 Pa (about 14.7 psi). Typical sound pressure waves represent very small disturbances in ambient pressure. Sound pressure level is defined by

$$L_\mathrm{p} = 10\ 1_\mathrm{g}\left[p_\mathrm{rms}^2/p_\mathrm{ref}^2\right] = 20\ \mathrm{lg}\left[p_\mathrm{rms}/p_\mathrm{ref}\right] \tag{2.1}$$

where L_p = sound pressure level in decibels (dB), lg = common (base-ten) logarithm, p_rms = root-mean-square sound pressure (Pa) and p_ref = reference pressure = 20×10^{-6} Pa.

Sound pressure represents the difference between instantaneous absolute pressure and ambient pressure. For a pure-tone sound wave of amplitude P,

$$p_\mathrm{rms} = P/2^{1/2}.$$

The reference pressure is the nominal threshold of hearing, corresponding to zero dB. Sound pressure may be determined from sound pressure level by the following relationship:

$$p_\mathrm{rms} = p_\mathrm{ref} \times 10^{Lp/20} = 2 \times 10^{[L_\mathrm{P}-100]/20.} \tag{2.2}$$

A-WEIGHTING

Human hearing is frequency-dependent. At low sound levels, sounds with frequencies in the range from about 1 kHz to 5 kHz are perceived as louder than sounds of the same sound pressure, but with frequencies outside of that range. A-, B- and C-weighting schemes were developed to compensate for the frequency-dependence of human hearing at low, moderate and high sound levels. Other weightings are also used, including SI-weighting which relates to speech interference. A-weighting has gained the greatest acceptance; many standards and codes are based on sound levels in A-weighted decibels (dBA). When noise is measured in frequency bands, the weighting adjustment may be added to each measured value. Sound level meters incorporate weighting networks so that weighted sound level is displayed directly. A-weighting adjustments are shown in Table 1.

TABLE 1

Some representative sound levels are given in Table 2. Most values are approximate; actual noise sources produce a wide range of sound levels.

EQUIVALENT SOUND LEVEL

Sound energy is proportional to mean-square sound pressure. Equivalent sound level is the energy-average A-weighted sound level over a specified time period. Thus,

$$L_\mathrm{eq} = 10\ \mathrm{lg}\left[\left(1/T\right)\int_0^T 10^{L/10}\,\mathrm{d}t\right] \tag{4.1}$$

where L_eq = equivalent sound level (dBA), L = instantaneous sound level (dBA) and T = averaging time, often 1 hour, 8

TABLE 2
A-weighted sound levels

Approximate sound level	Noise source or criterion
140	Threshold of pain
122	Supersonic aircraft^{A}
120	Threshold of discomfort
112	Stage I aircraft^{A}
110	Leaf blower at operator
105	OSHA 1 hr/da limit^{B}
99	EEC 1 hr/da limit^{B}
90	OSHA and EEC 8 hr/da limit^{B}
70	EPA criterion for hearing conservation^{C}
67	DOT worst hour limit^{D}
65	Daytime limit, typical community ordinance
45	Noise limit for virtually 100% indoor speech intelligibility
35	Acceptable for sleep
0	Threshold of hearing

Notes:
A: Aircraft measurements 500 ft beyond end of runway, 250 ft to side.
Stage 3 aircraft in current use are quieter.
B: Criteria for worker exposure (US Occupational Safety and Health Administration and European Economic Community).
C: Environmental Protection Agency identified 24-hr equivalent sound level.
D: Department of Transportation design noise level for residential use.

hours, 24 hours, etc. The time period may be identified by the subscript, e.g. L_{eq24} for a 24 hour averaging time.

Integrating sound level meters compute and display equivalent sound level directly. If equivalent sound level is to be determined from a number of representative instantaneous measurements or predictions, the above equation may be rewritten as follows:

$$L_{\mathrm{eq}} = 10\ \mathrm{lg}\left[(1/N)\sum_{i=1}^{N} 10^{L_i/10}\right]. \tag{4.2}$$

If a large number of readings are involved, it is convenient to incorporate the above equation into a computer program. If the base-10 logarithm is not available on the computer it may be obtained from

$$\mathrm{lg}(x) = \ln(x)/\ln(10) \tag{4.3}$$

where ln is the natural (base-e) logarithm.

Example Problem: Equivalent Sound Level

Considering four consecutive 15-minute intervals, during which representative sound levels are 55, 58, 56 and 70 dBA respectively. Determine equivalent sound level for that hour. Solution:

$$L_{\mathrm{eq}} = 10\ \mathrm{lg}(1/4)\left(10^{55/10} + 10^{58/10} + 10^{56/10} + 10^{70/10}\right)$$
$$= 64.5\ \mathrm{dBA}.$$

It can be seen that higher sound levels tend to dominate when determining L_{eq}. Note that the mean average sound level (55 + 58 + 56 + 70)/4 = 59.8 has no significance.

DAY–NIGHT SOUND LEVEL

Day–night sound level takes into account the importance of quiet during nighttime hours by adding a 10 dBA weighting to noise during the period from 10 pm to 7 am. It is given by

$$L_{\mathrm{DN}} = 10\ \mathrm{lg}\left\{[1/24]\left[\int_{7\mathrm{am}}^{10\mathrm{pm}} 10^{L/10}\,\mathrm{d}t + \int_{10\mathrm{pm}}^{7\mathrm{am}} 10^{(L+10)/10}\,\mathrm{d}t\right]\right\} \tag{5.1}$$

where L_{DN} = day–night sound level and t = time (hours).

COMBINING NOISE FROM SEVERAL SOURCES

Correlated sound waves. Sound waves with a precise time and frequency relationship may be considered correlated. A sound wave arriving directly from a source may have a precise phase relationship with a reflected sound wave from the same source. The sound level resulting from combining two correlated sound waves of the same frequency depends on the phase relationship between the waves. Reactive mufflers and silencers are designed to produce reflections that cancel the progressive sound wave.

Active noise control is accomplished by generating sound waves out-of-phase with the noise which is to be cancelled. Active noise control systems employ continuous measurement, signal processing, and sound generation.

Uncorrelated noise sources. Most noise sources are not correlated with one another. The combined effect of two or more uncorrelated sources is obtained by combining the energy from each at the receiver. To do this, we may add mean-square sound pressures. In terms of sound levels, the result is

$$L_{\mathrm{T}} = 10\ \mathrm{lg}\sum_{i=1}^{N} 10^{L_i/10} \tag{6.1}$$

where L_T = total sound level due to N contributions L_i (dBA as measured or predicted at the receiver).

For two contributions, the total sound level is

$$\begin{aligned} L_{\mathrm{T}} &= 10\ \mathrm{lg}\left[10^{L1/10} + 10^{L2/10}\right] \\ &= L_1 + 10\ \mathrm{lg}\left[1 + 10^{-\mathrm{DIF}/10}\right] \end{aligned} \tag{6.2}$$

where L_1 = the greater sound level and DIF = $L_1 - L_2$, the difference between the two sound levels.

The last term in equation 6.2 may be identified as L(add), the quantity to be added to L_1 to obtain total sound level L_T. L(add) is tabulated against DIF, the difference in levels, in Table 3. Values are given to the nearest one-tenth decibel. Although measured and predicted sound levels are often reported to the nearest whole decibel, fractional values are often retained for comparison purposes, and to insure accuracy of intermediate calculations.

Note that addition of the contributions of two equal but uncorrelated sources produces a total sound level 3 decibels higher than the contribution of one source alone.

If the difference between contributions is 10 or more decibels, then the smaller contribution increases total sound level by less than one-half decibel. If the difference is 20 or more decibels, the smaller contribution has no significant effect; for DIF ≥ 20, $L(\text{add}) < 1/20$. This is an important consideration when evaluating noise control efforts. If several individual contributions to overall sound level can be identified, the sources producing the highest sound levels should be considered first. Figure 1 is a graph showing the effect of combining noise levels.

Example Problem: Combining Noise Contributions

The individual contributions of five machines are as follows when measured at a given location: 85, 88, 80, 70 and 95 dBA. Find the sound level when all five are operating together.
Solution:

Using equation 6.1, the result is $L_T = 10\ \lg[10^{85/10} + 10^{88/10} + 10^{80/10} + 10^{70/10} + 10^{95/10}] = 96.25$ dBA. We could use Table 3 instead. Combining the levels in ascending order, the result is

$$70 + 80 = 80.4 \text{ and}$$
$$80.4 + 85 = 86.3 \text{ and}$$
$$86.3 + 88 = 90.3 \text{ and}$$
$$90.3 + 95 = 96.3 \text{ dBA}$$

Fractional parts of one dBA are only retained for purposes or illustration.

For several sources which contribute equally to sound level at the receiver, total sound level is given by

$$L_T = L_1 + 10 \lg n \tag{6.3}$$

where L_1 = sound level contribution at the receiver due to a single source and n = the number of sources. Table 3 and Figure 2 show the effect of combining n equal (but uncorrelated) contributions.

SOUND FIELDS

The region within one or two wavelengths of a noise source or within one or two typical source dimensions is called the **near field.** The region where reflected sound waves have a significant effect on total sound level is called the **reverberant field.** Consider an ideal nondirectional noise source which generates a spherical wave. For regions between the near field and the reverberant field, sound intensity is given by

$$I = W/\left[4\pi r^2\right] \tag{7.1}$$

TABLE 3

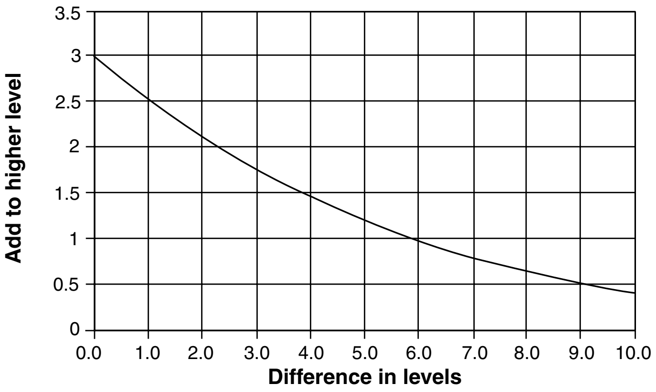

FIGURE 1 Combining noise levels.

where I = sound intensity (W/m^2), where sound pressure and particle velocity are in-phase, W = sound power of the source (W) and r = distance from the source (m). The above equation is called the inverse square law.

Scalar sound intensity level is given by

$$L_I = 10\lg[I/I_{ref}] \tag{7.2}$$

where L_I = scalar sound intensity level and $I_{ref} = 10^{-12}$ W/m^2. For airborne sound under typical conditions, sound pressure level and scalar sound intensity level are approximately equal, from which

$$L_p \approx L_I = 10\lg W - 20\lg r - 109 \tag{7.3}$$

for the spherical wave where L_p and L_I are expressed in dB. If sound power has been A-weighted, L_p and L_I are in dBA.

When the inverse-square law applies, then sound levels decrease with distance at the rate: 20 lg r. Thus, if sound level is known at one location, it may be estimated at another location. Table 4 and Figure 3 show the distance adjustment to be added to sound level at distance r_1 from the source to obtain the sound level at distance r_2.

MEASUREMENT AND INSTRUMENTATION

Sound level meters. The sound level meter is the basic tool for making noise surveys. A typical sound level meter is a hand-held battery-powered instrument consisting of a microphone, amplifiers, weighting networks, a rootmean-square rectifier, and a digital or analog sound level display. The A-weighting network is most commonly used. This network electronically adjusts the signal in accordance with Table 1, so that sound level is displayed in dBA. When measuring out-of-doors, a windscreen is used to reduce measurement error due to wind impinging on the microphone. Integrating sound level meters automatically calculate equivalent sound level. If a standard sound level meter is used, equivalent sound level may be calculated from representative measurements, using the procedure described later.

Frequency analysis. The cause of a noise problem may sometimes be detected by analyzing noise in frequency bands. An octave band is a frequency range for which the upper frequency limit is (approximately) twice the lower limit. An octave band is identified by its center frequency defined as follows:

$$f_c = \left[f_L f_u\right]^{1/2} \tag{8.1}$$

where f_c = the center frequency, f_L = the lower band limit, and f_u = the upper band limit, all in Hz. The center frequencies of the preferred octave bands in the audible range are 31.5, 63, 125, 250 and 500 Hz and 1, 2, 4, 8 and 16 kHz. The center frequencies of the preferred one-third-octave bands are those listed in the first column of Table 1 (Section 3).

Real-time analyzers and Fast-Fourier-Transform (FFT) analyzers examine a signal in all of the selected frequency bands simultaneously. The signal is then displayed as a bargraph, showing the sound level contribution of each selected frequency band.

Sound intensity measurement. Vector sound intensity is the net rate or flow of sound energy. Vector sound intensity measurements are useful in determining noise source power in the presence of background noise and for location of noise sources. Sound intensity measurement systems utilize a two-microphone probe to measure sound pressure at two locations simultaneously.

The signals are processed to determine the particle velocity and its phase relationship to sound pressure.

Calibration. Acoustic calibrators produce a sound level of known strength. Before a series of measurements, sound measurement instrumentation should be adjusted to the calibrator level. Calibration should be checked at the end of each measurement session. If a significant change has occurred, the measured data should be discarded. Calibration data should be recorded on a data sheet, along with instrumentation settings and all relevant information about the measurement site and environmental conditions.

Background noise. When measuring the noise contribution of a given source, all other contributions to total noise are identified as background noise. Let the sound level be measured with the given source operating, and then let background noise alone be measured. The correction for background noise is given by

$$\mathrm{COR} = 10\ \lg\left[1 - 10^{-\mathrm{DIF}/10}\right] \tag{8.2}$$

where DIF = Total noise level – background noise level, and the noise level contribution of the source in question is given by:

$$L_{\mathrm{SOURCE}} = \text{Total noise level} + \mathrm{COR}.$$

Background noise corrections are tabulated in Table 5 and plotted in Figure 4. Whenever possible measurements should be made under conditions where background noise is negligible. When total noise level exceeds background noise by at least 20 dB, then the correction is less than 1/20 dB. Such ideal conditions are not always possible. Truck noise, for example, must sometimes be measured on a highway with other moving vehicles nearby. If the difference between total noise level and background noise is less than 5 dB, then the contribution of the source in question cannot be accurately determined.

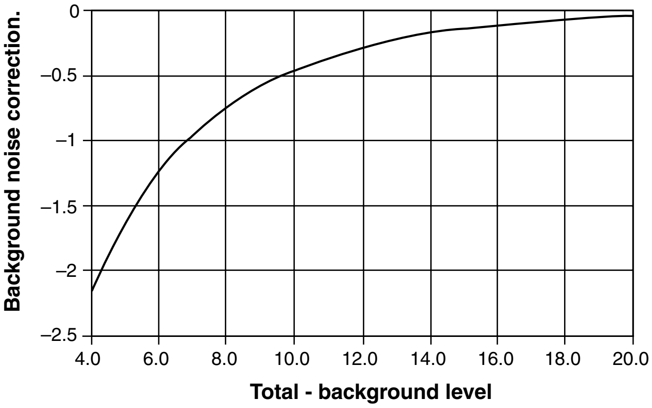

FIGURE 4 Background noise correction.

HEARING DAMAGE RISK

The frequency range of human hearing extends from about 20 Hz to 20 kHz. Under ideal conditions, a sound pressure level of 0 dB at 1 kHz can be detected. Human hearing is less sensitive to low frequencies and very high frequencies.

Hearing threshold. A standard for human hearing has been established on the basis of audiometric measurements at a series of frequencies. An individual's hearing threshold represents the deviation from the standard or audiometric-zero levels. A hearing threshold of 25 dB at 4 kHz, for example, indicates that an individual has "lost" 25 dB in ability to hear sounds at a frequency of 4 kHz (assuming the individual had "normal" hearing at one time).

A temporary threshold shift (TTS) is a hearing threshold change determined from audiometric evaluation before, and immediately after exposure to loud noise. A measurable permanent threshold shift (PTS) usually occurs as a result of long-term noise exposure. The post-exposure audiometric measurements to establish PTS are made after the subject has been free of loud noise exposure for several hours. A compound threshold shift (CTS) combines a PTS and TTS. There is substantial evidence that repeated TTS's translate into a measurable PTS. Miller (1974) assembled data relating TTS, CTS and PTS resulting from exposure to high noise levels.

Occupational Safety and Health Administration (OSHA criteria. OSHA (1981, 1983) and the Noise Control Act (1972) set standards for industrial noise exposure and guidelines for hearing protection. OSHA criteria have resulted in reduced noise levels in many industries and reduced the incidence of hearing loss to workers. However, retrospective studies have shown that some hearing loss will occur with long-term exposure a OSHA-permitted sound levels.

The basic OSHA **criterion level** (CL) is a 90 dBA sound exposure level for an 8 hour day. An **exchange rate** (ER) of 5 dBA is specified, indicating that the permissible daily

TABLE 6
Allowable exposure times

Time *T* hr/da	Sound level *L* dBA
32*	80
16	85
8	90
4	95
2	100
1	105
1/2	110
1/4 or less	115

*The 32 hr exposure time is used in evaluating noise dose when sound levels vary.

exposure time is halved with each 5 dBA sound level increase. The **threshold level,** the sound level below which no contribution is made to daily noise dose, is 80 dBA (threshold level is not to be confused with hearing threshold). When noise exposure exceeds the **action level** (85 dBA) a hearing conservation program is to be implemented. A hearing conservation program should include noise exposure monitoring audiometric testing, employee training, hearing protection and record-keeping.

According to OSHA standards continuous noise exposure (measurable on the slow-response scale of a sound level meter) is not to exceed 1151 dBA. For sound levels L where $80 \leq L \leq 115$ dBA allowable exposure time is given by

$$T = 8/\left[2^{(L-\mathrm{CL})/\mathrm{ER}}\right] = 8/\left[2^{(\mathrm{L}-90)/5}\right] \qquad (9.1)$$

where T = allowable exposure time (hours/day). The result is shown in Table 6.

Noise dose. When sound levels vary during the day, noise dose is used as an exposure criterion. Noise dose is given by

$$D_{\%} = 100\sum_{i=1}^{N} C_{\mathrm{i}}/T_{\mathrm{i}}$$

where C = actual exposure of an individual at a given sound level (hr), T = allowable exposure time at that level and N = the number of different exposure levels during one day. Noise dose $D_{\%}$ should not exceed 100%. As an alternative to monitoring and calculations, workers may wear dosimeters which automatically measure and calculate daily dose.

An exchange rate of 3 dB is used in occupational noise exposure criteria by some European countries. This exchange rate is equivalent to basing noise exposure on L_{eq}.

Environmental Protection Agency (EPA) identified levels. Using a 4 kHz threshold shift criterion, protective noise levels are substantially lower than the OSHA criteria. EPA (1974, 1978) in its "Levels" document identified the equivalent sound level of intermittent noise:

$$L_{\mathrm{eq24}} = 70\ \mathrm{dBA}$$

as the "(at ear) exposure level that would produce no more than 5 dB noise-induced hearing damage over a 40 year period". This value is based on a predicted hearing loss smaller than 5 dB at 4 kHz for 96% of the people exposed to 73 dBA noise for 8 hr/da × 250 da/yr × 40 yr. With the following corrections, the 73 dBA level is adjusted to L_{eq24} = 70 dBA the protective noise level:

−1.6 dBA to account for 365 da/yr exposure,
−4.8 dBA to correct for 24 hr/day averaging,
+5 dBA assuming intermittent exposure and
−1.6 dBA for a margin of safety.

NON-AUDITORY EFFECTS OF NOISE

The relationship between long-term exposure to industrial noise and the probability of noise-induced hearing loss is well-documented. And, we can estimate the effect of intrusive noise on speech intelligibility and masking of warning signals. Equivalent sound levels and day-night sound levels based on hearing protection, activity interference, and annoyance are given in Table 9. The United States Census Bureau identified noise as the top complaint about neighborhoods, and the major reason for wanting to move. In a typical city, about 70% of citizen complaints relate to noise. The most common complaints are aircraft noise, highway noise, machinery and equipment, and amplified music.

Noise tolerance varies widely among individuals. It is difficult to relate noise levels to psychological and non-auditory physiological problems. But there is anecdotal evidence that violent behavior can be triggered by noise. In a New York case, one man cut off another man's hand in a dispute over noise. In another noise-related incident, a New Jersey man operated his motorcycle engine inside his apartment, leading a neighbor to shoot him.

Chronic noise exposure has been related to children's health and cognitive performance. In a study of British schools, Stansfield and Haines (2000) compared reading skills of students at four schools with 16-hour equivalent sound levels less than 57 dBA and four schools with levels greater than 66 dBA. After adjustment for socioeconomic factors, lower average reading scores were found at the noisier schools. The difference was equivalent to six months of learning over four years.

A study by Zimmer et al. (2001) examined aircraft noise exposure and student proficiency test results at three grade levels. Communities with comparable socioeconomic status were selected for the study. Noise-impacted communities with a day-night sound level greater than 60 dBA and communities with a level of less than 45 dBA were compared. If proficiency test results are extrapolated to educational attainment and salary level, one could predict a 3% salary level disadvantage for students from the impacted communities.

COMMUNITY NOISE

Contributors to community noise include aircraft, highway vehicles, off-road vehicles, powered garden equipment, construction activities, commercial and industrial activities, public address systems and loud radios and television sets. The major effects of community noise include sleep interference, speech interference, and annoyance.

Highway noise. Noise levels due to highway vehicles may be estimated from the Federal Highway Administration (FHWA) model summarized by the sound level vs. speed relationships in Table 7. These values make it possible to predict the impact of a proposed highway or highway improvement on a community.

The contribution that a given class of vehicles makes to hourly equivalent sound level is given by

$$L_{eqH} = L_o + 10\,\lg\left[D_o V/S\right] + A_B + A_D + A_F + A_G + A_S - 25 \tag{10.1}$$

TABLE 7
Energy mean emission levels for vehicles

Heavy trucks	87	<50

Sound levels at 15 meters. Source: Barry and Reagan (1978).

where D_o = 15 m, V = volume (vehicles/hr), S = speed (km/hr). $A_{B, D, F, G}$ and $_S$ are adjustments for barriers, distance, finite highway segments, grade and shielding due to buildings, respectively. Each term is applied to a given class of vehicles and traffic lane. For acoustically absorptive sites, the distance adjustment is

$$A_D = 15\lg\left[D_o/D\right] \tag{10.2}$$

where D = distance from the traffic lane (m). Hourly equivalent sound level at any location is predicted by combining the contributions from all vehicle classes and traffic lanes. The result is

$$L_{eqH(COMBINED)} = 10\lg\sum_{i=1}^{N} 10^{L_{eqHi}/10}. \tag{10.3}$$

Design noise levels for highways. Design noise levels specified by the Federal Highway Administration (1976) are summarized in Table 8. Noise predictions based on projected traffic on proposed highways are compared with the design levels. These data aid in selecting a highway design and routing alternative including the "no-build" alternative.

Aircraft noise. Noise contour maps are available for most major airports. These enable one to make rough predictions of the impact of aircraft noise on nearby communities. Federal Aviation Administration publications (1985a and b) outline aircraft noise certification procedures and aircraft noise compatibility planning. Many of the existing airport noise contour maps are based on the descriptor **Noise exposure forecast (NEF).** An approximate conversion from NEF to L_{DN} is given by

$$L_{DN} \approx \text{NEF} + 35 \tag{10.4}$$

where L_{DN} = day-night sound level (± about 3 dBA).

Community noise criteria. There are thousands of different community noise ordinances, with a wide range of permitted sound levels. Their effectiveness depends largely on the degree of enforcement in a particular community. The Environmental Protection Agency has identified the noise

TABLE 9
Protective noise levels

Effect	Level (dBA)	Area
Hearing protection	$L_{eq24} \leqslant 70$	All areas. See Section 9.
Outdoor activity	$L_{DN} \leqslant 55$	Outdoors in residential areas.
Interference and annoyance	$L_{eq24} \leqslant 55$	Outdoor areas where people spent limited amounts of time.
Indoor activity	$L_{DN} \leqslant 45$	Indoor residential areas.
Interference and annoyance	$L_{eq24} \leqslant 45$	Other indoor areas with human activities such as schools, etc.

levels in Table 9 as protective of public health and welfare. All are based on an average 24 hour day.

Control of community noise. Environmental noise problems are particularly difficult to solve due to problems of shared responsibility and jurisdiction. In many cases, Federal laws preempt community regulations. Highway noise and aircraft noise, often the most significant contributors to community noise levels, are largely exempt from local control. In spite of the difficulties encountered, however, the importance of protecting the quality of life makes environmental noise control efforts worthwhile. Depending on the circumstances, some of the following courses of action may be considered.

a) Review the applicable noise ordinance. Compare it with a model noise ordinance. Check to see if specific limits are set in terms dBA. Determine whether or not sound level meters are available and whether or not the ordinance is actually enforced.
b) Meet with representatives of the local governing body or environmental commission. Make them aware of noise related problems in the community.
c) Initiate a campaign for public awareness with regard to the environment including the noise environment. Make use of the local papers.
d) Consider a ban or limitation on all-terrain-vehicles (ATV's). Determine whether muffler requirements are actually enforced.
e) Encourage planning and zoning boards to require an environmental impact statement (EIS), including a noise report, before major projects are approved.
f) Support noise labeling for lawn mowers and other power equipment.
g) Attend and participate in hearings involving plans for airports, heliports, and highways. Consider noise impact when evaluating the cost/benefit ratio for proposed facilities.
h) Evaluate the feasibility of noise barriers on existing and proposed highways in sensitive areas.
i) Support legislation to reduce truck noise emission limits.
j) Support legislation enabling airport curfews.

NON-IONIZING RADIATIONS

Lasers, microwave ovens, radar for pleasure boats, infrared inspection equipment and high intensity light sources generate so-called "non-ionizing" radiation.

Electromagnetic radiations which do not cause ionization in biological systems may be presumed to have photon energies less than 10–12 eV and may be termed "non-ionizing."

Because of the proliferation of such electronic products as well as a renewed interest in electromagnetic radiation hazards, the Congress enacted Public Law 90-602, the "Radiation Control for Health and Safety Act." This Act has as its declared purpose the establishment of a national electronic product radiation control program which includes the development and administration of performance standards to control the emission of electronic product radiation. The most outstanding feature of the Act is its omnibus coverage of all types of electromagnetic radiation emanating from electronic products, that is, gamma, X-rays, ultraviolet, visible, infrared, radio frequencies (RF) and microwaves. Performance standards have already been issued under the Act for TV sets, microwave ovens and lasers. In similar fashion, the recent enactment of the federal Occupational Safety and Health Act gives attention to the potential hazards of non-ionizing radiations in industrial establishments.

For the purposes of this chapter more formal treatment is given to ultraviolet (UV) radiation, lasers, and microwave radiation than the visible and infrared (IR) radiations. However the information on visible and IR radiation presented in the section on Laser Radiation is generally applicable to non-coherent sources. It should become obvious in reading the material which follows that the eye is the primary organ at risk to all of the non-ionizing radiations.

NATURE OF ELECTROMAGNETIC ENERGY

The electromagnetic spectrum extends over a broad range of wavelengths, e.g. from $<10^{-12}$ to $>10^{10}$ cm. The shortest wavelengths are generated by cosmic and X-rays, the longer wavelengths are associated with microwave and electrical power generation. Ultraviolet, visible and IR radiations occupy an intermediate position. Radiation frequency waves may range from 10 kHz to 10^{12} Hz, IR rays from 10^{12} ; 4×10^{13} Hz (0.72 μm), the visible spectrum from approximately 0.7–0.4 μm, UV from approximately 0.4–0.1 μm and γ- and X-radiation, below 0.1 μm. The photon energies of electromagnetic radiations are proportional to the frequency of the radiation and inversely proportional to wavelength, hence the higher energies (e.g.10^{8} eV) are associated with X- and γ-radiations, the lower energies (e.g.10^{-6} eV) with RF and microwave radiations.

Whereas the thermal energy associated with molecules at room temperature is approximately 1/30 eV, the binding energy of chemical bonds is roughly equivalent to a range of <1–15 eV, the nuclear binding energies of protons may be equivalent to 10^{6} eV and greater. Since the photon energy necessary to ionize atomic oxygen and hydrogen is of the order of 10–12 eV it seems in order to adopt a value of approximately 10 eV as a lower limit in which ionization is produced in biological material.

An extremely important qualification however is that non-ionizing radiations may be absorbed by biological systems and cause changes in the vibrational and rotational energies of the tissue molecules, thus leading to possible dissociation of the molecules or, more often, dissipation of energy in the form of fluorescence or heat.

In conducting research into the bioeffects of the non-ionizing radiations the investigator has had to use several units of measurement in expressing the results of his studies. For this reason Appendix A, containing definitions of many useful radiometric terms has been included. Appendix B provides a simple means for expressing radiant exposure and irradiance units in a number of equivalent terms.

ULTRAVIOLET RADIATION

Physical Characteristics of Ultraviolet Radiation

For the purpose of assessing the biological effects of UV radiation the wavelength range of interest can be restricted to 0.1–0.4 μm. This range extends from the vacuum UV (0.1 μm) to the near UV (0.4 μm). A useful breakdown of the UV region is as follows:

UV region	γ-range (±m)	(eV)
Vacuum	<0.60	>7.7
Far	0.16–0.28	7.7 4.4
Middle	0.28–0.32	4.4 3.9
Near	0.32 0.4	3.9 3.1

The photon energy range for wavelengths between 0.1 and 0.4 μm is 12.4–3.1 eV, respectively.

Representative Sources of Ultraviolet Radiation

The manor source of UV radiation is the sun, although absorption by the ozone layer permits only wavelengths greater than 0.29 μm to reach the surface of the earth. Low and high pressure mercury discharge lamps constitute significant manmade sources. In low pressure mercury vapor discharge lamps over 85% of the radiation is usually emitted at 0.2537 μm, viz. at germicidal wavelengths. At the lower pressures (fractions of an atmosphere) the characteristic mercury lines predominate whereas at higher pressures (up to 100 atmos.) the lines broaden to produce a radiation continuum. In typical quartz lamps the amount of energy at wavelengths below 0.38 μm may be 50% greater than the radiated visible energy, depending on the mercury pressure. Other manmade sources include xenon discharge lamps, lasers, and relatively new types of fluorescent tubes, which emit radiation at wavelengths above 0.315 μm reportedly at an irradiance less than that measured outdoors on a sunny day.

Biological Effects of Ultraviolet Radiation

The biological action spectrum for erythema (reddening) produced by UV radiation of the skin has been the subject of investigation for many years. The most recent data show that a maximum erythemal effect is produced at 0.260 μm with the secondary peak at approximately 0.290 μm. Erythemal response to wavelengths above 0.32 μm is predictably poor. The greatly increased air absorption of wavelengths below 0.25 μm and difficulty in obtaining monochromatic radiations in this region probably account for the lack of definitive bioeffects data. This may change with the increase in the number of UV lasers.

Wavelengths between 0.28 and 0.32 μm penetrate appreciably into the corium of the epidermis; those between 0.32 and 0.38 μm are absorbed in the epidermis, while those below 0.28 μm appear to be absorbed almost completely in the stratum corneum of the epidermis.

Depending on the total UV dose, the latent periods for erythema may range from 2 to several hours; the severity may vary from simple erythema to blistering and desquamation with severe secondary effects. A migration of melanin granules from the basal cells to the maphigian cell layers of the epidermis may cause a thickening of the horny layers of the skin. The possible long-term effects of the repeated process of melanin migration is not completely understood. The available data seem to support the contention that some regions of the UV may produce or initiate carcinogenesis in the human skin. The experiments which have supported this contention indicate that the biological action spectrum for carcinogenesis is the same as that for erythema.

Cases of skin cancer have been reported in workers whose occupation requires them to be exposed to sunlight for long periods of time. The reportedly high incidence of skin cancer in outdoor workers who are simultaneously exposed to chemicals such as coal tar derivatives, benzpyrene, methyl cholanthrene, and other anthracene compounds raises the question as to the role played by UV radiation in these cases. It is a matter of common knowledge that significant numbers of workers who routinely expose themselves to coal tar products while working outdoors experience a photosensitization of the skin.

Abiotic effects from exposure to UV radiation occurs in the spectral range of 0.24–0.31 μm. In this part of the spectrum, most of the incident energy is absorbed by the corneal epithelium at the surface of the eye. Hence, although the lens is capable of absorbing 99% of the energy below 0.35 μm only a small portion of the radiation reaches the anterior lenticular surface.

Photon-energies of about 3.5 eV (0.36 μm) may excite the lens of the eye or cause the aqueous or vitreous humor to fluoresce thus producing a diffuse haziness inside the eye that can interfere with visual acuity or produce eye fatigue. The phenomenon of fluorescence in the ocular media is not of concern from the bioeffects standpoint; the condition is strictly temporary and without detrimental effect.

The development of photokeratitis usually has a latency period varying from 30 min to as long as 24 hrs depending on the severity of the exposure. A sensation of "sand in the eyes" accompanied by varying degrees of photophobia, lacrimination and blepharospasm is the usual result. Blepharospasm is a reflex protective mechanisms characterized by an involuntary tight closing of the lids, usually over a damaged cornea.

Exposure Criteria

The biological action spectrum for keratitis peaks at 0.28 μm. At this wavelength, the threshold for injury has been determined to be approximately 0.15×10^6 ergs. It has been suggested that the corneal reaction in due primarily to selective absorption of UV by specific cell constituents, for example, globulin.

Verhoeff and Bell (1916) gave the first quantitative measurement of the UV energy necessary for threshold damage as 2×10^6 ergs/cm^2 for the whole UV spectrum. More recent data by Pitts, using 10 nm bands of radiation produced a threshold of approximately 0.5×10^5 ergs/cm^2 in rabbit eyes.

The exposure criteria adopted by the American Medical Association based on erythemal thresholds at 0.2537 μm radiation are as follows: 0.5×10^{-6} W/cm^2 for exposure up to 7 hr; 0.1×10^{-6} W/cm^2 for exposure periods up to and exceeding 24 hr. Although these criteria are generally thought to be very conservative, i.e. stringent, they are nevertheless in common use.

The American Conference of Governmental Industrial Hygienists (1982) recommend threshold limit values (TLV) for UV irradiation of unprotected skin and eyes for active wavelengths between 0.2 and 0.315 μm (200 and 315 nm)[37]. Typical values are: for 200 nm, a TLV of 100 mJ/cm^2; for 240 nm, a TLV of 10 mJ/cm^2; for 280 nm, a TLV of 3.4 mJ/cm^2; and for 315 nm, a TLV of 1 J/cm^2.

Measurement of Ultraviolet Radiation

Various devices have been used to measure UV radiation, e.g. photoelectric cells, photoconductive cells, photovoltaic cells, and photochemical detectors. It is common practice to employ the use of selective filters in front of the detecting device in order to isolate that portion of the UV spectrum of interest to the investigator.

A commonly used detector is the barrier or photovoltaic cell. Certain semiconductors such as selenium or copper oxide deposited on a selected metal develop a potential barrier between the layer and the metal. Light falling upon the surface of the cell causes the flow of electrons from the semiconductor to the metal. A sensitive meter placed in such a circuit will record the intensity of radiation falling on the cell.

Ultraviolet photocells take advantage of the fact that certain metals have quantitative photoelectric responses to specific bands in the UV spectrum. Therefore a photocell may be equipped with metal cathode surfaces which are sensitive to certain UV wavelengths of interest. One of the drawbacks of photocells is solarization or deterioration of the envelope, especially with long usage or following measurement of high intensity UV radiation. This condition requires frequent recalibration of the cell. The readings obtained with these instruments are valid only when measuring monochromic radiation, or when the relationship between the response of the instrument and the spectral distribution of the source is known.

A desirable design characteristic of UV detectors is to have the spectral response of the instrument closely approximate that of the biological action spectrum under consideration. However, such an instrument is unavailable at this time. Since available photocells and filter combinations do not closely approximate the UV biological action spectra it is necessary to standardize (calibrate) each photocell and meter. Such calibrations are generally made at a great enough distance from a standard source that the measuring device is in the "far field" of the course. Special care must be taken to control the temperature of so-called standard mercury lamps because the spectral distribution of the radiation from the lamps is dependent upon the pressure of the vaporized mercury.

A particularly useful device for measuring UV is the thermopile. Coatings on the receiver elements of the thermopile are generally lamp black or gold black to simulate black body radiation devices. Appropriate thermopile window material should be selected to minimize the effects of air convection, the more common windows being crystal quartz, lithium chloride, calcium fluoride, sodium chloride, and potassium bromide.

Low intensity calibration may be made by exposing the thermopile to a secondary standard (carbon filament) furnished by the National Bureau of Standards.

Other UV detection devices include (1) photodiodes, e.g. silver, gallium arsenide, silver zinc sulfide, and gold zinc sulfide. Peak sensitivity of these diodes is at wavelengths below 0.36 μm; the peak efficiency or responsivity is of the order of 50–70%; (2) thermocouples, e.g. Chromel-Alumel; (3) Golay cells; (4) superconducting bolometers, and (5) zinc sulfide Schottky barrier detectors.

Care must be taken to use detection devices having the proper rise time characteristics (some devices respond much too slowly to obtain meaningful measurements). Also, when measurements are being made special attention should be given to the possibility of UV absorption by many materials in the environment, e.g. ozone or mercury vapor, thus adversely affecting the readings. The possibility of photochemical reactions between UV radiation and a variety of chemicals also exists in the industrial environment.

Control of Exposure

Because UV radiations are so easily absorbed by a wide variety of materials appropriate attenuation is accomplished in a straightforward manner.

In the case of UV lasers no firm bioeffects criteria are available. However the data of Pitts may be used because of the narrow band UV source used in his experiments to determine thresholds of injury to rabbit eyes.

LASER RADIATION

Sources and Uses of Laser Radiation

The rate of development and manufacture of devices and systems based on stimulated emission of radiation has been truly phenomenal. Lasers are now being used for a wide variety of purposes including micromachining, welding, cutting, sealing, holography, optical alignment, interferometry, spectroscopy, surgery and as communications media. Generally speaking lasing action has been obtained in gases, crystalline materials, semiconductors and liquids. Stimulated emission in gaseous systems was first reported in a helium-neon mixture in 1961. Since that time lasing action has been reported at hundreds of wavelengths from the UV to the far IR (several hundred micrometers). Helium–neon (He–Ne) lasers are typical of gas systems where stable single frequency operation is important. He–Ne systems can operate in a pulsed mode or continuous wave (CW) at wavelengths of 0.6328, 1.15, or 3.39 μm depending upon resonator design. Typical power for He–Ne systems is of the order of 1–500 mW. The carbon dioxide gas laser system operates at a wavelength of 10.6 μm in either the continuous wave, pulsed, or Q-switched modes. The power output of CO_2–N_2 systems may range from several watts to greater than 10 kW. The CO_2 laser is attractive for terrestrial and extra-terrestrial communications because of the low absorption window in the atmosphere between 8 and 14 qm. Of major significance from the personal hazard standpoint is the fact that enormous power may be radiated at wavelength which is invisible to the human eye. The argon ion gas system operates predominantly at wavelengths of 0.488 and 0.515 μm in either a continuous wave or pulsed mode. Power generation is greatest at 0.488 μm, typically at less than 10 W.

Of the many ions in which laser action has been produced in solid state crystalline materials, perhaps neodymium (Nd^{3+}) in garnet or glass and chromium (Cr^{3+}) in aluminum oxide are most noteworthy. Garnet (yttrium aluminum garnet) or YAG is an attractive host for the trivalent neodymium ion because the 1.06 μm laser transition line is sharper than in other host crystals. Frequency doubling to 0.530 μm using lithium niobate crystals may produce power approaching that available in the fundamental mode at 1.06 μm. also through the use of electro-optic materials such as KDP, barium–sodium niobate or lithium tantalite, "tuning" or scanning of laser frequencies over wide ranges may be accomplished. The ability to scan rapidly through wide frequency ranges requires special consideration in the design of protective measures.

Perhaps the best known example of a semi-conductor laser is the gallium arsenide types operating at 0.840 μm; however, semiconductor materials have already operated over a range of approximately 0.4–5.1 μm. Generally speaking, the semiconductor laser is a moderately low-powered (milliwatts to several watts) CW device having relatively broad beam divergence thus tending to reduce its hazard potential. On the other hand, certain semiconductor lasers may be pumped by multi-kV electron beams thus introducing a potential ionizing radiation hazard.

Through the use of carefully selected dyes, it is possible to tune through broad wavelength ranges.

Biological Effects of Laser Radiation

The body organ most susceptible to laser radiation appears to be the eye; the skin is also susceptible but of lesser importance. The degree of risk to the eye depends upon the type of laser beams used, notably the wavelength, output power, beam divergence, and pulse repetition frequency. The ability of the eye to refract long UV, visible, and near IR wavelengths is an additional factor to be considered in assessing the potential radiation hazard.

In the UV case of UV wavelengths (0.2–0.4 μm) produced by lasers the expected response is similar to that produced by non-coherent sources, e.g. photophobia accompanied by erythema, exfoliation of surface tissues and possible stromal haze. Absorption of UV takes place at or near the surface of tissues. The damage to epithelium results from the photochemical denaturization of proteins.

In the case of IR laser radiation damage results exclusively from surface heating of the cornea subsequently to absorption of the incident energy by tissue water in the cornea. Simple heat flow models appear to be sufficiently accurate to explain the surface absorption and damage to tissue.

In the case of the visible laser wavelengths (0.4–0.75 μm) the organ at risk is the retina and more particularly the pigment epithelium of the retina. The cornea and lens of the eye focus the incident radiant energy so that the radiant exposure at the retina is at least several orders of magnitude greater than that received by the cornea. Radiant exposures which are markedly above the threshold for producing minimal visions on the retina may cause physical disruption of retinal tissue by steam formation or by projectile-like motion of the pigment granules. In the case of short transient pulses such as those produced by Q-switched systems, acoustical phenomena may also be present.

There are two transition zones in the electromagnetic spectrum where bio-effects may change from one of a corneal hazard to one of a retinal hazard. These are located at the interface of the UV-visible region and the visible–near IR region. It is possible that both corneal and retinal damage as well as damage to intermediate structures such as the lens and iris could be caused by devices emitting radiation in these transitional regions. Several investigators noticed irreversible changes in electroretinograms with attendant degeneration of visual cells and pigment epithelium, when albino and pigmented rats were exposed to high illumination environments.

The chronic and long term effects of laser radiation have not been fully explored.

The biological significance of irradiating the skin with lasers is considered to be less than that caused by exposure of the eye since skin damage is usually repairable or reversible. The most common effects on the skin range from erythema to blistering and charring dependent upon the wavelength, power, and time of exposure to the radiation. Depigmentation of the skin and damage to underlying organs may occur from exposure to extremely high powered laser radiation, particularly Q-switched pulses. In order that the relative eye-skin hazard potential be kept in perspective, one must not overlook possible photosensitization of the skin caused by injection of drugs or use of cosmetic materials. In such cases the maximum permissible exposure (MPE) levels for skin might be considerably below currently recommended values.

The thresholds for producing retinal lesions at all visible wavelengths were considered to be approximately the same i.e., 5 to 10 W/cm^2, until more recent investigations discovered a much greater sensitivity of the eye to blue wavelengths. The mechanism for this enhanced sensitivity is explained on the basis of photochemical, rather than thermal effects.

Exposure Criteria

Permissible levels of laser radiation impinging upon the eye have been derived from short term exposure and an examination of damage to eye structures as observed through an ophthalmoscope. Some investigators have observed irreversible visual performance changes at exposure levels as low as 10% of the threshold determined by observation through an ophthalmoscope. McNeer and Jones found that at 50% of the ophthalmoscopically determined threshold the ERG B wave amplitude was irreversibly reduced. Mautner has reported severe changes in the visually evoked cortical potential at 25% of the ophthalmoscopically determined threshold. Since most, if not all, of the so-called laser criteria have been based on ophthalmoscopically-determined lesions on the retina, the findings of irreversible functional changes at lower levels causes one to ponder the exact magnitude of an appropriate safety factor which should be applied to the ophthalmoscope data in order to derive a reasonable exposure criterion.

There is unanimous agreement that any proposed maximum permissible exposure (MPE) or threshold limits value (TLV) does not sharply divide what is hazardous from what is safe. Usually any proposed values take on firm meaning only after years of practical use. However, it has become general practice in defining laser exposure criteria to:

1) Measure the radiant exposure (J/cm^2) or irradiance (W/cm^2) in the plane of the cornea rather than making an attempt to calculate the values at the retina. This simplifies the measurements and calculations for the industrial hygienists and radiation protection officers.
2) Use a 7 mm dia. limiting aperture (pupil) in the calculations. This assumes that the largest amount of laser radiation may enter the eye.
3) Make a distinction between the viewing of colimated sources, for example lasers and extended sources, such as fluorescent tubes or incandescent lamps. The MPE for extended source viewing takes into account the solid angle subtended at the eyes in viewing the light source; therefore the unit is W/cm^2·sr (Watts per square centimeter and steradian).
4) Derive permissible levels on the basis of the wavelength of the laser radiation, e.g. the MPE for neodymium wavelength (1.06 μm) should be increased, i.e. made less stringent by a factor of approximately five than the MPE for visible wavelengths.
5) Urge caution in the use of laser systems that emit multiple pulses. A conservative approach would be to limit the power of energy in any single pulse in the train to the MPE specified for direct irradiation at the cornea. Similarly the average power for a pulse train could be limited to the MPE of a single pulse of the same duration as the pulse train. More research is needed to precisely define the MPE for multiple pulses.

Typical exposure criteria for the eye proposed by several organizations are shown in Wilkening (1978). These data do not apply to permissible levels at UV wavelengths or to the skin. A few supplementary comments on these factors are in order: There appears to be general agreement on maximum permissible exposure levels of radiation for the skin, e.g. the MPE values are approximately as follows for exposure times greater than 1 sec, an MPE of 0.1 W/cm^2; exposure times $10^{-1}-1$ sec, 1.0 W/cm^2; for $10^{-4}-10$ sec, 0.1 J/cm^2, and for exposure times less than 10^{-4} sec, 0.01 J/cm^2. The MPE values apply to visible and IR wavelengths. For UV radiations the more conservative approach is to use the standards established by the American Medical Association. These exposure limits (for germicidal wavelengths viz. 0.2537 μm) should not exceed 0.1×10^{-6} W/cm^2 for continuous exposure. If an estimate is to be made of UV laser thresholds then it suggested that the more recent work of Pitts be consulted.

Major works to be consulted on hazard evaluation and classification, control measures, measurement, safety and training programs, medical surveillance and criteria for exposure of the eye and skin to laser radiation are the American National Standards Institute (ANSI) and Bureau of Radiological Health (BRH) documents. Also see the ACGIH document for additional laser, microwave and ultraviolet exposure criteria. A major work on laser safety, soon to be released, is the laser radiation standard of the International Electrotechnical Commission (IEC).

Measurement of Laser Radiation

The complexity of radiometric measurement techniques, the relatively high cost of available detectors and the fact that calculations of radiant exposure levels based on manufacturers' specifications of laser performance have been found to be sufficiently accurate for protection purposes, have all combined to minimize the number of measurements needed in a protective program. In the author's experience, the output power of commonly used laser systems, as specified by the manufacturers, has never been at variance with precision calibration data by more than a factor of two.

All measurement systems are equipped with detection and readout devices. A general description of several devices and their application to laser measurements follow.

Because laser radiation is monochromatic, certain simplifications can be made in equipment design. For example, it may be possible to use narrow band filters with an appropriate type of detector thereby reducing sources of error. On the other hand, special care must be taken with high powered beams to prevent detector saturation or damage. Extremely short Q-switched pulses require the use of ultrafast detectors and short time-constant instrumentation to measure instantaneously power. Photoelectric detectors and radiation thermopiles are designed to measure instantaneous power, but they can also be used to measure total energy in a pulse by integration, provided the instrumental timeconstants are much shorter than the pulse lengths of the laser radiation. High current vacuum photo-diodes are useful for measuring the output of Q-switched systems and can operate with a linear response over a wide range.

Average power measurements of cw lasers systems are usually made with a conventional thermopile or photovoltaic cells. A typical thermopile will detect signals in the power range from 10 μW to about 100 mW. Because thermopiles are composed of many junctions the response of these instruments may be non-uniform. The correct measure of average power is therefore not obtained unless the entire surface of the thermopile is exposed to the laser beam. Measurements of the cw power output of gas lasers may also be made with semiconductor photocells.

The effective aperture or aperture stop of any measurement device used for determining the radiant expose (J/cm^2) or irradiance (W/cm^2) should closely approximate, if not be identical to, the papillary aperture. For purposes of safety the diameter should correspond to that of the normal dark-adapted eye, i.e. 7 mm. The response time of measurement system should be such that the accuracy of the measurement is not affected especially when measuring short pulse durations or instantaneous peak power.

Many calorimeters and virtually all photographic methods measure total energy, but they can also be used for measuring power if the time history of the radiation is known. Care should be taken to insure that photographic processes are used within the linear portion of the film density vs. log radiant exposure (gamma) curve.

Microammeters and voltmeters may be used as read out devices for cw systems; microvoltmeters or electrometers coupled to oscilloscopes may be used for pulsed laser systems. These devices may be connected in turn to panel displays or recorders, as required.

Calibration is required for all wavelengths at which the instrument is to be used. It should be noted that Tungsten Ribbon filament lamps are available from the National Bureau of Standards as secondary standards of spectral radiance over the wavelength region from approximately 0.2–2.6 μm. The calibration procedures using these devices permit comparisons within about 1% in the near UV and about 0.5% in the visible. All radiometric standards are based on the Stefan–Boltzmann and Planck laws of blackbody radiation.

The spectral response of measurement devices should always be specified since the ultimate use of the measurements is a correlation with the spectral response of the biological tissue receiving the radiation insult.

Control of Exposure

In defining a laser hazard control program, some attempt should be made to classify the lasers or laser system according to their potential hazard. For example, one may wish to classify the lasers in terms of their potential for exceeding the Maximum Permissible Exposure (MPE) level or Threshold Limit Values (TLV). This could mean that a classification of "low powered," "exempt" or special "protected" lasers could evolve. "Exempt" may apply to lasers and laser systems which cannot, because of inherent design parameters, emit radiation levels in excess of the MPE; "low powered" could refer to systems emitting levels greater than the MPE for direct exposure to collimated beams but less than the MPE for extended sources; "high powered" could refer to systems that emit levels greater than the MPE for direct exposure to collimated laser beams as well as the MPE for extended sources; a "protected" laser system could be one where by virtue of appropriate engineering controls the emitted levels of radiation are less than any MPE value. Other variations are possible. Once a classification scheme has been established it is possible to devise engineering measures and operating procedures to maintain all radiation at or below the desired levels, the stringency of the controls being directly related to the degree of risk to personnel in each category.

It stands to reason that certain basic control principles apply to many laser systems: the need to inform appropriate persons as to the potential hazard, particularly with the discharge of capacitor banks associated with solid state Q-switched systems, the need to rely primarily on engineering controls rather than procedures, e.g. enclosures, beam stops, beam enlarging systems, shutters, interlocks and isolation of laser systems, rather than sole reliance on memory or safety goggles. The "exempt" laser system is an exception to these measures. In all cases, particular attention must be given to the safety of unsuspecting visitors or spectators in laser areas.

"High powered" systems deserve the ultimate in protective design: enclosures should be equipped with interlocks. Care should be taken to prevent accidental firing of the system and where possible, the system should be fired from a remote position. Controls on the high powered systems should go beyond the usual warning labels by installing an integral warning system such as a "power on" audible signal or flashing light which is visible through protective eye wear.

Infrared laser systems should be shielded with fireproof materials having an appropriate optical density (O.D.) to reduce the irradiance below MPE values. The main hazard of these systems is absorption of excessive amounts of IR energy by human tissue or by flammable or explosive chemicals.

Before protective eye wear is chosen, one must determine as a minimum the radiant exposure or irradiance levels produced by the laser at the distance where the beam or reflected beam is to be viewed, one must know the appropriate MPE value for the laser wavelength and finally one must determine the proper O.D. of protective eyewear in order to reduce levels below the MPE. Likewise, the visible light transmission characteristics should be known because sufficient transmission is necessary for the person using the device to be able to detect ordinary objects in the immediate field of vision.

MICROWAVE RADIATION

Physical Characteristics of Microwave Radiation

Microwave wavelengths vary from about 10 m to about 1 mm; the respective frequencies range from 30 MHz–300 GHz. Certain reference documents, however, define the microwave frequency range as 10 MHz–100 GHz. The region between 10 MHz and the IR is generally referred to as the RF or radiofrequency region.

Certain bands of microwave frequencies have been assigned letter designations by industry; others, notably the ISM (Industrial, Scientific, Medical) frequencies have been assigned by the Federal Communications Commission for industrial, scientific and medical applications.

Source of Microwave Radiation

Microwave radiation is no longer of special interest only to those in communications and navigational technology. Because of the growing number of commercial applications of microwaves, e.g. microwave ovens, diathermy, materials drying equipment, there is widespread interest in the possible new applications as well as an increased awareness of potential hazards. Typical sources of microwave energy are klystrons, magnetrons, backward wave oscillators and semiconductor transmit time devices (impatt diodes). Such sources may operate continuously as in the case of some communications systems or intermittently, e.g. in microwave ovens, induction heating equipment and diathermy equipment or in the pulsed mode in radar systems. Natural sources of RF and microwave energy also exist. For example, peak field intensities of over 100 V/m are produced at ground level by the movement of cold fronts. Solar radiation intensities range from 10^{-18} to 10^{-17} watts per square meter per Hz ($\mathrm{Wm^{-2}Hz^{-1}}$) however, the integrated intensity at the earth's surface for the frequency range of 0.2–10 GHz is approximately 10^{-8} mW/cm^2. This value is to be compared with an average of 10^2 mW/cm^2 on the earth's surface attributable to the entire (UV, visible IR and microwave) solar spectrum.

Biological Effects of Microwave Radiation

The photon energy in RF and microwave radiation is considered to be too low to produce photochemical reactions in biological matter. However, microwave radiation is absorbed in biological systems and ultimately dissipated in tissue as heat. Irradiation of the human body with a power density of 10 mW/cm^2 will result in the absorption of approximately 58 W with a resultant body temperature elevation of 1°C, a value which is considered acceptable from a personal hazard standpoint. By way of comparison, the human basal metabolic rate is approximately 80 W for a person at rest; 290 for a person engaged in moderate work.

Microwave wavelengths less than 3 cm are absorbed in the outer skin surface, 3–10 cm wavelengths penetrate more deeply (1 mm–1 cm) into the skin and at wavelengths from 25–200 cm penetration is greatest with the potential of causing damage to internal body organs. The human body is thought to be essentially transparent to wavelengths greater than about 200 cm. Above 300 MHz the depth of penetration changes rapidly with frequency, declining to millimeter depths at frequencies above 3000 MHz. Above 10 GHz the surface absorption of energy begins to approach that of the IR radiation.

The observed effects of radiofrequency radiation on biological systems seem to depend more on a differential rate of energy deposition than in the case with ionizing radiation where biological effects seem to be related more to energy and integral (time independent) quantities, such as absorbed dose.

The National Council on Radiation Protection and Measurements (NCRP) has attempted to consolidate the many quantities and units used to describe absorption of radio frequency electromagnetic energy by introducing the term "specific absorption rate" (SAR). The specific absorption rate is the rate at which electromagnetic energy is absorbed at a point in a medium per unit mass of the medium, and is expressed in W/kg. Energy absorption is a continuous and differentiable function of space and time and one may speak of its gradient and its rate, hence the time derivative of the incremental energy (dW) absorbed in an incremental mass (dm) contained in a volume element (dV) of a given density (ρ) may be expressed:

$$\mathrm{SAR} = \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\mathrm{d}W}{\mathrm{d}m}\right) = \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\mathrm{d}w}{\rho\,\mathrm{d}V}\right).$$

Carpenter and Van Ummersen (1968) investigated the effects of microwave radiation on the production of cataracts in rabbit eyes. Exposures to 2.45 GHz radiation were made at power densities ranging from 80–400 mW/cm^2 for different exposure times. They found that repeated doses of 67 J/cm^2 spaced a day, a week, or 2 weeks apart produced lens opacities even though the single threshold exposure dose at that power density (280 mW/cm^2) was 84 J/cm^2. When the single exposure dose was reduced to 50 J/cm^2 opacities were produced when the doses were administered 1 or 4 days apart, but when the interval between exposures was increased to 7 days no opacification was noted even after 5 such weekly exposures. At the low power density of 80 mW/cm^2 (dose of 29 J/cm^2) no effect developed but when administered daily for 10 or 15 days cataracts did develop. The conclusion is that microwaves may exert a cumulative effect on the lens of the eye if the exposures are repeated sufficiently often. The interval between exposures is an important factor in that a repair mechanism seems to act to limit lens damage if adequate time has elapsed between exposures.

Certain other biological effects of microwave radiation have been noted in literature. One of these is the so-called "pearl chain effect" where particles align themselves in chains when subjected to an electric field. There is considerable disagreement as to the significance of the pearl chain effect.

Investigators at the Johns Hopkins University have suggested a possible relationship between mongolism (Down's Syndrome) in offspring and previous exposure of the male parent to radar. This suggested relationship was based on the finding that of 216 cases of mongolism, 8.7% of the fathers having mongol offspring vs. 3.3% of the control fathers (no mongol offspring) had contact with radar while in military service. This possible association must be regarded with extreme caution because of many unknown factors including the probability of a variety of exposures to environmental agents (including ionizing radiation) while in military service.

Soviet investigators claim that microwave radiation produces a variety of effects on the central nervous system and without a temperature rise in the organism. Claims are also made for biochemical changes, specifically a decrease in cholinesterase and changes in RNA at power density levels of approximately 10 mW/cm^2. The reported microwave effects on the central nervous system usually describe initial excitatory action, e.g. high blood pressure followed by inhibitory action and low blood pressure over the long term. Electroencephalographic data have been interpreted as indicating the presence of epileptiform patterns in exposed subjects. Other reported effects ranged from disturbances of the menstrual cycle to changes in isolated nerve preparations.

Field interactions with brain tissue in cats have been assessed by effects on calcium ion fluxes. Increases in calcium efflux of the order of 20% have been reported under conditions of direct stimulation of synaptic terminals. Moreover, exposure of intact animals (cats) to a 450 MHz 0.375 mW/cm^2 field, amplitude modulated at 16 Hz produced a sharp rise in calcium efflux, with a response curve identical to that obtained by direct electrical stimulation of brain tissue at the same intensity.

In addition, power and frequency "windows" have been reported, that is enhanced biological responses have been elicited within narrow bands of incident power and radiation frequency.

What is often overlooked in any description of the biological effects of microwave radiation is that such radiations have produced beneficial effects. Controlled or judicious exposure of humans to diathermy or microthermy is widely practiced. The localized exposure level in diathermy may be as high as 100 mW/cm^2.

Exposure Criteria

Schwan in 1953 examined the threshold for thermal damage to tissue, notably cataractogenesis. The power density necessary for producing such changes was approximately 100 mW/cm^2 to which he applied a safety factor of 10 to obtain a maximum permissible exposure level of 10 mW/cm^2. This number has been subsequently incorporated into many official standards. The current American National Standards Institute C95 standard requires a limiting power density of 10 mW/cm^2 for exposure periods of 0.1 hr or more; also an energy density of 1 milliwatt-hour per square centimeter (1 mWh/cm^2) during any 0.1 hr period is permitted. The latter criterion allows for intermittency of exposure at levels above 10 mW/cm^2, on the basis that such intermittency does not produce a temperature rise in human tissue greater than 1°C. More recently, Schwan has suggested that the permissible exposure levels be expressed in terms of current density, especially when dealing with measurements in the near or reactive field where the concept of power density loses its meaning. He suggests that a permissible current density of approximately 3 mA/cm^2 be accepted since this value is comparable to a far field value of 10 mW/cm^2. At frequencies below 10 100 KHz this value should be somewhat lower and for frequencies above 1 GHz it can be somewhat higher.

The most recent proposal of the American National Standards Institute (ANSI) specifies a frequency dependent criterion, with a minimal elvel of 1 mW/cm^2 in the so-called resonant frequency range of the human body (approximately tens of MHz to several hundred MHz) and higher permissible levels at lower and higher frequencies.

The performance standard for microwave oven specifies a level of 1 mW/cm^2 at any point 5 cm or more from the external oven surfaces at the time the oven is fabricated by manufacturer. 5 mW is permitted throughout the useful life of the oven.

Because Soviet investigators believe that effects on the central nervous system are more appropriate measure of the possibly detrimental effects of microwave radiation than are thermally induced responses, their studies have reported "thresholds" which are lower than those reported in Western countries. Soviet permissible exposure levels are several orders of magnitude below those in Western countries.

The Soviet Standards for whole body radiation are as follows: 0.1 mW/cm^2 for 2 hr exposure per day and 1 mW/cm^2 for a 15–20 min exposure provided protective goggles are used. These standards apply to frequencies above 300 MHz. Recent reports indicate that the Soviet Union has raised the above mentioned value of 0.01 mW/cm^2 to 0.025 mW/cm^2; also, the Soviet value of 0.001 mW/cm^2 for continuous exposure of the general population has been raised to 0.005 mW/cm^2.

There appears to be no serious controversy about the power density levels necessary to produce thermal effects in biological tissue. The nonthermal CNS effects reported by the Soviets are not so much controversial as they are a reflection of the fact that Western investigators have not used the conditioned reflex as an end point in their investigations.

Measurement of Microwave Radiation

Perhaps the most important factor underlying some of the controversy over biological effects is the lack of standardization of the measurement techniques used to quantify results. To date, unfortunately, there seems to be little promise that such standardization will be realized in the near future.

The basic vector components in any electromagnetic wave are the electric field (*E*) and the magnetic field (*H*). The simplest type of microwave propagation consists of a plane wave moving in an unbounded isotropic medium, where the electric and magnetic field vectors are mutually perpendicular to each other and both are perpendicular to the direction of wave propagation. Unfortunately the simple proportionality between the *E* and *H* fields is valid only in free space, or in the so-called "far field" of the radiating device. The far field is the region which is sufficiently removed from the source to eliminate any interaction between the propagated wave and the source. The energy or power density in the far field is inversely proportional to the square of the distance from the source and in this particular case the measurement of either *E* of *H* suffices for their determination.

Plane-wave detection in the far field is well understood and easily obtained with equipment which has been calibrated for use in the frequency range of interest. Most hazard survey instruments have been calibrated in the far field to read in power density (mW/cm^2) units. The simplest type of device uses a horn antenna of appropriate size coupled to a power meter.

To estimate the power density levels in the near field of large aperture circular antennas one can use the following simplified relationship

$$W = \frac{16P}{\pi D^2} = \frac{4P}{A}\left(\text{near field}\right),$$

where *P* is the average power output, *D* is the diameter of the antenna, *A* is the effective area of the antenna and *W* is power density. If this computation reveals a power density which is less than a specified limit, e.g. 10 mW/cm^2, then no further calculation is necessary because the equation give the maximum power density on the microwave beam axis. If the computed value exceeds the exposure criterion then one assume that the calculated power density exists through-out the near field. The far field power densities are then computed from the Friis free space transmission formula

$$W = \frac{GP}{4\pi r^2} = \frac{AP}{\lambda^2 r^2}\left(\text{far field}\right),$$

where λ is the wavelength, r is the distance from the antenna and G is the far field antenna gain.

The distance from the antenna to the intersection of the near and far fields is given by

$$r_1 = \frac{\pi D^2}{8\lambda} = \frac{A}{2\lambda}.$$

These simplified equations do not account for reflections from ground structures or surfaces; the power density may be four times greater than the free space value under such circumstances.

Special note should be made of the fact that microwave hazard assessments are made on the basis of average, not peak power of the radiation. In the case of radar generators, however, the ratio of peak to average power may be as high as 10^5.

Most microwave measuring devices are based on bolometry, calometry, voltage and resistance changes in detectors and the measurement of radiation pressure on a reflecting surface. The latter three methods are self-explanatory. Bolometry measurements are based upon the absorption of power in a temperature sensitive resistive element, usually a thermistor, the change in resistance being proportional to absorbed power. This method is one of the most widely used in commercially available power meters. Low frequency radiation of less than 300 MHz may be measured with loop or short ship antenna. Because of the larger wavelengths in the low frequency region, the field strength in volts per meter (V/m) is usually determined rather than power density.

One troublesome fact in the measurement of microwave radiation is that the near field (reactive field) of many sources may produce unpredictable radiative patterns. Energy density rather than power density may be a more appropriate means of expressing hazard potential in the near field. In the measurement of the near field of microwave ovens it is desirable that the instrument have certain characteristics, e.g. the antenna probe should be electrically small to minimize perturbation of the field, the impedance should be matched so that there is no backscatter from the probe to the source, the antenna probe should behave as an isotropic receiver, the probe should be sensitive to all polarizations, the response time should be adequate for handling the peak to average power of the radiation and the response of the instrument should be flat over a broad band of frequencies.

In terms of desirable broad band characteristics of instruments it is interesting to note that one manufacturer has set target specifications for the development of a microwave measurement and monitoring device as follows: frequency range 20 KHz–12.4 GHz and a power density range of 0.02–200 mW/cm^2 ± 1 dB. Reportedly two models of this device will be available: one a hand held version complete with meter readout, the other a lapel model equipped with audible warning signals if excessive power density levels develop.

APPENDIX A

Useful radiometric and related units

Term	Symbol	Description	Unit and abbreviation
Radiant energy	O	Capacity of electromagnetic wages to perform work	Joule (J)
Radiant power	P	Time rate at which energy is emitted	Watt (W)
Irradiance or radiant flux density (dose rate in photobiology)	E	Radiant flux density	Watt per square meter ($W \cdot m^{-2}$)
Radiant intensity	I`	Radiant flux of power emitted per solid angle (steradian)	Watt per steradian ($W \cdot sr^{-1}$)
Radiant exposure (dose in photobiology)	H	Total energy incident on unit area in a given time interval	Joule per square meter ($J \cdot m^{-2}$)
Beam divergence	ϕ	Unit of angular measure. One radian ≈ 57.3° 2π radians = 360°	Radian

APPENDIX B

Conversion factors A−radiant energy units

	erg	joule	W/sec	± W/sec	g-cal
erg =	1	10^{-7}	10^{-7}	0.1	2.39×10^{-8}
10 joule =	1	1	10^{6}	0.239	
W sec =	107	1	1	10^{4}	0.239
±W sec =	10	10^{-6}	10^{-6}	1	2.39×10^{-7}
g-cal =	4.19×10^{7}	4.19	4.19	4.19×10^{6}	1

W sec cm^2 =	10^{7}	1	1	10^{6}	0.239
±W sec cm^2 =	10	10^{-6}	10^{-6}	2.39×10^{-7}	
g−cal cm^2 =	4.19×10^{7}	4.19	4.19	4.19×10^{6}	1

C-irradiance (dose rate) units

	erg/cm^2 · sec	joule/cm^2 · sec	W/cm^2	±W/cm^2	g−cal/cm^2 · sec
erg/cm^2 · sec =	1	10^{-7}	10^{-7}	0.1	2.39×10^{-6}
joule cm^2· sec =	10^{7}	1	1	10^{6}	0.239
W/cm^2 =	10^{7}	1	1	10^{6}	0.239
±W/cm^2 =	10	10^{-6}	10^{-6}	1	2.39×10^{-7}
g-cal/cm^2 · sec =	4.19×10^{7}	4.19	4.19	4.19×10^{6}	1

A tabular summary of typical characteristics of instrumentation used for electromagnetic field measurements is available in an NCRP report.

Control Measures

The control of excessive exposures to microwave radiation is basically an engineering matter. The engineering measures may range from the restriction of azimuth and elevation settings on radar antennas to complete enclosures of magnetrons in microwave ovens. The use of personnel protective devices have their place but are of much lower priority importance to engineering controls. Various types of microwave protective suits, goggles and mesh have been used for special problems.

It has been shown that cardiac pacemakers, particularly those of the demand type, may have their function compromised by microwave radiation. Furthermore, the radiation levels which cause interference with the pacemaker may be orders of magnitude below levels which cause detrimental biological effects. The most effective method of reducing the susceptibility of these devices to microwave interference seems to be improved shielding. Manufacturers of cardiac pacemakers "… have successfully redesigned and shielded the units so that they can adequately withstand power densities of at least 10 mW/cm^2 without interference with their function."

OCEANOGRAPHY

INTRODUCTION

Before beginning a discussion of the origin and structure of the world's oceans, one should first reflect on the reasons for our interest in these bodies of water, which together comprise approximately seventy percent of the earth's surface area. Perhaps one of the more obvious reasons is the enormous wealth of natural resources hidden in the oceans' depths, including vast reserves of food and energy sources. This abundance has of course led to an increased human presence in and along much of the world's oceans, prompting considerable concern for the short and long term consequences of man's activities in this fragile environment.

An additional focus of recent oceanographic research has been the role of the sea in global climate variations, spurred by the recognition that these variations are driven largely by fluctuations in the air-sea momentum and heat exchange. This role was dramatically illustrated in the 1982–1983 El Nino event, which sparked such wide-ranging weather aberrations as flooding in southern California and droughts in Australia, and is widely believed to have had an oceanic origin (Rienecker and Mooers, 1986).

In addition to these varied and multi-disciplinary research activities, the increasing strategic importance of the world's oceans has been one of the prime motivations behind recent advances in underwater communication, depth measurement, and perhaps most significantly, the remote sensing of ocean physical processes. In the political forum, this strategic importance, along with the economic benefits of the natural resources mentioned earlier, continues to provoke international debate over such issues as fisheries management, ocean dumping, and the demarcation of territorial ("exclusive zone") boundaries.

Clearly, therefore, the oceans mean many different things to many different people. The common thread is the need and desire to learn more about these fascinating and fundamentally important bodies of water. In the following, we shall attempt to provide some insight into the makeup and behavior of the sea, from its origins to its various modes of motion. Realizing the short-comings of an overview treatment of such complex subject matter, the interested reader is urged to pursue in more detail any of the specific topics addressed in this article.

ORIGIN AND STRUCTURE OF THE OCEANS

It is generally believed that most of the water now present on the surface of the earth originated in the earth's interior. The prevailing scientific opinion holds that the earth was formed through the gradual compaction of an accumulation of particles, primarily silicon compounds, and iron and magnesium oxides. The heat released as a result of this compaction and radioactive decay was sufficient to produce a molten mass, the heaviest material sinking under the action of gravity to form the earth's core and the lightest "floating" to the surface to form the crust. This formative period was characterized by intense volcanic activity. It is widely accepted that the molten material introduced to the earth's surface through this activity served as the conduit for the release of hydrogen and oxygen into the atmosphere (primarily in the gaseous form) with some eventually condensing to form liquid water at the surface. Sediments discovered in Australia in 1980 appear to be of marine origin and have been dated at approximately 3.5 billion years old (Ross, 1982), indicating that surface water has been present over a significant portion of the earth's history.

The horizontal movements that produced the present-day sea-floor are, in geologic terms, a very recent occurrence. In fact, measurements indicate that the most ancient regions of the present deep ocean floor are no more than 225 million years old (Gross, 1977). The oldest dated sediments from the Atlantic Ocean indicate an age of approximately 165 million years (Sclater and Tapscott, 1979), while those of the Pacific reveal a relatively "young" water body at approximately 120 million years old (Heezen and MacGregor, 1973).

The mechanism for the creation and growth of the ocean basins is commonly referred to as continental drift, or in more general terms, as plate tectonics. The basic concept can be explained as follows. The outer shell of the earth (the lithosphere) is actually composed of a number of rigid plates.

These plates are in constant motion relative to each other. As one would expect, the borders between adjoining plates are regions of intense seismic activity.

The visible manifestation of this activity varies according to its strength, and ranges from seismically inactive mountain belts to active volcanic chains. Along areas where plates are diverging ("ridge axes"), there is a constant formation of new surface area, as volcanic material from the earth's interior rises to fill the gap caused by the plate divergence. Quite logically then, and in light of the fact that the earth is undergoing little or no expansion, there must be zones where plates are converging. These areas are called subduction zones and are characterized by the sliding of one plate beneath the edge of the adjoining plate. The theory of seafloor spreading states that the ocean basins were formed, and are continuing to change at a rate of order 2 centimeters per year (EOS, 1988) as a result of the divergence of plates along axes called oceanic ridges. As an example of this phenomenon, as recently as 165 million years ago, the continents bordering what is now the Atlantic Ocean were very much more closely separated, possibly constituting one very large land mass. The plates on which these continents rest then began diverging along an axis known as the Mid-Atlantic ridge, creating the ocean basin that presently exists. This ridge runs along the approximate centerline of the Atlantic Ocean, from Iceland south to approximately 1800 kilometers north of Antarctica.

For the purpose of categorization, we can divide the world's oceans into three bodies: the Atlantic Ocean (including the Arctic, Baltic, and Mediterranean Seas), bordered by the Americas, Africa, Europe, and the Arctic land mass; the Pacific Ocean, bordered by the Americas, Asia, Australia, and Antarctica; and the Indian Ocean, bordered by Africa, Asia, Australia, and Antarctica.

Table 1 indicates the area and average depth of the three ocean basins (including adjacent seas). Note that the Pacific Ocean encompasses the largest area and has the largest average depth of the three. We should caution that this separation of the oceans into three, distinct bodies of water is somewhat misleading, since the adjacent seas (e.g., the Mediterranean and Arctic) are often quite different from the major ocean basins in physical, chemical and biological characteristics. As partial evidence of this point, we also list in Table 1 the area and depth of the three ocean basins, excluding the adjacent seas. Note that in comparison with the Pacific and Indian Oceans, a much larger percentage of the Atlantic Ocean's assigned area consists of smaller seas. The neglect of these seas results in a more uniform average depth among the three major oceans, although the Pacific remains the largest and deepest on average.

In general, if one were to move seaward from the boundary between continent and ocean, one would first encounter a continental shelf, characterized by relatively shallow water with depth gradually increasing in the seaward direction to a maximum of the order to 200 meters. The continental slope would then be encountered, representing the transition structure from shallow to deep ocean, and characterized by an abrupt increase in water depth to the order of 3000 meters. One typically finds that the water depth will continue to increase away from the continent (although at a slower rate) to maximum depths of between 5000 and 6000 meters until reaching the spreading centers, or mid-ocean ridges discussed earlier. The water depth generally decreases toward the ridges to the order of 2000 meters.

This pattern of increasing depth away from the continents, followed by decreasing depth as the ridge axis is approached appears at first glance to be a contradiction to the theory of ocean basin formation explained earlier. If we are to accept the notion of a mid-ocean ridge, or zone of divergence, at which new ocean crust is continually being uplifted and forced out on either side of the ridge axis, we would expect to find shallow water depths along these axes, and symmetrically increasing depths as one approaches the continental land masses on either side. The reason for this apparent contradiction is the process of sedimentation, the deposition of land-derived sediments along the ocean floor. As one would expect, ocean regions most closely bordering the continents experience the highest rates of sedimentation, both through wind-driven atmospheric input as well as the more dominant mechanism of water-borne inputs at the coast. Rates of sediment accumulation in these regions vary considerably, but have typical magnitudes of several hundred meters (vertically) per million years on most continental shelves. The rate of sedimentation decreases by an order of magnitude on the continental slope, to tens of meters per million years. Finally, there is in general very little or negligible deposition in the deep ocean. Figure 1 illustrates a typical cross-section of the ocean floor as it exists today; the product of the combined actions of seafloor spreading and sedimentation.

SEA WATER PROPERTIES

As a forcing mechanism for both deep water and coastal motions, a tracer for the identification of water movements, and a critical parameter in the acoustic characteristics of ocean waters, density, ρ, is perhaps the most important seawater property to ocean engineers and scientists. In fact, many oceanographic calculations require a knowledge of the water density to an accuracy of 6 significant digits! In practice, the

TABLE 1
Area and average depth of major ocean basins

Ocean Basin	Area (10^6 km^2)	Average Depth (meters)
	Including Adjacent Seas	
Indian	74.917	3897
Atlantic	106.463	3332
Pacific	179.679	4028
	Excluding Adjacent Seas	
Indian	73.443	3963
Atlantic	82.441	3926
Pacific	165.246	4282

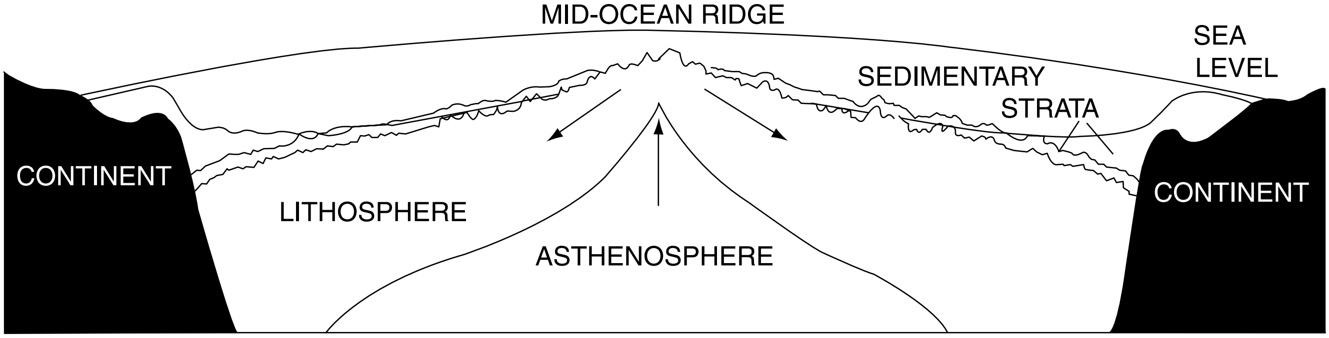

FIGURE 1 Typical seafloor cross-section (Sclater and Tapscott, 1979).

density is often related to the water salinity, S, and temperature, T, through an equation of state (e.g., Fofonoff, 1962).

In many oceanographic applications, the water density is expressed in terms of a sigma-t value, σ_t, which is a measure of the density at atmospheric pressure, $p = 0$. Furthermore, since very slight variations in water density can have significant physical, chemical and biological implications, the sigma-t values are tabulated in the form: $\sigma_t, = (\rho - 1) \times 10^3$. As an example, the density of sea water at 20°C and salinity 35% (35 parts per thousand) at atmospheric pressure is not written as $\rho = 1.024785$ g/cm^3, but rather as $\sigma_t = 24.785$.

The temperature distribution in the ocean, although highly variable in space and time, is generally characterized by a layer of relatively warm water at the surface, underlain by dense, colder water. Variations in deep ocean temperature, that is, excluding shallow coastal areas, can exceed 25°C, with a typical range of 20°C at the surface to 2°C near the bottom. These values exclude isolated aberrations such as the very saline, 56°C water found at the bottom of the Red Sea, and the hot springs ("black smokers") located along the mid-ocean ridges of the eastern Pacific, where fluid having temperatures as high as 350°C seeps through cracks in the diverging ridge axis (Edmond, 1986).

The dense bottom water in most cases originates in the polar regions, as we shall discuss later. Typically, the temperature of the surface layer is strongly dependent on surface atmospheric conditions (i.e., air temperature, solar intensity and wind speed). In the absence of strong vertical mixing, the temperature in this region decreases with depth in a region commonly referred to as the thermocline. Below the thermocline, the temperature is usually significantly more uniform with depth. Thermocline development varies in depth and duration with latitude. In the temperate regions, the thermocline is seasonal, developing only during the warmer months of the year, and achieving an average depth on the order of 100 meters. In the tropical regions, the thermocline is a relatively constant feature, with depths often exceeding 1000 meters. In both regions, periods of strong surface winds can induce vertical turbulent mixing sufficient to break down the thermocline and create a surface layer of uniform density exceeding several hundred meters in depth.

The salinity of the world's oceans is, in general, much less variable than the temperature, typically ranging from 33 to 37 parts per thousand. Exceptions include coastal regions, where rainfall and river runoff can add appreciable amounts of fresh water to the nearshore waters and reduce the salinity. In addition, tropical ocean regions tend toward higher salinity as a result of the high evaporation (which removes only fresh water) and low precipitation (which adds fresh water) rates relative to temperate ocean areas. Large variations in salinity can also occur in the polar regions. Ice formation, through its extraction of very nearly fresh water from the underlying ocean surface, results in the deposition of brine at the surface and the creation of a layer of very cold, saline water. Conversely, during ice melting, large amounts of fresh water are introduced to the surface layer, considerably reducing the local salinity.

OCEAN CIRCULATION

For the purposes of this discussion, we shall divide the currents that together comprise the oceanic circulation into two components, each distinguished by the forcing mechanism responsible for the water motion: 1) Wind-driven surface currents, and 2) Density-driven deep ocean currents. We shall follow these discussions with a brief examination of shallow water coastal circulation.

Wind-Driven Currents

The surface currents that describe much of the wind-driven ocean circulation are familiar to most readers. On the east coast of North America, the Gulf Stream carries warm water from off the coast of Florida northward to Nova Scotia, then running northeast and becoming the North Atlantic Current. In the Pacific Ocean, the Kuroshio carries warm water from a region south of Japan in a northeasterly direction, becoming the North Pacific Current.

Before discussing these and other features of the wind-driven ocean circulation, we should first examine the characteristics of the atmospheric circulation. Of course, this motion varies considerably in space and time, making any prediction of global synoptic wind patterns an extremely difficult, if not impossible, task. We can, however, derive some useful information by averaging the wind field observed at each latitude circle over many years. Figure 2 illustrates the resulting, long-term averaged wind characteristics. The following patterns are apparent:

1) Between latitudes 30°N and 30°S, there is a zone of easterly (from the east) winds, with an equatorward component, commonly referred to as the "Trade Winds".
2) Between latitudes 30°N and 60°N, and 30°S and 60°S, there exists zones of westerly winds, each with a poleward component.
3) Near each pole, there exists a zone of easterly winds, each with an equatorward component.

We note that the Trade Winds are a fairly consistent feature of the overall wind field, whereas the winds in the northern and southern zones are highly variable and often associated with large, transient storm systems. For this reason, the zones of westerly winds north and south of the Trade Wind zone are often referred to as the "Roaring Forties". Along the equator, at the convergence of the two components of the Trade Winds, lies a region of relatively light winds, commonly referred to as the "Doldrums".

Note that at the wind divergence located at 30°N and the wind convergence at 60°S, we can expect regions of anticyclonic (clockwise) wind gyres, whereas in the vicinity of 60°N and 30°S, we expect cyclonic (anticlockwise) gyres, as illustrated in Figure 2.

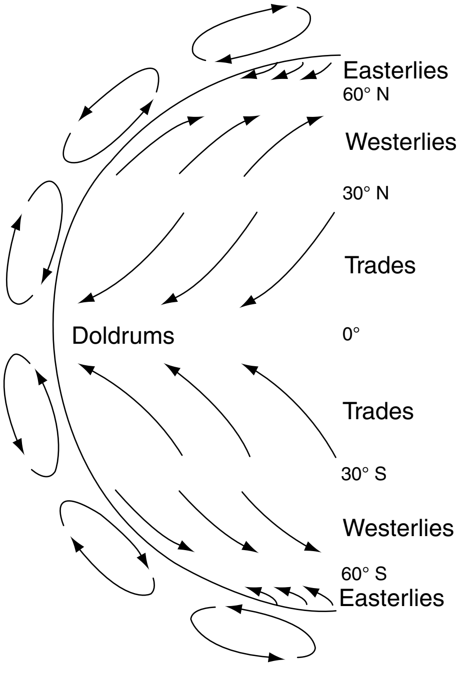

FIGURE 2 Long-term averaged wind pattern (Ross, 1982).

The long-term averaged surface circulation of the world's oceans bears a strong resemblance to the above described pattern of atmospheric motion, with some modifications due to the influence of the continental landmasses. The main features of this circulation are illustrated in Figure 3. Note especially the presence of wind-induced surface current gyres, as expected from our description of the atmospheric circulation.

We here depart from what has been up to now a purely descriptive treatment of the wind-driven motion, to examine the equations governing this air-sea interaction. For simplicity, and in the interest of generality, we shall here confine ourselves to the problem of a steady (constant in time), uniform (constant in space) surface wind blowing over an infinitely wide, infinitely deep, constant density ocean. For a much more detailed treatment of the complexities of upper ocean wind-driven dynamics, the reader is referred to Price *et al.* (1987).

In physical terms, our problem specification corresponds to a very large, relatively stationary storm system acting on the deep ocean (that is, excluding shallow, continental shelf areas).

The primary forcings acting on our water column, or vertical slice of the water body, are: 1) the surface wind stress; 2) the internal, turbulent shear stresses; and 3) the Coriolis "force".

The surface wind stress will be represented as a steady, uniform shear stress acting in the x-direction: τ^S. The internal turbulent shear stresses, which dominate over the viscous shear stresses, can be defined in a manner analogous to the viscous stresses, so that:

$$\tau_x = \rho A_v \frac{du}{dz},$$

$$\tau_y = \rho A_v \frac{dv}{dz},$$

where our coordinate system is defined in Figure 4. The quantities τ_x, and τ_y represent the horizontal (x and y) components of the turbulent shear stress. The quantities u and v are the x and y components, respectively, of the water velocity. Note that u and v are functions only of the vertical coordinate, z, because of our assumption of a steady, horizontally uniform wind stress. The constant, A_v, represents the turbulent eddy viscosity coefficient. Strictly speaking, A_v is a function of the turbulent flow field and should be modelled accordingly as another unknown in our system of equations (see, e.g., Blumberg and Mellor, 1983). In the interest of obtaining an analytic solution to the governing equations and so obtain useful information about the gross features of the wind-driven water motion, we shall here set A_v as constant. The quantity, ρ, is the (constant) water density.

The Coriolis "force" is not, strictly speaking, a force, but is rather the result of applying Newton's second law to the earth's rotating reference frame. In physical terms, this "force" causes a deflection of motion to the right (left) in the northern (southern) hemisphere.

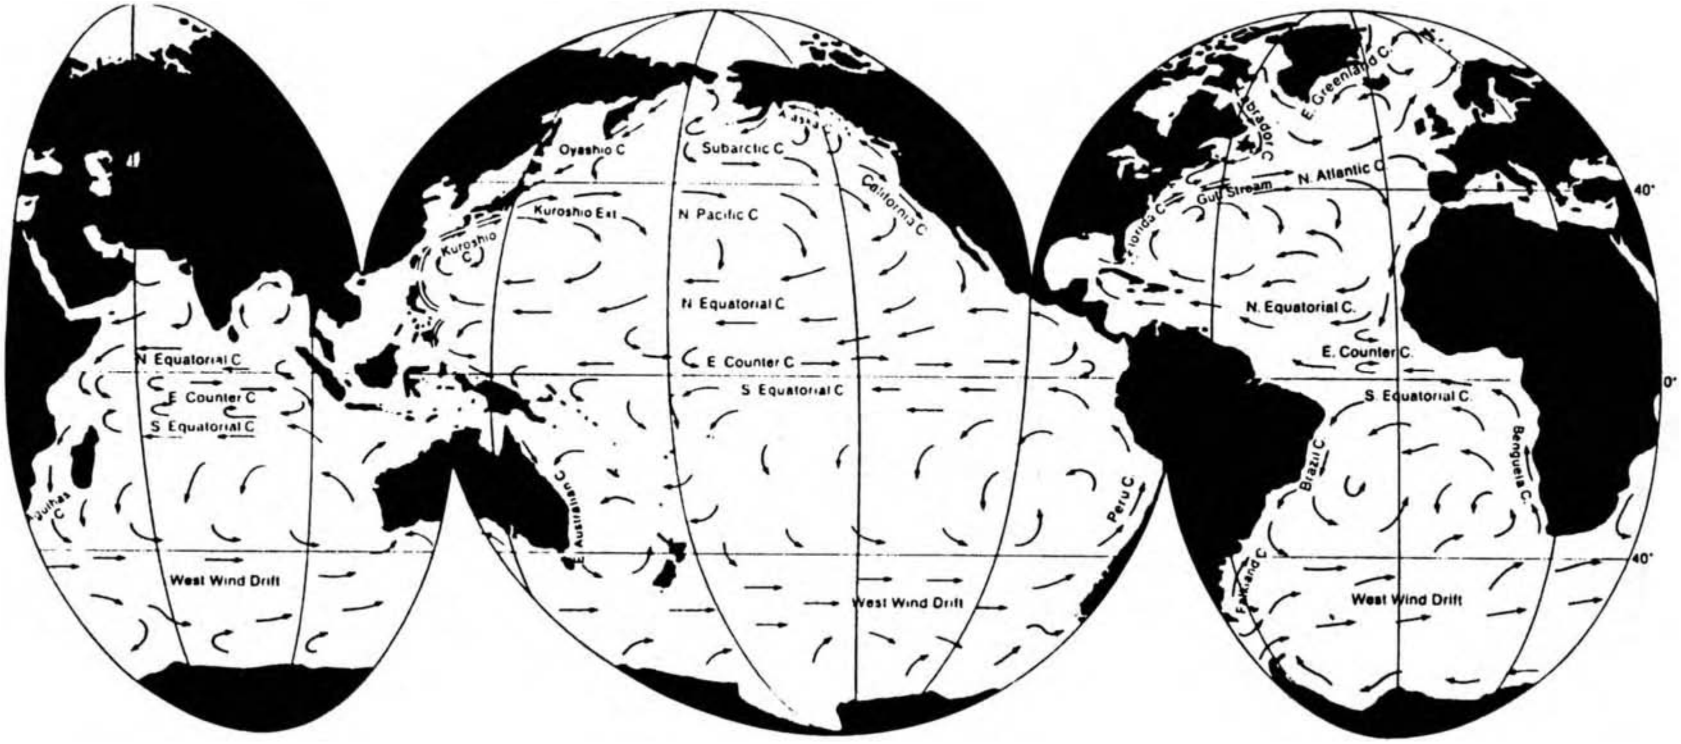

FIGURE 3 Long-term averaged ocean surface circulation (Ross, 1982).

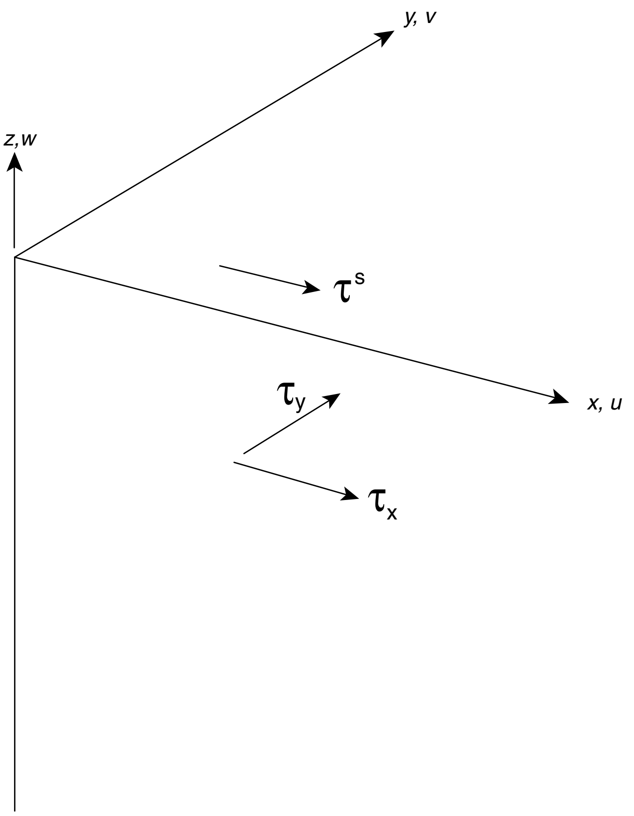

FIGURE 4 Coordinate system.

With the simplifications and assumptions described above, the Navier-Stokes equations governing the motion of a homogeneous ocean in the northern hemisphere become:

$$\rho fu = A_v \frac{d^2v}{dz^2},$$

$$-\rho fu = A_v \frac{d^2u}{dz^2},$$

where f is the Coriolis parameter, and is equal to $2\omega \sin\phi$, where ω is the angular velocity of the earth and ϕ is the latitude of interest.

The previous two equations can be combined to give two fourth-order differential equations, one for u and one for v. Solution of these equations requires knowledge of the boundary conditions for u and v. We specify that u and v must decrease to zero at infinite depth (i.e., as z goes to negative infinity). At the water surface, $z = 0$, we specify that the turbulent shear stress must equal the applied surface wind stress. With these boundary conditions, the solution of our equations becomes:

$$u = \frac{\tau^s}{\rho(A_v f)^{1/2}} \cos((f/2A_v)^{1/2} z - 45)\exp((f/2A_v)^{1/2} z),$$

$$v = \frac{\tau^s}{\rho(A_v f)^{1/2}} \sin((f/2A_v)^{1/2} z - 45)\exp((f/2A_v)^{1/2} z).$$

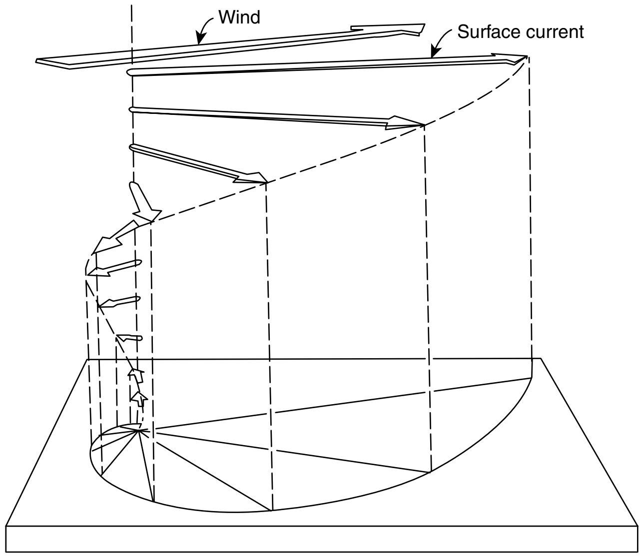

FIGURE 5 Vertical variation of wind-driven water motion (Gross, 1977).

Examination of our result illustrates that the water velocity decreases exponentially with depth from a maximum at the surface, while at the same time experiencing a rotation in direction. This vertical spiral, illustrated in Figure 5, is commonly referred to as the "Ekman Spiral", after V.W. Ekman, who first investigated the problem (Ekman, 1905). Note that the surface water velocity (i.e., at $z = 0$) is directed at an angle of 45° to the right of the wind direction (in the northern hemisphere). This theoretical result, obtained with several simplifications and assumptions, is not far removed from observations which indicate surface water motions directed at approximately 10° to 40° to the right of the wind direction. For a more complete theoretical treatment of this problem, including the effects of unsteadiness, and a varying eddy viscosity, the reader is referred to Madsen (1977).

A further interesting conclusion can be obtained by vertically integrating our expressions for u and v from the surface to the "bottom", z = negative infinity. The quantities thus obtained, U and V, represent the total volume flux of water in the x and y direction, respectively. Performing the integration, we obtain $U = 0.0$ and $V = -\tau^S(f\rho)$. This result indicates that the total water flux in the wind-driven water column (termed the "Ekman Transport") is directed 90° to the right (left) of the wind stress in the northern (southern) hemisphere!

Our solution for the Ekman Transport offers an explanation for the coastal phenomena known as "upwelling" and "downwelling". Clearly, if a wind acts along a coastline with the coast to the left (in the northern hemisphere), the total Ekman Transport will be directed in the offshore direction, with most of the flux occurring in the surface region of the water column (remember, the velocity decreases exponentially from the surface). Conservation of water mass dictates that this volume of water must be replaced, and this "replacement" water can only come from the offshore, bottom region. This process, known as upwelling, is actually much more complex than the general explanation given here, with the onset and subsidence dependent on many factors in addition to the surface wind magnitude and direction, including temperature variations and turbulent mixing (Send *et al.,* 1987). The phenomenon of downwelling is induced by the opposite forcing scenario, with the wind blowing along a coast with the shoreline to the right (left) in the northern (southern) hemisphere. Downwelling is characterized by a transport of nearshore surface waters downward and in the offshore direction.

Upwelling is of great concern to ocean scientists because of its potentially significant impact on climate and water quality. The offshore bottom water brought to the nearshore region is often nutrient-rich. This input of nutrients can have either beneficial or detrimental effects, providing sufficient food sources to support a large fisheries population (e.g., the Peruvian coastline) or promoting algal growth and deoxygenation in the coastal waters, as seen in the 1976 shellfish die-off along the coast of New Jersey (Swanson and Sindermann, 1979). The transport of relatively cold bottom water to the shallow nearshore region can also alter the heat exchange between the atmosphere and the ocean, with potentially significant consequences for the regional climate.

In our introduction, we alluded to the 1982–1983 El Nino event as evidence for the ocean's influence on climate variations. Generally speaking, an El Nino event is characterized by a warming of the coastal waters off the coasts of Peru and Ecuador. Under normal circumstances, these waters are held relatively cool by the upwelling activity typical of this region of the eastern Pacific. The atmospheric circulation of this area is characterized by what is commonly referred to as the Southern Osciollation: the seasonal shift in atmospheric surface pressure between the Australian Indian Ocean region and the southeastern Pacific. The Southern Oscillation has been shown to influence surface pressure, temperature and rainfall variations over much of the earth (Barnett, 1985). It has been postulated by many scientists that the disastrous effects of severe El Nino events (e.g., abnormal rainfall variations on a global scale) are due to the alternation of the Southern Oscillation by the nearshore surface warming along Peru and Ecuador. Although evidence of a direct connection between El Nino and alternations in the Southern Oscillation is by no means complete (Deser and Wallace, 1987), there is little doubt that the warming and cooling of ocean surface waters has a significant impact on atmospheric circulation, potentially on a global scale.

Density-Driven Deep Ocean Currents

The wind-driven ocean circulation, because of its forcing from an applied shear stress at the water surface, does not persist at great depth, as shown in our solution indicating an exponential decrease in velocity with depth. Using this solution, we can define an "Ekman Depth", or depth of influence of the surface wind stress as: $D_e = \pi(2A_v/f)^{1/2}$.

Depending on the magnitude of the turbulent eddy viscosity, A_v, and the latitude of interest, the Ekman Depth can vary from order of 100 meters to 1000 meters. Since the average depth of the world's oceans is approximately 4000 meters, one may be led to believe that the waters of the deep ocean remain motionless. However, quite the contrary is true. Measurements indicate that the oxygen content of the ocean's deep waters is much higher than would be expected for a motionless water volume, thereby indicating that motion does indeed occur at great depth. As alluded to earlier, water masses can be characterized by their temperature and salinity. This T/S structure can be employed to track specific water volumes from point of origin to final destination. Using this methodology, scientists have, over the last 200 years, identified several large scale, deep ocean flows.

The initial question in addressing the deep ocean transport of water masses must necessarily concern the identification of point of origin of specific water types. The two dominant water masses associated with deep ocean transport are North Atlantic Deep Water and Antarctic Bottom Water.

The first water type we will consider is Antarctic Bottom Water. This water is formed primarily on the south-west continental shelf of Antarctica (i.e., the Weddell Sea). During ice formation at the water surface, brine is expelled from the sea water, creating a layer of cold, highly saline water immediately below the ice. Because of its significantly higher density, this water sinks at the shelf break (the steep slope connecting the continental shelf with the deep ocean), and mixes with the relatively warm, saline deep water transported by the North Atlantic Deep Water current (discussed later). This mixture is more dense than either of the constituent water types, and therefore sinks toward the ocean bottom, becoming Antarctic Bottom Water. This water then moves in two directions, northward to the North Atlantic, and eastward around the Antarctic continent.

The second water type, North Atlantic Deep Water, is formed in the Norwegian Sea, which is separated from the Atlantic Ocean by a submarine ridge running from Greenland to Europe. We know that at the lower latitudes near the equator, the surface waters undergo considerably more heating and evaporation than those of the mid and high latitudes, where surface cooling and precipitation dominate. As one would expect, therefore, the surface waters of the lower latitudes are considerably warmer and more saline than those of the higher latitudes. The wind-driven Gulf Stream carries a large volume of this warm, saline water from the lower latitudes northward, some of it eventually being transported into the Norwegian Sea. This transport is sufficiently fast that the water remains highly saline relative to the surrounding North Atlantic water. As this saline water is cooled at the surface, it becomes increasingly dense, finally sinking to the bottom layers of the Norwegian Sea. This water then flows back into the North Atlantic over the submarine ridge mentioned earlier. Since the water depth at the ridge is only 800 meters at its deepest location, much shallower than the equilibrium depth of the very dense bottom water, this water flows over the ridge and down toward the bottom of the North Atlantic, falling thousands of meters much like an underwater waterfall. The water mixes with the surrounding water during its vertical flow, resulting in a very dense water mass, although not as dense as the Antarctic Bottom Water. The North Atlantic Deep Water therefore flows in a southerly direction, on top of the northward flowing Antarctic Bottom

Water, eventually reaching the South Atlantic and flowing eastward around Antarctica.

The travel time for the North Atlantic Deep Water to reach the Antarctic continent has been estimated as being on the order of 1000 years. Of course, we do not expect this water to remain unchanged during such a journey. Mixing processes alter the density of the water by mixing it with the less dense water overlying it. It is this gradual mixing, in fact, that creates the relatively warm, saline deep water which arrives at the Weddel Sea to be mixed with the cool, saline shelf water and form Antarctic Bottom Water.

Current speeds of the North Atlantic Deep Water and the Antarctic Bottom Water vary greatly. Maximum speeds as high as 20 cm/sec have been measured near the ocean bottom beneath the Gulf Stream (Pierce and Joyce, 1988). However, as indicated by the estimated travel time of the North Atlantic Deep Water, the average deep water current velocity is much lower, most likely on the order of 1 cm/sec.

Coastal Ocean Circulation

We have already discussed the generation of surface (wind-driven) and bottom (density-driven) currents, identifying the dominant, or best known, of each. Our examples, however, were confined to the "interior", or deep ocean regions, far removed from the shallow water areas that border most of the continents. As mentioned earlier, the coastal oceans are typically characterized by a shallow continental shelf, gently sloping seaward to a continental slope, which drops relatively abruptly to the deep ocean. Most seismically inactive areas, such as the eastern coast of the United States, possess a relatively wide (100–200 km) continental shelf, whereas seismically active areas, such as the Pacific coast of the United States, typically possess a very narrow shelf-slope region.

Coastal ocean regions differ from the deep ocean both in forcing and response. As one would expect, many of these differences arise from the relatively shallow water depths encountered along a continental shelf. Clearly, the surface wind stress is responsible for much of the coastal ocean circulation, especially the short term, highly variable components of the flow. However, the response of the water column differs from that of the deep ocean for the simple reason that the water depth is often considerably less than the "depth of penetration" of the wind stress, the Ekman Depth alluded to earlier. Since the wind-induced motion does not therefore decrease to zero before the ocean bottom is reached, the flow experiences a resistance due to skin friction and form drag over roughness elements on the bottom. For ocean circulation modelers, the estimation-parameterization of this bottom flow resistance is a formidable task. A knowledge is required, not only of the roughness characteristics of the bottom, but also the variation of these characteristics in both time and space as the sediments are influenced by near-bottom motions and bottom-dwelling marine organisms. For an excellent treatment of the complexities of the flow within the continental shelf "bottom boundary layer", the reader is referred to Grant and Madsen (1986).

Of course, the proximity of coastal ocean regions to land also influences the water circulation. In the vicinity of freshwater inflows, the nearshore circulation is altered by the presence of density-driven motions. Typically, the fresh water moves on top of the saline ocean water, eventually becoming mixed in the vertical and horizontal directions, primarily through wind-induced turbulent mixing. Before this mixing is complete, however, the horizontal and vertical density gradients will induce water motions, often quite different from those anticipated from the local (i.e., wind) forcing. As an example, the mean flow along the Middle Atlantic Bight (the continental shelf region running from Cape Cod south to Cape Hatteras) is toward the southwest, opposed to the mean eastward wind stress experienced in the area. Although still a topic of active research, the explanation for this flow appears to lie in the presence of a mean along shelf pressure gradient, quite possibly originating from freshwater input north of the region (Chapman *et al.,* 1986). The land boundary itself is also responsible for phenomena unique to the coastal ocean. Topographic variations, both in the horizontal plane and along the ocean bottom can induce secondary motions by virtue of the variation in flow resistance along the boundaries. These motions, as in the case of the density-driven flows mentioned previously, can often run counter to the local, primary forcing.

One of the most significant differences between the two types of coastal boundaries mentioned earlier (narrowshelf and wide-shelf) is the influence of deep ocean water motions on the nearshore circulation. As one might expect, narrow shelf areas are more prone to deep ocean forcing. For this reason, fluctuations in the location and magnitude of deep ocean surface currents (e.g., the California Current along the Pacific coast of the United States) can greatly influence the nearshore water motion, as can wind-driven upwelling events. Regions possessing a wide continental shelf, however, are characterized by quite different flow regimes. Recent evidence (Chapman and Brink, 1987; Chapman *et al.*, 1986) indicates that shallow continental shelves remain effectively isolated from deep ocean forcing. The circulation on these shelves is dominated by wind-driven motions, with tidal forcing and freshwater inflows (hence, density-driven currents) important, especially in nearshore areas.

We should here note that in regions of energetic deep water motions, the shelf and slope are occasionally influenced by these motions. As a case in point, continental shelf motions along the east coast of the United States can be affected by the northward flowing Gulf Stream. This influence takes the form of circulation cells, or eddies (commonly referred to as Gulf Stream Rings) shed from the Gulf Stream and driven toward the shelf region. As these short-lived eddies (typically 1–3 weeks, Lee and Atkinson (1983)) approach the shallow shelf-slope boundary, their forward motion is impeded by the bottom topography, thereby limiting their influence on inner shelf motions. However, the rotational motion of the eddies themselves can entrain extremely large volumes of shelf-slope water, removing this water out to the deep ocean and replacing it with Gulf Stream water (Garfield and Evans, 1987; Evans *et al.*, 1985).

WIND WAVES

In this section, we will treat the generation and characteristics of wind-induced surface gravity waves. These are waves formed at the air–sea interface by the action of a surface wind stress. The term "gravity wave" infers that the restoring force, or that force which seeks to restore the water surface to its equilibrium position, is the force due to gravity. An example of a different type of restoring force is the force due to surface tension. This force is actually the result of molecular attraction among water molecules, which, at the air—water interface, creates a net, adhesive force retaining the water molecules at the water surface. As one would expect, this force is only important in cases of very small scale motions, such as capillary waves, and is therefore unimportant for our purposes.

Early theories of wind-wave generation include the work of Kelvin (1871) and Helmholtz (1888), who examined the onset and growth of wave forms arising from instabilities at the interface of two fluids, each with different density and moving at different velocities. Although providing the basis for much of our present knowledge of flow instabilities and turbulence, the Kelvin–Helmholtz mechanism proved inadequate as a description of the onset of wind wave generation. The theory predicts wave generation only at surface wind speeds exceeding approximately 14 miles/hour, far greater than the minimum wind speeds required for wave generation observed in nature.

Jeffreys (1924, 1925) introduced what is commonly referred to as the "sheltering hypothesis" of wind wave generation. He proposed that the airflow over a previously rough water surface separates on the downwind sides of crests much the same as the flow separation observed in the lee of a cylinder. The resulting asymmetry in wind velocity leads to an asymmetric pressure distribution along the water surface, giving rise to a resultant force in the direction of the airflow. Theoretically, this pressure forcing will continue to add energy to the waveform as long as the velocity of the airflow exceeds the phase velocity of the wave.

Although providing valuable insights into the growth of wind waves, the sheltering hypothesis failed to address the critical question of the onset of wave generation because of its assumption of a previously rough water surface. This problem of wave generation on an initially smooth water surface was examined by Phillips (1957), who proposed that the initiation of wave formation is due to the presence of turbulence in the airflow overlying the water surface. Associated with this turbulence are random fluctuations in velocity, and hence, pressure. One can imagine that in areas of high pressure, the water surface will be depressed, whereas in regions of low pressure, the interface will, relatively speaking, rise, thereby creating a waveform at the air–water interface. Phillips proposed that the pressure fluctuations will continue to act on those waveforms having a phase speed equal to the speed of the turbulent pressure fluctuations, so that selective growth of only certain wave frequency components occurs.

Phillips' mechanisms was found to provide an excellent description of the initial stages of wind-wave formation. The problem of continued wave growth was addressed by Miles (1957). Using a model of shear flow instability similar to the Kelvin–Helmholtz theory mentioned earlier, Miles illustrated that a coupling exists between the airflow and the wave motion. In addition to the airflow doing work on the water surface, the perturbations in the water surface (i.e., the waveforms) can induce instabilities in the airflow. The energy transfer due to these instabilities in what is essentially a two-fluid shear flow is responsible for continued wave growth.

Although the Phillips–Miles mechanism for the initiation and growth of surface wind waves was proven quite accurate, measurements of the long-term evolution of wave fields indicated the importance of a third factor, the interaction among the individual wave components themselves. Recall from our previous discussion that selective generation and growth of different wave frequencies occurs, depending on the relative speeds of the wave forms and the turbulent pressure fluctuations overhead. The resulting water surface is therefore not characterized by a single, uniform wave form, but is rather composed of a multitude of wave components, each with a different frequency, amplitude, and wavelength. For this reason, wave data are typically analysed with the use of a wave spectrum (analogous to the color spectrum of optics), separating the observed sea into its various frequency or wavelength components. Phillips (1960) and Hasselmann (1962) illustrated that these individual components interact nonlinearly, resulting in a transfer of energy from the central frequencies of the spectrum to the high and low frequencies. As measurement and modeling techniques have improved over the last 25 years, functional relations for all of the forcing mechanisms mentioned here have been developed, and have led to the creation of quite accurate computer algorithms for the prediction of surface wind waves.

In seeking to describe the characteristics of a specific wave field, perhaps the most important relationship is the "dispersion relation", which defines the relationship between the wave frequency, ω, and the wavenumber, k:

$$\omega^2 = gk \tanh(kh),$$

where g is the acceleration due to gravity, h is the water depth, $\omega = 2\pi/T$, T is the wave period (time of travel of one waveform), $k = 2\pi/L$, and L is the wavelength. Figure 6 illustrates the most commonly used surface wave parameters.

The term, "dispersive," signifies that waves of different frequencies move at different phase speeds, $C = \omega/k$. Clearly, therefore, longer waves have higher phase speeds. Note also the dependence on water depth, h, with a given wave in deep water having a higher phase speed than the corresponding were in shallow water. Simply speaking, this depth dependence is responsible for the refraction of wave as they approach at an angle to the shoreline, with the portion of the wavetrain in deeper water leading that portion located in shallow water.

Several interesting observations can be obtained by examining the dispersion relation in the two limits of very deep and very shallow water depths. Note that "deep" and "shallow" water waves are defined by the water depth relative to the wavelength, as illustrated in the dependence on (kh). For this reason, a deep water wave is often termed a "short" wave and a shallow water wave, a long wave. In the case of short waves, we have a very large value for (kh) so that the quantity, tanh(kh) goes to unity and the dispersion relation

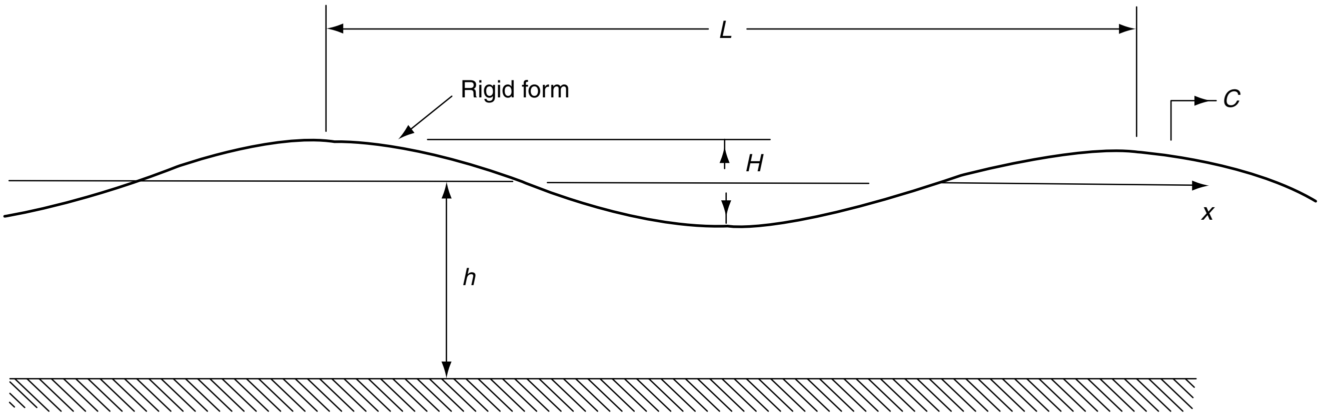

FIGURE 6 Definition sketch-surface water characteristics.

becomes: $\omega^2 = gk$. The wave characteristics (e.g., wavelength, phase speed, etc.) are therefore independent of depth.

For very shallow (long) waves, we have (kh) much less than one, so that tanh(kh) goes to (kh) and the dispersion relation becomes: $\omega^2 = gk^2h$. The wave characteristics are now strongly dependent on water depth. A further observation is that shallow water waves all move at the same phase speed, $C = (gh)^{1/2}$.

The two-dimensional fluid motion beneath a surface wave can be described by the following relations:

$$U = \frac{agk \cosh k(z + h)}{\omega \cosh(kh)} \cos(kx - \omega t),$$

$$W = \frac{agk \sinh k(z + h)}{\omega \cosh(kh)} \sin(kx - \omega t),$$

where U and W are the horizontal and vertical components, respectively, of the water motion; z is the vertical position of interest, decreasing from $z = 0$ at the surface to $z = -h$ at the bottom; and a is the wave amplitude, measured from the equilibrium, or still water level, to the wave crest.

Note that the wave-induced water velocities, U and W, are 90° out of phase, indicating that the fluid particle trajectories beneath surface waves are elliptical in shape. Since the value of $\sinh k(z + h)$ decreases to zero while $\cosh k(z + h)$ decreases to unity as one approaches the bottom ($z = -h$), the fluid motion becomes more and more horizontal with depth. Theoretically, at the bottom the wave-induced motion is purely horizontal.

Once again, if we examine the limits of shallow water and deep water waves, we can make some interesting observations. In the case of deep water (short) waves, we have very large (kh), and, noting that $\sinh(x) = \cosh(x)$ for large x, the particle trajectories are circular in shape. For shallow water, or long waves, we have very small (kh) so that the vertical velocity, W, is much smaller than the horizontal velocity, U, and the particle motions are almost exclusively horizontal.

We should caution that the equations noted here are derived from the linear form of the Navier-Stokes equations. That is, the non-linear, or convective acceleration terms have been assumed very small. This assumption is satisfied when the ratio of the wave height, $H = 2a$, to the wavelength, L, is very small: $H/L \ll 1$, or in physical terms, when the wave steepness is very small. For this reason, the equations listed here constitute a description of "linear," or "small amplitude" water waves. It follows that in regions where the wave steepness is relatively large (in the breaking wave zone, for example) our theory loses some of its accuracy, and one should be careful in its application. A classic treatment of the derivation of the governing equations for both linear and non-linear water waves can be found in Whitham (1974).

TIDES

Ocean tides can be described as the periodic rise and fall of the ocean surface. The forcing responsible for this motion is the gravitational attraction of the moon, sun and (to a much lesser extent) the other planets. Because of its close proximity to the earth, however, the moon plays the dominant role in tidal forcing.

A simple explanation for the generation of tides can be obtained from an examination of the earth-moon system. We know that the attractive force due to gravity is inversely proportional to the square of the separation distance between two bodies: $F \propto 1/d^2$. For this reason, the ocean surface closest to, or facing the moon experiences a much higher attractive force than does the ocean surface on the opposite side of the earth. The water surface on the opposite side of the earth. The water surface facing the moon is therefore "pulled" toward the moon. At the same time, the attractive force of the moon "pulls" the entire earth from under the ocean surface on the opposite side of the earth. The net result, therefore, is an increase in water surface elevation on both the side of the earth facing the moon and the side opposite. Two peak tides are therefore created at the same time on opposite sides of the earth. Since the earth rotates once in 24 hours, we expect two high tides and two low tides each day. However, the cycle, or lunar day is actually approximately 24 hours, 50 minutes, so that each day the high and low tides occur approximately 50 minutes later.

Of course, the above description of the generation of ocean tides is rather simplistic. In actuality, we have the additional influences of the sun and planets, sometimes enhancing and sometimes reducing the moon-induced tide. Perhaps more importantly, variations in ocean water depth greatly influence the movement of the tidal "wave", this influence becoming very apparent in the continental shelf-slope region. In spite of the these complexities, we have at the present time an excellent understanding of the physics of tide generation and tidal wave propagation. Tide prediction algorithms have been developed and proven surprisingly accurate among much of the world's coastlines. Of course, accuracy is a relative word and should be measured against the requirements of ocean scientists. As these requirements dictate still more accurate tidal elevation predictions, new algorithms must be developed. An example of such a development is the recent work in spectral modelling of shallow water tidal wave propagation, with accuracy in sea surface elevation of the order 2 centimeters (Vincent and Le Provost, 1988).

Recent Advances in Oceanographic Research The global impacts of El Nino events have become more clearly defined in the interval since this article first appeared. The need to develop models for prediction of El Nino occurrences became obvious following the severe event in 1982/83 and the even stronger one in 1996/97. There has been a significant effort to integrate advances in observations from satellites (with coverage of the global ocean) with *in situ* measurements from ships and buoys and to incorporate these into coupled numerical models of the climatology of the ocean and atmosphere. The evidence seems compelling that the occurrence of El Nino is closely associated with the oscillation in sea level pressure between the western and central regions of the tropical Pacific Ocean. A non-dimensional index of this oscillation is found by subtracting the measured pressure in Darwin, Australia from that measured in Tahiti and then dividing by the standard deviation of this pressure difference obtained from the long term records at these locations.

Under conditions without an El Nino this index is generally slightly positive but can undergo reversals of sign. During significant El Nino events this index becomes strongly negative, indicating that the typical low pressure on the western side of the tropical Pacific has changed dramatically.

Conceptually, during normal years the strong easterly trade winds move warm surface water into the western portion of the Pacific with much cooler water occurring along the west coast of South America and extending into the Eastern Equatorial Pacific. The elevation of the sea surface is about 0.5m higher near Indonesia than off Ecuador. Prior to the onset of El Nino the east to west pressure gradient along the equator diminishes as the Southern Oscillation Index becomes negative. As a result the trade winds diminish (even reversing direction) and the warmer surface water in the western tropical Pacific moves eastward eventually warming the near surface waters along the equator and the west coast of South America. The effects of the occurrence of an El Nino on weather are significant and on a global scale. Following an El Nino there can be an over recovery with stronger trade winds and more intense upwelling of colder deep water along the Peruvian Coast. This La Nina is associated with a positive Southern Oscillation index and has important global effects as well. The connection of El Nino and the Southern Oscillation is sufficiently strong to give rise to the acronym ENSO to denote these two phenomena and their interconnections.

Another large scale oscillation has been detected for the North Pacific Region. Termed the Pacific Decadal Oscillation, PDO, it is chiefly characterized by an alternation of a warm phase with a cool phase, with time scales of 2–3 decades. During the warm phase, sea surface temperatures in the central North Pacific are lower than average with warmer than average temperatures occurring along the west coasts of North and South America. For the cool phase these anomalies reverse with cooler water occurring along the west coast and the central region sea surface temperatures being warmer than average. Although there is no persistent connection between the PDO and ENSO the most severe El Nino events have all coincided with the warm phase of the PDO.

Observations of the oceanographic and meteorological conditions at the sea surface on a global scale from satellites have become increasingly useful. An example of this is provided by the 12 year success of the measurement of the dynamic topography of the sea surface using a high frequency radar altimeter and sea surface temperature using a microwave radiometer onboard the Topex Poseidon satellite. The technical difficulties in the accurate determination of sea surface topography are formidable. The position of the satellite relative to the Earth must be accurately known, the earth's geoid (the level surface most closely aligned with mean sea level) must be well defined and the effect of open ocean tides must be removed from the observations. The Topex Poseidon satellite repeats observations over the same oceanic region once every 10 days and during that period it collects data from 95% of the ice free global ocean. The reported accuracy of the departures of the mean elevation of the sea surface from the geoid is about 0.04m. Thus, the change in elevation of the sea surface across the Gulf Stream of the order of 1.0 meters is easily discerned. Given the spatial distribution of sea surface elevation, $\varsigma(x, y)$ then the surface geostrophic current components, u and v, in the x and y directions respectively are found from the following equations expressing the near balance between the Coriolis force and the component of gravity along the sloping isobaric sea surface:

$$fu = -g\,\partial\,\varsigma(x, y)/\partial y\;,\quad fv = g\,\partial\,\varsigma(x, y)/\,\partial y\;,$$

where g is the acceleration of gravity and f is, as before, the Coriolis parameter. The observations from the Topex Poseidon satellite provide estimates of the geostrophic currents at very high spatial resolution and with a temporal resolution of 10 days. These data are useful since surface currents measured directly are in substantial agreement with the calculated geostrophic currents. The 12+ year mission of this satellite (1992–2005) allowed for detailed observations of development and time history of the very intense ENSO event in 1997/98 and the subsequent La Nina. In addition to radar altimeter observations other satellite borne instruments have been used to map the distribution and evolution of sea surface temperatures using infrared radiometers, to estimate surface wind stress over the sea and ocean surface wave characteristics from scattering of microwave radars.

More conventional observational techniques are required to monitor subsurface distributions of temperature, salinity, and currents. A consequence of the intense ENSO event in 1982/83 was the recognition that atmospheric and oceanographic processes in the tropical Pacific were important precursors of such events. One result of this was the initiation of the ten year international Tropical Ocean Global Atmosphere, TOGA, program and the deployment over this period of an array of instrumented buoys called the Tropical Atmosphere Ocean, TAO, array and presently the TAO/TRITON array. The present array of 67 buoys are deployed along eleven longitudinal transects from 135°E to 95°W with coverage from 8°N to 8°S. Measurements include air temperature, relative humidity, barometric pressure, long and short wave radiation, wind velocity, together with sea surface and subsurface temperatures to a depth of 500m. Buoy data are transmitted in near real time via satellite.

An important feature of extensive ocean observation programs such as TOPEX POSEIDON and TAO/TRITON is the widespread and timely dissemination of data products via the Internet. The Pacific Marine Environmental Laboratory of the National Atmospheric and Oceanic Agency manages the TAO array and is responsible for data quality control and availability. TAO data may be obtained from the Internet site http://www.pmel.noaa.gov/tao/jsdisplay/. The Physical Oceanography Distributed Active Archive Center, PODAAC, of the NASA Jet Propulsion Laboratory at the California Institute of Technology provides data management for a variety of satellite observations of the ocean and atmosphere. These data may be accessed at the Internet site http://podaac.jpl.nasa.gov/. The development of numerical models of the ocean and of the atmosphere began in the 1950s. Increases in computer power and in global observational programs have led to a steady evolution of such models into useful predictive tools. One significant recent development has been the creation of fully coupled atmosphere and ocean climatological models. One example of this model development is the Community Climate System Model, CCSM, developed by the National Center for Atmospheric Research. It includes the atmosphere, the ocean, the land areas, and regions of sea-ice. All are coupled by computing fluxes between them. This model is an example of a recent trend in oceanography (and other sciences) to make models readily available to the "community" of potential users. In the case of CCSM it is available online from its web site together with user manuals and other aids for its successful implementation. The CCSM has demonstrated its predictive skill through comparison with observed climatic variability. A particular example is its ability to hindcast recent El Nino events with reasonable accuracy.

OIL SPILLAGE INTO WATER—TREATMENT

The general subject of treatment of oil spillage represents a relatively new area of technology that is unique in that it encompasses chemical, mechanical, and biological disciplines. There are three major aspects to the problem of oil spills.

1) PREVENTION OF THE SPILL;
2) CONTAINMENT AND RECOVERY OF THE SPILL;
3) TREATMENT OF THE SURFACE OIL.

Although this discussion is mainly directed toward the treatment of the spilled oil, the related areas will also be considered in order to put the overall subject in the correct perspective.

PREVENTION OF THE SPILL

The Prevention of Oil Spillages is the Primary Consideration

It should be emphasized that prevention is the first consideration and, of course, the most complete solution. In the industrial and governmental communities, the major effort has been directed toward this area. There is extensive ongoing research for example, ranging from operational areas such as collision avoidance techniques and training to more novel approaches such as the gellation of crude oil. In this latter approach several chemical systems have been developed to gel the oil cargo. This in-situ solidification thereby prevents the release of oil from a damaged cargo compartment that may be in danger of failure.

Details of this gellation system can be found in US Patent 3,634,050.[1] Other details, such as the effects of mixing, crude oil type, chemical concentration, and so on, on the strength of the gel have been outlined by Corino.[2] Gellation is a novel approach to prevent the release of oil. However the fact that there have been no commercial uses of this method since its conception twenty five years ago raises questions regarding its practicality.

Finally, the removal of the oil cargo from a grounded tanker is another area where the threat of the release of a fluid and mobile oil cargo to the marine environment has been mitigated by advances in salvage techniques. The offloading of the grounded SS General Colocotronis on a reef off Eleuthera Island in March–April 1969 and the well documented recovery of Bunker C oil from the sunken tanker SS Arrow in Chedabucto Bay, Nova Scotia during the winter of 1970[3] are two outstanding examples of this prevention technique.

This latter incident represented a singular achievement in light of the weather conditions encountered during early March in Nova Scotia. Over 6000 tons of viscous Bunker C oil were recovered from the sunken wreck. The salvage team used a hot tap technique to penetrate the tanker cargo tanks and then used a steam traced pumping system to transfer the oil to a barge at the surface.

A more recent and massive removal of oil was the EXXON VALDEZ in March 1989 after its grounding on a reef in Prince William Sound. Although approx 250,000 Bbls of North Slope Crude oil was spilled from the grounded vessel, 80 percent of its cargo was still in the tanker. This offloading was a significant marine engineering feat since care must be taken to offload such a large vessel in the correct sequence since otherwise hull stresses could cause the vessel to break up.

CONTAINMENT, RECOVERY OR REMOVAL OF THE SPILLED OIL

If a spill has occurred, it is universally agreed that the recommended procedure is to contain and physically recover it with or without the use of adsorbents. It is obviously the most direct solution to spill incident, if conditions permit its execution. This approach may entail three processes:

1) Confinement of the spill by spill booms.
2) Recovery of the spill by sorbing agents. In this area, more recent advancements have been solidifying agents (Solidifiers).
3) Physical removal of the contained oil by oil pickup devices.
4) Controlled burning of spilled oil.

These aspects of the recovery approach are interrelated as will be appreciated by the following discussion.

Confinement of the Spill by Spill Booms There are many oil spill booms commercially available today. Unfortunately they are significantly limited by the velocity of the surface current and wave height. Although there are variations in the materials of construction, strength, geometry, etc., of these various boom designs, as evidenced by the number available and the range of costs, their general forms are quite similar. Almost any type of floating barrier will hold back and contain some amount of oil under quiescent

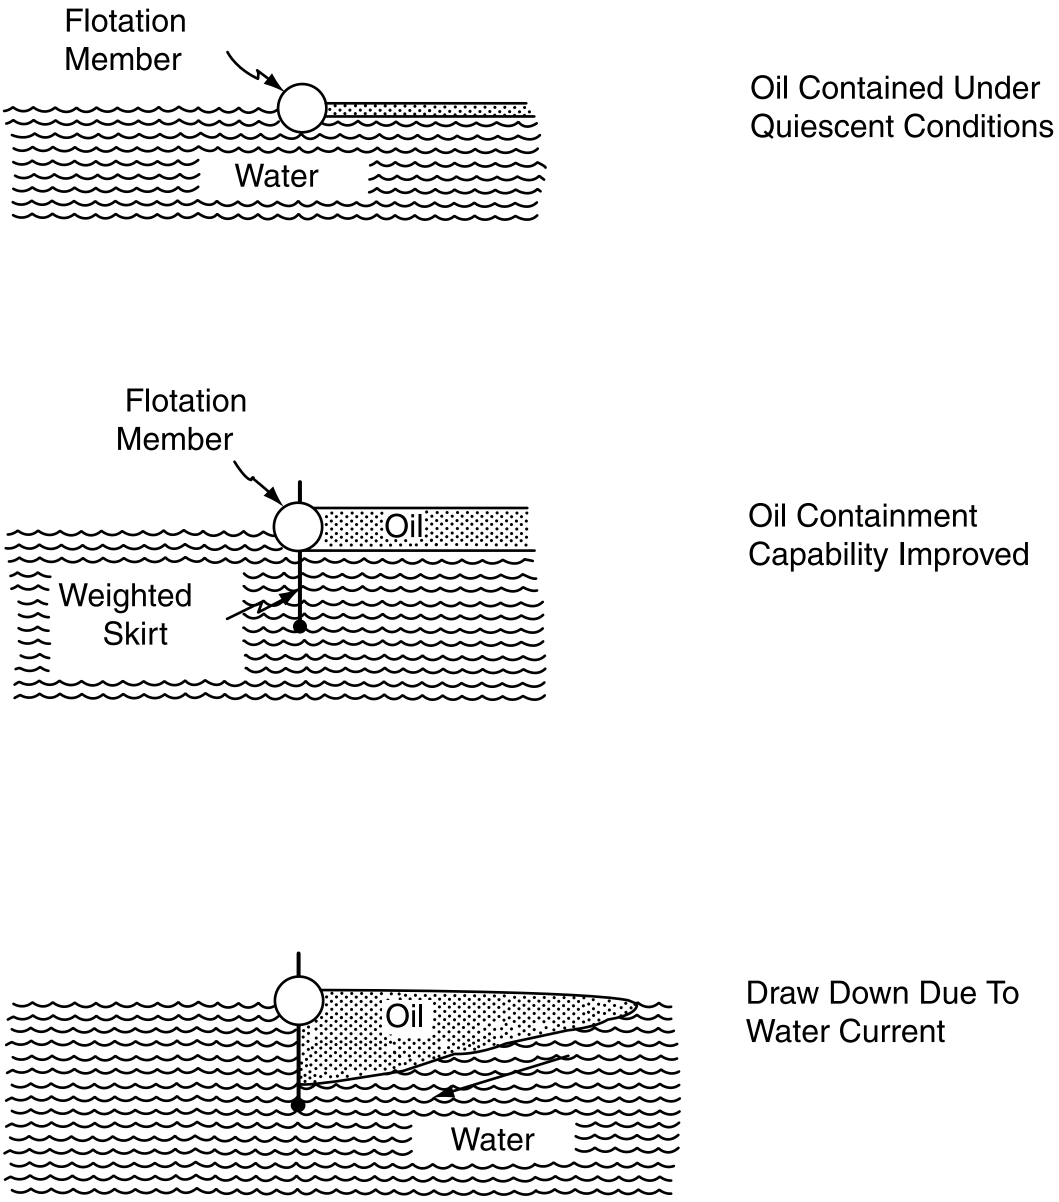

FIGURE 1 Mechanical boom principle.

conditions. Indeed, telephone poles have been employed in more than one spill instance as a jury rig emergency measure. To improve the capacity of such a floating barrier, a weighted skirt is hung from the flotating member illustrated in Figure 1. Design requirements for spill booms have been published by Lehr and Scherer[4] and Hoult,[5] among others. By a rather cursory inspection of Figure 1, we may now appreciate some of these requirements such as:

Sufficient freeboard to prevent overtopping by waves; Adequate skirt length below water surface to confined a sufficient quantity of oil;

Adequate flexibility to permit the boom to bend under wave action and maintain its retention of the oil spill;

Sufficient mechanical strength to withstand the forces imposed by the environment.

Some of the difficulties of oil retention against the action of a steady current are illustrated in Figure 1. A discussion of draw down phenomena by Hoult[6] outlines that a gradient in oil thickness, h, is established by the stress imposed by the current flow. There is, based on the fluid dynamics of the contained volume of oil in the presence of a water current, a limiting water velocity above which oil droplets are entrained and flow underneath the barrier.

The deployment of the above described mechanical booms is also an important consideration. In the event of a spill, the speed of response is, of course, most critical. Hence,

TABLE 1
Boom Classification

	Hs Maximum		Freeboard		Draft	
Environment	ft	meters	inches	centimeters	inches	centimeters
Calm Water	1	0.3	4–10	10–25	6–12	15–30
Harbor	3	0.9	10–18	25–46	12–24	30–61
Offshore	6	1.8	>18	>46	>24	>61

easily deployed lightweight booms are desirable. However, these desired properties are not necessarily consistent with making booms stronger and more capable of withstanding severe sea conditions.

These are the criteria and mechanism of operation of oil spill booms. It is beyond the scope of this chapter to present the many commercial and changing commercial products. In the world Catalog of Oil Spill Response Products, booms have been divided into three categories based on maximum operating significant wave height (Hs). Table 1 shows the ranges of freeboard and draft corresponding to the expected maximum waves. A boom size can thus be selected based on the expected environment.

In the *World Catalog of Oil Spill Response Products,* booms have been divided into three categories based on maximum operating significant wave height (Hs). Table 1 shows the ranges of freeboard and draft corresponding to the expected maximum waves. A boom size can thus be selected based on the expected environment.

Boom Selection Matrix The selection of a boom depends on how rapidly it is needed and how readily it can be utilized. Deployment speed and ease relate to the number of people, the amount of time, and any special equipment (Winches, etc.—even wrenches) necessary to move the required amount of boom from storage to the launch site, to deploy it, and to position it around the spill. For example, self-inflatable booms can be deployed very rapidly either from reels or bundles. Experience has shown, however, that this rapid response boom should be replaced by a more rugged boom if extended deployment is required. Thus, deployment ease must often be traded off against ruggedness and durability.

The matrix shown in Table 2 can be used to select the optimum boom for a specific application since it indicates:

- Generic types of boom that are most suitable in a given environment
- Selected booms that have the most needed performance characteristics
- Choices with the most desirable convenience features.

Excess or reserve buoyancy is the surplus of flotation over boom weight as deployed, and is a measure of resistance to boom submergence. Wave response is a measure of conformance to the water surface and is usually improved by increasing boom water-plane area and flexibility. Other characteristics should be evident from the headings.

To use the matrix correctly, follow these steps:

1. Identify the most probable environmental conditions in which the boom will be used. Note those types of booms with an acceptable rating (1 or 2).
2. Identify the most needed performance characteristics for the intended application. From the booms chosen above, select the ones that have an acceptable rating (1 or 2) in the most important performance characteristics.
3. Identify the most desirable convenience features. With booms from steps 1 and 2 above, select the boom with the best rating in the convenience features of interest.

These data (Table 1 and 2) were extracted and used with the permission of EXXON from a very informative OIL SPILL RESPONSE FIELD MANUAL by Exxon Production Research Company published in 1992.

Recovery of the Spill by Sorbing Agents A most direct manner of physically removing the spilled oil is by use of sorbents. These materials are buoyant, and preferentially wetted by and adsorb oil. In essence, they permit this sorbed oil to be physically "picked up" from the water. In addition to making the collection of oil an easier task, the oil is prevented from spreading and remains as a more congealed mass.

Materials that have been found useful for this service vary from simple, naturally occurring materials such as straw, sawdust, and peat to synthetic agents, such as polyurethane foam and polystyrene powder. The oil pickup capability varies greatly. For example, values of oil pickup, i.e., weight of oil sorbed per weight of adsorption material, have been reported by Struzeski and Dewling[7] for straw as 3 to 5, although higher values have been reported. Polyurethane foam, by comparison, is capable of oil pick up values of 80. A complete investigation of sorbents for oil spill removal has been published by Schatzberg and Nagy.[8] Of interest is the variation in the oil pickup capability of a given sorbent based on the type of spilled oil. For example, in Schatzberg's controlled tests, oil pickup by straw was 6.4 for heavy crude oil and 2.4 for light crude oil. For urea formaldehyde foam, however, oil pickup was 52.4 for heavy crude and 50.3 for light crude. Also some

Notes:

* Hs = Significant Wave Height.

* V = Velocity of Surface Current.

Not *all* the booms of a particular generic type have the rating shown in the matrix. But at least one or more commercially available booms of the generic type in question have the rating shown.

* Specially-designed high-current models may be available (river boom).

sorbents are much less effective for oil adsorption if contacted by water prior to application to the spill.

Although highly effective sorbents are available as noted above, techniques for harvesting (recovering) the oil soaked sorbent have been limiting. For example, there have been prior instances of oil soaked straw recovery by manual pickup with pitchforks. However, there is development work underway to mechanize this step as well as the application procedure. In this regard, some very practical observations on the use of sorbents have been made by an IMCO subcommittee on Marine Pollution. This guidance manual outlined that "the use[9] of absorbents involves six basic operations, the supply, storage, and transportation of the material and then the application, harvesting and disposal of the contaminated absorbent." The manual further observes that some of the early applications of sorbents such as the Torrey Canyon and Santa Barbara suffered because of the lack of effective and efficient harvesting techniques.

More recently, since the early 1990s a new approach to oil pickup was conceived by the use of SOLIDIFIERS.

Solidifiers are products which, when mixed with oil, turn the oil into a coherent mass. They are usually available in dry granular form. Unlike sorbents that physically soak up liquid, solidifiers bond the liquid into a solid carpet-like mass with minimal volume increase, and retain the liquid for easy removal. The bonded material also eliminates dripping-sponge effect by not allowing the material to be squeezed out, minimizing residue or contamination. Some polymers, in sufficient quantity or of high molecular weight, can actually convert the oil to a rubber-like substance.

Solidifiers are most commonly used during very small oil spills on land or restricted waterways to immobilize the oil and enhance manual recovery. There has been little documented use of solidifiers on large spills or open water. However, the possibility that they may reduce the spread of waterborne oil by solidifying it and increase recovery and removal rates is a concept with significant potential benefit.

The effectiveness of a solidifier is based on the amount of product and time it takes to "fix" a given volume of oil. The less effective products require larger amounts to solidify oil. Fingas *et al.* (1994) presented results from effectiveness tests on various solidifiers and found that generally between 13–44 percent by weight of the product to oil was required to solidify Alberta Sweet Crude over a 30-minute period.

The entire treatment of solidifiers as an aid to oil spill response is well covered in an MSRC publication.[10]

Physical Removal of the Contained Oil by Oil Pickup Devices Since oil containment booms have a fixed capacity for oil spill containment, it is important to consider means to physically remove the contained oil from the surface. The use of sorbents has been discussed. An alternate approach is to remove the fluid oil by means of skimming devices.

Oil skimmers have been divided into five categories:[11]

- Oleophilic surfaces (belts, disc, ropes, and brushes, either acting independently, mounted on a vessel or used in combination with a boom)
- Weirs (simple, self-leveling, vortex assisted, auger assisted, vessel-mounted, and weir/boom systems)
- Vacuum units (portable units and truck-mounted units)
- Hydrodynamic devices (hydrocyclone and water jet types)
- Other methods (including paddle belt and net trawl).

The selection of the optimum skimmer for a particular spill is based on site conditions such as the sea state and characteristics of the spilled oil e.g. viscosity and emulsion-forming tendency.

There are over 100 commercially available skimmers on the market that fall within the generic types previously mentioned. These are summarized in publications such as the WORLD CATALOG OF OIL SPILL RESPONSE PRODUCTS.

For example, for the principle of oleophilic surfaces, these can comprise either a sorbent belt, an oleophilic rope or a solid oleophilic disc that rotates through the surface oil film. In heavy sea conditions this type would be more effective than a wier type that is more suited to protected in-shore areas.

Controlled Burning of the Spilled Oil Burning represents a surface treatment of an oil spill that is attractive in that the oil is essentially removed from the water. However, some of the negative aspects of this approach that have hampered its widespread acceptance and use may be summarized as follows:

In many spill instances, there is an obvious concern regarding the combustion of the oil for safety reasons. Spills near harbors, tankers, offshore platforms would create an obvious hazard if set afire.

A minimum thickness of oil is required to establish combustion.

Air pollution is a concern in some instances. There is continuing evaluation and development burning of agents.

As reported by Alan Allen,[12] there are fire retardant booms and ignition methods available to burn the oil under proper conditions e.g. oil film thickness and amount of emulsified water in the oil. An effective burn after the EXXON VALDEZ spill on Sat. March 25, 1989 was reported by Allen in this publication.

The very encouraging burn rate statistics suggest that only 2% of the original relatively fresh oil remained as residue.

In this regard, it is relevant to quote the author of this publication in its entirety because of its concise and sufficient analysis of this technique by one well recognized in this method.

"It should be recognized that the elimination of spilled oil using in-situ burning must be considered in light of the full range of potential impacts (safety, air quality, etc.) associated with the burning of oil an water. The mechanical removal of spilled oil is by far the preferred cleanup technique whenever possible. Burning, on the other hand, may provide a safe, efficient and logistically simple method for eliminating oil under certain conditions. As a backup for mechanical cleanup techniques, in-situ burning can provide a useful means of eliminating large quantities of oil quickly, while avoiding the need for recovered oil storage containers. Anyone considering the use of burning should be sure that all regulatory controls have been satisfied, that the ignition and burning operations can be carried out safety, and that the temporary reductions in local air quality represent the lower of all other environmental impacts should the spilled oil not be burned."

TREATMENT OF THE SURFACE OIL

Chemical Treatment of Surface Oil Should Be Considered as an Alternate Solution

It is generally agreed, as indicated above, that situations can arise where the spill cannot be contained and recovered because sea conditions, weather state, and so on, are beyond the current operating capability of containment devices. There are also instances wherein the logistics of containment and recovery equipment, that is, containment boom availability and/or deployment time and effort, could indicate chemical treatment as the most practical and expedient handling technique. When physical recovery of the oil pollutant is impractical, there are, in effect, two courses of action possible. In one case, the oil may be permitted to remain as intact cohesive slick on the surface of the water and possibly reach shore. The alternate course is to "treat" this surface oil—such treatment essentially directed toward the removal of the oil from the water surface and the enhancement of its ultimate removal from the environment. This many be accomplished by chemical dispersion.

The Ecological and Economic Damage Caused by an Untreated Oil Spill Can Be Extensive

The damage resulting from an untreated oil spill is both visually apparent and extensive. It encompasses both biological as well as property damage. The potential damage may be summarized as follows:

Marine fowl, particularly diving birds, are particularly vulnerable to an oil spill. As reported by Nelson-Smith,[13] sea birds are most obvious victims of an oil spill due to "mechanical damage." The oil penetrates and clogs the plumage which the bird depends upon for waterproofing and heat insulation. For example, a duck with oil-impregnated plumage is under the same stress at a moderate temperature of +59°F as a normal bird would be under a more severe temperature condition at –4°F. Some statistics regarding bird damage have been cited by McCaull.[14] More than 25,000 birds, mostly guillemots and razorbills, were killed after the Torrey Canyon grounding. The guillemot casualties equaled the entire breeding stock between the Isle of Wright and Cardigan Bay. Bird losses in the Santa Barbara spill, according to the state Department of Fish and Game, totaled 3500.

Shore contamination by beached oil represents biological, as well as property damage. The tendency of oil to cling to shore surfaces, such as beach sand, sea walls, and the resultant property damage, are well established. This is perhaps the most apparent and widely publicized damaging aspect as attested by lawsuits on the part of tourist interests, property owners, etc. There is also, in a biological sense, a physical smothering effect on some attached, intertidal organisms such as mussels and barnacles. The effects of untreated oil coming ashore is well illustrated by Blumer *et al.*[15] regarding a No. 2 diesel fuel spill from the barge Florida in Buzzards Bay, Massachusetts in September 1969. Oil was incorporated into the bottom sediment to at least 10 meters of water depth, testifying to the wetting effect of untreated oil in this instance, the oil was physically dispersed by the heavy seas but retained its adhesive characteristics. Therefore, it is deduced that the oil droplets probably came into contact with and wetted and upswept, suspended particulates which later settled again to the bottom. Other spill instances depicting the importance of this aspect that of the incorporation of oil into the sediment-have been reported by Murphy.[16] In the Buzzards Bay and several other spill incidents of distillate fuels cited by Murphy, there has been a significant kill of all marine life in the area since these highly aromatic products are known to be much more toxic than whole crude oil.

Persistent tarry agglomerates are formed as the spilled oil weathers at sea. There has been increasing attention directed to the presence of tar-like globules ranging up to 10 cm in diameter in the open sea. As reported by Baker[17] during the voyage of Thor Heyerdahl's papyrus boat, Ra, during five separate days, they sailed through masses of these agglomerates whose age could be substantiated by the growth of goose barnacles adhering to them. There have been other incidents reported recently by the International Oceanographic Foundation[18] and a well documented survey was made by the research craft, R.V. Atlantis, as reported by Horn *et al.*[19] In this latter investigation, tarry agglomerates were present in 75% of over 700 hauls with a surface skimming (neuston) net in the Mediterranean Sea and eastern North Atlantic. The amount of tar in some areas was estimated at 0.5 milliliter in volume per square meter of sea surface.

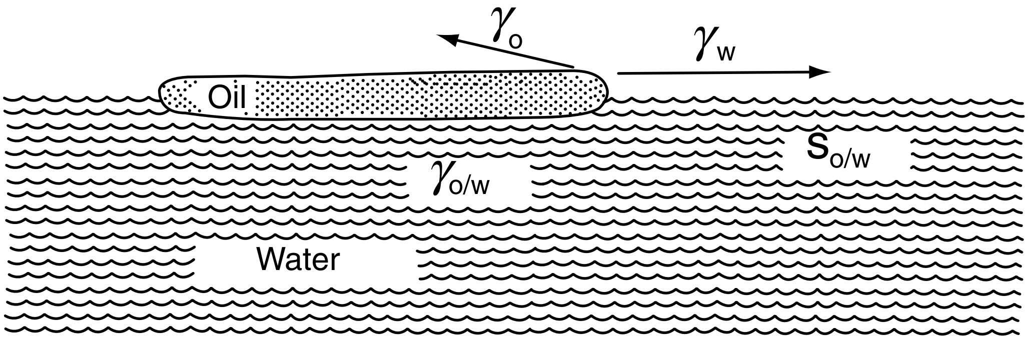
The Behavior of Spilled Oil at Sea

Before consideration of the mechanism of dispersing oil and its associated effects, an understanding of the behavior of spilled oil at sea will be useful. When a volume of oil is spilled onto the surface of water, the oil has a driving force to film out or spread-in essence, a spreading pressure usually expressed as a Spreading Coefficient. This Spreading $S_{o/w}$, is readily quantified and is determined by a balance of the surface tension forces as follows.

$$S_{o/w} = \gamma_w - \gamma_{o/w} - \gamma_{o,} \tag{1}$$

wherein:

$S_{o/w}$ is the spreading coefficient for oil on water ergs/cm^2 or dynes/cm



$S_{o/w}$, Spreading Coefficient For Oil On Water,

$$= \gamma_w - \gamma_o - \gamma_{o/w}$$

Measured Value For Kuwait Crude Oil On Sea Water

$$S_{o/w} = 61 - 28 - 22$$
$$= 11 \text{ Dynes/cm}$$

FIGURE 2 The spreading behavior of spilled oil.

1.5	Barely Visible	25
3.0	Silver Sheen	50
6.0	First Trace Of Color	100
12.0	Bright Bands Of Color	200
80.0+	Dark Colors	1330+

FIGURE 3 Oil slick appearance during spreading.

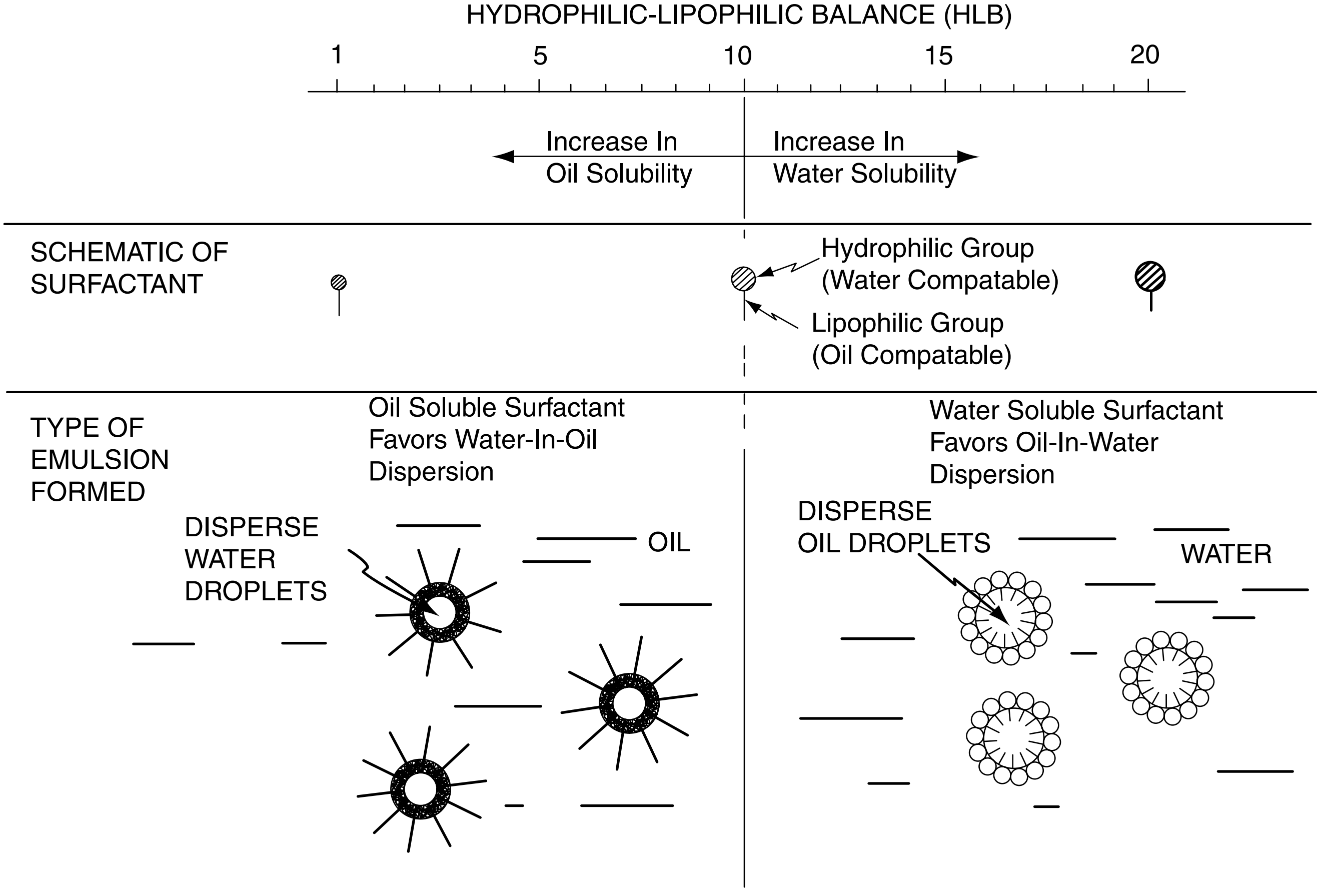

FIGURE 4 Influences of surfactant structure on type of dispersion.

γ_w is surface tension of water, dynes/cm
γ_o is surface tension of oil, dynes/cm
$\gamma_{o/w}$ interfacial tension of oil and water, dynes/cm.

By an examination of the force balance shown in Figure 2 it can be seen that if $S_{o/w}$—the resultant spreading force is positive, the oil will spread on the water; if negative, it will not spread but remain a "lens" of Liquid. For example, spreading coefficient values for Kuwait Crude on sea water, reported by Canevari[20] are positive and confirm that for this system the oil readily spreads on the water phase. Garrett[21] has summarized spreading pressures of various oils on sea water that vary from 25 to 33 dynes/cm. Cochran[22] has also published values that generally agree with these level on sea water. As one can see from Figure 3, for positive spreading coefficients, the oil is capable of filming out to very thin films. A film thickness of only 3.0×10^{-6} inches representing a spill of 50 gallons of oil distributed over a surface area of one mile will be quite visible as a "flat" silver sheen on the surface of the water.

However, the initial spreading rate of a large volume of spilled oil is based on the volume and density of the oil in essence, sort of static head that overcomes other factors such as interfacial tension.

The Mechanism of Dispersing Surface Oil Slicks by Chemical Dispersants

The dispersion of surface oil films as fine oil droplets into the water column is promoted by the use of a chemical dispersant. This oil spill dispersant consists primarily of a surface active agent (surfactant) and a solvent. The solvent is added as a diluent or vehicle for the surfactant. It also reduces the viscosity and aids in the uniform distribution of the surfactant to the oil film.

A surfactant is a compound that actually contains both water compatible (hydrophilic) and oil compatible (lipophilic) groups. Due to this amphiphatic nature, a surfactant locates and arranges itself at an oil–water interface as schematically shown in Figure 4. The surfactant's molecular structure, e.g. ratio of hydrophilic to lipophilic portion, determines the type of dispersion (oil droplets dispersed in water phase or water droplets dispersed in oil phase), as well as stability of the dispersion. In essence, a surfactant that is principally water soluble disperses oil-in-water and established water as the continuous phase; a surfactant that is principally oil soluble, the converse. This is Bancroft's Law,[23] which has been tested and proven empirically true over the years. A convenient classification for surfactants therefore, is based on the ratio or balance of the water compatible portion to the oil compatible portion-sometimes referred to as HLB (Hydrophilic–Lipophilic Balance).[24]

This relationship between the molecular structure of the surfactant and the emulsion type is also shown in Figure 4 and the physical concept behind Bancroft's Law may be appreciated. For example, it can be visualized that for a more water compatible surfactant, the physical location of the larger hydrophilic group on the outside of the dispersed oil droplets results in a more effective "fender" to parry droplet collisions and prevent droplet coalescence. The converse, location and the larger portion of the surfactant in the dispersed rather than the continuous phase, would be geometrically awkward and unstable.[25] The mechanism of oil slick dispersion by the application of chemical dispersants has been covered in some detail by Poliakoff[26] and Canevari,[27,28,29] among others. From the above discussion, one can see that the chemical dispersant (surfactant) will locate at the oil–water interfaced reduce interfacial tension. This will then act to increase the spreading tendency of the oil film as shown by Eq. (1). More important, it promotes fine droplet formation which can be expressed as:

$$W_k = A_{o/w}\gamma_{o/w,}, \qquad (2)$$

where:

Wk mixing energy, ergs
$A_{o/w}$ interfacial area, cm^2
$\gamma_{o/w}$ interfacial tension, dynes/cm.

Thus, for the same amount of mixing energy, a reduction of $\gamma_{o/w}$ will result in a corresponding increase in $A_{o/w}$.

It is important to emphasize that, as can be realized from the above discussion, the chemically dispersed oil does not sink. Rather, the surfactant merely enhances small droplet formation for a given amount of mixing energy. Smaller diameter oil droplets have a much lower rise velocity per the familiar Stokes Law. Hence, once the oil is chemically treated, and placed 3 to 5 feet below the surface of the water by the mixing process, it does not rise to the surface as readily, as illustrated by Figure 5.

There are many surfactants that will aid the formation of fine droplets in the above manner. It has already been noted that the surfactant structure (Hydrophilic–Lipophilic Balance) influences the efficiency of the emulsifier. However, a more subtle and less tractable requirement for an effective dispersant is the prevention of droplet coalescence once the fine oil droplets are formed. This is illustrated by Figure 6 wherein a volume of oil has been dispersed by a chemical surfactant and maintained in suspension by gentle bubbling of air. After 24 hours, there has been no coalescence or separation of these fine oil droplets. In the control sample, with similar volume of oil and mixing energy, the oil separated almost immediately and reformed an intact, cohesive film of oil.

In essence then, an effective dispersant must parry droplet collisions physically. For example, dispersed oil may separate in a sample bottle but even though there may be a "creaming" effect, i.e. oil droplets concentrate near the surface, the droplets should not coalesce to reform an intact slick. It is this same "fendering" action that reduces the tendency of the droplets to stick to a solid surface.

The Physical and Environmental Incentives for Dispersing Oil Slicks

Consideration of the previous summary of the potential damaging aspects of an untreated and unrecoverable oil spill indicates that the removal of the intact, cohesive mass of oil from the surface of the water yields more than a cosmetic effect as is often claimed. For this alternate approach when conditions do not permit the recovery of the spilled oil, the removal of oil from the surface by dispersing it into fine droplets yields established benefits that can be summarized by the following discussion:

1) Oil properly dispersed with a chemical dispersant will not stick to a solid surface. As previously outlined, the physical fending action of a properly selected surface-active agent prevents the oil droplets from coalescing after dispersion. This same property also inhibits the oil from wetting out on a solid surface. This has become a controversial point and it has actually been claimed that the converse is true. For example, in the First Report of the President's Panel on Oil Spills,[30] it has been stated that such agents cause the oil to "spread into the sand-surfaces which untreated oil would not wet." A laboratory experiment was conducted to evaluate this aspect. A mixture of 256 cc of sea water, 95 cc of beach sand (New Jersey shore area), and 20 cc Kuwait Crude, were placed in a graduate. This represented a vertical cross section of the marine environment after an oil spill. The mixture was then agitated to simulate the possible contact of sediment by the oil when turbulent conditions existed. After mixing, the sample was settled to separate the oil–sand water phases. In a body of water, either the oil may be driven down into contact with the sandy bottom or the sand may be suspended in the body of water by wave action, such as deduced from the previously cited Buzzards Bay spill. The graduate was then purged with clean water to simulate the return of the environment to a non-contaminated condition.

   The experiment was then repeated using 20 cc of Kuwait Crude Oil and 4 cc of a chemical dispersant (5 parts oil/1 part dispersant).

   Virtually no "treated" oil impregnated the sand. For the experiment with the untreated crude oil, an analysis of the oil content of the sand bed indicated that 11.20 cc of oil remained of the initial 20 cc.
2) Oil removed from surface water prevents bird damage. The aforementioned hazard to marine fowl that is presented by the surface oil film is

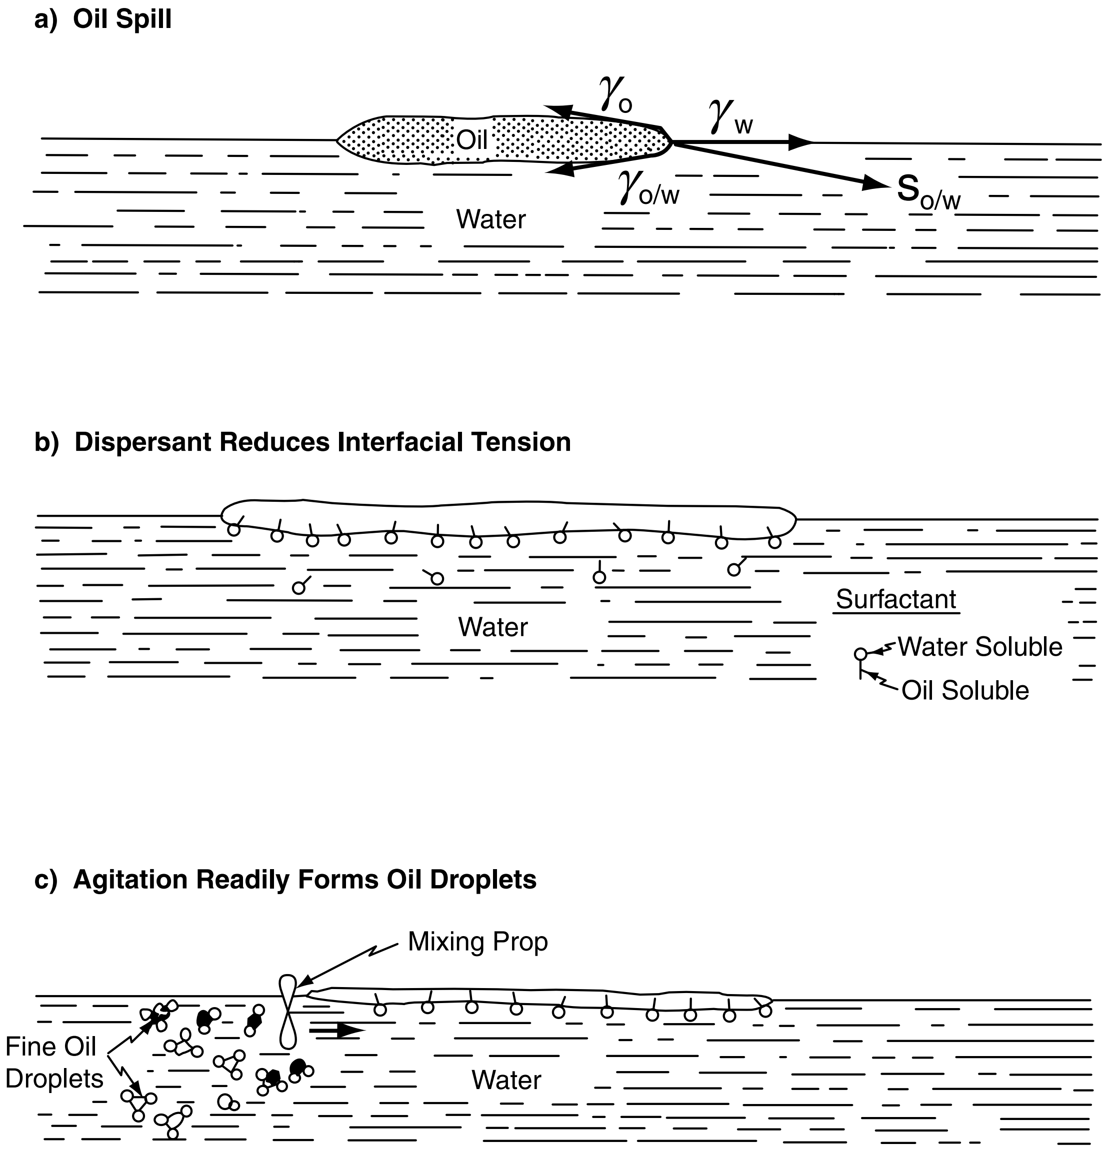

FIGURE 5 Dispersant enhances droplet formation.

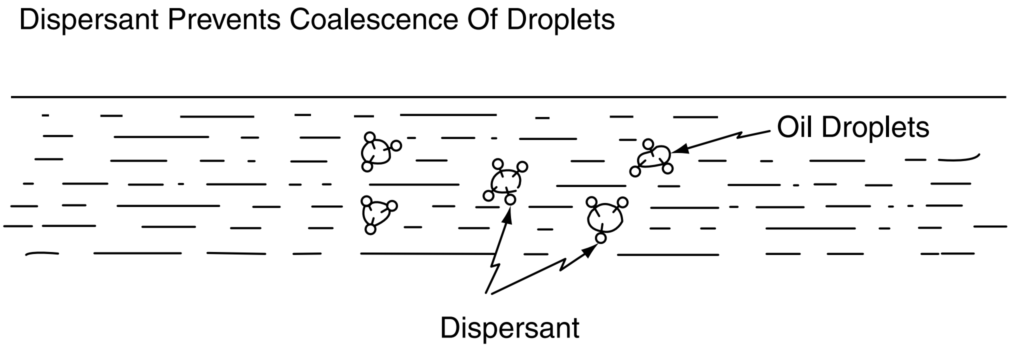

FIGURE 6 Dispersant maintains oil droplets in suspension with mild agitation..

clearly eliminated when the oil is dispersed as fine droplets into the water column. These dispersed droplets are placed several feet below the water surface by the mixing process.

3) The fire hazard from the spilled oil is reduced by dispersion of the oil several feet into the water column. The removal of this combustible material from the water's surface and from contact with the atmosphere prevent possible combustion of the spilled oil. This is perhaps the most accepted benefit accruing from the use of dispersants. It has provided the motivation for many past instances of dispersant applications.
4) The rate of biodegradation of the oil is enhanced. This is the historical basis for the dispersion of oil. It is perhaps the most significant contribution of dispersants. The order of magnitude increases in interfacial area that are generated by the dispersant greatly increases the rate of biodegradation of the oil. ZoBell[31] has reported biodegradation rates that are one or two orders of magnitude higher in laboratory experiments in which the oil is emulsified. Not only is the physical state of the oil, that is, small droplets, more conducive to bacterial action, but it is also made available to a much larger population of microbial organisms. This particular reference has been one of the most complete treatments of the subject of oil biodegradation to date.

   A study by Robichaux and Myrick[32] presented the results of a study of the effects of chemical dispersing agents on the rate of microbial destruction of crude oil in aqueous environments. Increased destruction rates of up to 15 times the rate of untreated oil/water mixtures were reported.
5) The formation of persistent tar lumps from an untreated oil spill is prevented. The tarry agglomerates (up to 10 cc dia.) found on the ocean surface, as mentioned previously represent a small percent residue of the crude oil. If the crude oil had been dispersed into 10 μ to 1 mm diameter droplets, these large residue agglomerates would not have formed and their persistence in the marine environment would have been greatly reduced.

The Concern Regarding the Chemical Dispersion of Oil Spills

Clearly then, from a consideration of the foregoing, the removal of oil from the surface of the sea has merits in mitigating the damage resulting from a spill. It is more than a cosmetic, hide-it-from view effect. What then are the negative aspects to their use? What is the ecological price for introducing the chemical dispersant and dispersed oil into the water column?

The major concern regarding the use of dispersants are twofold as covered in the following discussion.

The Toxic Effects of the Chemical Dispersants

This has been an area of great concern since their use has become significant. There is a basis for this concern. It was highlighted by the investigation by Smith *et al.*,[33] after the Torrey Canyon that indicated that in some areas, particularly in the intertidal zone, the chemicals used were more toxic to the marine life than the oil itself.

During this period (1967–1968), the chemical formulations available to disperse spilled oil were derived mainly from cleaning agents, hence the term "detergent" was used quite commonly. To permit these agents to dissolve tar-like residues and perform their cleaning function, an aromatic solvent, such as heavy aromatic naphtha, was generally employed. The short term acute toxicity of aromatic hydrocarbon to marine life is well-known. Blumer[34] states that low boiling aromatics are toxic to man as well as all other organisms and that it was the great tragedy of the Torrey Canyon that the detergents used were dissolved low boiling aromatics. The Toxicity of these aromatic solvent constituents were extensively studied by the Marine Biological Laboratory of the UK. Their acute toxicity was evident since 5 ppm of kerosene extract solvent killed 50% of the Elminius nauplius larvae in 21 minutes. Their analyses of the more common detergents (dispersants) used during the Torrey Canyon indicated that they contained some portion of aromatics.

In addition to these toxic aromatic solvents, the surfactants were typically selected from the class compounds formed by the reaction of hydroxy-containing compounds (e.g. phenol or alcohol) with ethylene oxide. A typical surfactant might be ethoxylated nonylphenol. The number of ethylene oxide groups added to the nonylphenol hydro-phobe may be controlled to any desired extent to adjust the degree of water solubility of the material. These types of surfactants, although effective emulsifiers, were quite detrimental to marine life.

However, there has been research directed toward formulating dispersants that would have little effect on marine life. For example, water is now used as the solvent in products where it is compatible with the particular surfactants. High boiling saturated hydrocarbons which are similar to the type of hydrocarbon that occur naturally in the marine environment have a low order of toxicity and are also employed as solvents in some of the more recent dispersants. This modification of the solvent, and the selection of generic types of surface-active agents that are not considered to be chemically toxic, have resulted in the development of dispersants that have greatly reduced toxicity. This can be illustrated by the study of J.E. Portmann,[35] summarized in Table 3. For example, three dispersant products used during the Torrey Canyon spill and identified as Torrey Canyon Dispersants A, B, C, have 48 hr LC_{50} values of 8.8, 5.8, and 6.6 ppm, respectively. These concentrations represent the amount of the specific agent to kill 50% of the test species (Crangon crangon) in 48 hours. The toxicity of a typical Torrey Canyon surfactant, ethoxylated nonlphenol is shown at 89.5 ppm. By

TABLE 3
Development of low toxicity dispersants illustrated by Portmann Study

Dispersant E	56.0
Dispersant E + oil	75.0
Dispersant F	3200^{+}
Dispersant F + oil	1800^{+}

comparison, the Toxicity levels of three dispersant products developed since the Torrey Canyon, identified as Post Torrey Canyon, Dispersants D, E, F, are 7500–10,000; 3300–10,000; and >3300 ppm, respectively. These concentrations are orders of magnitude greater than the level applied by conventional application in the field.

Other agencies have confirmed this finding. Table 4 illustrates results of a recent study by the Fisheries Research Board of Canada entitled, "Toxicity Tests with Oil Dispersants in Connection with Oil Spill at Chedabucto Bay N.S."[36] Again, the large difference in toxicity due to the surfactant-solvent recipe can be noted in the summary of results (Table 4). These values represent 4 day LC_{50} values in fresh water to Salmon (Salmo salar L) and vary from "Toxic" (1–100 ppm) to "Practically non-toxic" (>10,000 ppm). Over 25 research institutions are known to have conducted studies on these lower toxicity chemicals. Testing by Dr. Molly Spooner,[37,38] among others, has encompassed juvenile species, planktonic life and other very sensitive forms of marine life.

Clearly then, the concern and conclusion that all chemical dispersants are in themselves inherently toxic is incorrect. Some of the most effective emulsifiers/dispersants available are those derived from and found in the natural environment.

The Toxic Effects of the Dispersed Oil

When the surface film of oil is dispersed several feet or more into the water column, it is unfortunately made available to other forms of marine life in addition to the hydrocarbonoxidizing bacteria. Necton and other filer feeder many now come into contact with dispersed oil droplets that they otherwise may have escaped as surface oil. This is, effect, the "ecological price" for the cited benefits of dispersing oil. There are published data on the acute toxicity levels of dispersed oil such as that from the State of Michigan[39] presented as Table 5. This does indicate an approximate tolerance level of a thousand ppm or more for dispersed oil. It can also be noted that the toxicity of the chemical is reflected in the toxicity level of 1000 ppm or so for dispersed oil, however it should be noted that (1) it is unlikely that fish would remain in this inhospitable environment for 96 hours and (2) the dispersed oil has a driving force to dilute itself. Of greater concern than these short term acute effects is the possibility that the finely dispersed oil droplets represent a more subtle contaminant and may cause long-range detrimental effects. However, it should also be noted that crude oil is a natural rather than man-synthesized material. Wheeler North[40] reported after extensive research into several spill incidents, "Unlike many of the products man liberates into the environment, crude oil is a naturally occurring substance. From time to time it appears on the earth's crust by natural processes of exudation."

More Recent Dispersant Research Has Involved Improvement in Effectiveness

The previous discussion regarding the dispersion mechanism cited the need for mixing energy, W_k. This is normally supplied by means of a work boat applying the chemical. However, consider the rate by which this work is accomplished by the boat's wake and propeller. A typical work boat may apply energy to swath 50 ft wide at a speed of 5 knots thereby only mixing 35 acres per hour of ocean.

Therefore, in recent years, research has been directed at eliminating the need for the tedious, time consuming mixing process.

In essence, a "self-mix" dispersant formulation has been developed that requires essentially no energy to be applied to the oil-water interface in order to generate a dispersion of fine oil droplets. This has greatly enhanced the scope and potential of chemical dispersion particularly for large spills. For example, since mixing is no longer needed, aerial application alone would be feasible. Some aircraft uniquely adapted for this service, such as the canadiar CL-215, carries 1500 gallons of dispersant and covers 3000 acres per hour based on a 150 knot speed and treated swath width of 150 feet. Extensive use has already been made of commercial DC-4's and DC-6's for this purpose. A very novel development of a load on tank and spray system for even larger aircraft is now in place.

The Mechanism of More Recently Developed Self-Mix Dispersants

The mechanism of the self-mix chemical dispersants goes beyond the simple thesis represented by Eq. (2). In an ideal no-mixing system true spontaneous emulsification (or "self-mixing") is postulated to occur in the following manner. The chemical surfactant formulation is made compatible with the bulk oil. However, when the oil phase comes into contact with a water boundary rather than air, part of the surfactant

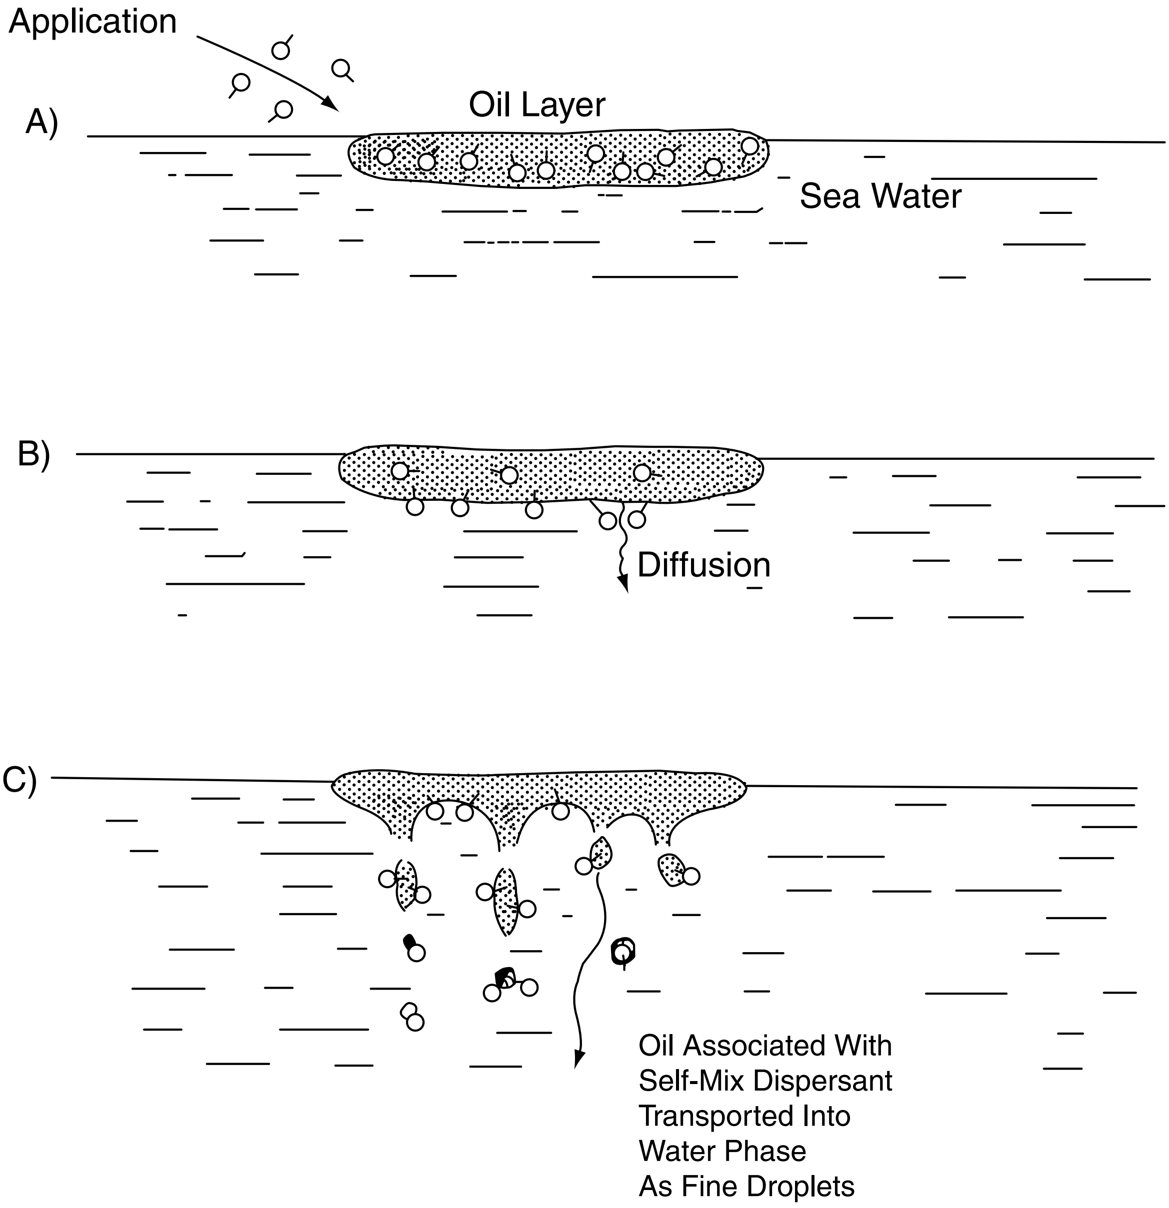

FIGURE 7 Mechanism of self-mix dispersion.

has a strong driving force to diffuse into the water phase. In this transport process, a small amount of oil "associated" with the surfactant is carried into the water phase. A continuation of this process produces a series of fine oil droplets migrating from the oil phase into the water phase as schematically shown by Figure 7.

In the graphical presentation of Figure 7, the surfactant formulation can be seen to be compatible with the crude oil phase as shown in (A). However, due to the nature of the specific compounds, there is a driving force for part of the formulation of diffuse into the water phase when it contacts an oil/water interface (B). During this diffusion, some oil associated with the surfactant as fine oil droplets is carried along with the surfactant into the water column as shown in (C). In essence, a three component system—oil + water + surfactant is formed at the interface. As the surfactant diffuses into the water phase, the associated oil is thrown out of solution.

The migration of the surfactant from the oil into the water phase-in essence, the source of energy for spontaneous emulsification comes from the redistribution of materials. It can be seen that for this system to work in the field as an oil slick dispersant, the surfactant must be brought into contact with the oil phase initially.

It is also interesting to observe that as the surfactant diffuses through the interface, a reduction in interfacial tension occurs. Over the entire oil/water interface, there are dissimilar values of interfacial tension due to the somewhat random diffusion of the surfactant at varying sites along the interface. Any difference in interfacial tension produces a spreading pressure, II, which causes rapid movement of the interface. This interfacial turbulence also aids in the dispersion of the oil into the water phase.

Field Tests Support the Role of Chemical Dispersants to Minimize Oil Spill Impact

In summary, there is an increased awareness and recognition that there is a role for chemical dispersants in minimizing damage from oil spills. The improved effectiveness afforded by the self-mix dispersant system has been demonstrated.

Over the past 10 years, there have been a number of major field tests that have demonstrated under real life conditions the effectiveness and biological safety of this approach. These have been reviewed and summarized in a study by the National Research Council.[41]

In order to establish that the transient, rapidly diluting concentrations of dispersed oil are not harmful, actual measurements of the biological effects were made during several controlled oil spills.

For examples, on August 19, 1981 a field experiment was carried out in Long Cove, Searsport, Maine, which simulated the dispersal of oil slicks in the nearshore zone.[42] The object of this experiment was to obtain quantitative information on the fate and effects of dispersed and non-dispersed oil in the nearshore area. An upper and lower intertidal sampling are within a 60 × 100 meter test plot were exposed to dispersed oil in water resulting from the discharge of 250 gallons of oil premixed with 25 gallons of COREXIT 9527 dispersant. Release of treated oil was around high-water slack tide on the surface of the water. The maximum water depth over the test areas was 3.5 meters. Untreated crude oil (250 gallons) was released on an ebbing tide within a separate, boomed-off 60 × 100 meter test plot. A third test plot served as an oil-free reference plot. To evaluate the effects on the intertidal infaunal community structure, chemical and biological analyses were carried out concurrently throughout the pre- and post-spill periods. The conclusions reached by the Bowdoin College scientists are quoted as follows:

- No evidence of any adverse effects was observed on infaunal community structure from the exposure of intertidal sediments to dispersed oil under real spill treatment conditions.
- There is clear evidence that the undispersed oil treatment caused some mortality of a commercially important bivalve and increased densities of opportunistic polychaetes.
- The results seen in the test plot that received untreated oil, are consistent with studies of real-world oil spills.

PARTICULATE EMISSIONS

EMISSION STANDARDS

Allowable levels of particulate emissions are specified in several different ways, having somewhat different methodologies of measurement and different philosophies of important criteria for control. Permissible emission rates are in a state of great legislative flux both as to the definition of the suitable measurement and to the actual amount to be allowed. This section summarizes the various types of quantitative standards that are used in regulating particulate emissions. For a detailed survey of standards, the reader should consult works by Stern,[1] Greenwood *et al.*,[2] and the Public Health Service.[3]

A recent National Research Council report proposes future studies on the nature of particulate emissions, their effect on exposed populations and their control[4]. Friedrich and Reis[5] have reported the results of a 10-year multinational European study on characteristics, ambient concentrations and sources of air pollutants.

The following paragraphs give an overview of standards for ambient particulate pollution and source emission. The precise and practical methodology of making accurate and/or legally satisfactory measurements is beyond the scope of this article. Books such as those by Katz,[6] Powals *et al.*,[7] Brenchly *et al.*,[8] and Hawksley *et al.*[9] should be consulted for detailed sampling procedures. In the Federal Register USEPA announced the implementation of the PM-10 regulations (i.e., portion of total suspended particulate matter of 10 μm or less particle diameter).[40,41]

Ringlemann Number

Perhaps the first attempt at quantifying particulate emissions was developed late in the 19th century by Maximilian Ringlemann. He developed the concept of characterizing a visible smoke plume according to its opacity or optical density and originated the chart shown in Figure 1 as a convenient scale for estimation of opacity. The chart consists of four grids of black lines on a white background, having fractional black areas of 20, 40, 60 and 80% which are assigned Ringlemann Numbers of 1–4. (Ringlemann 0 would be all white and Ringlemann 5 all black.) For rating a smoke plume, the chart is held at eye level at a distance such that chart lines merge into shades of grey. The shade of the smoke plume is compared to the chart and rated accordingly. The history and use of the Ringlemann chart is covered by Kudlich[8] and by Weisburd.[9]

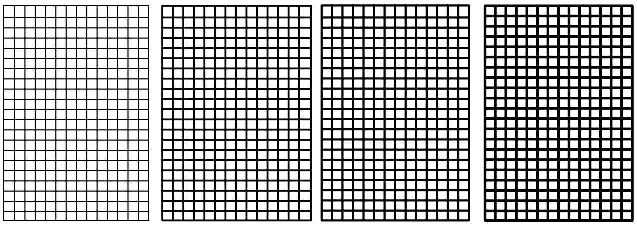

FIGURE 1 Ringlemann's scale for grading the density of smoke.

In actual practice, opacity is seldom determined by use of the chart, although the term Ringlemann Number persists. Instead, observers are trained at a "smoke school."[10] Test plumes are generated and the actual percentage of light attenuation is measured spec-trophotometrically within the stack. Observers calibrate their perception of the emerging plume against the measured opacity. Trained observers can usually make readings correct to ± 1/2 Ringlemann number.[11,13] Thus, with proper procedures, determination of a Ringlemann Number is fairly objective and reproducible.

The Ringlemann concept was developed specifically for black plumes, which attenuate skylight reaching the observer's eye and appear darker than the sky. White plumes, on the other hand, reflect sunlight and appear brighter than the background sky so that comparison to a Ringlemann chart is meaningless. The smoke school approach is quite applicable, however. Observations of a white plume are calibrated against the measured light attenuation. Readings of white plumes are somewhat more subject to variation due to relative locations of observer, plume, and sun. It has been found that observations of equivalent opacity taken with the observer facing the sun are about 1 Ringlemann number higher[13] than those taken in the prescribed method with the sun at the observer's back. Nevertheless, when properly made, observations of Ringlemann numbers are reproducible among observers and agree well with actual plume opacity.

Opacity regulations specify a maximum Ringlemann number allowable on a long-term basis but often permit this to be exceeded for short prescribed periods of time. For instance, a typical requirement specifies that emissions shall not exceed Ringlemann 1, except that for up to 3 min/hr emissions up to Ringlemann 3 are permitted. This allowance is of considerable importance to such operation as soot blowing or rapping of electrostatic precipitator plates, which produce puffs to smoke despite on overall very low emission level.

Federation regulations of the Environmental Protection Agency[14] specify that opacity observations be made from a point perpendicular to the plume, at a distance of between two stack heights and one quarter of a mile, and with the sun at the observer's back. For official certification, an observer under test must assign opacity readings in 5% increments (1/4 Ringlemann number) to 25 plumes, with an error not to exceed 15% on any single reading and an average error (excluding algebraic sign of individual errors) not to exceed 7.5%. Annual testing is required for certification. In view of previous studies,[11,13] this is a very high standard of performance and probably represent the limits of visual quantification of opacity.

Perhaps the greatest advantage of the Ringlemann Number approach is that it requires no instrumentation and very little time and manpower. Readings can usually be made by control authorities or other interested parties without entering the premises of the subject source. Monitoring can be done very frequently to insure continual, if not continuous, compliance of the source. Finally, in terms of public awareness of particulate emissions, plume appearance is a logical candidate for regulation. Air pollution is, to a great extent, an aesthetic nuisance affecting the senses, and to the extend that plume appearance can be regulated and improved, the visual impact of pollution is reduced.

The Ringlemann Number concept has drawbacks reflecting its simple, unsophisticated basis. Most serious is that, at present, there is no really quantitative relationship between stack appearance and the concentration of emissions. Additional factors; such as particle size distribution, refractive index, stack diameter, color of plume and sky, and the time of day, all have a marked effect on appearance. On a constant weight concentration basis, small particles and large smoke stacks will produce a poor Ringlemann Number. Plumes that have a high color contrast against the sky have a very strong visual impact that does not correspond closely to the nature of the emissions. For example, a white plume may be highly visible against a deep blue sky, but the same emission can be practically invisible against a cloudy background. As a result, it is often difficult to predict whether or not proposed control devices for a yet unbuilt plant will produce satisfactory appearance. Certain experience factors are presented in Table 1 for emissions, measured on a weight concentration basis, which the Industrial Gas Cleaning Institute has estimated will give a Ringlemann 1 or a clear stack.

A second objection is that Ringlemann number is a purely aesthetic measurement which has no direct bearing on physiological effects, ambient dirt, atmospheric corrosion, or any of the other very real and costly effects of particulate air pollution. There is some concern that regulations of very low Ringlemann numbers will impose very costly control measures upon sources without producing a commensurate improvement in the quality of the environment. Thus a high concentration of steam will produce a visually prominent plume, but produce virtually no other undesirable effects. Opacity restrictions are usually waived if opacity is due entirely to steam but not if any other particles are present, even if steam may be the major offender.

Instrumental Opacity

Many factors affecting the visual appearance of a smoke plume are external variables, independent of the nature of the emissions. In addition, visual reading cannot be taken at all at night; and manpower costs for continuous daytime monitoring would be prohibitive. For these reasons, instrumental measurements of plume opacity are sometimes desirable.

A typical stack mounted opacity meter is shown in Figure 2. It consists, basically, of a light source, an optical path traversing the smoke stack, and a phototube receiver which responds to the incident light intensity and, hence, to the light attenuation caused by the presence of smoke. Various techniques including beam splitting, chopper stabilization, and filter comparison are used to maintain stable baselines and calibrations. At present, however, there is no way to distinguish between dust particles within the gas stream and those which have been deposited on surfaces in the optical path. Optical surfaces must be clean for meaningful measurements, and cleanliness is difficult to insure for long periods of time in dusty atmosphere. The tendency, therefore, is for such meters to read high, indicating more smoke than is actually present. For this reason, and because of reluctance to have a continuous record of emissions, there has not been a very strong push by industries to supplant Ringlemann observations with opacity meters.

Stack mounted opacity meters, of course, will not detect detached plumes, which may contribute to a visual Ringlemann observation. Detached plumes are due to particles formed by condensation or chemical reaction after gas leaves the stack and are thus beyond detection of such a meter.

At present, Texas is the only state with emissions control regulations based on use of opacity meters,[15] as described by McKee.[11] The Texas regulations is written so that smoke of greater optical density (light attenuation per unit length of light path) is permitted from low velocity stacks or small diameter ones. Basically, a minimum transmittance of 70% is allowed across the entire (circular) stack diameter if the stack has an exit velocity of 40 ft/sec, and adjustment equations are provided for transmittance and/or optical path length if non-standard velocity or path length is used.

Perhaps the greatest dissatisfaction with emission regulations based either on visual observation number or on instrumental opacity is due to the fact that there is presently no

TABLE 1
Industrial process emissions expected to produce visually clear (or near clear) stack

Industrial classification	Process	Grains/ACF @Stack exit temp. (°F)

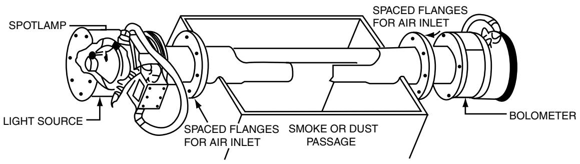

FIGURE 2 Stack mounted opacity meter (Bailey Meter Co.).

quantitative procedure for design of equipment to produce complying plumes. Equipment vendors will usually guarantee collection efficiency and emission concentrations by weight, but they will not give a guarantee to meet a specified opacity. This is indeed a serious problem at a time when a large precipitator installation can cost several million dollars and take twenty months to fabricate and install. Overdesign by a very conceivable factor of two can be very expensive in unneeded equipment. Underdesign can mean years of delay or operation under variance or with penalty payments.

Some progress has been made in applying classical theories of light scattering and transmission to the problem of predicting opacity. This effort has been greatly hampered by paucity of data giving simultaneous values of light attenuation, particle size distribution, and particle concentration in a stack. Perhaps the most comprehensive work to date has been that of Ensor and Pilat.[16]

Weight Limits on Particulates

Perhaps the least equivocal method of characterizing and specifying limits on particulate emissions is according to weight, either in terms of a rate (weight of emissions per unit time) or in terms of concentration (weight per unit volume). Measurement of emission weights must be done by isokinetic sampling of the gas stream, as outlined in the following section on measurement. Although the principles of such measurement are simple, they are difficult and time consuming when applied with accurate methodology to commercial installations. For this reason, such measurements have not previously been required in many jurisdictions and are almost never used as a continual monitoring technique.

Limits on weight rate of emissions are usually dependent on process size. Los Angeles, for instance, permits emissions to be proportional to process weight, up to 40 lbs/hr particulates for a plant processing 60,000 lbs/hr of material. Larger plants are limited to 40 lbs/hr. For furnaces, the determining factor is often heat input in BTU/hr rather than process weight. In cases where a particular plant location may have several independent units carrying out the same or similar processes, regulations often require that the capacities be combined for the purposes of calculating combined emissions.

Concentration limits are usually independent of process size. For instance, the EPA specifies incinerator emission of 0.08 grains particulates per standard cubic foot of flue gas (0.18 gm/NM^3) Dilution of the flue gas with excess air is usually prohibited, or else correction must be made to standard excess air or CO$_2$.

Ground Level Concentrations of Suspended Particulates

A limit on ground level concentration of particulates is an attempt to regulate emissions in accordance with their impact on population. A smoke stack acts as a dispersing device, and such regulations give incentive to build taller stacks in optimum locations.

In theory, ground level concentrations can be measured directly. Usually, however, emissions are measured in the stack, and plume dispersion equations are then used to calculate concentration profiles. Plume dispersion depends on stack height, plume buoyancy (i.e. density relative to ambient air), and wind velocity, and wind patterns. In addition, plumes are never stationary but tend to meander; and correction factors are usually applied to adjust for the sampling time at a fixed location. Dispersion calculations are usually easier than direct ground level measurements; and in cases where many different sources are present, calculation offers the only practical way to assess the contributions of a specific source. A recent evaluation of plume dispersion models is given by Carpenter *et al.*[15]

In some states, a plume dispersion model is incorporated into a chart which gives an allowable weight rate of emissions as a function of effective stack height and distance from property lines. An example of this approach is shown in Figure 3.

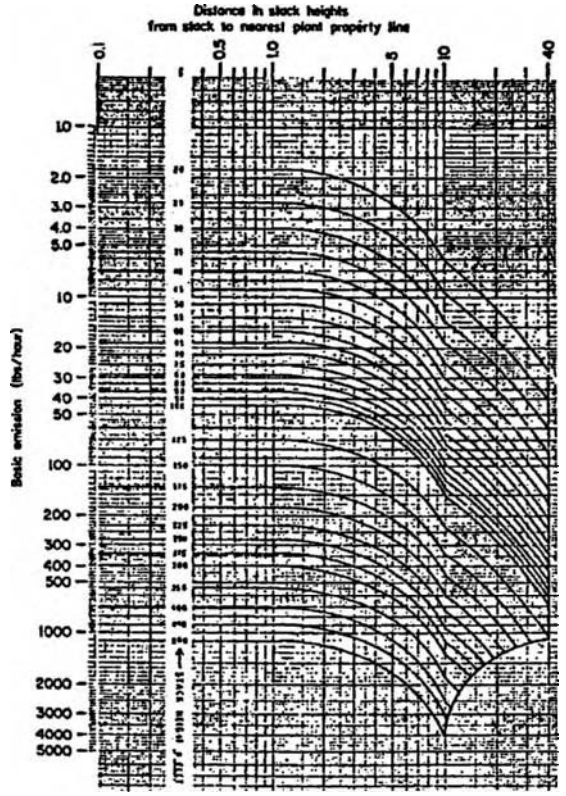

FIGURE 3 Emission requirements for fine particles based on plume dispersion model (New Jersey Air Pollution Code).

The particular regulation shown also accounts for differing toxicity of certain particulates and allocates the emission factors of Table 2 accordingly.

Very often permissible ground level concentrations are set according to other sources in the area. Thus a plant would be allowed greater emissions in a rural area than in a heavily industrialized neighbourhood.

Dust fall

A variant on the ground level concentration limit is a dustfall limit. This basically superimposes a particle settling velocity on ground level concentration to obtain dustfall rates in weight per unit area per unit time. This is a meaningful regulation only for large particles and is not widely legislated at present.

Federal Clean Air Statutes and Regulations

The major federal statutes covering air pollution are PL 88–206 (The Clean Air Act of 1963), PL 90–148 (The Air Quality Act of 1967) PL 92–157, PL 93–115, PL 95–95 (The Clean Air amendments of 1977), and PL 95–190, Administrative standards formulated by the Environmental Protection Agency (EPA) are given in the Code of Federal Regulations Title 40, Chapter 1, Sub-chapter C, with regulations on particulates in parts 50, 51, 52, 53, 58, 60, 61, and 81.

TABLE 2
Emission effect factors (for use with Fig. 3) (New Jersey Air Pollution Control Code)

Material	Effect factor
Fine Solid Particles	
All materials not specifically listed hereunder	1.0
Antimony	0.9
A-naphthylthiourea	0.5
Arsenic	0.9
Barium	0.9
Beryllium	0.003
Cadmium	0.2
Chromium	0.2
Cobalt	0.9
Copper	0.2
Hafnium	0.9
Lead	0.3
Lead arsenate	0.3
Lithium hydride	0.04
Phosphorus	0.2
Selenium	0.2
Silver	0.1
Tellurium	0.2
Thallium	0.2
Uranium (soluble)	0.1
Uranium (insoluble)	0.4
Vanadium	0.2

The EPA has established National Ambient Air Quality Standards (NAAQS). For suspended particulate matter the primary standard (necessary to protect the public health with an adequate margin of safety) is 75 μg/M^3 annual geometric mean with a level of 260 μg/M^3 not to be exceeded more than once per year. All states have been required to file state implementation plants (SIP) for achieving NAAWS. It is only through the SIP's that existing pollution sources are regulated.

The EPA requires no specific state regulations for limits on existing sources, but suggestions are made for "emission limitations obtainable with reasonable available technology." Some of the reasonable limits proposed for particulates are:

1) Ringlemann 1 or less, except for brief periods such as shoot blowing or start-up.
2) Reasonable precautions to control fugitive dust, including use of water during grading or demolition, sprinkling of dusty surfaces, use of hoods and vents, covering of piles of dust, etc.
3) Incinerator emission less than 0.2 lbs/100 lbs refuse charged.
4) Fuel burner emissions less than 0.3 lbs/million BTU heat input.
5) For process industries, emission rates E in lbs/hr and Process weight P in tons/hr according to the relationships:

$$E = 3.59\,P^{0.62} \text{ for } P \leqslant 30 \text{ tons/hr.}$$
$$E = 17.31\,P^{0.16} \text{ for } P \geqslant 30 \text{ tons/hr.}$$

"Process weight" includes all materials introduced to the process except liquid and gaseous fuels and combustion air. Limits should be set on the basis of combined process weights of all similar units at a plant.

In considering what emission limits should be established, the states are encouraged to take into account local condition, social and economic impact, and alternate control strategies and adoption of the above measures is not mandatory. It is expected, however, that such measures will become the norm in many areas.

For new or substantially modified pollution sources, the EPA has established new source performance standards. The standards for particulate emissions and opacity are given in Table 3. Owners may submit plants of new sources to the EPA for technical advice. They must provide ports, platforms, access, and necessary utilities for performing required tests, and the EPA must be allowed to conduct tests at reasonable times. Required records and reports are available to the public except where trade secrets would be divulged. The states are in no way precluded from establishing more stringent standards or additional procedures. The EPA test method specified for particulates measures only materials collectable on a dry filter at 250°F an does not include so called condensables.

In addition to new source performance standards, major new stationary sources and major modifications are usually subject to a "Prevention of Significant Deterioration" review. If a particulate source of more than 25 tons/year is located in an area which attains NAAQS or is unclassifiable with respects to particulates, the owner must demonstrate that the source will not violate NAAQS or PSD concentration increments. This requires modelling and preconstruction monitoring of ambient air quality. If the new or expanded source is to be located in an area which does not meet NAAQS, then emission from other sources must be reduced to offset the new source. The regulation regarding emission offsets and prevention of significant deterioration are relatively recent. A summary of federal regulations as of 1981 has recently been published as a quick guide to this rapidly changing field.[18]

In recent years, regulation of particulate emissions from mobile sources has been initiated. The burden is essentially on manufacturers of diesel engines. Because the emission requirements and test procedures are quite complex and because the target is highly specific, a comprehensive discussion is beyond the scope of this article. Some representative standards are: Diesel engines for urban buses, 0.019 grams/megajoule, and other diesel engines for road use, 0.037 grams/megajoule:[19] Non-road diesel engines, 1 gram/kilowatt-hour for sizes less than 8 kilowatts in tier 1 down to 0.2 grams/kilowatt-hour for units larger than 560 kilowatts in tier 2.[20] Locomotives, 0.36 grams/bhp-hr for switching service in tier 1 down to 0.1 grams/bhp-hr for line service in tier 3.[21] Marine diesel engines, 0.2 grams/KwH to 0.5 grams/KwH, depending on displacement and tier.[22] Note that the emission units above are as specified in the printed regulation.

Particulate emission standards are also being promulgated by agencies other than the Environmental Protection Agency. In general, these are workplace standards. An example would be the standard for mobile diesel-powered transportation equipment promulgated by the Mine Safety and Health Administration. This specifies that the exhaust "shall not contain black smoke."[23]

MEASUREMENT OF PARTICULATE EMISSIONS

As a first step in any program for control of particulate emissions, a determination must be made of the quantity and nature of particles being emitted by the subject source. The quantity of emissions determines the collection efficiency and size of required cleanup equipment. The particle size and chemical properties of the emitted dust strongly influence the type of equipment to be used. Sampling for this purpose has been mainly a matter of industrial concern. A last step in most control programs consists of measuring pollutants in the cleaned gas stream to ensure that cleanup equipment being used actually permits the pertinent emission targets to be met. With increasing public concern and legislation on air pollution, sampling for this purpose is increasingly required by statute to determine compliance with the pertinent emission regulations. To this end the local pollution control authority may issue a comprehensive sampling manual which sets forth in considerable detail the procedures to be used in obtaining raw data and the computations involved in calculating the pertinent emission levels.

Complete and comprehensive source testing procedures are beyond the scope of this paper. References 24–28 give detailed instruction for performance of such tests.

Sampling of gas streams, especially for particulates, is simple only in concept. Actual measurement require specialized equipment, trained personnel, careful experimental and computational techniques, and a considerable expenditure of time and manpower. Matters of technique and equipment are covered in source testing manuals as mentioned above and are briefly summarized later in this paper. Two additional complicating factors are usually present. First is the frequent inaccessibility of sampling points. These points are often located in duct work 50–100 ft above ground level. Scaffolding must often be installed around the points, and several hundred pounds of equipment must be lifted to that level. Probe clearances are often critical, for in order to make a sample traverse on 12 ft dia. stack, a 14 ft probe is needed, and clearance must be available for insertion into the sampling port as well as a means for suspending the probe from above. At least one professional stack sampler is an amateur mountain climber and puts his hobby to good use on the job. A second complicating factor is the adverse physical conditions frequently encountered. A somewhat extreme but illustrative example is a refinery stream recently sampled. Gas temperature was 1200°F requiring special probes and gaskets and protective clothing for the workers. The gas stream contained 10% carbon monoxide creating potential hazards of poisoning and explosion especially since duct pressure was slightly above that of the atmosphere. Temperature in the work area was in excess of 120°F contributing further to the difficulty of the job.

In preparation for a sampling program, work platforms or scaffolding and valved sample ports must be installed. All special fittings for adapting the sampling probes to the ports should be anticipated and fabricated. Arrangements must be made with plant operating personnel to maintain steady operating conditions during the test. The test must be carefully planned as to number and exact location of traverse sample points, and probes should be premarked for these locations. Flow nomographs for sampling nozzles should be made; and all filters, impingers, and other element of sampling trains should be tared. With that advance preparation a 3 man sampling team would require 1–2 days to position their equipment and make gas flow measurements and 2 sample transverses at right angles in a large duct or stack.

Measurement of Gas Flow Rates

A preliminary step in determination of emission rates from a stack is measurement of the gas flow rate. Detailed procedures in wide use including the necessary attention to technique have been published by the ASME,[20] ASTM,[19] the Environmental Protection Agency, referred to as EPA,[21]

TABLE 3
Federal Limits of Particulate Emissions from New Stationary Sources

(Through 2004 Codified in CFR, Title 40. Chapter 1/Part 60)

Subpart	Source	Particulate Emissions	Opacity (%)
D	Fossil fired steam generators	13 ng/j	20*
			(27% for 6 min/hr)
Da	Electric utility steam generators	43 ng/j	20*

*Continous monitoring by capacity meters required

The above standards apply to current construction. Existing unmodified units may have lower standards.

Many applications require continuous monitoring of operating variables for process and control equipment.

the Lost Angeles Air Pollution Control district, referred to as APCD,[21] and the Western Precipitation Division, referred to as WP.[21] This article will only treat the general procedures and not significant differences between popular techniques.

Velocity Traverse Points Because of flow non-uniformity, which almost invariably occurs in large stacks, the stack cross section in the sampling plane must be divided into a number of smaller areas and gas velocity determined separately in each area. Circular ducts are divided by concentric circles, and 2 velocity traverses are made at right angles. Figure 4 shows a typical example. Location of the sample points can be determined from the formula

$$R_n = D\sqrt{\frac{2n-1}{2N}}$$

where

R_n = distance from center of duct to the "nth" point from the center
D = duct diameter
n = sample point number, counting from center
N = total number of measurement points in the duct. The number of sample points along one diameter is $N/2$.

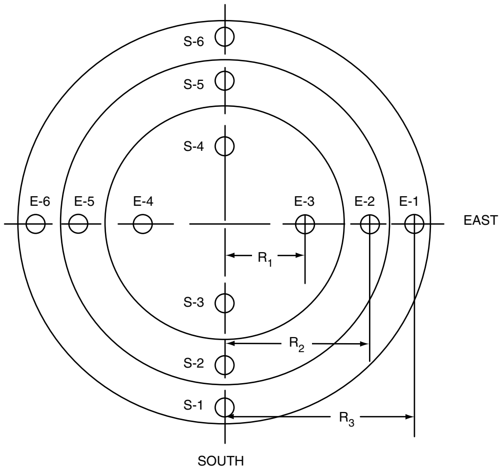

FIGURE 4 Velocity and sampling traverse positions in circular ducts.

For rectangular ducts the cross section is divided into N equal rectangular areas such that the ratio of length to width of the areas is between one and two. Sample points are at the center of each area.

The number of traverse points required is usually specified in the applicable test code as a function of duct area or diameter. Representative requirements are shown in Table 4.

TABLE 4
Required traverse points

Code	Duct sizes	Number of points
EPA[8]	2 ft dia.	12 minimum
More according to Figure 2 if near flow disturbance		
WP[17]	<2 ft^2	4
	>2–25 ft^2	12
	25 ft^2	20 or more
APCD[14]	1–2 ft^2 (rectangular)	4
and	2–12 ft^2	6–24
ASTM[15]	>12 ft^2	24
	1–2 ft dia.	12
	2–4 ft	16
	4–6 ft	20
	>6 ft	24 or more
These numbers should be doubled where only 4–6 duct diameters of straight duct are upstream.		
ASME[16]	<25 ft^2	8–12
	>25 ft^2	12–20
Double or triple these numbers for high nonuniform flow.		

Very often more points are required if the flow is highly nonuniform or if the sampling point is near an elbow or other flow disturbance. Figure 5 shows the EPA adjustment for flow nonuniformity.

Velocity Measurement Velocity measurements in dusty gases are made with a type S (special or staubscheibe) pitot tube, shown in Figure 6, and a draft gage manometer. Gas velocity is given by

$$V = C\sqrt{2gh_L\rho_L/\rho_g}$$

where

V = gas velocity
C = pitot tube calibration coefficient. This would be 1.0 for an ideal pitot tube, but type S tubes deviate considerably.
g = acceleration of gravity
h_L = liquid height differential in manometer
ρ_L = density of manometer liquid
ρ_g = gas density.

It is necessary to measure the temperature and the pressure of the gas stream and estimate or measure its molecular weight in order to calculate density.

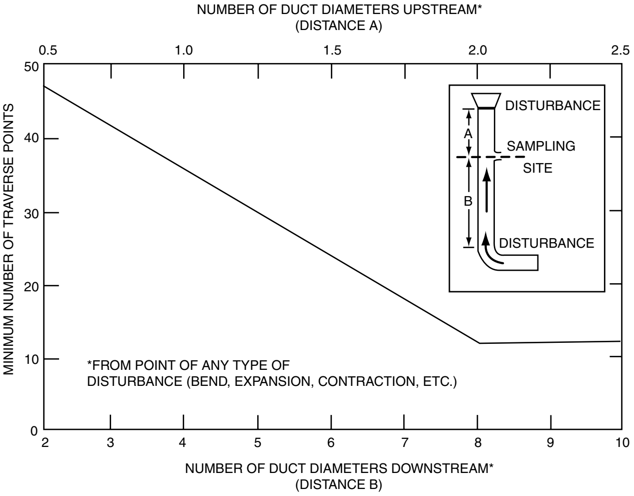

FIGURE 5 Sampling points required in vicinity of flow disturbance (EPA).

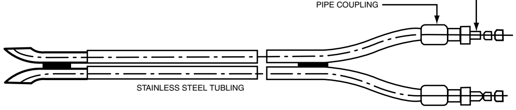

FIGURE 6 Type S Pitot tube for use in dusty gas stream.

Gas Analysis For precise work gas composition is needed for three reasons (1) so that molecular weight and gas density may be known for duct velocity calculations, (2) so that duct flow rates at duct condition can be converted to standardized conditions used for emission specifications. Standard conditions are usually 70°F, 29.91 in. mercury barometric pressure, moisture free basis with gas volume adjusted to 12% CO_2. Some codes differ from this, however. (3) For isokinetic sampling moisture content at stack conditions must be known in order to adjust for the fact that probe gas flow is measured in a dry gas meter at ambient conditions.

Gas analysis for CO_2, CO, and O_2 is almost always done by Orsat analysis. Moisture may be determined gravimetrically by condensation from a measured volume of gas as required by EPA.

Overall Flow Rate Total flow rate is calculated from duct area and average gas velocity as determined by the pitot tube measurements. Pitot tube traverse points are at the center of equal areas so no weighting is necessary to determine average velocity. This gives flow at duct conditions which is usually converted to standard conditions.

Measurement of Particulate Concentrations in Stacks

Standard methods for measuring particulation concentrations in stacks depend on the principle of isokinetic sampling. Since particles do not follow gas streamlines exactly but tend to travel in straight lines, precautions must be taken that the gas being sampled experiences no change in velocity or direction in the vicinity of the sampling point. This is done by using a thin walled tubular probe carefully aligned with the gas flow and by withdrawing gas so that velocity just within the tip of the probe equals that in the main gas stream. Several recent studies[29–31] have measured effects of probe size, alignment, and velocity on accuracy of sampling. The sampled gas is drawn through a train of filters, impingers, and a gas meter by means of a pump or ejector. Typical probes are shown in Figure 7, and several types are commercially available. With these probes the necessary gas sampling velocity must be previously determined by pitot tube measurement, and the gas flow rate at the flow meter is adjusted (taking into account gas volume changes due to cooling and condensation between stack and meter) to equal that velocity. An alternate method is to use a null nozzle, which contains static pressure taps to the outside and inside surfaces of the sample probe as shown in Figure 8. Flow through the probe is adjusted so that the static pressures are equal at which point the velocities inside and outside the probe should be the same. The null nozzle greatly simplifies sampling, but null nozzles require careful periodic calibration and are not generally used for high precision work.

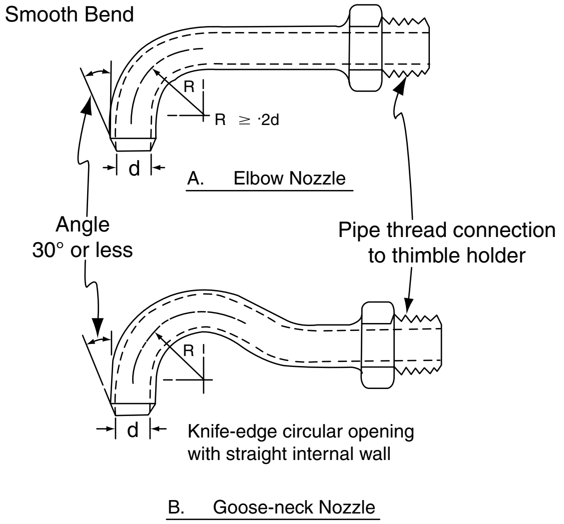

FIGURE 7 Nozzles for particulate sampling.

The sampling train of filters and impingers, which collects the particles, is usually carefully specified in the test method or governmental regulation in force. Differences between sampling trains to some extent reflect different technical solutions to the sampling problem but they also reflect differences in the philosophy of what exactly should be measured.

Perhaps the most widespread train will be that specified by the EPA[14] for testing new emission sources, shown in Figure 9. The original intent was to collect and measure not only particles which actually exist in the stack at stack conditions, but also solids or droplets that can be condensed out of the stack gas as it is cooled to ambient conditions. The filter is heated to avoid condensation and plugging. The first two impingers contain water to collect most of the condensables. The third impinger is empty and serves as an additional droplet tray while the fourth impinger is filled with silica gel to collect residual water vapor. Although the impingers in the train collect condensibles, present regulations are written only in terms of the solid particulates which are collected in the filter.

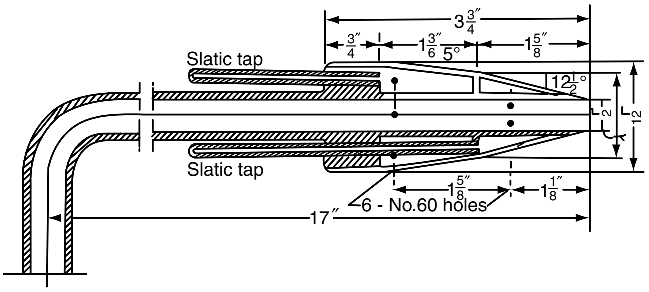

FIGURE 8 Null type nozzle for isokinetic sampling.

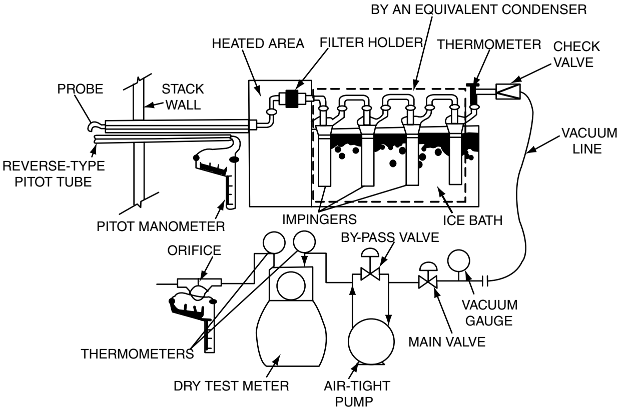

FIGURE 9 Environmental Protection Agency particulate sampling train.

The ASME power test code,[27] in contrast, is designed to measure performance of devices such as precipitators and cyclones, and thus is concerned only with substances which are particulate at conditions prevailing in the equipment. This test usually used a filter assembly with the filter very close to the sampling probe so that the filter may be inserted into the stack avoiding condensation. No impingers are used.

To some extent filter characteristics are determined by process conditions. Alundum thimbles and glass wool packed tubes are used for high temperatures. If liquid droplets are present at the filter inlet, glass-wool tubes are the only useful collection devices, because conventional filters will readily become plugged by droplets. Glass-wool collection greatly complicates quantitative recovery of particles for chemical or size analysis.

In sampling a large duct having several traverse points for flow and particle measurement, particles for all points on a traverse are usually collected in a single filter impinger train, thus giving an average dust concentration. Each sample point is sampled for an equal time but at its own isokinetic velocity. The probe is then immediately moved to the next point and the flow rate adjusted accordingly. Sample flow rate is adjusted by rotameter or orifice readings, but total gas flow during the entire test is taken from a dry meter.

Minimum sampling time or volume is often set by regulation. Examples are:

Bay area[24]—Sample gas volume = 20 $L^{0.8}$, where volume is in standard cubic ft, and L is duct equivalent dia. in ft.

A maximum sampling rate of 3 SCFM is specified and a minimum time of 30 min.

ASME[27]—Minimum of 2hr with at least 10 min at each traverse point through two complete circuits.

APCD[25]—5–10 min/point for a total run of at least 1 hr.

Industrial gas cleaning institute—At least 2 hr or 150 ft^3 sample gas or until sample weight is greater than 30% of filter weight.

Emissions are calculated from test volumes of weight of particulates collected and volume of sample gas through the gas meter. Care must be taken to include particles deposited on tubing walls as well as those trapped by the filter. If condensibles are to be included, the liquid from the impinger train is evaporated to dryness, and the residue is weighed and included with the particulates. Corrections to the gas volume depend on sample train operation and on standard conditions for reporting emissions, and these are spelled out in detail in the specific test codes to be used. Results are usually expressed both as grains per cubic foot (using standard conditions defined in the code) and as lbs/hr from the whole stack.

Measurement and Representation of Particle Size

A determination of the emitted particle size and size distribution is a desirable element in most control programs. Collection efficiency of any given piece of equipment is a function of particle size, being low for small particles and high for large ones, and capital and operating costs of equipment required increased steadily as the dust particle size decreases.

Perhaps the simplest method of particle size measurement, conceptually at least, is by microscope count. The minimum size that can be counted optically is about 0.5μ which is near the wavelength of visible light. Electron microscopes may be used for sizing of smaller particles. Counting is a laborious procedure, and sample counts are often small enough to cause statistical errors at the very small and very large ends of the distribution. This method requires the smallest sample size and is capable of giving satisfactory results. Care must be taken in converting from the number distribution obtained by this method to mass distribution.

A second simple method is sieve analysis. This is commonly used for dry freely flowing materials in the size range above 44μ, a screen size designated at 325 mesh. Using special shaking equipment and very delicate micromesh sieves particles down to 10μ can be measured. Error can be caused by "blinding" of the sieve mesh and sticky or fine particles, incomplete sieving, and particle fragmentation during sieving. A sample size of at least 5–10 g is usually required.

Another class of measurement techniques is based on the terminal falling velocity of particles in a gas (air). The quantity measured is proportional to ρd^2, where ρ is particle density and d is diameter. Hence a separate determination of density is needed. One such device is the Sharples Micromerograph (Sharples-Stokes Division, Penwalt Corporation, Warminster, Pennsylvania). The device records the time for particles to fall through a 2 m high column of air onto the pan of a continuously recording balance. Templates are available to convert fall time to ρd^2. The Micromerograph is mechanically and electrically complex but easy to use. An objection is that a significant fraction of the injected particles stick to the column walls and do not reach the balance pan. This effect can sometimes be selective, and it thus gives a biased size distribution.

A second sedimentation device is the Roller elutriator tube, Figure 10. A powder sample is placed in the tube and air is passed upwards through it for a specified time. A separation is effected with small particles being carried overhead and large ones remaining in the tube. Often a series of tubes of decreasing diameter are connected in a cascade with each successive tube having a lower air velocity and retaining finer particles. The Roller method was used quite widely in the petroleum industry for many years. However, it is slow, requires a large sample, does not give clean particle size cuts, and is sensitive to tube orientation. It is therefore being supplanted by newer methods.

A third sedimentation is centrifugal sedimentation. This is the standard test method of the Industrial Gas Cleaning Institute, and use of such devices of the Bahco type has been standardized by the ASME.[32] The Bahco analyzer consists of a rapidly spinning rotor and a superimposed radial gas flow from circumference to center. Larger particles are centrifuged to the outside diameter of the rotor, while small ones are carried to the center with a cut point determined by gas velocity and rotor speed.

Still another method is the Coulter Counter. In this technique the test powder is dispersed in an electrolyte, which is then pumped through a small orifice. Current flow between electrodes on each side of the orifice is continuously

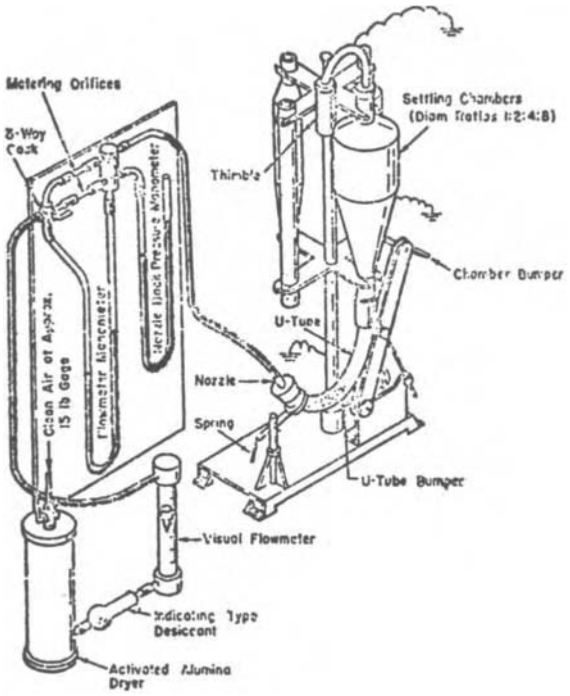

FIGURE 10 Air classifier for subsieve particle size analysis.

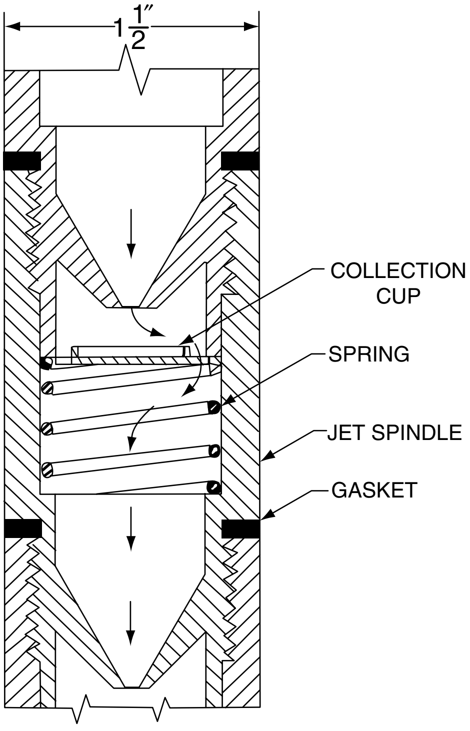

FIGURE 11 Stage of typical cascade impactor (Monsanto).

monitored. Passage of a particle through the orifice momentarily reduces current to an extent determined by particle size. The device electronically counts the number of particles in each of several size ranges, and a size distribution can then be calculated. The method is capable of giving very good results, and newer model counters are very fast.

A novel liquid phase sedimentation analyzer is the Sedigraph (Micrometrics Instrument Corporation, Norcross, Georgia). The particle sample dispersed in liquid is put into a sample cell and allowed to settle. Mass concentration is continuously monitored be attenuation of an X-ray beam, and this is mathematically related to particle size, X-ray location and time. The instrument automatically plots particle diameter as cumulative weight percent. The device can cover the size range from 0.1–10μ in a single operation, a much wider range than can be conveniently analyzed by most analyzers.

Laser optics techniques relying on light scattering, Fraunhofer diffraction, or light extinction are becoming the method of choice in many applications. The Leeds and Northrop "Microtrac" and Malvern Instruments Co. laser particle and droplet sizer are representative of such techniques. These Instruments can measure particles in a flowing gas stream, and thus can theoretically be used on line. More often a collected particulate sample is dispersed in liquid for analysis.

Impingement devices such as the Anderson Impactor, or in the impactors developed by May or Batelle, may be used to measure particle sizes *in situ* in a combined sampling and sizing operation. As is shown in Figure 11 such a device consists of a series of orifices arranged to give gas jets of increasing velocity and decreasing diameter, which jets impinge on collection plates, Successive stages collect smaller and smaller particles, and the size distribution of aspirated particles can be obtained from the weight collected on each stage and the size "cut point" calibration of the stage. Several studies of calibrations have been published,[33-37] and discrepancies have been pointed out.[38] Impactors must be operated at constant known gas flow rate and for this reason are not capable of giving true isokinetic sampling under conditions of fluctuating duct velocity. This is one of the few types of devices which may be applied to liquid droplets, which coalesce once collected. It is capable of size determination well below 1μ (finer than most devices). Because it eliminates recovery of particles from a filter and subsequent handling, it can be useful in measuring distributions at low concentrations.

Most particles emitted to the atmosphere are approximately spherical so that the exact meaning of "diameter" is not usually important in the context. For highly irregular particles a great many different diameters many be defined, each with particular applications. For purposes of particulate control equipment, persistence of airborne dusts, and physiological retention in the respiratory tract, the most meaningful diameter is usually the "aerodynamic" diameter, that of the sphere having the same free fall velocity as the particle of interest. This is the diameter measured by sedimentation, eleutriation, and inertial impaction techniques.

A large number of methods are available for expressing particle size distributions, each having properties of fitting certain characteristic distribution shapes or of simplifying

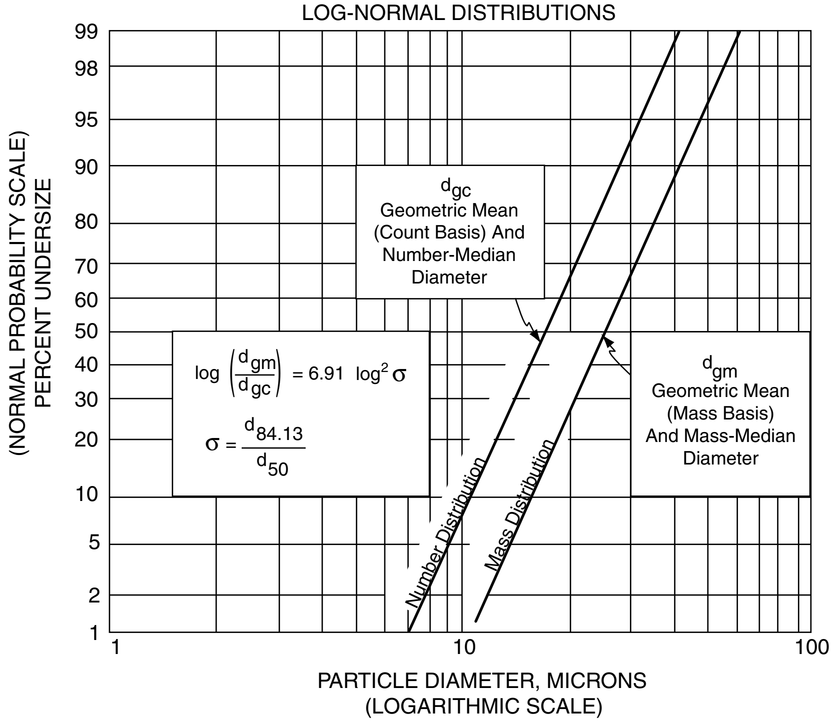

FIGURE 12

certain mathematical manipulations. A comprehensive summary of various distribution functions is given by Orr.[39] The most useful function in emission applications seems to be the long-normal distribution. Commercial graph paper is available having one logarithmic scale and one cumulative normal probability scale. If particle size is plotted vs. cumulative percentage of sample at or below that size, the log-normal distribution gives a straight line. A large percentage of emissions and ambient particulate distributions have log-normal distributions, and plotting on log-probability paper usually facilitates interpolation and extrapolation even when the line is not quite straight. For a true log-normal distribution very simple relationships permits easy conversion between distributions based on number, weight, surface area, and so on, which are covered in Orr.[39] Relationships between weight and number distribution are shown in Figure 12.

PARTICULATE REMOVAL

TYPES AND CHARACTERISTICS OF CLEANING EQUIPMENT

Three principal considerations enter into the selection of particulate removal equipment. Cleaning efficiency must be sufficient to meet the desired particulate emission levels, but efficiency much beyond this lower limit is usually unwarranted. Equipment operating characteristics, such as temperature and pressure drop limitations, must be compatible with the specific process application. Economic factors such as purchase and operating cost, delivery time, and reliability must also be considered.

Cleaning performance of specific particulate removal equipment is perhaps most usefully expressed in the form of a grade efficiency curve. This is the relationship of dust particle size (or a related property such as free-fall velocity) versus corresponding collection efficiency for that size particle. Overall collection efficiency is obtained by integrating the product of weight fraction increment times collection efficiency at that particle size over the cumulative weight fraction from 0 to 1. Since collection efficiency is highly dependent on particle size, this approach permits calculation of overall efficiency for any particle size distribution of dust entering the device. This is a more useful way of expressing performance than is the use of adjectives such as high efficiency or low efficiency.

Representative grade efficiency curves are shown in Figure 1. The figure should not be used for design purposes, because for a given type of equipment the exact placement of a curve depends on design characteristics and operating conditions. The figure is useful for preliminary screening and evaluation of relative merit of different types of collectors.

Extensive coverage of operating principles and design methodology is given by Stern,[1] Brauer and Varma,[2] Theodore and Buonicore,[3] and Licht.[4] More recent comprehensive treatments have included those by Cooper and Alley[5], Heumann[6] and Schneller[7]. Manufacturers literature and specifications have been conveniently collected[8] for many types of particulate collectors. The recent NAPCA study[9] is perhaps the most comprehensive attempt at a direct comparison of different types of equipment from the standpoint not only of operation and efficiency, but also of economics. This chapter will attempt to survey the features, performance, and selection of some of the major types of equipment in current pollution control applications.

Cyclones

Cyclones are one of the cheaper and simpler dust collectors available, but they have a relatively low efficiency unless used with coarse dust. A basic cyclone is shown in Figure 2. Dusty gas enters the tangential inlet, typically at velocities of 50–100 ft/sec. Gas flows in a helical path, first downward in an annulus and then upward in the center, passing out the top of the cyclone through the outlet pipe. Particles are driven to the cyclone walls by centrifugal forces on the order of 100 g and exit from the dust outlet at the bottom of the cyclone cone.

In many applications cyclone alone can give satisfactory particulate removal. For more stringent requirements cyclones are often used in series with other equipment with complementary characteristics. For example, cyclones can operate at almost any dust loading that a gas stream can carry and become increasingly efficient at higher loadings so that they are useful as pre-cleaners for equipment such as filters that would be choked by a high dust loading. Cyclone efficiency increases with gas throughput in direct contrast to precipitators, and thus they may serve to damp out effects of changing operating conditions.

Cyclone Performance The conceptual simplicity of cyclone operation has encouraged considerable theoretical analysis of particle collection efficiency. The usual approach is to calculate the acceleration the particle experiences based on inlet velocity and cyclone barrel diameter, and compute a terminal velocity of particles in a radial direction based on Stokes Law. A maximum distance a particle must travel before being collected at the cyclone wall is selected (usually the width of the cyclone inlet), and a gas residence time is calculated. The result is that one can calculate a critical particle diameter, the minimum size that can, according to such oversimplified theory, be collected at 100% efficiency as well as efficiencies for smaller parties. Stern[10] has compared several such calculations.[11–17] A more recent review by Strauss[18] has included references.[19–23]

All of the above mentioned equations employ extremely simplified models of gas flow. They assume instantaneous particle acceleration and no interaction of particles as well as absence of non-idealities such as particle re-entrainment. For such reasons this purely theoretical approach has not been very successful in predicting quantitative cyclone efficiencies. It gives, however, an acceptable basis for scaling of an experimental efficiency to other operating conditions and somewhat different sizes and geometries of cyclone. A semi-empirical

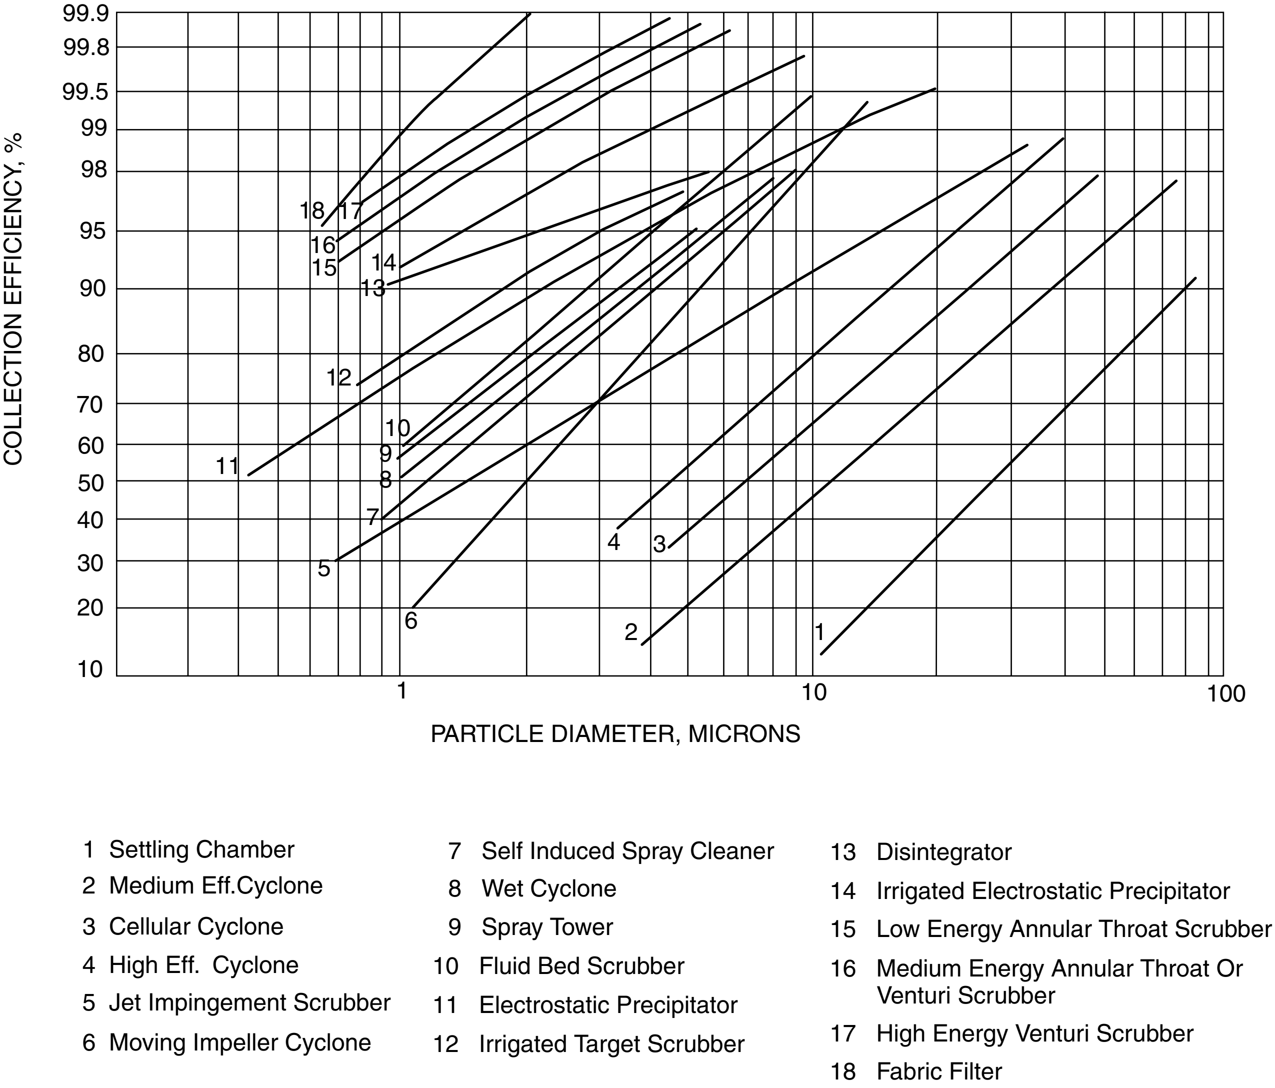

FIGURE 1 Typical grade efficiency curves.

approach can be based on the normalized grade efficiency curve shown in Figure 3. A survey of many experiments on efficiency[21–23] indicates that most cyclone grade efficiency curves have approximately the same shape. Using the theoretical basis for calculating critical particle diameter but introducing an empirical constant, one can calculate , the particle diameter at which collection efficiency is 50% at standard dust loading:

$$d^{\circ}_{50} = 1.16\sqrt{\frac{\mu WD}{\rho U^{2} t}}, \qquad (1)$$

where

μ = gas viscosity
W = cyclone inlet width
D = cyclone barrel diameter
ρ = particle density
U = gas velocity at inlet
t = average gas residence time.

Gas residence time is given by

$$t = \frac{V}{hWU},$$

where

V = cyclone volume
h = cyclone inlet height.

The above equation is applicable at dust concentrations of about 5 grains/ft^3 which is a standard concentration for

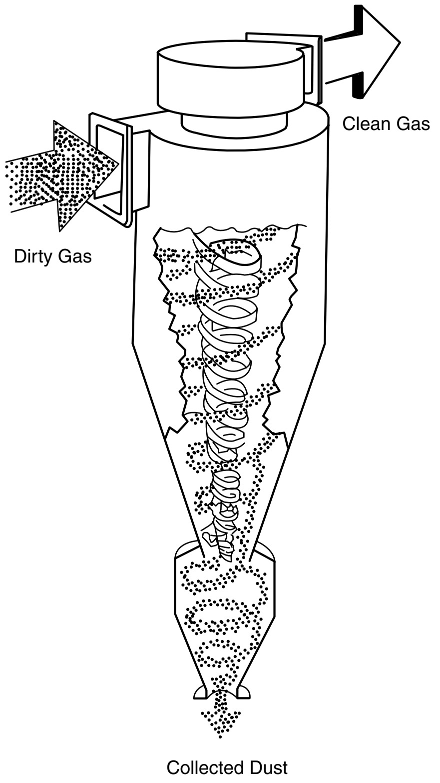

FIGURE 2 Conventional cyclone operation (The Ducon Co.).

cyclone testing. Studies of the effect of loading on grade efficiency have shown[24,25] that cyclone efficiency is very sensitive to dust loadings, and for this reason a correction to equation (1) is necessary for other concentrations:

$$\frac{d_{50}^{\circ}}{D_{50}} = \left(\frac{L}{L^{\circ}}\right)^{0.2}, \tag{2}$$

where the reference loading L° is 5 grains/ft^3. Using Eq. (2) for d_{50}, efficiency for other particle diameters d can be found from Figure 3.

Equation (1) can give directional effects for many geometric changes in design; but if data are available on the actual geometry of interest, it is much more satisfactory to use such data to modify the numerical constant in the equation. It is especially important to note that modifications to outlet pipe diameter to not enter into Eq. (1), and the numerical constant is for cyclones with normal ratios of outlet to inlet area of 1.3 to 1.5. For certain applications area ratios well below 1.0 are now being offered. Such cyclones have higher pressure drop. Unfortunately, suitable published data are not available on this effect to permit quantitative prediction of effect on efficiency.

Although some reviews have compiled "consensus" dimensions for cyclone design, quite a range of relative dimensions exists within the bounds of good design practice. Design is a compromise among efficiency, cyclone throughput, and pressure drop, and improvement in one factor will

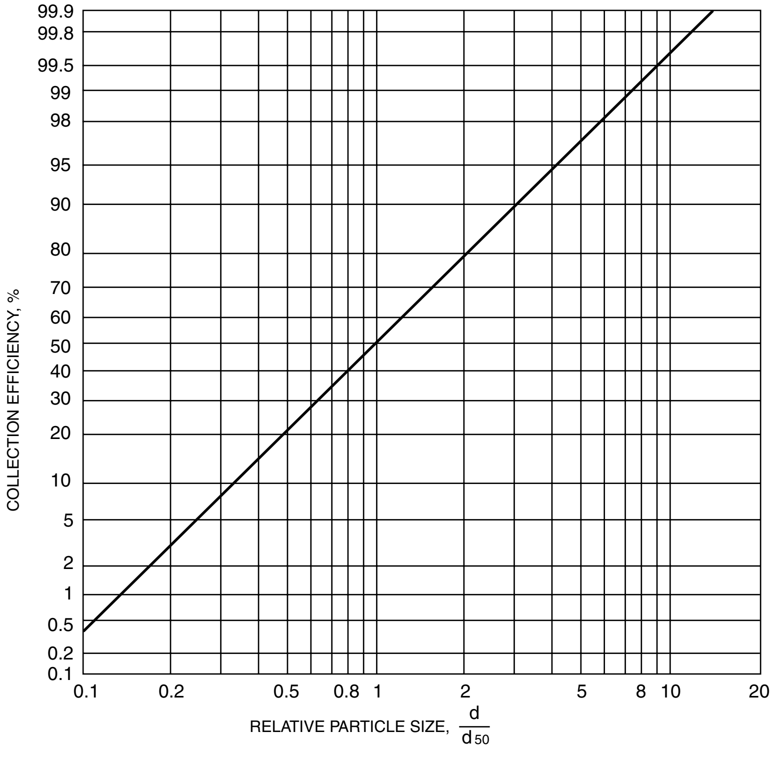

FIGURE 3 Generalized cyclone grade efficiency.

almost always result in debits to another. An example is shown in Figure 4 of three cyclones studied by Van Ebbenhorst Tengbergen.[24] They are drawn to the same scale and sized to have the same gas throughput and the same pressure drop. The relative costs of A : B : C are estimated as 4 : 3 : 9, but the difference in cost is reflected in the grade efficiency curves.

Pressure Drop Although pressure drop is much easier to measure than overall or grade efficiency, prediction of pressure drop from theoretical principles is not in good agreement with experiment. Stern[10] has analyzed the pressure drop predictions of several authors[26–28] and has concluded that a constant value of $X = 16$ in the equation

$$h_n = X\,\frac{H_i W_i}{d_0^2}, \tag{3}$$

where

h_n = pressure drop is expressed as inlet velocity heads
H_i = inlet height
W_i = inlet width
d_0 = outlet pipe dia.

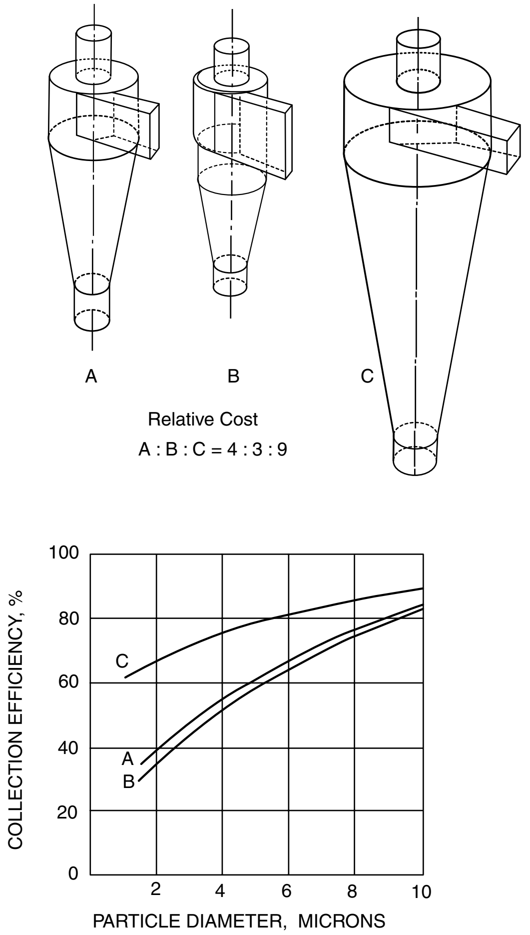

FIGURE 4 Relative sizes, costs, and grade efficiencies of different cyclone designs having same throughput and pressure drop.[21]

gives as good agreement with experimental data as does any equation for X which includes geometric factors. Measures values of X do indeed cover a wide range of values, and use of a constant value of X is merely a best guess in absence of data on the specific cyclone. Fortunately, because measurement is straightforward and simple, most vendors supply reliable information on pressure drop for their own cyclones.

For most cyclone applications the only pressure drop of interest is that from gas inlet to gas outlet. In some applications the pressure drop from gas inlet to the dust outlet at the bottom of the cone is also important. Such is usually the case for cyclones above fluid beds where collected dust is returned directly to the bed through a fluidized standpipe or dipleg. Too great a pressure drop to the dust outlet will preclude a satisfactory pressure balance in the dipleg and prevent proper discharge of particles. As a first approximation pressure drop from inlet to dust outlet can be taken as 13.5 inlet velocity heads.

Cyclones in Series Cyclones are often installed in series either with other cyclones or as pre-cleaners ahead of more efficient dust collecting equipment. As pre-cleaners they are especially attractive because efficiency increases with dust loading and because they seem able to handle almost any dust loading that a gas stream can carry to the inlet. Some cyclones in fluid catalytic crackers operate at inlet loadings of over 1lb dust per actual cubic foot of gas. Two stages of internal cyclones in a cat cracker often operate at an overall collection efficiency of 99.997% on catalyst with a particle density of 75–80 lbs/ft^3 and a mass median dia. of 60 μ. A third stage of cyclone in this application may be expected to operate at about 85% efficiency, however, because that stage sees much finer particles at much lower loading. Cat cracking cyclones typically operate at pressure drops of about 1 psi/stage, higher than is tolerable in many applications.

Optimum Cyclone Size and Parallel Operation The choice of one or a few large cyclones as opposed to many smaller cyclones operated in parallel represents a balance between the lower cost of a few large cyclones combined with easy manifolding against the inherently higher efficiency of the smaller cyclones. Each application is different, but the considerations that apply in determining size of cat cracker cyclones may prove instructive:

1) Cracking catalyst is highly erosive necessitating periodic repair of internal metal surfaces or refractory linings. The cyclones must permit access for such repairs, which sets a minimum barrel dia. of about 3½ ft.
2) Cyclone length is proportional to diameter, and headroom plus dipleg pressure balance often limits its diameter (a 5 ft dia. cyclone is typically 17 ft long). Reactor openings also limit diameter as does reduced efficiency.

The result is that in this application cyclone diameters usually range from about 3½ to 5 ft. A large cat cracker regenerator may have 20 pairs (primary and secondary) of cyclones in parallel. The secondary cyclones discharge into a common plenum head.

Operating Conditions Upper temperature limits for cyclones are limited by materials consideration to about 1700°F in conventional designs. They can withstand pressures of several psi with normal design, but for high pressure operation enclosure or special fabrication is required. Only fairly freely flowing material can normally be discharged, and special design or operating techniques are required for sticky or coking material. Low efficiency on fine particles usually precludes use where a significant fraction of material to be collected is below 10 or 15 μ in dia.

Multicellular Cyclones

Examination of Eq. (1) in the discussion of cyclones shows that d_{50}° becomes smaller and collection efficiency therefore increases as cyclone diameter decreases. Advantage is taken of this effect in multicellular cyclones, which have diameters in the range of 6–10 in. as compared to several feet for conventional cyclones. Because they are small, many cellular cyclones must be operated in parallel, and they are designed to facilitate manifolding into arrays which may number several hundred. Figure 5 shows a typical cellular cyclone. For ease of manifolding it is constructed with an axial inlet with swirl vanes to impart spin to the gas instead of having the tangential inlet of large cyclones. They are usually cast or molded in standardized designs instead of being custom fabricated as large cyclones are. An array of cellular cyclones is shown in Figure 6. This type of collector is designed to operate at low pressure drop, typically less than 4in. of water. This makes it attractive for use for fly ash recovery in power plants, where only slight pressure drops can normally be accommodated.

Arrays of cellular cyclones in parallel suffer an efficiency debit compared to single cyclones of the same design. This is usually attributed to unequal distribution of gas among cyclones abetted by the low pressure drop, and to recirculation patterns of gas down through one cyclone dust outlet and up through the next. The gas upflow causes a loss of efficiency. Many vendors will cite grade efficiency curves for a single cyclone which are, however, not representative of manifolded arrays. The magnitude of the performance debit can be seen in Figure 7.

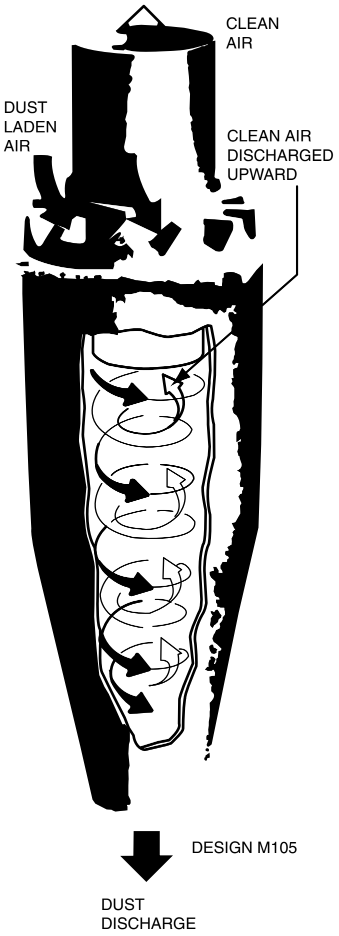

FIGURE 5 Multicellular cyclone with axial inlet vanes. (Courtesy: Wheelabrator Air Pollution Control.)

Electrostatic Precipitators

Electrostatic precipitators enjoy an image of being the ultimate in high efficiency air pollution control equipment. There is an element of reality in such a judgment, but precipitators are extremely expensive in terms of investment, operation, and space requirements, and they are often subject to obscure maladies which may cause collection efficiency to be far less than expected. Thus installation of a precipitator will be costly and may not solve a particulate emission problem.

The strong points of precipitators are (1) very low pressure drop (less than 1 in. of water, compared to about 3in. for cloth filters, 5–30 in. for centrifugal collectors and up to 60 in. for high energy scrubber); (2) sizes to handle very high gas flow rates; (3) potential of high collection efficiency on fine dust; (4) ability to operate at high temperatures (800°F is reached in commercial practice and pilot units have operated at 1700°F) and (5) dry collection of particles avoiding water pollution problem. These factors have been particularly suited to the requirement of coal-fired power plants, which constitute probably the most widespread users of precipitators or any other high efficiency particle collectors.

The standard text on electrostatic precipitator principles and practice is that by White.[29] A more recent work by Oglesby and Nichols[30] also includes an extensive survey of precipitator installations and performances. Other general references include the monographs by Rose[31] and Gottsclich.[32]

FIGURE 6 Typical manifolding arrangement of multicellular cyclones. (Courtesy: Wheelabrator Air Pollution Control.)

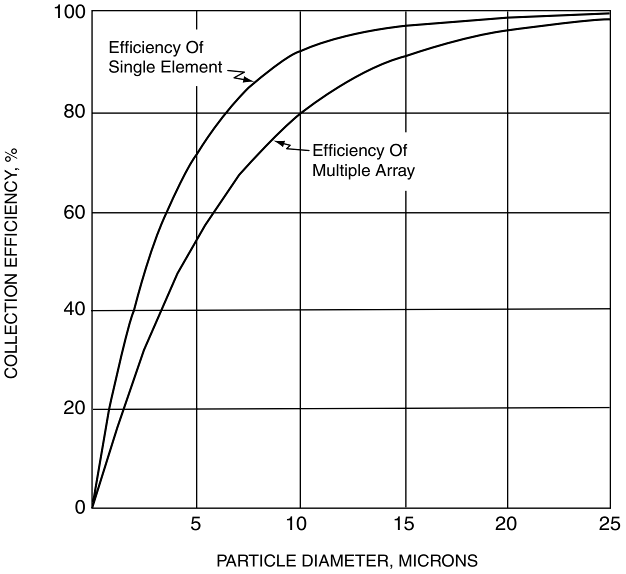

FIGURE 7 Performance debit for manifolding of multicones.

An excellent monograph on practical aspects of precipitator specification, operation, testing, maintenance, and troubleshooting has been recently published by Katz.[33]

Precipitator Operation Electrostatic precipitators have been constructed in a great many configurations. Contemporary commercial practice is fairly standard, however, and only this will be considered here. A typical precipitator, shown in Figure 8, consists of an array of parallel vertical plates, spaced about 9 or 10 in. spacing. Rows of wires hang vertically between the plates. These wires, called discharge electrodes, are maintained at a voltage of 30–60 kV with respect to the grounded plates. The very high electric field gradient near the wire electrode produces a corona discharge generating a high concentration of ions, which in turn charge the dust particles in the flowing gas stream. Under influence of the voltage gradient particles migrate to the plates, also called collector electrodes, where the charge is largely dissipated. A residual charge retains particles on the plates, and they are periodically dislodged by rapping. When dislodged, the particles fall in clumps into collection hoppers beneath the electrodes.

Gas flow across a flat plate surface tends to re-entrain collected dust particles causing an appreciable debit to collection efficiency. Various types of baffles are therefore used to shield the plate surface and provide a stagnant collection zone. The usual baffles are vertical and are perpendicular to the plate surface. They are typically 20 in. apart and extend 1.5 in. from the plate surface. Experimental and theoretical studies have shown that with such baffles re-entrainment of typical dusts by gas flow at the plate surface is not significant at gas velocities below 6 to 8 ft/sec.[34] This is well above recommended precipitator gas velocity.

The power supply for a precipitator consists of a high voltage step-up transformer and a rectifier. Rectifiers of various types have been used over the years, but solid state silicon rectifiers are almost universal in new installations. Unfiltered double half wave rectification is usually used. Full wave rectification is preferable for certain high current applications, and a simple change in connections usually suffices to change between the two wave forms.

Particle collection is enhanced by high voltage and current, but excessive voltage causes undesirable arcing or sparking between the electrodes. An arc is an ionized short circuit which diverts most current away from charging and collecting particles and also causes an undesirable voltage drop. Impingement of the arc on dust collected on the plate electrode can cause reentrainment. Optimum overall collection efficiency usually occurs when power input is adjusted to a spark rate of about 50–100 discharges/min. Modern precipitator control systems will automatically adjust voltage to maintain a preset sparking rate. Saturable core reactor control came into use in the late 1950's and a decade later this was being supplanted by entirely solid state (thyristor, i.e. silicon controlled rectifier or "S.C.R.") controls. SCR control has appreciably lower power losses and much faster response characteristics than the saturable core reactor and is able to operate at appreciably higher voltage and current without excessive sparking.

Large precipitators are usually sectionalized into several chambers in parallel and (within chambers) several electrical fields in series with respect to gas flow. Chambers can usually be independently isolated from gas flow so that one chamber may be shut down for maintenance while the others remain on stream. Use of several electrical fields in series permits optimum voltage control in each field. Outlet

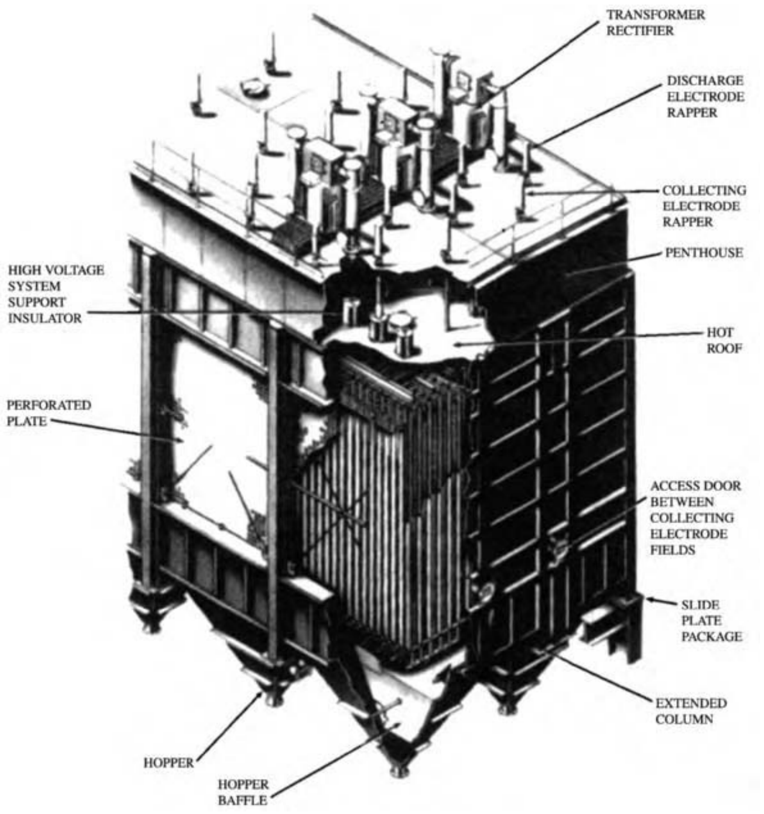

FIGURE 8 Perspective view of electrostatic precipitator showing main features of construction. (Courtesy Research Cottrell.)

fields with low dust concentrations can tolerate higher voltage without excessive sparking than can inlet fields. Further electrical sectionalization within fields is often desirable. A spark discharge momentarily hurts the performance of an entire electrical section, and small sections obviously limit the extent of the disturbance.

Electrodes are rapped with either pneumatic or solenoid rappers. Variable frequency and intensity controls are usually provided so that rapping may be optimized. Ideally that dust layer should be dislodged before becoming so thick as to interfere with electrical performance but after becoming thick enough to drop off in a coherent clump of particles. Rapping to an appreciable extent redisperses collected particles back into the gas stream, and a puff of dust is often seen in effluent gas when electrodes are rapped.

Precipitator Performance Parameters Precipitator collection efficiency is commonly expressed by the Deutsch[35] equation:

$$\eta = 1 - \exp\left(-\frac{AW}{Q}\right), \tag{4}$$

where

η = collection efficiency
A = plate electrode area
Q = volumetric gas flow rate
W = effective migration velocity rate of the dust.

In practice the migration velocity is an empirical constant which depends on the application and dust and gas properties. Typical migration velocities are given in Table 1. Although a considerable range of values is shown for some applications, a large part of such variation can be attributed to known causes and effects and does not represent uncertainty.

White[26] has derived a theoretical equation for migration velocity

$$W = \frac{E_o E_p d_p}{4\pi\mu},$$

where

E_o = charging field gradient, stat V/cm
E_p = collecting field gradient, stat V/cm
d_p = particle diameter, cm
μ = gas viscosity, poise.

Values of W measured on commercial installations are lower by a factor of 2–5 than the theoretical value above. Although the theoretical W is of little use for qualitative

TABLE 1
Representative precipitation rates for various applications[27]

Application	Precipitation rate w ft/sec	
	Average	Range
Utility fly ash	0.43	0.13–0.67

Cupola	0.10	—
Blast furnace	0.36	0.20–0.46

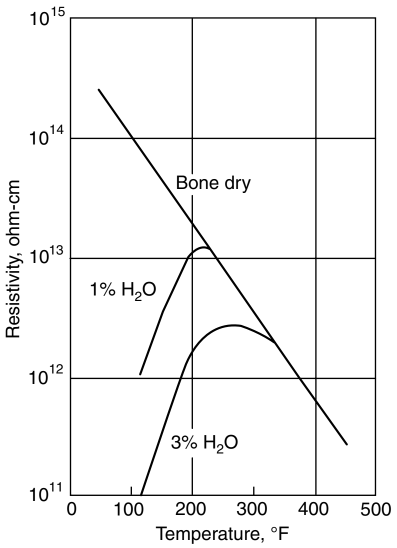

Figure 9 Effect of temperature and humidity on particle resistivity.[29]

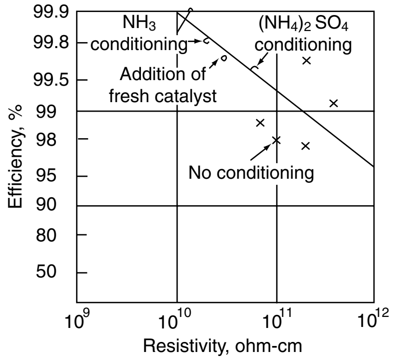

Figure 10 Effect of gas conditioning on efficiency of electrostatic precipitators.[26]

design, it does give a clue as to the influence of operating conditions of W. The term E_oE_p is roughly proportional to the power input to the precipitator, and it is clear that this should be as high as possible. From the dependence of W on d_p it is clear that precipitators have a higher collection efficiency for large particles than small ones. This is seldom taken into account in current design procedures in which an average particle size is included in the empirical W for an application.

Dust resistivity can have a very pronounced, although not quantitatively predictable, effect on precipitator performance. If the *in situ* resistivity of a dust layer collected on the plate electrode is less than about 10^7 Ω-cm, the electrical force holding the dust particles to the electrode will be low, and significant amounts of dust may be reentrained into the gas stream. If the resistivity is above 2×10^{10} Ω-cm, excessive sparking and back corona will occur hurting electrical performance and efficiency. Resistivity is a function not only of the dust but also of temperature and gas composition. At low temperatures surface conduction is predominant due to a thin layer of adsorbed moisture, and this decreases with increasing temperature. Volume conduction is important at high temperatures and decreases with temperature. A maximum resistivity usually occurs at about 400°F due to these opposing tendencies as is shown in Figure 9.

Gas conditioning by addition of moisture or other substances is sometimes practiced in order to improve the dust resistivity and enhance electrical performance of the electrodes. In certain instances addition of 10–20 ppm of ammonia has dramatically improved precipitator performance. Sulfur trioxide has also been used successfully, but it is expensive and creates its own pollution and safety problems. The effect of resistivity change, caused by conditioning, on precipitator efficiency is shown in Figure 10. In some gas streams conditioning agents may be naturally present which enhance precipitator operation. For instance, as indicated in Figure 11, power plants burning high sulfur fuel have improved performance due to the conditioning properties of sulfur combustion products. The present trend towards mandating use of low sulfur fuels in many urban areas will have an adverse effect on particulate removal.

Equation (4) shows the dependence of efficiency on gas flow rate provided flow is uniform. If gas velocities are different throughout the precipitator due to maldistribution of flow, the equation will be applicable only to local efficiency and the overall precipitator efficiency will be considerably lower. For instance a precipitator which could operate at 98% efficiency with even gas distribution would operate at only 96.5% efficiency if the same total gas flow were maldistributed so that half of the precipitator received 30% more than average and the other half received 30% less than average. Sharp turns and rapid expansion and contraction in dust work often make it difficult to achieve good gas distribution. Very often preliminary flow distribution tests are made on $\frac{1}{6}-\frac{1}{16}$ scale clear plastic models using smoke as a tracer. Such model tests are helpful in calling attention to duct work designs which will

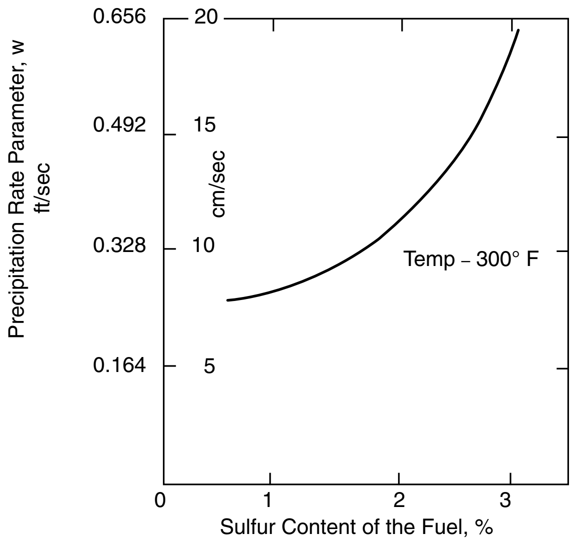

Figure 11 Effect of sulfur in fuel on precipitation velocity.[27]

cause poor gas flow patterns and allowing trials of baffle, diffusers, and turning vanes to reduce the problems.

Fabric Filtration

The process of particulate removal by filtration is one of the oldest methodologies in the gas cleaning field. Fabric filters possess several advantages, the most important one being that dust collection efficiencies of better than 99% are obtainable with sub-micron particles. Fabric filters are reliable, and relatively simple to operate, require moderate capital and operating costs and can be designed to handle a wide range of particulate loadings and gas flows. On the other hand, the choice of a fabric material limits the temperature, and corrosivity characteristics of the gas and high humidities must be avoided in order to prevent cake formation.

Removal of particulates from a gas stream by fabric filtration involves passing the gas through a filter medium made of a porous fabric. The solid is deposited on the fabric with a resultant increase in the flow resistance of the gas. A means of removing the solid matter which is built up on the filter is thus necessary to avoid excessive pressure drop of the gas through the filter cake.

Industrially, the filtration medium is contained in equipment known as a baghouse. These baghouses function to hold a large area of the filter exposed to the gas flow. The filter medium itself is generally in a tubular shape with gas flowing from the inside, through the medium and exiting outside the tubes.

This section will deal with the mechanisms of particulate collection on fabric filters, some of the design parameters of baghouses, performance characteristics of baghouses, and some data on the cost of baghouse equipment and the cost of running a fabric filtration.

Mechanisms of Particle Collection

Particulate collection by fabric filters essentially involves the capture of a particle by a collecting body. The gas stream carries the particles close to the collecting body, where a variety of mechanisms are involved in the actual capture. The mechanism or mechanisms which predominate depend on the size and velocity of the particles, and on the characteristics of the filter element itself.

The three major collection mechanisms involved in fabric filtration are (1) Interception, (2) Inertial Impaction, and (3) Diffusion. In addition to these three mechanisms, gravity, electrostatic, and thermal forces may act to modify filtration performance in special cases, but in general, these effects are negligible.

The mechanism of interception can be visualized as follows. The particle is assumed to follow the streamlines of the gas flow. As the gas flows by the collector, the streamlines are bent. Interception occurs when the streamlines on which the particle travels come close enough to the collecting body such that the particles comes into contact with the body. The efficiency of interception is a function of the ratio of the diameter of the particle to the diameter of the target body and to some extent to the flow characteristics of the stream. Ranz[36] has developed an expression for the efficiency in the case of a cylindrical target

$$\eta = \frac{1}{2.002 - \ln \mathrm{Re}_c}\left[(1+R)\ln(1+R) - \frac{R(2+R)}{2(1+R)}\right] \quad (1)$$

The acrylics (for example Orlon®, Acrilan®, Creslan®, and Crylon®) can be used at temperature up to about 275°F, but have relatively poor resistance to alkalis. Their resistance to acids and moist gases leads to application in the metallurgical industries as well as others such as carbon black, cement, fertilizers, solvents, and galvanizing.

The polyesters (for example Dacron®, Fortrel®, Vycron®, and Kodel®) can be used at temperatures of 250°F and have good resistance to alkalis as low temperatures.

Glass, Nomex®, and Teflon® are the fibers of choice of high temperature application (400–500°F). Glass is superior to the others in terms of high chemical and thermal resistance but suffers from very poor resistance to abrasion. Abrasion resistance can be improved by coating the glass fibers with a lubricant such as silicon oil or graphite. Applications include cement, gray iron cupolas, and electric arc steelmaking. Nomex®, an aromatic polyamide from duPont, can be used at temperatures up to about 400°F and excellent abrasion and flexural resistance.

Cloth Cleaning A large amount of effort in the development of fabric filters has gone into methods of removing the deposited cake from the fabric. Several considerations are important with regard to cloth cleaning.

1) The cleaning time should be much smaller than the filtering time, otherwise effective use is not being made of the filter.

TABLE 2
Relative properties of some common fabrics

Fiber	Max. temp. (dry) °F	Resistance to moist heat	Resistance to abrasion	Resistance to mineral acids	Resistance to alkalis
Cotton	180	G	G	P	G
Wool	200	F	F	F	P
Rayon	200	G	G	P	F
Nylon	200	F	E	P	G
Polypropylene	200	F	E	G	E
Acrylic	260	G	G	G	F
Polyester	275	F	E	G	F
Nomex	400	E	E	F	G
Teflon	400	E	F	E	E
Glass	550	E	P	E	P

E = excellent; G = good; F = fair; P = poor.

2) The cake should be removed uniformly.
3) Some residual cake is necessary after cleaning for efficient filtering.
4) The cleaning operation should not result in a large dispersion of dust because either a refiltration operation would be necessary or the efficiency of the filter would suffer.
5) The cleaning method should not result in excessive bag damage.

In general, the filter cloth is cleaned by shaking, gas flow reversal, or some combination of the two methods.

Mechanical shaking from the upper fastening is the most common method of cleaning the filter bags. Amplitudes vary from less than 1 in. to a few inches, and the frequency is usually several cycles per second. During the cleaning, the filtration is stopped, otherwise the dust will have a tendency to work through the bags and result in internal abrasion. For this purpose, the baghouse is built in several compartments to allow the isolation of one compartment at a time for cleaning. One disadvantage of this method of cleaning is the relatively large amount of fabric flexure involved especially at the top of the bags.

The second method of cleaning the bags is by flow reversal. If the dust cake is loosely adhering to the bag, then only a low-pressure reversal of fast flow will be necessary for cleaning; however, partial collapse of the bag can be done for the more adherent cakes. Although this method avoids some of the problems associated with bag flexure during shaking, it does have several disadvantages. Reverse flow without bag collapse requires that some support structures be placed within the bags (rings, screens etc.) which leads to difficulty in changing bags and chafing effects. Also, the reverse air used for cleaning has to be refiltered which results in a larger baghouse for a given filtration capacity.

A combination of the above two methods has been devised which is known as pulse cleaning. In this method, a pulse of compressed air is released from nozzles which results in a combination of flow reversal and fabric deformation. A unique feature of pulse cleaning is the short time required for cleaning. Therefore pulse cleaning is useful for equipment which must handle very high dust leadings. One of the major disadvantages of the method is its tendency to over-clean, especially for baghouses equipped with woven bags.

Other variations are available such as reverse jet cleaning which employs a jet of compressed air supplied from a ring which travels up and down on the outside of the bag. Occasionally, sonic vibration is used to aid in the cleaning.

Baghouse Construction The type of baghouse construction depends on the moisture condensation and temperature considerations. Below a temperature of about 135°F, an open-sided design can be used (inside filtration) which is the least expensive type. A closed baghouse is used at higher temperatures, and above 160°F, the structure is usually insulated.

Materials of construction are selected with regard to corrosiveness of the gas handled. Steel, aluminium, and asbestos cement are some typical materials of construction.

Performance of Fabric Filters The two parameters which are important in determining the performance of the fabric filters are its efficiency and pressure drop. The efficiency is a measure of how effectively the device is performing its job. The pressure drop is one of the major variables which determines operating cost because it affects the fan power necessary to move the gas through the filter, and also determines the frequency and duration of the cleaning cycle.

There are several factors affecting filter efficiency. The major one is particle size. In general, particles having diameters $>1\ \mu$ will be filtered with a $+99\%$ removal efficiency. Efficiencies are about 90% for particles $<1\ \mu$. In a typical baghouse application, most of the particles passing through the filter are of sub-micron size.

The amount of dust buildup on the filter medium also affects the efficiency of collection, because a particle has a greater probability of being trapped by one of the filtration mechanisms discussed previously if there is a greater amount of cake. Thus, cleaning should not be too thorough.

TABLE 3
Breakdown of capital and operating costs for fabric filtration

A. Capital investment

Item	Percentage of total cost
Planning and design	4.2
Baghouse, FOB	33.6

Item	Percentage of total cost
Electric power	11.4
Labor	28.6
Plant overhead	23.8
Cloth	9.5
Depreciation	15.2
Interest	11.5

The dust loading *per se* does not affect the efficiency significantly; however in the case of very low dust loadings (<0.5 gr/ft^3), a low efficiency will be observed for a time because of the low dust buildup on the fabric. To cirumvent this problem, a precoat is often used.

The relative humidity of the gas affects the efficiency somewhat, depending on the material being filtered. For some particles, an increase in relative humidity results in increased particle adhesion force, which tends to increase the rate at which the openings in the filter medium are bridged, resulting in an increase in the collection efficiency. The filtering velocity does not appear to affect efficiency significantly, except that higher velocities would tend to force more dust through defects in the cloth.

The pressure drop of the gas through the filter is a function mainly of the gas velocity, the thickness of the dust cake, and of the particle characteristics which determine the porosity of the cake which has built up. There have been a number of studies on pressure drop through fabric filters and the reader is referred to Billings and Wilder[37] for a more complete treatment of this subject.

Economics of Fabric Filtration

A detailed survey of fabric filtration costs was done by Billings and Wilder.[37] There was a relatively large range of reported costs. Capital investment was found to vary from less than $l per cfm to greater than $10 per cfm. operating costs varied from about $17 per cfm per year Values of about $2.50/cfm capital and $1.10/cfm annual operating can be considered typical. These costs are broken down into component parts into Table 3. It is apparent from an examination of the items contribution to the total economic picture that the costs for an installation will depend a great deal on many factors specific to the installation and gas being handled.

GUARANTEE SPECIFICATIONS

Equipment vendors usually make a guarantee of overall particle collection efficiency as a part of bid proposals, but historically such guarantees have been more an indication of anticipated performance than an enforced or enforceable contract for several reasons. The isokinetic sampling always necessary for a proper efficiency test is difficult and time consuming and in some cases, e.g. for internal cyclones above fluid beds, it is a practical impossibility. Secondly, in the days of less stringent emission statutes the mere presence of control equipment often served to satisfy the spirit if not the letter of the law. Most guarantees in the past were written for a fixed set of operating conditions and were not legally enforceable at the deviant conditions that usually obtained during a test. Finally a legal recourse to poor performance is seldom spelled out in a contract. In the present climate of stringent emission limits and enforcement thereof, of substantial penalties for non-compliance, and of long equipment delivery times, purchasers are obliged to become more insistent that equipment perform according to a strict guarantee. Accordingly, the following suggestions are made for the writing of a performance specification.

A guarantee can only deal with the cleaning efficiency of a piece of equipment on the dusty gas stream actually entering it. Vendors quite understandably will refuse to guarantee an outlet loading, a Ringlemann number, or a dustfall, because these depend directly on the amount and particle size of dust entering the equipment as well as on the inherent capabilities of that equipment. In addition, optical properties of plumes are too little understood for generally acceptable prediction of Ringlemann numbers, even when the concentration and particle size of the emissions are known.

Performance guarantees are often written for a single set of design conditions without any provision for adjustment if, as usually happens, the design and actual test conditions are different. In such a situation the likelihood of proving and receiving compensation for substandard performance is small. It is therefore desirable that a range of operating conditions be specified and a procedure be defined for adjusting the guarantee performance at design conditions to a consistent performance at other conditions. The adjustment should be based on generalized efficiency relationships, e.g. Eq. (1) for cyclones and (4) for precipitators, or else on vendors design procedures. For instance Eq. (1) predicts that for a given cyclone, the response to changes in operating conditions is given by

$$d_{50} \propto \sqrt{\frac{\mu}{\rho U}}.$$

This used with the generalized grade efficiency curve, Figure 1, and the dust loading correction will give a suitable adjustment for changes in operating conditions so that starting from a guarantee performance at design conditions corresponding performance for other conditions may be calculated. In essence this establishes a guarantee envelope or curve to replace guarantee of a single point.

"Outlet stoppers," that is, low outlet dust loadings to be accepted as *prima facie* evidence of satisfactory performance regardless of actual efficiency, are sometimes included in guarantees. The reasons are that isokinetic sampling is laborious and increasingly imprecise at low dust loadings, and that certain types of equipment are thought to have inherent limits on outlet loadings, for example precipitators have rapping losses which may control overall efficiency in the low loading range. It is felt, however, that outlet stoppers should be used only to exclude certain tests of the guarantee and not as evidence that the guarantee has been met. Cases are known in which the purchaser desired an outlet loading of approximately .003 grains/ft^3 in order to meet anticipated regulations, but precipitator vendors specified outlet stoppers of .01 grains/ft^3.

Generally speaking, it is desirable to the purchaser to operate equipment for a number of weeks before making a guarantee acceptance test. Deterioration from factory performance will often occur in such a time span. This time span should be used only as a shakedown period and not a life test.

Consideration should be given to the action to be taken if equipment does not satisfy the guarantee performance, and a guarantee will usually be the better for spelling out such remedies. One frequent clause specifies that the vendor remove below par equipment and refund the purchase price. This gives considerable incentive to the vendor to meet the guarantee, but removal of pollution control equipment may mean complete shutdown or production at a loss of tens of thousands of dollars per day to the user. Another arrangement is the bonus-penalty clause, under which the vendor on a sliding scale receives a bonus or pays a penalty if equipment performs above or below guarantee. At present the bonus payment aspect is unattractive to the purchaser, because he receives no benefit from producing less pollution than the law allows although this would change if a system of effluent taxation were implemented. Most often the most satisfactory approach is to require the vendor to upgrade installed equipment and make additions as needed so that the guaranteed performance level is reached.

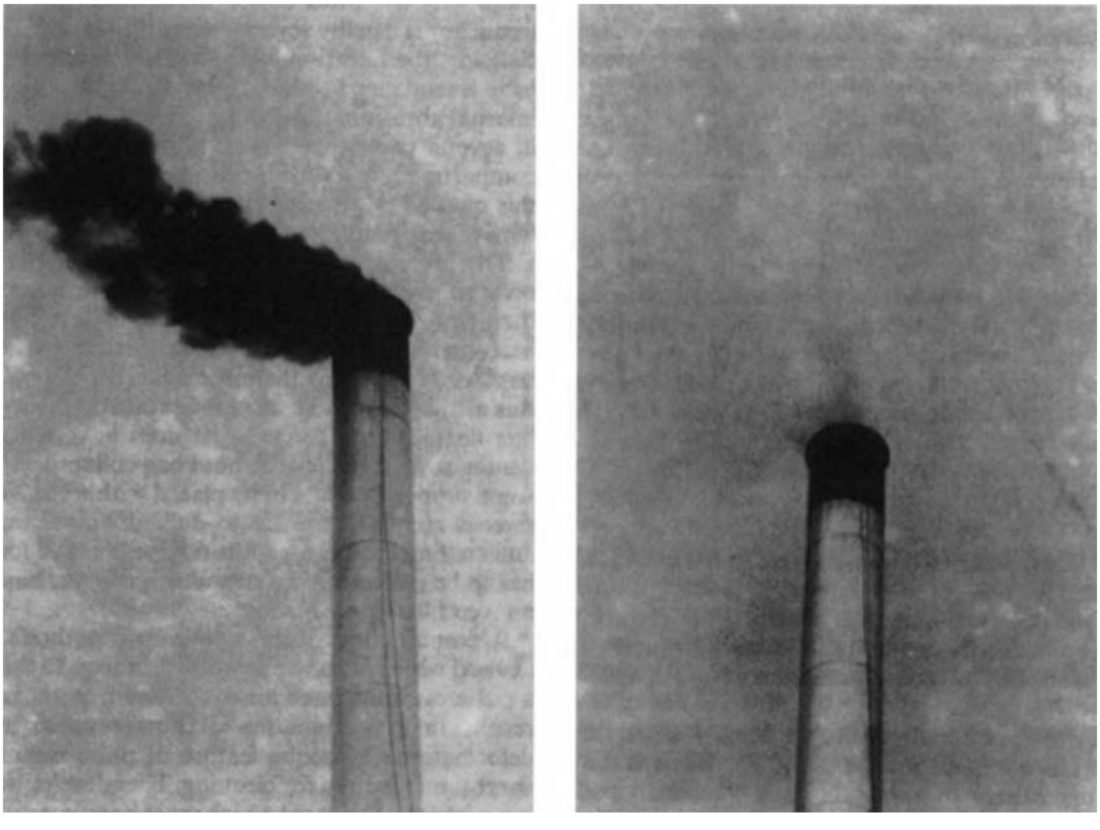

FIGURE 12 Before and after. The photograph on the left shows the typical dense smoke and soot being emitted from the stack of an industrial oil-fired boiler during the daily tube blowing or cleaning process. The photograph on the right shows the same stack during tube blowing with an emission control unit in operation.

PCBs AND ASSOCIATED AROMATICS

INTRODUCTION

Polychlorinated biphenyls (PCBs) are a family of chemical compounds which do not exist in nature but which are manmade. Commercial mixtures are clear, pale yellow liquids manufactured by the replacement of hydrogen atoms on the biphenyl molecule by chlorine. The reaction is controlled according to the percentage replacement of hydrogen and results in a product which contain chlorobiphenyls with one or, more usually, several chlorine atoms attached to each molecule.

The family of polychlorinated biphenyls can contain from 1 to 10 chlorine atoms arranged within the molecule in 209 different ways. The different molecular combinations are called congeners. The congeners which comprise the series of compounds with the same number of chlorine atoms are known as an homologous series.

The congeners are named according to the homologous series to which they belong. For example, a PCB containing 3 chlorine atoms would be called a trichlorobiphenyl, or one with 5 chlorine atoms a pentachlorobiphenyl. The homologous series of PCBs and the number of isomers contained in each are listed in Table 1.

The synthesis of biphenyl and its subsequent reaction with chlorine to yield polychlorinated biphenyls is shown in Figure 1.

PCBs have been manufactured by various companies throughout the world and are often referred to by the manufacturer's trade name. Table 2 lists the main producers.

The perceptions of risk associated with ownership and operation of PCB containing equipment is related to the risk of fires, spills, cleanup or noncompliance with regulations. The following time line focuses on the development of PCB risk perceptions as new knowledge grew from the time that PCBs were first used in industrial applications.

1881

PCBs were first described in the chemical literature in 1881 by Schmidt and Schultz.

1929–1931

PCBs were developed by the Federal Phosphorus Company and Swann Research Co. The latter business was bought by Monsanto in the Early 1930's.

The available data on the toxicity of PCBs were first summarised in an article published in 1931 (Smyth, 1931).

1933

The first reported episode of PCB-related toxicity occurred in 1933, at the Swann Chemical Co. Twenty three of 24 men working on the manufacture of PCB almost simultaneously developed skin eruptions that were diagnosed as 'chloracne'. Some of the men also complained of lassitude. The investigators report on the episode concluded that the toxic agent was an unidentified impurity, which had probably appeared

TABLE 1

Chlorobiphenyl	Empirical Formula	# of Isomers	Weight% Cl
mono	$C_{12}H_9Cl$	3	18.8
di	$C_{12}H_8Cl_2$	12	31.8
tri	$C_{12}H_7Cl_3$	24	41.3

Pyroclor	Monsanto (U.K.)	United Kingdom

in the PCB when a new source of crude benzene was used for making the biphenyl. When purchase from this benzene source was discontinued, and the process better enclosed, the chloracne problem disappeared.

1936

Halowax acne was a term first coined by Jones and Alden in 1936 to describe chloracne induced by PCBs. PCBs were being manufactured in a distillation process in which biphenyl was extracted from coal tar using benzene, styrene, toluene and xylene. Once the biphenyl was extracted, it was chlorinated with chlorine gas to produce PCB.

Chloracne was identified in workers manufacturing Aroclors [Schwartz, 1936].

1937

An early case report of death by cirrhosis of the liver with acute yellow atrophy may be attributable to PCNs rather than PCBs [Drinker *et al.,* 1937].

1938

Morphological changes were observed in rats dosed orally with PCBs (Aroclor 1265) in concentrations as low as 0.001 mg/Kg/d [Bennett *et al.,* 1938].

1943

Good and Pensky described the formation of acneiform eruptions in workers manufacturing Aroclors.

An investigation of dermatitis among cable strippers in the shipbuilding industry revealed lesions, cysts and keratinization of skin in not only the workers, but also in some spouses and children [Schwartz, 1943].

1944

Skin lesions similar to chloracne in humans were observed in three species of laboratory animals subcutaneously exposed to Aroclor 1242 at levels ranging from 7 mg/Kg/d to 138 mg/Kg/d [Miller, 1944].

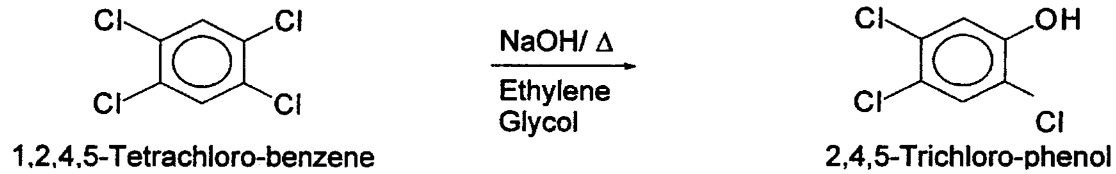

FIGURE 2 The intended reaction produces TCP.

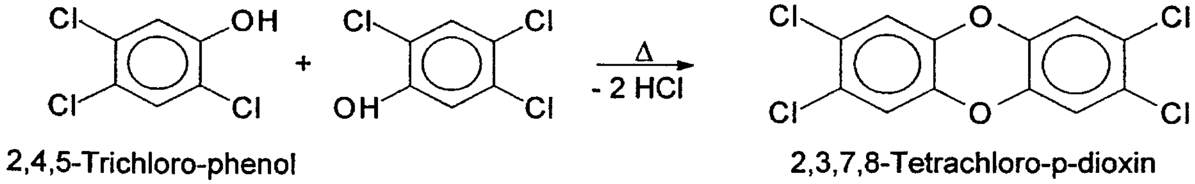

FIGURE 3 The dimerization of chlorophenates yields PCDDs.

1949

PCBs extracted from air were analyzed by Jacobs (1949) before the advent of gas chromatography.

1950

In the 1950–1952 time frame, an episode of PCB poisoning occurred when 7 of 14 people exposed to vapors from a leaking PCB-filled heat exchanger developed chloracne. [Meigs, 1954].

1952

Askarel used in capacitors up to 1952 was Aroclor 1254. After 1952 the type of askarel was changed to Aroclor 1242.

1953

Badische Anilin had an industrial accident on 17th November, 1953 and is one of seven similar accidents which have been recorded. The process involved the manufacture of trichlorophenol from tetrachlorobenzene (Figure 2).

The Seveso incident, which occurred in 1976, is perhaps the best documented industrial accident of this type. Thermographic records at the Seveso plant showed an uncontrolled rise in the temperature of the reaction vessel, following failure of a safety shutdown device. The mixture was heated at 230° to 240°C for 4 to 5 hours and 3 to 4 atmospheres before a safety disc ruptured and released nearly the entire mixture (Figure 3).

1954

Meigs *et al.* estimated that about 1 year was required to develop chloracne after the beginning of exposure to air with a concentration of 0.1 mg PCB/m^3. PCB was used as a heat exchange fluid for a reaction chamber. There was leakage of vapour which exposed a group of 7 to 14 workers.

1956

A Monsanto accident in the manufacture of chlorophenols occurred in the Monsanto Nitro Plant during 1949. A similar accident also occurred at Badische Anilin in Germany on 17th November, 1953.

Monsanto described their experience in a 1956 memorandum with personnel from Badische Anilin: "A thorough systematic investigation has isolated impurities in the trichlorophenol process (or residues) which will cause the same effects in rabbits." The materials mentioned include "pentachlor naphthalene" and "chlorinated diphenyl oxide".

PCDFs and PCDDs can be formed from chlorophenols in three different ways as follows:

1) the dimerization of chlorophenates;
2) the cyclization of polychlorinated diphenyl ethers (PCDPEs);
3) the cyclization of polychlorinated phenoxy phenols, termed pre-dioxins.

1 The dimerization of chlorophenates has been shown in the reaction shown above.

2 Polychlorinated diphenyl ethers are formed in the polychloro-phenol synthesis according to the following reaction (Figure 4).
The formation of PCDFs from the cyclization of polychlorinated diphenyl ethers is as follows (Figure 5).

3 Polychlorinated phenoxy phenols are termed 'pre-dioxins' for the reason that they are intermediates in the cyclization sequence (Figures 6 and 7).

One or more of the steps in the formation of PCDDs has a high activation energy. Activation energy in chemical

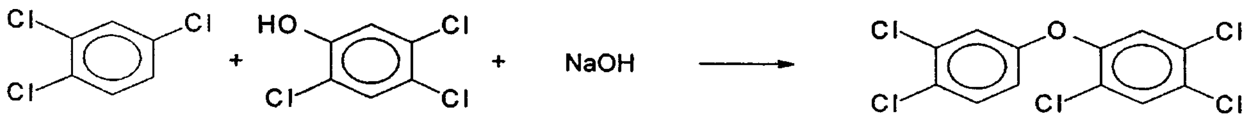

FIGURE 4 Formation of polychlorinated diphenyl ethers (PCDPEs) can lead to the formation of polychlorinated dibenzofurans (PCDFs).

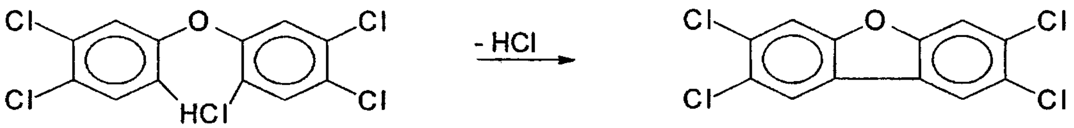

FIGURE 5 Loss of HCl produces cyclization of the diphenyl ether to a dibenzofuran.

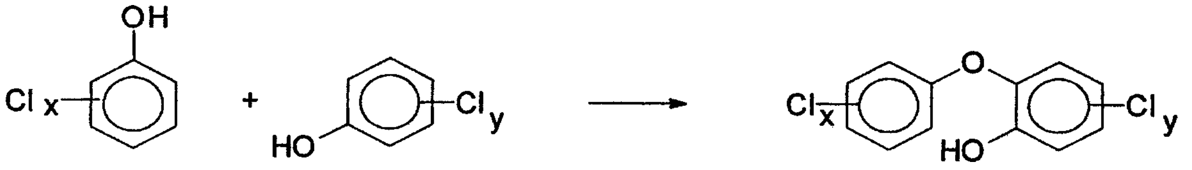

FIGURE 6

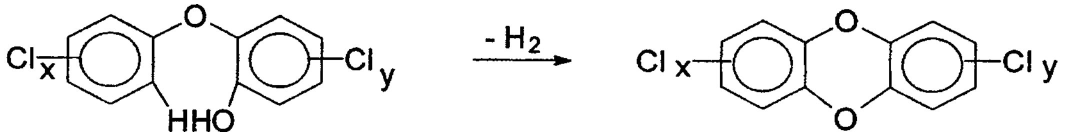

FIGURE 7 Loss of H_2 from the pre-dioxin produces PCDD.

thermodynamics is a concept which describes the energy flow in a reaction from reactants to products. When there is a high activation energy barrier, the reactants require more energy to attain an activated state than when there is a low activation barrier. Once the reactants have gained enough energy to form an activated intermediate they can either return to the reactant form or proceed to a stable product. The balance between the forward and backward reaction directions is an equilibrium condition which may be heavily weighted in favor of either the reactants or products. The high activation energy in the formation of PCDDs contributes directly to their low yields. The residue from the trichloro-phenol distillation in the Monsanto synthesis was reported to be 20 times less effective in producing liver necrosis in rabbits than the residue of the fraction remaining after heating to above 230°C. The boiling points of many dioxin precursors are lower than the reaction temperature range in which PCDDs are formed and therefore there is a loss of precursor molecules before reaction can occur.

The possibility of pressure differences in the formation of the residues are only one of several key parameters which make the comparison difficult. It is, nevertheless, clear that the residue derived from the high temperature distillation was substantially more toxic than the pentachloro naphthalene studied. The health effects of PCNs had been described in the literature some 17 years before but the effect observed on rabbits left in the operating area after the BASF accident was surprising—they died from liver necrosis after a *one week* exposure!

1957

A review of characteristic chloracne lesions appeared in 1957 by Schwartz *et al.*

1962

Threshold limit values for PCBs in workroom air were set in 1962 by the American Conference of Governmental Industrial Hygienists. Under “Chlorodiphenyl—42% Chlorine” it was stated that “Acne, systemic poisoning and even death may result from exposure to chlorinated diphenyls.” The references indicated were [Schwartz, L.: Am. J. Pub. Health; **26**, 586 (1936) and Drinker, C.K., Warren, M.F., Bennett, G.A.: J. Ind. Hyg. & Tox.; **19**, 283 (1937)]. A threshold limit value of 1 mg/m^3 was recommended to offer good protection against severe systemic toxicity but may not guarantee complete freedom from chloracne. In other words, it was recognized that there was a risk of severe systemic toxicity and that chloracne was a separate issue.

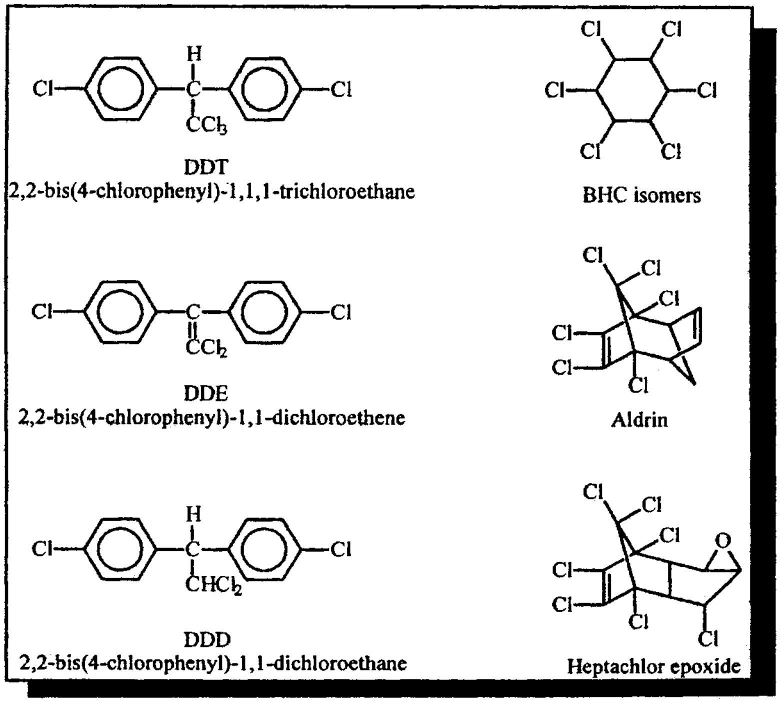

FIGURE 8 Widespread contamination by these compounds complicated the analytical quantitation of PCBs.

Chick edema disease was linked to PCB exposure when chicks were placed in galvanized cages that were coated with an epoxy resin paint. The paint had not hardened prior to placing the chicks in the cages, and within three weeks the chicks showed symptoms resembling those that had been reported as chick edema in incidents resulting from toxic components in chicken feed [McCune *et al.,* 1962].

Chick edema disease was linked to PCB exposure when chicks were placed in galvanized cages that were coated with an epoxy resin paint. The paint had not hardened prior to placing the chicks inside the cages, and within three weeks the chicks showed symptoms resembling those that had been reported as chick edema in incidents resulting from toxic components in chicken feed [McCune *et al.,* 1962]. Aroclor 1242 was determined to be the causative agent. Prompted by this initial finding, further studies on the effects of PCBs in chicks were conducted. Studies on chicks fed Aroclor 1242 showed high mortality, hydropericardium (accumulation of water in the sac that surrounds the heart), hemorrhagic edematous lungs (abnormal swelling from blood and fluid accumulation in the lungs), kidney tubular dilation and lesions, swollen liver, and a dose-dependent pathology [McCune, 1962; Flick *et al.,* 1965]. Growth rates of chicks were slowed in a dose-dependent manner and defeathering and dermatitis were reported [Flick *et al.,* 1965].

1963

A study with chick embryos showed 0% hatchability in high Aroclor 1242-dosed embryos. Embryo's showed beak deformity, edema and growth retardation [McLaughlin *et al.,* 1963].

1966

In 1966 the American Conference of Governmental Industrial Hygienists amended their description of the suggested limit of "Chlorodiphenyl—42% Chlorine—Skin" and stated that "Acne is not an invariable warning sign of impending, more severe, systemic toxicity" (Figure 8).

Jensen identified Aroclors 1254 and 1260 while analyzing for DDT [Jensen 1966]. He detected the presence of certain unidentified peaks in specimens of white-tailed eagle feathers dating as far back as 1942. Since DDT was used widely as a pesticide only after 1945 it was apparent that the pesticide-like chemical found in the samples was not a DDT break-down product, DDE or DDD. In 1967 G. Widmark unambiguously identified the contaminants as PCBs using MS.

The initial work by Jensen (1966, 1969) and of Risebrough (1968) sparked an immediate concern that PCBs had become ubiquitous in the environment. The information was reported in the San Francisco Chronicle of February 24, 1969. In an open letter to Monsanto's customers, the Environmental Health department, gave a cautious overview of the findings on March 3, 1969.

1967

G. Widmark published "IUPAC Commission of Methods of Pesticide Analysis: Possible Interference by PCBs."

Also: Jensen, S. and G. Widmark: OECD pesticide conference report on unintended residues in the environment.

1968

Risebrough *et al.* (1968) published in Nature: "Polychlorinated Biphenyls in the Global Ecosystem". Found that the eggshell thickness of fragments of a peregrine falcon egg was 34% less than the thickness of eggshells present in the same area 21 years previously.

September, 1968: Information sent by Westinghouse on "Inerteen and Environmental Contamination" described that "It has been indicated by several laboratories that measurable amounts of the PCBs are present in our general environment and may have some effect on certain species of wildlife. While askarels are generally regarded as being non-toxic to humans, it is reasonable to assume that very high standards of control will be issued by the Government in the overall program against pollution". The bulletin indicated that Monsanto had arranged for return of scrap Inerteen fluid in sealed drums and indicated that "Inerteen soaked coils, insulation scrap, filter cartridges, and other materials must be stored until appropriate methods can be provided to dispose of them properly."

In October 1968, Japanese health officials became aware of an epidemic disease which came to be known as "Yusho".

The cause of the disease was the ingestion of PCB contaminated rice oil over a period of about eight months [Kuratsune *et al.,* 1972]. The epidemic became the subject of a special issue of the journal Fukuoka Acta Medica in June 1969 [Kuratsune *et al.,* 1969]. The incident is important because it clearly documents the potential for reproductive and transplacental effects in humans.

About 325 patients with acneiform eruptions had been treated in northern Japan between the summer of 1968 and January 1969. The apparent cause of the poisoning was traced to the consumption of a particular brand of rice bran oil.

By May 1970 the total number of cases had risen to 1,291. The common symptoms included acneiform eruptions, hyperpigmentation of the skin, nails and mucous membranes, swelling of the upper eyelids, and hyperemia of the conjunctivae.

The 'Yusho' incident and another very similar accident in Taiwan, known as the 'Yu-Cheng' incident, are fully discussed in a later section.

The Yusho incident prompted the US Food and Drug Administration to initiate a national survey to determine the extent and levels to which PCBs might have made their way into the food chain.

1969

Analytical methods for the detection of PCBs in food became recognised as routine by the Food and Drug Administration (FDA).

Kuratsune *et al.* (1969) published an article entitled "Study on 'Yusho' or Chlorobiphenyls Poisoning".

Among the women with Yusho who were pregnant at the time of the outbreak, some were examined for observations that might indicate reproductive effects upon human exposure to PCBs. Since these case reports are based upon a small sample of Yusho cases, there observations cannot be verified statistically and are therefore only indicators that PCBs in rice oil might result in some reproductive effects that are not inconsistent with those reported in laboratory studies. Out of nine pregnant women, all of whom had characteristic Yusho poisoning, two incidents of stillbirth were reported in which the fetuses manifested Yusho symptoms such as brown staining of skin, nails and gingive [Taki *et al.,* 1969].

February 24, the *San Francisco Chronicle* carried a major feature about "a menacing new pollutant" in marine life research carried out by Dr. Robert Risebrough of the University of California.

March 3, 1969: Information on the San Francisco Chronicle's article is circulated to Monsanto customers in a letter dated March 3, 1969.

On March 7, 1969 the Associate Commissioner for Science and Deputy Associate commissioner for Compliance asked the Bureau of Science to evaluate foods sampled for pesticides for evidence of PCBs. None was indicated using the analytical methods of that time except for traces of PCB in fish from the Great Lakes.

March 10–14, 1969: District pesticide experts were given analytical information concerning PCB and told to be aware of the possibility of its presence in foods. (Pesticide Analytical Workshop 3/10–14/69).

PCB was identified as a contaminant of many of the fish analyzed as part of proceedings against the City Smoke Fish Co. of Detroit, MI (June and July 1969). The fish also contained DDT above 5 ppm.

July 1969: Cow's milk was found to be contaminated with PCBs (July 1969) from cows given feed treated with herbicides that had been diluted with PCBs.

On September 13, 1969 the Baltimore District Office of the FDA reported PCB in West Virginia milk. The source was traced to the use of an Aroclor as a solvent for pesticide spray.

Regulatory action at 0.2 ppm PCB on a whole milk basis was established by the FDA on December 16, 1969.

1970

Aroclor 1260 was discontinued in 1970. 1254 was an available alternative.

Monsanto, the only producer of PCBs in the US alerted its customers to the potential problem of environmental contamination. Major electrical equipment manufacturers were requested to relay the information to end-use customers with advice as to proper destruction of PCBs. Monsanto advised clients from 1970 onwards to be careful not to let water that may contain PCBs get into sumps or drains that would lead into the sewer system.

In 1970, the FDA prepared a summary of the available information on the chemistry and toxicity of PCBs. [US Dept. of Health, Education, and Welfare (1970): "Supplement 1—Status Report on the Chemistry and Toxicology of PCBs of

Aroclors"; Washington, D.C.: Bureau of Foods, Food and Drug Administration, Public Health Service.]

During 1970, the Council on Environmental Quality (CEQ) studied regulatory approaches to the problem of toxic chemicals in the environment. In its report published in 1971, CEQ identified PCBs as a major problem. [Council on Environmental Quality (1971): "Toxic Substances"; Washington, DC.]

Vos *et al.* (1970) published "Identification and Toxicological Evaluation of Chlorinated Dibenzofuran and Chlorinated Naphthalene in Two Commercial PCBs".

Increased levels of porphyrins are consistent with chronic hepatic porphyria that has been associated with exposures to other polyhalogenated aromatics. This condition can range from a subclinical state, where increased urinary porphyrin excretion results in no observed adverse effects, to porphyria cutanea tarda (PCT) which is a skin disease resulting in excessive light sensitivity, scaling, and itching. Increased levels of coproporphyrins and protoporphyrins in faeces and porphyrins in liver, bile and the small intestines of chicks fed Aroclor 1260, Clophen A60 and Phenoclor DP6 were reported by Vos and Koeman (1970).

Morphological changes in monkeys were observed with doses ranging from 1.4 mg/Kg/d to 16.4 mg/K/d and also mice dosed with 12.8 mg/Kg/d [Nishizumi, 1970].

Aroclors 1221, 1232, 1242 and 1248 in high doses, bind to estrogen receptors in the rabbit uterus [Bitman and Cecil, 1970].

Close parallels between the toxic effects of PCBs and PCDFs/PCDDs were established in a series of studies and reported in major scientific reviews such as [Crow, 1970].

Cleanup methods for analysis were devised to separate DDT and its analogues from some of the PCBs [Amour and Burke, 1970].

The Pesticide Regulation Division of the FDA issued PR Notice 70–25 instructing manufacturers and formulators of economic poisons containing PCBs and PCTs to change their formulations to exclude these classes of compounds.

Open letter from GE Electric Utility Sales Division to electric utility customers expresses environmental concerns and starts "As you are well aware the public concern with pollution is rapidly escalating."

February 3, 1970: The FDA initiated a regulatory threshold value of 5 ppm PCB in the edible flesh of fish, February 3, 1970.

August 1970: Fish near the effluent of Monsanto's Annison plant were found to contain PCB in August 1970.

August 1970: Cow's milk was found to be contaminated with PCBs (August 1970) from cows given feed that had been stocked in silos coated with PCB-based products.

September 1970: The Office and Science and Technology panel on Hazardous Trace Substances reviewed cadmium, arsenic and PCBs. Also, the National Swedish Environment Protection Board held a conference on PCBs. One of the sessions of the conference highlighted "environmental problems". This conference, perhaps for the first time, brought together the extent of understanding of the manufacture, use, extent of environmental contamination, analytical methods, and biological effects of PCBs.

September 14, 1970: An open letter from Monsanto, dated September 14, 1970 states: "As a supplier of askarel fluids namely Inerteen, Pyranol, and Aroclors which do contain PCBs, we wish to inform you that the FDA announced a guideline for PCB of 5 ppm in fish and 0.2 ppm in milk. Therefore, control of waste and spills is imperative."

A letter was sent to Monsanto customers requesting information on the quantities of PCB fluids that might be shipped to Monsanto for disposal so that the company could design an appropriate sized incinerator.

October, 1970: At the October Double Client Committee meetings, a subcommittee was formed to investigate PCB disposal problems.

October 12–14, 1970: The International Electrotechnical Commission Technical Committee No. 10; Liquid and Gaseous Dielectrics Subcommittee 10B; Insulating Liquids Other than Hydrocarbon Oils indicated in its minutes of meeting dated October 12–14, 1970: "Agenda–Item 5—To review current concern with the finding of PCBs in some environments and what action should be taken in recommending precautions in the application, processing and effluent disposal of askarels to prevent them becoming environmental contaminations … Copies of IEEE and ASTM documents were circulated by the US Delegation. A French Delegate circulated copies of a publication from Prodelac (a French producer of askarels)."

October 28, 1970: Minutes of the IEEE Insulating Fluids Subcommittee dated October 28, 1970 indicated "Monsanto will, however, discontinue by the end of 1970, the sale of Aroclors for application as plasticizers, heat transfer agents, hydraulic fluids and other non-electrical applications."

November 19, 1970: A NEMA letter to (ANSI) dated November 19, 1970, regarding the proposed committee on the disposal of askarel used in electrical equipment indicates " … The Monsanto Company has already taken steps to limit the availability of askarel to those users where the fluid is essential and is contained in a closed system, such as is the case for transformers and capacitors. With the cooperation of transformer and capacitor manufacturers, steps have been taken to alert all known users on the problem and on corrective measures. Monsanto has also instituted a means for disposing of askarel-soaked waste materials, coils, insulation, scrap, discarded capacitors, etc."

November 1970: Occurrence of PCBs in chickens following absorption from PCB-containing plastic wrappings.

In December 1970, Monsanto sent a letter to end users of PCB products requesting information on the amount and types of solid PCB contaminated materials that might be shipped to Monsanto for disposal. Monsanto was in the process of sizing the design for a kiln to incinerate PCB wastes and intended to make the service generally available.

1971

In 1971 Monsanto began to phase out production of the more highly chlorinated Aroclors: 1232, 1248, 1260, 1262 and 1268.

In 1971 Monsanto introduced Aroclor 1016, which had an average chlorination similar to Aroclor 1242 but with fewer of the more highly chlorinated compounds. At the end of 1975, only Aroclors 1221, 1016, 1242 and 1254 were still being produced.

Up to this point in time (1971) the principal government "control" actions for PCBs were the result of 'persuasion' by the Federal Government rather than by direct regulatory exercise. The Government possessed no real regulatory authority to control the manufacture, distribution or use of PCBs. However, strong influence was brought to bear by the several Government inquiries of the time—especially the PCB Interdepartmental Task Force. The principal recommendation of the PCB Task Force was the discontinuance of all uses of PCBs except in electrical capacitors and transformers. The latter uses were judged to be both essential to industry and represented 'closed' systems. Thus, the major action of PCB manufacturing phaseout and use restrictions were taken 'voluntarily' by Monsanto.

An OECD study on the sampling and analysis of residues in wildlife involved 23 laboratories in 13 OECD member countries between 1966 and 1971 and confirmed that residues of organochlorine pesticides, PCBs and mercury were to be found in a wide variety of species, in different habitats, and in areas where PCBs have not been deliberately released.

The OECD published a case study report of PCB and mercury pollution in Japan in 1976. The general situation regarding PCB pollution was described as follows: "Environmental pollution of PCBs was first recognized in Europe followed by the US then Japan. Results of field investigations demonstrated that PCB pollution in organisms inhabiting the natural environment was at a severe level. In Japan, analytical results indicating concentrations of residues in wild animals were first reported in 1971. In January of 1972, a standard method for the analysis of PCBs was established by the research group of the Ministry of Health and Welfare sponsored by Science and Technology Agency, whereby the uniform analysis of PCB residues in wild animals was realized.... A national survey concerning environmental pollution of PCBs was conducted from May to December, 1972. During this period, the water quality of 1,084 locations and bottom sediments sampled from 1,445 places was inspected."

During 1970, the Council on Environmental Quality (CEQ) studied regulatory approaches to the problem of toxic chemicals in the environment. In its report "Toxic Chemicals" published in 1971, CEQ identified PCBs as a major problem. [Council on Environmental Quality, 1971].

The instructions for handling Westinghouse's Inerteen insulating fluid referenced the ANSI C107.1–1974 for complete information on handling and disposal of Askarels. The document also included a section on "Environmental Considerations" which stated "It has been shown by several laboratories that measurable amounts of the PCBs, particularly those with more than 50% chlorination, are present in the general environment and are a threat to certain species of wild-life.... To be sure that the Inerteen and Inerteen contaminated materials do not contaminate the environment they must be incinerated in approved equipment." A disposal section in the handling instructions describes the disposal of Inerteen liquid, solvent rinses contaminated with Inerteen, solids contaminated with inerteen and the cleaning of contaminated drums.

The American Conference of Governmental Industrial Hygienists retained a threshold limit value of 1 mg/m^3 in 1971 and stated "Exposure to the vapor and fume of chlorodiphenyl may result in acne, irritation of respiratory passages, and injury to the liver.... Several deaths due to atrophy of the liver occurred among workers exposed to the fumes of chlorodiphenyls and chloronaphthalenes."

Transplacental passage of Aroclors 1221 and 1254 in rabbits was observed [Grant *et al.,* 1971] when PCB residues were found in higher concentrations in fetal liver than in tissues of dosed does.

Placental and adipose tissues of stillbirths from Yusho mothers confirmed the presence of Kanechlor components [Kuratsune *et al.,* 1971].

The total quantity of contaminated rice oil ingested by patients in the Yusho incident of 1968, as well as the dose rate of ingestion of PCBs was estimated[38] by Yoshimura, 1971.

Studies of Yusho patients have revealed symptoms of numbness, pain, hypothesia or areflexia of the limbs in about 50% of cases [Murai and Kuroiwa, 1971].

From 1971 to December 1975 a frequent method of disposal of askarel capacitors was to throw them into a dumpster for disposal in various landfills.

The State of Massachusetts enacted a bill in 1971 to prohibit the discharge of any chemical solution containing PCBs into the environment.

A paper was presented at the 1971 Doble Client Conference to report activities of the special Doble subcommittee on askarel disposal problems.

February 23, 1971: ANSI meeting of the committee on Use and Disposal of Askarel of the Power Equipment Division, February 23, 1971. "The committee noted that the purpose of this meeting is to review developments since the August 20, 1970 meeting and develop recommendations to ANSI on a suggested program of action, including priorities for various activities, list of organizations to be invited to participate, etc.

The formation of the ANSI committee had as its objectives to:

"1) Serve as a source of technical information and advice for Federal, State and local authorities and for the information of all others concerned.
2) Encourage the development of suitable disposal facilities and maintain a list of their capabilities and locations, for the information of all concerned.
3) Serve as the advisory group for US participation in CEE, IEC, COPANT, SEGRA and other international organizations."

Between February and October 1971 TCP/PCDD/PCB was sprayed on a horse arena in Missouri. Still bottom residues from TCP manufacture were contained in the waste oil used to control dust in Missouri horse arenas. When the waste oil storage tank was examined, it was found to contain 300 ppm TCDD.

July 1971: A Monsanto PCB bulletin [Monsanto, 1971] was issued in July 1971 entitled 'Handling, Waste Control and Disposal of PCBs'. The document was "*Produced and distributed as a service to industry by Monsanto*". It was pointed out that Pydraul®, a fire resistant hydraulic fluid, was no longer manufactured with PCBs but other products had a place in continued applications provided that common sense and good maintenance procedure were used towards eliminating any threat to the environment from PCBs.

Monsanto offered nine guidelines to prevent the escape of PCBs into the environment. In conclusion, the disposal of solids was suggested in a properly operated landfill not located near any water system.

The Monsanto position was explained in a series of points which included Monsanto's recommendation that PCB contaminated solids could be buried as a satisfactory disposal option provided that the site was dry. Tests by Monsanto and others of PCBs in the environment had shown that the higher chlorinated PCB congeners were being retained in organisms and that there was an absence of PCBs with three chlorines or less. Some initial successes had been obtained using biodegradation of PCBs under lab conditions. The apparent lack of lower chlorinated species in the environment led Monsanto to develop Aroclor 1016 as a more environmentally acceptable product. By this time, Monsanto had made it known that it would supply Aroclors only to the electrical industry since the electrical applications were considered to be enclosed. Information was presented which suggested that the health effects of PCBs were minimal. Interestingly, the health effects observed in the Yusho incident were thought to have been caused by PCDFs as impurities which were typically found 'in some European PCBs'. The correlation between PCBs and PCDFs had been shown by Vos *et al.* (1970) who found that the relative concentrations of the PCDF isomers present in Yusho oil and in two samples of used heat exchanger PCBs (Kanechlor 400 and Mitsubishi-Monsanto T1248) were strikingly similar. The mechanism for the interconversion of PCBs into PCDFs was not published until 1979 [Buser and Rappe, 1979].

By 1971 Monsanto had determined that about 75% of the PCBs in the environment could be attributed to plasticizers, lubricants, hydraulic fluids, incineration of PCB materials and open dumps with the remainder coming from the electrical industry. It was concluded that there was sufficient biological evidence to indicate that PCBs can be deleterious to the health of animal and human life and that, even though it could not be expressed quantitatively, it was inappropriate for electrical equipment manufacturers to ignore the weight of the evidence against PCBs.

Electrical equipment manufacturers were to inform customers about the nature of PCBs, and the hazards associated with them. Instructions were to be provided on the proper disposal of units containing PCBs. PCB management controls were to be initiated in manufacturing facilities. Customers were to be informed that the disposal of PCB liquid waste should be done by sending the material to Monsanto for incineration while failed or non-serviceable units should be sent back to the manufacturer so that the PCB in the unit could be disposed of adequately. All of the maintenance and repair shops were to be alerted concerning the nature of PCBs and, again, a procedure set up for the proper use and disposal of the liquid and solid waste. Equipment manufacturers intended to encourage NEMA and other industrial organizations to establish uniform use, handling and disposal standards. Field records of PCB equipment performance were to be obtained.

June 1971: The National Industrial Pollution Control Council published "The Use and Disposal of electrical Insulating Liquids" in June 1971 and included in their report recommendations to minimize the possibility of entry into the environment of PCBs used in capacitors and transformers. These regulations were later developed by a committee of ANSI.

In July 1971, leakage of a heat exchanger fluid caused contamination of pasteurized fish meal which in turn was fed as a ration to chickens and catfish.

In July 1971: discovery of PCBs in food wrappings due to recycling of copy paper in the production of paper pulp.

Occurrence of PCBs in turkey and chicken fed PCB-containing products (reason unknown).

FDA began recall of 50 tons of meat, 300 tons of fish feed, and 3,300 tons of fish meal contaminated with PCBs caused by a leak in a heat exchanger system.

In August 1971, Westinghouse's Power Transformer Division issued an updated set of 'Instructions for Handling Inerteen® Insulating Fluid P.D.S. 54201 CM and Installation and Maintenance of Inerteen Transformers.' [Westinghouse, 1971], which incorporated the earlier supplemental notice of environmental concerns and waste disposal. In this version of the guide disposal suggestions are much more explicit and contain recommendations for Inerteen liquid, solvent-rinses contaminated with Inerteen and solids, including drums, contaminated with Inerteen. Environmental concerns were also expressed to the equipment purchaser much more explicitly in this document than in the earlier 1968 version: "*… a carefully planned program of waste disposal must be followed at every step of the equipment life. This includes manufacture, repair and final disposition of the fluid and the Inerteen contaminated parts.*"

On August 3, 1971, FDA called an Interagency meeting of spokesmen from several Federal agencies and research laboratories to review PCBs. OST released its report on PCB environmental impact in March 1972.

September 1971, Monsanto introduced Aroclor 1016 as a replacement for Aroclor 1242 in capacitors. The fluid was made by vacuum distillation of Aroclor 1242 to remove the more highly chlorinated PCB homologs since these were recognized as being less biodegradable than the lower chlorinated congeners.

September 1, 1971 representatives of several Agencies of the Federal Government established an Interdepartmental Task Force to coordinate the scientific efforts relative to understanding PCBs. The Agencies involved were USDA, EPA, the Council on Environmental Quality and the Office of Science and Technology. The OST took the lead role and the work was conducted under what became known as the Interdepartmental Task Force on PCBs. The Task Force was announced on September 5, 1971 in a joint FDA–USDA press conference.

September 15, 1971: The OST Panel on Hazardous Trace Substances and the Governmental Task Force met jointly with representatives of the Monsanto Co. The principal agenda item of this meeting was a request for information concerning the amounts and usage, and estimates of losses into the environment.

October 1, 1971: Norway enacted regulations which came into effect on October 1, 1971 which required prior authorization for the use of PCBs.

December 1971: Monsanto adopted a policy not to sell any more dielectric fluids to its customers before they entered into an indemnity agreement.

December 20–21, 1971: National Institute of Environmental Health Sciences symposium on PCBs held at Durham, NC on December 20–21, 1971. Members of the press, especially science writers, were invited to attend. Thus, the aims of the conference were to educate both scientists and the public about the science of PCBs and its interpretation.

1972

PCBs were the subject of an increasing number of papers reported in the scientific literature dealing with the environment between 1970 and 1971. A conference which dealt with the environmental problem of PCBs was held in September 1970 in Sweden and in August 1971, an environmental quality workshop was convened in Durham, New Hampshire by the National Academy of Sciences.

The lay press, prompted by the newsworthiness of several accidental PCB spills and the widespread finding of PCBs in the environment, published many articles in 1970–1971 which dealt with PCB contamination. Many PCB reports involved the contamination of foodstuffs.

The Federal Department of Agriculture made an extensive surveillance of food in cooperation with the Department of Agriculture and established 'Action Levels' for PCBs in milk, poultry and fish. Action levels are temporary thresholds for regulatory decision pending the establishment of regulatory policy and procedure. During 1970 and 1971, the FDA used these guideline values in several seizures of foods found to be contaminated with PCBs.

Following announcements in the public press in 1971 there began to be political enquiries made by Senator McGovern and Governor Miliken of Michigan (Figure 9).

By August 1971, the FDA was being pressured into taking a position in which public pressure and advocacy demanded a stronger position against the use of PCBs. FDA initiated a meeting to discuss the scientific issues concerning PCBs which involved several Government agencies and Federal research laboratories. Following this meeting the FDA asked the President's Science Advisor to provide a focus for the Government's actions and decisions concerning PCBs. The request was made because:

- the PCB issue cut across several Federal agencies;
- the issue was becoming politically stressful for the FDA;
- the Office of Science and Technology (OST) had already started a scientific review of PCBs (October 1970).

The OST review committee became known as the Panel on Hazardous Trade Substances and had as its goal the identification of the needs for information by the Government in making judgments concerning trace hazardous substances.

On September 1, 1971 the FDA met with the USDA, EPA, the Council on Environmental Quality (CEQ) and the OST to explore options concerning PCBs. The OST adopted the lead role and this group became known as the Interdepartmental Task Force on PCBs. The Task Force met with Monsanto, the only US producer of PCBs to request information concerning the amounts of PCBs produced, patterns of distribution and usage, and estimates of losses into the environment.

A model was developed for the rates and routes of environmental transport of PCBs based on Monsanto's information. The model coefficients were tested wherever possible by physical measurement and analytical monitoring. The exercise pointed up gaps in the knowledge base. In particular, analytical methods for PCBs were not well developed and biological effects were not well defined.

The final Interdepartmental Task Force report, in addition to being a review of the scientific information of the time also dealt with the benefits of PCBs derived from a National Bureau of Standards (NBS) report. This review became the basis for the rule-making decision to maintain electrical uses of PCBs and to restrict other applications.

The Task Force report reviewed the Federal regulations for their applicability to PCBs in part to determine the power of the Government to control and limit the manufacture, distribution, use and disposal of PCBs. Regulatory authorities were capable of responding to specific incidents of contamination but the Government had no power to prevent more PCBs from entering the environment.

Despite mounting public pressure calling for an outright ban on PCBs the Commissioner of the FDA held a press conference in which he deferred the decision making process until further review and deliberation of perspectives had been accomplished.

During this time period, the National Institute of Environmental Health Sciences had initiated its own review of scientific knowledge concerning PCBs and it brought together the scientific community and the public in a conference to discuss the findings in December 1971. The result of the information exchange was to reduce the sensationalism surrounding PCBs and to reduce the newsworthiness of the now more scientific issues. The result was that a dramatic decline occurred in the number of sensational newspaper reports concerning PCBs.

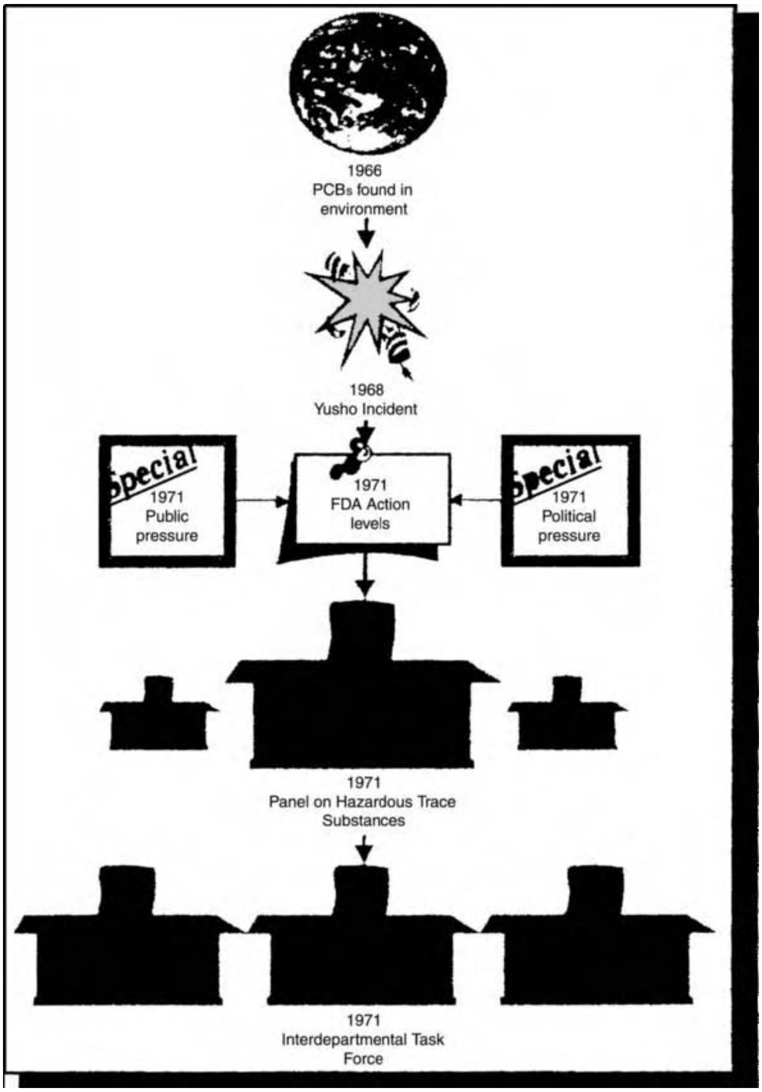

FIGURE 9 Time-line for the development of PCB regulations.

At this point in time (1971), the Government had no direct regulatory authority to control the manufacture, distribution or use of PCBs. However, the Government did possess 'persuasive' influence and, beginning in 1970, Monsanto had begun to reduce the sales of PCBs and 'voluntarily' discontinued sales for use in paints, plasticizers, sealants, adhesives, hydraulic systems and other 'open systems'.

The principal recommendation of the Interdepartmental Task Force was the discontinuance of all uses of PCBs except in 'closed systems' such as transformers and capacitors. This decision derived from an analysis of the benefits of PCBs, the economics of fluid replacement and the availability of substitute fluids. Non-electrical uses in open systems were viewed as either not essential, potentially or actually contributory to the environmental load, or had suitable replacement fluid alternatives.

True regulatory control by the Government in 1971 was limited to persuasive influence. The gap between persuasion and regulation was closed by the enactment of the Toxic Substances Control Act.

In summary, the factors which led to the successful regulation of PCBs were as follows.

- Only one manufacturer was involved and end-users were easily identified.
- A model for the rates and routes of dissipation of PCBs into the environment was developed and the benefits of PCBs were weighed against the risks.
- Scientific information underwent several peer reviews and was widely disseminated.
- The rule-making process was an open one which education both the regulators and the regulated communities.

Kuratsune *et al.* (1972) “Epidemiologic Study on Yusho, a Poisoning Caused by Ingestion of Rice Oil Contaminated with a Brand of PCB.”

Kuratsune (1972) “Results of Lab Examinations of Patients with Yusho Symptoms”.

Enzyme induction in rats had been reported at levels as low as oral doses of 0.03 mg/Kg/d [Litterest *et al.,* 1972] and porphyria had been observed in rats fed PCBs at levels ranging from 6.8 mg/Kg/d to 37.6 mg/Kg/d [Kimbrough *et al.,* 1972].

The first report that adenofibrosis occurred in the livers of rats fed Aroclor 1254 and 1260 was made in 1972 [Kimbrough *et al.,* 1972].

Bioaccumulation in humans was shown in analyses of 4,000 adipose tissue samples from the US Dept. of Health Education and Welfare Human Monitoring Survey which estimated that 41–45% of the US population has PCB levels greater than 1.0 ppm PCB, identifying food chain exposure and occupational exposure as possible sources [Price and Welch 1972].

February 4, 1972: Open letter from Monsanto, dated February 4, 1972 states that customers must sign a ‘Special Undertaking by Purchasers of PCBs’. The document contained wording which put intending buyers on notice of the environmental issues. This was a ‘hold harmless’ agreement.

February 8–9, 1972: Both the capacitor and transformer sub-committees of ANSI committee C-107 on the use and disposal of askarel and askarel-soaked materials met on February 8–9, 1972. The committees discussed analytical methods for PCBs and a series of questions and answers on PCB concerns.

Monsanto discontinued direct sales of PCB products in 1972.

March 1972: OST released its report on PCB environmental impact in March 1972. As well as serving as a review of the scientific aspects of PCBs, the Task Force explicitly reviewed a number of broad aspects of the PCB question. Most important, perhaps, was the exploration of the benefits or utility of PCBs and of the industrial and commercial dependencies built up over the years. This explicit review of benefits of PCBs was of vital important for decision-making on PCBs. The National Bureau of Standards engaged in a review and analysis of the benefits and even the “essentiality” of each of the several uses of PCBs. In this, the NBS received advice from the National Industrial Pollution Control Council especially for electrical uses of PCBs. This review became the basis for the ultimate decision to preserve electrical uses of PCBs (for which there were true dependencies and no satisfactory substitutes) and to restrict other uses. The Task Force Report reviewed all of the pertinent Federal regulatory laws for their applicability to PCBs. The review pointed out that existing regulatory authorities were capable of responding to specific incident of contamination of foodstuffs once they were recognised. However, it acknowledged that the Government’s legal strength was generally “ . . . inadequate to prevent more PCBs from entering the environment.”

Despite the recommendation of the 1972 Interdepartmental Task Force on PCBs [Interdepartmental Task Force on PCBs. “Polychlorinated biphenyls and the Environment”; NTIS (COM-72-10410) May 1972] that discharges of PCBs be strictly controlled, EPA did not effect a policy of stringently curtailing discharges of PCBs from point sources until December 1975.

Comments by GE [GE 1972] on the notice of proposed rule making in the Federal Register of March 8, 1972 included a report entitled ‘The Tole of PCBs in Electrical Equipment’ dated February 4, 1972. The report addressed the risks and alternatives to the use of askarels in transformers. It was pointed out that the US experience over 40 years had resulted in very few cases of nonchronic chloracne or other temporary skin lesions or irritations. By the time that this report was published, however, numerous studies had been done on the Yusho incident and many researchers were in the process of debating the causative agents in the poisoning episode.

An assessment of the risk of ownership of PCB equipment included a consideration of the probability of leaks from originally sealed equipment. Reference was made to the fact that specific control measures had already been instituted by manufacturers and that these would be supplemented by a committee of ANSI.

The distribution of membership in the ANSI committee C-107 on “Use and Disposal of Askarel Used in Electrical Equipment” included members from equipment manufacturers, US government bodies, manufacturing associations, utility representatives, waste disposal companies and consulting engineers. The membership of the ANSI committee is shown in Table 3.

Monsanto advised that the company had adopted certain policies with respect to its further sale and delivery of all PCB products used as dielectric fluids. In particular, Monsanto had decided that it would deliver Aroclors only to manufacturers of electrical equipment who had entered into an agreement with Monsanto to indemnify and hold the company harmless in the use of their products. The letter had copies attached of the proposed agreement and a copy of an article by Gustafson (1970) on PCBs found in the food chain.

The ‘Special Undertaking by Purchasers of PCBs’ contained wording which put intending buyers on notice of the environmental issues viz. “*Buyer acknowledges that it is aware and has been advised by Monsanto that PCB’s tend to persist in the environment; that care is required in their handling, possession, use and disposition; that tolerance limits have been or are being established for PCB’s in various food products.*”

May 1972: The Interdepartmental Task Force (ITF) report on PCBs was issued publicly in May 1972 and was accompanied by a statement of Governmental ‘thinking’ and Governmental ‘action’. Perhaps the major conclusion reached in the report, which became an objective in Government decisions, was that of limited restriction of PCBs. This was a direct outcome of the analysis performed by the National Bureau of Standards of the utility and essentiality of PCBs

1	Capacitor Manufacturer Serving as an Independent Member

Monsanto released information concerning its PCB production figures from 1930–1971 to the Dept. of Commerce in November 1971 as 4.3×10^5 tons PCB.

which pointed to the possibility of an increase in fires and explosions from encases or enclosed transformers if PCBs could no longer be used—representing the possibility of trading one hazard for a different hazard. In addition, the ITF had reviewed the patterns of environmental dispersal of PCBs which had been lost from their point of application. Electrical applications were seen as 'closed' and were not thought to be contributory to environmental distribution. Other uses of PCBs were reviewed as either not essential, potentially or actually contributory to the environmental 'load', or were found to have suitable available substitutes. These conclusions pointed to an elimination of essentially all other uses of PCBs in heat exchange fluids, hydraulic fluids, and the miscellaneous category of 'plasticizer' uses. This objective of limited restriction became the basis for Governmental persuasion of the Monsanto Company to restrict its distribution and sales of PCBs.

June 1, 1972: The Swedish government enacted regulations effective June 1, 1972 which required prior authorization for the use of PCBs, or compounds containing PCBs, and the PCB content to be indicated on wrappings.

June 1972: Import and production of PCBs were banned in Japan. Continued use of PCBs was to be allowed in dielectric (September 1, 1972) and heat transfer applications (July 1, 1972) when complete recovery could be assured.

September 1972: Instructions for shipment, installation and storage of oil-filled power transformers were made effective in September 1972 at the Westinghouse Sharon transformer division [Westinghouse 1972]. The manual does not mention PCBs specifically but refers to an instruction manual, I.B. 45-063-100, for the proper sampling, testing and handling of the oil.

October 1, 1972: Switzerland enacted regulations which came into effect on October 1, 1972 in which PCBs or PCB-containing products may not be sold to the public or to light industry while heavy industrial use became subject to prior authorization.

Late 1972: A letter from Monsanto was attached to all order acknowledgements by the Monsanto Customer Service Department which read: "As we have previously notified you by way of correspondence since early 1970, the material described on the acknowledgement order contains polychlorinated biphenyls. PCBs are highly stable chemical compounds that are not readily biodegradable. Therefore, when placed in the environment they must be considered contaminants and may adversely affect some species of animals and marine life … You must take every precaution to prevent any entry of polychlorinated biphenyls into the environment through spills, usage, leakage, disposal, vaporization or otherwise."

1973

A 'gentleman's agreement' had been reached in the Netherlands that, as of January 1, 1973, PCBs would no longer be used by manufacturer's of:

—paints, inks and lacquers,
—adhesives, resins, etc.,
—wire and cable coatings,
—lubricating oils,
—hydraulic fluids,
—copy paper.

During 1973 and 1974, the EPA proposed the establishment of water quality criteria for PCBs in industrial discharges as part of a program for establishing such criteria for a larger group of pesticides. However, PCBs were not covered in the effluent standards that were eventually promulgated.

Louw *et al.* "Vapor Phase Chemistry of Arenes. Part II. Thermolysis of Chlorobenzene and Reactions with Aryl Radicals and Chlorine and Hydrogen Atoms at 500°C". The pyrolysis of chlorobenzene was interpreted as a free radical reaction sequence involving $\bullet C_6H_4Cl$, •Cl and •H as carriers.

Kanechlor 500 and Aroclor 1254 were found to be carcinogenic in male mice [Ito 1973].

Dioctyl phthalate was introduced as a non-PCB dielectric fluid for capacitors.

The OECD announced a decision in February 1973 to control the manufacture and trade of PCBs but allow for the production of PCBs to be used in closed systems. It recommended that Member countries give priority attention to the elimination of PCBs in hydraulic liquids (other than in mining), lubricating oils, vacuum pump fluids and cutting oils and request that firms use, as PCB replacements, materials which are less hazardous to human health and the environment than the range of PCBs in use (in 1973).

March 5, 1973: A spill of about 630 gallons of transformer oil occurred on State Highway 58, South of Kingston, TN on March 5, 1973. The clean-up cost $1.7 million.

July 6, 1973: Federal Register lists PCBs in a proposed list of toxics and pollutants.

July 6, 1973: Federal Register **38**, 18096 (1973): FDA issued rules limiting sources by which PCBs may contaminate feed, food and packaging materials. Transformers were specifically exempted from the restrictions.

September 7, 1973: In September 1973 EPA published a list of "toxic pollutants" which included PCBs. The list was unchanged from that published on July 6, 1973.

December 27, 1973: EPA proposed toxic pollutant effluent standards for the nine toxic substances, including PCBs (38 FR 35388).

1974

The ANSI C-107 standard was issued in 1974 and at the time it was approved the committee contained representatives from electrical utilities, as well as IEEE.

The ANSI C-107 guide, in a section on risks, mentions that "*… limited amounts of PCBs can get into the environment during the manufacture, delivery, improper use, maintenance, repair and disposal of transformers and capacitors.*" Under §3.3 'Plant Housekeeping and Employee Safety' it is indicated that procedures and limits are given to be met by manufacturers as well as users.

Large capacitors were to carry a caution label containing the wording "*To avoid possible environmental contamination, it (PCB) should be disposed of only in supervised dry landfill areas meeting state requirements or in incineration facilities designed for disposal of PCBs.*"

It is mentioned in the guide that an askarel-filled transformer scrapped for any reason should be considered as a source of materials requiring special handling and disposal procedures. It was suggested that cellulosic materials derived from the core/coil assembly should be incinerated in a high temperature furnace while coil structures could be solvent washed and subsequently treated as normal scrap. The disposal of askarel waste, including liquid and solid wastes could be done in controlled landfills or deep-wells where permitted by federal, state and local regulations. New transformers were to have a warning label which indicated that care should be taken to prevent entry of PCBs into the environment and that, in case of malfunctions or leaks, that owners should consult the instruction manual or the manufacturer. Westinghouse's instruction manuals already contained [Westinghouse I.B. 45-063-99C effective August 1971] specific instructions on the material disposal requirements of both liquids and solids.

§4.2.3.6 describes two methods for the ultimate disposal of askarel-filled transformers. One method involved complete draining, dismantling and disposal of askarel-soaked components using methods referred to earlier in the standard. The second alternative states that disposition of askarel transformers by means of junk or scrap dealers should be avoided unless the units are first drained and flushed.

The instructions for handling Westinghouse's Inerteen insulating fluid referenced the ANSI C107.1-1974 for complete information on handling and disposal of Askarels. The document also included a section on "Environmental Considerations" which stated "It has been shown by several laboratories that measurable amounts of the PCBs, particularly those with more than 50% chlorination, are present in the general environment and are a threat to certain species of wild-life.… To be sure that the Inerteen and Inerteen contaminated materials do not contaminate the environment they must be incinerated in approved equipment." A disposal section in the handling instructions describes the disposal of Inerteen liquid, solvent rinses contaminated with Inerteen, solids contaminated with inerteen and the cleaning of contaminated drums.

ANSI C-107.1-1974 standard on "Guidelines for Handling and Disposal of Capacitor- and Transformer-grade Askarels Containing Plychlorinated Biphenyls" issued in 1974.

January 28, 1974: EPA held a thirty day evidentiary hearing on the proposed effluent standards for the nine toxic substances, including PCBs.

March 5, 1974: Federal Register **39**, 8325 (1974): Public hearings on effluent standards.

March 15, 1974: A leak of 265 gallons of PCBs into the Duwamish River in Seattle cost $148,000 for partial recovery. Dredging of 50,000 cubic yards of river bottom in 1976 cost about $300,000.

March 21, 1974: Federal Register **39**, 10603 (1974): Correction—Effluent Standards.

August 1974: Two local EPA personnel took samples of fish, sediment and water below the GE outfall at Ft. Edward and found 355 ppm PCB in the fish. The report was not acted upon in EPA for a year until it finally reached a chemist at EPA's National Water Quality Laboratory in Duluth, Minn. A review of the PCB report was written and sent to the EPA regional office in New York.

December 31, 1974: GE is granted a federal permit, with the full blessings of NYDEC, to discharge up to 30 pounds per day into the Hudson River.

1975

1975: Federal Register **40**, 11563 (1975): FDA regulations concerning PCBs in paper/food packaging material.

Despite the recommendation of the 1972 Interdepartmental Task force on PCBs [Interdepartmental Task Force on PCBs. "Polychlorinated biphenyls and the Environment"; NTIS (COM-72–10410) May 1972] that discharges of PCBs be strictly controlled, EPA did not effect a policy of stringently curtailing discharges of PCBs from point sources until December 1975. Thus, GE was allowed to discharge under its NPDES permit, issued under FWPCA, 30 lb. of PCBs per day into the Hudson river. When the extent of pollution was brought to light in 1975, the allowable amount of PCBs discharged was reduced to approximately 1.5 pounds per day and a limit set of 3.5 ounces per day effective June 1, 1977. EPA did not set a toxic pollutant effluent standard for PCBs under authority of section 302 of FWPCA until February 2, 1977.

A report on the 'Handling and Disposal of PCBs from Repairs of Electrical Transformers' was published in December 1975 [Versar, 1975]. The purpose of the study was to review the responses to a questionnaire sent out to 13 companies involved with transformer repair at a total of 131 locations. One of the more pertinent findings was that transformers scrapped by the owner/user may be a serious potential source of pollution. While those transformers which are junked by repair shops are governed by a detailed NEMA specification (ANSI C-107/1974) the disposal of transformers through local junk yards may result in significant pollution because of lack of information on proper disposal procedures concerning PCB contaminated transformers. It was noted that uncontrolled handling of PCB filled transformers by junk yards was thought to have occurred in the past.

September 1975: A five-region council, the Lake Michigan Toxic Substance Committee of Midwest States, passed a resolution urging State agencies to support a ban on all PCB uses except those determined necessary by public hearing.

September 1975: CRC Critical Reviews on Environmental Control: description of the health effects of PCBs with an extensive bibliography of the early literature.

September 8, 1975: Ogden Reid (NYDEC Commissioner) brought action against GE to reduce discharge to 2 lb. per day (from 30 lb. per day) by December 31, 1975 and to zero by September 30, 1976.

October 1975: Wisconsin State officials held public hearings on the need for a statewide PCB ban.

October 6, 1975: EPA issued a draft set of water quality criteria under section 304(a) of the Federal Water Pollution Control Act.

November, 1975: An administrative hearing was begun on the discharge of PCBs into the Hudson river, chaired by a Columbia University Law Professor, Abraham Sofaer, to determine if GE had violated state water quality standards and, if so, what sort of restitution the company should reasonably make. GE presented an 'affirmative defense' which held that it had been granted both state and Federal permits to discharge PCBs. Sofaer agreed that this argument had "more than superficial appeal" but that it was not enough to excuse GE from the general requirements of its permit, which forbade the company to violate state water quality standards even if the precise prohibitions were not spelled out. Accordingly, Sofaer ruled that "GE has discharged PCBs in quantities that have breached applicable standards of water quality."

November 3, 1975: Background information on PCBs was published by the Office of Occupational Health Surveillance and Biometrics National Institute for Occupational Safety and Health, November 3, 1975 to inform the occupational health community of the then current knowledge concerning industrial uses and the toxicity of PCBs. The document contains an extensive bibliography of early literature. The report states that "Prior to the environmental concern surrounding the persistence and ubiquitousness of PCBs, [Interagency Task force on PCBs: PCBs and the Environment COM-72-10419, Washington, DC, March 20, 1972.] they were more widely used in industry as fluids for heat transfer systems, hydraulic systems, gas turbines, and vacuum pumps.... "

November 19–21, 1975: EPA and other Federal agencies held a PCB conference in Chicago, II. Several articles on the environmental effects of PCBs that appeared in the popular press shortly before the conference [Boyle, R.H.: "Of PCB ppms from GE and a SNAFU from EPA and DEC"; Audubon **77**, 127 (1975): and Boyle, R.H.: "Poisoned Fish, Troubled Waters"; Sports Illustrated, September 1, 1975, pp. 14–17 (1975)] caused considerable public interest in the conference and a number of demands that EPA regulate PCBs.

December 12, 1975: EPA announced the inclusion of PCBs in a national monitoring program designed to provide information for future possible regulation under the Safe Drinking Water Act.

December 30, 1975: EPA published a proposed list of hazardous substances for discharge into navigable waters which included PCBs.

1976

In early 1976, EPA requested Versar to expand its scope of work to include a study of wastewater treatment technology that could be used to reduce the concentration of PCBs in industrial effluents. [Versar report, May 16, 1979.]

Nagayama *et al.*[39] (1976) "Determination of Chlorinated Dibenzofurans in Kanechlors and Yusho Oil." The presence of key compounds of concern were identified in Yusho oil (Table 4).

The instructions for handling Inerteen insulating fluid referenced the ANSI C107.1-1974 for complete information on handling and disposal of Askarels. The document also included a section on "Environmental Considerations" which stated "It has been shown by several laboratories that measurable amounts of the PCBs, particularly those

TABLE 4

In Service Age (yr.)	Temperature(°C)	PCBs(ppm)	PCQs*(ppm)	PCDFs(ppm)
14	180–270	968,400	31,000	510
3	200–220	999,000	690	277
0‡	—	999,800	209	33

* PCB = polychlorinated quaterphenyl.

‡ = not used.

with more than 50% chlorination, are present in the general environment and are a threat to certain species of wildlife.... To be sure that the Inerteen and Inerteen contaminated materials do not contaminate the environment they must be incinerated in approved equipment."

A disposal section in the handling instructions describes the disposal of Inerteen liquid, solvent rinses contaminated with Inerteen, solids contaminated with Inerteen and the cleaning of contaminated drums.

February 9, 1976: The NYDEC found GE to have violated two State laws by its discharge of PCBs.

February 17, 1976: Ogden Reid (Comm. NYDEC) announced that he would issue orders closing the Hudson River as a commercial fishery for most species of fish because of PCB contamination.

February 13, 1976: The Hudson River was ordered closed to commercial fishing with the exception of chad.

February 24–25, 1976: The transformer subcommittee of ANSI met on February 24 and 25, 1976 and issued minutes which contained the following: "Transformers with Replacement Fluids: Apparatus that has contained PCBs which have been replaced with another fluid should be labeled as indicated below, and the disposal ultimately should follow the same disposal procedures as those recommended for PCB liquids and PCB-filled apparatus."

February 25, 1976: Versar Task I final report: "It is estimated that approximately 1.5 billion pounds of PCBs have been sold for industrial use in the US since initiation of production around 1930. Of this amount, at least 95% is still in existence; most is in service in capacitors and transformers, but about 290 million pounds are believed to reside in landfills and dumps and about 150 millions pounds are believed to be 'free' in the environment. The magnitude of these values indicates that there is a strong future threat from PCBs in land disposal sites,".... "Although PCB content in industrial wastes can be reduced through various approaches (treatment, substitution, etc.), the large amounts of PCBs already contained in land disposal sites present a severe hazard for the future." ... "Monsanto and portions of the electrical equipment industry which use PCBs have greatly reduced PCB releases to water and land over the past few years, primarily through improvement of plant housekeeping, improved waste collection and handling, and disposal of liquid wastes through incineration."

March 26, 1976: Senator Nelson introduced an amendment to the Toxic Substances Act which would eliminate the remaining uses of PCBs unless EPA finds that there is not a serious health hazard. The amendment was incorporated into TSCA as Section 6(e) and became a legislated requirement when TSCA was signed into law on October 11, 1976. The effective data of TSCA was January 1, 1977.

April 1, 1976: EPA issued recommended procedures for disposal of PCBs by industrial users under the Solid Waste Disposal Act. Recommended options for the disposal of PCB-containing wastes were given in priority order as (1) incineration and (2) controlled land disposal. In the case of land disposal it was mentioned that wastes containing PCBs should not be disposed of with other mixed wastes in a sanitary landfill. At this point in time the characteristics of transport of PCBs through soil were not definitively established. The regulations pointed out that "The ubiquity and persistence of PCBs indicate that their disposal should be carefully controlled until additional data are developed." Non-chemical waste landfills were then strongly contrasted with the following description of a chemical waste landfill. "In general terms, a chemical waste landfill provides complete long term protection for the quality of surface and subsurface waters from hazardous waste deposited therein, and against hazards to public health and the environment. Such sites should be located or engineered to avoid direct hydraulic continuity with surface and subsurface waters. Generated leachates should be contained and subsurface flow into the disposal area eliminated. Monitoring wells should be established and a sampling and analysis program conducted."

June 1976: Instructions for handling Inerteen® insulating fluid and installation and maintenance of inerteen transformers were issued by Westinghouse's Small Power Transformer Division in June 1976 [Westinghouse, 1976]. A section was included on environmental considerations in which PCBs were described as extremely persistent in the environment. In closing the section, Westinghouse goes beyond the recommendation of the ANSI C-107 guideline by indicating that the Inerteen and Inerteen contaminated materials should be incinerated in approved equipment. No mention is made of the second ANSI guideline alternative of draining and flushing the transformer carcass before disposal in a scrap yard. The suggested method of disposal is quite the opposite and leads to the ultimate destruction of PCB contaminated, porous materials such as absorbing clay, filter paper, cartridges, sawdust, rags and insulation while the non-porous metallic transformer components are solvent cleaned and the solvent incinerated.

June 28, 1976: Westinghouse indicated to its managers on June 28, 1976 that it would cease manufacture of Inerteen Transformers after December 31, 1976.

July, 1976: Publication of the "Final Report of the Subcommittee on the Health Effects of polychlorinated and polybrominated biphenyls; Dept. of Health, Education and Welfare, Washington.

July 23, 1976: Federal Register **41**, 30468 (1976): EPA published proposed toxic pollutant effluent standards for PCBs.

August, 1976: New York Times Magazine article on PCBs in the Hudson: "Last August, after months of negotiations, GE agreed to pay the State Department of Environmental Conservation, $3 million to help restore the river and another $1 million for research. The state will chip in $3 million of its own for restoration.... In fact, until very recently, it had a permit issued by the EPA and endorsed by the state–that specifically authorized it to discharge up to 30 pounds of PCBs into the river daily. By contributing $3 million of its own toward restoration as part of the agreement the DEC has tacitly acknowledged its own failure as a watchdog.".... "The August agreement, by contrast, was accomplished by negotiation after a rigorous but comparatively swift ex-judicial hearing sponsored by the DEC and chaired by a law professor from Columbia University. The whole process took less than a year. And while the parties never saw the inside of a courtroom, the agreement nonetheless puts American companies on notice that they may be held responsible for what they do to the environment even when they have not been specifically prohibited from doing it."

Seven California class 1 landfills were listed as approved disposition service companies together with nine other, principally incineration, options.

August 24, 1976: Rep. Gilbert Gude (R-MD) proposed a last-minute amendment to the House version of the Toxic Substances Control Act singling out PCBs for special restrictions. The August 24, 1976 edition of the New York Times reported: "The House of Representatives voted 319–45 to ban within three years the manufacture of PCBs, a class of chemicals that has been linked to cancer and birth defects, water pollution and wildlife contamination ... some House members said during today's debate that they felt that banning PCBs was a moral responsibility to the people ... ".

In October 1976, Congress passed the Toxic Substances Control Act. The continued use of PCBs in totally enclosed systems was allowed.

December 8, 1976: Federal Register **41**, 53692 (1976): Panel discussion/formation of PCB work group.

As of December 31, 1976 the Westinghouse South Boston, Virginia Small Power Transformer Division ceased manufacture of Inerteen transformers.

Instructions for handling Inerteen® insulating fluid P.D.S. 54201 CM and Installation and maintenance of Inerteen transformers were reissued from Westinghouse's Small Power Transformer Division in February 1976 [Westinghouse, 1976a]. Also included was information on actions to be taken when an Inerteen transformer was found to be leaking in transit.

As of December 31, 1976 the South Boston, Virginia Small Power Transformer Division ceased manufacture of Inerteen transformers.

A National conference on PCBs sponsored by EPA was held in November 1975 in Chicago.

1977

January 19, 1977: Federal Register **42**, 3701 (1977): Notice of Jan. 24, 1977 public meeting.

February 2, 1977: Federal Register **42**, 6531 (1977): Effluent Standard Regulations.

Section 307 (a) of the Federal Water Pollution Control Act required the EPA to publish a list of toxic pollutants, and submit proposed and final effluent standards for toxic pollutants. PCBs were one of the nine toxic pollutants contained in EPA's final listing of proposed pollutants on September 7, 1973 but did not publish the final toxic pollutant effluent standards for PCBs until February 3, 1977.

April 1, 1977: The FDA proposed the reduction of temporary tolerances for PCBs in milk, dairy products, poultry, eggs, fish and shell-fish.

April 21, 1977: Federal Register **42**, 20640 (1977): Proposed procedures for rule-making under Section 6 of TSCA.

May 24, 1977: Federal Register **42**, 26564 (1977): Proposed marking and disposal regulations.

July 15, 1977: Federal Register **42**, 36484 (1977): Deadline for reply comment period to proposed marking and disposal regulations of May 24, 1977.

Monsanto terminated the manufacture of PCBs in July 1977.

Effective August 31, 1977 Monsanto stopped accepting PCB waste returns.

1978

February 17, 1978: Federal Register **43**, 7150 (1978): EPA promulgated marking and disposal regulations.

April 21, 1978: Federal Register **43**, 17060 (1978): National Cancer Institute report on the carcinogenicity of Aroclor 1254.

June 7, 1978: Federal Register **43**, 24802 (1978): Proposed PCB ban regulations.

June 7, 1978: Federal Register **43**, 24818 (1978): Requires notification of intent to export PCBs.

July 18, 1978: Federal Register **43**, 30882 (1978): List of approved PCB disposal facilities.

August 2, 1978: Federal Register **43**, 33918 (1978): Corrections to marking and disposal regulations.

August 25, 1978: Federal Register **43**, 38057 (1978): Incorporates hearing record of effluent standard regulations into hearing record for ban regulations.

August 25, 1978: Federal Register **43**, 38087 (1978): List of Approved PCB disposal facilities.

October 26, 1978: Federal Register **43**, 50041 (1978): List of approved PCB disposal facilities.

November 1, 1978: Federal Register **43**, 50905 (1978): Interim rules-applications for exemption from PCB manufacturing ban.

December 20, 1978: Federal Register **43**, 59432 (1978): List of approved PCB disposal facilities.

1979

February 16, 1979: Federal Register **44**, 10266 (1979): Definition of "Discharge" under Clean Water Act.

February 16, 1979: Federal Register **44**, 10271 (1979): Defines reportable quantities of PCBs spilled into waterways, reporting requirements and fines.

March 12, 1979: Federal Register **44**, 13575 (1979): Request for comments on citizens' petition to give Regional Administrators authority to approve alternate disposal methods.

1981

August 15, 1983: Versar report "Exposure Assessment for Incidentally Produced PCBs: Appendix D: Prediction of Human Exposure for Hydraulic and Heat Transfer Authorized Uses:

- The USEPA's May 1979 regulation on PCBs, entitled "Polychlorinated Biphenyls Manufacturing, Processing, Distribution in Commerce, and Use Prohibitions" (40CFR 761.30 Subpart B, Authorizations), authorizes the use of PCBs until July 1, 1984, in hydraulic systems, in heat transfer systems, for research and development (small quantities), and as a microscopy mounting medium.
- After discontinuing production of their heat transfer oil in 1972 (Therminol), Monsanto notified all known Therminol users that hazards were associated with PCB use, offered to accept all fluid drained from PCB-containing heat transfer systems, and suggested that systems be refilled with non-PCB oil. Monsanto did not extend this service to users of PCB hydraulic fluid (Pydraul).
- Die casting hydraulic systems operate at high temperatures and require a fire-resistant hydraulic oil such as the type containing PCBs. PCBs have also been used in other general hydraulic systems (e.g., metal stamping equipment, forges, furnace lid lifts, presses), although not as commonly as in die casting hydraulic systems. It is likely that the PCB contamination of many hydraulic systems results from the reuse and recycling of PCB-containing hydraulic oils.
- Releases to water from hydraulic systems: PCB releases to water from hydraulic systems result from leakage and draining of fluid. Individual hydraulic systems are known to leak amounts of fluid equivalent to 0.25 to 10 volumes annually. This amount varies with machine age, maintenance, operating pressure, and configuration (e.g., fluid lines, seals, fittings). It is estimated that the average system leaks at a rate of 2 volumes/year.
- The leaked fluid recovery rate is the fraction of oil that has leaked from hydraulic systems and has been collected (typically with troughs or collection pans) and recycled into the system as topping fluid. Estimates of fluid recovery range from 30% to 80% for die casting systems and from 10% to 50% for general hydraulic systems. Leaked hydraulic fluid that is not recovered either volatilizes or seeps into the wastewater system.
- The average fluid capacity of a die casting system is 350 gallons; it is assumed that this is also the average volume of a general hydraulic system.
- The PCB regulations of May 1979 require that hydraulic and heat transfer systems that have PCB concentrations greater than 50 mg/Kg be drained and resampled annually until the concentration is reduced below 50 mg/Kg.
- Approximately 20.3 million pounds of PCB-containing heat transfer fluid was produced between 1962 and 1972 in the US.
- An average heat transfer system uses 400 gallons of fluid and has an average leakage of 0.2 volumes of fluid annually.
- PCB releases of heat transfer systems to water: PCB releases to water from heat transfer systems result from leakage and draining of fluid. The leakage rates in typical heat transfer systems range from 0.05 to 0.7 equivalent volumes of fluid annually. These rates are less than those for typical hydraulic systems, since heat transfer systems operate under less pressure, have fewer external fluid lines, and do not perform work on external components (pistons). A typical leak rate is 0.2 equivalent volumes of fluid annually. Recovery of leaked heat transfer fluid ranges from 20% to 40%: the average is estimated to be 25%. Leaked heat transfer fluid that is not recovered either volatilizes or seeps into the wastewater system.
- Occupational PCB air concentrations derived from hydraulic systems:
    - Die casting systems have peak operating temperatures of 100°C and average operating temperatures of 60°C. General hydraulic systems have peak operating temperatures of 82°C and average operating temperatures of 52°C. Portions of some die casting systems can have surface temperatures of 200°C.
    - Hydraulic systems leak continuously, covering the reservoir, fittings, hoses, and portions of the machine and floor below with fluid. These surfaces are therefore sources of volatilized PCBs. The average hydraulic machine has a 350-gallon reservoir with an appropriate outer surface area of 6.2 m^2.

- Occupational PCB air concentrations derived from heat transfer systems:
    - Heat transfer systems have much higher operating temperatures (average 180°C) and much lower leakage rates (0.2 volumes/yr) than do hydraulic systems. Therefore, less fluid will be lost through leakage and a higher proportion of leaked fluid is expected to volatilize from heat transfer systems.

September 1, 1983: Report on "Carcinogenic Risk Assessments of PCBs"; Health and Environmental Review Division of Office of Toxic Substances; September 1, 1983: document summarizes the results of four previous risk assessments for cancer conducted by FDA, OTA, CAG/EPA, and OTS.

October 1983: The Office of Pesticides and Toxic Substances of EPA published "Regulatory Impact Analysis of the Proposed Rule Regulating Inadvertent PCB Generation from Uncontrolled Sources."

1984

March 16, 1984: Chemical Manufactures Association wrote to EPA to request further discussions regarding PCB spill cleanup—"For several years, we have been concerned that various EPA regions have applied different approaches to determine the adequacy of PCB clean-up." In particular, they referred to a decision in which GE was required to clean up "to the lowest level of concentration below 50 ppm which is practically attainable through the use of normal cleanup methods."

August 22, 1984: Tests of new dioxin destruction processes involving chemical, biological and vaporization methods were being developed at Times Beach, Missouri, starting August 22, 1984. Dioxin had been found at more than 30 sites in the state, causing the EPA to relocate residents, in contaminated areas. [Environment Reporter, September 14, 1984].

1985

May 23, 1984: Plant Engineering reported that GE claimed that both aerobic and anaerobic naturally occurring bacteria were degrading the PCBs in the Hudson river to less chlorinated, less toxic forms and that, in deeper sediment samples, estimated to be about 25 years old, the process is about 75% complete.

1987

September 1987: A PCB trial burn report for the USEPA Combustion Research Facility liquid injection incinerator system was published in September 1987. It describes a trial burn of PCB laden oil and No. 2 fuel oil (about 40% A1260) injected into the liquid incinerator. Destruction efficiencies in excess of 99.99999% were achieved.

1988

July 22, 1988: EPA list of approved PCB disposal companies: 7 incinerators, 2 alternate thermal, 11 chemical, 4 physical separation, 1 biological, 8 chemical waste landfills, 9 companies with PCB disposal method applications.

PROPERTIES OF PCBs

The more chlorine used in the manufacture of PCBs the greater the viscosity of the product and the greater its resistance to heat, moisture and electrical degradation. The properties of PCBs which are the most important from the point of view of usage and environmental exposure risk are as follows:

- PCBs are heat stable and have no flash or fire point;
- very chemically stable and unreactive;
- excellent dielectric fluids;
- only slightly soluble in water, very soluble in oils and organic solvents;
- Very low volatility in air;
- highly lipophilic. (Table 5, 6, 7, 8)

COMMERCIAL APPLICATIONS OF PCBs

Because of their physical properties, PCBs found extensive applications in electrical equipment such as power transformers and capacitors, as well as in hydraulic machinery, vacuum pumps, compressors and heat-exchanger fluids. Other uses include:

- lubricants
- fluorescent light ballasts
- paints
- glues
- waxes
- carbonless copy paper
- inks, including newspapers
- dust-control agents for dirt road
- solvents for spreading insecticides
- cutting oils.

Table 9 illustrates the diversity of applications in the United States of different Aroclors.

A numbering system used in Aroclor products describes, firstly the number of carbon atoms in the molecule by the first two digits (12) and, secondly, the last two digits indicate the percentage of chlorine in the product. For example, Aroclor 1254 is biphenyl with 6 carbon atoms in each of two phenyl rings and 54% chlorine by weight.

Aroclor 1016 is an exception to the rule. It was not manufactured with 16% chlorine but rather is the name given to a product obtained by distilling Aroclor 1242. The distillate product contained 41% chlorine and the percentage of the relatively low boiling, low chlorine isomers, with 3 or 4 chlorine

TABLE 9
A variety of Aroclors were used throughout industry

Application	Types of Aroclor Used
Transformers	1242, 1254, 1260
Capacitors	1016, 1221, 1242, 1254
Vacuum pumps	1248, 1254
Hydraulic fluids	1232, 1242, 1248, 1254, 1260
Heat exchangers	1242
Waxes	1242, 1254, 1268
Dust-control agents	1254, 1260
Inks, lubricants, cutting oils	1254
Carbonless copy paper	1242

$C_{12}HCl_9$	—	—	—	1

atoms per molecule, also increased, relative to Aroclor 1242. The product is more biodegradable and less toxic than Aroclor 1242. Aroclor 1242 was the principal capacitor impregnant in the U.S. prior to about 1971 when it was replaced by Aroclor 1016.

Table 10 shows the percentage distribution of isomers amongst different homologous series.

Table 11 shows the IUPAC numbering and substitution pattern for PCB congeners.

The numbering system for PCB congeners is important because it allows isomers to be referred to easily and without ambiguity. In particular, instances in which particular congeners are recognized, such as in chromatographic analyses of commercial PCB products, and in considerations of toxic isomers, the IUPAC numbering system is extremely valuable.

Receptor-mediated responses are characterized by the stereoselective interaction of ligands with receptors. Structure-activity relationships for PCBs have been extensively investigated and are thought of as the basis for the role of the Ah receptor in initiating the toxic effects observed

with PCBs and related compounds. The PCB binds to a receptor protein and is transported into the nucleus, occupies a nuclear binding site and turns on gene expression similar to the way steroid hormone-receptor complexes turn on genes. The most toxic PCB congeners, namely isomers #77, 81, 126 and 169 are dioxin-like in their coplanar conformation. The four coplanar PCBs are approximate isostereoisomers of 2,3,7,8-tetrachloro-p-dioxin, as shown in the following diagram. The most biologically active compounds are substituted at the para- and at least one meta- position of both phenyl rings and do not contain any orthochloro substituents. These compounds, fortunately, do not occur as major constituents in commercial PCB mixtures. Substitution patterns such as the (2,6), (3,5), (2,4,6) and (3,4,5) are not commonly found in commercial mixtures. The number of chlorines on the two rings seldom differs by more than one for an odd number of chlorines in the molecule, and is usually equal for an even number of chlorines. Because of this, the number of congeners found in technical PCBs is far less than the theoretical number.

The introduction of a single ortho-chloro substituent into the biphenyl ring results in decreased coplanarity between the two phenyl rings due to steric interactions. Nevertheless, the isomers bind to the Ah receptor and cause dioxin-like responses although their potency is less than the coplanar PCBs. The mono-ortho- PCBs are shown in Figure 12.

Di-ortho- substitution of the four coplanar PCBs results in 13 possible di-ortho-coplanar PCBs. This substitution pattern would result in more steric hindrance to coplanarity than the mono-ortho- congeners and it would therefore be expected that they would exhibit weaker dioxin-like effects. The di-ortho- compounds are shown in Figure 14.

In more general terms, PCBs can be separated into six different structural classes. Class I and Class II compounds are the coplanar and mono-ortho-coplanar PCBs, respectively. Class III are mono-ortho-coplanars, which lack a chlorine in a paraposition. Class IV PCBs are the di-ortho-coplanar compounds. Classes I to IV are dioxin-like in decreasing order of potency. Class V and Class VI are the tri- and tetra-ortho-PCBs which are not coplanar and do not elicit significant dioxin-like activity. The six classes are shown with representative examples in Figure 15.

In summary, the coplanar PCB congeners are toxic and bind with high affinity to the Ah receptor and are highly dioxin-like. The mono-ortho-coplanar PCBs exhibit less toxicity than the coplanar isomers and interact with the

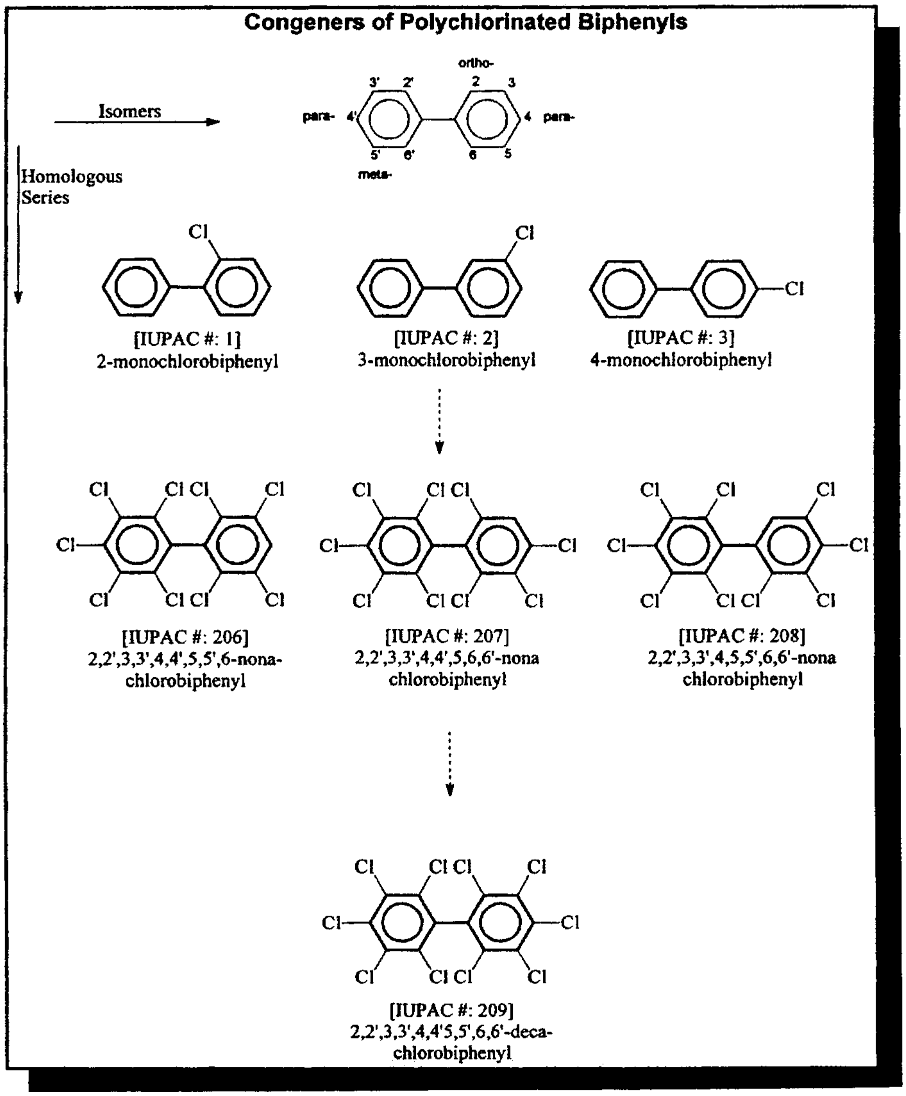

FIGURE 10 PCB congeners are isomers contained in homologous series.

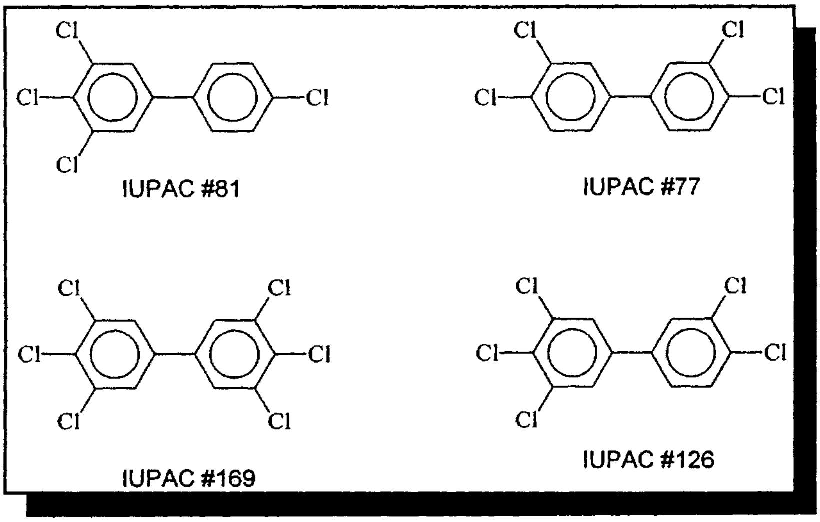

FIGURE 11

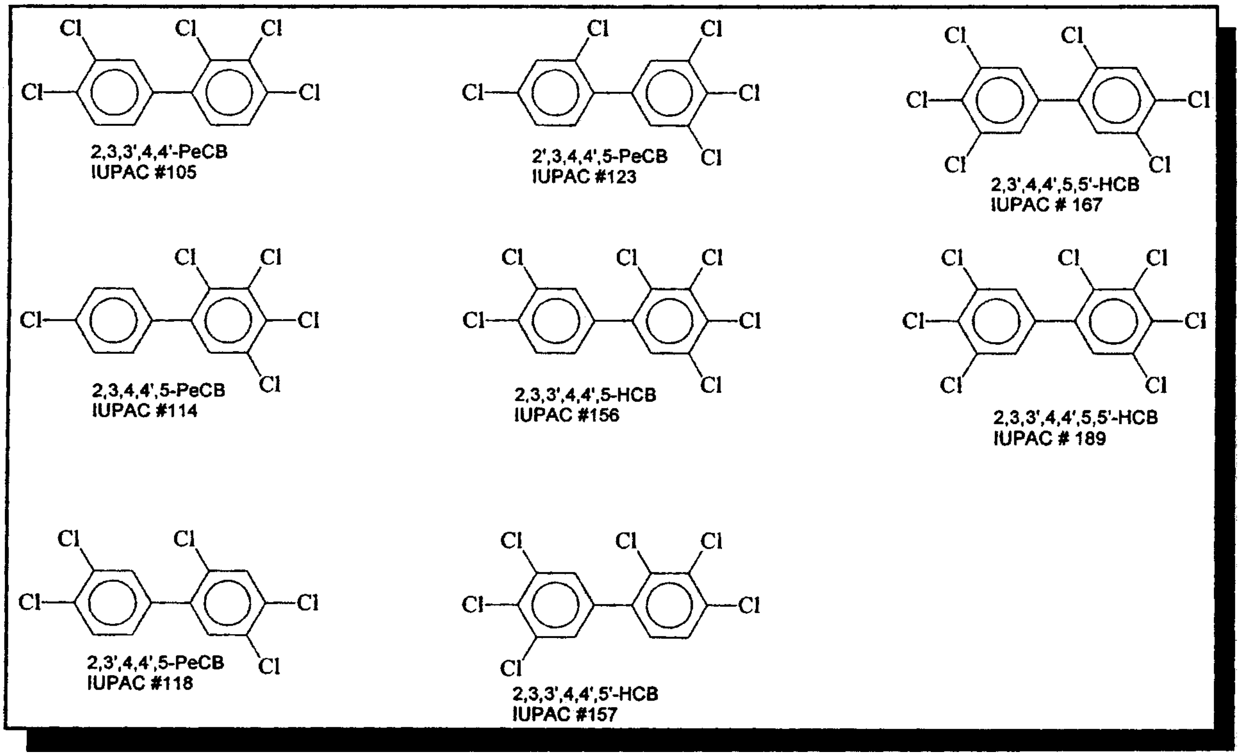

FIGURE 12 Mono-ortho-chlorobiphenyls.

Ah receptor with much lower affinity, but elicit dioxin-like responses. The di-ortho-coplanar PCBs are very insoluble so that receptor-binding activity cannot be readily measured, but at sufficiently high doses, dioxin-like responses have been observed. PCB congeners which lack a para-chloro substituent also produce weak dioxin-like effects.

The main mechanism of PCB metabolism in birds and mammals involves the insertion of oxygen into two adjacent carbon atoms on the ring by hepatic microsomal oxidases (HMOs) to form a transient arene oxide intermediate which then becomes degraded to hydroxylated PCBs. For example, the metabolism of 4,4'dichlorobiphenyl

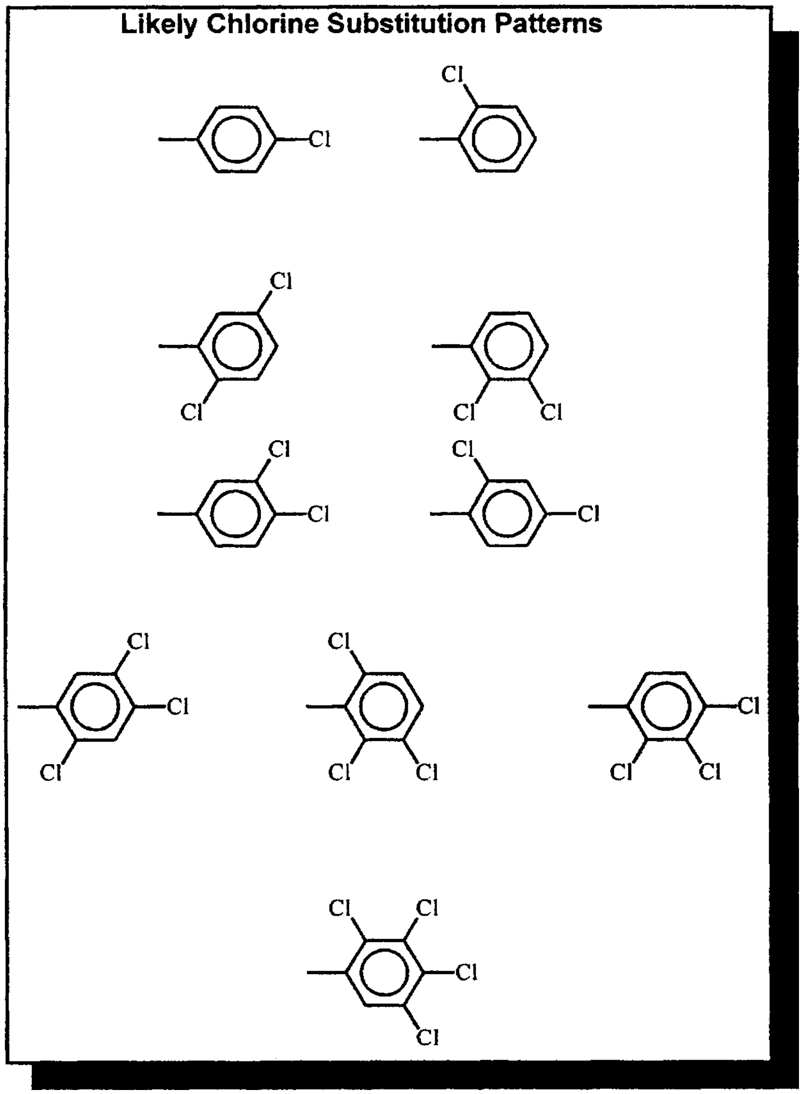

FIGURE 13 Likely substitution patterns.

in the rat yields four monohydroxy-, four dihydroxy-, and two trihydroxy-metabolites. The mechanism is shown in the figure below as epoxidation of the biphenyl nucleus followed by epoxide ring opening accompanied by a 1, 2-chlorine shift. Subsequent cyclisation of the hydroxylated derivatives produced either by metabolism or as a result of photo degradation in the environment or as a reaction by-product of a PCB disposal method, can lead to the formation of chlorinated dibenzofurans. The transformation of only 0.002% of a major constituent of an Aroclor mixture to the corresponding chlorinated dibenzofurans would produce concentrations in the mixture corresponding to the values reported by Vos *et al.* [Vos, 1970] as toxicologically significant.

Table 12 shows the concentrations of toxic PCB congeners which have been found in commercial PCB mixtures.

The toxic isomers of interest are shown in Figure 17.

The manufacturing process for PCBs caused the chlorination of the hydrocarbons present to yield a number of polysubstituted products. In some cases, the initial reaction mixture was contaminated with trace quantities of dibenzofurans and naphthalenes. The polychlorinated dibenzofuran (PCDFs) and polychlorinated naphthalene (PCNps) products are compounds of concern even in trace quantities. Based on a vast amount of published information in scientific journals the causative agent of health effects attributed to PCBs is most likely due to the presence of PCDFs-see the section on “The Perception of PCB Health Effects; the Yusho and Yu-Cheng Poisonings.”

Table 13 indicates the concentrations and types of polychlorinated dibenzofurans in commercial products.

COMPOUNDS OF CONCERN

In 1968 a group of workers at Kyushu University in northern Japan determined that a group of patients with acneiform eruptions similar to chloracne had ingested contaminated rice oil used in cooking. The symptoms of the poisoning suggested that it was due to organochlorine compounds. The word "Yusho" or "rice oil" disease is used to describe the incident. The number of recognized victims over a period of about ten years rose to a total of approximately 1800 people.

The rice oil contamination was determined to be Kanechlor 400 which was produced as an approximately

48% by weight chlorine substituted biphenyl. The fluid was used by the rice oil manufacturer as a fire hazard reduction measure in an indoor heat exchanger.

The PCB concentration in Yusho oil was found to be about 1000 ppm PCB (Kuratsune *et al.*[4]). As analytical capabilities increased there has been a parallel increase in the speculation that the causative agents found in the rice oil such as polychlorinated dibenzofurans (PCDFs) and polychlorinated quaterphenyls (PCQs) (Masuda and Yoshimura[5]) had much greater relative toxicities. Original estimates of the PCB contamination were in the range of2000–3000 ppm PCB but were found to be in error primarily because of the analytical interference presented by PCQs.

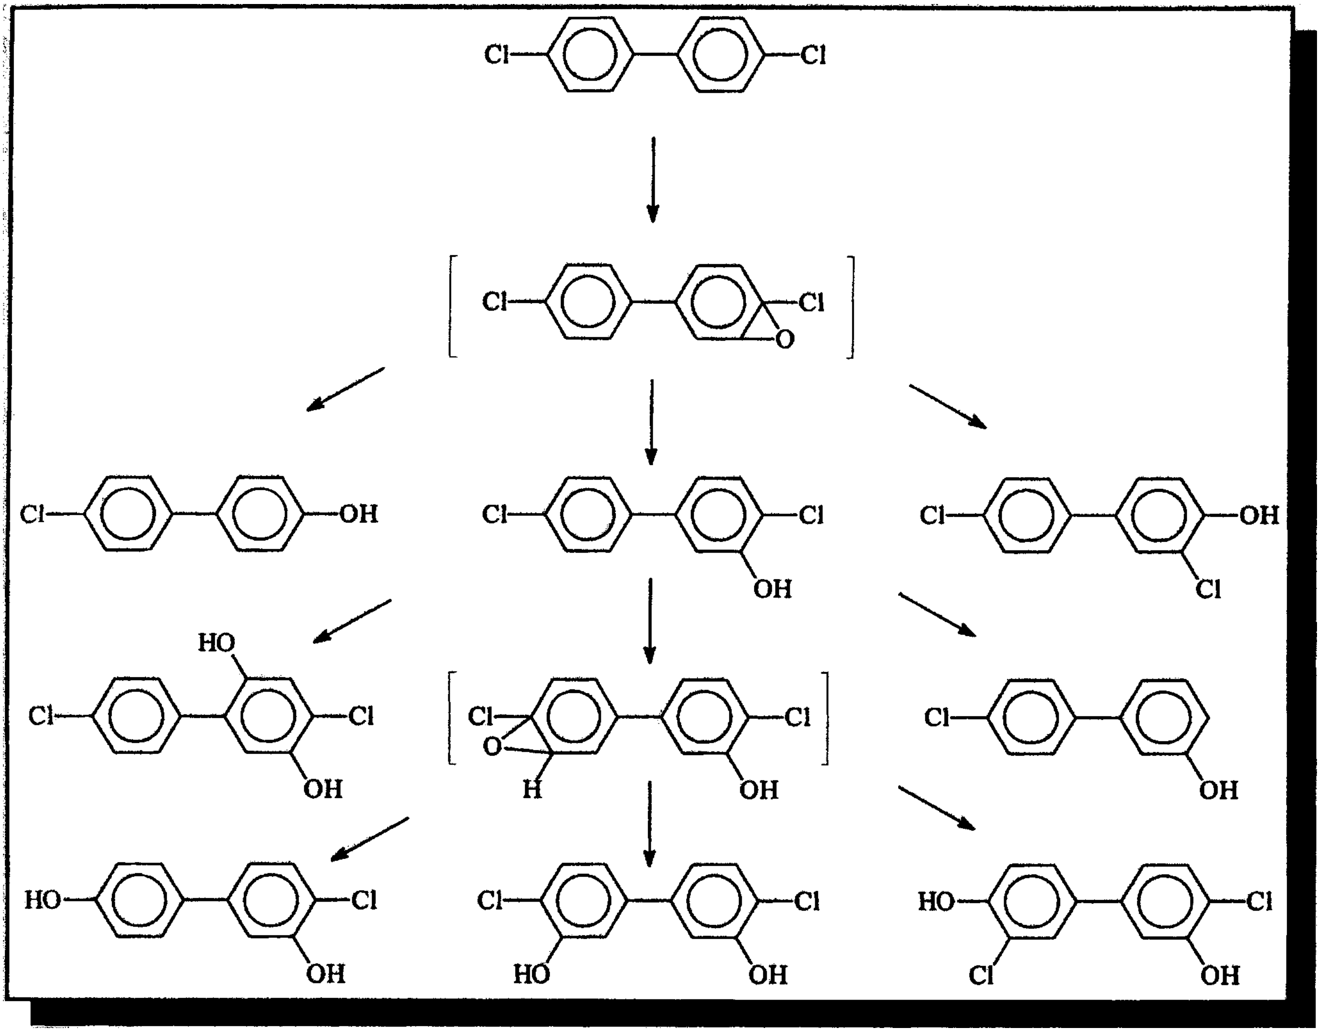

FIGURE 16 PCB metabolism in birds and mammals.

A poisoning very similar to the Japanese Yusho incident occurred in Taiwan in 1978–1979 and is known as the "Yu-Cheng" incident. In this case also, a leaking heat exchanger caused the contamination of rice oil during the manufacturing process with a mixture of Kanechlor 450 (48% Cl) and Kanechlor 500 (54% Cl). 1,843 cases of poisonings were reported during the period 1978–1979 (Masuda and Yoshimura;[5] Kunita *et al.*;[6] Chen *et al.*[7]). The PCB concentration in the oil was less in this incident than in Yusho but the higher dose rates to the victims resulted in approximately the same total dose.

Hsu *et al.*[8] have estimated that the minimum effective dose of PCBs in the Yu-Cheng incident was 0.3 to 0.5 g. The ratio of PCDFs to PCBs in the Yu-Cheng rice oil was found by Chen *et al.*[7] and Kunita *et al.*[6] to be approximately 1 : 300 and therefore the minimum effective total dose for PCDFs is of the order of 1 mg.

The assessment of potential toxicity is exacerbated by the fact that not all PCB, PCDF, PCDD, and so on, isomers are equally toxic. It is therefore not sufficient to analyze for the presence of a class of compounds but also necessary to quantitate the biologically active isomers within a class.

There are 209 PCB isomers contained within the 10 homologous series of PCBs, see Table 10. The series result from the number of chlorine atoms which substitute hydrogen on the biphenyl rings. A commercial arocior mixture may contain 60 or more different isomers.

PCBs are absorbed in the fatty tissues of humans. The ultimate fate of the PCB isomers depends upon their pharmacokinetics so that the analysis of isomers remaining in a tissue may show little resemblance to the isomers originally ingested. Less chlorinated PCBs tend to be metabolized more readily than their higher chlorinated congeners and therefore arociors such as aroclor 1260 or 1254 tend to bioconcentrate more than aroclor 1242.

There have been several studies which have concluded that past exposure to PCBs is associated with excess mortality or morbidity from cancer in human populations (Bertazzi

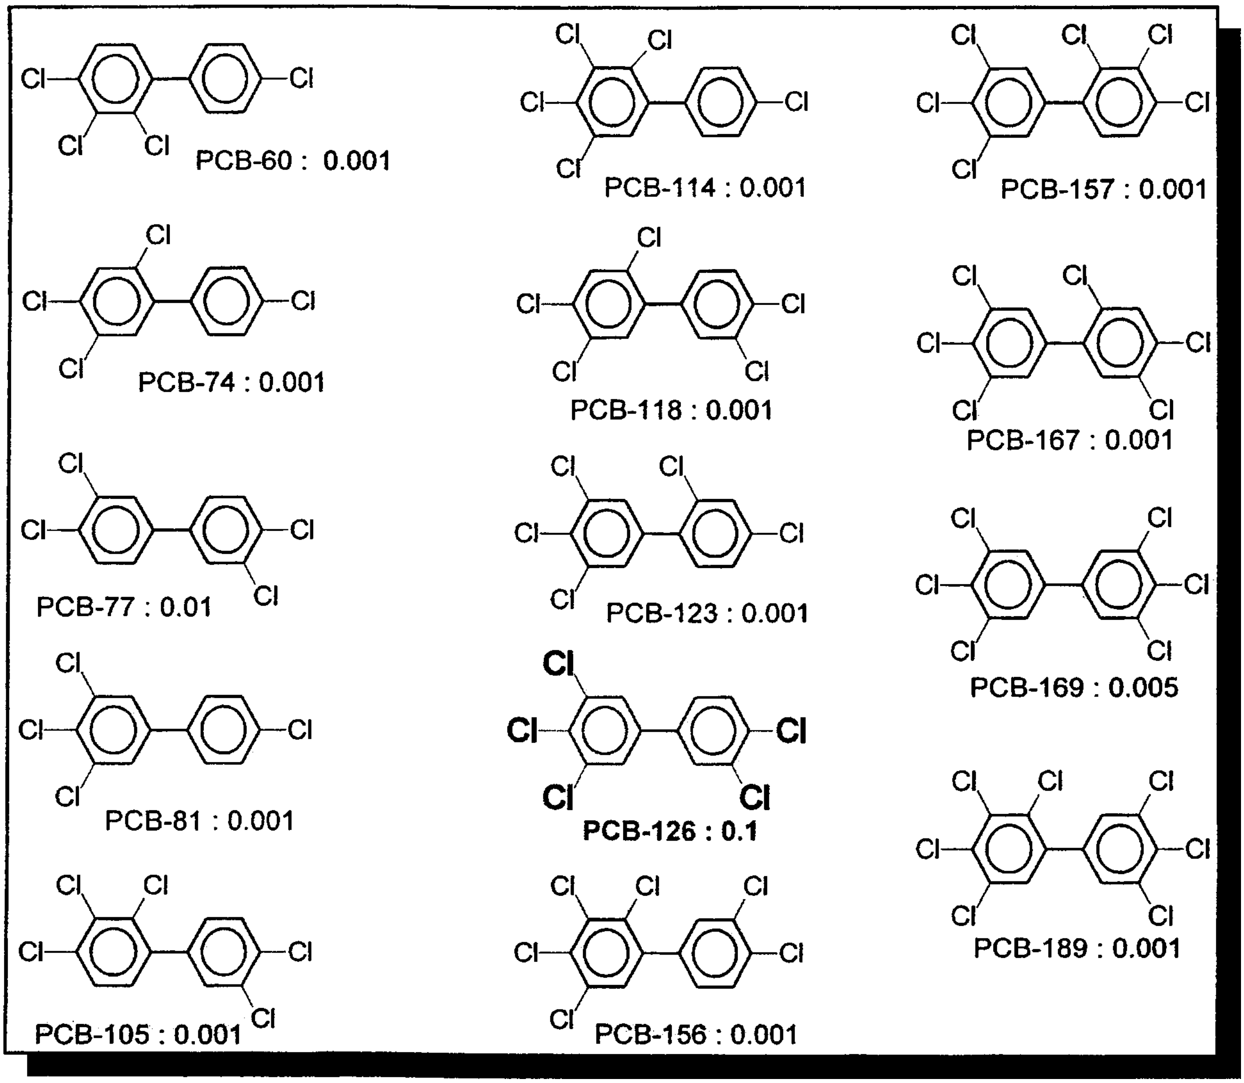

FIGURE 17 The dioxin-like isomers of PCBs.

et al.;[8] Humphrey;[10] Unger *et al.*[11]). However, the health effects in occupationally exposed workers are typically complicated by such factors as incomplete exposure information, job turnover and low chemical specificity.

The most prominent and consistent health effect associated with exposure to PCBs are chloracne and dermatitis. These effects usually clear up quickly and, if they were the only effects, would reduce the need for concern. It is beyond the scope of this paper to investigate all the health effects associated with PCBs but there is little doubt that PCBs are compounds of concern. The concentration at which this occurs is much higher than that of many other classes of chlorinated aromatic compounds. The risk associated with exposure to PCBs can be separated into a consideration of the biological activity of PCB isomers contained in the PCB mixture and the biological activity and probability of formation of degradation products and oxidation products.

Estimates of the dosage of toxic compounds received by victims of the Yusho and Yu-Cheng poisonings were somewhat dependent upon the chemical specificity of the analytical methods used. There is no doubt that the PCB involved had under gone partial oxidation and consequently, the overall toxicity of the fluid was the combined effect of compounds of concern.

In 1970 Vos *et al.*[12] showed a correlation between the toxic effects of European PCBs and the concentration levels of PCDFs. The relative concentrations of the PCDF isomers present in Yusho oil and in two samples of other used heat exchanger PCBs (Kanechlor KC400 and Mitsubishi-Monsanto T1248) were found to be strikingly similar. This fact underscores the work of Kunita *et al.*[6] who have concluded that not only are PCDFs orders of magnitude more toxic than PCBs but claimed also that there is a synergistic action between them. The evidence suggests that PCDFs were a major causative agent in the Yusho and Yu-Cheng incidents.

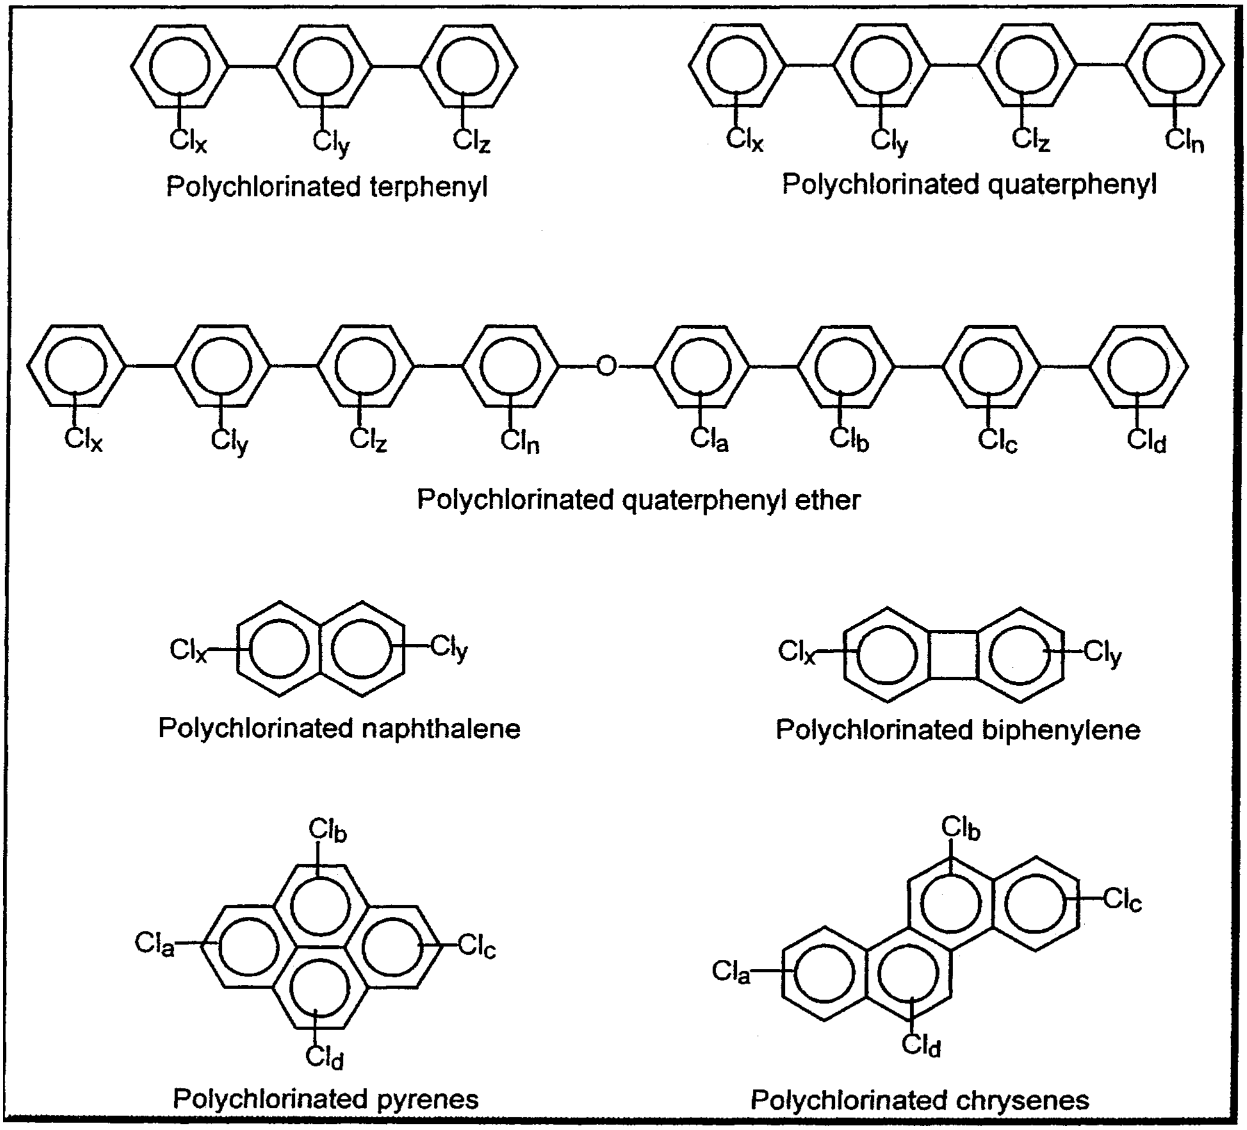

FIGURE 18 Compounds of concern.

It is not yet possible to estimate the sensitivity of humans to the toxic effects of PCDDs. It has been suggested that humans are resistant to the toxic effects of PCDDs. The supposition is not presently verifiable because of the lack of characterization of human exposure. There is no doubt, however, that the 2,3,7,8-tetrachlorodibenzo-dioxin (2,3,7,8-TCDD) isomer is a potent toxin which has caused impaired reproduction and/or birth defects in every species tested and has been described as the most toxic compound known to man.

In addition to PCDFs and PCDDs mentioned above there are several classes of polychlorinated aromatic hydrocarbons which may be contained as impurities or degradation products of PCBs. These classes include polychlorinated terphenyls (PCTs), polychlorinated quaterphenyls (PCQs), polychlorinated quaterphenyl ethers (PCQEs), polychlorinated naphthalenes (PCNs), polychlorinated biphenylenes (PCPs), polychlorinated pyrenes (PCPYs) and polychlorinated chrysenes (PCCYs).

Polychlorinated terphenyls have been found (Allen *et al.*[13]) to have qualitatively similar enzyme inducing effects to those of PCBs but appear to be less potent (Goldstein[14]). Mixtures of PCBs and PCTs have been marketed but were not widely used.

Polychlorinated quaterphenyls were found as contaminants of Yusho and Yu-Cheng oils but for a long time were an unrecognized interference in the quantitation of PCB contamination in these incidents. Studies by Hori *et al.*[15] and Kunita *et al.*[6] showed that the toxic effects of PCQs are similar to PCBs.

Polychlorinated quaterphenyl ethers (PCQEs) have been identified in Yusho and Yu-Cheng oils. This class of compounds does not seem to have been tested for toxicity but structure/activity relationships do not predict that they should be particularly toxic. Nevertheless, cyclization to a phenyl substituted dibenzofuran possibly could yield a toxic product. The likelihood of the cyclization reaction provides a measure for the concern to be accorded the presence of ether precursors.

Polychlorinated naphthalenes (PCNs) have been characterized in commercial PCBs and probably resulted from the presence of naphthalene as an impurity in the biphenyl raw material used for the manufacturing process. Typical concentrations in PCB fluids are less than 600 ppm. Results obtained by Kimbrough[16] and Goldstein,[14] indicated that it is unlikely that PCNs would add significantly to the toxicity of PCBs at the concentration levels typically observed in commercial mixtures, although the stereochemical requirement of planarity to include enzyme activity is fulfilled.

Polychlorinated biphenylenes (PCPs), because of their structure, are expected to be as toxic as the correspondingly substituted PCDDs. According to Poland and Glover,[17] 2,3,6,7-tetrachlorobiphenylene is approximately as potent as 2,3,7,8-TCDD. PCPs have been found to result from the reductive conditions which occur in the early stages of askarel transformer fires and are therefore compounds of concern (Smith *et al.;*[18] Rappe *et al.;*[19] Williams *et al.*[20]) (Figure 18).

Polychlorinated pyrenes (PCPYs) and polychlorinated chrysenes (PCCYs) have been identified as components of the soot from an askarel transformer fire (Rappe *et al.*[21] Williams *et al.*[20]). The toxicities of these classes of compounds have not been determined but their concentrations are so low that they probably do not add significantly to the overall toxicity of the degraded PCB.

THE PERCEPTION OF PCB HEALTH EFFECTS: THE YUSHO AND YU-CHENG POISONINGS

As was mentioned above, a large part of what is currently known about the effects of human exposure to PCBs is derived from two incidents of poisoning which occurred in Japan in 1968 and in Taiwan in 1978. Both episodes involved the contamination of rice oil used for cooking purposes, both involved approximately the same number of people and both involved the same total dose of PCBs (Table 14).

The poisoning in Japan in 1968 became the subject of a special issue of the journal Fukuoka Acta Medica in June 1969.[27] Many of the papers which have been written on various aspects of the poisonings have been published in series and there are now over 200 of them. Most of these papers are in Japanese with English abstracts but there have also been reviews written in English.[27–37]

About 325 patients with acneiform eruptions had been treated in northern Japan between the summer of 1968 and January 1969. The apparent cause of the poisoning was traced to the consumption of a particular brand of rice bran oil.

By May 1970 the total number of cases had risen to 1,291. The common symptoms included acneiform eruptions, hyperpigmentation of the skin, nails and mucous membranes, swelling of the upper eyelids, and hyperemia of the conjunctivae.

PCB concentration in the rice oil varied with the production batch. The highest concentration was found to be 3,000 ppm PCB in oil shipped on February 5, 1968 and only traces were found in oils produced after February 19, 1968. The oil was consumed between March and October 1968 and the first known clinical examination of a Yusho patient occurred on June 7, 1968. The onset of Yusho symptoms occurred in the majority of patients in June, July and August of 1968. The total quantity of contaminated rice oil ingested by patients as well as the dose rate of ingestion of PCBs has been estimated by several workers (T. Yoshimura *et al.*[38]) (Table 15).

A typical quantity of oil consumed was 800–1200 mL containing about 2g of PCB. For victims who had ingested more than 720 mL of oil the attack rate of Yusho symptoms was 100%. The PCB content of Yusho oil was about 1,000 ppm PCB as Kanechlor 400 (J. Nagayama *et al.*[39]). Clinical features of Yusho poisoning are listed below in Table 16.

Undegraded Kanechlor 400 has been found to contain about 18 ppm PCDFs while the Yusho oil contained 5 ppm PCDFs and 1,000 ppm PCBs. In addition, polychlorinated quaterphenyls, PCQs, were found in the oil at concentrations similar to the PCBs. The presence of these compounds initially caused the estimates of PCB contamination to be stated at the 2000–3000 ppm PCB level. Table (14) shows the concentrations of PCDFs and PCBs in samples of Yusho oil.

The presence of PCDFs in the Kanechlor 400 mixture is of great concern because if PCBs are not the major toxic constituents of the mixture then either the ingested rice oil contained contaminated PCBs or degraded PCBs. Several authors have investigated the presence of PCDFs and other toxic contaminants in commercial products prior to use. Table 14 indicates the PCDF concentration in a number of different rice oil products compared with the analysis of a sample of the type used in the heat exchanger. Table 13 indicates the levels of PCDFs in different Aroclors as well as German and Japanese products. The data do not support the hypothesis that the PCDFs were present in the Kanechlor 400 as manufactured because of their high relative concentrations in Yusho oils. Instead, chemical degradation of the PCBs must have occurred, albeit in extremely low yield, to produce degradation products of concern at concentrations of concern. The production of PCDFs is markedly affected by factors such as temperature, time, the presence of oxygen and catalytic metals such as copper or iron. Miyata and Kashimoto[41] have demonstrated that steel acts as an effective catalyst when Kanechlor 400 is heated to 360°C for 20 days. The effect of different catalysts is shown in Table 15 (Table 17).

It would be unusual to find a commercial PCB in an application which would involve such high temperatures unless the system was faulting in some way. The kinetics of chemical reactions, as a rule of thumb, increase by a factor of 2 for every 10°C rise in temperature. In other words, the quantity of PCDFs produced in twenty days at 350°C would be expected to be about half the amount formed at 360°C under

TABLE 14
The most highly PCB contaminated Yusho oils also contained the highest relative concentrations of PCDFs

Sample	PCB Concentration (ppm)	PCDF Concentration (ppm)	PCDF:PCB ratio

360	20	steel + water	72.1	46.6

Miyata H. and T. Kashimoto.[4]

similar conditions. Only a very small fraction of the PCDFs produced at 360°C would be expected to be formed at 250°C. The presence of PCDFs in heat exchanger fluids operated in the range 200°–270°C was investigated by Miyata and his results are shown in Table (16). The PCDF concentration in the fluids increased by a factor of up to 15.5.

Nagayama *et al.*[42] have confirmed the hypothesis that PCDFs as well as PCQs are produced in the degradation process within heat exchangers. They found that the concentration of PCDFs increased by as much as 40 to 50 times the original level i.e., up to about 740 ppm PCDF by heating the PCB mixture to 300°C for 7 weeks followed by heating to 350°C for 4 weeks in the presence of iron.

The concentration of PCDFs in service aged transformer askarels has been shown to occur by Chittim *et al.*[43] It was found that a correlation existed between the concentration of tetrachlorodibenzofurans (T_4CDFs) and the length of time the fluid had been in service. The small number of samples tested was insufficient to obtain a definite correlation between TCDF concentration and transformer load. While the results indicated that transformer load is probably a major factor in the formation of PCDFs, the effects of discharging or arcing appeared to be negligible.

It has been observed that some PCB products were manufactured with trace PCDF contamination caused by the presence of dibenzofuran in the biphenyl starting material (see Table 12). Fortunately, North American starting materials seem to have been purer than those available in Japan and very small amounts of PCDFs are found in undergraded US PCB products. An alternative route of formation might be derived from the use of sodium hydroxide to remove traces of HCl produced during the PCB synthesis. Miyata and Kashimoto[41] found that in the presence of catalytic metals, such as copper and iron found in heat exchangers and transformers, there is up to a 15.5 fold increase in the PCDF concentration in a temperature range of 180 to 270°C (Tables 18 and 19).

Brown *et al.*[45] have also investigated the levels of bioactive PCDF congeners in PCB dielectric fluids obtained from capacitors and transformers. Both service aged and unused equipment was investigated and no indication was found of a higher level of PCDFs caused by PCB degradation. None of the equipment had malfunctioned and failed due to overheating but had all either never been used, or had been operated for a documented period of up to 30 years. The distinction between operating and failed units was not made, nor was

TABLE 16

Percent distribution of symptoms of Yusho reported by 189 patients examined before October 31, 1968

Symptoms	Males N = 89	Females N = 100
Dark brown pigmentation of nails	83.1	75.0

TABLE 17

The increase in PCDF concentration in service aged Kanechlor 400 heat exchanger fluids is greater even than the increase found in high temperature catalyzed fluids

In Service Age (yr.)	Temperature (°C)	PCBs (ppm)	PCQs* (ppm)	PCDFs (ppm)
14	180–270	968,400	31,000	510
3	200–220	999,000	690	277
0‡		999,800	209	33

* PCB = polychlorinated quaterphenyl.

‡ = not used.

there sufficient data to observe any possible trends which may exist between PCDF formation and temperature/load/dissolved oxygen conditions. It can only be surmised that the onset of a hot-spot which is severe enough to cause degradation of cellulosic or Class A dielectric insulation would result in the failure of the equipment in a time which would be too short to allow the formation of PCDFs.

An EPRI report on the degradation of PCBs under electrical discharge has shown that PCDFs are not formed.[46] The PCB components of Yusho oils were primarily tetra- and pentaCBs with lesser quantities of tri-, hexa- and hepta-CBs and small quantities of octa- and nonCBs. In contrast to the predominance of tetra- and pentaCBs in the rice oil, Yusho patients showed predominantly hexa- and hepta-CBs in their blood which indicates that a selective metabolism of the lower CBs had occurred over a period of about 7 years. This is a very significant finding when considering the relative toxicity of different PCB formulations. In the case of Aroclor 1016, for example, the predominant components are mono- and di-CBs with $<0.1\%$ of hexa-CBs. Aroclor 1016, therefore, would not be expected to bioaccumulate to the same extent as a PCB mixture containing a larger percentage of chlorine such as Aroclor 1254.

PCDFs appear to have a different distribution in the body from that of PCBs. There tends to be accumulation in the liver. About forty PCDF congeners have been identified in Yusho oil but, of these, only 10 were found above the detection limits in the blood of patients. Two tetra-, two penta- and two hexa-CDFs were identified.[47] The distribution of PCQs among blood, liver and adipose tissue of Yusho patients has been found to be similar to that of PCBs although the rate of elimination of PCQs appears to be similar to, or even a little faster than that of PCBs.[48]

TABLE 18
The relative ratios of toxic contaminants in Yusho and Yu-Cheng oils are constant

Type of oil	Concentrations in Oil (ppm)			
	PCBs	PCQs	PCDFs	PCDF : PCB

201–300	24	4
301–400	17	3
401–500	4	1
>500	5	1

Cull and Dobbs[44] analysed two service aged PCB transformers but did not find an unusually high concentration of PCDFs.

A similar incident to the Yusho poisoning occurred in Taiwan in 1978–1979 and is now known as the "YuCheng" incident. There are many coincidental similarities between the two poisonings. Approximately 2,000 victims were identified in the Yu-Cheng incident compared with a total of about 1,800 Yusho victims. The sources of poisoning, the toxic constituents and their health effects are very similar.

The source of the toxic constituents in the Yu-Cheng incident was derived from Kanechlor 400 and 500 used in a heat exchanger for the production of rice oil. The concentration of polychlorinated aromatic hydrocarbons in the oil was lower in Yu-Cheng than in Yusho but because the rate of ingestion was higher in Yu-Cheng the total doses were approximately the same. The amount of PCBs ingested by victims in the two incidents was about 0.8 to 1.8 g.

Table 14 shows the distribution of toxic constituents contained in the Yusho and Yu-Cheng oils and from the ratios of PCBs: PCDFs it is possible to calculate the minimum effective dose of PCDFs about 1 mg. The blood PCB levels found in Yu-Cheng victims measured within the first year of exposure range between 3 and 1,156 ppb although 44% of the cases had 51–100 ppb in their blood as shown in Table 19.

The relative rates of elimination of PCBS, PCQs and PCDFs from the blood has been established to be PCQ > PCDF > PCB although the differences between them are small.[6] The prominent clinical features of Yu-Cheng have been correlated with exposure to Yu-Cheng oil as well as to estimates of intake and blood levels of PCBs. Features include pigmentation of the skin, gingiva and nails, chloracne, meibomian gland enlargement, and eye discharge. Subjective complaints against Yu-Cheng patients include increased eye discharge, edema of eyelids, vision disturbances, general malaise, numbness of joints, headache and dizziness, pain in joints and muscles and other less frequently occurring ailments.

Several investigators have concluded that PCDFs were the primary causative agents in both Yusho and Yu-Cheng poisonings. Toxicity studies with PCQ mixtures similar to those in Yusho oil suggest that PCQs are less toxic in rats and cynomolgus monkeys than either PCBs or PCDFs.[6]

A blood concentration of 40 ppb in Yu-Cheng victims was found to be a level above which severe skin and ocular effects became frequent. This is in contrast with the blood levels of PCB exposed populations who have as much as 300 ppb in their blood without there being evidence of severe health effects. This observation points to the relative effect of other constituents in the Yusho and Yu-Cheng oils as well as the possibility of PCB isomer differences. For example, highly toxic PCB isomers such as 3,3',4,4'-tetraCB are 2,3,3',4,4',5-hexa-CB were more prominent in the tissues of Yusho and Yu-Cheng victims than are normally found in samples of Kanechlor 400.[52,53]

Blood levels of PCBs in Yusho and Yu-Cheng victims retuned to background levels over a period of about 7 years but the signs and symptoms of Yusho have persisted for over 25 years. The above data suggest that even though the ratio of PCBs: PCDFs in both Yusho and Yu-Cheng poisoning incidents were about 200:1 the greater toxicity of PCDFs seem to be more than sufficient to offset the difference. No single line of evidence is conclusive but, taken together, they do provide a compelling argument for the conclusion that PCDFs were the primary causative agents.

THE FORMATION OF COMPOUNDS OF CONCERN

Compounds of concern can be contained in PCB fluids for a variety of reasons. For example, they may be formed from impurities in the feedstock used to manufacture PCBs or from the cyclization of PCBs induced by heat, or even from phenolic or ether precursors.

Polychlorinated terphenyls, quaterphenyls and napthalenes could result from feedstock contamination by traces of the aromatic hydrocarbons before the mixture was chlorinated. PCNs have been identified as a pyrolysis product from an askarel transformer fire. Their formation has been explained (Buser[54]) in a laboratory study by invoking the formation of benzyne intermediates or the re-arrangement of intermediates formed between an ortho-chloro phenyl radical with a chlorobenzen (Figure 19).

The overall effect of radical reactions on the product distribution during askarel degradation will be effected by both temperature and the availability of oxygen. Chittim *et al.*[43] have analyzed unused North American askarels and found that they contained less than 0.05 ppm of PCDFs. It is therefore of concern that these workers found a correlation between the concentration of TCDFs in used askarel with the length of time the fluid had been in service. The degradation of PCBs in electrical equipment is discussed above in the section on the perception of PCB health effects.

The Power Transformer Guide ANSI-C57.92-1981 lists a maximum top oil limit of 110°C which may occur when the maximum hot spot conductor temperature is at 180°C due to short term loading. The Distribution Transformer Guide ANSI C57.91-1974 lists a maximum top oil temperature of 120°C which may occur at maximum conductor hot spot temperature of 200°C. Maximum fluid temperatures in a transformer could exceed values in the overload guide if units are subjected to more severe loads. Units with extreme overloads would be expected to overheat and fail. The most probable cause of eventful transformer failure is violent rupture (Doble 1982) and the quantities of any compounds of concern which may be produced is determined by the availability of oxygen in an oxygen depleted, high temperature reaction zone of short duration (Figure 20).

Buser[54] has shown that pyrolysis of chlorobenzenes at 600°C in the presence of excess air yielded about 1% of tetra- to octa-CDFs and tetra- to octa-CDDs. It has also been shown (Buser and Rappe[55]) that the pyrolysis of PCBs occurs intramolecularly by four alternative reaction routes to yield different isomeric PCDF products.

The thermal degradation of PCBs can result in a complex set of reactions which may produce compounds of concern under uncontrolled conditions. The mechanism of the formation of dioxins under pyrolysis conditions is discussed later in this section. Temperature and residence time relationships have been extensively studied to establish the conditions necessary for satisfactory destruction (Mescher *et al.*[56]). It was found, for example, that with a Is residence time, most PCB decomposition occurred in a temperature range between 640°C and 740°C. Commercial incineration equipment for the destruction of PCBs must therefore be designed so that the energy input to disrupt the molecule is made available either by supplying a very high temperature or a satisfactorily long residence time. Several types of incinerator are found useful for this purpose and include rotary kilns, high temperature fluid wall reactors, plasma pyrolysis units, circulating bed combustors and so on.

Uncontrolled reactions which lead to the formation of chlorophenols as a side reaction product have the potential to generate PCDFs and/or PCDDs in the following ways:

1) The dimerization of chlorophenates;
2) The cyclization of polychlorinated diphenyl ethers (PCDPEs);
3) The cyclization of polychlorinated phenoxy phenols.

The Seveso accident occurred in 1976 and was one of six similar occurrences in which uncontrolled reaction conditions caused the dimerization of trichlorphenol produced from tetrachlorobenzene and sodium hydroxide in ethylene glycol to yield PCDDs. The reactions are shown in an early section in explanation of the chemistry observed in 1956. In the case of liquid systems, reactants are retained in the reaction zone for periods of time which are long compared to the time required for the formation of product. In a gaseous reaction, on the other hand, such as in a flame, the reaction zone is relatively short-lived and the yield of product is therefore less. The importance of even statistically unlikely reactions lies in the toxicity of the products. The pyrolysis of PCDPEs follows two competitive reaction pathways viz., reductive dechlorination or ring closure to PCDFs.

The cyclization of polychlorinated phenoxy phenois is also a bimolecular reaction which yields PCDDs under the influence of heat. The above discussion has considered which compounds are of concern and how they may be generated in uncontrolled reactions. There have been many methods developed for the PCB decontamination of materials and these will be discussed more fully later. Incineration methods have already been mentioned. In general, dechlorination reactions of PCBs involve an initial addition of an electron to the aromatic molecule. The end result of the reaction should be that there is no remaining organically bound chlorine. In that case none of the chlorinated toxic compound classes discussed above can be present in the reaction residue. However, depending upon the chemistry involved and the stoichiometric excess of reagent, toxic intermediates can be produced which, while satisfying the requirements for the removal of PCBs, can produce a severe problem where only a relatively slight hazard existed before the process was applied.

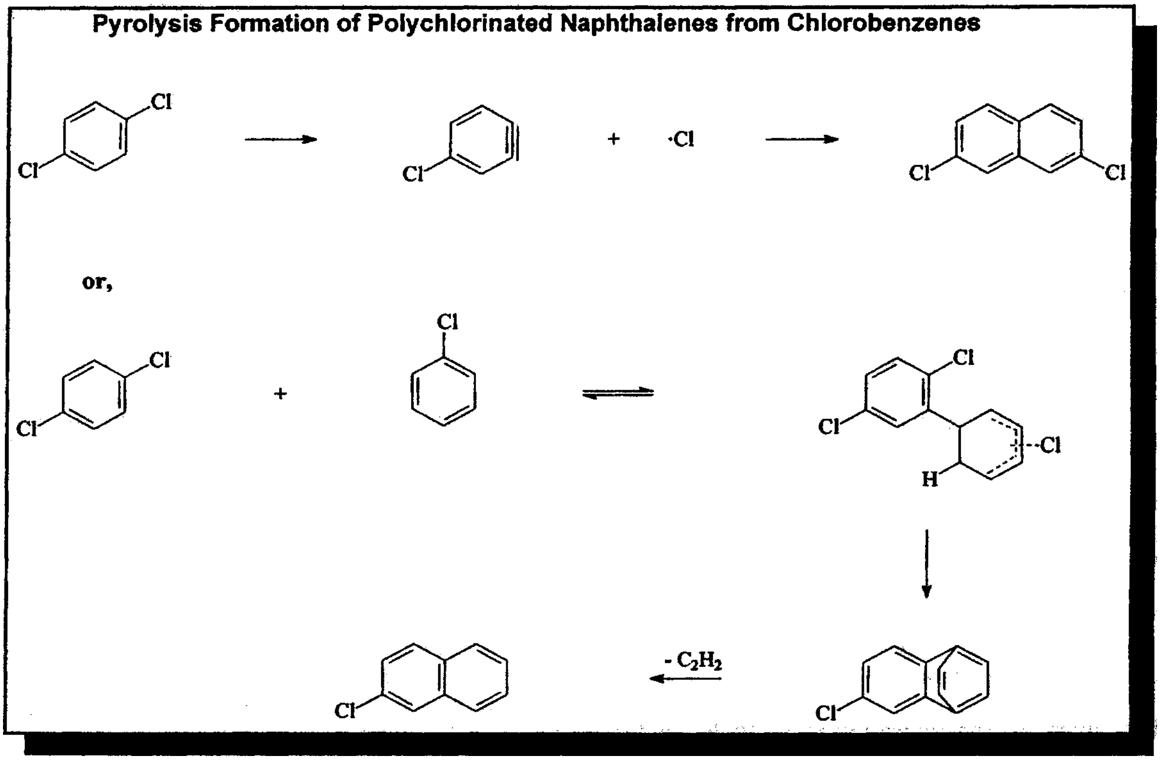

FIGURE 19 Benzyne or other free radical formation of polychlorinated naphthalenes.

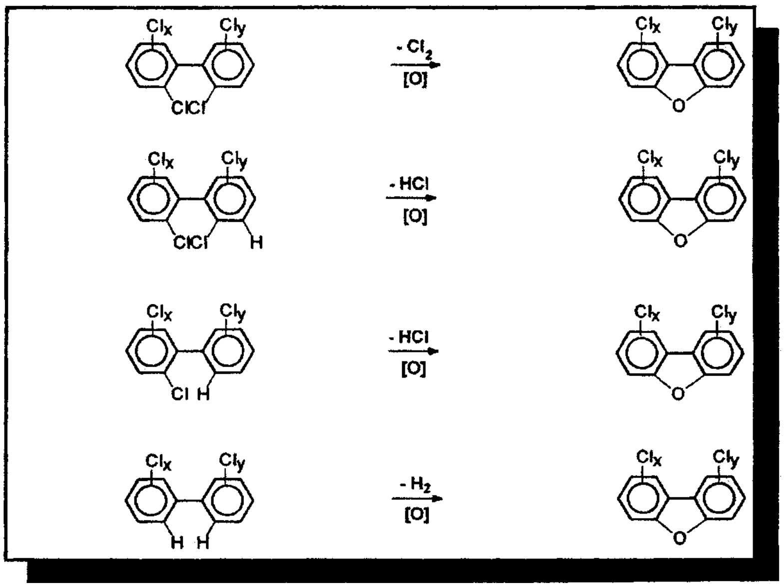

FIGURE 20 Pyrolysis formation of PCDFs from PCBs.

From a chemical point of view there is little difference between whether the electron is derived from an alkali metal or an organometallic reagent or from radiation induced electrons. The gamma-ray radiolysis of halogenated benzenes was investigated by Choi and Willard in 1962[57] using a high specific activity Co^{60} source. Aria *et al.*[58] were the first to apply the method to PCB solutions and in 1974 their work was extended by Sawai *et al.*[59]

Sawai *et al.* used Co^{60} gamma-rays to induce electrons in deoxygenated solutions of PCBs in alkaline isopropanol. They found that the presence of small amounts of electron acceptors resulted in an inhibition of dechlorination. Also, the formation of chloride ion and the consumption of hydroxide ion were approximately equal at each dose. The results paralleled the study by Webber 1983 in which transformer askarels were irradiated in dielectric insulating oil with Sr^{90} β-particles. It was found that the dechlorination reaction did occur but that, in the absence of potassium hydroxide and isopropanol, the degradation required impracticably long irradiation times.

The reaction scheme which explains the experimental data is shown in Figure 21.

- The beta particle radiolysis of water produces hydroxyl radicals and solvated electrons, reaction (1).
- The solvated electrons react with PCBs to give a PCB radical anion, reaction (2).
- The anion stabilizes itself by eliminating chlorine as chloride to leave a PCB radical, reaction (3).
- In the presence of isopropanol the PCB radical can easily abstract hydrogen to become a PCB molecule with one less chlorine than at the beginning of the reaction sequence, reaction (4).
- The isopropanol radical formed in the hydrogen abstraction step reacts with the hydroxyl ions from the potassium hydroxide in the system to produce acetone radical ions, reaction (5).
- The acetone radicals become stabilized as acetone after interaction with PCBs to yield PCB radical anions, reaction (6).
- The reaction sequence continues in this way until total dechlorination has occurred.

Hydroxyl radicals are extremely reactive species and are produced in very small amounts relative to the isopropanol present. It is consequently more likely that reaction will take place with isopropanol than with a small amount of PCB or an even smaller concentration of PCB radicals. Also, the concentration of PCB radicals is so small relative to the macro amount of isopropanol present that coupling to produce a polychlorinated quaterphenyl is unlikely. Certainly mixtures of PCBs are destroyed by β-particle radiolysis most efficiently when the solution is free of oxygen and contains an alkaline hydrogen donor to allow free radical chain propagation. However, in the absence of isopropanol and

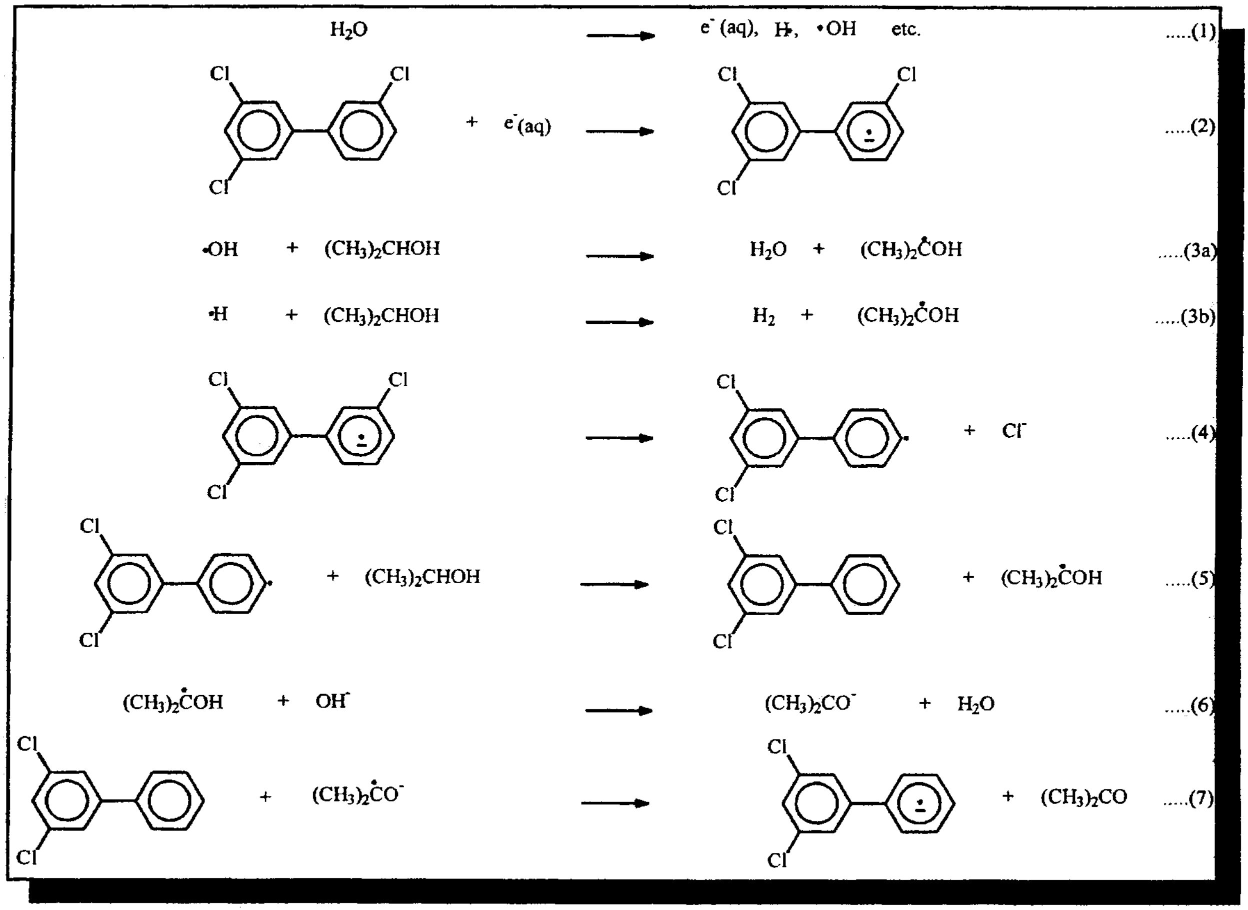

FIGURE 21 The radiolysis of PCBs with 2 MeV Sr^{90} β-particles.

hydroxyl anions the radiolysis reaction requires very much larger irradiation doses and hence very much longer reaction times. Under these circumstances the concentration of hydroxyl radicals which are produced is similar to the concentration of PCB radicals and hydroxylation occurs to give a polychlorinated phenol. Intramolecular cyclization of the hydroxylated intermediates can occur as discussed earlier to yield PCDDs.

As a method for the PCB decontamination of oils the process is impractical but it serves to illustrate how the reaction conditions may *induce* rather than *reduce* a potential hazard.

The analysis of polychlorinated non-oxygenated toxic compounds is made extremely difficult because of the lack of suitable standards. The presence of such classes of compounds as PCQs, PCBPs, PCPYs and PCCYs has nevertheless been established when askarel has been degraded under anaerobic conditions.

Sodium dispersions are effective in the dechlorination of PCBs and were first applied by Japanese workers in 1973 who used it to decontaminate kerosene extracts of PCB contaminated sewage sludge. The method was applied in the decontamination of electrical insulating oils by Webber *et al.,*[60] who found that even high concentrations of askarels would react to give a non-toxic polyphenyl sludge. The mechanism was investigated by Pilgrim and Webber[61] and Webber and Wilson.[62] It was postulated that chlorinated biphenyl radical anions are produced by interaction of the PCB molecule in solution with metallic sodium in suspension. The radical anion eliminates chlorine as chloride to form a chlorobiphenyl radical which, in turn, abstracts available hydrogen from oil components to yield a partially dechlorinated PCB. The reaction continues in the presence of a stoichiometric excess of sodium until total dechlorination is achieved. The reaction sequence is discussed in more detail in the section below on PCB disposal methods.

In the absence of a readily available quantity of abstractable hydrogen the biphenyl radicals tend to couple and form quaterphenyls and higher polyphenyls. This reaction is relatively less likely to occur that the dechlorination reaction when an excess of sodium is present and consequently the quaterphenyls which are formed either have few remaining chlorine atoms on the rings or are completely dechlorinated.

Quaterphenyls and hexaphenyls are slightly soluble in mineral insulating oil and become totally dechlorinated. The sludge is predominantly hexa- and polyphenyl compounds. Work done by Brown and Webber[62] on the NMR of polymerized biphenyls has indicated that electrical conductivity through the polymer chains is dependent upon the extent of electron orbital overlap between the ring constituents of the polymer. Thus, when a small excess of alkali metal reagent is maintained in contact with insulating oil for a long time, in order to minimize the use of reagent for example, polyphenyls are produced which are dissolved in the oil. The power factor of the processed oil then increases dramatically to $>10\%$ (ASTM D924) compared with that of useful oil of $<0.1\%$. An increase in power factor corresponds to an increase in the concentration of polar constituents in the oil.

The concentration of polyphenyls in the oil and the extent of their chlorination was not investigated, but, since PCQs are not expected to be more toxic than PCBs, and because they are only produced in trace quantities, the practical limitation to their presence lies in the power factor of the product oil rather than their toxicity.

In 1970 Vos 79 (Vos *et al.,* 1970) showed a correlation between the toxic effects of European PCBs and the concentration levels of PCDFs. The major PCDF components contained in Yusho oil were the highly toxic 2,3,7,8-tetra-CDF and 2,3,4,7,8-penta-CDF. The relative concentrations of the PCDF isomers present in Yusho oil and in two samples of used heat exchanger PCBs (Kanechlor KC 400 and Mitsubishi-Monsanto T 1248) were found to be strikingly similar[74] (Nagayama *et al.,* 1976). This fact underscores the findings of other workers in this field that there is a connection between the toxicity of degraded PCB fluids, including tri-/tetrachlorinated benzene/PCB blends, and the concentration of PCDFs. The overall toxicity of the fluid may then be attributable, as Vos indicates, to the two particular PCDF isomers mentioned earlier.

In addition to the formation of PCDFs and PCDDs from PCBz/PCB fluids there are also several classes of polychlorinated aromatic hydrocarbons which may be contained as impurities or degradation products of PCBs. These classes are shown in Figure 22 and include:

- polychlorinated terphenyls (PCTs),
- polychlorinated quaterphenyls (PCQs),
- polychlorinated quaterphenyl ethers (PCQEs),
- polychlorinated naphthalenes (PCNs),
- polychlorinated biphenylenes (PCPs),
- polychlorinated pyrenes (PCPYs) and
- polychlorinated chrysenes (PCCYs).

Polychlorinated quaterphenyls were found as contaminants of Yusho and Yu-Cheng oils and for a long time were an unrecognized interference in the quantitation of PCB contamination in these incidents. Studies 88 (Hori *et al.,* 1982) show that the toxic effects of PCQs are similar to PCBs.

Polychlorinated quaterphenyl ethers (PCQEs) have been identified in Yusho and Yu-Cheng oils. This class of compounds does not seem to have been tested for toxicity but structure/activity relationships do not predict that they should be particularly toxic. Nevertheless, cyclization to a phenyl substituted dibenzofuran possibly could yield a toxic product. The likelihood of the cyclization reaction provides a measure for the concern to be accorded the presence of ether precursors.

Polychlorinated naphthalenes (PCNs) have been characterized in commercial PCBs and may have resulted from the presence of naphthalene as an impurity in the biphenyl raw material used in the manufacturing process. Typical concentrations in PCB fluids are less than 600 ppm. Results obtained by 89 (Kimbrough, 1981); 90 (Goldstein, 1980)

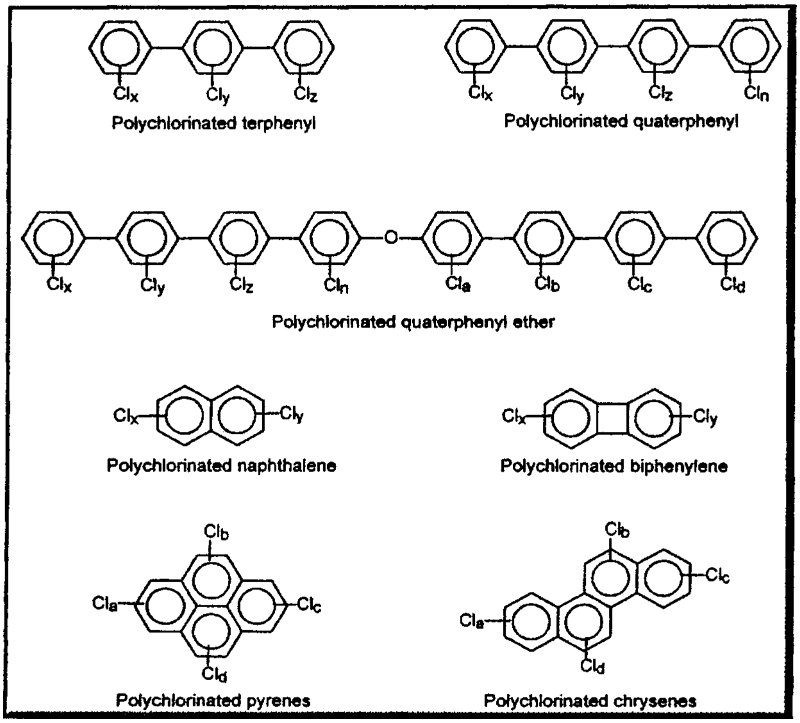

FIGURE 22 Compounds of concern.

indicated that it is unlikely that PCNs would add significantly to the toxicity of PCBs at the concentrations which are typically observed.

Polychlorinated biphenylenes (PCPs), because of their structure, are expected to be as toxic as the correspondingly substituted PCDDs. Accordingly to Poland and Glover (1977) 2,3,6,7-tetrachloro-biphenylene is approximately as potent as 2,3,7,8-TCDD. PCPs have been found to result from the reductive conditions which occur in the early stages of askarel transformer fires and are therefore compounds of concern [see Smith *et al.* (1982); Rappe *et al.* (1982); Rappe *et al.* (1983)].

Polychlorinated pyrenes (PCPYs) and polychlorinated chrysenes (PCCYs) have been identified as components of the soot from an askarel transformer fire (Rappe *et al.,* 1983).

Rubey[64] was studied the thermal decomposition of 2,3′,5,6′-pentaCB in different atmospheres and temperatures with a residence time of 2s. The decomposition temperatures range from about 700°–950°C. Similarly, a plot of PCB degradation in which the formation and decomposition of PCDFs is superimposed on the destruction of 2,3′,4,4′,5-pentaCB shows that the formation of PCDFs occurs at 700°–800°C and their yield increases up to about 900°C. Above 900°C there is rapid decomposition of both the PCB and the PCDFs.

Several physico-chemical factors influence incineration and are listed here to indicate the complexity of the process.

- exposure temperature
- the oxygen composition of flame and non-flame atmospheres
- gas phase residence times in different heated zones
- oxygen concentrations and associated gradients
- pressure
- flame contact time
- spatial and temporal variations in temperature.
- thermodynamic and kinetic properties of the compounds involved.

An extensive treatment of the quantitative prediction of the formation of PCDFs from PCBs under pyrolysis conditions is beyond the scope of this paper but a review of the literature does allow a semi-quantitative assessment of the likelihood of PCDF formation and decomposition in flames under a variety of conditions. In addition, thermodynamic factors will influence the enthalpies of activation and the frequency factors for decomposition of PCDFs depending upon their degree of chlorination (Tables 20, 21).

The chemical reactions and mechanisms which take place in combustion systems can be extremely complex and different systems of reactions, such as free radical decompositions, can occur simultaneously. The intractability of the mathematics used to model such systems depends to some degree upon the number and type of simplifying assumptions which are applied. For example, a steady-state approximation, in which the rate of formation and decomposition of a species is constant, can be applied in certain situations. Then, the equation which relates the rate of change of a species in its steady-state with the concentrations of the other species, can be solved in terms of the concentrations of the other species by setting the differential equal to zero.

Chlorobenzene pyrolysis

PCBz studied	Chlorobenzene pyrolysis Process	Product	Yield	Ref.
Mixture of tri-/tetra-CBz; PC_5Bz	Pyrolysis in air	PCDD, PCDF, PCB, higher chlorinated benzenes, Cl-phenols	2,000 ppm	156
Monochlorobenzene	Pyrolysis in N_2	Mono- and di-Cl-biphenyl	50 ppm	96
Monochlorobenzene	Pyrolysis	di-Cl-biphenyl	10%	157

A second simplification can sometimes be made in good approximation when one or more reactions occur much faster than other reactions in the system. Under these conditions, partial-equilibrium is assumed. This allows the expressions which describe forward and backward reactions to be equated. Further simplifications can be made using sensitivity analysis of solution variables in which numerical solutions are derived for small changes in input variables to determine the magnitude of induced change. When reactions or species are found which have little overall effect, the equilibrium equations and terms which involve the species can be dropped and the conservation equations are thereby simplified.

A reaction mechanism for the formation of dioxins has been suggested by Altwicker *et al.* (1990):

$$\text{Precursor}_{(g)} + \text{Precursor}_{(ads)} \rightarrow \text{PCDD}_{(ads)}$$

$$\text{PCDD}_{(ads)} \rightarrow \text{PCDD}_{(g)}$$
$$\text{PCDD}_{(ads)} \rightarrow \text{non-toxic product}$$
$$\text{PCDD}_{(ads)} \rightarrow \text{non-toxic decomposition product.}$$

In generalized terms, formation and destruction can also occur by a mechanism such as the following:

Polychlorinated phenol → polychlorinated phenoxy
radical
↓
polychlorinated
2-phenoxyphenols
(pre-dioxins)
↓

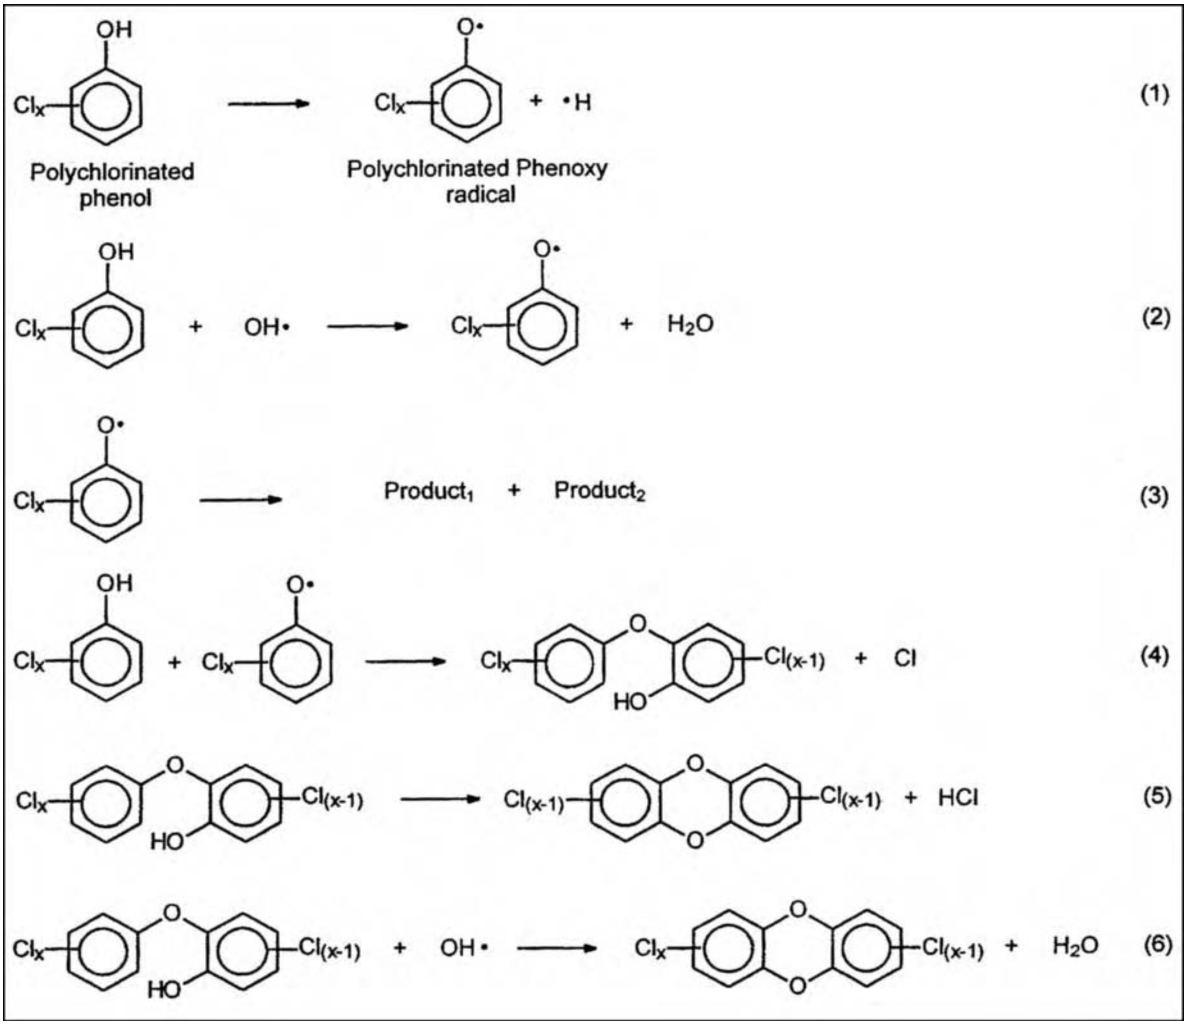

FIGURE 23 Mechanism of dioxin formation in flames [Schaub and Tsang, 1983].

PCDDs
polychlorinated phenoxy radical → non toxic combustion product
PCDDs → non-toxic combustion product.

Increasing substitution by chlorine by chlorophenols would be expected to result in slower rates of attack by hydroxyl radical and therefore the more highly chlorinated dioxins are likely to be less reactive towards bimolecular decomposition with hydroxyl radicals than the lesser chlorinated congeners. One would therefore expect that the dioxin isomers distribution would tend to be skewed toward higher chlorinated species.

The unimolecular rupture of the weakest bond yields a polychlorinated phenoxy radical (Figure 25) .

The phenoxy radical is also produced when hydroxyls radicals cause hydrogen atom abstraction. If, alternatively, •OH addition occurs, then the adduct may undergo further reaction with oxygen, or some other species, to give ring opening and thereby reduce the likelihood of dioxin formation.

When the phenoxy radical decomposes by eliminating CO, it forms non-dioxin products.

Polychlorinated 2-phenoxy-phenols are termed predioxins because, in this configuration, the molecule is stereochemically able to cyclize into the dioxin. The bimolecular reaction can also occur in other positions around the ring which would then not produce pre-dioxins.

The unimolecular elimination of HCl from the predioxin yields dioxin.

The reaction is actually two reactions in one. The hydrogen abstraction reaction is similar to reaction (2) and will ultimately depend upon the equilibrium concentration of •OH radicals. The polychlorinated 2-phenoxy-phenoxy radical produced reacts very fast unimolecularly to yield a dioxin and eliminated either H or Cl.

R represents a gaseous organic fuel molecule. It is assumed to allow hydrogen abstraction to form a fuel free radical species which is more stable than the original phenoxy radical.

Both species are free radicals and therefore are likely to react very fast. The products indicated are not meant to

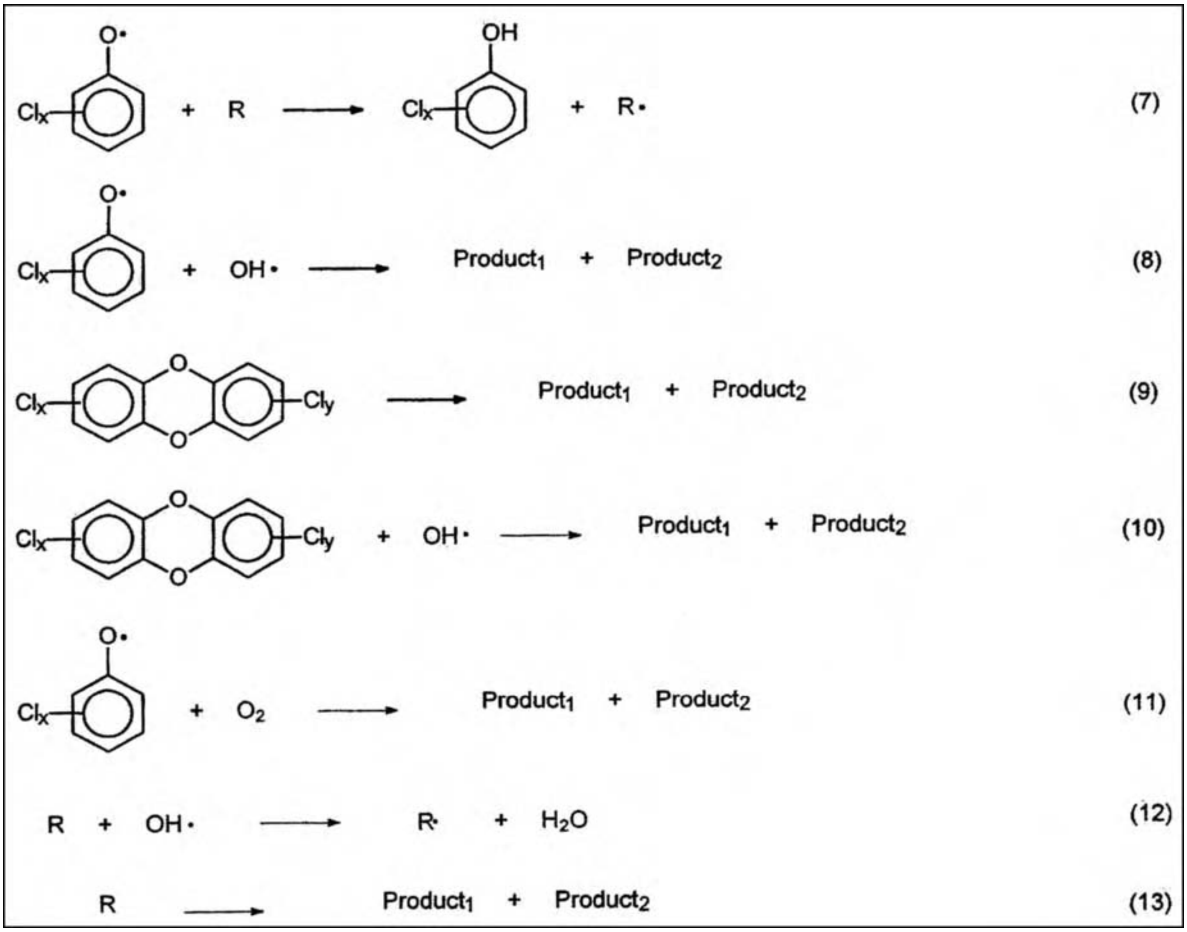

FIGURE 23 (continued) Mechanism of dioxin formation in flames [Schaub and Tsang, 1983].

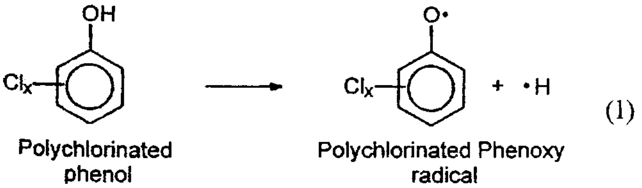

FIGURE 24

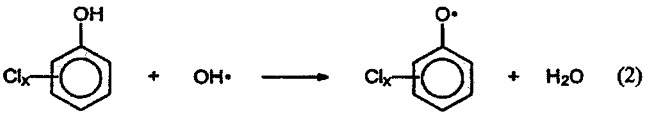

FIGURE 25

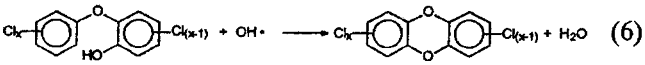

FIGURE 29

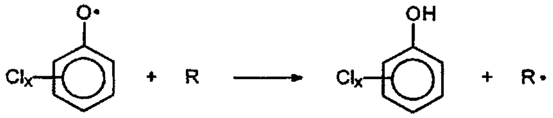

FIGURE 30

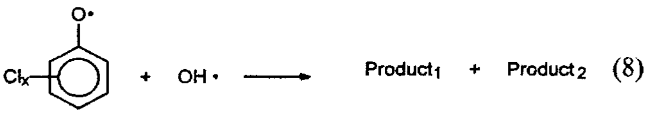

FIGURE 31

FIGURE 32

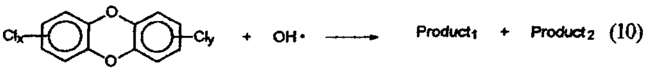

FIGURE 33

represent the same species as in reaction (3) or reactions (9), (10), (11) or (13).

The unimolecular dissociation of dioxin takes place when the molecule is heated sufficiently.

This reaction represents the disruption of the ring system with an hydroxyl radical to yield non-dioxin products.

A major reaction pathway is expected to be the bimolecular decomposition of phenoxy radicals with molecular oxygen when oxygen is present in excess, as is usually the case in incineration, as opposed to pyrolysis in a reductive atmosphere.

The production of fuel radicals by hydrogen abstraction from fuel is likely to be slower than the reaction between hydroxyl radicals and the phenoxy radicals of reaction (8) but this reaction will dominate especially in areas where there are fuel-rich pockets in the incineration process.

The decomposition of fuel into products describes a wide range of reactions.

Schaub and Tsang derived estimates of the rate constants for each of the steps in the reaction sequence by comparing literature values for similar chemistries and calculated four situations governed by different mole fractions. The first case, for example, assumed the condition that no O_2 or fuel is available in the region in which the reaction mechanism is taking place. This was modeled so that the formation of dioxin could be exaggerated.

In the second case, concentrations were calculated on the basis of there being oxygen available for reaction but at an initial mole fraction which corresponded to about 60% of the value needed for stoichiometric combustion. Under normal conditions incinerators are run with excess oxygen or at least a stoichiometric amount. This condition deemphasizes the rate of loss of chlorophenoxy radical in reaction 11 and consequently biases the calculation in favor of dioxin formation. The third scenario models a fuel-rich pocket in a post-combustion zone environment where no oxygen is available for the reaction sequence.

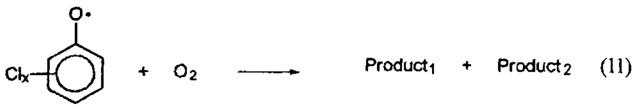

FIGURE 34

$$\mathrm{R} + \mathrm{OH}\cdot \longrightarrow \mathrm{R}\cdot + \mathrm{H_2O} \tag{12}$$

FIGURE 35

$$\mathrm{R} \longrightarrow \mathrm{Product_1} + \mathrm{Product_2} \tag{13}$$

FIGURE 36

Case four is similar to case three but includes the availability of oxygen (Figures 37, 38, 39).

The correlation between combustion temperature and the concentration of dioxin in the example scenarios is illustrated in the above figures. The three curves were not plotted together because the axes extend over significantly different ranges. While the absolute concentrations predicted by the model are relatively unimportant, it is significant that, under post-combustion mixing, in an intermediate temperature zone, unburned chlorophenol is predicted to react with hydroxyl radicals to produce PCDDs. Clearly, high temperatures, and a sufficient quantity of air and fuel are able to provide conditions which will combust chlorophenols into products which are not PCDDs. Conditions can occur during operation of the incinerator in which the amount of PCDD produced is extremely small but, most importantly, some conditions will allow the formation of PCDDs at concentrations which are 5 to 10-orders of magnitude higher than those produced under 'designed' operating conditions.

The rate of destruction of organic material is determined from the kinetic differential equation which relates concentration at a given moment of time to the rate constant for the reaction:

$$\frac{\mathrm{d}C}{\mathrm{d}t} = -k \cdot C \tag{1}$$

where

C = concentration at time, t
k = rate constant.

Upon integration,

$$t = \frac{1}{k} \cdot \ln\left(\frac{C_0}{C}\right) \tag{2}$$

where,

C_0 = initial concentration at time $t = 0$.

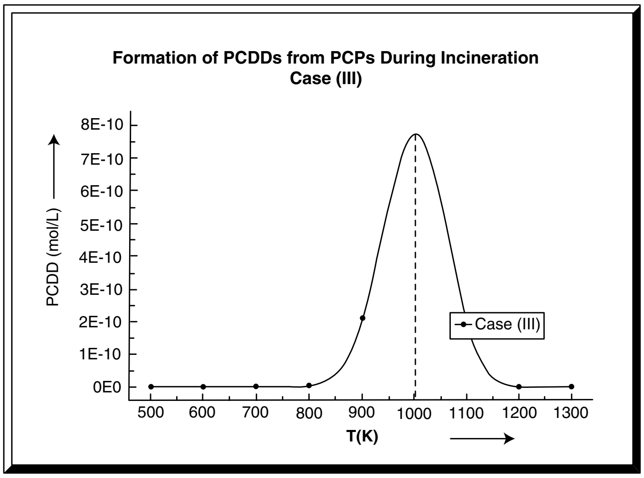

FIGURE 37

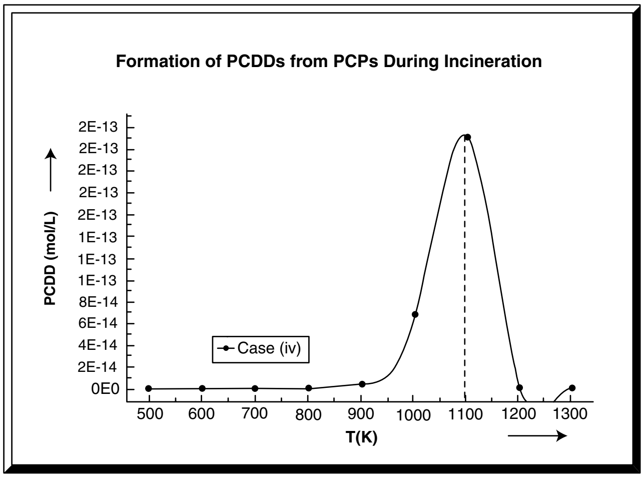

FIGURE 38

Rate constants can be expressed in terms of an Arrhenius expression:

$$k = A\cdot e^{(-(E/R\cdot T)} \tag{3}$$

where

A = frequency factor
E = activation energy
R = Universal gas constant.

From statistical mechanics, the term exp[$-E/RT$] can be taken to mean the fraction of molecular collisions which have an energy E or greater. The pre-exponential term was applied to introduce into the theory a steric collision term intended to describe the need for an orientation of the colliding molecules to produce reaction.

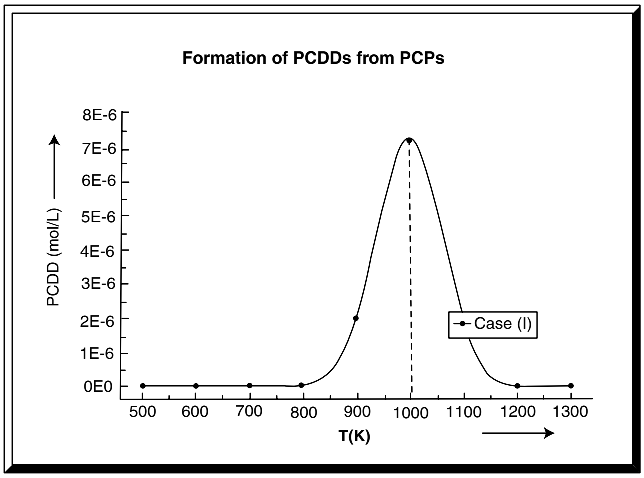

FIGURE 39

Substituting for k in equation (2) yields:

$$t = \frac{1}{A\cdot\exp[-(E/R\cdot T)]}\cdot\ln\left(\frac{C_0}{C}\right)$$

$$\ln\left(\frac{C_0}{C}\right) = A\cdot t\cdot\exp\left(-\frac{E}{R\cdot T}\right)$$

$$\therefore\left(\frac{C_0}{C}\right) = \exp\,[A\cdot t\cdot\exp\left(-\frac{E}{R\cdot T}\right)$$

$$\therefore\frac{C_0-C}{C} = \text{ Destruction Efficiency, } (N)$$

$$= \exp\left[A\cdot t\cdot\exp\left(-\frac{E}{R\cdot T}\right)-1\right]$$

$$\therefore (N+1) = \exp\left[A\cdot t\cdot\exp\left(-\frac{E}{R\cdot T}\right)\right].$$

$$\text{Rearranging, } T = -\frac{E}{R\cdot[\ln\,(\ln(1+N))-\ln A-\ln t]} \tag{4}$$

where

N = destruction efficiency
A = frequency factor (second^{-1})
E = activation energy (cal/g-mole)
R = universal gas constant
= 1.987 (cal/g-mole-°K)
T = combustion temperature (°K).

Table 22 shows the destruction kinetics for several components of transformer askarels and the calculated temperatures necessary to achieve a destruction efficiency of 99.9999% with a range of residence times.

TABLE 22
Destruction Kinetics During the Incineration of Askarel

Compound	Frequency Factor(1/sec)	Activation Energy (cal/g-mole)	Destruction Temperature(°K)/Residence Time (sec)			
			0.5	1	2	7
Monochlorobenzene	$8.0 \cdot 10^4$	23,000	1,056	993	937	851
Dichlorobenzene	$3.00 \cdot 10^8$	39,000	1,023	987	954	899
Trichlorobenzene	$2.20 \cdot 10^8$	38,000	1,013	977	944	889
Tetrachlorobenzene	$1.90 \cdot 10^6$	30,000	1,068	1,019	973	900
Hexachlorobenzene	$1.90 \cdot 10^6$	72,600	983	965	948	918
Pentachlorobenzene	$1.10 \cdot 10^6$	70,000	962	944	927	898

Residence time calculations can be made from consideration of an ideal plug-flow reactor in which the temperature, composition and velocity of the gases are considered to be uniform within any cross-section of the furnace.

The mean residence time,

$$t = \frac{V}{Q} \cdot 60 \tag{5}$$

where
t = mean residence time in seconds
V = furnace volume, cu. Ft
Q = volumetric flow rate, scfm.

The actual flow rate is proportional to temperature,

$$Q' = Q \cdot T \tag{6}$$

where,
Q' = actual flow rate
T = temperature

from equations (5) and (6),

$$t = \frac{V}{Q \cdot T}. \tag{7}$$

The flow through the incinerator is not isothermal and so is not well approximated by the plug flow reactor unless the time-temperature distribution is taken into account as follows.

The differential form of the residence time equation is:

$$\mathrm{d}t = \frac{\mathrm{d}V}{Q'}$$

$$\mathrm{d}V = A_\mathrm{f} \cdot \mathrm{d}x$$

where
A_f = the arc of the furnace
$\mathrm{d}x$ = an element of the axial length of the furnace.

Then, from equation (7),

$$dt = \frac{A_\mathrm{f}}{Q \cdot T} \cdot \mathrm{d}x. \tag{8}$$

If a linear temperature gradient is assumed along the incinerator axis, and the temperature at a point x_m is T_m and the exit temperature T_e is at a distance x_e then,

$$\frac{(T - T_\mathrm{m})}{(x - x_\mathrm{m})} = \frac{(T_\mathrm{e} - T_\mathrm{m})}{(x_\mathrm{e} - x_\mathrm{m})}.$$

Rearranging,

$$T = \frac{1}{(x_\mathrm{m} - x_\mathrm{e})} \cdot [x \cdot (T_\mathrm{m} - T_\mathrm{e}) - T_\mathrm{m} \cdot x_\mathrm{e} + T_\mathrm{e} \cdot x_\mathrm{m}].$$

Substituting into equation (8),

$$\mathrm{d}t = \frac{A_\mathrm{f}}{Q} \cdot \frac{(x_\mathrm{m} - x_\mathrm{e})}{[x \cdot (T_\mathrm{m} - T_\mathrm{e}) - T_\mathrm{m} \cdot x_\mathrm{e} + T_\mathrm{e} \cdot x_\mathrm{m}]} \cdot \mathrm{d}x$$

$$\int \mathrm{d}t = \frac{A_\mathrm{f}}{Q} \cdot \int \frac{(x_\mathrm{m} - x_\mathrm{e})}{[x \cdot (T_\mathrm{m} - T_\mathrm{e}) - T_\mathrm{m} \cdot x_\mathrm{e} + T_\mathrm{e} \cdot x_\mathrm{m}]} \cdot \mathrm{d}x$$

$$\therefore (t - t_\mathrm{m}) = \frac{A_\mathrm{f}}{Q} \cdot \ln\left(\frac{T}{T_\mathrm{m}}\right) \cdot \frac{(x_\mathrm{m} - x_\mathrm{e})}{(T_\mathrm{m} - T_\mathrm{e})} \tag{9}$$

If T_m is close to the furnace entrance, then

$$x_\mathrm{m} \ll x_\mathrm{e}.$$

If $t_\mathrm{m} = 0$, by definition, then

$$t = \frac{A_\mathrm{f}}{Q} \cdot \ln\left(\frac{T}{T_\mathrm{m}}\right) \cdot \frac{(-x_\mathrm{e})}{(T_\mathrm{m} - T_\mathrm{e})}$$

The furnace volume, $V = A \cdot x_e$

$$\therefore t = \frac{1}{Q} \cdot \frac{V}{(T_e - T_m)} \cdot \ln\left(\frac{T}{T_m}\right) \tag{10}$$

that is, the residence time, *t,* is the time spent by the gas above a temperature, *T.*

In partial plug flow kinetics, there is some longitudinal mixing which allows some of the gas to exit the hot zone along a 'fast path'. If the fast path is assumed to be half of the mean residence time, t_f, then,

$$t_f = \frac{V}{2 \cdot Q \cdot (T_e - T_m)} \cdot \ln\left(\frac{T}{T_m}\right). \tag{11}$$

A plot of Eqs. (10) and (11) are shown in Figure 40.

The mean residence time of a material has been calculated on the assumption that it is passing through a 113,000 L incinerator with a gas velocity of 400,000 L/min, a maximum temperature of 1600°C and an exit temperature of 650°C.

A 99.9999% combustion efficiency is a mandated requirement for an incinerator burning PCBs. The PCB contaminated material introduced into the combustion zone must, according to 40 CFR 761.40, be maintained for 2-seconds at 1200°C (±100°C), that is, 2200°F (±200°F), with 3% excess oxygen in the stack gas, or, 1.5 sec residence time at 1600°C (±100°C), that is, 2900°F (±200°F) with 2% excess oxygen in the stack gas.

The figure indicated that a 99.9999% destruction and removal efficiency could be obtained for tetrachlorobenzene in the example incinerator when the mean residence time is 0.7 sec or less. In the case of pentachlorobiphenyl, the residence time would have to be less than about 1.1 sec. If either the tetrachlorobenzene or the PCB passed through the hot zone on a fast-path, the model predicts that the required destruction efficiency would not be achieved since the curves are predominantly above the fast-path temperature-time curve. Note that a residence time of 2.0 sec at 2200°F (1200°C) predicts that a 6–9's DRE might be achieved for both substances, but that these conditions are a lower limit for the incinerator to achieve this level of destruction. A temperature of 2900°F (1600°C) for 1.5 sec would seem to be a much surer set of conditions to achieve 6–9's destruction because then both of the curves for the compounds of interest would lie substantially below the mean residence time and fast-path residence time curves in the model.

Toxic Equivalency Factors and Human Exposure Many of the PCB congeners yield several different PCDF isomers upon pyrolysis. Consequently, in addition to the discussion above on the toxicity of individual PCB isomers present in Aroclor 1016, the following consideration of PCDF isomer toxicity is made of evaluate the risk of generation of PCDFs in a worst case scenario. The analysis of PCDFs in individuals exposed to the Yu-Cheng poisoning showed that the most persistent congeners were the 2,3,7, 8-tetra- 1,2,3,7,8-penta-, 2,3,4,7,8-penta-, and 1,2,3,4,7,8-hexachlorodibenzofuran. Mixtures of these PCDFs with 6 of the most toxic PCBs found in the contaminated oil were prepared as a reconstituted mixture and tested to determine the relative potencies of PCBs and PCDFs (Safe *et al.*[65]). It was shown that PCDFs are from 680 to 2,210 times more toxic than the PCBs. It was therefore suggested that PCDFs were the major etiologic agents in the Yusho and Yu-Cheng poisonings (Table 23).

The relative potencies of PCB and PCDF congeners were measured in terms of their enzyme induction. For example, ED_{50} values are defined as the concentration of chemical which results in 50% of the maximal enzyme induction observed in the dose-response procedure used for each PCDF. The smaller the value for the induction potency or the receptor binding affinity of an isomer, the more toxic the compound. Table 23 lists the relative potencies of some of the most toxic PCDFs. There are considerable differences in the observed activities of PCDFs which differ with respect to Cl substitution at the C-2 and C-3 or C-7 and C-8 positions. In all cases the C-3 or C-7 substituted isomers are the most active. PCDF isomers which differ only in their Cl substitution at C-1 (or C-9) and C-4 (or C-6) positions show that the enzyme induction and receptor binding activities of the C-1 isomers were all lower than the corresponding C-4 substituted isomers.

The toxicity of PCDFs in animals has been reviewed by several authors and while there is very little isomer specific toxicity data for congeners other than 2,3,7,8-TCDF, the generalization has been made that there is a close similarity between the biological activity of PCDFs and that of the structurally similar PCDDS. This is illustrated in Table 18, which shows the relative potency of some PCDF isomers relative to TCDD.

Nagayama *et al.*[67] noted that strains of mice can be separated into two groups after treatment with 3-methylcholanthrene (3-MC) according to whether or not they were AHH responsive. Similarly, the toxicity of PCDFs and PCDDs to mice has been shown to correlate with AHH response (Nagayama *et al.*[68]). The authors therefore attempted to determine the presence of a similar susceptibility in humans by correlating the AHH activity in the lymphocytes of Yusho patients and their skin symptoms (Nagayama *et al.*[69]).

Interpretation of the data given above leads to the conclusion that when PCBs are pyrolyzed, only the formation of PCDF isomers which contain 4 or more Cl substituents need be of concern. In particular, tetra- and higher chlorinated congeners with lateral substitution are the most significant. It should be noted that PCDDs are not generated at all by the pyrolysis of PCBs (Table 24).

The four mechanisms of ring closure illustrated in Figure 20 can be used to predict the isomer distribution of PCDF products although not their relative amounts. Table 25 indicates the PCDF isomers with more than three chlorines which can be obtained from Aroclor 1016. The potentially most toxic mixture of compounds which could be derived from Aroclor 1016 in a worst case scenario would, from the above prediction of the isomers formed, be of very low toxicity. The PCDF isomers which could theoretically be produced would

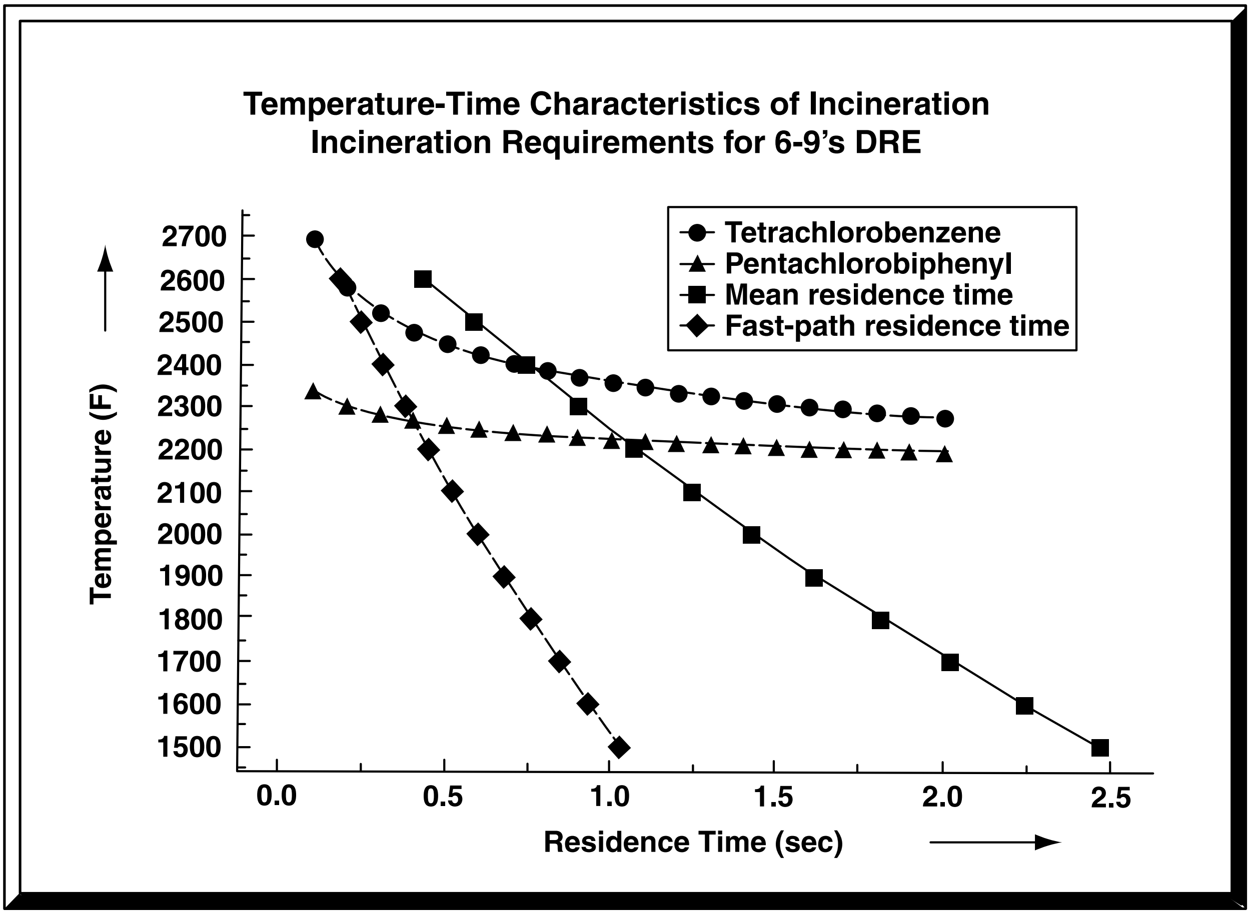

FIGURE 40 The area above the curves shows the temperature-time correlation needed for 99.9999% DRE.

TABLE 23
PCDF toxicity decreases with decreasing lateral Cl substituents

PCDF	Induction potency AHH	Receptor binding affinity
2,3,4,7,8-PeCDF	2.6×10^{-10}	1.5×10^{-8}
1,2,3, 7,8-PeCDF	2.5×10^{-9}	7.5×10^{-7}
1,3,4, 7,8-PeCDF	1.6×10^{-8}	2.0×10^{-7}
1,2,3,7,9-PeCDF	9.0×10^{-8}	4.0×10^{-7}
2,3,4,7,9-PeCDF	7.9×10^{-9}	2.0×10^{-7}
1,2,4,7,8-PeCDF	1.1×10^{-7}	1.3×10^{-6}
2,3,4,7-TCDF	1.8×10^{-8}	2.5×10^{-8}
2,3,4,8-TCDF	4.1 × 10-8	2.0 × 10-7
1,2,3,7-TCDF	2.7 × 10-5	1.1 × 10-7

only amount to the conversion of a total of 5.7% of the PCB present. The quantity of active PCDF isomers which could be generated is extremely low and, typically, conversion from PCB to PCDF takes place under optimum pyrolysis conditions only to the extent of 4% and usually much less. The conversion factor for the yield of slightly biologically active PCDF isomers derived from Aroclor 1016 is therefore a maximum of 0.002, that is, a PCDF : PCB ratio of 1 : 450. Not only is the relative ratio of PCDFs : PCBs one half of the 1 : 200 typical of Yusho and Yu-Cheng oils but, in addition, none of the toxic PCDF isomers found in the Yusho and Yu-Cheng incidents could possibly be present when Aroclor

TABLE 24
The most active compounds are those with Cl substitution at the 2,3,7, and 8 positions

	Relative potency	
PCDF	TCDF	TCDD
Dibenzofuran	$<10^{-4}$	$<10^{-6}$

1016 is pyrolysed because of the PCB isomer distribution present in the undegraded product.

Erickson *et al.*[23] have determined PCDF formation from PCBs under fire conditions when PCB contaminated oils are burned under a variety of conditions. The results indicated that the optimum conditions for PCDF formation from PCBs occurred near 675°C for 0.8 s or longer, with 8% excess oxygen. The residence time of the PCBs in the hot zone did not significantly affect the PCDF formation in the range 0.3 to 1.5 s. A linear relationship was found for PCDFs formed versus the amount of PCBs present. A 4% conversion efficiency of PCBs was observed.

The New York State Department of Health has developed the concept of "2,3,7,8-TCDD equivalents" as a measure of the effective toxicity of polychlorinated aromatic chemicals present in a mixture. The parameter is used as a determinant for the assessment of exposure and risk. The algorithm used to derive the exposure equivalents takes into consideration the relative toxicity of individual compounds. In short, if the heat exchanger fluids involved in the Yusho and Yu-Cheng incidents had been Aroclor 1016 rather than more highly chlorinated PCBS, it is very unlikely that the events would not have been noticed.

PCB concentrations in the blood of two groups of patients were statistically correlated,[31] in the period 1973–1980 and 27 patients in 1981–1984. The AHH activity in the 1973–1980 group showed a positive correlation with blood PCB concentration but the correlation was less statistically significant for the 1981–1984 group. Both group AHH activities showed a correlation to their former PCB in blood concentrations but much less correlation to the later PCB concentrations. Consequently, AHH activity of Yusho patients at the onset of symptoms was probably higher than in its later stages since PCBs and PCDFs had been eliminated from the body. Yusho patients with higher AHH activity showed more serious skin lesions than patients with lower AHH activity.

Furst *et al.*[70] have analysed the distribution of PCDF and PCDD isomers in human milk samples from West Germany and found that all of the samples contained a "typical" pattern of PCDFs and PCDDs. The first study of this type was reported by Rappe and his co-workers[71] on the identification of specific isomers in human milk samples derived from Sweden and West Germany. In addition, the levels of the congeners identified in all of the samples were of nearly the same proportion in each.

However, there was relatively little correlation between either the PCDFs or PCDDs with the concentration of PCBs. This suggests that the sources of contamination may not be the same. Interestingly, the correlation coefficients for isomers which differed by one chlorine are strikingly higher than those for compounds which differ by more than one chlorine. The PCDFs show a similar consistency. No explanation was offered for the observation but it would be interesting to extend the study to draw possible correlations between the isomer distributions found in foods and those which are excreted in breast milk.

The selective accumulation of tetra- to octa-chlorinated dibenzo-p-dioxins and dibenzofurans in foods and human tissues in northern Japan was reported by Y. Takizawa and H. Muto in 1987.[72] They found that the distribution of isomers was similar in food samples and in human tissue samples. Foods with a high fat content such as fish/shellfish and meats contained high concentrations of PCDFs and PCDDs relative to non-fat foods such as vegetables. The following table illustrates the levels of contamination in daily foods in northern Japan (Table 26).

TABLE 25
Aroclor 1016 contains 0.4% by weight of PCBs with more than 4 Cl substituents

Tables 27 and 28 show the calculated daily intake of PCDDs and PCDFs from foods. The values used for the daily intake of different types of food were derived from "Nutrition Survey Data, Japanese Agency of Health and Welfare, Daiichi Press, Tokyo, 1982" as reported by Y. Takizawa and H. Muto[72].

Table 29 compares the ratio of PCDD : PCDF isomers found in both the calculated values from foods and the observed ratios in human tissues.

There seems to be a good correlation between the dietary intake of PCDDs and PCDFs and the amounts found in each of the tissue types except for octachlorinated isomers. The reason for this may be that the source of O_8CDDs in tissues may be other than food. The best correlation is found between the penta-hepta isomers. Since there are a large number of factors which have not been considered in these tables, such as obesity and pharmacokinetics, it is somewhat surprising that the correlations are as good as they are.

People in industrialized countries have an adipose tissue level of PCDDs of about 1000–1200 ppt whereas people in non-industrialized countries have much lower levels. PCDF levels in industrialized countries are not usually below 50 ppt.

The estimation of health risk to humans was initially based on the amount of 2,3,7,8-TCDD/F present. In order to better estimate the risk caused by exposure to a mixture of different PCDD and PCDF isomers the concept of "TCDD Equivalents" have been introduced. Several models have

been developed. In addition to Eadon's model,[73] derived from data on soot samples taken from the Binghamton state office building fire, there are also models proposed by Danish and Swiss groups as well as the USEPA[74]. A re-examination of the USEPA model was presented by J.R. Olsen *et al.*[75]

Table 30 shows the "TCDD Equivalent" factors used in different models. The TCDD equivalents of a mixture of isomers can be calculated by multiplying the amount of each isomer with its TCDD equivalent from Table 30 and then summing the individual isomer contributions to the mixture.

Samples of human breast milk taken from areas in Vietnam which were sprayed with Agent Orange have shown markedly increased 2,3,7,8-TCDD levels even 10–15 years after cessation of the contamination. Some of the isomers of PCDDs and PCDFs found in the mother's milk were indicative of other contamination sources such as pentachlorophenol wood and paper preservative as well as, possibly, incineration products. The importance of such studies can be considered in terms of health risks to infants.

Schecter *et al.*[76] have observed that the body burden of 2,3,7,8-TCDD alone in nursing mothers from the south of Vietnam in 1973 was close to the adverse effect level calculated to cause chloracne in occupationally exposed workers based upon the "tolerable daily intake" of 30 pg/Kg of body weight over a 70 year lifetime, nursing infants in both North America and South Vietnam ingest more than a lifetime dose of PCDD/F in their first year.[77]

The levels of 2,3,7,8-TCDD in human adipose tissue in North America have been reported for populations in St. Louis, Atlanta, Utah and in Canada by R.L. Sielken.[78] He pointed out that the random level of 2,3,7,8-TCDD in human tissue is more likely to have a lognormal distribution than a normal

distribution since there was a positive correlation between the dioxin level and age. Sielken's correlation for the St. Louis population was

$$\log_e[\text{TCDD}] = 1.02 + 0.023 + \text{age}; \; r = 0.72.$$

The observation might be partially explained by persons ingesting a contaminated diet but does not support an initially high exposure of the population to contaminated mother's milk. Schecter *et al.*[79] have compared the results from several workers on the concentrations of PCDDs and PCDFs in human milk derived from north and south Vietnam and the United States. They then went on to calculate the 2,3,7,8-TCDD equivalents contained in the milk and to derive the ratio between the first year intake and the recommended intake values. The data showed that in south Vietnam, and a small percentage of the population in the US are exposed to 2,3,7,8-TCDD concentrations in mothers milk which are sometimes very much greater than the limits set by both the USEPA and the United States Public Health Services Centers for Disease Control (USCDC). The calculations are extended in Table 31 to include the data reported by Ogaki *et al.*[80] on Japanese foodstuffs.

Table 32 shows the estimated daily intake of total 2,3,7,8-TCDD equivalents by nursing infants in South and North Vietnam, Japan and the United States. It has been assumed that an average consumption of milk is 800 mL/day and that the body is 10 Kg. The "Acceptable Daily Intake" or ADI value for the ingestion of 2,3,7,8-TCDD set by the EPA for an assumed 70 year lifespan is 1 pg/Kg/d. Adults are assumed to be 55 Kg for Vietnamese residents and 70 Kg for North Americans.

The data in Table 31 were used to calculate 2,3,7,8-TCDD equivalents in Table 32. The daily intake of a nursing baby was derived on the assumption that an average of 800 mL of milk were consumed per day. The first year intake is then 365 times the daily intake corrected for an assumed body weight of 10 Kg. It is further assumed that there is no further ingestion or excretion of PCDDs/PCDFs during the 70 year lifespan of the individual. Under such a condition,

the body mass would serve to dilute the contaminant concentrations ingested during the first year. It is assumed that a North American adult grows to 70 Kg and an individual in Vietnam and Japan grows to about 55 Kg.

The ratio of the first year intake to the recommended intake values of EPA and CDC are shown in the last two columns of Table 33. For a cancer risk of 1-6, the 70 year lifetime recommended intake values for 2,3,7,8-TCDD are 160 and 16000 pg/Kg for the EPA and CDC, respectively. According to these criteria, a child in North America will have consumed between 189 and 858 times the lifetime limit recommended by the EPA. If there is no further ingestion or excretion of contamination then the adult will have received 27 to 124 times the EPA recommended limit. If one considers the CDC values instead than a North American child will have received between 1.8 and 8.2 times the CDC recommended dose or between 0.27 and 1.2 times the CD recommended dose over the person's lifetime.

There is clearly a substantial difference between the 2,3,7,8-TCDD equivalents found in south Vietnam in 1970 and those found in 1984. The groups tested were different and reflect the use of Agent Orange for military purposes. The derived data for the industrial nations of south Vietnam, Japan, and North America are very close and are contrasted with data for north Vietnam where there is infrequent use of synthetic industrial and agricultural chemicals.

The "Acceptable Daily Intake" or ADI method for the determination of health risk from chemicals presupposes that there is a threshold level below which there is no biological response. A safety factor is then applied to account for variations in individual susceptibility. Current ADI values for 2,3,7,8-TCDD are predicated on a threshold value of 1 pg/Kg/d derived by Kociba *et al.* in 1978. Danish authorities chose a safety factor of 200 to define a "Tolerable Daily Intake", or TDI, value of 5 PPq.

A second method of risk assessment is the cancer statistical method which calculates for a given risk level of usually 10^{-6}, the amount of chemical exposure which can occur over a 70 year lifespan. The model assumes a constant dose level in a population and an incremental unit risk.

The EPA has estimated that the incremental unit risk derived from the ingestion of 1 ppq of 2,3,7,8-TCDD in the body over a lifetime may lead to an additional 156 cancer incidents per million people exposed.[81] At this point in time it is not clear what the health risks of the effects of PCDDs and PCDFs are to humans.

PCB Degradation in Building Fires The formation of pyrolysis products will ultimately depend upon factors such as the following:

- the time that the askarel mixture is at a temperature which allows a reaction yield of significance,
- the volume and surface area of droplets of askarel emitted in an eventful failure,
- the availability of oxygen and
- the effect of soot particles on the dissipation of heat and the availability of oxygen.

Real-world experience has shown that the eventful failure of electrical equipment can be all too frequently catastrophic. In particular, it is irrefutable that transformer fires do produce askarel oxidation products in significant quantities. As discussed earlier, studies have indicated that the breakdown of askarel transformer dielectric systems due to multi-stress aging may produce toxic products at concentrations of concern. The yield and distribution of products can be expected to depend upon the availability of oxygen. The major quantity of toxic products will undoubtedly be derived after the failure of the transformer has resulted in a fire situation.

When a transformer is retrofilled to <500 ppm PCB, one would expect that the rate of conversion of PCBs would be very much less than in the case of an askarel fire. It becomes increasingly less probable that a large enough quantity of pyrolysis products would be produced as the concentration of PCBs and chlorobenzenes is reduced. These qualitative expectations were realized when a fire occurred in the basement transformer vault of the Electrical Engineering laboratory of the University of Manitoba in 1982. The six transformers involved in the fire contained mineral oil contaminated with 250 ppm PCB. An electrical failure caused one of the transformers to arc and catch fire. All six transformers were damaged. During fire-fighting attempts a transformer exploded and distributed PCB contaminated soot onto the walls. No PCDFs were found. PCDDs, which are typically formed at an order of magnitude less concentration than PCDFs, were not detected either.

The fire which occurred on February 5, 1981 in the Binghamton State Office Building in Binghamton, New York, involved a PCB filled transformer located in the basement. It has been estimated that between 50 and 100 gallons of PCB dielectric fluid were involved in the fire. The building was closed and sealed shortly after the fire and remains closed today in 1996. PCBs and oxidation products were distributed throughout the 18-story structure via two ventilation shafts. Analysis of soot samples revealed high concentrations of PCBs, PCDFs, PCDDs and also other classes of toxic chlorinated aromatic compounds (Table 34).

The concentration of compounds of concern in the soot particles varied between floors in the building. A composite sample was analysed and found to contain three orders of magnitude more of 2,3,7,8-TCDF (270 ppm) and 2,3,7,8-TCDD (2.8 ppm) than fireplace soot. The average PCB concentration in the air was 1.48 $\mu g/m^3$ while dust samples in the spaces above ceilings averaged 1,995 $\mu g/m^2$.

Exposed horizontal surfaces in offices had 162 $\mu g/m^2$ while vertical surfaces and walls had about 7 $\mu g/m^2$. PCB contamination was found inside closed filing cabinets and

desk drawers at levels of about 75 μg/m^2. The current cost of the cleaning operation is estimated at $46,000,000 and exceeds the cost of construction. The expense to dispose of the building and replace was estimated at about $100,000,000 in 1981. Approximately $1.2 billion in law suits have been entered against the State in this incident (Table 35).

The initial cleanup activity was to discard all the furniture and inexpensive articles covered by soot. Some of the larger items which were destroyed were as follows:

- 930 desks;
- 522 tables;
- 850 file cabinets;
- 110 map files;
- 200 typewriters;
- 15 postage machines;
- 15 computer terminals;
- 1,950 chairs;
- 325 bookcases;
- 310 storage cabinets;
- 292 benches, stools, couches,
- 5 microfiche readers.

A 26,000 gallon water treatment plant was installed in the basement to handle the PCB-contaminated rinse waters. In addition, a pollution control system was constructed to eliminate the flow of potentially contaminated air from the building to the outside environment.

The magnitude and scope of the remedial activities were as follows:

- inventory of all equipment and records;
- removal of furniture and office equipment;
- open all duct shafts for cleaning;
- shred and bale all paper materials;
- removal of all carpet;
- removal of all bathroom and corridor accessories;
- installation of temporary lighting on 16 floors;
- vacuum exhaust dust shafts in bathrooms;
- removal of exhaust dust shafts from bathrooms;
- removal of duct work in basement;
- removal of insulation from terminal boxes in basement;
- removal of records and shelving from storage in basement;
- washing and vacuuming all office areas;
- removal, cleaning and replacement of all lighting fixtures and terminal boxes;
- removal of vinyl and ceramic tile flooring;
- removal of kitchen equipment;
- washing and vacuuming of all floors, stairways and chases;
- washing of 2,160 floor lights, 130 lobby lights, over 9,600 restroom accessories, 3,800 ceiling accessories and 2,500 heating accessories;
- washing and vacuuming of the basement with removal of insulation and plaster ceiling;
- washing and vacuuming elevator shafts and pits;
- removal of fire-proofing from restrooms;
- sealing ventilation chases; and
- disposal of 2,646 cubic yards of carbon (Table 36).

A PCB transformer fire also occurred in the transformer vault at One Market Plaza, San Francisco on May 15, 1983. The vault contained three transformers which contained Aroclor 1242 as the dielectric fluid, undiluted by chloro-

benzenes. A faulty electrical cable caught fire and fell onto an energized askarel transformer. The transformer circuit breaker failed and allowed the unit to remain energized for at least three hours. Approximately 30 gallons of Aroclor 1242 leaked from the transformer during the fire.

Soot laden smoke issued from the sidewalk grating adjacent to the building for about three hours and contaminated the switch gear room and some areas of the adjacent parking garage. The fire activated a ventilating air system within the building which was designed to draw air from the ground level intake to the first and second basements and to various retail stores on the plaza level as well as to floors 2 through 6 of the Steuart Street Tower. Dry wipe samples showed contamination of about 720 μg TCDF/100 cm^2 and the building was closed.

The maximum concentrations of PCBs and PCDFs in air were calculated on the basis of measured component ratios. For example, the ratio of 2,3,7,8-TCDF to PCBs was found to be about 1 : 240,000 in air inside the vault but 1:160,000 in air on the 21st floor. Note that PCDDs were not formed because there were no chlorobenzenes used in the dielectric liquid. Analysis of the soot collected in the vault showed the presence of the same classes of compounds as found in the Binghamton incident. The conversion of PCBs to PCDFs seemed to have occurred with approximately the same efficiency as in Binghamton.

The cost of cleanup was close to $20,000,000 with one additional million dollars spent to replace the electrical equipment in the vault. The largest civil suit was that brought by the Fire Department for $100 million.

In September 1983, a fire occurred in a transformer vault under the plaza on the same block as the First National Bank building in Chicago. Smoke issued from a sidewalk grating for about 45 min. but, fortunately, significant PCB contamination was limited to the vault. It was estimated that 1–4 gallons of dielectric fluid were pyrolyzed but, interestingly, no PCDFs or PCDDs were detected in the soot. Cleanup costs were estimated to be $50,000–$100,000 and no civil damage suits were filed.

The known costs of the fire related incidents described in Table 34 has led the EPA to assess an average clean-up cost per incident of $20,000,000. PCDFs and PCDDs are recognized as ubiquitous environmental contaminants. The following Table 37 shows the background contamination levels in two office buildings in Boston, MA. Neither building had been involved in an electrical transformer failure. Two sets of data are shown, one for high skin contact areas and one for elevated horizontal surfaces. A high skin contact area is taken to mean one in which a person might have prolonged direct dermal contact such as desks, tables, counters and file cabinets. Elevated horizontal surfaces are those six feet or more above the floor such as the tops of storage cabinets or bookshelves. Background levels of

J.R. Kominsky and C.D. Kwoka.[87] Background levels of PCBs have been investigated by NIOSH. Their data are shown in Table 32 for comparison.

PCBs in non-manufacturing buildings have been investigated by NIOSH. Their data are shown in Table 38 for comparison.

Reported eventful failures of PCB contaminated electrical equipment have been well documented only in the United States, Canada, Finland and Sweden. Table 39 lists some of the major PCB fires in Scandinavia. The toxic Substances Control Act was the first regulatory authority which the EPA had concerning PCBs. Section 6(e) of TSCA requires proper disposal of PCBs, and prohibits the manufacture, processing, distribution in commerce, and use of PCBs. Under section 6(e)(2) of TSCA the EPA allows the use of PCBs in "a totally enclosed manner" such as transformers, capacitors and electromagnets based upon considerations of cost and risk reduction. However, when the August 1982 rule was promulgated it was based upon the assumption that the principal route of release of PCB-containing dielectric fluid into the environment was from leaks and spills. Since that time, it has been found that fires involving transformers occur frequently enough to present a significant risk and this has led the EPA to reconsider the August 1982 rule and place the following additional restrictions and conditions on the use of PCB transformers (40 CFR Part 761:50 FR 29170) July, 1985:

1) High secondary voltage PCB transformers (480 V and above, including 480/277 V) configured in a network fashion and used in or near commercial buildings must be removed from use, placed into storage or disposal, disposed, or reclassified to PCB contaminated or non-PCB status by Oct. 1, 1990.
2) PCB transformers can no longer be installed in commercial buildings after Oct. 1, 1985.
3) PCB transformers used in or near commercial buildings (other than high secondary voltage network PCB transformers) must be equipped with enhanced electrical protection, by Oct. 1, 1990, to avoid failures and fires from sustained electrical faults.
4) All transformers must be registered with appropriate emergency response personnel and with building owners by Dec. 1, 1985.
5) All PCB transformer locations must be cleared of stored combustible materials by Dec. 1, 1985.
6) All PCB transformer fire-related incidents must be immediately reported to the National Response Center, and measures must be taken as soon as practically and safely possible to contain potential release of PCBs and incomplete combustion products to waterways.

EPA defines commercial buildings to include all types of buildings other than industrial facilities and would include locations such as office buildings, shopping centers, hospitals, and colleges. A PCB transformer located in or near a commercial building is located on the roof of, attached to the exterior wall of, in the parking area of, or within 30 meters of a commercial building.

The EPA has had to consider both the benefits of PCBs as well as the availability of substitute materials balanced against the costs of regulatory control measures. It was concluded that the removal or retrofill of PCB transformers is both the most effective and the most costly measure to reduce the frequency of serious transformer fires. It was suggested that a less costly, but also less effective, alternative could be represented by providing better electrical protection of the equipment. The effectiveness of increased electrical protection is expected to approach that of phaseout/retrofill but EPA recognizes that electrical protective devices are also subject to malfunction and that PCB transformer fires can result from less common mechanisms of failure. At this point it would be useful to clarify what is meant by the retrofill and reclassification of PCB transformers. The retrofill of a PCB filled transformer involves the replacement of the original PCB dielectric fluid with a substitute oil. The main advantage of retrofilling is that an owner's liability is minimized at minimum cost. In addition, record keeping and reporting requirements are reduced or eliminated and servicing is allowed.

There are three categories of PCB transformers:

- A PCB transformer is defined as one which contains more than 500 ppm PCB.
- A PCB contaminated transformer is one which contains PCBs in the concentration range 50–500 ppm PCB.
- A non-PCB transformer contains less than 50 ppm PCB.

If the flushed carcass is buried in an approved chemical waste landfill there is the possibility of long term liability associated with PCB leaching. Alternatively, carcasses can be cleaned to less than 10 μg PCB/100 cm^2 and the clean metal returned to the secondary metals market.

PCB transformers may not receive servicing which requires the removal of the core/coil assembly. Inspections must be made for leaks and records kept. When the unit is to be replaced, the fluid must be burned in an approved incinerator and the transformer carcass either incinerated or flushed. PCB contaminated transformers (50–500 ppm PCB) do not need to be inspected for leaks and may be repaired or serviced as necessary. EPA reaffirmed its August 1982 determination that the continued use of PCB contaminated transformers does not present unreasonable risks to public health and the environment.

Non-PCB transformers, containing less than 50 ppm PCB, may be used with almost no restrictions since the unit is then not under TSCA purview. The may 1979 PCB ban rule prohibits rebuilding of PCB transformers but does allow for their reclassification. Under the provisions for reclassification the equipment must be put back into service for three months before the bulk oil is tested for its PCB concentration. The final rule clarifies the definition of in-service use for transformers by specifying a minimum dielectric fluid temperature of 50°C to correspond to a condition of light electrical loading. If a unit is retained as a PCB transformer an immediate cash outlay is avoided but this might not be the lowest-cost option in the long term.

For example, if the unit should require servicing at some time in the future it will have, instead, to be scrapped. If tests showed that the transformer was about to fail it would not be possible to retrofill it and service the unit as a PCB contaminated or PCB free unit until it had been set back in operation for 90 days after the retrofill. This may be neither possible nor feasible, depending upon the condition of the transformer. If an owner makes the decision not to continue to operate a unit as a PCB transformer he has then to choose between replacement with a new unit (retrofit) or retrofill of the old one. The age and performance history of the transformer become factors as well as how long the unit is likely to be needed.

TRANSFORMER RETROFILL OPERATIONS

The retrofill operation, as it is conventionally practiced today, consists of multiple stages, each of which involves draining, flushing and filling. The process can apply to two different situations, viz. (1) contaminated mineral oil transformers with >500 ppm PCB and (2) askarel filled transformers in which the coils are impregnated with PCB.

(1) In the case of a PCB contaminated mineral oil transformer it would be possible to reduce the PCB concentration of the working fluid by first draining the transformer and refilling it with non-contaminated oil. Since the PCBs are contained predominantly in the oil, and are not impregnated into the porous insulation, it is possible to retrofill the transformer to a required concentration level by repeated washings, as necessary. The effectiveness of the washings becomes increasingly important as the concentration of the original contamination increases since repeated dilution of residual contamination produces several times the original volume of the transformer tank for disposal. In addition, the presence of trapped, high concentration oil in the core/coil assembly, which is not easily removed by conventional flushing procedures, causes the bulk oil to become re-contaminated.

(2) In the case of an askarel transformer which is impregnated with PCBs, a simple flushing or vapor cleaning process leaves about 2.5% of the original askarel contained in the core/coil assembly. For a typical 250 gal. askarel transformer the impregnated fluid amounts to about 6 gal. A PCB concentration of 500 ppm PCB in a 250 gal. transformer is equivalent to little more than about one coffee mug in volume.

The equilibrium distribution of PCBs between transformer solid materials and the liquid dielectric in a 500 KVA transformer has been found to be about 97.5% in the bulk oil and 2.5% distributed unevenly among the paper, core steel and wire. The vast majority of the PCBs in the solid materials of an impregnated transformer is contained in the paper.

The diffusion of PCBs under the action of a strong concentration gradient from the interior of the paper towards the very low concentration in the bulk retrofill fluid is a slow process governed by Fick's laws. If the retrofilled transformer is not put into operation and remains at ambient temperature, then the viscosity of the askarel may be high enough to prevent diffusion at a significant rate. However, the EPA requires that the reclassification procedure should put the transformer under a normal load or, alternatively, that the bulk oil is heated to more than 50°C for a period of 90 days following the completion of the retrofill operation(s). The power losses of the transformer under load conditions produce heat which, in turn, reduces the viscosity of the impregnated askarel and increases its diffusivity. If the concentration level of PCBs can be reduced to such an extent that subsequent leaching does not yield a concentration which is above the 500 ppm PCB limit imposed by the EPA 90 days after the process has been completed then, according to the letter of the law, the unit can be reclassified as "PCB contaminated". However, experimental data on units which have been retrofilled with a simple vapor cleaning process have shown that the PCB leaching rate under normal load conditions is in the range of 1.5–2.5 ppm PCB per day. If the trapped PCBs are able to leach out into the bulk retrofill fluid at a rate of as little as 1 ppm PCB per day, it would need approximately one year before the fluid concentration had climbed above 500 ppm PCB and the unit would have to be regarded once again as a PCB transformer.

The following cost elements enter the business alternatives of replace vs. retrofill:

Replacement

- Basic cost of transformer and dielectric coolant.
- Miscellaneous fittings: stress cones, etc.
- Possible rental of mobile substation during changeover.
- Crane rental.
- Labor (probably at overtime rates).
- PCB packaging, transport and disposal.
- Purchase cost of flushing solvent to prepare transformer carcass for landfill disposal.
- Packaging, transport and disposal of flushing solvent.
- Transport to and disposal in EPA-approved landfill for transformer carcass.

Retrofill

- An initial, fundamental decision must be made concerning whether to change the classification of the transformer to "PCB contaminated" i.e., <500 ppm PCB, or to <50 ppm PCB to remove the unit from TSCA purview.
- Dielectric fluid costs.
- Solvent flushing fluid, depending upon the retrofill method.
- Transport of oil, solvent and materials to and from the site.
- Gaskets, parts, hosing, fittings etc.
- PCB disposal, solvent disposal.
- Downtime 4 h to 48 h, depending upon the level of decontamination required and the process used.
- Repeated electrical outages, depending upon the retrofill process chosen.
- PCB-in-oil analyses, dielectric fluid properties report.

The following cost comparison compares the options of retrofill or replacement of askarel filled transformers. The comparison is complicated by the many variables which are involved and therefore a range of costs has been considered as they apply to two different sizes of PCB filled transformers.

EPA has completed an analysis of the costs of retrofilling PCB transformers to reduce the PCB concentration to below 500 ppm PCB and has estimated that the cost will vary in the range from $15,500 for a 50 KVA transformer to $32,000 for a 3,000 KVA transformer. The example above is for an "average" or "typical" size transformer or about 225 gal. oil capacity and shows that the cost savings over replacement will be about $20,000 per unit. Clearly, the larger and more inaccessible a transformer the more cost effective retrofilling becomes (Table 40).

Despite the extensive work which has been done over the last few years on the validation of different fire hazard assessment methods for askarel replacement fluids there is still no consensus of opinion. Experience derived from the

use of less flammable fluids, however, points to the fact that both hydrocarbon and silicone oils do perform satisfactorily and are suitable as askarel replacement fluids.

The decision to retrofill rather than replace a contaminated transformer depends, as discussed above, upon a number of different factors. For example, the cost of new oil and the cost of labor have to be weighed against the benefits of reduced maintenance, service and disposal costs, the impact of public perception, and reductions in the possible costs of leaks, spills or fires. Once a decision has been made to retrofill, the usefulness of the action is governed by the effectiveness of the process to mitigate the problem of PCB leaching from the impregnated coil.

A cleaning process for the decontamination of PCB contaminated mineral oil in electrical equipment has been described in the form of guidelines by the Ontario Ministry of the Environment (1978). The stages involved are as follows:

- The transformer is emptied of bulk PCB by opening the drain valve. The unit is allowed to drain into an appropriate container for at least 24 h.
- The drain valve is then closed or the unit sealed and filled with solvent and left filled for at least 24 h.
- The solvent should then be drained and the transformer rinsed two more times by filling and draining with clean solvent.
- The second and third rinses may be retained for use as the first rinse in decontaminating other equipment.

The PCB solute in the mineral oil is distributed throughout the liquid and solid phases of the transformer. The PCB concentration remaining in the oil at equilibrium can be calculated from the partition coefficients for PCB between the transformer solid materials and the oil and the residual amounts of flushing liquid remaining in the tank between each stage.

Considerable work has been done on the solvent decontamination of electrical equipment and results have been reported by S.H. Hawthorne[91]. It was found that draining alone removed 91–96% of the PCB while a combination of draining and cleaning with trichloroethylene reduced the PCB concentration by 99.76%. Soaking the drained transformer with hot solvent followed by vapor phase degreasing enabled 99.10% of the PCB to be removed. When an extended soak of 36 days was given to the transformer after the cleaning procedure had been completed the amount of PCB removed increased from the above figures to 99.04%, 99.96%, and 99.72% respectively, that is, the remaining PCB concentrations were 600 ppm, 400 ppm and 2,800 ppm.

Hawthorne's data allow some important conclusions:

- A simple transformer flushing procedure is effective in reducing the initial PCB concentration of an askarel filled transformer to less than 500 ppm.
- The PCB remaining after each cleaning process resided almost exclusively in the interstices between the steel core plates and in the paper and insulation of the copper coils, with little or no PCB remaining on the internal surfaces of the case and radiators.
- After the cleaning procedure had been completed the transformers were soaked for 36 days with the solvent from the third soak to remove the most rapidly leached PCBs. During this time it was found that the PCB concentration levelled out to a pseudo-plateau at 3500 ppm PCB in trichloroethylene after 10 days. In other words, 1000 ppm PCB had been leached out of the core/coil assembly in 10 days (100 ppm PCB/day). Also, the PCB concentration did not increase more than about 140 ppm PCB in the 26 days following the start of the plateau. This means that the leaching rate during this period is about 5 ppm PCB/day.
- The use of hot solvent was found to be more effective than cold solvent. Thus, when the retrofill had been completed and the transformer is put back under load, the heated oil can be expected to leach PCBs at a greater rate than if the transformer were not in operation. According to Hawthorne's results the initial leaching rate should be at least 5 ppm PCB/day.
- The lowest PCB concentration attained before the transformer was put back into service was 400 ppm PCB. If the leaching rate remained steady at 5 ppm PCB/day for the 90 days required by EPA, then the concentration would climb above 500 ppm PCB and the unit would remain a PCB transformer, by definition. This assumes that the leaching rate is 5 ppm PCB/day. It is also assumed that the leaching rate remains constant at its initial, and therefore probably highest, rate. Even so, the results illustrate that a simple solvent flushing technique is able to reduce the PCB concentration into the range where the transformer, in the absence of leaching from the core/coil, could be reclassified as a PCB contaminated unit.

An alternative method of cleaning involves vapor degreasing the unit by spraying the cold internal surfaces with a solvent vapor such as trichloroethylene generated by boiling the solvent in an external vessel. The principle of operation is not unlike the soxhlet extraction of materials.

The process offers numerous advantages:

- the volume of contaminated solvent is kept to a minimum;
- the solubility of PCBs in the hot solvent is greater than in cold liquid and therefore the extraction process is less time consuming;
- the low viscosity solvent is able to penetrate the capillaries of the paper and core laminations and remove the PCBs from all the surfaces within the transformer.

The action of the vapor phase degreasing process is to initially dissolve the PCB on surfaces. Beyond this, capillary penetration takes place and the PCB in the outer layer of paper is replaced with solvent. When the transformer is filled with oil and put back into operation, the non-viscous solvent held in the paper quickly diffuses into the much larger quantity of more viscous dielectric fluid. During this time, the PCB concentration of the absorbed solvent is high because the concentration gradient which it sees is between an initial value of zero and about 700,000 ppm PCB in the interior of the paper. The initial leaching of absorbed solvent into the oil therefore gives a rapid rise in bulk oil PCB concentration. When the outer layer of trapped solvent has been replaced by slightly contaminated bulk oil there is again an almost constant concentration gradient but now the PCBs must diffuse through a medium which is about 450 times more viscous than the originally trapped solvent. Diffusion rate is inversely proportional to viscosity. Overall, the observed leaching rate of PCB will depend upon the relative viscosities of the solvent and oil (and hence temperature) and the depth of penetration of the solvent i.e., the distance the PCB must diffuse.

The depth of penetration attainable by vapor degreasing alone is unknown. The results which have so far been obtained indicate that the leaching rate in the first 90 days is sufficient to increase the PCB concentration to more than the allowed 50 ppm PCB limit and, depending upon the efficiency of the operation, can be greater than 500 ppm PCB after 90 days. Thus the depth of penetration of the degreasing solvent, using existing techniques, can only be very small and the main action of the process is to remove bulk PCB from tank walls and core/coil surfaces.

In the Webber process, which is unique, the leaching effect of residual impregnated PCBs is mitigated by a physicochemical process. The method has been proven in a pilot plant to allow the permanent reclassification of transformers in a single operation. The recontamination of the replacement fluid can be either totally eliminated or reduced to such an extent that the transformer stays reclassified for the remainder of its useful life. Further tests are planned to extend and further validate the data so that warranties can be made concerning the future reclassified usage of the retrofilled equipment.

Figure 41 shows a curve relating the increase in residual PCB concentration with time of transformer operation after application of a vapor phase cleaning apparatus to a 750 kVA network transformer which originally contained about 270 gal. of askarel. The curve consists of two main regions, an initially steep slope leading to a pseudo-plateau region which extends for more than 250 days. The initial slope of the curve is about 6 ppm PCB/day for the first 90 days after the transformer was put back in operation and about 1.3 ppm PCB/day thereafter.

In an isotropic medium, Fick's first law of diffusion states that the amount of a substance diffusing through a medium is proportional to the concentration gradient acting as the driving force and a constant for the medium which is the diffusivity, that is,

$$X = -D\frac{\partial C}{\partial x} \qquad (12)$$

where

X = mass of diffusing substance,
D = diffusivity,
C = concentration of diffusing substance,
x = distance.

Fick's second law of diffusion describes the flux of diffusing substance:

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x}\left[D\cdot\frac{\partial C}{\partial x}\right]$$

where

$\frac{\partial C}{\partial x}$ = concentration change measured in the x-direction

For the sake of approximation and mathematical simplicity, assume that D, the diffusion coefficient, is constant.

Then,

$$\frac{\partial C}{\partial t} = D\cdot\frac{\partial^2 C}{\partial x^2} \qquad (13)$$

The diffusion of PCBs through insulating paper into the bulk oil of the transformer can be modeled as follows.

Assume that the x–y dimensions of an impregnated paper are large compared with its thickness so that edge effects can be ignored. Assume that the paper is homogeneous and of thickness $2d$, and also that the bulk oil is maintained homogeneous.

The space occupied by the paper is $-d \leqslant x \leqslant +d$
The space occupied by the oil is $-d - a \leqslant x \leqslant -d$
and, $d \leqslant x \leqslant +a$

where 'a' is the depth of the bulk oil in the x-direction.

The boundary conditions are:

$t = 0$, $C = 0$ at $-d < x < -d$
and, $C = 0$ otherwise.

At equilibrium, the rate at which PCBs leave the paper is equal to the rate at which PCBs enter the paper, that is,

$$a\cdot\frac{\partial C}{\partial t} = \pm D\cdot\frac{\partial^2 C}{\partial x^2} \qquad x = \pm d,\ \mathrm{t} > 0 \qquad (14)$$

The solution to a problem of this sort is given by J. Crank (1956) in terms of an infinite series as follows:

$$\frac{X_t}{X_\infty} = (1+\alpha)\cdot\left[1 - \frac{\alpha}{(\Pi^{1/2}\cdot\beta^{1/2})} + \frac{\alpha^3}{(2\cdot\Pi^{1/2}\cdot\beta^{1/2})} - \frac{\alpha^5}{(4\cdot\Pi^{1/2}\cdot\beta^{1/2})} + \ldots\right] \qquad (15)$$

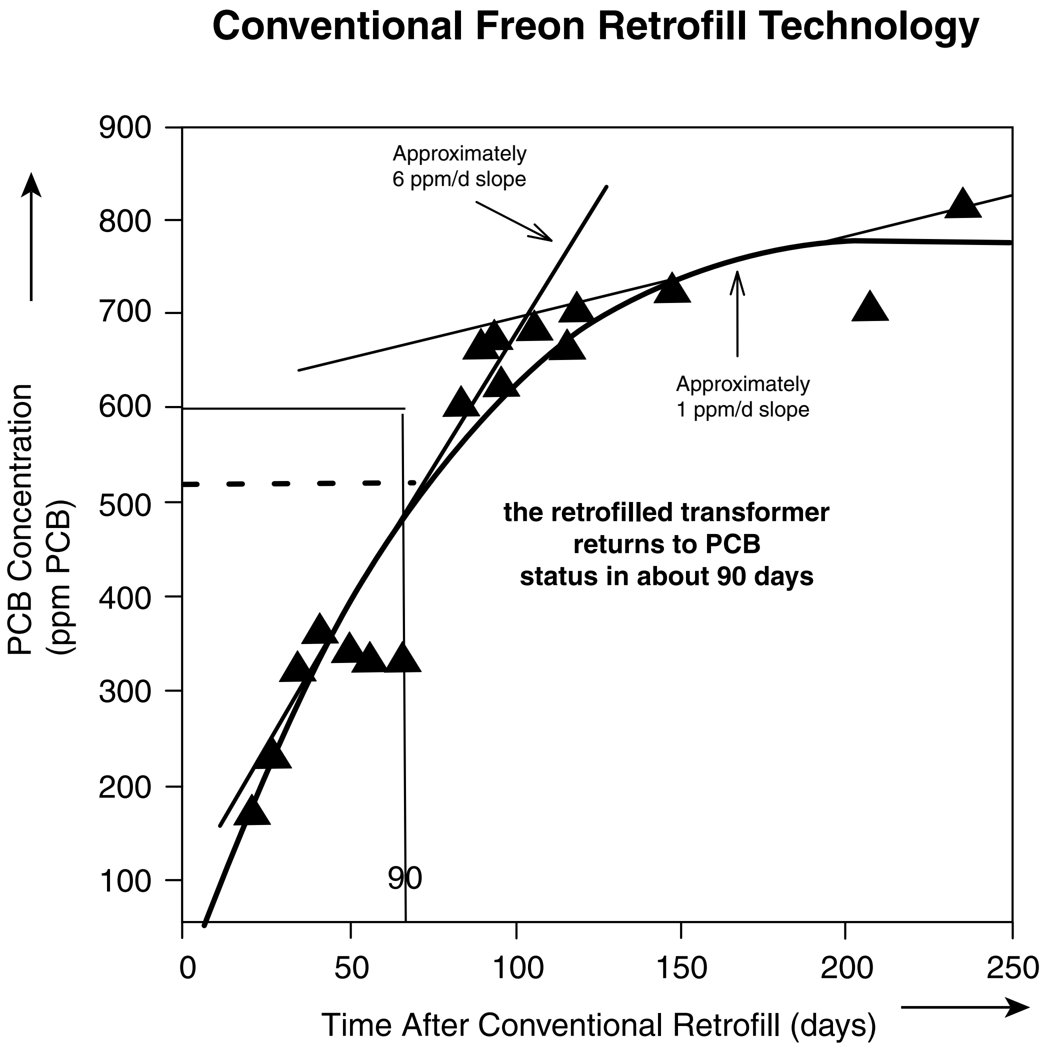

FIGURE 41 Conventional retrofill processes allow continued PCB leaching from the core/coil assembly.

where

X_t = mass desorbed at time, t

X_∞ = mass desorbed at infinite time.

$$\alpha = \frac{1 - \frac{X_\infty}{X_s}}{\frac{X_\infty}{X_s}}$$

where (X_s) is the total solute in the system.

(X_s) and (X_∞) are experimental quantities and therefore (α) can be obtained directly.

A function of time and diffusivity can be defined as:

$$\beta = D \cdot \frac{t}{d^2}. \tag{16}$$

Knowing (α), a series of curves can be drawn relating (X_t/X_∞) with ($\beta^{1/2}$).

The experimental value of (α) is matched to the corresponding theoretical curve of (X_t/X_∞) vs. $\beta^{1/2}$ and since $\beta = D \cdot t/d^2$ a value can be obtained for the diffusion constant, D.

Measurements of the PCB content of impregnated dielectric papers show that a typical paper will contain 58 ± 3% by weight of an askarel such as Inerteen 70/30. Then, to calculate the total quantity of askarel absorbed in the paper one needs to approximate the amount of paper in a typical design.

For a 500 KVA transformer, the approximate quantities of the different types of materials are as follows:

Paper	~	27 lb
Core steel	~	947 in^2
Oil	~	85 gal.

Thus, the amount of askarel impregnating the paper

$= 12.3 \times 10^2 \times 0.58$ g
$= 7{,}100$ g askarel $= 5{,}000$ g PCB.

If it is assumed that the pseudo-plateau shown in the figure above does allow a reasonable approximation of the total PCB leached into the bulk oil within the service lifetime of the transformer then,

$$X_\infty \approx \{X_s - [785 \text{ (ppm PCB)} \times 10^{-6} \times (0.878 \times 8.34) \text{ (lb/gal)} \times 270 \text{ (gal.)} \times 454 \text{ (g/lb)}]\}.$$

If the paper quantity is assumed, for the purpose of calculation, to be proportional to fluid volume from one design to another then,

$$\begin{aligned} X_s &= 12.3 \times 10^3 \times 0.58 \times 270/84 \\ &= 22{,}931 \text{ g} \end{aligned}$$

therefore,

$$\begin{aligned} X_\infty &= 22{,}931 - 705 \\ &= 22{,}226 \text{ g} \end{aligned}$$

that is,

$$X_\infty / X_s = 0.969.$$

The calculation puts an upper bound on the extent of the leaching problem since the model used in the calculation assumes that sufficient time has been allowed to achieve equilibrium. In the experimental arrangement used, the time to reach equilibrium was not a limiting factor since this was long compared with the time required for the diffusion of PCBs into and out of single, as opposed to bundled, sheets of paper. A transformer, however, presents a more complicated situation: the time to achieve true equilibrium may be beyond the service live-expectancy of the transformer since the migration of PCBs through different thicknesses of layered paper is the rate determining factor which governs the total fractional uptake.

The data shown in the above figure for a retrofilled askarel transformer suggest that PCBs will leach at the rate of about 1.3 ppm PCB/day for a period of perhaps years. It is therefore not possible to determine with any accuracy what mass of PCBs migrate into the oil when a final equilibrium is reached. If one assumes that, in the *best* case, a saturation level has been reached after 240 days, then an approximate 'best case' correlation curve can be calculated between $\beta^{1/2}$ and X_t/X_∞ as follows.

From above, $X_\infty/X_s = 0.969$

$$\begin{aligned} \alpha &= \frac{1 - \dfrac{X_\infty}{X_s}}{\dfrac{X_\infty}{X_s}} \\ &= 3.2 \times 10^{-2} \end{aligned}$$

$$\beta = D \cdot \frac{t}{d^2}.$$

Assume that $D = 7.6 \times 10^{-10}$ (cm²/sec)
$d = 1$ (cm)
then, $\beta = 7.6 \times 10^{-10} \cdot t$ (sec).

If the transformer is to be reclassified as 'PCB contaminated' then it must not be greater than 500 ppm PCB after 90 days of operation after the retrofill,

that is, $$\frac{X_t}{X_\infty} = \frac{500}{785} = 0.637.$$

By interpolation,

$\beta^{1/2} = 0.036$ when $X_t/X_\infty = 0.638$
that is, $0.0362 = 7.6 \times 10^{-10} \cdot t$
hence, $t = 19.7$ days.

In other words, an initial clean layer of 1 cm of paper will allow the bulk oil to reach 500 ppm PCB in about 20 days.

The correlation shown in Figure 42 has been calculated between the depth of the cleaned layer and the time required for the PCB concentration of the bulk oil to reach 500 ppm PCB using different values for the diffusion coefficient.

The experimentally determined diffusion coefficient for the migration of Inerteen 70/30 through kraft paper is about 7.6×10^{-10} cm²/sec. Under these conditions, if the cleaned layer is about 4.3 cm deep, the transformer will become a PCB transformer one year after the retrofill has been completed.

If the transformer is to be reclassified as 'non-PCB,' then it must not be greater than 50 ppm PCB 90 days after the retrofill procedure has been completed,

i.e., $$\frac{X_t}{X_\infty} = \frac{50}{785} = 0.064$$

hence, $t \simeq 7$ days.

The correlation between the depth of the cleaned layer and the time of reach 50 ppm PCB is shown in Figure 43 for different values of the diffusion coefficient. Clearly, the time to reach a bulk oil concentration of 50 ppm PCB is much shorter for a given depth of cleaned layer and is critically dependent upon the diffusion coefficient.

Figure 44 shows how the depth of the cleaned layer must vary for different values of the diffusion coefficient in order to obtain a defined reclassification status. If the diffusion coefficient becomes larger than about 10^{-8} or 10^{-9} cm²/sec then the correlation shows that the depth of the cleaned layer must become much greater than it is practicable to achieve.

It is interesting to note that if the cleaned layer is 4.3 cm and the diffusion coefficient is the experimentally measured value of 7.6×10^{-10} cm²/sec, then there is little doubt that the transformer would be reclassified after 90 days. However, after one year of operation it would become a PCB transformer

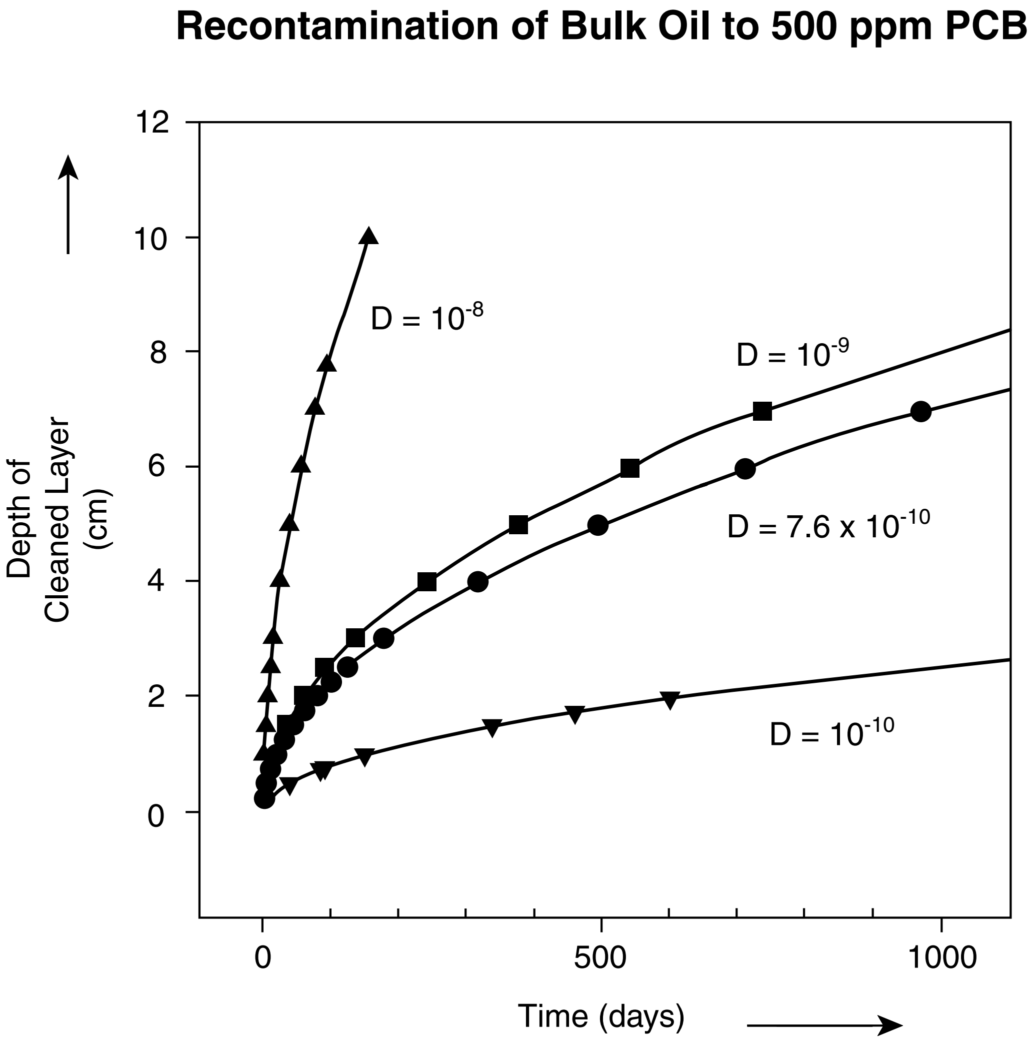

FIGURE 42 The time for the bulk retrofill oil to reach 500 ppm PCB depends on the extent of cleaning and the type of paper used.

again (by EPA definition) *even if it had been initially reclassified as 'non-PCB'*.

From the experimental curve of Figure 41, at $t = 90$ days,

$$\frac{X_{90}}{X_{\infty}} = \frac{560}{785} = 0.713$$

hence, $\beta^{1/2} = 0.0617$

$D = 7.6 \times 10^{-10}\ \text{cm}^2/\text{sec}$(by experiment)

hence, $d = 1.25$ cm.

If the transformer is left in operation long enough to allow the viscosity of the residual impregnating fluid to increase due to the preferential migration of chlorobenzenes then, eventually, the diffusion coefficient will shift from

$$\begin{gathered} D = 7.6 \times 10^{-10}\ \text{cm}^2/\text{sec} \\ \rightarrow D_{\infty} \\ \sim 10^{-10}\ \text{cm}^2/\text{sec.} \end{gathered}$$

The transformer will need to be drained and the oil decontaminated to less than 2 ppm PCB (EPA requirement) when these new conditions are met. An alternative would be to dispose of the contaminated oil as PCB fluid and use new oil to refill the transformer. There is considerable doubt that the diffusion coefficient will become low enough to merit this technique. A further drawback in the method lies in the fact that, during the long waiting period which would

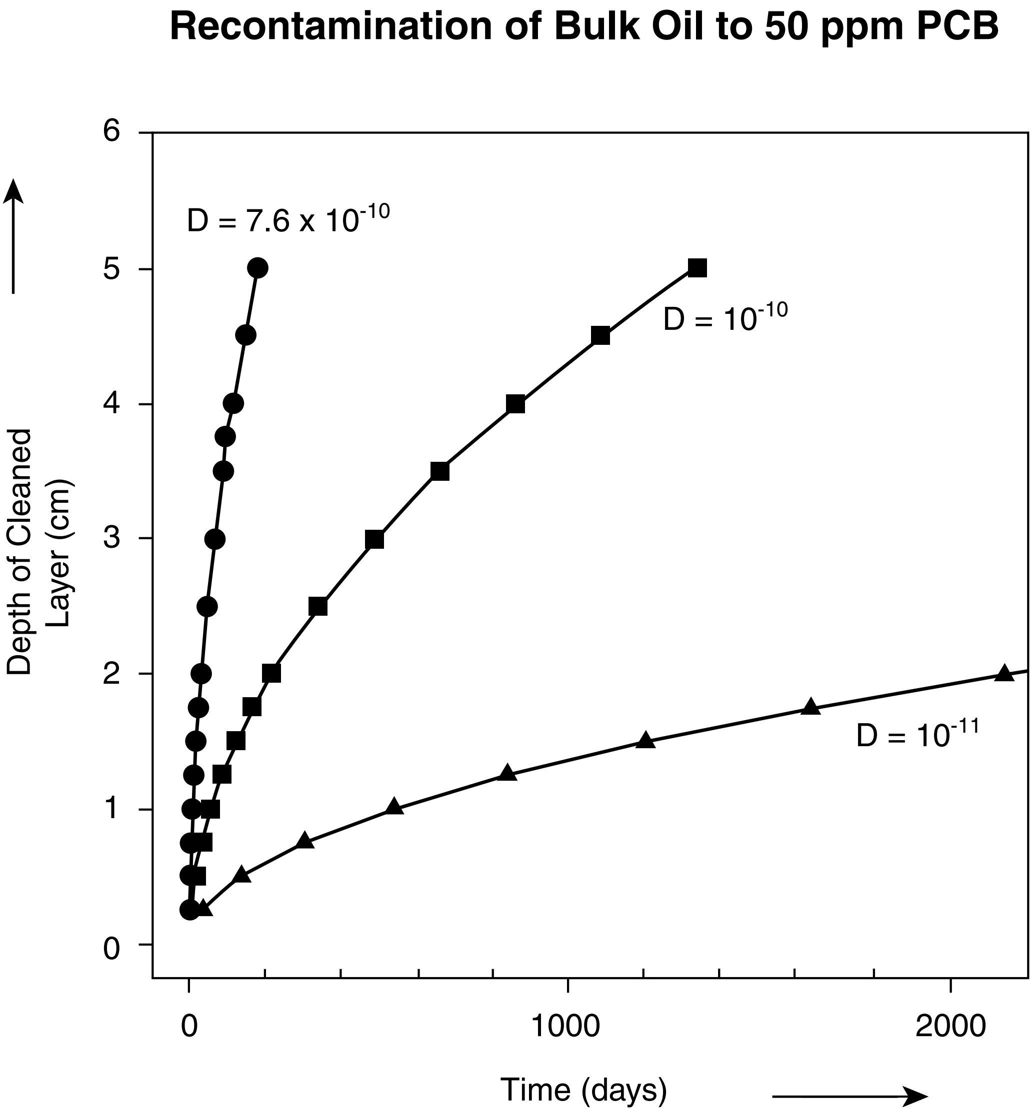

FIGURE 43 Correlations between the depth of the cleaned layer and the time to reach 50 ppm PCB in the bulk retrofill fluid.

be necessary to observe a reduction in the rate of diffusion, the transformer would have to be considered PCB filled as though no retrofill operation had taken place.

The continued leaching of PCBs with a lowered diffusion coefficient of ~10^{-10} cm^2/sec will cause the PCB concentration of the bulk oil to increase above 500 ppm PCB in a period of time which can be calculated as follows:

$$\frac{X_t}{X_\infty} = \frac{500}{785} = 0.637$$

hence, $\beta^{1/2} = 0.036$ as found earlier
hence, $t = 234$ days.

Thus, even if the transformer is reclassified at the end of the EPA mandated 90 day period by a process which involves simple vapor cleaning, leaching and re-retrofill, the technique cannot provide continued, reclassified use of the transformer for its remaining useful life. Indeed, it is not likely to be able to maintain the unit's reclassified status as a PCB contaminated transformer for as long as one year.

If it is hoped that the transformer can be reclassified as a non-PCB unit then,

$$\frac{X_t}{X_\infty} = \frac{50}{785} = 0.0637$$

then, $\beta^{1/2} = 0.0215$
and, $t = 84$ days.

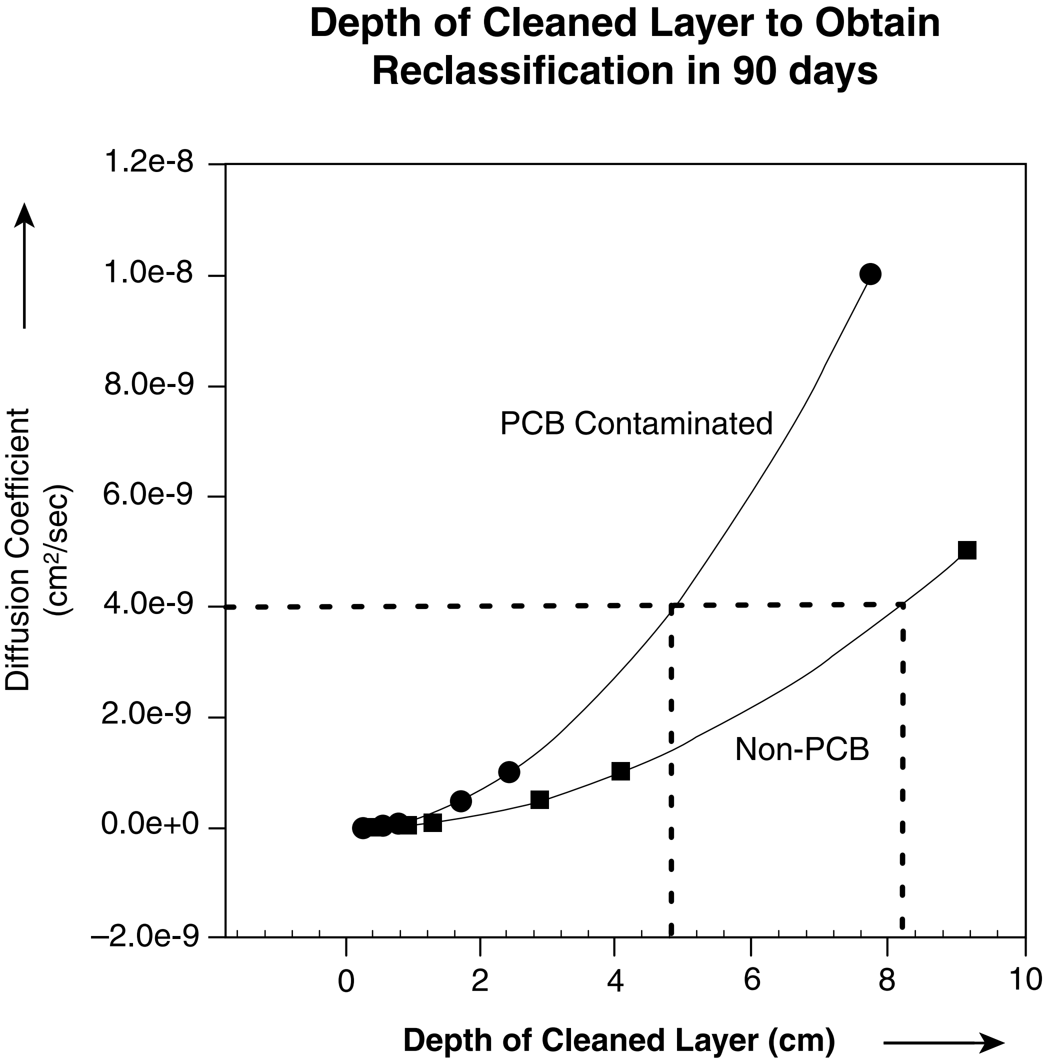

FIGURE 44 For diffusion coefficients $>10^{-8}$ cm²/sec the depth of the cleaned layer to prevent bulk oil contamination becomes impossibly large.

In other words, even if the transformer can be reclassified as non-PCB at the end of 90 days operation, it is likely that it will have to be considered as PCB contaminated very soon afterwards and that it will become a PCB transformer again in less than one year.

The relative importance of the adsorption of PCBs to their absorption can be assessed as follows.

The Freundlich adsorption isotherm is represented by the equation,

$$\frac{X}{M} = k \cdot C^n \tag{17}$$

where X and M are the masses of adsorbate and adsorbent, respectively and 'k' and 'n' are Freundlich coefficients. C is the equilibrium value of the PCB in the bulk oil.

Experiments were conducted at 50°C since this is the temperature required by the EPA when a retrofilled transformer is to be reclassified and also at 110°C representative of the top oil temperature. The following table shows results obtained for two different types of dielectric papers (Table 41).

TABLE 41
Freundlich Adsorption Coefficients

Paper	Temperature (°C)	Freundlich coefficients k	n
Dicy	50	0.49	1.05
	110	2.75	0.77
Diamond	50	1.32	0.78
	110	0.04	1.22

$X/M = 1.32.C^{0.784}$ for diamond paper at 50°C

X = 200 g.

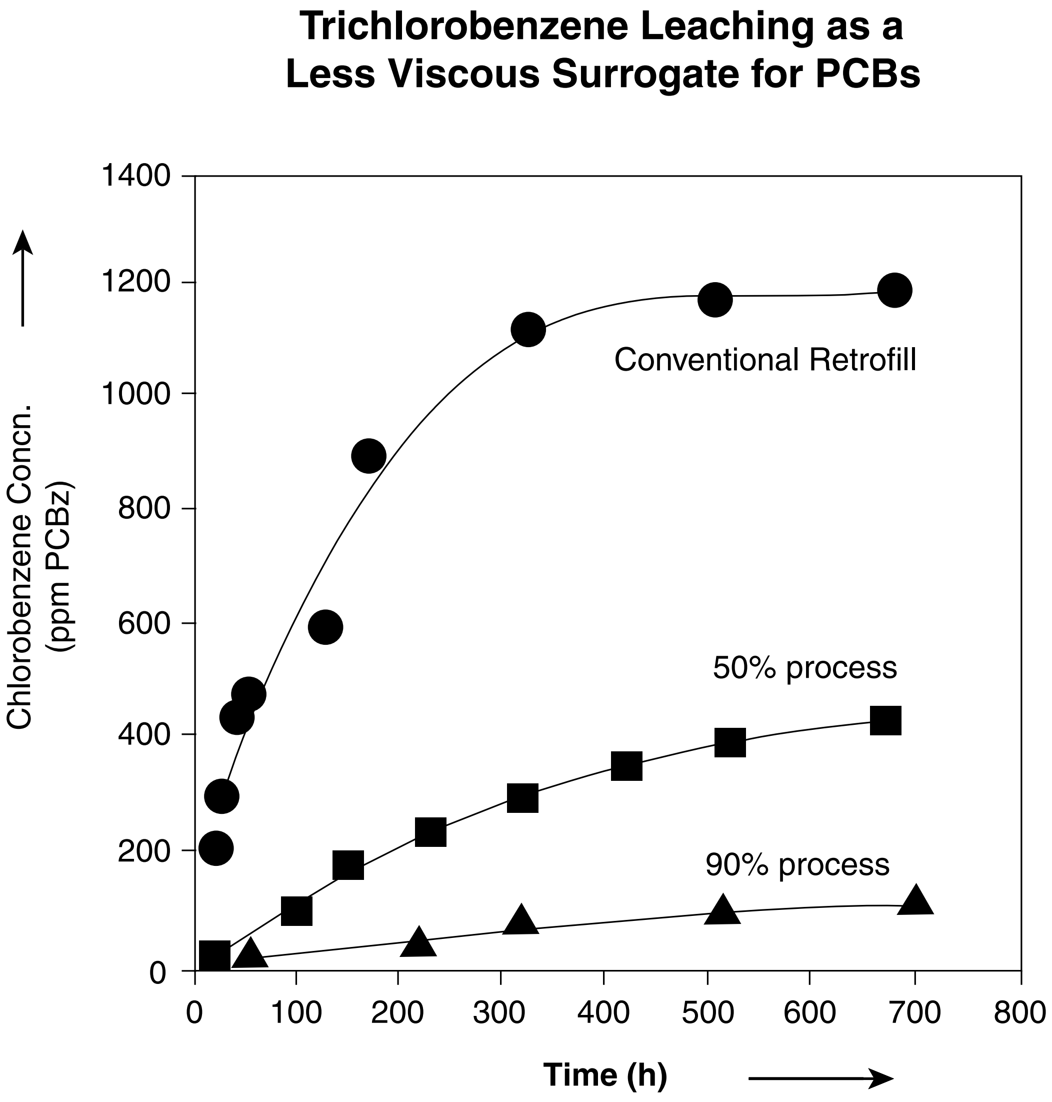

FIGURE 45 The completed process allowed the permanent reclassification of the bulk retrofill fluid.

Thus, the quantity of PCBs adsorbed on the paper is extremely small relative to the total quantity of PCBs adsorbed by the paper.

Figure 45 illustrates the effect which processing can have on mitigating the leaching problem. The data were obtained using chlorobenzenes as a non-viscous surrogate for PCBs in order to more easily quantitate any observed leaching. The completed process allowed permanent reclassification of the bulk retrofill fluid.

The model used virgin transformer materials impregnated with chlorobenzenes. The bulk oil was homogenized before samples were taken and the temperature of the tank adjusted to 50°C. Samples of impregnated kraft paper were wound into a coil and immersed in the oil. Several different kinetic runs were made with different thicknesses of paper as well as different numbers of layers forming the overall wad of paper.

The experimental conditions shown in Figure 45 were found convenient because a series of complete leaching curves could be compared over a period of about 30 days rather than the 300 days found for a 750 KVA transformer. It is clear that sufficient time had elapsed to be able to compare a conventional vapor cleaning retrofill system result with the processing necessary to avoid the leaching problem.

It was found that processing beyond simple vapor cleaning could be continued to the point where leaching was completely stopped. In actual practice, however, such a rigorous level need not be achieved since, if the leaching rate is reduced by, say, an order of magnitude from the measured value of 1.3 ppm PCB/day then, instead of about one year of reclassified use, the unit would retain its classification for ten years. In this example, if the transformer's life-expectancy was only for a further five years then clearly it would remain reclassified for the remainder of its useful life. The extent of processing can be tailored to the level of reclassification required and the life-expectancy of the transformer.

A method which is often used for the PCB decontamination of mineral oil transformers is to drain the fluid into drums for disposal, flush and drain the transformer with a flushing oil, and then refill the unit with uncontaminated mineral oil. The volume of flushing oil needed to reduce the PCB concentration of the retrofilled transformer to less than 50 ppm PCB depends upon the initial concentration of the oil and the amount of residual oil left after each flushing operation.

The PCB concentration after a drain and flush sequence can be predicted according to the following equation:

$$C_1 = C_0 \cdot \left[\frac{R}{100} + \frac{P_s}{P_1} \right] \cdot \left[1 - \frac{P_s}{100} \right] \qquad (18)$$

where

C_1 = PCB concentration in oil after draining and refilling.
C_0 = PCB concentration in oil before draining and refilling.
R = Percent of fluid remaining in the transformer after draining.
P_s = Percent of PCB in solid materials before draining.
P_1 = Percent of PCB in oil before draining.

The mathematics assumes that the oil in the tank is homogeneous and therefore represents a 'best-case'situation. In a transformer, however, the volume of oil trapped in the interstices of the windings are not likely to be removed by a simple drain and flush procedure. Then, when the unit is put back into service, the trapped, highly PCB contaminated, original oil, gradually convects into the retrofilled bulk oil to give an apparent leaching effect. If the trapped, original oil had a PCB concentration of 2000 ppm PCB and becomes diluted by a factor of 40 by convection, then the final concentration of the retrofilled fluid will be 50 ppm PCB.

The higher the PCB concentration in the mineral oil, the more likely it will become necessary to remove trapped oil in order to achieve a retrofilled concentration of less than 50 ppm PCB. The areas which must be cleaned in particular are the core/coil assembly and other regions which contain flow restrictions.

It has been mentioned above that a vapor cleaning system has been proven successful in removing surface PCB contamination from areas previously considered inaccessible. The method has the advantage that a minimum quantity of PCB contaminated fluid is derived for disposal in contrast to the drain and flush method which produces several times the volume of the transformer tank. Also, as the level of PCB contamination in the mineral oil increases, the vapor cleaning method become increasingly necessary and eventually becomes the only viable, cost-effective procedure.

THE VIABILITY OF PCB REPLACEMENT FLUIDS

The need to reduce or eliminate PCBs from the dielectric fluid of transformers is partly because of the generation of compounds of concern in a fire incident. However, it is also important to consider that the original reason for the use of transformer askarels was because they were intended to provide a measure of fire safety.

Fire hazard factors for replacement askarel transformer fluids are neither well defined nor easily estimated, but include:

- the ignition sources available:
- the availability of fire protection systems:
- the ease of ignition of the transformer:
- the close environment of the transformer:
- the effects of burning liquid on the surroundings:
- the depletion of oxygen by burning liquid:
- the smoke evolution from burning liquid:
- the toxicity of combustion products:
- the temperature at which the liquid is used.

The test methodology used to describe a system as complicated as a real transformer fire is complex, and while the factors which affect fire hazards can be listed in broad terms, their interdependent description in an overall assessment is difficult using the rudimentary test methods presently available. More importantly, the interpretation of such results to provide a quantitative measure of the overall fire hazard should be treated with caution.

Ideally, a fire hazard assessment should be predicated on incidence studies in actual usage. Such an assessment is difficult for "less flammable" fluids, i.e., fluids with a fire point above 300°C, because of the lack of statistics on fires in which these fluids are involved.

Section 450-23 of the National Electrical Code specified in the past that the controlling provision for fluids used in indoor transformer applications should be that the insulating liquid have a 300°C fire point. The required temperature has some validity in that it is known that flaming will not persist in a wood slab not subjected to supplemental heating unless the average temperature within the slab is greater than about 320°C.

In the absence of primary current limiting fusing, the intensity and duration of a high energy arc are limited by the recovery capability of the liquid. When there is sufficient energy to produce an explosion, liquid aerosol and gaseous decomposition products are expelled from the transformer as a hot plume. The magnitude and probability of potential loss will be partially dependent upon whether the plume ignites. Subsequently, the effect of the transformer failure will depend upon the ignitability of the fluid and the material surrounding the transformer.

A report was issued by the National Electrical Manufacturers Association (NEMA) in 1980 concerned with "Research on Fire Safety Test Methods and Performance Criteria for Transformers Containing PCB Replacement Fluids". The scenario used by NEMA to describe an eventful failure is as follows:

1) Incipient fault induction period.
2) Growth of incipient fault to large arc.
3) Failure of electrical protection devices to remove the transformer from the line before tank rupture.

4) Tank rupture with scattering fluid, gaseous decomposition products, solid insulation, steel components and molten conductor leading to ignition of nearby combustible building materials and furnishings by the transformer.
5) Scattered materials in static condition within minutes after tank rupture resulting in ignition of combustible building materials and furnishings.

NEMA has recognized that the principal underlying cause of transformer failures involves insulation breakdowns. A typical failure was described as beginning as an insulation failure in the high voltage winding which initiates a low current, high impedance fault. This turn to turn or layer to layer fault progresses rapidly, involving additional turns and layers. The coil impedance decreases and the fault current increases. An alternative failure model begins with a high impedance path to ground along the surface of insulation (tracking).

The following scenario was formulated to serve as the basis for a worst case failure:

1) Due to malfunction, the electrical breakers and/or fuses which are directly associated with the particular transformer are inoperative. The sustained presence of a severe overload current therefore goes undetected, permitting the insulating oil to overheat significantly.
2) As a consequence of the overload, the average oil temperature in the tank reaches 135°C. (Note, the NEMA study accepted this temperature as "an arbitrary but reasonable level to assume under the circumstances.")
3) Insulating deterioration occurs, causing charring or tracking of the high voltage insulation. A fault to ground develops through the train of bubbles or along the insulation surface to ground. The tracking fault then rapidly flashes into a long, high current arc.
4) Once the long arc has developed the sequence involves the following:

    a. The long arc rapidly decomposes the surrounding oil into gases.
    b. A high pressure (several hundred psi) gas bubble develops around the arc under the oil.
    c. The pressurized bubble rapidly accelerates the oil upward towards the gas space and also subjects the tank walls below liquid level to a severe overpressure.
    d. Depending on the tank geometry, failure occurs either near the bottom, below the oil surface or at the top by ejection of the cover.

5) Ignition of the hot oil spray results from one or more of the following sources:

    a. The hot solid particles of insulation and conductor which are produced by the arcing fault.
    b. The arc drawn by the ejected bushing.
    c. The hot gas bubble of arc decomposed oil which, at a temperature of about 3000°C initially drove the oil out of the tank, is itself ejected.

The theory of pressure phenomena due to arcing in liquid filled transformers has been studied and relationships derived between arcing and tank pressure (EPRI project 325[88]). Tests were conducted on different types of arcs to corroborate the results. For example, current flowing through an expulsion fuse produces a higher arc-voltage gradient than does the same current in a free arc in oil. Higher voltage resulted in higher arc energy, and was accompanied by higher peak pressure in the tank. Faults contained within the coil's windings were found to produce less pressure on the transformer than either an open arc or an expulsion fuse. In particular, short length winding faults were found to be less severe than one inch arcs drawn directly in oil. Peak values of below-oil pressures were observed when the melting of a fuse wire initiated the arc, since this resulted in a high, near instantaneous rise in arc current. The maximum pressures developed under the oil for fuse initiated arcs were found to be very high, in the range of 20–30 atmospheres.

Electrical failure resulting in rupture of cylindrical 10 kVA tanks has been reported to exceed 100 kW-sec. but for rectangular tanks this value increases to 800–1400 kW-sec. Values for cylindrical tanks are found to grow rapidly with increasing tank size. Therefore, eventful failure is much more likely in small cylindrical tanks.

The real world test parameters discussed above have been incorporated into the fire hazard assessment model used by UL (Webber[89]) to determine the compliance of transformer fluids with section 450.23 of the National Electrical Code. In order to be complaint with the code, transformers insulated with less-flammable liquids are permitted to be installed without a vault in Type I and Type II building of approved noncombustible materials in areas in which no combustible materials are stored, provided there is a liquid confinement area, the liquid has a fire point of not less than 300°C and the installation complies with all restrictions provided for in the listing of the liquid. UL has identified the need for pressure relief devices and current limiting fusing to limit the effect of possible high current arcing faults.

The purpose of the tests was to determine the flammability of dielectric liquids after an explosion. Approximately ten galloons of each of the fluids under test were placed in separate transformer tanks and preheated to 150°C. Each container had internal electrodes designed to force the arc upward into the gas space. Although the temperature at the point of arcing was several thousand degrees, the duration was only for a few cycles and therefore the temperature of the fluid in a container the size of even a small distribution transformer cannot be significantly affected. The 150°C used in the test was probably higher than would reasonably by expected to occur and therefore the same tests were also run at 120°C. It was found that a fireball was not produced at the lower fluid temperature.

When the test conditions were made sufficiently severe to expel liquid and gas from the transformer at high temperature, a high molecular weight paraffinic hydrocarbon oil produced a smaller fireball, lower fireball temperature and shorter fire residence time than any of the other fluids tested, including silicone dielectric oils. Catastrophic failure tests methods such as that described above are difficult to standardize because of the many factors which contribute to the results. Nevertheless, the scenario used is substantially more realistic than many other fire tests applied to less flammable fluids. For example, ignitability tests to determine whether a fluid would contribute to a fire showed that, under all the test conditions applied, a high temperature hydrocarbon fluid exercised a considerable advantage over other fluids with respect to time of ignition. The advantage was lost in badly conceived experiments where gasoline was added to the fluid as a fire starter to the hydrocarbon oil. Tests to determine the ignitability of fluids are difficult to standardize and have been abandoned because of it. However, the ignition of a combustible material is the first step in any fire scenario and therefore is important to fire prevention.

Since arcing is the most common failure mode of devices incorporating insulating fluids, R. Hemstreet[90] made an attempt to assess spray flammability. His experimental arrangement starts a flow through a nozzle and the liquid temperature is gradually increased until the spray sustains ignition at a measured distance of the igniter flame from the nozzle.

The burning rate in a gas is proportional to the square of the gas pressure. Therefore, for two fluids of different viscosity, or the same fluid at different temperatures, the pressure in the aerosol cloud will be greater for the thinner fluid because more of it can be pumped through the nozzle in a given time. One would therefore expect that the minimum distance of the igniter flame to cause combustion would be larger in the case of a non-viscous fluid than in a viscous one or, equivalently, that the minimum igniter distance will increase for a given fluid as the temperature increases. This is shown to be the case in Hemstreet's results. Clearly, the experimental factors in an apparently simple test to rank fluids can be extremely complicated. For example, it was found that an air velocity of greater than about two feet per second had a considerable effect on the fluid temperature required for ignition as the nozzle distance was increased.

The overall shape of a temperature–distance curve in experiments of this sort is likely to be strongly influenced by the presence of decomposition products, either originally present in the fluid or induced by the igniter flame. The minimum temperature at which a liquid ignites depends on such factors as the degradation produced in the fluid by the flame and prior thermal and electrical stresses.

Heat release rate was measured in Hemstreet's work after removal of the ignition source and measurements are sometimes significantly different from results obtained using a sustained ignition source. Heat release raw data derived from measurements done on a quiescent pool of fluid provide information which has been used to calculate suggested clearances between the burning pool, presumably around the transformer, and the walls and ceilings of the room in which the unit is housed. The test does not consider the interference of silica crust produced over a quiescent pool of silicone oil. In the unlikely event that the conditions necessary to maintain a quiescent condition were to exist in a real building fire, the wicking action of the crust causes the silicone oil to burn longer than high temperature hydrocarbon oils under the same conditions (Webber[89]).

Thermal Decomposition of PCB Replacement Fluids

The suitability of fluids as replacement dielectrics for PCBs depends not only on the electrical properties of the liquids but also their decomposition products. Part of the reason is that the buildup of oxidation products in in-service fluids degrades its electrical properties and also because the decomposition products may be toxic. In particular, combustion products derived from PCB replacement fluids should not be toxic.

Several fluids have been promoted as replacement dielectric fluids in capacitors and transformers, of which, some are listed in Table 42.

The capacitor fluids are usually based on a single major constituent whereas the transformer oil are typically derived from oils or are polyalkylated siloxane oils. Decomposition products derived from single or, at least well characterized, compounds are more easily analyzed than those obtained from complex mixtures such as refined oils. Dielectric mineral oils have been in use in transformers for many years and are not usually considered to represent a high health risk even though they contain many aromatic compounds. Indeed, part of the usefulness of naphthenic oils which gives them an advantage over their paraffinic counterparts, is their ability to solubilize the sludge of oxidation products formed during in-service aging. Table 43 lists the percentage of different classes of hydrocarbons found in naphthenic transformer oils to illustrate the starting complexity with which oxidation studies are faced.

RTEmp transformer oil was developed as a non-toxic PCB replacement fluid and was derived from high molecular weight paraffinic material. The major thermal decomposition products at 600°C in air include benzene, which is known carcinogen, and traces of other compounds, as shown in Tables 44 and 45. Benzene is also formed, in greater yield, when RTEmp is heated[158] at 700°C under nitrogen. It is very difficult to assess the health risks associated with the presence of trace quantities of pyrolysis products. Since the formation of monoalkylated benzenes is two to three orders of magnitude less than the amount which occurs naturally in nontoxic naphthenic transformer oils, it is not likely that the decomposition products formed from high molecular weight paraffinic oils would cause much concern.

Thermal decomposition products derived from PCB replacement capacitor fluids are much more easily characterized and are shown in Table 46. While the thermal decomposition products of PCBs yield PCDF and PCDD products which are toxic at the μg/Kg level, the toxicities of products derived from the alkylaromatic capacitor fluids in the absence of chlorine sources, are toxic at the mg/Kg level. In the presence of chlorine sources, however, it would be possible to generate PCBs as well as polychlorinated methylanthracenes and, conceivably, PCDFs as well.

TABLE 42
PCB replacement fluids and their thermal decomposition products

PCB replacement fluid	Thermal decomposition products
RTEmp	benzene, toluene, cyclopentadiene, phenol, acetic acid
Polydimethylsiloxane	cyclic siloxanes, short-chain hydrocarbons, amorphous silica
Chlorinated benzenes	chlorophenols, PCBs, PCDDs, PCDFs, PCNs, PCDPEs, PCBPs
Tetrachloroethylene	HCl, phosgene
Phthalates	phthalic anhydride, alkenes, alcohols, aldehydes
Phenylxylylethane	styrene, phenylxylylmethane, phenol, methylanthracene
n-Propyl-biphenyl	dihydrophenanthrene
Iso-propyl-biphenyl	biphenyl, biphenylcarboxaldehyde

THE ANALYSIS OF PCBS

The widespread applicability of PCBs since their introduction in 1930 up to 1976 resulted in worldwide environmental contamination. By 1968, PCBs had become the most abundant of the chlorinated aromatic pollutants, rivaling DDE (Risebrough *et al.,* 1968).

Jensen's paper in 1966 confirmed the presence of PCBs in fish after repeated encounters of gas chromatographic elution patterns while analyzing for DDT and other chlorinated pesticides. The earlier failures by researchers in this field to recognize the presence of PCBs must certainly have contributed to the overestimation of DDT in the environment. The shift in emphasis to the analysis of PCBs in environmental matrices after 1966 reversed the roles almost overnight and PCB residues were then described to have interferences from a wide variety of organochlorine pesticides.

Use of a halogen-sensitive detector such as an electron capture detector in conjunction with a nonpolar stationary phase such as OV-101 or SE-30 in a gas chromatographic system had resulted in interferences with DDT, DDD and DDE as well as early eluting pesticides such as BHC isomers, aldrin, and heptachlor epoxide because of similar retention times.

Dependent upon the matrix selected for analysis, three distinct analytical protocols emerged involving either no prior separation, separation via column chromatography or separation with destruction or conversion of interfering compounds.

Cleanup methods have been devised to separate DDT and its analogues from some of the PCBs (Amour and Burke, 1970).

The figure below shows the structural similarity between DDT and PCB structures. PCBs extracted from air have been analyzed by Jacobs (1949) before the advent of gas chromatography. The PCBs were quantitated by determining chlorine after combustion over heated platinum.

Several papers in the late 1960's and early 1970's discuss problems associated with the sampling of environmental matrices for PCB analysis. Harvey and Teal (1973) showed that nylon netting adsorbs PCBs and hydrocarbons and that they are desorbed if exposed to water containing PCBs and hydrocarbons in lower than equilibrium concentration.

The boat used to take water samples can be an important source of analytical contamination (Grice *et al.,* 1972). Polystyrene particles recovered from the ocean were found (Carpenter *et al.,* 1972) to contain 5 ppm Aroclor 1254. Jensen *et al.* (1972) found that plankton samples collected from the wake of the boat were contaminated by PCBs from the ship's paint and contained 4 to 14 times more PCBs than samples collected 7 ft. abeam of the boat.

Laboratory contamination is always of concern in trace analysis and several workers have found that significant interferences can be retained by reagent water unless precautions are taken (Bevenue *et al.,* 1971). Several workers (Giam and Wong, 1972; Bevenue *et al.,* 1971; Levi and Nowicki, 1972) have discussed cleanup treatments for solid materials used in PCB analyses such as silica gel, florisil, sodium sulfate, glass wool and aluminum foil. Lamont and Cromartie (1969) recommended a cleanup method for extraction thimbles used to hold solid samples during solvent extraction of PCBs.

Ahling and Jensen (1970) extracted PCBs from water by passing the water sample over a coated solid material. From 10 to 176 L of water were treated in this way and then the solid material was extracted with petroleum ether to recover the PCBs. Gesser *et al.* (1971) described the use of polyurethane foam to quantitatively extract PCBs from water.

TABLE 46
Combustion and Pyrolysis Products of PCB Replacement Fluids

Trade Names	Primary Components	Combustion Products	Pyrolysis Products
Wemcol Edisol II Edisol III	 n-Propylbiphenyl	 Dihydrophenanthrene	 Dihydrophenanthrene
	 Isopropylbiphenyl	 Biphenylcarboxaldehyde  C3-Alkylbiphenyl	 Biphenyl
Selectrol Dielektrol	 Phenylxylylethane	 Styrene  Benzaldehyde  Phenol	 Phenylxylylmethane  Methylanthracene  Phenylxylylethene

Aue *et al.* (1969, 1972) showed the applicability of surface-bonded silicones to adsorb PCBs from water. Extraction methods for PCBs from soil, sediment, sludge and paper have used more polar solvents or solvent mixtures than that used for the analysis of water. Holden (1970), for example, used a mixture of hexane and isopropanol to extract PCBs from sewage sludge.

PCBs from non-carbon copy paper were extracted with acetone in a Soxhlet apparatus for 3 days (Kuratsune and Masuda, 1972).

PCB extraction from biological samples tends to be complicated by problems of incomplete extraction, cleanup losses etc. Extraction techniques have most often used Soxhlet extraction to conserve the volume of solvent or a percolation system with large volumes of solvent to obtain satisfactory recovery efficiency. Soxhlet extraction was used by Zitko (1972) in the extraction of tissue samples using 100 mL of hexane in a 1 hour extraction. Acker (1970) used a combination of solvents passed through a tissue sample homogenized with sea sand and packed into a column. The method served to remove interferences from the PCBs contained in a pentane fraction. A procedure was developed for the PCB extraction of milk by Noren and Westöö (1968) using ethyl ether and petroleum ether, centrifuging and removing the separated phases.

The Yusho incident (1968) occurred shortly after Jensen's report on PCBs (1966). The incident prompted the US Food and Drug Administration (FDA) to initiate a national survey to determine the exact extent and levels to which PCBs might have made their way into the food chain by indirect use of PCB contaminated animal feed, industrial and environmental sources, and the use of PCB-containing paper food-packaging materials. The survey resulted in a 'Notice of Proposed Rule Making' to limit the levels of PCBs in foods in 1972.

The survey found that several accidents involving PCBs had contaminated animal feed and subsequently the poultry and eggs intended for human consumption. Other parts of the survey indicated that the use of PCB-containing coatings on the inner walls of grain silos had been responsible for PCB residues in milk derived from dairy cows which fed on the grain stored in such silos. The FDA concluded that it would be in the best interest to limit the ways in which PCBs might enter the food chain as well as limit the levels of PCBs in food.

Since part of the problem with PCBs was the vulnerability of food and feed commodities to direct contamination through accidental causes, the EPA issued rules governing the continued deployment of PCBs in certain industrial applications. These regulatory controls were made under the Toxic Substances Control Act of 1976 and proposed the discontinued use of PCBs in heat transfer systems in plants manufacturing or processing food, drugs and cosmetics. An interagency alert notice [1979] was then issued by the EPA to urge voluntary compliance in removal of equipment containing PCBs and replacement with non-PCB units to prevent food contamination.

On February 24, 1969 the San Francisco Chronicle carried a major feature on work reported by R. Risebrough (1968) and that of S. Jensen (1966). Jensen had reported the identification of PCBs while analyzing for DDE.

The early analytical method applied to the quantitation of PCBs in oils uses a calibration technique developed by Webb and McCall in 1973. The method is based upon the detector response comparison obtained for a commercial PCB mixture with that of the sample and uses packed column gas chromatography with, typically, an electron capture detector (see ASTM method D-4095). Slight variations in the Aroclor manufacturing process, or chemical alteration of the analyte PCB, causes problems with the quantitation. Reasonable results can be achieved, however, in the analysis of insulating oils where the PCB have not been degraded. More sophisticated analytical methods have been published by Albro *et al.*[22]; Erickson[23]; Leo *et al.*[24]; and Stalling *et al.*[25]

The USEPA methods manual, SW-846, of test procedures is commonly used to quantitate PCBs in environmental samples. The manual describes both the method of sample cleanup as well as of analysis. The protocols are given in SW-846 as method 8080 using packed columns or 8081 with capillary columns. Each sample is spiked with surrogate compounds and extracted using methods 3510 or 3520 for liquids or methods 3540, 3541 or 3550 for solids. Cleanup methods use silica gel adsorption (method 3630) sulphuric acid/potassium permanganate destruction of interfering compounds, including pesticides (method 3665) and/or sulfur cleanup by agitation with powdered copper, elemental mercury or tetrabutyl ammonium sulfite (method 3660).

The electron capture detector used in the gas chromatograph is extremely sensitive towards compounds which contain halogen atoms, such as the chlorine of PCBs. However, the detector is not totally insensitive to other elements such as oxygen and sulfur. Indeed, the sensitivity of the gas chromatographic quantitation is very dependent upon the level of interferences present.

The sample chromatograms derived from the electron capture detector in the gas chromatograph are interpreted according to the pattern of peaks and their retention times relative to known standard mixtures. In the case of PCB contamination, the Aroclor products, such as Aroclor 1016, 1242, etc., each has a characteristic "fingerprint".

Aroclor 1016 was derived from the vacuum distillation of Aroclor 1242 which removed the less volatile, more highly chlorinated congeners of the mixture. The PCB congener composition of Aroclors 1016 and 1242 are given in Table 47.

Packed columns for GC analysis do not have enough separating power for individual components of a PCB mixture to yield anything but a series of envelopes. The pattern formed by the envelopes tend to be characteristic of the PCB mixture and therefore the pattern, taken as a whole, is usually recognizable as PCB and may be quantitated as such by comparison with the envelopes produced by a standard Aroclor mixture.

The pattern produced on packed columns by some samples shows that the electron capture detector was responding to components which, in all probability, contained a highly electronegative i.e., electron attracting, element, such as chlorine. The pattern of envelopes in the chromatogram may not be distinguishable as any standard Aroclor product. Since there is often no reason to suspect that any other chlorinated compounds similar to PCBs may be present in a sample the origin of the chlorine is usually an sometimes erroneously attributed to PCB.

Attempts are sometimes made to remove interferences from the oil to allow an unequivocal identification of PCB by gas chromatography/mass spectroscopy (GC/MS). The mass selective detector in place of the electron capture detector is typically used as an identification tool for individual compounds and compound types. The response obtained in the machine is compared with a computer stored library of known compound responses. The closest matched response at the gas chromatographic retention time of the species is usually evidence enough to establish the identity of the component of interest.

The GC/MS technique applied to complex matrices such as oils tends to swamp the detector with naturally occurring

compounds in the oil matrix. The signal then combines to give a resultant which is unintelligible to the mass spectrometer's computer.

If, at first, a standard method of quantitation does not provide an unequivocal identification of PCBs, an unconventional method might be adopted. For example, extensive cleanup of the sample, starting with solvent extraction to concentrate the PCBs, if present, and followed by the recommended cleanup protocols would yield a sample which could be usefully analysed by a combination of coupled instruments known as gas chromatography/mass spectrometry/mass spectrometry (GC/MS/MS).

The coupled technique is typically used for ultra-trace analysis of dioxins and was designed to provide unequivocal identification of trace amounts of PCB-like compounds.

Quantitation of the gas chromatographic results obtained from the use of packed columns and an electron capture detector, i.e., GC/ECD, are calculated on the assumption that peak area is directly proportional to the amount of PCB present. The relationship between peak area and component concentration is usually linear and a sample peak which is half the size of a standard peak will result from a sample which contains half as much as the standard. If, however, some of the peak area is the result of a co-eluting material which is not the analyte of interest then it will appear that there is more present than is actually the case and the quantitative result will be biased on the high side.

PCBs are not highly volatile compounds and consequently the GC conditions have to be such that the column used for separation must be heated to about 200°C. The volatility of PCBs increases with temperature and as the amount of chlorine in the molecules decreases. Aroclor 1016, because it contains a high proportion of the less chlorinated congeners is more volatile than, say, Aroclor 1254 which has a higher average number of chlorines per molecule. The effect is that at the normal GC operating temperature, Aroclor 1016 is eluted much faster, in about 10 minutes, than Aroclor 1254, in about 20 minutes. The interfering components of the mixture tend to be more volatile than even the constituents of Aroclor 1016 and consequently these are eluted quickly and tend to spill over into the early part of the PCB "fingerprint". Since the amount of interfering substances can be very much higher than the amount of PCB, and even though the detector is less sensitive to the interfering substances, the co-elution of PCBs with other detector responsive materials causes a combinative effect on the peak area and a high quantitation bias is obtained. The relative effect of the interfering compounds on the quantitation of Aroclor 1254 is usually much less because the peaks which are used for quantitation elute much later than the interfering materials and the extent of overlap of the interference and PCB peak areas is usually much less.

Some of the problematic effects of interferences can be avoided by a combination of rigorous sample cleanup and subsequent analysis by capillary column GC. Capillary column technology allows for much greater resolution of the components of mixtures and consequently PCB components tend to become separated from interfering materials. There is still a very strong need for adequate sample cleanup but the presence of interfering non-PCB components becomes much more easily recognized.

The following analytical results illustrate the discussion:

- the correlation coefficient for the standard curve, which is a measure of the linearity of the detector response in the concentration range of interest, is sometimes better if one chooses peaks which appear later in the chromatogram than those normally used in the early part of the chromatogram;
- the correlation coefficient tends to become less than satisfactory for three early peaks usually chosen for quantitation when co-eluting interferences are present;
- the apparent concentration of PCBs in the samples can fall dramatically when the standard curve is calculated on the basis of peaks which appear later in the chromatogram than the early peaks which may be the ones routinely chosen for quantitation. This indicates that there is a substantial difference between the chromatograms of the standards and the samples.

The analytical data in Table 48 were predicated on the assumption that the PCB contamination in the samples were due to a single Aroclor, namely Aroclor 1016, and that the relative peak intensities in the chromatogram matched those of an available standard Aroclor 1016. This can clearly lead to a high bias in the result when the quantitation method uses peak areas which contain a significant contribution from interfering substances. Such a simplistic approach is not suitable for the quantitation of PCB contamination derived from partially decomposed Aroclors, mixtures of Aroclors, or PCBs which may not have originated from an Aroclor.

TABLE 48
The apparent PCB concentration of samples is drastically altered by the method of calculation

	Calculated PCB concentration (ppm Aroclor 1016)		
Sample #	Early peaks	Late peaks	Later peaks
A	61.7	51.7	8.7
B	16.7	<D.L.	<D.L.
C	19.0	<D.L.	<D.L.

The chromatograms of the samples used for the above discussion do contain a distribution of PCBs which match the pattern found in Aroclor 1016. However, the relative amounts of PCB congeners in the standard and the samples do not match. The samples may have been derived, for example, from a batch of Aroclor 1242 which had been distilled to yield only the most volatile fraction as Aroclor 1016. This might explain why there is relatively little of the less volatile, more highly chlorinated congeners. Chemical degradation, on the other hand, tends to dechlorinate the more highly chlorinated material first and then, as the chlorines are removed, the mixture becomes more concentrated in the less chlorinated material until it too eventually becomes dechlorinated.

Different isomers of PCB with the same number of chlorine substituents can cause substantially different responses from electron capture detectors. The accurate quantitation of PCBs therefore relies on the similarity between the sample chromatogram and the standard Aroclor.

A calibration technique was proposed by Webb and McCall which employed individual peak response factors.

A table was developed for each Aroclor in which the weight-percent composition of each peak in the chromatogram was identified by whole numbers which represented their retention times relative to a reference compound defined as 100. The weight-percent compositions of Aroclors were determined using GC/MS.

The column used was a packed column with poor chromatographic resolution compared with today's capillary columns. The individual peak calibrations were valid only for the specific lots of Aroclors tested.

Sawyer[26] has conducted a similar characterization to Webb and McCall and concluded that individual peak calibration is the most reliable approach for samples containing a non-Aroclor residue.

The method of peak by peak comparison is used in ASTM D-4059. The concentration of PCB in each peak in the chromatogram is calculated from the individual response factors of the detector. The total PCB content is then obtained by summing the concentrations associated with each peak.

An alternative, but more approximate, calculation, noted by ASTM, can be made using the responses of the larger, more cleanly separated peaks in both the standard and the sample. Again, this makes the assumption that the chromatograms of the standard and sample match one another. ASTM notes that the PCB concentration calculated in this way may be incorrect because the PCB content in an individual peak may be reduced or relatively enhanced by a non-standard isomer distribution or impurities. In order to minimize the effect of variations between Aroclors, ASTM suggests the use of a minimum of three peaks in the sample being analyzed but adds that the simplified calculation should not be used in circumstances where maximum accuracy is required. Indeed, EPA SW-846-8080 indicates in $7.6.5.3 that PCB to residues should be quantitated by comparing total area or height of residue peaks to total area or height of peaks from appropriate Aroclor reference materials.

The following calculations take the above considerations into account on a different set of samples. Based on three sets of calibration data for early, late and total areas of peaks, chromatograms were recalculated to yield significantly different data as shown in Table 49.

The area of the chromatogram attributable to Aroclor 1016 in a standard was approximately 59%. The remaining 41% is attributable to a region from the start of timing to 2.16 min. Of this total, 39% is the response of the detector to the solvent. This leaves only 2.5% which might be attributable to Aroclor 1016. Thus, the error induced in the calculation by leaving this portion of the chromatogram out entirely is very small relative to the error induced by including non-PCB detector response in the same retention time range. For example, for the sample marked as [‡] in Table 49, the area of the total chromatogram which occurred prior to 2.19 min. was 74%. This should be compared with the 41% in an Aroclor 1016 standard. In other words, in this case, about 70% of the total sample chromatogram area is attributable to non PCB components.

§ 7.6.5.3 of the USEPA SW-846/8080 method states the following: "Quantitate PCB residues by comparing total area or height of residue peaks to total area or height of peaks from appropriate Aroclor(s) reference materials. Measure total area or height response from a common baseline under all peaks. Use only those peaks from the sample that can be attributed to chlorobiphenyls. These peaks must also be present in a chromatogram of reference materials. Mixtures of Aroclors may be required to provide a best match of GC patterns of sample and reference."

The gas chromatographic trace, in many cases, does not conform with what would be expected from a standard Aroclor and, consequently, the quantitation of the PCB components must be done by comparing total area or height of residue peaks to total area or height of peaks from appropriate Aroclor(s). These requirements have been met in Table 50 and are contrasted with other methods of calculation.

It was not reasonable to attempt to quantitate the PCB residue contained in these samples by peak height because in part, the chromatogram derived from the instrumentation typically does not lend itself to that type of quantitation method. In order to illustrate the point, PCB concentrations have been calculated using the peak height method with peaks appearing at different retention times and the results listed in Table 51.

The peak height method is clearly not acceptable. Inconsistencies in the peak height ratios have also been calculated. The peak height ratios of peaks in a standard Aroclor pattern should remain the same from sample to sample. However, because the samples contained PCB residues and were not standard Aroclors the peak height ratios vary. Peak height ratios are presented in Table 52. For this fact alone, the method of peak height analysis is not valid for these samples and the analyst must revert to the only other alternative provided by the EPA SW-846 8080 method, that is, the comparison of total areas.

Similar inconsistencies are shown by determining relative area ratios. Table 53 shows the result of calculating area ratios relative to a peak at $R_t = 7.75$ min which is prominent in the standard samples.

Clearly, the experience of the analyst is critical to the analytical data derived. The precision and accuracy of an analytical protocol, as measured by standard methods, may indicate that the quantitation of ideal mixtures is within the expected limits. Without such a measure of control there is a much reduced likelihood of achieving reliable, scientifically defensible, results.

THE DISPOSAL OF POLYCHLORINATED BIPHENYLS: CONCENTRATIONS OF CONCERN

Methods for the dechlorination and destruction of polychlorinated biphenyls are reviewed in terms of the fundamental principles involved and the reaction products formed. This section is organized into three parts (1) the disposal of askarel liquids; (2) the disposal of PCB contaminated liquids and (3) the remediation of PCB contaminated soils. Figure 46 presents disposal methods for high concentration PCBs.

(1) PCBs are refractory organic compounds which require a large energy input for their decomposition. The methods in use for the destruction of fluids which contain high percentages of PCBs are therefore typically large energy sources. The most widely used method for the disposal of askarel fluids, and that preferred by the EPA is high temperature incineration. However, other methods discussed here include chemical methods, a DC arc and the use of a microwave plasma.

(2) The EPA defines a PCB fluid as one which contains more than 500 ppm of PCB. For this discussion, liquids are considered to be contaminated with

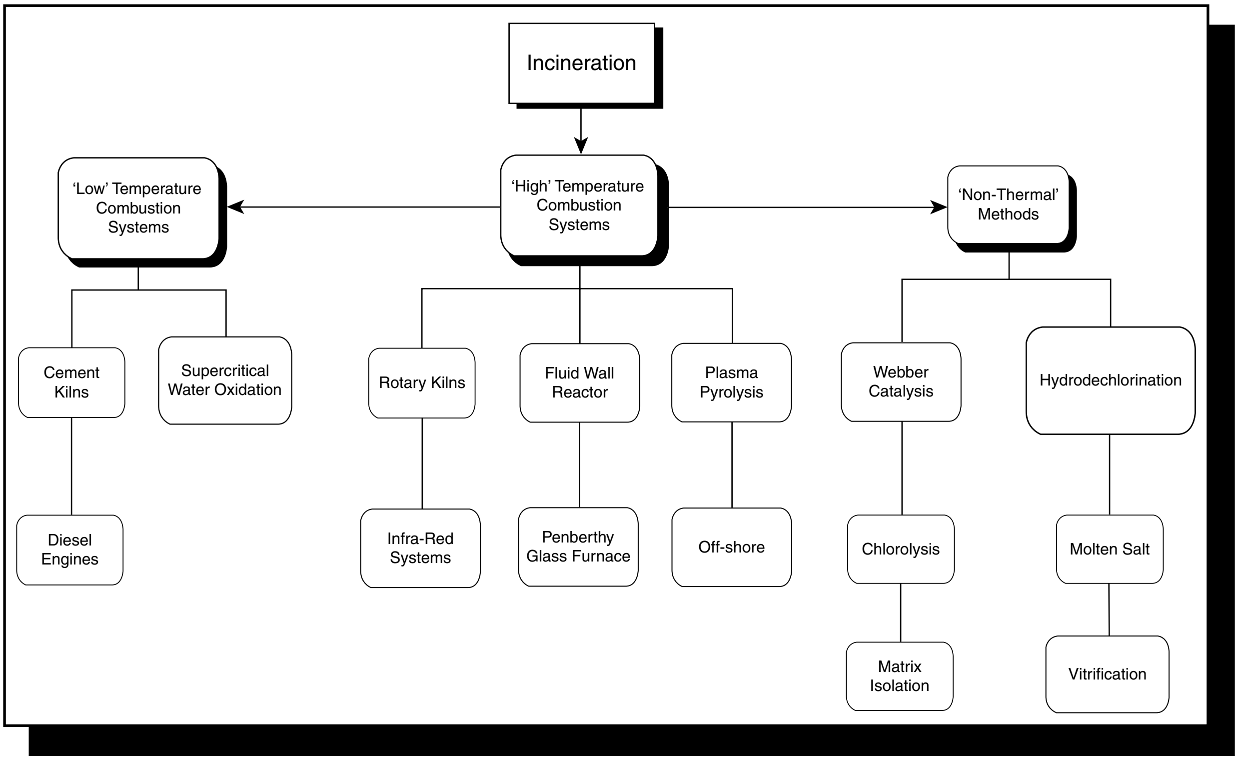

FIGURE 46 Disposal methods for the high concentration PCB fluids.

PCBs even if they are at the several hundred ppm concentration level. This is because the methods which are aimed primarily at the decontamination of low concentration liquids tend to remain effective up to levels as high as, perhaps, 1% (10,000 ppm) and, in any case, well into the range defined by the EPA as "PCB fluid".

(3) The remediation of PCB contaminated soils can present a wide range of PCB concentrations for destruction. This section reviews several different methods used on a large scale or being developed for field use and includes an outline of information on the application of a novel electrochemical technology.

It is sometimes possible to reclaim the liquid for re-use. Several of the numerous alternative chemical methods of PCB dechlorination as well as physical separation methods can be made to yield decontaminated liquids.

The stability and lack of reactivity of PCBs are benefits and at the same time, liabilities. Their thermal stability to oxidation and in the extreme case, combustion, and resistance to harsh chemicals such as strong acids, bases, oxidizing and reducing agents, has made the removal of PCBs from electrical and other uses extremely difficult.

The PCB decontamination methods presently available fall into four major classes and are either physical, physicochemical, chemical or biochemical. The literature concerning PCBs is expanding rapidly. This paper is not intended to be a complete review of every disposal option, but rather an overview of some of the more scientifically interesting systems.

(1) THE DISPOSAL OF PCB LIQUID

PCB liquid is taken to include those commercial PCB mixtures which were diluted with tri- and tetra-chlorobenzenes and which typically contain about 70% PCBs. There is an important distinction to be made between askarel fluids in which PCBs are the majority constituent and fluids which contain more than 500 ppm PCB but in which PCBs are not a majority component. The EPA requires that any fluid with a concentration of more than 500 ppm PCB must be considered as a "PCB fluid". The name "askarel" is a generic name used for PCB formulations. Other names found frequently in the literature are manufacturer's trade names such as "Aroclor". "Inerteen", "Chlorphen", "Safe-T-Kuhl", "Pyrochlor" etc. The most commonly used askarel in North America was Monsanto's "Aroclor" and these two names are often interchanged. Figure 57 shows some of the disposal options available for askarels.

INCINERATION

EPA research into the thermal degradation of PCBs has involved the use of commercial mixtures and pure isomers

in a precisely controlled thermal environment. Temperature and residence time relationships were established for the conditions necessary to produce a specified destruction efficiency. It was concluded that with a 1 sec. residence time, most of the pyrolysis occurred within a narrow temperature range between 640°C and 740°C (Mescher *et al.*[56]). The results were based on the disappearance of PCBs rather than the accumulation of degradation products. The lower molecular weight PCBs are less thermally stable than the higher molecular weight congeners. The residence time of the molecules in the high temperature zone is therefore a critical parameter in determining the overall efficiency of the degradation. However, the destruction and removal efficiency (DRE) of an incineration process for a given compound does not consider the toxicity of any pyrolysis products. The DRE is defined as

$$DRE = \frac{(W_{\text{feed}} - W_{\text{out}})}{W_{\text{feed}}} \times 100$$

where,

W_{feed} = mass feed rate of a compound to the incinerator,

W_{out} = Mass emission rate of the incoming compound past the incineration zone.

Water and carbon dioxide are the main products of combustion for organic material. However, incineration equipment does not always produce complete combustion and the effluent or residues can contain organic material of varying complexity which is derived from either incomplete combustion or thermal synthesis. A better understanding and acceptance of the pyrolysis data accumulated over the last few years has given rise to the concepts of Principal Organic Hazardous Constituents (POHCs) and Products of Incomplete Combustion (PlCs).

POHCs can be any incoming hazardous waste stream but in the particular case of refractory organic compounds such as PCBs, TCBzs and other halogenated compounds, the pyrolysis chemistry is complex and can lead to the generation of PlCs which are much more toxic than the original POHC. There is a wide variety of equipment available for the incineration of waste organic materials, but the suitability of the incinerator for refractory compounds such as PCBs is restricted to those which allow the use of high temperatures and a suitably long residence time to achieve a DRE of 99.9999%.

A rotary kiln is usually large and expensive to operate but does fulfill the required conditions. Such kilns are used by Energy Systems Corporation in El Dorado, Arkansas and SCA/Chemical Waste Management in Chicago, Illinois. The kiln consists of a refractory lined cylinder with its axis slightly inclined to produce a tumbling action which mixes the wastes. The advantage of the design lies in the wide range of wastes which can be accommodated because the residence time can be controlled to the extent necessary for complete combustion. Combustion temperatures range from 870°C to 1650°C.

Halogenerated wastes can be used to fire cement kilns. This has been done by the St. Lawrence Cement Co. in Mississauga, Ontario, and the Peerless Cement Co. in Detroit, Michigan. The calcium oxide of the cement apparently reacts with the chlorine in the PCB to form calcium chloride. The resulting cement is not contaminated by organic material because the kiln operates at about 1500°C. The process has the advantage that some amount of chloride imparts beneficial mechanical properties to the cement.

Hazardous waste has been used as a supplemental fuel in a lime kiln located near Manitowoc, Wisconsin in a research program run by Monsanto Research Corp. for the EPA. The DRE for each POHC has been measured together with the chlorine and trace metals pyrolysis products. The concentration of stack gas pollutants under baseline and waste fuel test burn conditions were found to be similar and the DREs exceeded RCRA regulations for incineration. Perhaps a disadvantage of both rotary kilns and cement kilns is that they are operated on fixed land sites so that the PCB wastes must be transported to them through the surrounding communities. The siting of hazardous waste disposal facilities is, in general, complicated by the "not in my back yard" (NIMBY) syndrome. The result has been that companies have attempted to mobilize their disposal technology. Offshore incineration has been proposed. Bayer AG in Germany and Solvay Cie in Belgium began using a converted tanker, the 984 ton Matthias I, in 1969. After five years, the ship was replaced with the 3,445 ton tanker the Matthias II. Bayer, Solvay and Westab GMBH are also currently using the Vesta, a 1,356 ton incinerator ship which was converted in 1979.

Oceanic Combustion Services, a chemical waste management company, has used a converted chemical tanker fitted with two large incinerators. This ship, the Vulcanus, was the first to be used in US coastal waters. It sailed from the Mobile-Chickasaw port facility in Alabama to an EPA designated incineration site in the Gulf of Mexico. At-Sea Incineration Co. of Greenwich, Connecticut, also presented a plan to burn PCBs on an incinerator ship operating out of Port Newark, New Jersey. The $74.5 million program was aimed at the construction of two ships, each of which was to be capable of burning 1.3 million gal. of hazardous wastes at each sailing. The disposal rate of liquid wastes through each of the two onboard 170 ton incinerators was expected to be 70 gal./min.

The construction of large scale facilities for the land-based support of ocean incineration was an unresolved issue which contributed to the demise of ocean incineration. Instead, mobile incinerators are being tested which can be used onsite. The EPA has built and tested a reactor built onto a series of four flatbed trailers. A 4.9 meter long, 1.2 meter diameter kiln is mounted on the first trailer and operates at 1000°C with a nominal solids retention time of up to 60 minutes. A secondary combustion chamber operating at 1300°C is housed on the second trailer and provides a secondary retention time of 2 to 3 seconds. The third trailer houses a water quenching apparatus, a wet electrostatic precipitator and an alkaline scrubber for off-gas treatment. The fourth trailer is used for monitoring instruments and controls. The unit was developed at a cost of $10 million and subsequent units are projected to cost $5 million each.

The operating parameters of such equipment must typically provide very high temperatures to make up for the restriction on size which limits residence time. The unit has been extensively tested on 900,000 Kg of dioxin contaminated soil and 80,000 Kg of liquid waste and found to have a destruction and removal efficiency which meets the EPA criterion of 99.99999% while operating at a feed rate of over 2000 Kg per hour.

ENSCO Corporation has developed a mobile rotary kiln incinerator which has been used to treat up to 100 tons per day of contaminated soil. The unit operates in the range of 500° to 1000°C. The off-gas from the rotary kiln has a residence time of over two seconds in a secondary combustion chamber operating at 1000° to 1300°C in an atmosphere with excess oxygen. Acid gases produced in the combustion air are removed with a countercurrent flow of water which is passed through activated carbon filters and then neutralized. The unit operates at a feed rate of about 6 tons per hour and has been demonstrated to achieve 99.9999% destruction and removal efficiency in an 11,000 ton filed trial.

The J.M. Huber Corp. in Borger, Texas began working with Thagard Research Corporation on high temperature fluid wall (HTFW) reactor technology in 1976 and acquired the patents from Thagard. The general operating principle of the process is to rapidly heat materials to temperatures in excess of 4,000°C with a residence time of tenths of a second. The energy input to the waste measured as the integral over temperature and time is then sufficient to obtain the DREs required by RCRA. The technical problem posed in the application of the principle is that the reaction vessel must be able to withstand the operating conditions without becoming chemically or physically degraded. The core is a porous refractory cylinder heated externally by electric elements so that wastes fed into it are heated by radiant energy. The core material allows the permeation of a gas such as nitrogen through the core wall into the interior. The gas is admitted radially to produce an annular envelope which blankets the walls and reduces the contact of the reactants with the reactor. This device tends to avoid the degradation of the reactor. Nitrogen is used partly for the reason that it is transparent to the radiant infrared energy and also because the production of partially oxygenated pyrolysis products, such as PCDFs and PCDDs, is avoided.

In Huber's "Advanced Electric Reactor" a graphite core is maintained at 2200°C with a fluid wall of gaseous nitrogen to avoid oxidation of the carbon. The burned material emerges into a sealed steel container and the offgases are vented through activated carbon cylinders. Fixed site and mobile reactors based on the HTFW technology have been found effective on 2,3,7,8-TCDD contaminated soils. The capacity of the pilot plant is 5,000–15,000 tons/yr with costs in the range $77 to $385/ton.

Plasma pyrolysis of PCBs has been investigated (Barton *et al.*[92]) by both Lockheed Aerospace and the Royal Military College in Kingston, Ontario. The principle is applied on a large scale for the recovery of metals from waste dust generated in steel mills. A plasma consists of both charged and neutral particles exhibiting collective behaviour with an overall charge of close to zero. A common method of plasma generation is electrical discharge through a gas. In the case of a plasma torch, the plasma is stabilized by collimation and resembles the heat source used for atomic emission spectroscopy. Arc temperatures can occur of up to 50,000°K and the material entering the plasma tends to become atomized and ionized.

The overall efficiency of the process depends upon the conversion of the plasma electrical energy into thermal energy. Large scale generators convert about 85–90% of the electrical energy into usable heat and are therefore useful for the rapid decomposition of materials which would otherwise require a long residence time for complete pyrolysis. Nevertheless, extensive work has been done to determine the conditions necessary to avoid the release of chlorinated compounds with molecular weights larger than tetrachlorobenzene.

Pyrolysis Systems Inc. in Welland, Ontario has built the prototype mobile unit for the Department of Environmental Conservation of New York State, which is based on the work done at the Royal Military College. The unit has a throughout rate of one gallon per minute and has shown destruction efficiencies for askarel of the order of 99.9999999%. Atomization of fluids has been estimated to take place in less than one third of a millisecond. The estimated cost is about $300,000 per unit with electrical consumption of about 1.2 kWh/kg of feed. This is about one-tenth the energy cost of incineration. The system is not designed to destroy solid material.

The SKF Steel engineering plant in Hofors, Sweden is constructing a 6 MW plasma generator designed to treat 70,000 tons/yr of waste dust from the steel mill. The cost of the facility is estimated at $23 million dollars. Thus, there is no doubt that the plasma technology can be scaled up but the size of the associated generators and equipment imposes a limitation on its mobility. In the case of the treatment of PCB wastes the siting of a fixed facility is often a difficult, if not impossible issue to resolve so that the limitation of the method in terms of throughput rate is governed by political factors rather than technical considerations.

The circulating bed combustor manufactured by GA Technologies Inc., is an application of fluidized bed technology to the disposal of hazardous wastes. In a fluidized bed unit the temperature is limited to the melting point of the inert support material. In the case of sand this is about 1100°C. The bed acts as a large radiative surface to produce high destruction efficiencies as well as several operating advantages over other incinerator designs. Ogden Environmental Services uses a design in which a high velocity air flow suspends the fluidized bed to give a turbulent combustion zone at about 800° to 1100°C. Solids have a very long residence time of 30 minutes and are discharged with the bed materials into a cyclone and recirculated through the furnace. Gases have a 2 second residence time and are vented through a convective gas cooler and flue gas filter. Ogden has received a National TSCA PCB permit for the use of its circulating bed combustors.

Waste-Tech Services use fluidized bed systems for the destruction of both solids and liquids. Aluminum silicate firebrick particles are used as the bed material in a conical combustion chamber. Air is used to fluidize the bed.

A secondary reaction chamber maintains gases and suspended particulates at about 1100°C for 2 seconds in order to ensure that the required DRE is obtained. A wet scrubber is used to neutralize the acidic off-gas.

The Penberthy glass furnace for hazardous waste was developed by Penberthy Electromelt Inc. in Seattle, Washington. The Unit is a tunnel incinerator with a pool of molten glass maintained electrically at 1200°C. The high thermal capacity bed acts as the heat transfer medium. The unit is insensitive to the form of the waste introduced and the ash is periodically removed with the molten glass. The product is a non-leachable solid matrix which can be landfilled.

Offgas scrubbing is accomplished using either calcium carbonate towers, which react to produce calcium chloride, or wet scrubbing towers using alkaline water followed by an electrostatic precipitator. Particulates are removed with a ceramic filter element. The capacity of the unit can be provided from 100 lb/h to 25,000 lb/h. Its application to the incineration of PCBs has not yet been documented and its usefulness will probably depend on the relative cost of alternative energy sources.

Shirco Infrared Systems have applied a large scale combustion system in which the waste was treated by infrared energy developed by electrically powdered silicon carbide rods in a primary chamber at 1000°C. The residence time of material could be adjusted between 10 and 90 minutes. Volatile materials were given a 2 second residence time in a secondary chamber at 1260°C.

Each mobile unit could be erected on-site in about a week and be capable of processing between 10 and 45 Kg per hour.

SUPERCRITICAL WATER OXIDATION

The oxidation of organics by supercritical water oxidation is being developed by Modar Inc. of Natick, Massachusetts. A mobile pilot plant is being developed and has shown destruction efficiencies for chlorinated organics of 99.99%. The equipment is mounted on a flatbed truck with a capacity of about 0.5 gal. of organics/min. A fullscale unit with a capacity of 25,000 gallons per day is being designed.

The operating principle utilizes the properties of water above 375°C and 3,200 psi where the liquid and vapor phases have the same density (about 0.05 to 0.30 g/mL). Under these conditions hydrogen bonding is much reduced and the dielectric constant is diminished to between 3 to 10 with the result that water becomes a much better solvent for organics and salts are only partially ionized.

High pressure air or oxygen injected into the system causes rapid oxidation of organic material to carbon dioxide and water with chlorine eliminated as chloride. Inorganic salts are precipitated and the supercritical water used for power generation or high pressure steam. The waste stream is slurried with water to give a mixture of 5 to 10% organics and is heated and pressurized to supercritical conditions without charring. The exothermic heat of reaction is able to sustain the process at about 550°C. At the present time the application of this technology is assessed on a site by site basis. Supercritical oxidation of 2,3,7,8-TCDD wastes has been shown to take place with a DRE of 99.9999%.

WET AIR OXIDATION

Wet air oxidation of PCBs and aqueous wastes has been developed by Zimpro Inc., Rothschild, Wisconsin. Zimpro is a subsidiary of ENSCO. The operating principle of the process is similar to that of supercritical water oxidation. The pressure is adjusted to the autogenous pressure of water at the operating temperature, that is, in the range 300 to 3,000 psi between 175°C and 320°C. The process is primarily aimed at the treatment of aqueous wastes which are either too dilute to incinerate or which are toxic to biological treatment systems. If the chemical oxygen demand (COD) is greater than 10 to 15 g/L the exotherm of the oxidation reactions is sufficient to sustain the reaction, whereas incineration does not usually achieve energy sufficiency until the COD of the waste reaches 300 to 500 g/L, depending upon the temperature.

Chlorinated aromatics containing non-halogen functional groups such as phenols and anilines are relatively easily oxidized by the process compared with chlorobenzenes or PCBs. Zimpro is therefore evaluating the use of homogeneous catalysts to increase the destruction efficiency of refractory organics.

The Wetox process is similar to Zimpro's technology. It has been developed by the Ontario Research Foundation and is being marketed by Wet Com Engineering Ltd., Toronto, Ontario. A 25 gpm full scale unit has been put into successful operation at a chemical plant.

The turbulence produced by mixers in the reactor vessel creates eddies and induces the formation of bubbles. The air or oxygen in the system can then react at a faster rate and this, in turn, allows operation of the system at temperatures which are considerably less than in the wet oxidation process (about 225°C/580 psi compared with 175°–320°C/300–3,000 psi). The Wetox process typically reduces the COD of the waste feed by 75 to 95% and produces low molecular weight species in addition to carbon dioxide. Its usefulness for the oxidation of PCBs has not been reported.

MOLTEN SALT

The molten salt process is an old technology which has been considered during the past 25 years as a method for coal degassification. It can, however, be applied (Barclay, 1980[93]) to the destruction of organic and inorganic hazardous wastes, including PCBS. Rockwell Energy Systems Group has developed a system to treat both liquid and solid PCB waste. In 1986 Hydro Quebec built a $4 million salt system housed in several forty foot trailers. The PCB material is introduced at the bottom of a pool of molten sodium carbonate which is maintained at a temperature of about 900°C and reacts as it migrates to the surface. The sodium carbonate is converted to sodium chloride. PCB destruction in a 6-inch depth of molten salt was determined in the Rockwell Energy Systems Group process as a function of the pool temperature using 53–65% excess air and the destruction efficiencies found to vary in the range 99.99917% at 745°C to 99.99971% at 912°C. As the depth of the molten salt pool is increased so the destruction efficiency increases because of the longer residence time and Rockwell points out that the deeper salt beds of commercial units would probably achieve higher destruction efficiencies than was observed with the laboratory scale system.

The product gases were analyzed for CO, CO_2, HCl, Cl_2 and $COCl_2$. The sodium carbonate tends to react with acid gases and reduces the need for downstream scrubbing systems. It was found that less than 2 ppm HCl was formed provided that 1–2%, Ca_2CO_3 remained in the melt. Less than 0.25 ppm of phosgene was detected and about 0.5 ppm of Cl_2 (or perhaps NO^x).

Inorganic, high melting, products such as sodium chloride build up in the melt until it eventually solidifies and the destruction efficiency is reduced. The continuous process provides for this by adding more sodium carbonate to maintain the fluidity of the pool. However, even when the pool had been almost completely converted to sodium chloride PCB destruction continued. Under these circumstances the process can no longer be classified as a high temperature organic/inorganic reaction but rather is a pyrolysis. The EPA requires a 1200°–1600°C temperature for incineration coupled with a sufficient residence time at the chosen temperature to avoid inadvertent generation of products of incomplete combustion (PlCs) such as PCDFs and PCDDs.

Mobile molten salt reactors have been constructed but are costly. A system with a capacity of 225 lb/h was estimated by Rockwell to cost approximately $1.5 million. The solids handling equipment increases the cost by a further $250,000. The operational costs are not high once the capital cost is overcome because the reaction exotherm provides heat and the only reagent expended is sodium carbonate.

DIESEL DISPOSAL

D. and D. Disposals Ltd., based in Smithville, Ontario have evaluated the use of diesel engines to incinerate PCBs. Three six cylinder units were mounted onto a flatbed truck to give a throughout of about 8 gal. of PCB per hour. The cost estimate for each engine was about $300,000. The Ontario Research Foundation has undertaken measurements of PCB destruction efficiencies and found that 99.998% can be achieved when an 80/20 blend of diesel fuel/PCBs is burned at about 590°C in the cylinder head.

OZONOLYSIS

The Royal Military College in Kingston, Ontario and the University of California, Riverside, have both investigated the use of ozone to oxidize PCBS. A six- to eightfold excess of ozone over the amount required for stoichiometric reaction was found to produce a 90–95% conversion of PCBs. The extent of formation of PCDFs and PCDDs from askarel fluids can be expected to depend upon the particular reaction conditions so that the potential problems which the operation of the method may have are intended to be alleviated by critical control. About 100 lb of PCBs require approximately 100 lb of ozone. About 1000 kWh of electricity are used to produce this quantity of reagent and therefore the method is not likely to be as cost competitive as some incineration processes although it may be proven useful for the destruction of PCBs diluted into trace quantities in the environment. The application of the ozonolysis reaction to PCB contaminated waters is discussed below in the discussion on radiation methods.

Palauschek and Scholz[94] have applied ozone destruction methods to PCDFs and PCDDs in water. They found that degradation takes place only under alkaline conditions of pH 10 as a result of the generation of hydroxyl radicals by reaction between ozone and water. Ozone does not directly attack PCDDs/PCDFs in aqueous solution. The method is therefore not likely to be useful for the treatment of oily wastes in which the chlorinated aromatics are confined to the oil.

CHLOROLYSIS

Hydrocarbon wastes have been reacted into useful products by adding rather than removing chlorine. The chlorolysis reaction has been used on a large scale by Hoechst A.G. (Jackson[95]). The process involves the reaction of chlorine gas at high temperature (about 640°C) and pressure (about 25 MPa) with the partly chlorinated waste stream to yield carbon tetrachloride and hydrogen chloride. The generalized reaction is

$$C_xH_yCl_z + (4x + y - z)/2Cl_2 \rightarrow X\ CCl_4 + y\ HCl$$

The method has been used primarily to treat aliphatic wastes rather than PCBs and is limited to feedstocks which contain approximately 5% aromatics unless considerable modifications are undertaken. The reaction conditions necessary to treat askarels may involve an increase in the process residence time or the use of a catalyst to promote the reaction. The reaction products are easily separated from the process by distillation and the mixture which remains is then recycled to the reactor.

Carbon tetrachloride and hydrogen chloride are marketable reaction products. However, the health effects associated with carbon tetrachloride have tended to curtail its use. The reaction is exothermic, which helps to keep operating costs low, but the disadvantage of the process lies in the need to use high purity nickel construction at a high capital cost in order to overcome the extremely corrosive nature of the chemicals involved.

HYDRODECHLORINATION

Ahonkhai *et al.*[96] have investigated the thermal hydrodechlorination of hexachlorobenzene by passing chlorobenzene vapor into a quartz tubular flow reactor at different temperatures. Above about 900°C a $> 99\%$ conversion to HCl was observed. When H_2 was replaced by CH_4 the same reaction took place but it occurred with the formation of copious quantities of soot.

The catalytic hydrodechlorination of PCBs was investigated by Lapiere and co-workers[97] using either 61% nickel on Kieselguhr or 10% palladium on charcoal. The method requires the handling of high pressure hydrogen at 30–50 atmospheres and the HCl produced is a source of catalyst poisoning and corrosion problems. Approximately 90% dechlorination is achieved in five hours at 100–200°C.

A nickel catalyzed zinc reduction of PCB has been reported by N.S. Chu and S.C. Vick[98]. The reaction is best carried out in an aprotic solvent, such as dimethylformamide (DMF), rather than a protic solvent such as water or alcohol. The major reaction product of PCBs is biphenyl. The reaction of trichlorobenzene in a mixture of MDF and methanol was found to be essentially complete after four hours at 50°C.

The mechanism of reaction was suggested to parallel the $Pd(OAc)_2$ catalyzed dehalogenation reaction reported by Okamoto and Oka[99]. These authors explain their observations by proposing that a low valent metal complex was generated in situ and reacts with aromatic halides to give oxidative addition products which are then reduced by the alkoxide ion. The nickel catalyzed reaction of Chu and Vick was therefore suggested to involve similar steps as follows.

- the reduction of Ni(II) to Ni(0) by Zn;
- oxidative addition of aryl halide to the lower valent Ni and;
- reaction of the aryl-Ni species with alcohol solvent to form a reduced product or reaction with another aryl halide to give a coupling product.

A similar mechanism may exist for similar catalytic reactions involving the Pd or Ru catalyzed reduction of aromatic halides by hydrogen sources, such as hydrazine,[100] amine,[101] formate,[102] alcohol or alkoxide.[99]

A uniquely effective catalytic dechlorination method currently under investigation by the author and which will be the subject of patents, has been shown to completely dechlorinate Arochlor 1260, a transformer dielectric fluid, *in 4 minutes at room temperature.* The reagent, packed into a column configuration in a mobile system, allows the reaction to be used on-site for the destruction of askarels under mild chemical conditions without the liability of transportation and interim storage at a high temperature incinerator facility.

MATRIX ISOLATION

Solid solutions which are held together by weak Van der Waals forces are probably inapplicable to the fixation of PCBs. A chemically fixed product, on the other hand, is able to hold the contaminant even though it may fragment under service conditions. A third type of fixation product is one which contains microencapsulates. Microencapsulates consist of microscopic and macroscopic contaminant particles encased by the fixative to yield a product which maintains its integrity under environmental stress (Lubowik *et al.*[103]). PCB fluid has been disposed of as a nonleachable solid waste by microencapsulating it in concrete. The effectiveness of the method is limited for large volumes of PCBs because of the amount of concrete which is generated and the possible risk associated with the long term leachability of the product.

Organic wastes are not usually amenable to fixation but Envirosafe Services Inc., in Horsham, Pennsylvania has used pozzolanic chemistry to chemically fix PCBs in a rock-like product which has good load-bearing properties and which is hydrolytically stable. Three PCDD contaminated sites in Missouri have been used to assess the feasibility of cementitious and asphaltic stabilization techniques. Asphalt alone was found not to be satisfactory but a combination of lime and asphalt was found to solubilize the 2,3,7,8-TCDD sufficiently to avoid its detection in leachate studies.

VITRIFICATION

It situ soil vitrification is being proposed by Battelle (des Rosiers *et al.*[104]) in which heat from the electric current passed into electrodes placed in the ground converts the soil and its contaminants into a non-leaching fused glasslike material. Temperatures exceeding 20,000°C are produced. Gases and volatile materials are collected and treated on the surface. The product obtained is a grasslike material which is more or less homogeneous depending upon the duration of heating and the extent of convective mixing which has occurred while the zone is molten.

TRANSFORMER RETROFILL

The retrofilling of askarel transformers to a safe and cost-effective level would practically eliminate the 99.8% of PCBs located in transformers. Work done by M. Erickson *et al.*[23] at Midwest Research Institute on the formation of toxic pyrolysis products in PCB contaminated transformer oils has shown that there is a narrow range of temperature and oxygen conditions which permit the formation of PCDFs and PCDDs from PCBs and chlorobenzenes from dilute solutions. The probability of formation of toxic products from low concentration askarel residuals in retrofill fluids at concentrations of concern under real world conditions, however, seems to be extremely small. For example, a fire which occurred in the basement transformer vault of the Electrical Engineering Laboratory of the University of Manitoba during March, 1982 involved six mineral oil transformers contaminated with 250 ppm PCB. An electrical failure had caused one of the transformers to arc and catch fire. All six transformers were damaged by the fire. During fire-fighting attempts, a transformer exploded and sprayed PCB contaminated soot onto the walls. No PCDFs or PCDDs were detected.

When a transformer is retrofilled to < 500 ppm PCB one would expect that the rate of conversion of PCBs would be very much less than in the case of an askarel fire. It becomes increasingly less probable that a large enough quantity of pyrolysis products would be produced as the concentration of PCBs and chlorobenzenes is reduced. Indeed, the contaminated mineral oil fire in the University of Manitoba resulted in no detectable concentration of PCDFs in the soot. PCDDs, which are typically formed at an order of magnitude less concentration than PCDFs, were not detected either.

In 1970 Vos *et al.*[12] showed a correlation between the toxic effects of European PCBs and the concentration levels of PCDFs. The major PCDF components contained in Yusho oil were the highly toxic 2,3,7,8-TCDF and 2,3,4,7,8-pentaCDF. The relative concentrations of the PCDF isomers present in Yusho oil and in samples of used heat exchanger PCBs (Kanechlor KC 400 and Mitsubishi-Monsanto T 1248) were found to be strikingly similar (Kuratsune *et al.*[29]). The overall toxicity of the fluid may then be attributable to the presence of small quantities of PCDF as degradation products of PCBs.

A 1981 EPRI study[105] of the equilibrium distribution of PCBs between transformer solid materials and the liquid dielectric showed that, for a typical 500 kVA transformer, about 97.5% of PCBs are dissolved in the oil while only 2.5% are unevenly distributed among the paper, core steel and Formvar wire. The majority of the PCB on the solids is contained either adsorbed or absorbed in the paper.

An oil temperature fluctuation between 50°C and 110°C causes a maximum shift of only 0.6% in the amount of dissolved PCBs when adsorption/desorption is considered alone. The effect is much larger when multiple layers of paper are involved because the migration of absorbed PCBs through the capillaries of the impregnated paper causes a gradual leaching which results in a final PCB concentration in the bulk oil which usually exceeds the EPA definition of a PCB fluid.

The study contains important implications regarding the efficacy of retrofilling transformers using *current* technology. The difficulties in obtaining a cost effective retrofill solution would be avoided if technology were proven to circumvent the problem of PCB migration into the bulk oil. Here, again, it is important to recognize clearly the difference between the retrofill of PCB contaminated transformers and askarel transformers which have been impregnated with PCBs.

In the case of a PCB contaminated mineral oil transformer it would be possible to reduce the PCB concentration of the working fluid by first draining the transformer and refilling it with non-contaminated oil. Since the large majority of PCBs are contained in solution, and are not trapped by the porous insulation, it is possible to retrofill the transformer to a required concentration level by repeated washings, as necessary. The drained, PCB contaminated oil can be disposed of by one of the several suitable methods discussed in this section. On the other hand, even if all the askarel fluid of a PCB transformer were to be washed out there would, according to the EPRI report, still be about 2.5% of the original askarel contained in the core/coil assembly. For a typical 235 gal. PCB transformer this amounts to about 5.9 gal. of askarel impregnating the porous insulation. A PCB concentration of 500 ppm in a 235 gal. transformer amounts only to about one coffee mug in volume.

The diffusion of PCBs under the action of a strong concentration gradient from the interior of the paper towards the very low concentration in the bulk retrofill fluid has been discussed earlier. If the trapped PCBs are able to leach out into the bulk retrofill fluid at a rate of as little as 1 ppm per day, it would need less than 1.25 years before the fluid concentration had climbed above 500 ppm and the unit would have to be regarded once again as a PCB transformer.

The molecular geometry of the PCB molecule makes it susceptible to adsorption on carbon. Therefore, when an askarel transformer is drained and filled with polymethylsiloxane (silicone) oil rather than an oil which contains molecules with the geometry or benzene rings, the only aromatic structures present are those of the contaminant to be removed. The capacity of the carbon for the adsorption of aromatic species can be determined from Freundlich's characteristic isotherm. This can then be used to calculate the number of filters of a given size required to reduce the residual askarel concentration in the bulk oil to a defined lower concentration. The higher the initial concentration of PCBs remaining after draining the transformer, the larger will be the number of filters needed to adsorb the residual PCBs.

As more filters are used so the overall cost of the retrofill approaches the cost of a new transformer. The rate of PCB reduction is partly governed by the recontamination of the oil and partly by the adsorption/desorption/leaching process itself.

(2) THE DISPOSAL OF PCB CONTAMINATED LIQUIDS

Disposal options for PCB contaminated liquids are shown in Figure 47. As stated earlier, PCB contaminated liquids are understood to mean that the PCB is a minority constituent of the fluid, usually at a concentration measured in parts per million, but not necessarily less than the 500 ppm definition of PCB fluid regulated by the EPA.

The most easily identified large volume of PCB contaminated fluid is that used by the electrical industry in its mineral oil transformers and the emphasis in this paper is therefore placed upon the disposal of contaminated dielectric oils. Contaminated fluids can be incinerated in the same way as askarels but, in addition, the EPA has granted approval for some companies to destroy their own low-level oils in high efficiency boilers. The disadvantage of the process is that it not only destroys the PCBs but also the transformer oil.

Environmental Science and Engineering Inc. in Gainesville Florida has conducted an analysis of the pyrolysis products of dilute PCBs in a utility "High Efficiency Boiler" and found that PCDFs and PCDDs were not detectable by the GC/MS method used. PCBs were destroyed with

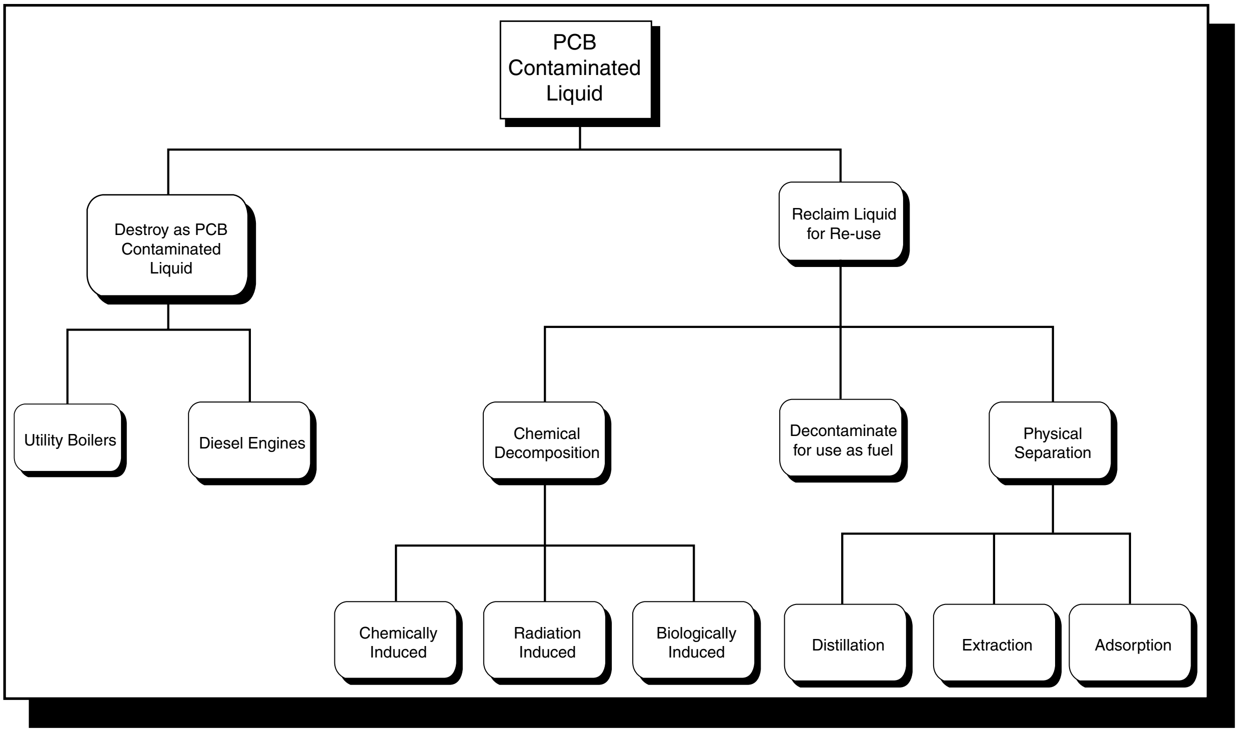

FIGURE 47 The disposal of PCB contaminated liquids.

99.99999% efficiency. Because of the increasing short supply of base stocks suitable for use as electrical transformer fluids it is becoming increasingly necessary to reclaim the oil. Also, the once empirical reclamation procedures practiced in the industry are on a sound scientific footing today so that there is no need for the concern that there once was regarding the performance of reclaimed product (Webber[106]).

Physical processing methods which do not chemically alter the components of the oil, and which do not leave residues of the process in the decontaminated fluid, are less likely to result in changes to the properties of the oil than are chemical destruction methods.

CHEMICAL EFFECTS OF DECONTAMINATION PROCESSES

The accepted properties of new mineral transformer oil and oil requiring reclamation are summarized in Table 54. It is appropriate at this point to describe the characteristics of transformer oil.

Power Factor The ratio of the power in watts dissipated in the oil, to the product of the effective sinusoidal voltage and current in volt-amperes. It is expressed numerically as the sine of the dielectric loss angle. An increase in power factor corresponds to an increase in the concentration of polar constituents in the oil and is used as a measure of the extent of oxidation.

Neutralization Number The total acid number is defined as the quantity of base, expressed in milligrams of potassium hydroxide, required to neutralize the acidic compounds in 1 g of oil. The acids present in service-aged oils are due to oxidative degradation.

Interfacial Tension The molecular attractive force between oil and water expressed in units of dynes per centimeter. As the concentration of polar contaminants in the oil increases the interfacial tension (IFT) value decreases. The test is therefore an indirect measure of the oxidation which has taken place in the oil.

An important question concerning reclamation is whether or not reclaimed oil is equivalent to new oil and, in particular, whether or not reclaimed PCB decontaminated oil is equivalent to new oil. The fuller's earth treatment of partially oxidized oils is primarily effective in reducing the neutralization number and power factor to acceptable levels but is relatively less effective in producing values of interfacial tension, color, etc., typical of new oils. Fuller's earth treatment does not remove PCBs or ditertiary-butyl-p-cresol (DBPC) oxidation inhibitor (Webber[106]). However, chemical processes for the PCB decontamination of oil involve highly reactive alkali metals or organometallic reagents which have a strong affinity for the most easily reduced components of the oil.

Polarographic reduction is a measure of the ease with which a compound will accept an electron and this therefore allows an assessment of the relative reactivities of radical

TABLE 54

Test	ASTM test method	New oil	Typical properties of oil requiring reclamation
Dielectric Breakdown	D–877	>30	22
(kV)	D–1816	>56	—
Power Factor 60 Hz, 25°C	D–924	<0.05	1.6
Neutralization Number (mg KOH/g oil)	D–974	<0.03	0.40
Interfacial Tension (dynes/cm)	D–971	40	18
Moisture Content (ppm)	D–1533	—	60

anions. Polarographic measurements are usually made in 75% aqueous dioxane solution of the flow of current through the solution as a function of the applied potential. When reduction takes place a wave of current is produced. The potential measured at the mid-point of the wave is referred to as the $e_{1/2}$, value. The $e_{1/2}$ values for some of the aromatic hydrocarbons which can be used for PCB decontamination agents, together with values for their electron affinities, are listed in Table 55.

TABLE 55

Compound	Electron affinity (eV)	$e_{1/2}$
Biphenyl	—	2.70
Naphthalene	0.152	2.50
Phenanthrene	0.308	2.46
Anthracene	0.552	1.9

As one goes down the list, the electron affinity of the larger aromatic molecules reflects the relative ease with which an electron added to the system can spread itself through the structure without causing high energy points of stress. The relative ease of reduction therefore follows the same order and anthracene is much more easily reduced than biphenyl. The reactivity of the radical ions is therefore expected to decrease down the list. Thus sodium biphenyl has been known for many years to quickly and quantitatively react with organochlorine compounds. The reaction is useful for use in the field as an inexpensive screening tool for potentially contaminated oils. Also, sodium naphthalenide is used in the Goodyear/(Smith and Bubbar) process (Smith and Bubbar[107]) for the PCB decontamination of fluids. The reactions of alkali metals and organometallic reagents with the classes of compounds typically found in insulating oils is perhaps best discussed in terms of compound classes. A typical distribution of compound types in mineral transformer oils is shown in Table 46.

ALKANES

Oils which are totally paraffinic are essentially inert to radical ions. It has been found for example, that when a sodium dispersion is made in a high molecular weight paraffinic oil direct from the manufacturer, and then subsequently filtered, that the oil properties remain unchanged.

ALKENES

This class of compounds is not expected to occur in significant quantities in transformer oils. If they were present, they would most probably undergo their most common reaction of polymerization and precipitate out of the oil into the sludge layer. An alternative possibility is that the olefin may add to the alkyl side chain of an alkyl aromatic compound. In either case it is most unlikely that the products of such reactions would deleteriously affect oil properties and indeed such reaction products may occur naturally in some oils.

ALDEHYDES AND KETONES

Aldehydes are a class of compound which, because of their reactivity, are not expected to be present in oxidized oil in significant quantities. Ketones, on the other hand, are known to be present as primary oxidation products (Webber[106]; Holy[108]).

The oxidation of hydrocarbons produces, successively, hydro-peroxides, alcohols and ketones, and finally acids. The fuller's earth reclamation process is effective in the removal of acids but does not remove their precursors. The presence of even small quantities of acid can cause a catalytic effect on the decomposition of ketones to give further acids. Oil which has been reclaimed by the conventional fuller's earth treatment is therefore likely to oxidize more rapidly than new oil with the same concentration of oxidation inhibitor and this is usually found in practice.

The reactions of aromatic ketones with radical anions lead to reduction of the ketone and yield an alcohol as the major product (Holy[108]). The importance of alcohols as oxidation inhibitors can be understood in terms of the mechanism of oil oxidation as follows:

$$
\begin{array}{lll}
\text{Initiator} + [\text{R}-\text{H}] & \rightarrow & \underset{\text{I}}{\text{R}\cdot} + \underset{\text{I}}{\text{R}'\cdot}\ (\text{Initiation}) \\
\text{R}\cdot + \text{O}_2 & \rightarrow & \underset{\text{II}}{\text{ROO}\cdot} \\
\text{ROO}\cdot + \text{R}-\text{H} & \rightarrow & \underset{\text{III}}{\text{ROOH}} + \text{R}\cdot\ (\text{Chain Propagation}) \\
\text{ROO}\cdot + \text{R}\cdot & \rightarrow & \text{ROOR}\ (\text{Termination}) \\
\text{R}\cdot + \text{R}'\cdot & \rightarrow & \text{R}-\text{R}'\ (\text{non-radical products}) \\
\text{ROO}\cdot + \text{R}'\text{OO}\cdot & \rightarrow & \underset{\text{IV}}{\text{ROH}} + \underset{\text{V}}{\text{RCOR}}
\end{array}
$$

The hydrocarbon in the initiation step splits into free radicals (I) which, with dissolved oxygen, forms peroxide radicals (II). The reactivity of a peroxide radicals depends upon its structure. If it is sufficiently reactive, it will be able to abstract a hydrogen atom from a nearby oil hydrocarbon molecule and partially stabilize itself as a hydroperoxide molecule and yield a further radical. This is the chain propagation step.

The peroxide radical, (II), can be terminated by reaction with the initial hydrocarbon radical, (I), to produce an ester. Alternatively, two peroxide radicals can react to give an alcohol and a ketone or two hydrocarbon radicals can react to form non-radical products.

The hydroperoxide can decompose as follows (degenerate branching):

$$
\begin{array}{l}
\text{ROOH} \rightarrow \text{RO}\cdot + \cdot\text{OH} \\
2\text{ROOH} \rightarrow \text{RO}\cdot + \text{H}_2\text{O} + \text{ROO}\cdot
\end{array}
$$

The reaction scheme illustrates why it is that a large variety of oxidation products is typically found in used oil. The rate of oxidation is determined by the concentration of peroxy radicals. When an oxidation inhibitor is added to the system, its primary function is to scavenge peroxy radicals and in doing so itself becomes a radical.

The important difference between the initial peroxy radical and the newly formed species is that the product radical is more stable than the reactant radical. The degree to which the product radical is more stable is a measure of the effectiveness of the compound as an oxidation inhibitor. Such compounds as phenol show an inhibitive effect towards oxidation in white mineral oil (Ingold[109]), but the most efficient inhibitors are found to be sterically hindered phenols such as di-tertiary-butyl-p-cresol, DBPC. From the above it would be excepted that the formation of aromatic alcohols from a chemical decontamination process in particular would give rise to "natural" oxidation inhibitors. It is probable that the inhibition produced in this way is less than would be achieved using DBPC but at least the oil should not be deleteriously affected.

The presence of oxidation inhibitors is important for the reasons that they are essential to the oxidation stability of the reclaimed oil and that oxidation inhibitor retards the free radical dechlorination reaction of reagents with PCBs. In some cases, for example reactions with metallic sodium, the dechlorination reaction shows a very marked "induction" period while the alkali metal reacts with oxidation inhibitor. The reaction products are highly colored because of their quinoidal structure and it is these compounds which are the cause of the yellow color normally attributed to oxidized oil. The quinoidal product is not sufficiently polar to be adsorbed by fuller's earth during the reclamation process and is not detrimental to the dielectric properties of the oil.

A characteristic of the reaction of alkali metals and organo-metallic reagents with oil components and PCBs is that a sludge is produced. Filtration of the fine precipitate, followed by washing and analysis by a variety of analytical procedures, shows (Webber *et al.*[61]) that the sludge contains predominantly non-chlorinated polyphenyls and is therefore not a toxic hazard.

Biphenyl is a reaction product together with a large range of high molecular weight polyphenyls. It is the production of partially soluble compounds in the intermediate molecular weight range which can sometimes cause problems. The reason is that long chain polyphenyls can exist as biradicals (Brown *et al.*[63]) and contribute strongly towards a high power factor oil. The effect is particularly noticeable when treatments are applied to mineral oils which contain more than a trace of high molecular weight aromatics. In these cases, if the oil is left standing in contact with organometallic reagents for a period of a few hours, the aromatics in the oil provide enough solubility for the polyphenyls to produce a power factor of more than 50%. The problem can usually be avoided by separating excess chemical reagent from the decontaminated oil immediately after the dechlorination reaction has taken place.

DISTILLATION AND EXTRACTION

The separation by distillation of transformer oil and askarels has been evaluated by Battelle-Columbus Laboratories and D.&D. Disposal Inc. Transformer oil is usually a high boiling fraction of crude oil which is distilled under vacuum to avoid degradation. The oil contains a large variety of low vapor pressure compounds. PCBs also have a low vapor pressure and the difficulty in separating a small quantity of contaminant from the oil lies in the overlap of the boiling ranges of the components. Since the PCBs are typically higher boiling than most mineral oil components, conventional distillation requires that most of the fluid be distilled before the PCBs can be separated as a residue. The process is both inefficient and requires a lot of energy.

Steam stripping is an alternative to vacuum distillation. Separations can be achieved at atmospheric pressure at temperatures which do not cause thermal degradation. The method shares the disadvantage of conventional distillation that many components exhibit overlapping boiling ranges. The addition to the PCB in oil system of an agent capable of forming a low boiling azeotrope has been investigated. In this case, separation can be accomplished by distilling a small quantity of azeotrope rather than a large quantity of transformer oil.

Solvent extraction of PCBs from transformer oil has been investigated by Oak Ridge National Laboratory using dimethyl formamide. A second stage solvent extraction with water reduces the volume of fluid for disposal. The process may be found particularly useful in the treatment of PCB contaminated lubricating oils since fluids of this type typically contain additives which tend to react with alkali metal organometallic dechlorinating reagents thereby making the process expensive in both reagent and additive replacement cost.

The Franklin Research Center has reported (laconianni *et al.*[110]) a study in which measurements were made of the partition coefficients of PCBs in a range of potential solvents while General Electric, under EPRI contract, has developed a solvent extraction process for separating PCB from mineral oil. Patents have been assigned to the USA for the extraction of PCBs from oils using organic solvents such as methanol or isopropanol. In these cases the extracted mixture can be distilled to recover solvent and the solvent recycled. The difficulties encountered with these methods may out-weight their potential advantages in the treatment of transformer oils. It does not seem likely that the solutions offered by physical methods will compete favourably with those offered by chemical destruction systems.

RADIATION

The dehalogenation of askarels involves an initial addition of an electron to the aromatic molecule. There is little chemical difference whether the electron is derived from metallic alkali metals or organometallic compounds or from electrons generated in solution by the absorption of radiation. The UV-photolysis of PCBs in organic solutions produces reductive dechlorination of the PCB as the main photochemical reaction while in aqueous or alcoholic solution replacement of the chlorine by a hydroxyl group also occurs (Plummer[111]). A review on the photochemical degradation of PCBs to yield less toxic and more toxic products has been written by Safe *et al.*[112]

The Atlantic Research Corporation in Alexandria, Virginia experimented with a UV/H_2 system to dechlorinate PCBs in 1983. More recently, G.A. Epling and coworkers at the University of Connecticut[113] have reported on a hydride-enhanced photoreaction of PCDDs in which the reaction system was found not to be overwhelmingly influenced by the presence of impurities. In general, impurities tend to quench target molecule excited states and competitive light absorption by impurities also causes a slowdown in the rate of photoreaction. In the PCDD isomer systems tested, however, the presence of borohydride caused an enhancement of photoreaction in the range of about 2 to 6 times the rate observed without borohydride. Also, the photoreaction in the presence of sodium borohydride proceeded to yield predominantly the direct dehalogenated product. Ultimately, the completely dechlorinated dibenzo-p-dioxin was formed.

BH_{4-} can be used as a strong nucleophile in the presence of catalytic amounts of tris(triphenylphosphine)-nickel(0). The reaction has been reported[159] by Shaw-Tao Lin and J.A. Roth (1979). The reaction uses conditions of about 70°C, a nitrogen blanket, and a reaction time of 16 hours to produce an 80% benzene yield.

Roth *et al.* (1994)[160] describes the hydrodechlorination of a series of PCBs. They found that $NaBH_4$ caused the dechlorination of mono- and di-chlorobiphenyls in DMF solution without catalysts, but the reaction was very slow (15–20 hours) and the extent of dechlorination was very small (1–5%). On the other hand, Ni_2B reactions in which a reactive form of hydrogen is on the surface of the solid was said to produce dechlorination. Roth also used a homogeneous dechlorination reaction with tetrakis-(triphenylphosphine)-nickel (0), which is an air sensitive complex soluble in dimethyl formamide. Small concentrations of around 2000 ppm PCB were dechlorinated between 60–100 minutes at room temperature.

The Westgate Research Corporation in Los Angeles, California has developed a process known as the Ultrox system which involves the UV-catalyzed ozone oxidation of chlorinated organics in industrial waters. Hydroxyl radicals are frequently proposed as the reactive species in the UV-ozonation of organic compounds. However, according to the experimental data obtained by Leitis *et al.*[114] the major oxidizing species in the UV/O_3 Ultrox system is ozone itself. Carbonhalogen bonds are broken before other structures are oxidized and the halogen atoms appear in solution as halide ions. A synergistic effect between ozone and UV light has been observed. The magnitude of the effect is greater at low (1 ppm) that at high (100 ppm) concentrations of PCB.

It is postulated that the mechanism of oxidation of chlorobenzene in the Ultrox process is as follows:

Chlorobenzene + UV/O_3 → chlorophenol
→ mixture of [(chloro)
catechol + (chloro)
resorcinol +
(chloro)hydroxyquinone → trihydroxyl(chloro)
benzenes
→ (chloro)muconic acids
→ maleic aldehyde
+ glyoxylic acid
→ oxalic acid
→ $CO_2 + H_2O$

A 40,000 gallon per day (gpd) Ultrox system consisting of a reactor and ozone generator, costs about \$125,000 with O&M costs per day of about \$175. For a 150,000 gpd system the equipment cost is about \$300,000. O&M costs for the large system are about \$330 per day so that the cost to process 1000 gal. of waste water, including monitoring labor, is about \$4.35 for the smaller unit and about \$2.21 for the larger system.

Virontec has applied the UV/O_3 technology in its RADINOX® process. A full-scale treatment system was applied to a PCP-contaminated wood preserving site in Oregon during 1988. Data from bench scale tests showed that PCP concentrations were reduced from 10 mg/L to 0.5 mg/L in a 30 gal./min. continuous flow reactor.

C.H. Langford and his co-workers[115] have studied the UV photodecomposition of several chloroaromatic compounds using a semiconductor catalyst. It was suggested that a photogenerated reactive species is desorbed from the TiO_2 surface by band-gap excitation. The species was not identified but it was pointed out that hydroxyl radicals have been considered as the reactive species in several studies and that the superoxide ion (O_2) shows nucleophilic and oxidative characteristics in a variety of systems (Matthews[116]). In particular, Sugimoto *et al.*[117] showed that polychlorinated aromatics were degraded by a superoxide ion initiated pathway.

R. Niessen *et al.*[118] have studied the phototransformation of phenols by excitation of nitrate ions. They pointed out that nitrates are probably one of the main sources of hydroxyl radicals in natural waters exposed to daylight. The gamma-ray radiolysis of halogenated benzenes was investigated by Choi and Willard" using a high activity Co^{60} source. It was found that many similarities existed between UV photolysis reactions and those initiated by gamma rays. The work was applied in 1971 to an environmentally persistent pesticide, DDT, and in the following year Arai *et al.*[58] applied the method to solutions of PCBs.

A high energy gamma-ray passing through matter typically leaves a track of ionized particles and electrons. The solvated electrons have a very high affinity for atoms such as chlorine and abstract them from the PCB molecule as chloride ion. The reaction leaves the original PCB in a highly reactive "free radical" state with one chlorine less than it had originally. A free radical chain reaction can then occur in which there is a cascade of progressively more dechlorinated free radical products. Eventually, a stable configuration is reached and biphenyl and polyphenyl products are observed.

Van de Graff generated electrons have been used to study the effects of high energy electron irradiation (3 MeV) on persistent toxic trace components in sludges and wastewater by Merrill *et al.*[119] at MIT. It was observed that in pure, deoxygenated solutions dechlorination did occur and that the reaction products became more water soluble than the starting compounds. Aromatic carbons and typical insulating oil compounds are resistant to breakdown by high energy radiations. A project was therefore undertaken for the Canadian Electrical Association (Webber[60]) to investigate the possibility of decontaminating electrical insulating oils using beta-particles (2 MeV electrons) from a radioactive Sr^{90} source.

Irradiations were conducted at Simon Fraser University using different askarels in transformer oil both with and without isopropanol, potassium hydroxide and air. The PCB mixtures were found to be dechlorinated by beta-particle radiolysis most efficiently in isopropanol/KOH solutions. The solution acts as an alkaline hydrogen donor and allows free radical chain propagation to occur in the absence of oxygen as a free radical scavenger. The reaction also occurs when commercial askarels are dissolved in transformer oils but very large radiation doses, and hence reaction times, are then required for complete dechlorination. The efficiency of the Sr^{90} induced beta-particle reaction measured in terms of its $G(Cl^-)$ value, was found to be only about 7×10^{-3} i.e., about 10^5 times smaller than the efficiency of the Co^{60} gamma-induced reaction in Willard and Choi's work[57] but about 400 times more efficient than the reaction induced by high energy, accelerated electrons. The work was stopped because of the lack of applicable reaction kinetics and because the method has the potential to produce the hydroxylated precursors of PCDFs and PCDDs. The reaction mechanism was discussed in an earlier section on the formation of compounds of concern and shown in Figure 18.

BACTERIOLOGICAL

The distribution and fate of PCBs in the environment depends on their dispersion and partition as well as their susceptibility to degradation by various routes.

A number of papers have been written on the subject[120–132] and this area of investigation may become increasingly important for the in-situ decontamination of soils and the cleanup of spills. Biological treatments for industrial waste systems have been in use for many years but it is only recently that new microbial strains have been developed which show promise for the treatment of environmentally persistent compounds.

In a study on the persistence of Aroclor 1254 in various California soils it was found by Iwata *et al.*[132] that some considerable changes had taken place after 1 yr. of incubation at 30°C and 40% moisture content. It was pointed out, however, that the loss of some of the components may have been due to evaporation. Bailey *et al.*[133] used C^{14}-labelled compounds to obtain material balances in their PCB degradation study in river water. They found that monochlorobiphenyl degraded rapidly ($t_{1/2}$ <2 days) to chlorobenzoic acid which, in turn, degraded to carbon dioxide and water. By way of contrast, the 2,2',4,4'-tetrachlorobiphenyl studied under similar conditions showed no measurable degradation during a period of 50 days. The degradability of PCBs in lake sediments has been found to decrease with an increasing degree of chlorination of the biphenyl. Half-lives for the different congeners range from a few days for dichlorobiphenyl to 200 days for pentachloro-compounds. Biodegradability is also affected by the position of chlorine substitution on the biphenyl ring. Neely[134] has developed a mathematical model to predict the lifetime of selected chlorobiphenyl congeners in the environment. His conclusions predict a half-life of about 3 days for monochlorobiphenyl, 150 days for di-, 579 days for tri-, 1044 days for tetra- and 3445 days for penta-.

Camoni *et al.*[135] evaluated the microbial degradation of TCDD in Seveso soil. Samples were analyzed in the presence and absence of organic compost. The results indicated a 25 No degradation of any of the% reduction in TCDD concentration in 480 days. Studies have also indicated that the average TCDD remaining in the soil after 1 year of weathering was approximately 50% at all the concentrations tested (1 to 10 ppm). The results are complicated by the uncertain contribution of photodegradative effects. On the other hand, research by Huetter *et al.*[156] and also by Young *et al.*[137] indicates that microbial degeneration of TCDD in soil is very slow under the most optimum conditions and therefore tends to support a conclusion that PCDDs are essentially non-biodegradable. Several strains of bacteria have been discovered which can metabolize PCBs. These represent five genera, Acetobacter, Acinetobacter, Alcaligenes, Klebsiella and Pseudomonas. The bacteria are found in river sediments.

A combination of photodegradation and bacterial degradation has been investigated by R.A. Clyde in Asheville, N.C.A. porous, high area, fiber webbing impregnated with bacteria was mounted inside a tubular reactor so that the webbing could be rotated on an axle and drawn through the solution flowing through the lower half of the tube. A subsequent chamber admitted UV light to degrade any reactive material remaining after the bacterial treatment. The process has been reported to be useful for the treatment of wastewaters containing metal ions and may be found useful for large scale application to PCB contaminated water. A patent was issued on the process (#4,446,236 May 1, 1984).

It is well known that biological degradation of oil occurs at an accelerated rate in the presence of emulsifiers. Petroleum Fermentations Inc. has several patents concerned with the production and use of such emulsifiers. Emulsification clearly plays an important role in promoting contact between PCB contaminated oil and bacteria in the aqueous phase. Researchers at the University of Georgia have found, for example, that Pseudomonas aeruginosa and Serratia liquefaciens, incubated in a medium containing Tween 80, were able to destroy 97% of the PCB present within 90 to 130 days.

The Polybac Corporation in Allentown, PA, have demonstrated the in-situ degradation of PCBs using a proprietary blend of bacteria. The higher chlorinated PCB isomers were found to be unaffected during the 5–6 month treatment program and were therefore chemically reduced prior to bacterial treatment.

Fundamental biochemical degradation mechanisms are not well understood. Chemical pathways are therefore difficult to predict and the potential exists for the release of hazardous compounds into the environment through incomplete degradation or system failure. Degradation rates in the field tend to be much slower than laboratory rates where pure cultures are tested on pure compounds. Also, the problem of PCB identification and quantitation can be very difficult in partially degraded mixtures and process streams.

The identification of chlorobiphenyl congeners has been the subject of extensive research. Safe *et al.*[138] at Texas A&M University has synthesized most of the 209 PCB congeners and has used these to identify the constituents of Aroclor mixtures using high resolution gas chromatography (HRGC). Similar work has been done by Pellizzari *et al.*[139] who identified 73 PCB congeners in a mixture of Aroclor 1016, 1254 and 1260 by HRGC/negative chemical ionization mass spectrometry (HRGC/NCI-MS). Publications by Stalling and his co-workers[140,141] describe a data base for the isomer specific determination of PCBs and a pattern recognition method for the classification and determination of PCBs in environmental samples. Current research is focusing on the application of "white rot" fungus, Phanerochacte Chrysosporium, to degrade toxic halogenated organics. The fungus enzyme is one of the strongest, nonspecific, oxidizing enzymes known. In labscale tests, pentachlorophenol in water was reduced from 250 mg/L to 5 mg/L in 24h (des Rosiers[142]).

The mechanism of action of P. chrysosporium involves an initial one electron oxidation to produce an aryl cation radical which then undergoes cleavage and further oxidation to produce quinones. The quinones are degraded further by a quinone reducing enzyme until finally all of the organically bound chlorine becomes chloride.

ELECTROCHEMICAL

Russling *et al.*,[143] at the University of Connecticut, has investigated the application of controlled potential electrolysis as a method to dechlorinate PCBs. Radical anions of such compounds as anthracene, 9,10-diphenylanthracene and phthalonitrile in dimethylformamide solution form radical anions at a Hg electrode surface. The radical anions react with PCBs in solution to produce chloride in much the same way as the mechanism of action of organometallic reagents. Stepwise reduction is observed with biphenyl as an end product.

Kinetics of the reactions were characterized by cyclic voltammetry. It was observed that the rate constant for the rate determining electron exchange between radical anion and chlorobiphenyl varied inversely with the difference in reduction potential between the radical anion and the chlorobiphenyl.

Hydrogen peroxide generated by an alternating current field has been used as an oxidant for the PCB decontamination of aqueous wastes. Westinghouse Electric Corporation in Pittsburgh, Pennsylvania, has patented an apparatus for the electrolysis of water which consists of a series of packed beds of alternating high and low electrical conductivity. Each bed has separately controlled pairs of electrodes. The low conductivity bed contains conductive particles such as carbon or nonconductive particles coated with oxides such as MnO_2 or PbO_2. The proportion of particles in the more conductive bed is about 30% oxide coated particles with the balance as conducting and/or absorptive particles. A series of beds was constructed in the effluent flow path and 29 volts/12 amps passed into each of the less conducting beds while 10 volts/15 amps was passed into each of the more conductive beds. The electrodes were cooled so that the process temperature could be minimized. The PCB concentration was reduced from 120 ppb to 1.5 ppb.

DECHLORINATION REACTIONS OF ALKALI METALS AND ORGANOMETALLIC REAGENTS

The chemical decontamination systems which have been developed all share a common factor based upon the transfer of electrons to the PCB molecule from an alkali metal such as sodium or potassium, or an organometallic reagent, such as an alkali metal-aromatic compound. The processes differ in details such as the air and moisture sensitivity of the reagent, side reactions to give partially dechlorinated toxic products, inhibition by radical scavengers such as oxidation inhibitors and the degree of processing required to produce a useful, decontaminated product. Public scrutiny has required that processes be researched very carefully to elucidate the details of reactions so that the PCB "problem" is removed rather than substituted.

The first large scale process for the PCB decontamination of fluids was developed (Parker[144]) by Goodyear Tire and Rubber Company in 1980 using the known chemistry of sodium naphthalenide (NaNp) as a dechlorinating agent for strongly bonded organic halogen compounds such as chlorobenzenes. The process was applied to the decontamination of heat transfer fluids containing about 120 ppm of PCBs. Earlier, in 1978, Oku *et al.*[145] reported the use of NaNp for the dechlorination of PCBs. Smith and Bubbar at the University of Waterloo, Ontario performed a research contract for the Canadian Electrical Association on the application of NaNp to PCB contaminated transformer oils in 1982. A patent issued on their process in 1982 (Smith and Bubbar[107]).

Sodium naphthalenide is prepared by reaction of an excess of dispersed sodium metal with naphthalene in a dry ether solvent, such as tetrahydrofuran, under a nitrogen atmosphere. The air unstable compound forms as dark green crystals and reacts with PCBs to form chloride ions, biphenyl and polyphenyls with a yield, based on chloride ion concentration, of 99.5%. Analysis of some of the non-chlorinated polymeric, aromatic residue by NMR spectroscopy indicated that one solvent tetrahydrofuran molecule was associated with each aromatic ring.

The reaction of NaNp with PCBs was found to be more efficient when the recovery of naphthalene was increased. This was interpreted as being due to the presence of an impurity produced from a side reaction which acts as an inhibitor to the dechlorination reaction. A similar inhibition of the dechlorination reaction was studied by Webber and Wilson[62] in the reaction between dispersed sodium and PCBs in oxidation inhibited transformer oils. The chemistry of this method is discussed later in this section.

Acurex Waste Technologies Inc. in Mountain View, California, have adapted the Goodyear/University of Waterloo process for use in the field to decontaminate transformer oils because naphthalene is a priority pollutant. The Acurex process utilizes a chemically similar, proprietary alternative. The large scale process developed by Goodyear was intended to yield a decontaminated fuel. The Acurex process yields a decontaminated oil which is filtered and returned to the customer for reuse or disposal although the extent of required further treatment is uncertain. Acurex does not recommend reuse of the oil. Smith and Bubbar are proposing a continuous, cyclic system which, it is claimed, can be built into a portable unit that could be carried on a trailer for on-site processing to yield a dielectrically acceptable oil.

Brown and Lynch at General Electric Company, Schenectady, New York, have obtained a patent (#4,377, 471) in March 1983, on a method for the dechlorination of PCBs in insulating oils by addition of a mixture of dispersed metallic sodium, an aprotic ion-complexing solvent such as tetrahydrofuran, and an oil-soluble electron carrier such as naphthalene. It was noted in Smith and Bubbar's patent on the action of NaNp that the presence of free sodium metal in the reaction medium, resulting from the use of an excess of sodium metal in the formation of sodium naphthalenide, appeared to enhance the effectiveness of the dechlorination reaction. The use of sodium dispersions for the removal of halogenated compounds from hydrocarbon oils is a well known reaction in the refining of oils. The application of the method to PCBs was described as early as 1973 by Japanese workers who used it to decontaminate kerosene used as a solvent for the extraction of PCBs from sewage sludge.

The B.C. Hydro process (Webber *et al.*[146]) for the decontamination of electrical insulating oils utilizes an alkali metal such as sodium dispersed directly into the contaminated oil. Rate studies of the reaction performed by Pilgrim and Webber[61] showed a trend which is characteristic of chemical treatments, namely that the more highly chlorinated PCBs react in a stepwise fashion to produce less chlorinated species which are ultimately completely dechlorinated. Samples withdrawn from the reacting dispersion were analyzed at periodic intervals by gas chromatography according to a method similar to the now standardized ASTM D4509. The later peaks in the chromatogram showed an initial decrease, declining sharply as the reaction proceeded. The intermediate peaks showed an initial increase, followed by a short plateau phase and a sharp decline. The least retained, least chlorinated congeners retain an almost constant peak height until the reaction is almost complete, at which time they quickly disappear from the chromatogram.

The suggested reaction scheme involves the formation of anion radical intermediates followed by a dechlorination step. Polyphenyls are produced from the reaction between biphenyl free radical species and a chlorobiphenyl free radical, followed by further dechlorination and ultimate precipitation as sludge. The reaction appears to be similar to the ENSR (SunOhio) PCBX process.

Further work by Pilgrim and Webber[61] on an accelerated PCB destruction process by metallic sodium in the presence of small quantities of isopropanol as a hydrogen donor showed that abstractable hydrogen altered the reaction kinetics and mechanism to such an extent that decontamination was completed in about 20 minutes at room temperature. Part of the accelerative effect is probably due to the regeneration of active sodium surface by direct reaction with isopropanol. The reaction with alcohol would tend to renew the sodium surface and avoid the passivating effect caused by the formation of sodium phenolate derived from 2,6-di-tertiary-butyl-p-cresol (DBPC) used as oxidation inhibitor. Evidence which suggests that an alteration of mechanism may have taken place is that relatively little polyphenyl sludge is produced in the accelerated reaction.

The inhibition of dechlorination by DBPC in the reaction of dispersed sodium with PCBs was investigated by Webber and Wilson[62]. The oxidation inhibitor interacts with peroxy radicals in solution to produce a phenoxy radical stabilized by resonance. The phenoxy radical undergoes second-order disproportionation to yield an unstable quinone methide. Subsequent dimerization occurs to produce an intensely yellow colored compound 3,3′,5,5′,-tetra-tert-butyl-4,4′-stilbenequinone and 1,2bis(3,5-di-t-butyl-4-hydroxyphenylethane).

To determine whether the stilbenequinone affected the PCB dechlorination reaction, a 1% Aroclor 1242 in oil solution was prepared with 0.3% of the stilbenequinone and heated with sodium dispersion. No reaction was observed in 10 hours where, in the absence of the stilbenequinone, complete dechlorination was observed in about 15 minutes. Exclusion of oxygen from the reaction, and the use of a dispersed form of sodium, was found to prevent the formation of the stilbenequinone and to overcome the inhibition of the PCB dechlorination reaction at concentrations of DBPC typical of transformer oil. When the sodium was dispersed into particles of about 10 μm and reacted under a nitrogen blanket, a 10,000 ppm Aroclor 1242 solution was completely dechlorinated in less than 15 min. at 130°C in the absence of DBPC. When the maximum recommended inhibitor concentration in dielectric oils of 0.3% DBPC was used, the reaction was complete in less than 30 min. under the same conditions. Exclusion of oxygen from the reaction mixture prevented the formation of stilbenequinone and thereby avoided the inhibition of dechlorination.

The interaction of metallic sodium with the oil produces a reducing environment which tends to react with both natural and added alcohol oxidation inhibitors to yield sodium chloride and, upon complete reaction, a dechlorinated polyphenyl sludge. When the reaction is conducted under a blanket of nitrogen there is little likelihood of producing toxic oxidation products such as PCDFs or PCDDs. Also the formation of the sodium salts of oxidation inhibitors and acids tend to precipitate and can be easily separated from the oil by filtration or washing. The product can then be easily reclaimed as a decontaminated dielectric oil suitable for further use by adding oxidation inhibitor.

Ontario Hydro has developed the laboratory scale reactions performed by the author at B.C. Hydro and has had success in cost effectively treating large quantities of oil to yield a reusable product. A disadvantage of the system is that excess alkali metal is very reactive and needs to be used with caution. Ontario Hydro has had built (1989) mobile, 40 foot trailers, containing processing equipment to apply the sodium technology.

ENSR's (SunOhio's) "PCBX" process is contained in a forty foot trailer accompanied by an auxiliary trailer containing reclamation and oil test equipment. The process has been engineered to be continuous, as opposed to a batch operation, and runs at about 10 gal./min. Oil is pumped from the transformer or storage tank, through a heater to a reaction chamber where dispersed sodium is metered into the process stream. The slurry is passed through a recovery system containing heat exchangers, filters, a centrifuge and vacuum degassing apparatus. PCBs are dechlorinated to less than 2 ppm PCB in oil.

Oxidation inhibitor is reported to be added to the product oil. No alteration of the oxidation stability of the product was observed when measured by ASTM D2440 and a low temperature modified version of ASTM D2112. The presence of sodium compounds in the oil returned to the transformer was shown to be less than 1 ppm. The cost of be "PCBX" trailers is high at about $500,000, but, like the B.C. Hydro process, it has been shown to be cost-effective in the treatment of a wide range of PCB concentrations.

Vertac Chemical Corporation in Memphis, Tennessee has developed and patented (Howard *et al.*[147]) a method for the destruction of PCDDs in agricultural chemicals. The PCDDs are formed in unwanted side reactions during the product synthesis. The process uses alkali metal alcoholates of short chain alkanols or polyalkoxyalkane glycols or alkali metal hydroxides to react with PCDDs. The extension of the process to the dechlorination of PCBs is obvious. The reaction takes place at about 140°–220°C at atmospheric pressure when sodium ethylene glycolate is used.

The alkali metal alcoholate can be produced by reacting alkali metal with a polyol. Alternatively, the reagent can be formed from an aqueous solution of sodium or potassium hydroxide with an alkane-polyol such as ethylene glycol in the presence of an azeotropic solvent under azeotropic distillation conditions.

The mechanism of reaction with TCDD is believed to occur in two steps:

$$\begin{aligned}\text{TCDD} + 4\text{NaOC}_2\text{H}_4\text{OH} &\rightarrow (\text{OC}_2\text{H}_4\text{OH}) \text{ — dibenzo-p-dioxin} + 4\text{NaCl}\\ &\rightarrow (\text{NaO})_4 \text{ — dibenzo-p-dioxin} + 4(\text{HOC}_2\text{H}_4)_2\text{O}\end{aligned}$$

The polyhydroxy aromatic species formed in the process are more readily decomposed by aerobic bacteriological action than the original toxic, water insoluble, stable compounds. The sodium phenolate product can be acidified and safely separated from the aqueous wash solution containing dissolved inorganic salts.

Brunelle and Singleton[148] have reported the reaction between potassium hydroxide, polyethylene glycol (PEG) and PCBs. It was found that the complete removal of up to 1% PCBs from transformer oil could be achieved in less than two hours at 100°C. The advantage of the system over process which involve alkali metal organometallic reagents is that it is not moisture or air sensitive.

The Franklin Institute in Philadelphia, Pennsylvania has patented the "NaPEG" process for the detoxification of transformer oils (Lee[149]). The reagent used is derived from the reaction of alkali metal with a polyglycol such as polyethyleneglycol with an average molecular weight of about 400. The preparation can be described in the following equations:

$$\text{Na} + \text{PEG} \rightarrow \text{NaO — (PEG)} + \text{H}_2$$

$$\text{NaO} \quad \text{(PEG)} + \text{O}_2 \rightarrow \text{NaPEG reagent}$$

The NaPEG agent, like the Vertac reagent and the GE reagent, is both air and water stable and therefore has a long shelf life without special handling precautions. Dechlorination of PCBs in transformer oils can be achieved by heating the reagent and oil at temperatures between 40°C and 180°C depending upon the particular reagent chosen and the degree of chlorination of the PCB. The reaction evolves hydrogen gas and produces polyhydroxylated biphenyls and sodium chloride. The effectiveness of the system has been proven on a large scale (Garland[150]) by the Philadelphia Electric Company (PECO) who have subsequently reused the decontaminated oil produced in a pilot plant. It was observed that air or oxygen was necessary to make the reagent active towards PCBs in insulating oils and that the use of pure oxygen enhanced the rate of dehalogenation by a factor of five. This is in contrast to Brunelle and Singleton's work described above since they found that the presence or absence of air (oxygen) had no effect on the rate or outcome of the reaction. Also, in order to preserve the oxidative stability of the oil the reactions were recommended[148] to be conducted under an inert atmosphere. Webber and Wilson's work[62] on the inhibition of PCB dechlorination in oxidation inhibited oils suggests that the cause of the NaPEG reagent inactivity may be that the DBPC oxidation inhibitor oxidatively dimerizes to produce the observed yellow solution of stilbenequinone which then acts as an efficient scavenger of the radicals produced in the dechlorination steps. The formation of phenoxy radicals in Webber and Wilson's work was indicated by ESR spectroscopy. The presence of peroxy species in the NaPEG process was also observed.

The structures of naphthalene, anthracene and biphenyl radical anions with alkali metal gagenions have been interpreted by the alkali metal spin density distributions in the aromatic systems (West[151]). Webber *et al.*[152] have utilized the chemistry of this organometallic series of complexes to produce a preferred process for the PCB decontamination of insulating oil which is unaffected by the presence of oxidation inhibitors and which can be used at moderately low temperatures in a continuous system to yield a dielectric quality, decontaminated product.

Tiernan *et al.*[153] at Wright State University have reported on the use of KPEG reagent on PCDD/PCDF contaminated soil at hazardous waste sites. A similar paper has also been given by DesRosiers[154]. A 40 foot mobile trailer containing a 2700 gallon stainless steel reactor was used with 600 gallons of KPEG to treat 1400–2000 gallons of waste material. The mixture was heated to 150°C for 1.5 h. Under optimal conditions the chemistry allows complete dechlorination. A practical destruction efficiency of $>99\%$ is observed at reaction temperatures above 70°C with reaction times of 15 minutes to 1 hour. Interestingly, bioassays of residues from the reaction were negative. The cost of the KPEG treatment has been estimated to be approximately $24.00/gallon i.e., about 10% of the cost of on-site incineration.

UNCONTROLLED REACTIONS

The extreme toxicity of PCDFs and PCDDs discussed earlier makes it imperative that uncontrolled side reactions in processes used to chlorinate PCBs should be investigated and steps taken to avoid the generation of concentrations of compounds of concern.

Uncontrolled reactions during the large scale preparation of trichlorophenol from tetrachlorobenzene and sodium hydroxide in ethylene glycol have resulted in runaway conditions on at least six occasions and resulted in the formation of PCDDs. The Seveso incident, which occurred in 1976, is the most recent and is probably the best documented. Ethylene glycol used as solvent in the reaction can undergo an exothermic base catalyzed polymerization above 180°C to produce substantial quantities of TCDD from the dimerization of chlorophenol.

If the reaction conditions in a process to destroy askarels can yield chlorophenols as a side reaction product then the potential exists for the generation of PCDFs and/or PCDDs. The reaction mechanisms which explain the formation of the cyclized products is described in an earlier section.

The dimerization of chlorophenates is a bimolecular reaction and therefore the products formed should be highly dependent upon the chlorophenate concentrations. The particular PCDD isomers formed in the system, and their quantities, will depend upon the relative kinetics of alternative reaction routes.

The pyrolysis of PCDPEs follows two competitive reaction pathways, viz., dechlorination or ring closure to PCDFs. The cyclization of pre-dioxins is a bimolecular reaction caused by heating. The final concentration of PCDDs in a heated chlorobenzene system should ultimately depend upon the concentration of polychlorinated phenols which are formed at an intermediate stage.

Louw, *et al.*[96,96a] have interpreted the pyrolysis of chlorobenzenes as a radical chain reaction involving $\cdot C_6H_4Cl$,Cl· and H· as carriers. The authors discuss a radical reaction sequence which explains the observed product pattern, including the formation of PCBs.

The formation of polychlorinated naphthalenes (PCNs) in Buser's experiments (Buser[55]) can be explained by either invoking the formation of benzyne intermediates or the rearrangement of intermediates formed between an ortho-chloro phenyl radical with a chlorobenzene.

The overall effect of radical reactions on the product distribution in a pyrolysis reaction will be affected by both temperature and the availability of oxygen. This is well illustrated in the product distributions found after accidental fires involving PCBz/PCB filled electrical equipment (see earlier section).

It would be ironic if a process aimed at the detoxification of PCBs, which have been shown to be for the most part nontoxic in humans, should inadvertently create a hazard as the result of uncontrolled side reactions to give products with a much greater apparent toxicity.

Analytical chemistry at the time of the "Yusho" incident in 1968 was at a stage of development in which the determination of analytes at the ppm concentration level was considered to be the forefront of the field. Vos showed in 1970 that PCDFs could be determined in the presence of a matrix of PCBs but it was not until about 10 years later in 1977/78 that analytical methodology had advanced to the point that PCDFs and PCDDs could be determined, albeit laboriously, with anything like a "standardized" method. At the present time, EPA method 613 for the target compound 2,3,7,8-TCDD, uses high resolution gas chromatography coupled to low resolution mass spectrometry and is capable of detection limits of about 10 ppb. Developments in tandem mass spectrometry promise to provide a very rapid screening method for the presence of target compounds and is sensitive to PCDDs in the ppt range.

A part of the problem in the interpretation of PCB disposal methods lies in the analytical requirements of uncontrolled reactions. For example, even though methodology has been developed which is able to determine compounds which were not considered at the time of the Yusho incident, it is currently not possible to determine some of the polychlorinated polyaromatic pyrolysis products of PCBs because of a lack of standard compounds. The key question which remains unanswered today is "What are the concentrations of compounds of concern?"

(3) THE PCB REMEDIATION OF SOILS

The cost-effective remediation of PCB contaminated soils is discussed in terms of the availability of current options and an assessment of the best available technology. Major categories of in-place treatment techniques are reviewed as well as a wide range of technologies for the treatment of excavated soils.

Treatment methods are used to reduce the toxicity, mobility or volume of PCB contaminated material and fall into two distinct groups. One group requires the use of large energy sources and requires a significant amount of setup time. The other group of technologies tend to be more mobile, use much less energy and apply a decontamination process to excavated soil.

This section focuses on the use of electrochemical methods for the treatment of soil extracts and, in particular, on a new electrochemical technology which has been demonstrated to be significantly superior.

The Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) mandates the Environmental Protection Agency (EPA) to select remedial actions which "utilize permanent solutions and alternative treatment technologies or resource recovery technologies to the maximum extent practicable". Also, a preferred remedial action is one which "permanently and significantly reduces the volume, toxicity, or mobility of hazardous substances, pollutants, and contaminants as a principal element."

The Toxic Substances Control Act (TSCA) requires that material contaminated with PCBs at concentrations above 50 ppm should be disposed of in an incinerator approved for the purpose or by an alternate method that achieves a level of destruction which is equivalent to incineration.

Other applicable or relevant and appropriate requirements (ARARs) which can apply to a PCB contaminated site might involve the Resource Conservation and Recovery Act (RCRA) as well as the Clean Water Act (CWA) and Safe Drinking Water Act (SDWA).

RCRA applies to PCBs when liquid waste that is hazardous under RCRA contains PCBs at concentrations greater than 50 ppm or non-liquid hazardous waste contains total hazardous organic constituents at concentrations greater than 1000 ppm. PCBs are specifically addressed under RCRA in 40 CFR 268, which describes the prohibitions on land disposal of various hazardous wastes. The land disposal restrictions require that prior to placing PCB contaminated material on the land, it must be incinerated unless a treatability variance is obtained.

The National Contingency Plan (NCP) established a general presumption that a treatability variance is warranted for CERCLA soil and debris because when the Act was put into effect there were no standards for disposal. Consequently, alternate treatment levels(161) are justified according to the treatability guidance levels set out by the EPA. To qualify for a treatability variance for PCBs, residuals after the alternate treatment should contain 0.1 to 10 ppm PCBs for initial concentrations up to 100 ppm, and for initial concentrations above 100 ppm, treatment should achieve 90 to 99% reduction in concentration.

Soil remediation techniques applied to hazardous waste sites are assessed in terms of the soil processes which affect them and the type of system to be used. Once a technology has been selected it must be monitored for treatment effectiveness until it is finally proven that decontamination has taken place to an acceptable level of risk.

In general, contaminated soil systems must be considered as four phases: (1) aqueous; (2) vapour or gas; (3) organic and (4) solid. The distribution of contamination between the phases is linked to the relative affinity of the components of concern for each phase and are represented as 'Distribution Coefficients'. A distribution coefficient is calculated as the ratio of the concentration of a chemical in one phase to its concentration in a second phase. PCBs, for example, are hydrophobic and so are largely retained by the non-aqueous phase liquid, usually referred to as *NAPL,* and the organic matter in the soil. Hence the distribution coefficient for PCBs in oil is very large.

The mobility of a component of concern through a soil bed is measured in terms of a retardation factor. The retardation factor describes the relative velocity of a constituent compared to the rate of movement of water through the subsurface. A retardation factor which is greater than unity indicates that a component is moving more slowly than water through a system. The retardation factor for PCBs is very large.

The combination of large distribution coefficients for NAPL and soil organic matter and a large retardation factor means that PCBs tend to remain at the surface of a spill site and migrate either by erosion or by dust emission. As a consequence, spill sites or landfills tend to be long term sources of PCBs.

Remedial response levels for PCBs are as follows:

soil	<10 mg/Kg (EPA/NYSDEC soil removal criteria)
air	<1.67 μg/m3 (NY State Ambient Air Level)
ground water	<1.00 μg/L (NYSDOH advisory level)
surface water	$<7.9 \times 10^{-5}$ μg/L (Clean Water Act)

The surface water criterion of $<7.9 \times 10^{-5}$ μg/L i.e., less than about 1.0 parts per trillion, for a lifetime cancer risk of 10^{-6} is below the method detection limit for EPA method 608 and even below the MDL for the method.

The extent and type of information obtained from modeling the migration and persistence of contamination is used to select treatment approaches for further evaluation with respect to their feasibility and cost effectiveness. Remediation is accomplished using one or more of three types of systems: (1) in-situ; (2) prepared bed, and (3) in-tank reactor.

There are five major categories of in-place treatment techniques:

- Extraction,
- Immobilization,
- Degradation,
- Attenuation, and
- Reduction of voltalization.

Extraction

Extraction involves washing contaminants from the soil with a suitable solvent. The solvent must be non-polluting and must not alter the soil properties in an unacceptable way. An efficient method is needed to capture the elutriate and while the method has shown application in the mining industry it is not likely to be suitable for PCBs.

Immobilization

Immobilization methods are intended to reduce the rate of release of contaminants from the soil so that the concentrations along pathways of exposure are restricted to within acceptable limits. Activated carbon is a strong adsorbent for PCBs and can be readily incorporated into soil. The amount of carbon which may be required is strongly affected by the amount of other organic material is the soil. Since the PCBs are retained at the site, re-application of carbon may be necessary as the original material erodes.

Degradation

Oxidation, reduction and polymerization reactions have been carried out in attempts to transform soil contaminants into less toxic or less mobile products.

Oxidation Chemical oxidation of compounds of concern with reagents such as ozone or hydrogen peroxide can lead to oxidation products which are more toxic than the original contaminants. For example, the formation of hydroxylated products would tend to increase the water solubility of PCBs and may even lead to the generation of polychlorinated dibenzofurans (PCDFs) or polychlorinated dibenzodioxins (PCDDs).

Reduction Reducing agents such as iron powder or sodium borohydride have been used to degrade toxic organics. An electrochemical method which uses iron/copper pellets has been applied to the treatment of PCBs in a tank reactor but has not been demonstrated as an in-place treatment method.

Reductive dehalogenation of PCBs can be applied using organometallic reagents and sodium based reagents similar to those developed by the author. The reagents are typically very reactive with water and were originally developed for the PCB decontamination of oils. A two-step procedure has been used for soil remediation in which the soil is first extracted and then solvent exchanged with a water immiscible solvent. The relatively dry, water immiscible solution is then reacted with a water sensitive, PCB reactive reagent.

Problems associated with water reactivity can be circumvented by using sodium polyethylene glycol. The alkali metal (APEG) reagent is water miscible and has been used with some limited success for the treatment of both PCB contaminated oils as well as soils(148,162).

Polymerization In-situ polymerization reactions have been initiated to react polymerizable organics into polymers which are less toxic and less mobile than the monomer compounds. This type of reaction is not applicable to PCBs.

Bioremediation In-situ biological remediation is an attractive technology because it represents a permanent cleanup remedy which, although slow compared with an in-tank reaction, can be allowed to proceed in-situ for as long as necessary. The disadvantage of the method is usually associated with the need to maintain environmental factors such as moisture, temperature, pH and microbial nutrients. A possible result of PCB degradation by microbial treatment is the formation of PCDFs.

Photolysis Photodecomposition of PCBs at soil surfaces has been reported in the presence of triethylamine as a proton donor. Methanol has been used as a proton donor for the photodecomposition of PCDDs. Some difficulty has been observed at the very low concentrations of concern in distinguishing photolysis from evaporation. Photodegradation is limited to the surface of contaminated soil.

Treatment Techniques Applicable to Excavated Soils

In contrast with in-situ soils a relatively wide range of technologies is applicable to the treatment of excavated soils:

- incineration,
- biological treatment,
- matrix isolation
- vitrification,
- chemical dechlorination,
- electrocoagulation
- solvent extraction,
- physicochemical adsorption.

Incineration Incineration methods are required to achieve a destruction and removal efficiency of 99.9999%. This is described as the six 9's rule in 40 CFR 761.70.

There is a wide variety of equipment available for the incineration of PCBs which ranges from large fixed site equipment to more mobile units. Rotary kilns, for example, are usually large and expensive to operate but can fulfill the six 9's destruction efficiency requirement.

A kiln consists of a refractory lined cylinder with its axis slightly inclined to produce a tumbling action which mixes the wastes. Residence times of PCB contaminated material in the hot zone can be controlled to the extent necessary for complete combustion. Combustion temperatures range from 870°C to 1650°C.

The following high energy destruction methods are either being used on a large scale or are in the development stages.

- Circulating Bed Incineration
- High temperature fluid wall reactor
- Rotary kiln
- Plasma arc
- Penberthy glass-melting furnace
- Molten salt
- Wet oxidation
- Supercritical water oxidation

Biological Treatment Biological treatments for industrial waste systems have been in use for many years but it is only recently that new microbial strains have been developed to degrade PCBs by either enhancing conditions for existing microbes or the application of proprietary strains.

Fundamental biochemical degradation mechanisms are not well understood. Chemical pathways are therefore difficult to predict and the potential exists for the release of hazardous compounds into the environment through incomplete degradation or the formation of more toxic products.

The EPA considers biological processes which involve the excavation of contaminated material for treatment to be eligible for a treatability variance when the process can be shown to achieve a residual concentration of 2 ppm PCB or less. The treatment residuals can only be re-deposited on-site without long-term management controls when the treatment by-products do not present a threat to the environment.

Matrix Isolation Solidification is a term which is applied to the encapsulation of a waste to prevent its leaching into the environment. For example, PCB contaminated soils have been encapsulated into concrete without the formation of chemical bonding between the PCB and the encapsulant. On the other hand, solidification implies that some degree of chemical interaction is taking place to inhibit leaching. For example, pozzolanic chemistry has been used to chemically fix PCBs in a rock-like product which has good load bearing properties and which is hydrolytically stable.

Vitrification Vitrification utilizes an electrical process which uses about 4 MW of power to produce an in-situ pyrolyzed mass between large electrodes placed in the soil. Volatilized organics have to be captured and treated. The process results in complete pyrolysis of a localised area. The perimeter of the treated area needs to be defined by an appropriate analytical procedure to determine the need for on-going management controls.

Chemical Dechlorination Once PCBs have been extracted from the soil into a non-aqueous solvent the concentrated extract can be treated with organometallic reagents such as those invented by the author. Alternatively, alkali metal polyethylene glycol reagents, (APEG), can be used which are not directly reactive with water.

Both sodium and potassium PEG derivatives have been used with limited success. The reagent efficiency varies with the type of Aroclor and the amount of dilution the reagent receives from water contained in the soil. Recovery of excess reagent by water washing tends to reduce the cost-effectiveness of the process although PCB reduction to below 2 ppm PCB has been achieved.

Electrocoagulation Coagulation is the process by which particles in water are destabilized so that they can be removed by solid/liquid separation processes such as sedimentation and filtration.

Electrocoagulation has been applied to the removal of contaminated soil washings, waste oils and the enhanced dewatering of sludges. The applicability of the technique to soils which have been solvent extracted to remove PCB contamination is not yet known.

Solvent Extraction Three extraction techniques are used to clean soil: water washing, solvent extraction and air stripping. The first two methods are applicable to the remediation of soils contaminated with PCBs.

Water washing alone is not effective in the removal of hydrophobic contaminants such as PCBs. However, when surfactants are added to the water washes laboratory studies have shown an extraction efficiency of more than 90%.

Water washes used without added surfactant were found to reduce the PCB concentration in a sample of soil by only about 13%. The action of the surfactant is to reduce the adsorptive bonding strength of the PCBs on the soil particles with the result than 90% PCB removal was achieved.

Approximately 95% of the surface area of a soil is represented by fine particulates. The fines represent about 15% of silt and 8% of clay. Therefore, a sieving process alone is able to provide a particulate mass which contains a large fraction of the total PCB contamination. The EPA Mobile Soil Washing System (MSWS) was designed[163] around the particle size concentration effect.

Solvent extraction with organic solvents tends to be more effective than water washing with surfactant solutions. Two general techniques are applied: (1) immersion extraction and (2) leaching.

An immersion extractor is simply a tank containing stirred solvent into which the soil is suspended and mixed. When the extraction equilibrium has been established, the solids are separated either by settling or centrifugation and the solvent is passed down the treatment train to be decontaminated and recycled.

Leaching extraction is a process in which solvent is allowed to percolate through the soil contained in a screened bottom tank. The solvent desorbs and dissolves the PCB contamination and is collected at the bottom of the tank. A series of beds of soil are treated in a countercurrent fashion to increase the extraction efficiency.

Critical fluid extraction is a method in which liquified hydrocarbon gases such as propane and butane are used as solvents for separating organic contaminants from soils, sludges and sediments. Feed material is typically screened to remove particles which are greater than 1/8″ diameter and then mixed with water to provide a pumpable slurry. The technology has been applied on a mobile 60-tpd treatment scale. A 98% PCB reduction(164) has been achieved from soil initially contaminated with 350 ppm PCB.

A basic extractive sludge treatment uses aliphatic amines, typically triethylamine, (TEA) as the solvent to remove contaminants, including PCBs. TEA has the interesting property that below 15°C it can simultaneously solvate oils and water. Above 15°C, water becomes immiscible and separates from the oil and solvent. The process has been designed to remove water and organics at low temperatures, separate the water from the organic phase at higher temperatures, and recover the solvent in high yield through distillation. A 70-tpd unit has been demonstrated[165] on PCB contaminated soils.

Physico-chemical Adsorption Activated carbon is a strong adsorbent for PCBs because of its structure. Powdered carbon which has a very high surface area to mass ratio is used. The long-term physical and chemical stability of activated carbon added to soil systems is unknown but the material tends to erode with the soil and also become distributed in the environment as particulate emissions.

Carbon beds have been used to adsorb PCBs from water as well as oils. The system acts as a PCB concentrator which is usually then sent for incineration.

The following Table 56 shows a number of innovative technologies which are being developed for the remediation of contaminated soils.

The wide variety of technologies in the above table have been applied to the PCB decontamination of soils with varying degrees of success. The methods can be separated into two groups. One group requires the use of large energy sources and need a significant amount of setup time but are relatively less selective with regard to the contaminants to be treated. The second group tend to be more mobile, use much less energy and apply a second process to the soil extract to treat a specific group of contaminants.

Electrochemical Treatment Processes for Excavated Soils

This section will discuss electrochemical methods which have been used for the dechlorination of PCBs and focus on data obtained with a method which appears to have widespread applicability. Other electrochemical methods will be discussed briefly.

A Westinghouse patent deals with an electrochemical method for the treatment of PCBs in which hydrogen peroxide is generated by an alternating current field passed through a series of packed beds of conductors. The high and low conductivity beds are placed adjacent to one another and each has separately controlled pairs of electrodes. The low conductivity bed contains conductive particles such as carbon or non-conductive particles coated with oxides such as MnO_2 or PbO_2. The proportion of particles in the more conductive bed is about 30% oxide coated particles with the balance as conducting and/or absorptive particles. A series of beds was constructed in the effluent flow path and 29 volts/12 amps passed into each of the less conducting beds while 10 volts/15 amps was passed into each of the more conductive beds. The electrodes were cooled so that the process temperature could be minimized. The PCB concentration was reduced from 120 ppb to 1.5 ppb.

Controlled potential electrolysis has been investigated as a method for the dechlorination of PCBs. Radical anions of such compounds as anthracene, 9,10-diphenylanthracene and phthalonitrile in dimethylformamide solution are formed at a mercury electrode surface. The radical anions react with PCBs in solution to produce chloride in much the same way as the mechanism of action of organometallic

TABLE 56

Developer	Technology	Applicable waste
In development	Electrochemical	PCBs, PCDFs, PCDDs, volatile & semivolatile organics, PAHs, PCPs, petroleum by-products, metals, synthetic organics
American Toxic Disposal Inc.	Vapor extraction	Volatile & semivolatile organics, PCBs, petroleum by-products
CF Systems Corp./ENSCO	Solvent extraction with liquified hydrocarbon gases	PCBs, volatile & semivolatile organics, petroleum by-products
Ozonics Recycling Corp.	Soil washing, catalytic ozone oxidation	Semivolatiles, pesticides, PCBs, PCP, PCDDs
Harmon Environmental Services	Soil washing	Heavy organic compounds
Western Research Institute	Contained Recovery of oily wastes	Coal tar derivatives, petroleum by-products
Resources Conservation Co.	Solvent extraction with triethylamine	High molecular weight organics
Chemical Waste Management	Low temperature thermal desorption	Volatile & semivolatile organics, PCBs
International Waste Technologies	In situ solidification/stabilization	PCBs
MoTec Inc.	Liquid/solid contact digestion	Halogenated & non-halogenated organics, pesticides
USEPA	KPEG process	PCBs
J.M. Huber	Mobile incineration	PCBs, organics
Penberthy Electromelt	Infra red vitrification	PCBs, organics
Westinghouse	Plasma pyrolysis	PCBs, organics
Battelle Memorial Institute	Radiofrequency heating	PCBs, organics

reagents. Step-wise reduction is observed with biphenyl as an end product. The results of a research program to demonstrate the effectiveness of an electrochemical process are described in detail in this section. Data are presented for the dechlorination of monochloro-benzene, hexachlorobenzene and PCBs.

Chlorobenzenes and PCBs are very insoluble in water and the initial solutions of these compounds were so concentrated that they entered the process as emulsions. The system broke the emulsion in five to ten minutes and produced a 98% reduction of contamination in the same time. Reactions were essentially complete in 30 minutes. PCBs, as Aroclor 1260, were reduced from an emulsion of 3,300 ppm PCB down to 0.2 ppm PCB in 30 minutes at room temperature in a safe, totally enclosed system.

Table 57 illustrates some of the results obtained with the process.

A solution of monochlorobenzene (MCBz) in methanol was added to water containing a supporting electrolyte. The resulting solution contained 39,400 ppb MCBz.

A low D.C. current was passed through the mixture at an initial pH of 7.4 and an ambient temperature of 24°C. As the reaction progressed the pH decreased to a plateau value of about 3.0 after 15 minutes and the temperature increased to a stable value of 47°C in the same time. Samples were withdrawn at regular intervals to be analysed by GC/ECD to determine residual chlorobenzene and GC/MS to identify reaction products. The final concentration of MCBz was 0.54 ppb.

The initial concentration of benzene in solution was 32 ppb. After 15 minutes this had decreased to less than 1 ppb. No other chlorinated species were found in the reacted mixture.

A similar experiment was conducted with hexachlorobenzene (HCBz) at a starting concentration of 11,500 ppb. The mixture was at first an emulsion of HCBz in water. The emulsion had completely disappeared within 5 minutes and the pH decreased from an initial 7.4 to about 4.0 in the same time. The temperature of the reaction mixture was controlled by a circulating water jacket which maintained the temperature at about 50°C.

The first sample analysed was taken after 30 minutes reaction. The HCBz concentration had decreased by a factor of 1000 from 11,500 ppb to 11.3 ppb.

A comparison of the chromatograms obtained after different reaction times clearly shows the formation of intermediate chlorobenzene congeners.

After 30 minutes reaction time there is a dramatic change in the concentration of HCBz while the concentrations of penta-, and tetra- and tri-chlorobenzenes were greater than in the starting solution, albeit at only 4–5 ppb or less. The concentration of lower chlorinated congeners decreased below the analytical detection limit with increasing reaction time. The treated solution after 90 minutes contained 10.1 ppb HCBz and sub-ppb levels of the tetra- and lower chlorinated congeners.

A trace of unquantitated Aroclor 1260 is evident in the starting solution. The chromatogram showed all of the charac-

TABLE 57

Contaminant of Concern (ppm)	Initial concentration (ppm)	Final concentration (ppm)
PCBs (Aroclor 1260)	3,300	0.2
PCBs (Aroclor 1260)	254	4.6
PCBs (Aroclor 1260)	22.5	0.007
Hexachloro-benzene	11.5	0.01
Monochloro-benzene	39.4	0.0005
2,3,7,8-TCDF	0.5 (ppt)	<0.03 (ppt)
AOX	43	0.97

teristic peaks of Aroclor 1260. After 30 minutes reaction time the peaks attributable to the more highly chlorinated congeners are either missing entirely or are much reduced. Peaks attributable to the constituents of Aroclor 1242 are missing from the original chromatogram but some are present in the sample after 30 minutes reaction time. The fractional reduction of PCBs in the presence of a relatively large quantity of HCBz is much smaller than the fractional reduction of HCBz in the same time.

A similar experiment was performed with a starting emulsion of Aroclor 1260 in water at 22,500 ppb PCB. Approximately 320 mg of Aroclor 1260 was dissolved in 100 mL of warm methanol and added to 7.9 L of water. The electrochemical cell arrangement was set up in the solution with a supporting electrolyte.

After about five minutes the emulsion had become a clear solution.

After thirty minutes the PCB concentration decreased from 22,500 ppb PCB to 27.9 ppb PCB. The last sample was taken after 90 minutes and the PCB concentration was found to be 7.1 ppb PCB. The chromatogram of the final solution was significantly different from that of the starting material and resembled a mixture of Aroclor 1260 and Aroclor 1242. The penta-, hexa- and septachlorinated biphenyls appeared to have completely reacted while trace quantities of di-, tri- and tetrachlorinated isomers remained.
