EDITORIAL ADVISORY BOARD

Thou ever-darting Globe! through Space and Air!
Thou waters that encompass us!
Thou that in all the life and death of us, in action or in sleep!
Thou laws invisible that permeate them and all,
Thou that in all, and over all, and through and under all, incessant!

Thou! thou! the vital, universal, giant force resistless, sleepless, calm,
Holding Humanity as in thy open hand, as some ephemeral toy,
How ill to e'er forget thee!

One thought ever at the fore—
That in the Divine Ship, the World, breasting Time and Space,
All Peoples of the globe together sail, sail the same voyage, are bound
to the same destination.

—Walt Whitman (ca 1890)

VOLUME 2

FOREWORD

The editors were honored to have had the foreword to the first four editions written by the eminent thinker and renowned environmental engineer, the late Dr. Abel Wolman. His insights through the decades proved to be accurate and his overview is shared in this fifth edition as inspiration to innovators in the coming decades and in memory of his distinguished contributions to the environmental field.

The 1980s appear in a world dominated by change at an unprecedented pace. Familiar and new problems tumble over each other and are communicated globally by the second, instead of by the month. Scientific and technologic choices are spawned day by day, while search for innovation is stimulated anew by government, universities, and private industry.

Practitioners are startled by these events and try to keep apace with society's demands by pressing for relevant research, implementation of findings, and translating their significance to the public they serve. It is within this challenging setting that a fifth edition of the *Encyclopedia of Environmental Science and Engineering* is born. Its content is intended to register the striking characteristics of the changes we note to eliminate the already obsolete and to expose the new on the horizon.

In the turbulence of the sixties and seventies, policies, plans, solutions, and regulations flowed without interruption from legislative and executive halls. The eighties might appropriately be devoted to post-audit stocktaking and reorientation of both policy and action. Clarification of purpose in confrontation of the problems of the environment is overdue. Validation of our efforts, over the last two decades, should provide an arena of productivity for science and engineering to guide us through the coming decades.

As manpower and money are always in short supply, even in so-called rich countries, they must be husbanded. How to use them with maximum competence and logic, minimum risk, and least cost is a continuing obligation in the protection and control of the biosphere.

We must extricate ourselves from adversarial combat in a world of negativism and move to an orderly identification of what we know and away from the hysterical search for a doubtful Utopia. The authors in this fifth edition continue the pursuit of new knowledge, calculated to bring new fruits of health, safety, and comfort to man and his environs. The charms, as well as the subtle hazards, of the terms "conservation, preservation, and ecology" need to be crystallized so that the public and their decision-makers practice this complex art with clearer conception and perception than is apparent in recent bitter confrontations.

ABEL WOLMAN

EDITORS' PREFACE

In the editors' preface to the fourth edition it was noted that there was good news and there was bad news. It is the same for this, the fifth edition. One suspects that this will always be the case.

The 2004 Nobel Prize for Peace has been awarded to Professor Dr. Wangari Maathai. Dr. Maathai's award was based on her efforts on behalf of conservation and women's rights. These efforts were made at great personal risk.

In addition, the Kyoto Protocol has been ratified by the requisite number of countries. The bad news is that some developed nations have declined to join this global effort. It is to be hoped that, in time, these countries will change their policies.

Protection of the environment is an ongoing struggle, and it is incumbent on all citizens of the planet to join in protecting the only home that we have.

EDITORS

James R. Pfafflin holds degrees from Indiana State University, Johns Hopkins University and the University of Windsor. He is a professional engineer in Ontario, a chartered engineer in the UK and also holds the title of European Engineer (EUR ING). He is a member of the Commissioned Reserve of the US Public Health Service.

Edward N. Ziegler is Associate Professor of Chemical & Biological Engineering at Polytechnic University and former director of its Environmental Science Program. Dr. Ziegler, a Distinguished Teacher Award recipient, teaches graduate courses, one in air pollution engineering control and another in chemical reactor analysis in addition to undergraduate chemical engineering courses. He earned his BS in Ch E from CCNY (City University of New York) and MS and PhD degrees from Northwestern University. He is a member of the American Institute of Chemical Engineers (Environmental Division) and the Air & Waste Management Association (Education Committee). Dr. Ziegler is also a consultant to private industry and government. He received a US Environmental Protection Agency bronze medal (Region 2) for his technical assistance to the Agency team in a power plant pollution control settlement.

A

ACID RAIN

OVERVIEW OF THE PROBLEM

Acid rain is the general and now popular term that pertains to both acid rain and acid snow. This article discusses the physical and chemical aspects of the acid rain phenomenon, presents results from a U.S. monitoring network to illustrate spatial and seasonal variability, and discusses time trends of acid rain during recent decades. A chemical equilibrium model is presented to emphasize that one cannot measure only pH and then expect to understand why a particular rain or melted snow sample is acidic or basic. Monitoring networks are now in operation to characterize the time trends and spatial patterns of acid rain. Definitions, procedures, and results from such measurement programs are discussed. The monitoring results are necessary to assess the effects of acid rain on the environment, a topic only briefly discussed in this article.

Chemicals in the form of gases, liquids, and solids are continuously deposited from the air to the plants, soils, lakes, oceans, and manmade materials on the earth's surface. Water (H_2O) is the chemical compound deposited on the earth's surface in the greatest amount. The major atmospheric removal process for water consists of these steps: (1) air that contains water vapor rises, cools, and condenses to produce liquid droplets, i.e., a visible cloud; (2) in some clouds the water droplets are converted to the solid phase, ice particles; (3) within some clouds the tiny liquid droplets and ice particles are brought together to form particles that are heavy enough to fall out of the clouds as rain, snow, or a liquid–solid combination. When these particles reach the ground, a precipitation event has occurred. As water vapor enters the base of clouds in an air updraft in step (1) above, other solid, liquid, and gaseous chemicals are also entering the clouds. The chemicals that become incorporated into the cloud water (liquid or ice) are said to have been removed by in-cloud scavenging processes often called rainout. The chemicals that are incorporated into the falling water (liquid or ice) below the cloud are said to be removed by below-cloud scavenging, often called washout.

Carbon dioxide gas, at the levels present in the atmosphere, dissolves in pure water to produce a carbonic acid solution with a pH of about 5.6. Therefore, this value is usually considered to be the neutral or baseline value for rain and snow. Measurements show that there are always additional chemicals in rain and snow. If a salt (sodium chloride) particle in the air is scavenged (captured) by a raindrop or snow flake, it does not alter the acidity. If an acid particle, such as one composed of sulfuric acid, is scavenged, then the rain or snow becomes more acid. If a basic particle, such as a dust particle composed of calcium carbonate, is scavenged then the rain or snow becomes more basic. It is important that both pH as well as the major chemicals that alter the pH of rain and snow be included in routine measurement programs. The adverse or beneficial effects of acid rain are not related only to the hydrogen ion concentration (a measure of acidity level), but also to the other chemicals present.

In following the cycle of chemicals through the atmosphere one considers (1) the natural and manmade sources emitting chemicals to the atmosphere, (2) the transport and transformation of the chemicals in the atmosphere, and (3) the removal of the chemicals from the atmosphere. Therefore, when one regularly measures (monitors) the quantity of chemicals removed from the atmosphere, indirect information is obtained about the removal rates and processes, the transport/transformation rates and processes, and the source characteristics.

A great number of projects have been carried out to measure various chemicals in precipitation. For example, Gorham (1958) reported that hydrochloric acid should be considered in assessing the causes of rain acidity in urban areas. Junge (1963) summarized research discussing the role of sea salt particles in producing rain from clouds. Even as far back as 1872, Robert Anges Smith discussed the relationship between air pollution and rainwater chemistry in his remarkable book entitled *Air and Rain: The Beginnings of A Chemical Climatology* (Smith, 1872). These three examples indicate that the measurement of chemicals in precipitation is not just a recent endeavor. Certainly one reason for the large number of studies is the ease of collecting samples, i.e., the ease of collecting rain or snow. Over time and from project to project during a given time period, the purpose for the rain and snow chemistry measurements has varied, and thus the methods and the chemical parameters being measured have varied greatly.

The surge of interest in the 1980s in the acidity levels of rain and snow was strongly stimulated by Scandinavian studies reported in the late 1960s and early 1970s. These studies reported that the pH of rain and snow in Scandinavia during the period from 1955 to 1965 had decreased dramatically. The Scandinavians also reported that a large number of lakes, streams, and rivers in southern Norway and Sweden were devoid or becoming devoid of fish. The hypothesis was that this adverse effect was primarily the result of acid rain, which had caused the the lakes to become increasingly more acidic.

Later studies with improved sampling and analysis procedures, confirmed that the rain and snow in southern Norway and Sweden were quite acid, with average pH values of about 4.3. The reports sometimes considered the idea that changes in the acidity of the lakes were partially the result of other factors including landscape changes in the watershed, but usually the conclusion was that acid rain was the major cause of the lake acidification and that the acid rain is primarily the result of long-range transport of pollutants from the heavily industrialized areas of northern Europe.

The rain and snow in portions of eastern Canada and the eastern United States are as acid as in southern Scandinavia, and some lakes in these areas also are too acid to support fish. Studies have confirmed that many of the lakes sensitive to acid rain have watersheds that provide relatively small inputs of neutralizing chemicals to offset the acid rain and snow inputs.

Any change in the environment of an ecological system will result in adjustments within the system. Increasing the acid inputs to the system will produce changes or effects that need to be carefully assessed. Effects of acid rain on lakes, row crops, forests, soils, and many other system components have been evaluated. Evans *et al.* (1981) summarized the status of some of these studies and concluded that the acid rain effects on unbuffered lakes constituted the strongest case of adverse effects, but that beneficial effects could be identified for some other ecological components.

During the 1980s a tremendous amount of acid rain research was completed. More than 600 million dollars was spent by United States federal agencies on acid rain projects. The federal effort was coordinated through the National Acid Precipitation Assessment Program (NAPAP). This massive acid rain research and assessment program was summarized in 1990 in 26 reports of the state of science and technology which were grouped into four large volumes (NAPAP, 1990): Volume I—Emissions, Atmospheric Processes, and Deposition; Volume II—Aquatic Processes and Effects; Volume III—Terrestrial, Materials, Health, and Visibility Effects; and Volume IV—Control Technologies, Future Emissions, and Effects Valuation. The final assessment document (NAPAP, 1991) was a summary of the causes and effects of acidic deposition and a comparison of the costs and effectiveness of alternative emission control scenarios. Since adverse effects of acid rain on fish have been of particular interest to the general public, it is appropriate to note the following NAPAP (1991, pages 11–12) conclusions on this subject:

- Within acid-sensitive regions of the United States, 4 percent of the lakes and 8 percent of the streams are chronically acidic. Florida has the highest percentage of acidic surface waters (23 percent of the lakes and 39 percent of the streams). In the mid-Atlantic Highlands, mid-Atlantic Coastal Plain, and the Adirondack Mountains, 6 to 14 percent of the lakes and streams are chronically acidic. Virtually no (<1 percent) chronically acidic surface waters are located in the Southeastern Highlands or the mountainous West.
- Acidic lakes tended to be smaller than nonacidic lakes; the percentage of acidic lake area was a factor of 2 smaller than the percentage of acidic lakes based on the numbers.
- Acidic deposition has caused some surface waters to become acidic in the United States. Naturally produced organic acids and acid mine drainage are also causes of acidic conditions.
- Fish losses attributable to acidification have been documented using historical records for some acidic surface waters in the Adirondacks, New England, and the mid-Atlantic Highlands. Other lines of evidence, including surveys and the application of fish response models, also support this conclusion.

In future years the effects on materials such as paint, metal and stone should probably be carefully evaluated because of the potentially large economic impact if these materials undergo accelerated deterioration due to acid deposition.

DEFINITIONS

Some widely used technical terms that relate to acid rain and acid rain monitoring networks are defined as follows:

1) **pH** The negative logarithm of the hydrogen ion activity in units of moles per liter (for precipitation solutions, concentration can be substituted for activity). Each unit decrease on the pH scale represents a 10-fold increase in acidity. In classical chemistry a pH less than 7 indicates acidity; a pH greater than 7 indicates a basic (or alkaline) solution; and a pH equal to 7 indicates neutrality. However, for application to acid rain issues, the neutral point is chosen to be about 5.6 instead of 7.0 since this is the approximate equilibrium pH of pure water with ambient outdoor levels of carbon dioxide.
2) **Precipitation** This term denotes aqueous material reaching the earth's surface in liquid or solid form, derived from the atmosphere. Dew, frost,

and fog are technically included but in practice are poorly measured, except by special instruments. The automatic devices currently in use to sample precipitation for acid rain studies collect rain and "wet" snow very efficiently; collect "dry" snow very inefficiently; and collect some fog water, frost and dew, but these usually contribute very little to the annual chemical deposition at a site.

3) **Acid Rain** A popular term with many meanings; generally used to describe precipitation samples (rain, melted snow, melted hail, etc.) with a pH less than 5.6. Recently the term has sometimes been used to include acid precipitation, ambient acid aerosols and gases, dry deposition of acid substances, etc., but such a broad meaning is confusing and should be avoided.
4) **Acid Precipitation** Water from the atmosphere in the form of rain, sleet, snow, hail, etc., with a pH less than 5.6.
5) **Wet Deposition** A term that refers to: (a) the amount of material removed from the atmosphere by rain, snow, or other precipitation forms; and (b) the process of transferring gases, liquids, and solids from the atmosphere to the ground during a precipitation event.
6) **Dry Deposition** A term for (a) all materials deposited from the atmosphere in the absence of precipitation; and (b) the process of such deposition.
7) **Atmospheric (or Total) Deposition** Transfer from the atmosphere to the ground of gases, particles, and precipitation, i.e., the sum of wet and dry deposition. Atmospheric deposition includes many different types of substances, non-acidic as well as acidic.
8) **Acid Deposition** The transfer from the atmosphere to the earth's surface of acidic substances, via wet or dry deposition.

PROCEDURES AND EQUIPMENT FOR WET DEPOSITION MONITORING

For data comparability it would be ideal if all wet deposition networks used the same equipment and procedures. However, this does not happen. Therefore, it is important to decide which network characteristics can produce large differences in the databases. The following discussion outlines procedures and equipment which vary among networks, past and present.

Site Location

Sites are selected to produce data to represent local, regional, or remote patterns and trends of atmospheric deposition of chemicals. However, the same site may produce a mixture of data. For example, the measured calcium concentrations at a site might represent a local pattern while the sulfate concentrations represent a regional pattern.

Sample Containers

The containers for collecting and storing precipitation must be different, depending on the chemical species to be measured. Plastic containers are currently used in most networks in measuring acidic wet deposition. Glass containers are considered less desirable for this purpose because they can alter the pH: For monitoring pesticides in precipitation, plastic containers would be unacceptable.

Sampling Mode

There are four sampling modes:

Bulk Sampling A container is continuously exposed to the atmosphere for sampling and thus collects a mixture of wet and dry deposition. The equipment is simple and does not require electrical power. Thus bulk sampling has been used frequently in the past, and it is still sometimes used for economic reasons. For many studies an estimate of total deposition, wet plus dry, is desired, and thus bulk sampling may be suitable. However, there is a continuing debate as to precisely what fraction of dry deposition is sampled by open containers. The fraction collected will probably depend on variables such as wind speed, container shape and chemical species. The continuously exposed collectors are subject to varying amounts of evaporation unless a vapor barrier is part of the design. When one objective of a study is to determine the acidity of rain and snow samples, bulk data pH must be used with great caution and ideally in conjunction with adequate blank data. For wet deposition sites that will be operated for a long time (more than one year), the labor expenses for site operation and the central laboratory expenses are large enough that wet-only or wet-dry collectors should certainly be purchased and used instead of bulk collectors in order to maximize the scientific output from the project.

Wet-Only Sampling There are a variety of automatic wet-only samplers in use today that are open only during precipitation events. Side-by-side field comparison studies have documented differences in the reaction time for the sensors, in the reliability of the instruments, and in the chemical concentrations in the samples from the different sampling devices. Wet-only sampling can also be achieved by changing bulk samples *immediately* (within minutes) at the beginning and end of precipitation events, but this is very labor-intensive if done properly.

Wet-Dry Sampling With this device, one container is automatically exposed during dry periods and the second container is exposed during precipitation periods. If the sample in the dry deposition container is not analyzed, the device becomes a wet-only collector.

Sequential Sampling A series of containers are consecutively exposed to the atmosphere to collect wet deposition samples, with the advance to a new container being triggered on a time basis, a collected volume basis, or both. These devices can be rather complicated and are usually operated only for short time periods during specific research projects.

Sample Handling

Changes in the chemicals in the sample over time are decreased through (1) the addition of preservatives to prevent biological change, (2) refrigeration, (3) aliquoting, and (4) filtering. Filtering is more effective than refrigeration for stabilizing samples for some species such as calcium and magnesium. For species such as organic acids, only chemical preservatives are certain to prevent change.

Analytical Methods

Several analytical methods are available to adequately measure the major ions found in precipitation, but special precautions are necessary because the concentrations are low and thus the samples are easily contaminated. Measurement of the chemical parameter pH, although deceptively easy with modern equipment, requires special care in order to arrive at accurate results because of the low ionic strength of rain and snow samples. Frequent checks with low ionic strength reference solutions are required to avoid the frequent problem of malfunctioning pH electrodes. The ions SO_4^{2-}, NH_4^+, Ca^{2+}, etc., are measured in modern laboratories by ion chromatography, automated colorimetry, flame atomic absorption, and other methods.

Quality Assurance/Quality Control

The chemical analysts actually performing measurements should follow documented procedures, which include measurements of "check" or "known" solutions to confirm immediately and continuously that the work is "in control" and thus is producing quality results. At an administrative level above the analysts, procedures are developed to "assure" that the results are of the quality level established for the program. These quality assurance procedures should include the submission of blind reference samples to the analysts on a random basis. Quality assurance reports should routinely be prepared to describe procedures and results so that the data user can be assured (convinced) that the data are of the quality level specified by the program. In the past, insufficient attention has been given to quality assurance and quality control. As a minimum, from 10 to 20% of the cost of a monitoring program should be devoted to quality assurance/quality control. This is especially true for measurements on precipitation samples that have very low concentrations of the acid-rain-related species and thus are easily contaminated.

CALCULATING PRECIPITATION pH

This section describes the procedures for calculating the pH of a precipitation sample when the concentrations of the major inorganic ions are known (Stensland and Semonin, 1982). Granat (1972), Cogbill and Likens (1974), and Reuss (1975) demonstrated that the precipitation pH can be calculated if the major ion concentrations are known. The procedure described below is analogous to that used by these previous workers but is formulated somewhat differently.

Three good reasons to have a method to calculate the pH are that:

1) The pH can be calculated for older data sets when pH was not measured but the major inorganic ions were measured (e.g., the Junge (1963) data set),
2) The trends or patterns of pH can be interpreted in terms of trends or patterns in the measured inorganic ions such as sulfate or calcium, and
3) The calculated pH can be compared with the measured pH to provide an analytical quality control check.

Gases (e.g., SO_2 and CO_2) and aerosols (e.g., NaCl and $(NH_4)_2SO_4$) scavenged by precipitation can remain as electrically neutral entities in the water solution or can participate in a variety of chemical transformations, including simple dissociation, to form ions (charged entities). The basic premise that the solution must remain electrically neutral allows one to develop an expression to calculate pH. Stated another way, when chemical compounds become ions in a water solution, the quantity of positive ions is equal to the quantity of negative ions. This general concept is extremely useful in discussing acid precipitation data.

As a simple example, consider a solution of only water and sulfuric acid (H_2SO_4). The solution contains H^+, OH^-, and ions. At equilibrium

$$(H^+)(OH^-) = 10^{-14}(m/L)^2$$

if the ion concentrations are expressed in moles/liter (m/L). Assuming $pH = 4$, then from the defining relation $pH = -\log(H^+)$ it follows that

$$(H^+) = 10^{-4}\ m/L$$

Therefore $(OH^-) = 10^{-10}$ m/L and thus (OH^-) is so small that it can be ignored for further calculations. Since the dissociation of the sulfuric acid in the water gives one sulfate ion for each pair of hydrogen ions, it follows that

$$(SO_4^{2-}) = 1/2(H^+) = 0.5 \times 10^{-4} m/L$$

It is useful to convert from moles/liter (which counts particles) to equivalents/liter (eq/L), as this allows one to count electrical charge and thus do an "ion balance." The conversion is accomplished by multiplying the concentration in m/L by the valance (or charge) associated with each ion. The example solution contains

$$(0.5 \times 10^{-4}\ m/L) \times (2) = 10^{-4}\ eq/L = 100\ \mu eq/L$$

of sulfate and

$$(1 \times 10^{-4}\ m/L) \times (1) = 10^{-4}\ eq/L = 100\ \mu eq/L$$

of hydrogen ion. Thus the total amount of positive charge (due to H^+ in this example) is equal to the total amount of negative charge (due to SO_4^{2-}) when the concentrations are expressed in eq/L (or μeq/L).

For most precipitation samples, the major ions are those listed in Eq. (1):

$$\begin{aligned}&\left(H^+\right)+\left(Ca^{2+}\right)+\left(Mg^{2+}\right)+\left(NH_4^+\right)+\left(Na^+\right)+\left(K^+\right)\\&\quad=\left(SO_4^{2-}\right)+\left(NO_3^-\right)+\left(Cl^-\right)+\left(OH^-\right)+\left(HCO_3^-\right)\end{aligned} \tag{1}$$

with each ion concentration expressed in μeq/L. In practice, if the actual measurements are inserted into Eq. (1), then agreement within about 15% for the two sides of the equation is probably acceptable for any one sample. Greater deviations indicate that one or more ions were measured inaccurately or that an important ion has not been measured. For example, in some samples Al^{3+} contributes a significant amount and therefore needs to be included in Eq. (1). It should be noted that assumptions concerning the parent compounds of the ions are not necessary. However, if one did know, for example, that all Na^+ and all Cl^- resulted from the dissolution of a single compound such as NaCl, then these two ions would not be necessary in Eq. (1) since they cancel out on the two sides of the equation.

There are actually two useful checks as to whether or not all the major ions have been measured. First, one compares to see that the sum of the negative charges is approximately equal to the sum of the positive charges. If all the sodium and chloride ions come entirely from the compound NaCl, then this first check would produce an equality, even if these major ions were not measured. The second check is whether the calculated conductivity is equal to the measured conductivity. The calculated conductivity is the sum of all the ions (in Eq. (1)) multiplied by the factors listed in Table 1. For low pH samples of rain or melted snow (i.e., pH < 4.5), H^+ is the major contributor to the calculated conductivity because of the relatively large value of its factor in Table 1.

TABLE 1
Conductance Factors at 25°C[a]

Ion	μS/cm per μeq/L
H^+	0.3500
HCO_3^-	0.0436
Ca^{2+}	0.0520
Cl^-	0.0759
Mg^{2+}	0.0466
NO_3^-	0.0710
K^+	0.0720
Na^+	0.0489
SO_4^{2-}	0.0739
NH_4^+	0.0745

[a] From *Standard Methods for the Examination of Water and Wastewater,* American Public Health Association, Inc., Wash., D.C., 13th Edition.

For precipitation samples, bicarbonate concentration is usually not measured. Thus both (HCO_3^-) and (OH^-) must be calculated from the measured pH. To calculate (OH^-) and (HCO_3^-) the following relationships for the dissociation of water and for the solubility and first and second dissociations of carbon dioxide in water are used:

Chemical Reaction

$$H_2O \qquad OH^- + H^+ \tag{2a}$$

$$Pco_2 \qquad H_2O\cdot CO_2 \tag{2b}$$

$$H_2O\cdot CO_2 \qquad H^+ + HCO_3^- \tag{2c}$$

$$HCO_3^- \qquad H^+ + CO_3^{2-} \tag{2d}$$

Equilibrium Relationship

$$K_W = (OH^-)(H^+) \tag{3}$$

$$K_H = \frac{\left(H_2O\cdot CO_2\right)}{Pco_2} \tag{4}$$

$$K_1 = \frac{\left(H^+\right)\left(HCO_3^-\right)}{\left(H_2O\cdot CO_2\right)} \tag{5}$$

$$K_2 = \frac{\left(H^+\right)\left(CO_3^{2-}\right)}{\left(HCO_3^-\right)} \tag{6}$$

For 25°C, $K_W = 10^{-2}$ (μeq $L^{-1})^2$, $K_H = 0.34 \times 10^{+6}$ μeq L^{-1}, $K_1 = 4.5 \times 10^{-1}$ μeq L^{-1}, and $K_2 = 9.4 \times 10^{-5}$ μeq L^{-1}.

$$\frac{\left(HCO_3^-\right)}{\left(CO_3^{2-}\right)} = \frac{\left(H^+\right)}{K_2} \tag{7a}$$

For T = 25°C and pH = 8, (H^+) = 0.01 μeq/L and thus:

$$\frac{\left(HCO_3^-\right)}{\left(CO_3^{2-}\right)} = \frac{0.01}{9.4\times10^{-5}} = 106 \tag{7b}$$

Thus the concentration of HCO_3^- is much greater than that of CO_3^{2-}. For lower pH values, HCO_3^- dominates CO_3^{2-} even more, and so CO_3^{2-} is not included in applications related to precipitation samples (i.e., Eq. (1)).

From Eqs. (4) and (5)

$$\left(HCO_3^-\right)\left(H^+\right) = K_H K_1 Pco_2 \tag{8}$$

From Eqs. (3) and (8)

$$\frac{\left(HCO_3^-\right)}{\left(OH^-\right)} = \frac{K_H K_1 Pco_2}{K_W} \tag{9}$$

where it is convenient to define

$$K = \frac{K_H K_1 Pco_2}{K_W} \tag{10}$$

Equation (1) is now rearranged to give

$$\begin{aligned}\left(H^+ - OH^- - HCO_3^-\right) &= \left(SO_4^{2-} + NO_3^- + C1^-\right) \\ &\quad - \left(Ca^{2+} + Mg^{2+} + Na^+ + K^+ + NH_4^+\right)\end{aligned} \tag{11}$$

With the definition

$$\begin{aligned}\text{Net Ions } &= \left(SO_4^{2-} + NO_3^- + Cl^-\right) \\ &\quad - \left(Ca^{2+} + Mg^{2+} + Na^+ + K^+ + NH_4^+\right)\end{aligned} \tag{12}$$

Eq. (11) becomes

$$\left(H^+ - OH^- - HCO_3^-\right) = \left(\text{Net Ions}\right) \tag{13}$$

With Eqs. (3), (9), and (10), Eq. (13) becomes the quadratic equation

$$(H^+)^2 - (\text{Net Ions})(H^+) - K_w(K + 1) = 0 \tag{14}$$

Solving for the concentration of H^+ gives

$$2(H^+) = (\text{Net Ions}) \pm [(\text{Net Ions})^2 + 4K_W(K + 1)]^{1/2} \tag{15}$$

The quantity in brackets in Eq. (15) is always positive and greater than (Net Ions), and therefore only the plus sign in front of the bracketed term provides non-negative and therefore physically realistic solutions for (H^+).

Equation (15) is rewritten in terms of pH as

$$\begin{aligned}pH = +6 - \log_{10}\{\{(\text{Net Ions}) + [(\text{Net Ions})^2 \\ + 4K_H K_1 Pco_2 + 4K_w]^{0.5}\}/2\}\end{aligned} \tag{16}$$

Equation (16) is plotted in Figure 1. If the major ions have been measured for a precipitation sample such that (Net Ions) can be determined with Eq. (12), then line B on the graph allows one to read the calculated pH. Any additional ion measured, besides those listed on the right side of Eq. (12), are simply added to Eq. (12) to make the determination of (Net Ions) just that much more accurate. If the water sample being considered is pure water in equilibrium with ambient carbon dioxide, then (Net Ions) = 0.0 and curve B indicates that the pH is less than or equal to 5.65.

The precipitation sample concentrations of HCO_3^-, OH^-, and H^+ are also shown in Figure 1, where the absolute value of the ordinate is used to read off these concentrations. It is seen that the HCO_3^- and H^+ curves approach curve B. That is, at low pH, $(H^+) \sim$ (Net Ions) and at high pH, $(HCO_3^-) \sim$ (Net Ions).

If $Pco_2 = 0$ (as it would be if one bubbled an inert gas such as nitrogen through the precipitation sample as the pH was being measured), then $K = 0$ in Eq. (10), and Eq. (16) is modified and provides the curves marked accordingly in Figure 1. In this case, with no present (cf. Eq. (8)), the asymptotic limit at high pH is provided by the OH^- curve.

The sensitivity of the pH prediction via Eq. (16) to the assumed equilibrium conditions of temperature and Pco_2 is displayed in Figure 1 by curves A to D (and of course the $Pco_2 = 0$ curve as the extreme case). At T = 25°C and $Pco_2 = 316 \times 10^{-6}$ atm, $K = 483$. Therefore at pH = 8, where $(OH^-) = 1$ μeq/L, $(HCO_3^-) = 483$ μeq/L, and this procedure explains the spacing between curves A to D and the OH^- curve in Figure 1. If the temperature is kept constant, K is proportional to Pco_2. So if we double the CO_2 level (e.g., move from curve B to C), the pH = 8 intercept for HCO_3^- jumps up to (2)(483) = 966. Curves A, B, C, and D (which are plots of Eq. (16) only at high (Net Ion) values) thus graphically demonstrate the sensitivity of pH to temperature and Pco_2. As a specific example consider that with curve B and at (Net Ions) = −49, the pH = 7; when Pco_2 is doubled (curve C), the same (Net Ion) value gives pH = 6.69; if the temperature is lower (curve D), then the pH = 6.15.

Figure 1 also demonstrates that a bimodal pH distribution would be expected if both high and low pH values are present in a particular data set. For example, assume all (Net Ion) values between +45 and −45 are equally likely. From (Net Ion) = 45 to 15, $\Delta pH = 0.48$; from (Net Ion) = 15 to −15, $\Delta pH = 1.65$; and from (Net Ion) = −15 to −45, $\Delta pH = 0.48$.

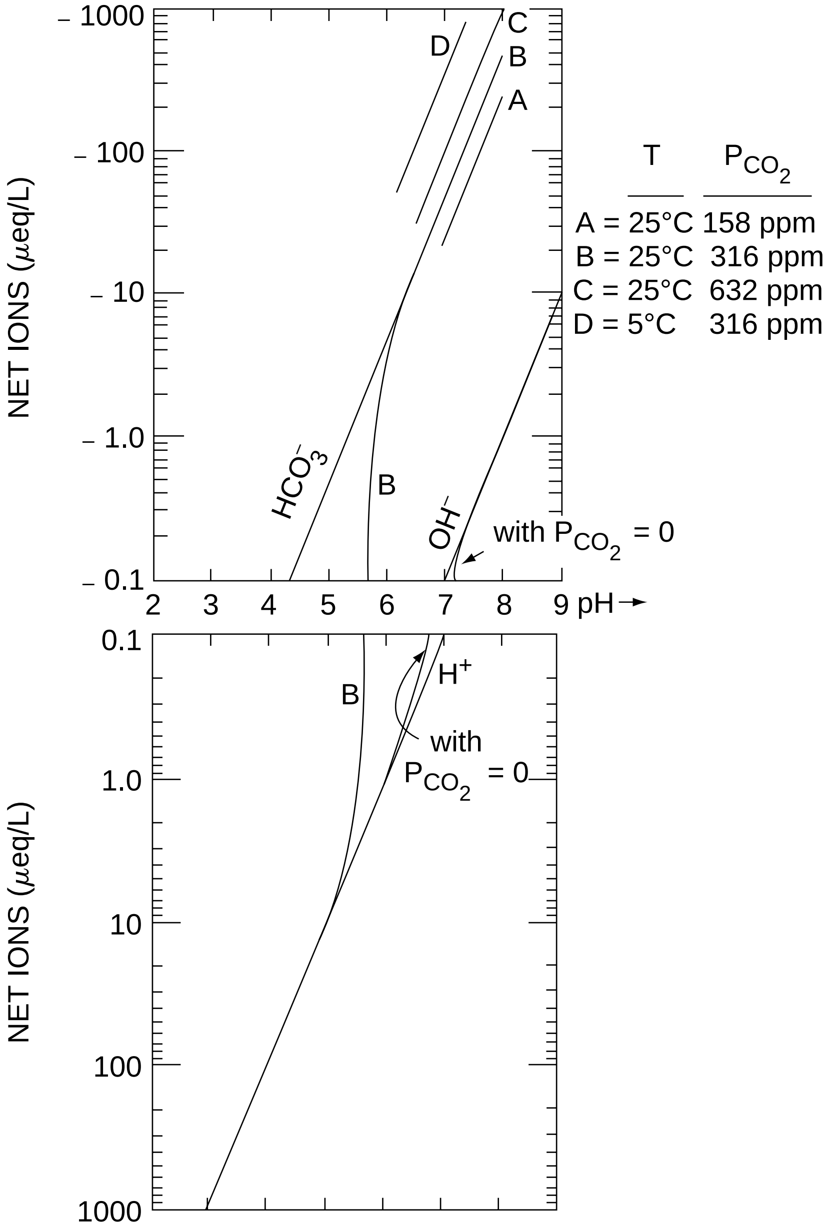

FIGURE 1 The concentration of Net Ions versus pH for precipitation samples with different values of *T* (temperature) and P_{CO_2}.

Therefore the pH will most frequently be either very large or very small, giving a bimodal distribution.

To calculate (HCO_3^-), for charge balance calculations, it is also useful to note that from equation (8),

$$\left(HCO_3^-\right) = \frac{\left(0.0153 \times 10^6\right) Pco_2}{\left(H^+\right)} \tag{17}$$

Thus, for $Pco_2 = 316 \times 10^{-6}$ atm,

$$\left(HCO_3^-\right) = \frac{4.84}{\left(H^+\right)} \tag{18}$$

Therefore, at pH = 5, $(H^+) = 10$ μeq L^{-1}, and (HCO_3^-) is only about 5% as large as (H^+).

In summary it should simply be noted that the measured ions can be combined according to Eq. (12) to produce the quantity called Net Ions, which can then be used with Eq. (16) or Figure 1 to predict the sample pH.

U.S. PRECIPITATION CHEMISTRY DATA

Many precipitation chemistry networks are being operated in the United States. Some of the networks include sites in many states, while other networks are limited to sites within a single state. For this discussion, example data from the National Atmospheric Deposition Program/National Trends Network (NADP/NTN) will be used.

The NADP/NTN began operation in 1978 with about 20 sites. By 1982 it had grown to approximately 100 sites, and by the late 1980s about 200 sites were in operation, with only the states of Rhode Island, Connecticut, and Delaware not having sites. American Samoa, Puerto Rico, and Canada each had one site. As of 1996 about 200 sites are operating. Even though the publicity about acid rain has decreased in the 1990s, the NADP/NTN has not decreased in size as some had expected. The NADP/NTN has six noteworthy characteristics:

1) The site locations were generally selected to provide precipitation chemistry data that will be representative of a *region* as opposed to a *local* area that might be dominated by a few pollution sources or by an urban area.
2) Sites are fairly long-term, operating for a minimum of five years and ideally for much longer.
3) Each site collects samples with the same automatic wet-dry collector. Sites are also equipped with a recording rain gage, an event recorder, a high-quality pH meter, a high-quality conductivity meter, and a scale to weigh the samples before they are sent to the laboratory.
4) Each site is serviced every Tuesday. The collecting bucket from the wet-side of the sampler is sent to the central laboratory each week.
5) There is a single Central Analytical Laboratory. This laboratory measures the chemical parameters for each rain and snow sample and returns clean sampling containers to the field sites. Since the inception of the program, this central laboratory has been at the Illinois State Water Survey in Champaign, Illinois.
6) Only the soluble portion of the constituents (sulfate, calcium, potassium, etc.) are measured. All NADP/NTN samples are filtered shortly after arriving at the central laboratory and this step operationally defines solubility. The fraction of the chemical species that is separated from the liquid sample and remains on the filter or remains on the inside surfaces of the collecting bucket is operationally defined as the insoluble fraction and is not measured by the NADP/NTN program. For species like sulfate, nitrate, and ammonium, the insoluble fraction is negligible while for potassium perhaps only 50 percent is soluble.

Data shown in Table 2 from the NADP/NTN weekly wet deposition network provide a quantitative chemical characterization of precipitation. Average results for the year 1984 for four sites are shown. Median ion concentrations, in units of microequivalents per liter (μeq/L), are listed. Bicarbonate (HCO_3^-) for the precipitation samples is calculated with the equations from the previous section by assuming that the samples are in equilibrium with atmospheric carbon dioxide at a level of 335×10^{-6} atm. Hydrogen ion (H^+) is calculated from the median pH for the weekly samples. The ions listed in Table 2 constitute the major ions in precipitation; this fact is supported by noting that the sum of the negatively charged ions (anions) is approximately equal to the sum of the positively charged ions (cations) for each of the four sites.

Sulfate, nitrate, and hydrogen ions predominate in the samples from the New Hampshire and Ohio sites, with levels being higher (and pH lower) at the Ohio site. For these two sites, about 70% of the sulfate plus nitrate must be in the acid form in order to account for the measured acidity (H^+). At the Nebraska site, sulfate and nitrate are higher than at the New Hampshire site, but H^+ is only 2 μeq/L (median pH = 5.80). Notice that for the Nebraska site the weighted average pH, which is a commonly reported type of average pH, is much smaller than the median pH. This indicates that one should be consistent in using the same averaging procedure when comparing pH for different data sets. If the sulfate and nitrate at the Nebraska site were in the form of acid compounds when they entered the rain, then the acidity was neutralized by bases before the rain reached the laboratory. However, irrespective of the details of the chemical processes, the net effect is that at the Nebraska site, ammonium (NH_4^+) and calcium (Ca^{2+}) are the dominant positive ions counterbalancing the dominant negative ions, sulfate (SO_4^{2-}) and nitrate (NO_3^-). For the Florida coastal site, sodium (Na^+) and chloride (Cl^-) are dominant ions derived from airborne sea salt particles that have been incorporated into the raindrops. Sulfate and nitrate are lower at the Florida site than at the other three sites. Finally, the ion concentrations for drinking water (the last column in Table 2) for one city in Illinois are much higher than for precipitation except for nitrate, ammonium, and hydrogen ion.

In summary, the data in Table 2 demonstrate that:

(a) Sulfate, or sulfate plus nitrate, is not always directly related to acidity (and inversely to pH) in precipitation samples;
(b) All the major ions must be measured to understand the magnitude (or time trends) of acidity of a sample or a site; and

[a] A site in central New Hampshire.

[b] A site in southeastern Ohio.

[c] A site in east-central Nebraska.

[d] A site in the southern tip of Florida.

[e] Levels in treated municipal well water (tap water) for a city of 100,000 in Illinois.

[f] Calculated with equation: $HCO_3^- = 5.13$ divided by H^+ for $Pco_2 = 335 \times 10^{-6}$ atm.

[g] Calculated from median pH.

[h] Sample volume weighted hydrogen ion concentration, expressed as pH. Some western sites have differences in weighted and median pH values of as much as 1 unit.

(c) Precipitation samples are relatively clean or pure as compared to treated well water used for drinking.

SPATIAL PATTERNS. The spatial distribution of five of the chemical parameters measured in the NADP/NTN weekly precipitation chemistry samples are shown in Figures 2–6. The "+" symbol indicates the location of the 180 sampling sites included in the analysis. A relatively long time period (1990–1993) was chosen for analysis in order to have sufficient data to produce stable patterns, but not so long that emissions of the major sources of the chemical parameters would have changed substantially. Samples for weeks with total precipitation less than two hundredths of an inch of equivalent liquid precipitation were not included. Every sample was required to pass rigorous quality assurance standards which included checks to assure that the proper sampling protocol was followed and that visible matter in the samples was not excessive and did not produce abnormally high concentrations of the chemical species measured. The nine sites at elevations greater than 3,000 meters were not included due to concerns about their representativeness. Completeness of data for each of the sites was judged in two ways. First, sites that started after January 1, 1990, or ceased operating before December 31, 1993, were excluded from the analysis if they operated

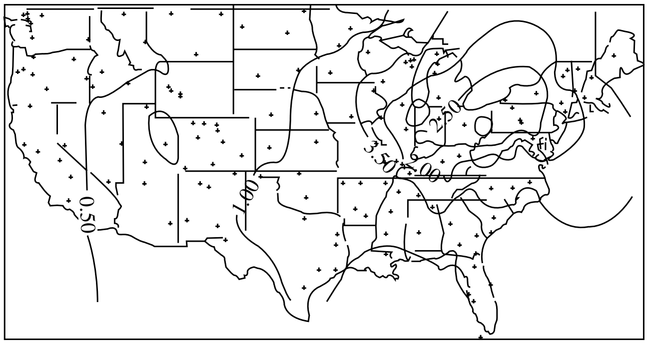

FIGURE 2 Median concentration (mg/L) of sulfate in precipitation for 180 NADP/NTN sites for the period 1990–1993.

less than 80 percent of the four-year interval (98 percent or 176 of the 180 selected sites operated for more than 95 percent of the interval). Second, sites with a low number of valid weekly samples were excluded. That is, if at least two hundredths of an inch of liquid precipitation would have fallen every week and if valid chemical measurements were obtained for each weekly sample, then 205 samples would have been available. In fact for the semi-arid western states, a large fraction of the weekly samples are completely dry. A decision was made to include in the analysis only those western sites with at least 100 valid samples and those eastern sites with at least 129 valid samples. For the 180 sites meeting all of the selection criteria, the median number of valid samples was 152.

Shown in Figures 2–6 are lines (isopleths) of median ion concentration or median pH. The isopleths are computer generated and include some automatic smoothing, but are very similar to hand-drawn contours. The concentrations are for the ion, i.e., for sulfate it is milligrams per liter of sulfate, not sulfur.

Sulfate concentrations in precipitation, shown in Figure 2, are highest in the Northeast with values exceeding 2.5 mg/L at sites in eastern Illinois, Indiana, Ohio, and western Pennsylvania. This is consistent with known high emissions to the atmosphere of sulfur from coal burning electrical power plants in this region. The sulfate levels decrease to the west of this area, with West Coast values being less than 0.5 mg/L.

The major anthropogenic sources for the nitrogen precursors which become nitrate in precipitation are high temperature combustion sources, which includes power plants and automobiles. The known locations for these sources are consistent with the observed nitrate concentrations in precipitation shown in Figure 3. Nitrate concentrations are high in the Northeast, from Illinois to New York. The high values of nitrate in southern California are reasonable considering the high density of people and automobiles in this area. The lack of high sulfate values in this California area reflects the lack of intensive coal combustion in the area.

Figure 4 shows the concentrations of calcium in precipitation. With respect to sources of the calcium, Gillette *et al.* (1989) have indicated that dust from soils and dust from traffic on unpaved roads are the major sources of calcium in the atmosphere. Dust devils in the southwestern states, wind erosion of agricultural fields, and crop production activities in areas with intensive agriculture are the major dust generation processes for soils. The elevated levels of calcium shown in Figure 4 in the Midwestern, plains, and western states are due to a combination of the location of the mentioned dust generating sources as well as the generally more arid conditions in these areas. The higher amounts and frequency of precipitation in the East, Southeast, and Northwest effectively shut off the dust sources by both keeping soil and road material damp and by causing dense vegetation to protect soil surfaces from erosion.

The ammonium concentration pattern shown in Figure 5 is similar to that for calcium but for different reasons. The high values in the Midwestern, plains, and western states are likely due to the emissions of ammonia from livestock feedlots. The 0.45 mg/L isopleth in the central United States encloses the region of large cattle feedlots. Emissions related to agricultural fertilizers may also be important. The site in northern Utah near Logan is in a small basin surrounded by mountains. This terrain and the relatively high density of livestock in the basin likely explains the very high ammonium levels there.

The median pH is shown in Figure 6. As was demonstrated with the data in Table 2, the pH can be understood only by considering all the major acidic and basic constituents. For example notice that a 4.2 pH isopleth encloses sites in Pennsylvania and New York while the maximum sulfate isopleth in Figure 2, with a value of 2.50 mg/L, is shifted further west. The other major acidic anion, nitrate, has its maximum further to the east than sulfate and the two basic cations shown in Figures 4 and 5 have decreasing concentrations from Ohio eastward. Therefore the location of the pH maximum isopleth becomes reasonable when all the major ions are considered.

The pH values in Figure 6 increase westward of Ohio with maximum values of about 6 for sites from southeastern South Dakota to the panhandle of Texas. Continuing westward, the pH values decrease to values less than 5.4 for Rocky Mountain sites in Wyoming, Colorado, and New Mexico, then increase again to values of 6 or higher for many sites in Utah and Nevada, and finally decrease again to values less than 5.4 for sites in the extreme northwestern United States.

The pH values shown in Figure 6 result from measurements made shortly after the samples arrive at the Central Analytical Laboratory in Illinois. During the interval of time between when samples are collected at the field site and until the pH is measured in Illinois, some acid neutralization occurs. In fact the pH determined at the local field site laboratory would be a couple hundredths of a pH unit lower (more acid) for samples with pH values in the 4s and several tenths lower for samples with pH values in the 5s or 6s. Therefore, a map showing the median of field pH values will be somewhat different than Figure 6. The use of other pH averaging procedures (e.g. weighted averages) can also produce substantial differences (for some locations) from values of the median pH shown in Figure 6.

TEMPORAL PATTERNS. In addition to determining the spatial patterns of chemicals in rain and snow, it is important to determine the temporal patterns. Research in the 1970s showed that the sulfate and hydrogen ion concentrations in precipitation in the northeastern United States were higher during the warm season than the cold season. A study by Bowersox and Stensland (1985) showed that this seasonal time dependence was more general, applying to other regions and other ions. For this 1985 study, NADP/NTN data for 1978–1983 were grouped by site into warm-period months (May–September) and cold-period months (November–March). Rigorous data selection criteria were applied, including a stipulation that at least ten valid concentration values be available for each site for each period. Median concentrations were calculated by site for each period. Then the ratios of the warm- to cold-period concentrations were calculated for each site. The means of the resulting site ratios for four regions are presented in Table 3. Sodium and chloride have ratio values *less* than 1.0 for three of the regions, probably because increased storm activity during the cold period injects greater quantities of sea salt into the air in the cold months than is injected in the warm months. Detailed explanations for ratio values being *greater than* or equal to 1.00 for the other ions, in all regions, have not been established. The interannual variation of photochemical conversion rates is certainly an important factor for some ions such as sulfate and hydrogen, while ground cover and soil moisture content are likely to be important factors for the dust-related ions. Meteorological features, such as stagnation conditions and typical wind direction, may also be important factors to explain the seasonality effect shown in Table 3.

For making pollution abatement decisions, the time trends of acid rain, on the scale of years, are important. There has been considerable debate in the literature with respect to the long-term time trends of chemicals in precipitation. Precipitation chemistry sampling locations, equipment, and procedures have varied in the last 30–40 years, producing inconsistent data sets that in turn have led to flawed interpretations and have resulted in controversy. A report from the National Research Council (1986) critically reviews much of the relevant literature. There is quite general agreement that over the last 100 years, the large increase of sulfur emissions to the atmosphere over the United States has increased the levels of sulfate in precipitation. The problem is in trying to quantify the changes for specific regions with enough precision to provide a database sufficient for policy decisions.

The reported changes in precipitation acidity since the mid-1950s are probably the result of three phenomena: the acidity differences related to changes in dust emissions from wind erosion of soils and traffic on unpaved roads; the acidity differences due to changes in sampling techniques; and the acidity differences due to changes in acidic emissions from combustion pollution. Since the combined effect of the first two components is large, the increases in acidity due to changes in sulfur and nitrogen emissions in the

TABLE 3

[a] MW is Midwest, SE is Southeast, NE is Northeast, and RM is Rocky Mountain.

[b] N is the number of sites in the region used in the analysis. States bordering the Pacific Ocean and states in the Great Plains were not included in this analysis.

Midwest and Northeast (or other regions) cannot be precisely quantified on the basis of the historical precipitation chemistry data.

The longest continuous precipitation chemistry record is for the Hubbard Brook site in New Hampshire, where the record began in 1963 (Likens *et al.*, 1984). The sampling method was to continuously expose a funnel and bottle, i.e. bulk sampling. From 1964 to 1982 sulfate decreased quite regularly, which seems to be consistent with the trend of combustion sulfur emissions for this area of the country. Values for pH did not show a significant change. The National Research Council (1986) tabulated the published trends for the Hubbard Brook data set to indicate that the results are sometimes sensitive to the specific type of analysis. For example, one publication indicated that nitrate increased from 1964 to 1971, and then remained steady through 1980. A second publication included the nitrate data for 1963 to 1983, and found no significant *overall* trend. A third publication, including data for 1964 to 1979, found a significant overall increase in nitrate. Bulk data should not generally be compared with wet-only data, however, comparisons have shown that the dry deposition component is relatively small for the Hubbard Brook site and thus it appears valid to suggest that the bulk trends are probably representative of wet-only trends.

The NADP/NTN weekly wet deposition data provides the best data set for trend analysis because of the comprehensive quality assurance program for the network and because of the good spatial coverage across the 48 states. Lynch *et al.* (1995) reported the most recent comprehensive summary of temporal trends in precipitation chemistry in the United States using data from 58 NADP/NTN sites from 1980 through 1992. Results showed widespread declines in sulfate concentrations accompanied by significant decreases in all of the base cations, most noticeably calcium and magnesium. As a result of the decreases in both acids and bases, only 17 of the 42 sites with significantly decreasing sulfate trends had concurrent significant decreasing trends in hydrogen ion (acidity). The decline in precipitation sulfate during this period is consistent with the known declines in sulfur dioxide emissions from electric power plants. The decline in base cations does not yet have a definitive explanation since the strengths of the various emission sources are not well known.

Phase I of Title IV of the 1990 Clean Air Act Amendments required specific reductions in sulfur dioxide emissions on or before 1 January 1995 at selected electric utility plants, the majority of which are located in states east of the Mississippi River. As a result of this legislation, large reductions in sulfur dioxide emissions were likely to have occurred in 1995, which should have affected sulfate and hydrogen ion concentrations in precipitation in this region. Lynch *et al.* (1996) compared the 1995 concentrations to those expected from the 1983–1994 trends and indeed found that sulfate and hydrogen ion decreased much more than expected due to just the 1983–1994 trends. Thus they concluded that acid rain in the eastern United States had decreased as a result of the Phase I emission reductions. Additional major emission reductions in sulfur dioxide are required in Phase II by the year 2000 so it will be important to look for corresponding additional reductions in acid rain.

REMOTE SITE PH DATA

Acid precipitation is also being measured at remote sites. pH data for more than 1700 daily or three-day samples collected in the Hawaiian Islands were reported by Miller and Yoshinaga (1981). The observed pH for the Hawaiian samples ranged from about 3.6 to 6.0. The average pH for about 800 daily samples collected at three sites in the Hilo, Hawaii area was 4.7. The pH decreased with altitude, with an average pH of 4.3 for 92 samples collected at a site at an altitude of 3400 meters. To check for the possibility of local volcanic emissions being the dominant source, samples were collected on the island of Kauai, which has no volcanic emissions and is 500 km north of the big island of Hawaii where all the other sampling took place. For the Kauai site, the average pH was 4.79, which is similar to the pH for the Big Island.

Galloway *et al.* (1982) have measured the chemistry of precipitation for several sites remote from manmade pollution. An important feature documented by these investigators is that the pH of samples from these remote sites increased significantly between the time of field collection and the time of sample receipt at the laboratory in Virginia. However, the pH of the samples remained stable when a chemical was added to stop bacterial activity in the samples. It was established that organic acids (from natural sources) are an important acid component in samples from the remote sites and without the pH stabilization procedure, the organic acids were lost during shipment and only the strong mineral acids and the elevated pH values were detected. For three remote sites in Australia, in Venezuela, and on Amsterdam Island, the weighted average pH values for stabilized samples were 4.8, 4.8, and 4.9 respectively.

The detection of acid rain at locations remote from manmade pollution has led researchers to suggest that departures of precipitation pH below 5.0, instead of the commonly used level of 5.6 or 5.7, would better indicate the local and regional manmade modulations to the natural global background. That is, perhaps we should define acid rain to be samples where pH is less than 5.0. However, since pH is in fact the balance of a group of ions, it is scientifically better to use the levels of these ions, and not just pH, to characterize samples as acid rain.

RECOMMENDATIONS FOR THE FUTURE

This discussion has focused on results of wet deposition measurements. However, both wet and dry deposition must be measured so that eventually a mass balance can be evaluated to account, year by year, for the pollutants put into the air. Therefore:

1) Wet deposition measurements across the United States should be continued indefinitely, just as we continue to monitor emissions, air quality, and weather variables such as precipitation amount and type, and
2) Dry deposition measurement techniques need continued development and evaluation, and a long-term monitoring network must become available to provide data for calculating total deposition (wet and dry).

ACOUSTICS OF THE ENVIRONMENT: see NOISE

AEROSOLS: see also PARTICULATE EMISSIONS; PARTICULATE REMOVAL

AEROSOLS

An aerosol is a system of tiny particles suspended in a gas. Aerosols or particulate matter refer to any substance, except pure water, that exists as a liquid or solid in the atmosphere under normal conditions and is of microscopic or submicroscopic size but larger than molecular dimensions. There are two fundamentally different mechanisms of aerosol formation:

- nucleation from vapor molecules (photochemistry, combustion, etc.)
- comminution of solid or liquid matter (grinding, erosion, sea spray, etc.)

Formation by molecular nucleation produces particles of diameter smaller than 0.1 μm. Particles formed by mechanical means tend to be much larger, diameters exceeding 10 μm or so, and tend to settle quickly out of the atmosphere. The very small particles formed by nucleation, due to their large number, tend to coagulate rapidly to form larger particles. Surface tension practically limits the smallest size of particles that can be formed by mechanical means to about 1 μm.

PARTICLE SIZE DISTRIBUTION

Size is the most important single characterization of an aerosol particle. For a spherical particle, diameter is the usual reported dimension. When a particle is not spherical, the size can be reported either in terms of a length scale characteristic of its silhouette or of a hypothetical sphere with equivalent dynamic properties, such as settling velocity in air.

Table 1 summarizes the physical interpretation for a variety of characteristic diameters. The Feret and Martin diameters are typical geometric diameters obtained from particle silhouettes under a microscope.

TABLE 1

Measures of particle size

		Definition of characteristic diameters	Physical meaning and corresponding measuring method
	geometric size	$(b+l)/2, (b+l+t)/3, (blt)^{1/3}, 3/(1/l+1/b+1/t), \sqrt{lb}, \sqrt{\{(2lb+2bt+2lt/6)\}}$	
		Feret diam. 	unidirectional diameter: diameter of particles at random along a given fixed line, no meaning for a single particle.
		Martin diam. 	unidirectional diameter: diameter of particles as the length of a chord dividing the particle into two equal areas.
	equivalent diam.	equivalent projection area diam. (Heywood diam.)	diameter of the circle having the same area as projection area of particle, corresponding to diam. obtained by light extinction.
		equivalent surface area diam. (specific surface diam.) $(s/\pi)^{1/2}$	diameter of the sphere having the same surface as that of a particle, corresponding to diam. obtained by absorption or permeability method.
		equivalent volume diam. $(6v/\pi)^{1/3}$	diameter of the sphere having the same volume as that of a particle, corresponding to diam. obtained by Coulter Counter.
breadth: *b* length: *l*		Stokes diam.	diameter of the sphere having the same gravitational setting velocity as that of a particle, $D_{st} = [18\ \mu v_t/g(\rho_p - \rho_f)C_c]^{1/2}$, obtained by sedimentation and impactor.

(*continued*)

TABLE 1 (*continued*)
Measures of particle size

Definition of characteristic diameters		Physical meaning and corresponding measuring method
thickness: t volume: v	aerodynamic diam.	diameter of the sphere having unit specific gravity and having the same gravitational setting velocity as that of a particle, $D_{ae} = [18\ \mu u_t/gC_c]^{1/2}$, obtained by the same methods as the above.
surface area: s	electrical mobility equivalent diam.	diameter of the sphere having the same electrical mobility as that of a particle, $D_e = n_p e C_c/3\pi\mu B_e$, obtained by electrical mobility analyzer.
	equivalent diffusion diam.	diameter of the sphere having the same penetration as that of a particle obtained by diffusion battery.
	equivalent light scattering diam.	diameter of the sphere having the same intensity of light scattering as that of a standard particle such as a PSL particle, obtained by light scattering method.

When particles, at total number concentration N, are measured based on a certain characteristic diameter as shown in Table 1 and the number of particles, dn, having diameters between D_p and $D_p + \mathrm{d}D_p$ are counted, the normalized particle size distribution $f(D_p)$ is defined as follows:

$$f(D_p) = \frac{1}{N}\frac{\mathrm{d}n}{\mathrm{d}D_p}, \tag{1}$$

where

$$\int_0^\infty f(D_p)\,\mathrm{d}D_p = 1.$$

The discrete analog which gives a size distribution histogram is

$$f(D_p) = \frac{1}{N}\frac{\Delta n}{\Delta D_p} \tag{2}$$

where Δn is the particle number concentration between $D_p - \Delta D_p/2$ and $D_p + \Delta D_p/2$.

The cumulative number concentration of particles up to any diameter D_p is given as

$$F(D_p) = \int_0^{D_p} f(D'_p)\,\mathrm{d}D'_p = 1 - \int_{D_p}^\infty f(D'_p)\,\mathrm{d}D'_p$$

$$\frac{\mathrm{d}F}{\mathrm{d}D_p} = f(D_p). \tag{3}$$

The size distribution and the cumulative distribution as defined above are based on the number concentration of particles. If total mass M and fractional mass dm are used instead of N and dn, respectively, the size distributions can then be defined on a mass basis.

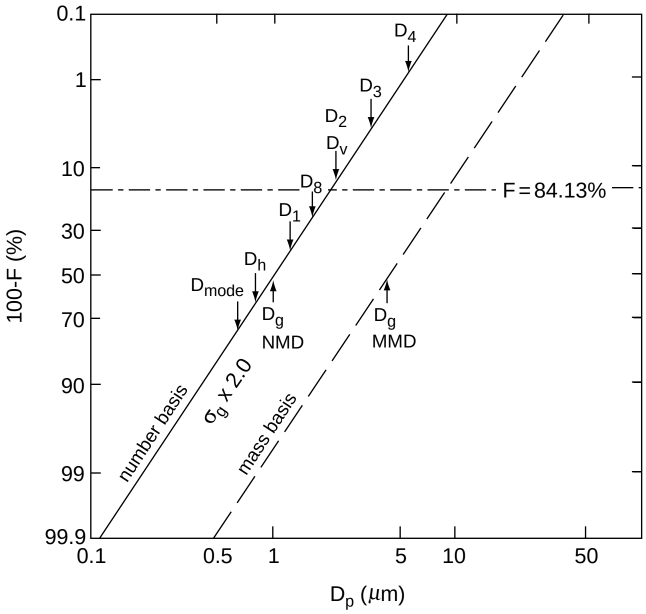

FIGURE 1 Log-normal size distribution for particles with geometric mean diameter of 1 μm and geometric standard deviation of 2.0. The different average particle diameters for this distribution are defined in Table 2.

Many particle size distributions are well described by the normal or the log-normal distributions. The normal, or Gaussian, distribution function is defined as,

$$f(D_p) = \frac{1}{\sqrt{2\pi}\sigma}\exp\left(-\frac{\left(D_p - \overline{D}_p\right)^2}{2\sigma^2}\right) \tag{4}$$

where $\overline{D}_p$ and σ are, respectively, the mean and standard deviation of the distribution. The mean diameter $\overline{D}_p$ is defined by

$$\overline{D}_p = \int_{-\infty}^{\infty} D_p f\left(D_p\right)\mathrm{d}D_p \tag{5}$$

and the standard deviation, indicating the dispersion of the distribution, is given by

$$\sigma^2 = \int_{-\infty}^{\infty} \left(D_p - \overline{D}_p\right)^2 f\left(D_p\right)\mathrm{d}D_p. \tag{6}$$

In the practical measurement of particle sizes, $\overline{D}_p$ and σ are determined by

$$\begin{gathered}\overline{D}_p = \frac{\sum n_i D_{pi}}{N} \\ \sigma = \left(\frac{n_i\left(D_{pi} - \overline{D}_p\right)^2}{N}\right)^{1/2}\end{gathered} \tag{7}$$

where n_i is the number of particles with diameter D_{pi} and N is the total particle number measured.

TABLE 2

Names and defining equations for various average diameters

	Defining equations	
	General case	In the case of log-normal distribution
number mean diam. D_1	$\frac{\Sigma\Delta nD_p}{N}$	$\ln D_1 = A + 0.5C = B - 2.5C$
length mean diam. D_2	$\frac{\Sigma\Delta nD_p^2}{\Sigma\Delta nD_p}$	$\ln D_2 = A + 1.5C = B - 1.5C$
surface mean, Sauter or mean volume-surface diam. D_3	$\frac{\Sigma\Delta nD_p^3}{\Sigma\Delta nD_p^2} = \frac{\Sigma\Delta sD_p}{S}$	$\ln D_3 = A + 2.5C = B - 0.5C$
volume or mass mean diam. D_4	$\frac{\Sigma\Delta nD_p^4}{\Sigma\Delta nD_p^3} = \frac{\Sigma\Delta mD_p}{M}$	$\ln D_4 = A + 3.5C = B + 0.5C$
diam. of average surface D_s	$\sqrt{\frac{\Sigma\Delta nD_p^2}{N}}$	$\ln D_s = A + 1.0C = B - 2.0C$
diam. of average volume or mass D_v	$\sqrt[3]{\frac{\Sigma\Delta nD_p^3}{N}}$	$\ln D_v = A + 1.5C = B - 1.5C$
harmonic mean diam. D_h	$\frac{N}{\Sigma(\Delta/D_p)}$	$\ln D_h = A - 0.5C = B - 3.5C$
number median diam. or geometric mean diam. NMD	$\exp\left[\frac{\Sigma\Delta n \ln D_p}{N}\right]$	NMD
volume or mass median diam. MMD	$\exp\left[\frac{\Sigma\Delta nD_p^3 \ln D_p}{\Sigma\Delta nD_p^3}\right]$ $= \exp\left[\frac{\Sigma\Delta m \ln D_p}{M}\right]$	$\ln \mathrm{MMD} = A + 3C$

$A = \ln \mathrm{NMD}$, $B = \ln \mathrm{MMD}$, $C = (\ln \sigma_g)^2$

N(total number) $= \Sigma\Delta n$, S(total surface) $= \Sigma\Delta s$, M(total mass) $= \Sigma\Delta m$

The log-normal distribution is particularly useful for representing aerosols because it does not allow negative particle sizes. The log-normal distribution function is obtained by substituting $\ln D_p$ and $\ln \sigma_g$ for D_p and σ in Eq. (4),

$$f\left(\ln D_p\right) = \frac{1}{\sqrt{2\pi}\ln \sigma_g}\exp\left(-\frac{\left(\ln D_p - \ln \overline{D}_p\right)^2}{2\ln^2 \sigma_g}\right). \quad (8)$$

The log-normal distribution has the following cumulative distribution,

$$F = \frac{1}{\sqrt{2\pi}\ln \sigma_g}\int_0^{D_p} \exp\left(-\frac{\left(\ln D_p - \ln D_g\right)^2}{2\ln^2 \sigma_g}\right) \mathrm{d}\left(\ln D_p\right). \quad (9)$$

The geometric mean diameter D_g, and the geometric standard deviation σ_g, are determined from particle count data by

$$\begin{aligned} \ln D_g &= \left(\sum n_i \ln D_{pi}\right)/N \\ \ln \sigma_g &= \left[\sum n_i \left(\ln D_{pi} - \ln D_g\right)^2 /N\right]^{1/2}. \end{aligned} \quad (10)$$

Figure 1 shows the log-normal size distribution for particles having $D_g = 1$ μm and $\sigma_g = 2.0$ on a log-probability graph, on which a log-normal size distribution is a straight line. The particle size at the 50 percent point of the cumulative axis is the geometric mean diameter D_g or number median diameter, NMD. The geometric standard deviation is obtained from two points as follows:

$$\sigma_g = \frac{D_p \text{ at } F = 84.13\%}{D_p \text{ at } F = 50\%} = \frac{D_p \text{ at } F = 50\%}{D_{po} \text{ at } F = 15.7\%}.$$

The rapid graphical determination of the geometric mean diameter D_g as well as the standard deviation σ_g is a major advantage of the log-normal distribution. It should be emphasized that the size distribution on a number basis shown by the solid line in Figure 1 differs significantly from that on a mass basis, shown by the dashed line in the same figure. The conversion from number median diameter (NMD) to mass median diameter (MMD) for a log-normal distribution is given by

$$\ln(\mathrm{MMD}) = \ln(\mathrm{NMD}) + 3(\ln \sigma_g)^2. \quad (11)$$

If many particles having similar shape are measured on the basis of one of the characteristic diameters defined in Table 1, a variety of average particle diameters can be calculated as shown in Table 2. The comparison among these diameters is shown in Figure 1 for a log-normal size distribution. Each average diameter can be easily calculated from σ_g and NMD (or MMD).

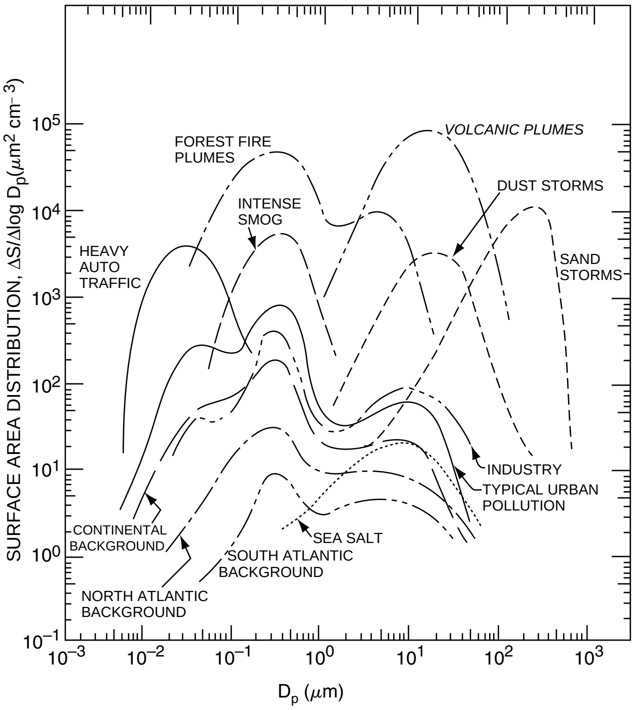

FIGURE 2 Surface area distributions of natural and anthropogenic aerosols.

Figure 2 indicates approximately the major sources of atmospheric aerosols and their surface area distributions. There tends to be a minimum in the size distribution of atmospheric particles around 1 μm, separating on one hand the coarse particles generated by storms, oceans and volcanoes and on the other hand the fine particles generated by fires, combustion and atmospheric chemistry. The comminution processes generate particles in the range above 1 μm and molecular processes lead to submicron particles.

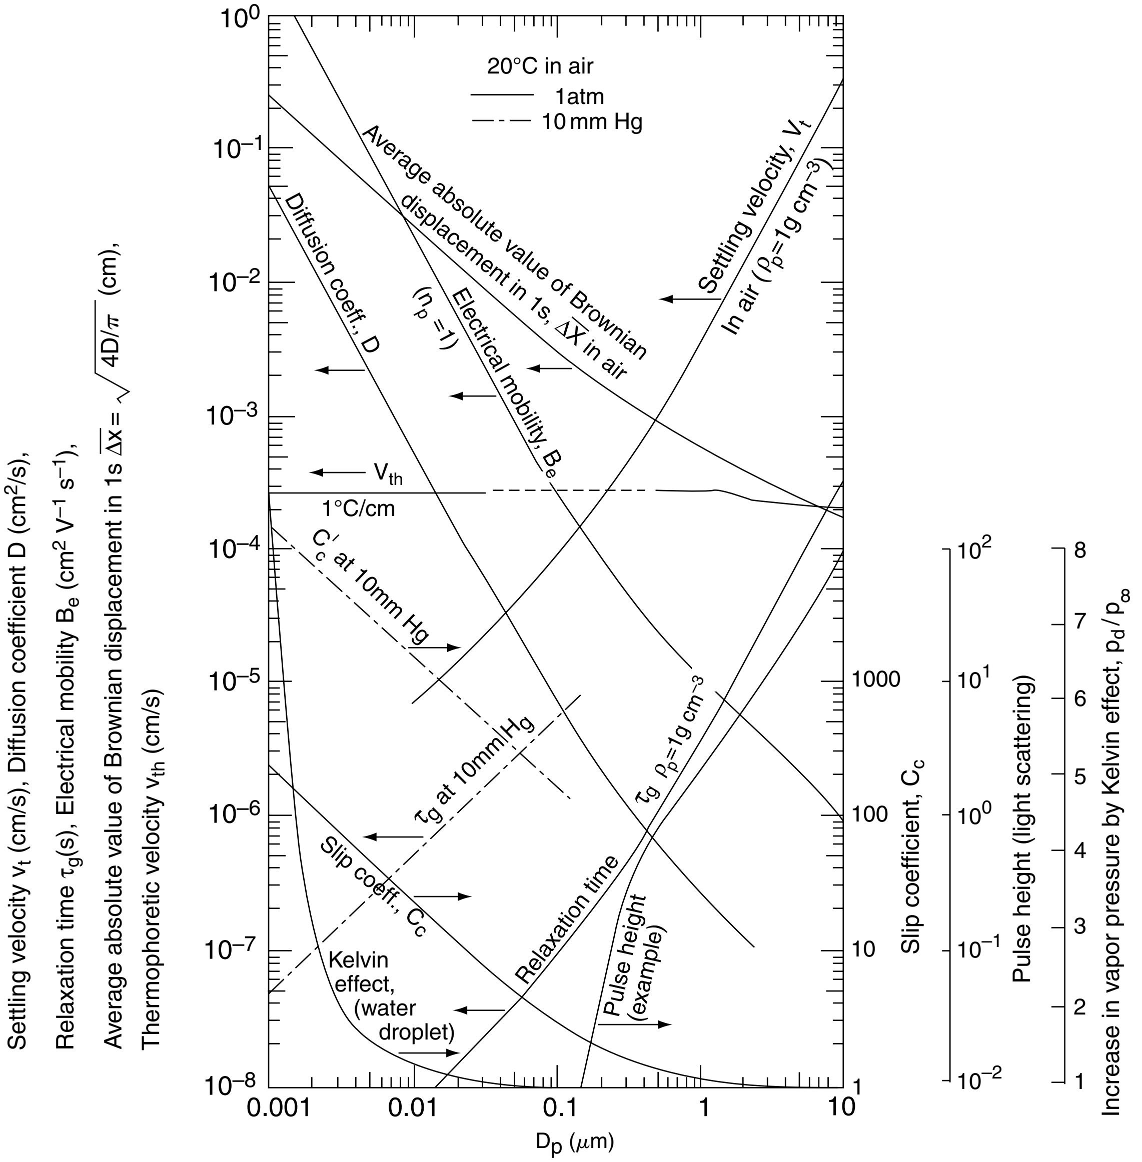
PARTICLE DYNAMICS AND PROPERTIES

Typical size-dependent dynamic properties of particles suspended in a gas are shown in Figure 3 together with defining equations (Seinfeld, 1986). The solid lines are those at atmospheric pressure and the one-point dashed lines are at low pressure. The curves appearing in the figure and the related particle properties are briefly explained below.

Motion of Large Particles

A single spherical particle of diameter D_p with a velocity u in air of density ρ_f experiences the following drag force,

$$F_d = C_D A_p (\rho_f u^2/2) \quad (12)$$



$$V_t = \frac{(\rho_p - \rho_f) g D_p^2 C_c}{18\mu} \quad (3.1) \qquad C_c = 1 + 2.514\frac{\lambda}{D_p} + 0.80\frac{\lambda}{D_p}\exp\left(-0.55\frac{D_p}{\lambda}\right) \quad (3.2)$$

$C_c' = 1 + (2/pD_p)\,[6.32 + 2.01 \exp(-0.1095 pD_p)]$ p in cm Hg, D_p in μm (3.3)

$$\overline{\Delta x} = \sqrt{\frac{4Dt}{\pi}} \quad (3.4) \qquad D = \frac{kTC_c}{3\pi\mu D_p} \quad (3.5)$$

$$\tau_g = \frac{\rho_p D_p^2 C_c}{18\mu} \quad (3.6) \qquad B_e = \frac{n_p\, e\, C_c}{3\pi\mu D_p} \quad (3.7)$$

$$P_d/P_\infty = \exp\left(\frac{4M\sigma}{RT\rho_l D_p}\right) \quad (3.8)$$

FIGURE 3 Fundamental mechanical and dynamic properties of aerosol particles suspended in a gas.

where A_p is the projected area of the particle on the flow ($= \pi D_p^2/4$), and C_D is the drag coefficient of the particle. The drag coefficient C_D depends on the Reynolds number,

$$\mathrm{Re} = u_r D_p \rho_f / \mu \tag{13}$$

where u_r is the relative velocity between the particle and air ($= |u - v|$, u = velocity of air flow, v = particle velocity), and μ is the viscosity of the fluid.

The motion of a particle having mass m_p is expressed by the equation of motion

$$m_p \frac{\mathrm{d}\mathbf{v}}{\mathrm{d}t} = \sum \mathbf{F} \tag{14}$$

where **v** is the velocity of the particle and **F** is the force acting on the particle, such as gravity, drag force, or electrical force. Table 3 shows the available drag coefficients depending on

TABLE 3

$\mathrm{Re}_p = \frac{vD_p\rho_f}{\mu}$, $\tau_g = \frac{\rho_p D_p^2}{18\mu}$, v_0: initial velocity, v_t: terminal velocity

Re_{p0}, Re_{pt}: Re_p at v_0 and at v_t respectively, C_{Dt}: drag coefficient at terminal velocity

Reynolds number and the basic equation expressing the particle motion in a gravity field.

The terminal settling velocity under gravity for small Reynolds number, v_t, decreases with a decrease in particle size, as expressed by Eq. (3.1) in Figure 3. The distortion at the small size range of the solid line of v_t is a result of the slip coefficient, C_c, which is size-dependent as shown in Eq. (3.2). The slip coefficient C_c increases with a decrease in particle size suspended in a gaseous medium. It also increases with a decrease in gas pressure p as shown in Figure 3. The terminal settling velocities at other Reynolds numbers are shown in Table 3.

τ_g in Figure 3 is the relaxation time and is given by Eq. (3.6). It characterizes the time required for a particle to change its velocity when the external forces change. When a particle is projected into a stationary fluid with a velocity v_o, it will travel a finite distance before it stops. Such a distance called the stop-distance and is given by $v_0\tau_g$. Thus, τ_g is a measure of the inertial motion of a particle in a fluid.

Motion of a Small Diffusive Particle

When a particle is small, Brownian motion occurs caused by random variations in the incessant bombardment of molecules against the particle. As the result of Brownian motion, aerosol particles appear to diffuse in a manner analogous to the diffusion of gas molecules.

The Brownian diffusion coefficient of particles with diameter D_p is given by

$$D = C_c kT/3\pi\mu D_p \tag{15}$$

where k is the Boltzmann constant ($=1.38 \times 10^{-16}$ erg/K) and T the temperature [K]. The mean square displacement of a particles $\overline{\Delta x^2}$ in a certain time interval t, and its absolute value of the average displacement $\overline{\Delta x}$, by the Brownian motion, are given as follows

$$\begin{aligned} \overline{\Delta x^2} &= 2Dt \\ \overline{\Delta x} &= \sqrt{4Dt/\pi} \end{aligned} \tag{16}$$

The number concentration of small particles undergoing Brownian diffusion in a flow with velocity $\mathbf{u}$ can be determined by solving the following equation of convective diffusion,

$$\frac{\partial N}{\partial t} + \nabla \cdot \mathbf{u}N = D\nabla^2 N - \nabla \cdot \mathbf{v}N \tag{17}$$

$$\mathbf{v} = \tau_g \sum \mathbf{F}/m_p \tag{18}$$

where N is the particle number concentration, D the Brownian diffusion coefficient, and $\mathbf{v}$ the particle velocity due to an external force $\mathbf{F}$ acting on the particle.

The average absolute value of Brownian displacement in one second, $\overline{\Delta x}$, is shown in Figure 3, which is obtained from $t = 1$s in Eq. (3.4). The intersection of the curves $\overline{\Delta x}$ and v_t lies at around 0.5 μm at atmospheric pressure. If one observes the settling velocity of such a small particle in a short time, it will be a resultant velocity caused by both gravitational settling and Brownian motion.

The local deposition rate of particles by Brownian diffusion onto a unit surface area, the deposition flux j (number of deposited particles per unit time and surface area), is given by

$$j = -D\nabla N + vN + uN. \tag{19}$$

If the flow is turbulent, the value of the deposition flux of uncharged particles depends on the strength of the flow field, the Brownian diffusion coefficient, and gravitational sedimentation.

Particle Charging and Electrical Properties

When a charged particle having n_p elementary charges is suspended in an electrical field of strength E, the electrical force F_e exerted on the particle is $n_p eE$, where e is the elementary charge unit ($e = 1.6 \times 10^{-19}$C). Introducing F_e into the right hand side of the equation of particle motion in Table 3 and assuming that gravity and buoyant forces are negligible, the steady state velocity due to electrical force is found by equating drag and electrical forces, $F_d = F_e$. For the Stokes drag force ($F_d = 3\pi\mu v_e D_p/C_c$), the terminal electrophoretic velocity v_e is given by

$$v_e = n_p eEC_c/3\pi\mu D_p. \tag{20}$$

B_e in Figure 3 is the electrical mobility which is defined as the velocity of a charged particle in an electric field of unit strength. Accordingly, the steady particle velocity in an electric field E is given by Eb_e. Since B_e depends upon the number of elementary charges that a particle carries, n_p, as seen in Eq. (3.7), n_p is required to determine B_e. n_p is predictable with aerosol particles in most cases, where particles are charged by diffusion of ions.

The charging of particles by gaseous ions depends on the two physical mechanisms of diffusion and field charging (Flagan and Seinfeld, 1988). Diffusion charging arises from thermal collisions between particles and ions. Charging occurs also when ions drift along electric field lines and impinge upon the particle. This charging process is referred to as field charging. Diffusion charging is the predominant mechanism for particles smaller than about 0.2 μm in diameter. In the size range of 0.2–2 μm diameter, particles are charged by both diffusion and field charging. Charging is also classified into bipolar charging by bipolar ions and unipolar charging by unipolar ions of either sign. The average number of charges on particles by both field and diffusion charging are shown in Figure 4. When the number concentration of bipolar ions is sufficiently high with sufficient charging time, the particle charge attains an equilibrium state where the positive and negative charges in a unit volume are approximately equal. Figure 5 shows the charge distribution of particles at the equilibrium state.

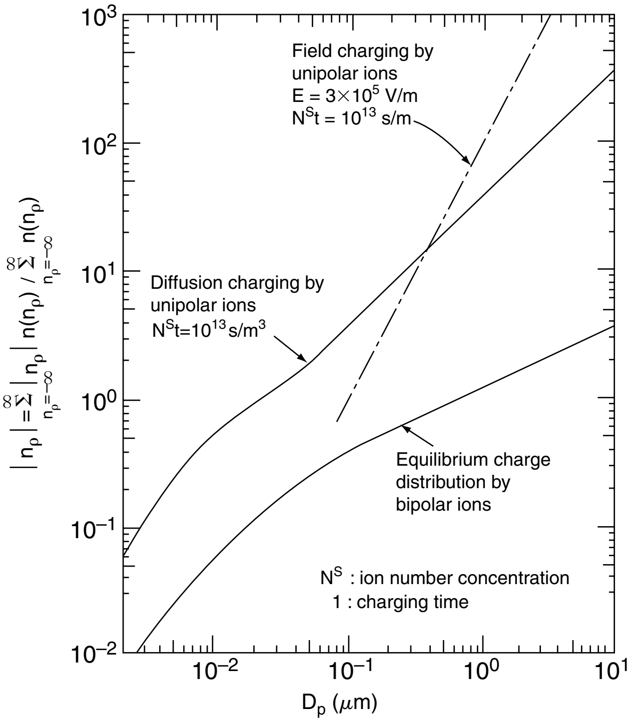

FIGURE 4 The average number of charges on particles by both field and diffusion charging.

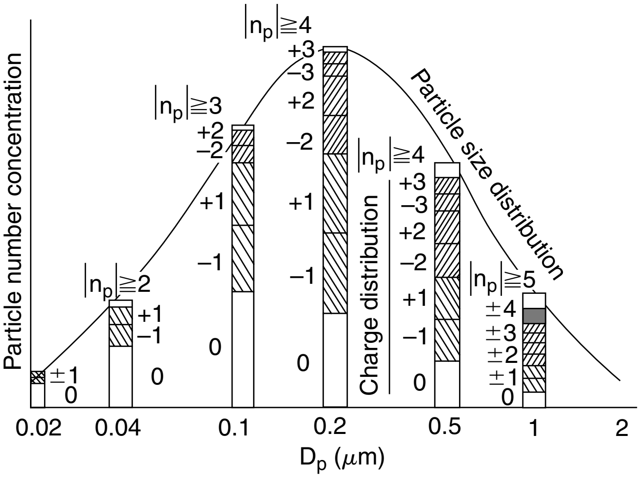

FIGURE 5 Equilibrium charge distribution through bipolar ion charging. The height of each section corresponds to the number concentration of particles containing the indicated charge..

Brownian Coagulation

Coagulation of aerosols causes a continuous change in number concentration and size distribution of an aerosol with the total particle volume remaining constant. Coagulation can be classified according to the type of force that causes collision. Brownian coagulation (thermal coagulation) is a fundamental mechanism that is present whenever particles are present in a background gas.

In the special case of the initial stage of coagulation of a monodisperse aerosol having uniform diameter D_p, the particle number concentration N decreases according to

$$\begin{aligned} dN/dt &= -0.5K_0N^2 \\ K_0 &= K\left(D_p, D_p\right) \end{aligned} \tag{21}$$

where $K(D_p, D_p)$ is the coagulation coefficient between particles of diameters D_p and D_p.

When the coagulation coefficient is not a function of time, the decrease in particle number concentration from N_0 to N can be obtained from the integration of Eq. (21) over a time period from 0 to t,

$$N = N_0/(1 + 0.5K_0N_0t). \tag{22}$$

The particle number concentration reduces to one-half its initial value at the time $2(K_0N_0)^{-1}$. This time can be considered as a characteristic time for coagulation.

In the case of coagulation of a polydisperse aerosol, the basic equation that describes the time-dependent change in the particle size distribution $n(v, t)$, is

$$\begin{aligned} \frac{\partial n(v,t)}{\partial t} &= \frac{1}{2}\int_0^v K(v', v-v')\,n(v',t)\,n(v-v',t)\,dv' \\ &\quad - n(v,t)\int_0^\infty K(v,v')\,n(v',t)\,dv' \end{aligned} \tag{23}$$

The first term on the right-hand side represents the rate of formation of particles of volume v due to coagulation, and the second term that rate of loss of particles of volume v by coagulation with all other particles.

The Brownian coagulation coefficient is a function of the Knudsen number $Kn = 2\lambda/D_p$, where λ is the mean free path of the background gas. Figure 6 shows the values of the Brownian coagulation coefficient of mono-disperse particles, $0.5\,K(D_p, D_p)$, as a function of particle diameter in

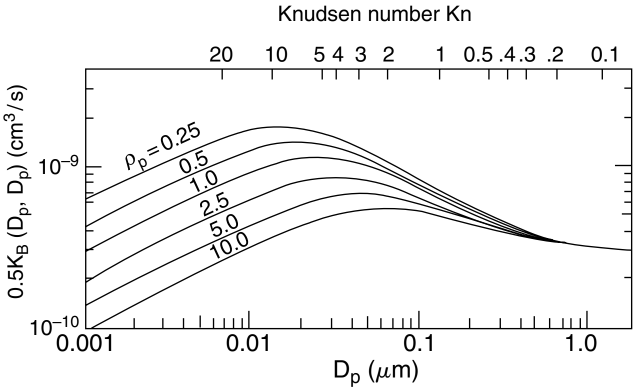

FIGURE 6 Brownian coagulation coefficient for coagulation of equal-sized particles in air at standard conditions as a function of particle density.

air at atmospheric pressure and room temperature. There exist distinct maxima in the coagulation coefficient in the size range from 0.01 μm to 0.01 μm depending on particle diameter. For a particle of 0.4 μm diameter at a number concentration of 10^8 particles/cm^3, the half-life for Brownian coagulation is about 14 s.

Kelvin Effect

p_d/p_∞ in Figure 3 indicates the ratio of the vapor pressure over a curved droplet surface to that over a flat surface of the same liquid. The vapor pressure over a droplet surface increases with a decrease in droplet diameter. This phenomenon is called the Kelvin effect and is given by Eq. (3.8). If the saturation ratio of water vapor S surrounding a single isolated water droplet is larger than p_d/p_∞, the droplet grows. If $S < p_d/p_\infty$, that is, the surrounding saturation ratio lies below the curve p_d/p_∞ in Figure 3, the water droplet evaporates. Thus the curve p_d/p_∞ in Figure 3 indicates the stability relationship between the droplet diameter and the surrounding vapor pressure.

Phoretic Phenomena

Phoretic phenomena refer to particle motion that occurs when there is a difference in the number of molecular collisions onto the particle surface between different sides of the particle. Thermophoresis, photophoresis and diffusiophoresis are representative phoretic phenomena.

When a temperature gradient is established in a gas, the aerosol particles in that gas are driven from high to low temperature regions. This effect is called thermophoresis. The curve v_{th} in Figure 3 is an example (NaCl particles in air) of the thermophoretic velocity at a unit temperature gradient, that is, 1 K/cm. If the temperature gradient is 10 K/cm, v_{th} becomes ten times higher than shown in the figure.

If a particle suspended in a gas is illuminated and nonuniformly heated due to light absorption, the rebound of gas molecules from the higher temperature regions of the particle give rise to a motion of the particle, which is called photophoresis and is recognized as a special case of thermophoresis. The particle motion due to photophoresis depends on the particle size, shape, optical properties, intensity and wavelength of the light, and accurate prediction of the phenomenon is rather difficult.

Diffusiophoresis occurs in the presence of a gradient of vapor molecules. The particle moves in the direction from higher to lower vapor molecule concentration.

OPTICAL PHENOMENA

When a beam of light is directed at suspended particles, various optical phenomena such as absorption and scattering of the incident beam arise due to the difference in the refractive index between the particle and the medium. Optical phenomena can be mainly characterized by a dimensionless parameter defined as the ratio of the particle diameter D_p to the wavelength of the incident light λ,

$$\alpha = \pi D_p/\lambda. \tag{24}$$

Light Scattering

Light scattering is affected by the size, shape and refractive index of the particles and by the wavelength, intensity, polarization and scattering angle of the incident light. The theory of light scattering for a uniform spherical particle is well established (Van de Hulst, 1957). The intensity of the scattered light in the direct θ (angle between the directions of the incident and scattered beams) consists of vertically polarized and horizontally polarized components and is given as

$$I = I_0 \frac{\lambda^2}{8\pi^2 r^2}\left(i_1 + i_2\right) \tag{25}$$

where I_0 denotes the intensity of the incident beam, λ the wavelength and r the distance from the center of the particle, i_1 and i_2 indicate the intensities of the vertical and horizontal components, respectively, which are the functions of θ, λ, D_p and m.

The index of refraction m of a particle is given by the inverse of the ratio of the propagation speed of light in a vacuum k_0 to that in the actual medium k_1 as,

$$m = k_1/k_0 \tag{26}$$

and can be written in a simple form as follows:

$$m = n_1 - in_2. \tag{27}$$

The imaginary part n_2 gives rise to absorption of light, and vanishes if the particle is nonconductive.

Light scattering phenomena are sometimes separated into the following three cases: (1) Rayleigh scattering (molecular scattering), where the value of α is smaller than about 2, (2) Mie scattering, where α is from 2 to 10, and (3) geometrical optics (diffraction), where α is larger than about 10. In the Rayleigh scattering range, the scattered intensity is in proportion to the sixth power of particle size. In the Mie scattering range, the scattered intensity increases with particle size at a rate that approaches the square of particle size as the particle reaches the geometrical optics range. The amplitude of the oscillation in scattered intensity is large in the forward direction. The scattered intensity greatly depends on the refractive index of the particles.

The curve denoted as pulse height in Figure 3 illustrates a typical photomultiplier response of scattered light from a particle. The intensity of scattered light is proportional to the sixth power of the particle diameter when particle size is smaller than the wavelength of the incident light (Rayleigh scattering range). The curve demonstrates the steep decrease in intensity of scattered light from a particle.

Light Extinction

When a parallel beam of light is passed through a suspension, the intensity of light is decreased because of the scattering and absorption of light by particles. If a parallel light beam of intensity I_0 is applied to the suspension, the intensity I at a distance l into the medium is given by,

$$I = I_0 \exp(-\gamma l) \tag{28}$$

where γ is called the extinction coefficient,

$$\gamma = \int_0^{\infty} C_{\text{ext}} n\left(D_p\right) \mathrm{d}D_p \tag{29}$$

$n(D_p)$ is the number distribution function of particles, and C_{ext} is the cross sectional area of each particle.

For a spherical particle, C_{ext} can be calculated by the Mie theory where the scattering angle is zero. The value of C_{ext} is also given by

$$C_{\text{ext}} = C_{\text{sca}} + C_{\text{abs}} \tag{30}$$

where C_{sca} is the cross sectional area for light scattering and C_{abs} the cross sectional area for light absorption. The value of C_{sca} can be calculated by integrating the scattered intensity I over the whole range of solid angles.

The total extinction coefficient γ in the atmosphere can be expressed as the sum of contributions for aerosol particle scattering and absorption and gaseous molecular scattering and absorption. Since the light extinction of visible rays by polluted gases is negligible under the usual atmospheric conditions and the refractive index of atmospheric conditions and the refractive index of atmospheric aerosol near the ground surface is $(1.33 \sim 1.55) - (0.001 \sim 0.05)i$ (Lodge *et al.*, 1981), the extinction of the visible rays depends on aerosol particle scattering rather than absorption. Accordingly, under uniform particle concentrations, the extinction coefficient becomes a maximum for particles having diameter 0.5 μm for visible light.

VISIBILITY

The visible distance that can be distinguished in the atmosphere is considerably shortened by the light scattering and light extinction due to the interaction of visible light with the various suspended particles and gas molecules. To evaluate the visibility quantitatively, the visual range, which is defined as the maximum distance at which the object is just distinguishable from the background, is usually introduced. This visual range is related to the intensity of the contrast C for an isolated object surrounded by a uniform and extensive background. The brightness can be obtained by integrating Eq. (28) over the distance from the object to the point of observation. If the minimum contrast required to just distinguish an object from its background is denoted by C^*, the visual range L_v for a black object can be given as

$$L_v = -(1/\gamma)\ln(-C^*) \tag{31}$$

where γ is the extinction coefficient. Introduction of the value of -0.02 for C^* gives the well known Koschmieder equation,

$$L_v = 3.912/\gamma \tag{32}$$

For aerosol consisting of 0.5 μm diameter particles ($m = 1.5$) at a number concentration of 10^4 particles/cm^3, the extinction coefficient γ is 6.5×10^{-5} cm and the daylight visual range is about 6.0×10^4 cm (=0.6 km). Since the extinction coefficient depends on the wavelength of light, refractive index, aerosol size and concentration, the visual range greatly depends on the aerosol properties and atmospheric conditions.

MEASUREMENT OF AEROSOLS

Methods of sizing aerosol particles are generally based upon the dynamic and physical properties of particles suspended in a gas (see Table 4).

Optical Methods

The light-scattering properties of an individual particle are a function of its size, shape and refractive index. The intensity of scattered light is a function of the scattering angle, the intensity and wavelength of the incident light, in addition to the above properties of an individual particle. An example of the particle size-intensity response is illustrated in Figure 3. Many different optical particle sizing devices have been developed based on the Mie theory which describes the relation among the above factors. The principle of one of the typical devices is shown in Figure 7.

The particle size measured by this method is, in most cases, an optical equivalent diameter which is referred to a calibration particle such as one of polystyrene latex of known size. Unless the particles being measured are spheres of known refractive index, their real diameters cannot be evaluated from the optical equivalent diameters measured. Several light-scattering particle counters are commercially available.

Inertial Methods (Impactor)

The operating principle of an impactor is illustrated in Figure 8. The particle trajectory which may or may not collide with the impaction surface can be calculated from solving the equation of motion of a particle in the impactor flow field. Marple's results obtained for round jets are illustrated in Figure 8 (Marple and Liu, 1974), where the collection efficiency at the impaction surface is expressed in terms of the Stokes number, *Stk*, defined as,

$$Stk = \frac{\rho_p C_c D_p^2 u_0}{18\mu\left(W/2\right)} = \tau \frac{u_0}{W/2} \tag{33}$$

where

$$\tau = \frac{\rho_p D_p^2 C_c}{18\mu} \tag{34}$$

$$C_c = 1 + 2.514\frac{\lambda}{D_p} + 0.80\frac{\lambda}{D_p}\exp\left(-0.55\frac{D_p}{\lambda}\right) \tag{35}$$

	light diffraction	gas liquid	number	1	high–low		

ρ_p is the particle density, μ the viscosity and λ is the mean free path of the gas. The remaining quantities are defined in Figure 8.

The value of the Stokes number at the 50 percent collection efficiency for a given impactor geometry and operating condition can be found from the figure, and it follows that the cut-off size, the size at 50 percent collection efficiency, is determined.

If impactors having different cut-off sizes are appropriately connected in series, the resulting device is called a cascade impactor, and the size distribution of aerosol particles can be obtained by weighing the collected particles on each impactor stage. In order to obtain an accurate particle size distribution from a cascade impactor, the following must be taken into account: 1) data reduction considering cross sensitivity between the neighboring stages, 2) rebounding on the impaction surfaces, and 3) particle deposition inside the device.

Various types of impactors include those using multiple jets or rectangular jets for high flow rate, those operating under low pressure (Hering *et al.*, 1979) or having microjets for particles smaller than about 0.3 μm and those having a virtual impaction surface, from which aerosols are sampled, for sampling the classified aerosol particles (Masuda *et al.*, 1979).

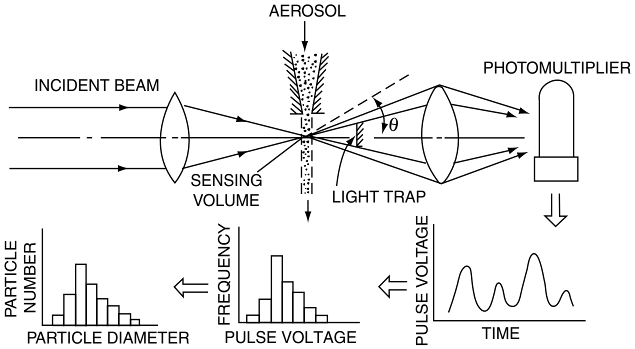

FIGURE 7 Measurement of aerosol particle size by an optical method.

(Other Inertial Methods)

Other inertial methods exist for particles larger than 0.5 μm, which include the particle acceleration method, multi-cyclone (Smith *et al.*, 1979), and pulsation method (Mazumder *et al.*, 1979). Figure 9 illustrates the particle acceleration method where the velocity difference between

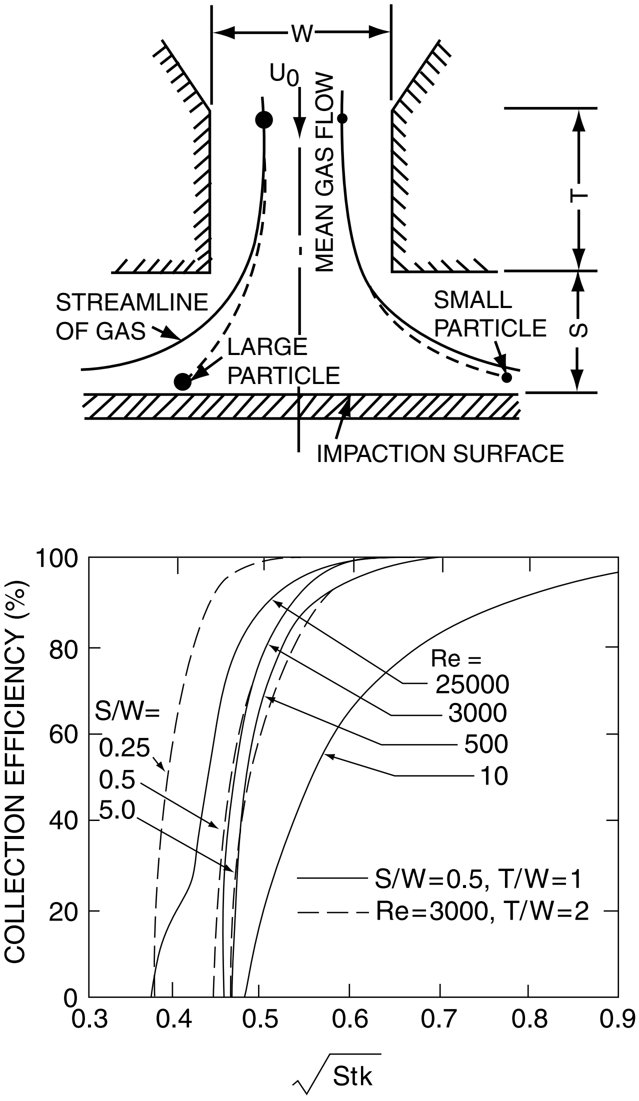

FIGURE 8 Principle of operation of an impactor. Collection efficiency of one stage of an impactor as a function of Stokes number, Stk, Reynolds number, Re, and geometric ratios.

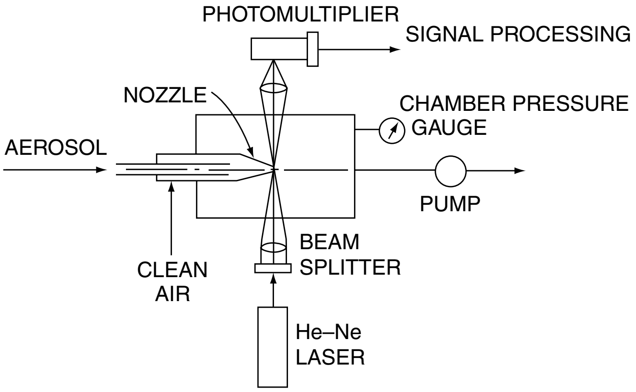

FIGURE 9 Measurement of aerosol particle size by laser-doppler velocimetry.

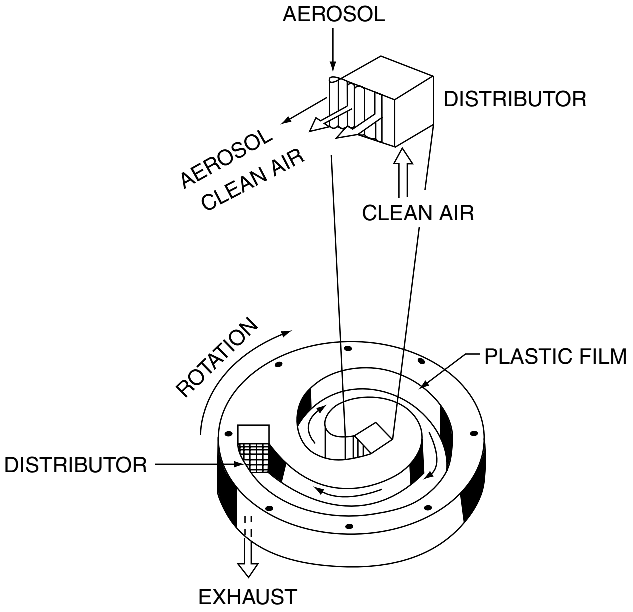

FIGURE 10 Spiral centrifuge for particle size measurements.

a particle and air at the outlet of a converging nozzle is detected (Wilson and Liu, 1980).

Sedimentation Method

By observing the terminal settling velocities of particles it is possible to infer their size. This method is useful if a TV camera and He–Ne gas laser for illumination are used for the observation of particle movement. A method of this type has been developed where a very shallow cell and a TV system are used (Yoshida *et al.*, 1975).

Centrifuging Method

Particle size can be determined by collecting particles in a centrifugal flow field. Several different types of centrifugal chambers, of conical, spiral and cylindrical shapes, have been developed for aerosol size measurement. One such system is illustrated in Figure 10 (Stöber, 1976). Particle shape and chemical composition as a function of size can be analyzed in such devices.

Electrical Mobility Analyzers

The velocity of a charged spherical particle in an electric field, v_e, is given by Eq. (20). The velocity of a particle having unit charge (n_p = 1) in an electric field of 1 V/cm is illustrated in Figure 3. The principle of electrical mobility analyzers is based upon the relation expressed by Eq. (20). Particles of different sizes are separated due to their different electrical mobilities.

FIGURE 11 Two types of electrical mobility analyzers for determining aerosol size. Charging, classification, detection and response are shown for both types of analyzers.

Two different types of electrical mobility analyzers shown in Figure 11 have been widely used (Whitby, 1976). On the left hand side in the figure is an integral type, which is commercially available (EAA: Electrical Aerosol Analyzer). That on the right hand side is a differential type, which is also commercially available (DMA: Differential Mobility Analyzer). The critical electrical mobility B_{ec} at which a particle can reach the lower end of the center rod at a given operating condition is given, respectively, for the EAA and DMA as

$$B_{ec} = \frac{(Q_a + Q_c)}{2\pi LV} \ln\left(\frac{r_1}{r_2}\right) \tag{36}$$

$$B_{ec} = \frac{Q_c}{2\pi LV} \ln\left(\frac{r_1}{r_2}\right), \Delta B_e = \frac{Q_a}{\pi LV} \ln\left(\frac{r_1}{r_2}\right) \tag{37}$$

B_{ec} can be changed by changing the electric voltage applied to the center rod. A set of data of the particle number concentration or current at every B_{ec} can be converted into a size distribution by data reduction where the number distribution of elementary charges at a given particle size is taken into account.

Electrical mobility analyzers are advantageous for smaller particles because v_e in Eq. (20) increases with the decrease in particle size. The differential mobility analyzer has been increasingly utilized as a sizing instrument and a monodisperse aerosol generator of particles smaller than 1 μm diameter (Kousaka *et al.*, 1985).

Diffusion Batteries

The diffusion coefficient of a particle D is given by Eq. (15). As shown in Figure 3, D increases with a decrease in particle size. This suggests that the deposition loss of particles onto the surface of a tube through which the aerosol is flowing increases as the particle size decreases. The penetration (=1–fractional loss by deposition) η_p for a laminar pipe flow is given as (Fuchs, 1964),

$$\begin{aligned} \eta_p &= 0.8191\exp(-3.657\beta) + 0.00975\exp(-22.3\beta) \\ &\quad + 0.0325\exp(-57\beta), \beta = \pi DL/Q \geq 0.0312 \end{aligned} \tag{38}$$

$$\eta_p = 1 - 2.56\beta^{2/3} + 1.2\beta + 0.177\beta^{4/3}, \beta < 0.0312 \tag{39}$$

where L is the pipe length and Q is the flow rate. A diffusion battery consists of a number of cylindrical tubes, rectangular ducts or a series of screens through which the gas stream containing the particles is caused to flow. Measurement of the penetration of particles out the end of the tubes under a number of flow rates or at selected points along the distance from the battery inlet allows one to obtain the particle size distribution of a polydisperse aerosol. The measurement of particle number concentrations to obtain penetration is usually carried out with a condensation nucleus counter (CNC), which detects particles with diameters down to about 0.003 μm.

AGRICULTURAL CHEMICALS: see PESTICIDES

AIR POLLUTANT EFFECTS

AIR POLLUTANTS

Air pollutants fall into two main categories: (1) those that are pervasive throughout areas because they are the products of daily-life activities such as transportation, power generation, space and water heating, and waste incineration, and (2) those generated by activities such as chemical, manufacturing, and agricultural processing whose pollutant byproducts tend to be localized in nearby areas or are spread long distances by tall stacks and prevailing winds.

Air pollutants are also categorized by their emission characteristics: (1) point sources, such as power plants, incinerators, and large processing plants; (2) area sources, such as space and water heating in buildings; and (3) mobile sources, mainly cars and trucks, but also lawn mowers and blowers and airplanes.

The United States has established National Ambient Air Quality Standards (NAAQS) for seven pollutants that are pervasive and are threats to public health and welfare. The Clean Air Act, which initiated this program, was passed in 1963 and last amended in 1990. The primary standards are intended to protect health, and the secondary standards protect public-welfare interests such as visibility and danger to animals, crops, and buildings.

The standards reflect, for the most part but not always, a conservative approach in favor of the protection of health. It is notable that the public, who in the final analysis must pay the cost, appears to be firmly committed to enforcement of the standards without overwhelming concern for costs.

The act requires the states to determine the status of their air quality and to find and introduce the controls that will enable them to meet these standards. Their proposal describing how and when the standards will be met is submitted to the EPA (U.S. Environmental Protection Agency) as an implementation plan for approval. Meeting target dates for air-quality standards has been problematic because the complex system that has to be managed includes important socioeconomic and political factors. For example, the close connection between air quality and daily activities such as transportation, waste disposal, and the heating of homes and workplaces requires education of the population to obtain their support for alternative and perhaps costly lifestyle choices in the vehicles they purchase, the packaging of articles they choose, and the type and cost of the fuels they use—choices they may be reluctant to make, even if they will improve the quality of their air environment. Choices benefiting air quality that carry disadvantages for important sectors of the economy are usually skillfully discouraged by some of those sectors.

CONTROL OF CRITERIA POLLUTANTS

Control of the criteria pollutants requires a measurement program to determine the daily and short-term patterns of the ambient concentrations, identification of the emitting sources, and design and implementation of strategies for their control. A detailed inventory of the sources causing the pollution is prepared. The effectiveness of control technology and potential regulatory strategies are evaluated and their availability determined with consideration given to the economic and political restraints on their implementation. In other words, the total system to be managed and its interactions have to be detailed and understood in order to evaluate the potential for successful control of the air pollution in an area.

The amount of exposure to the pollutants from independent or grouped sources depends upon the intensity of the activities producing the emissions, the effectiveness of the controls, and the quality of the surveillance instituted to ensure the continued proper use and maintenance of the controls. A factor that can be overwhelming is the pattern of the local meteorology and its effectiveness in dispersing emitted pollutants. The effects of dispersions from one area upon downwind areas should also be considered.

Detailed analysis of data accumulated over many years using unchanging analytical methods has shown that very significant changes in an area's air pollution can take place from year to year without significant changes in controls, primarily as the result of changes in the local weather patterns. The combination of 10 years of data at three sampling sites in New York City showed that its sulfur-dioxide pollution problems was clearly related to the sulfur content of the fuel that was burned in the city. The data for a 10-year period were combined on a week-by-week basis, with the result that the shape of the 10-year curve for ambient sulfur-dioxide concentrations and the long-term temperature curve for the city could be superimposed with significant success. Therefore, the sometimes great variations found between years when little change occurred in controls were caused by variations in the local atmosphere, demonstrating that the success or failure of control strategies cannot be evaluated with security over short intervals of time.

Pollutant	Primary Stds.	Averaging Times	Secondary Stds.
Carbon monoxide	9 ppm (10 mg/m^3)	8-hour[1]	None
	35 ppm (40 mg/m^3)	1-hour[1]	None
Lead	1.5 μg/m^3	Quarterly Average	Same as primary
Nitrogen dioxide	0.053 ppm (100 μg/m^3)	Annual (arith. mean)	Same as primary
Particulate matter (PM_{10})	50 μg/m^3	Annual[2] (arith. mean)	Same as primary
	150 μg/m^3	24-hour[1]	Same as primary
Particulate matter ($PM_{2.5}$)	15.0 μg/m^3	Annual[3] (arith. mean)	Same as primary
	65 μg/m^3	24-hour[4]	—
Ozone	0.08 ppm	8-hour[5]	Same as primary
	0.12 ppm	1-hour[6]	Same as primary
Sulfur oxides	0.03 ppm	Annual (arith. mean)	—
	0.14 ppm	24-hour[1]	—
	—	3-hour[1]	0.5 ppm (1300 μg/m^3)

---

1. Not to be exceeded more than once per year.
2. To attain this standard, the expected annual arithmetic mean PM_{10} concentration at each monitor within an area must not exceed 50 μg/m^3.
3. To attain this standard, the 3-year average of the annual arithmetic mean $PM_{2.5}$ concentrations from single or multiple community-oriented monitors must not exceed 15.0 μg/m^3.
4. To attain this standard, the 3-year average of the 98th percentile of 24-hour concentrations at each population-oriented monitor within an area must not exceed 65 μg/m^3.
5. To attain this standard, the 3-year average of the fourth-highest daily maximum 8-hour average ozone concentrations measured at each monitor within an area over each year must not exceed 0.08 ppm.
6. (a) The standard is attained when the expected number of days per calendar year with maximum hourly average concentrations above 0.12 ppm is ≤1, as determined by appendix H.

   (b) The 1-hour NAAQS will no longer apply to an area one year after the effective date of the designation of that area for the 8-hour ozone NAAQS. The effective designation date for most areas is June 15, 2004. (40 CFR 50.9; see Federal Register of April 30, 2004 (69 FR 23996).)

FIGURE 1 National Ambient Air Quality Standards.

The primary standards to protect health and the secondary standards to protect welfare, Figure 1, have improved with increasing knowledge about the effects of exposures and measurement technology.

EPIDEMIOLOGY

Epidemiology is the study of the occurrence and distribution of disease within a population as opposed to its study on an individual basis. An epidemiologist who undertakes to determine the acute and chronic effects caused by exposures of a population to a particular component of local air pollution faces complex problems that can be itemized as follows:

- In a community study the subjects under scrutiny are subjected to pollutants, known and unknown, other than the ones being investigated.
- Supporting clinical studies guiding the investigation are seldom based upon human data, but must depend upon studies using surrogate species that were exposed to much higher doses without the contaminants that may contribute to the effects found in the epidemiological study.

- The true dose is not always the simple product of the measured concentration and the duration of exposure, because of the complexity that can exist between exposure and response—the biologically active dose can be quite different.
- Individuals whose exposure and symptoms are being correlated very often spend the major part of their time indoors or traveling, where they may be subjected to different pollutants and different concentrations.
- Different pollutants will disperse and interact differently with the surroundings, introducing a location factor caused by the relationship of exposed individuals to the measurement site—for example, sulfur-dioxide concentrations will not vary as much as ozone concentrations, because the higher reactivity of ozone with structural materials and other compounds will affect its concentration at the receptor.

INFORMING THE PUBLIC

The aerometric networks established by cities and states have been gathering and analyzing data about air pollutants for many years. During these years, attempts were made to inform the public about the quality of its air environment, which can change from day to day and even hour to hour, and about the possible impact that local concentrations are having upon their health. The relationship between raw air-pollution data and its health-impact significance is complex; therefore, the attempt is made to present the information in a simplified manner that is understandable to the public. Toward this goal, the EPA has developed an Air Quality Index for daily reporting about what has been found in the air together with some indication of its potential effects on health. Important considerations are the variability in the susceptibility of the exposed population, meaning that what may have little or no effect on one group can be a serious concern for others, and that personal patterns of behavior of the exposed can affect the amounts of pollutants that they breathe. Individuals whose lifestyle requires them to move throughout an area (indoors, outdoors, and in vehicles) will receive very different exposures from those who stay at home, depending upon the pervasiveness of the pollutants. In particular, exposures to carbon monoxide will be much greater for those whose daily activities requires them to be in the vicinity of motor vehicles than for those who stay indoors or travel on railroads and subways.

The Air Quality Index designed by EPA reports the daily levels of ozone, particulate matter, carbon monoxide, sulfur dioxide, and nitrogen dioxide on a scale of 0 to 500. The range corresponds to six different categories of health concern that are also characterized by colors Table 1.

RISK REDUCTION

Air pollution affects people primarily through the respiratory system; therefore, the logical way to start minimizing risk is by avoidance of activities that increase one's inhalation of polluted air. When air-pollution levels are high, activities that cause increases in breathing rate should be minimized as much as possible, depending upon the importance and necessity of the activity and the seriousness of the pollution episode. As an example, jogging in the vicinity of vehicles where local ventilation is poor, as in the canyon streets of cities, should be avoided because of the high concentrations of carbon monoxide and other pollutants usually found in those areas. This is of special importance to people with asthma or heart diseases such as angina.

Children who spend their time playing outdoors should be restrained from overexerting themselves when ozone levels are high during warm-weather episodes, as should individuals with asthma or other respiratory diseases or those who are hypersensitive to ozone.

EFFECTS OF EXPOSURE TO CRITERIA POLLUTANTS

Respiratory-System Overview

An elementary understanding of studies describing the adverse health effects caused by the inhalation of gaseous or particulate air pollutants requires at least an elementary familiarity with respiratory-tract anatomy and dynamics. The respiratory tract can be considered to include three sections:

- Nasopharynx—nose and mouth down to epiglottis and larynx

TABLE 1

Air Quality Index	Health Concerns
0–50 Good (green)	Little or no risk
51–100 Moderate (yellow)	Concern for unusually sensitive people
101–150 Unhealthy for sensitive groups (orange)	The general public is unaffected, but people with health problems such as lung and heart disease may be affected
151–200 Unhealthy (red)	Everyone is affected to some degree, especially those in sensitive groups
201–300 Very unhealthy (purple)	A health alert exists; everyone should take precautions, especially those in sensitive groups
301–500 Hazardous (maroon)	Everyone is affected and everyone should take precautions

- Tracheobronchial—bronchi down to terminal bronchiole
- Pulmonary—respiratory bronchiole, alveoli ducts, and alveoli

The trachea divides into left and right bronchi, which divide many times into smaller and smaller tubes down to the respiratory bronchioles. These feed about 65,000 lobules, each containing approximately 5,000 thin-walled air sacs called alveoli. Thus, in an adult there are approximately 300 million alveoli whose thin walls, totaling 70 m^2 in area, contain hundreds of miles of tiny capillaries. Oxygen is added to and carbon dioxide is removed from the blood through the walls of these capillaries. The transfer of toxic chemicals into the blood also can takes place in the alveoli.

Starting in the nose, where the air is conditioned for proper temperature and humidity, the direction of airflow is changed many times, thereby causing the impaction and deposition of particles on the surfaces of the branching airways. These surfaces contain hairlike ciliary cells whose rapid, wavelike motion, over 15 times per second, carry impacted particles on a mucus layer upward into the trachea for subsequent ingestion.

The velocity of the airflow decreases from about 150 cm/sec at the start to almost zero in the alveoli; the smaller the particles, the greater the ease with which they turn corners, thus escaping impaction to penetrate to the alveoli, where they are collected via sedimentation. The larger particles and soluble gases will be trapped in the upper airways, where tissues and their defense mechanisms can be damaged reversibly or irreversibly depending upon the nature, intensity, and duration of the attack.

The amounts of a water-soluble gas or suspended particles that reach the pulmonary region are strongly dependent upon their inhalation pathway into the body. When inhaled through the nose instead of the mouth, they experience a number of chances of removal by impaction. In the case of sulfur dioxide this process is greatly enhanced by its very rapid solution in the watery fluids on the surface of nasal tissues. The greater tendency for mouth breathing combined with the greater intake of air that accompanies increased exertions contraindicates strenuous activity wherever pollutant levels are high.

Particle removal by deposition along the upper and lower respiratory system is strongly dependent upon particle size. Particles with an aerodynamic diameter above 10 μm are removed in the convoluted, moist passages of the nose and tracheobronchial region. While almost all those below 2 μm reach the pulmonary region, intermediate sizes tend to distribute themselves along both regions. When the particles are insoluble, they are removed in a few days from the upper respiratory system by mucociliary action; however, those that penetrate down farther can remain for many months or even years. Removal of particles also occurs by phagocytosis through the scavenging action of macrophages.

The size distribution of particles suspended in the atmosphere exhibits a log-normal behavior. The distribution by mass tends to separate into a fine and a coarse group depending principally upon whether they are formed by condensation of very small precursors, such as those produced in combustion, or are produced from larger particles by mechanical breakdown processes.

OZONE

Ozone is a very reactive chemical that readily attacks other molecules, including those in the tissues of the respiratory system. Exertions that increase the need for oxygen will increase air intake and allow ozone molecules to penetrate and damage the sensitive areas of the lungs. Ozone can aggravate asthma attacks by making individuals more sensitive to allergens that promote the attacks and more susceptible to respiratory infections. Lung tissue can be scarred by continued exposure to ozone over the years. Researchers at Johns Hopkins found that an increase of 10 ppb in weekly ozone levels in cities whose average level was 26 ppb was associated with a 0.52% daily increase in deaths the following week. They calculated that a 10-ppb reduction in daily ozone levels could save nearly 4,000 lives throughout the 95 urban communities included in the study. Out of 296 metropolitan areas, 36 have significant upward trends in the criteria pollutants; however, of these, only trends involving ozone had values over the level of air-quality standards.

The presence of ozone and other photochemical pollutants depends upon atmospheric conditions, notably temperature, as experience shows that this type of pollution is associated with warm temperatures. The precursors that are affected by elevated temperatures are volatile organic compounds (VOCs) and nitric oxide. Natural sources for these compounds are a less important factor than the emissions produced by human activities, but the long-range transport of the precursors while atmospheric conditions are converting them to photochemical oxidants means that that there is a possibility of picking up precursor material from natural sources en route. Control of this type of air pollutant is focused on controlling emissions of VOCs and nitrogen oxides. It should be noted that ambient concentrations of the criteria pollutant nitrogen dioxide have been found to be generally below the levels considered to be health-damaging; therefore, efforts to control its presence in the atmosphere is driven by the need to control ozone. The combustion of fuels and other materials provides sufficient energy to cause the nitrogen and oxygen in the air to react to form nitric oxide. The slow air oxidation of nitric oxide to nitrogen dioxide results in a mixture described as nitrogen oxides (NO_x).

The chemical reactions involved in the formation of photochemical oxidants from these precursors is complex. The basic reactions are:

$$NO_2 + h\nu = NO + O$$
$$O + O_2 + M = O_3 + M^*$$

where hν represents a photon and M and M^* represent material before and after absorbing energy from the ozone-formation reaction. In the absence of other molecules capable of reacting with the nitric oxide, the ozone is removed by the rapid reaction

$$NO + O_3 = NO_2 + O_2$$

Therefore, concentrations of ozone will remain quite small unless there is a competing reaction for rapid removal of the nitric oxide.

Many organic compounds can play the role of nitric-oxide remover in forming photochemical oxidants such as peroxyacetylnitrate (PAN, $CH_3COO_2NO_2$). VOCs possessing varying reactivities are able to remove nitric oxide and thus make possible the buildup of ozone:

$$VOC + NO \rightarrow NO_2 + \text{organic nitrates}$$

Although ozone is the major component, peroxynitrates, peracids, hydroperoxides, aldehydes, and a variety of other compounds are found in photochemical smog. Among the major sources releasing reactive organic compounds are automobile engines and tailpipes; gasoline stations; the use of solvents, paints, and lacquers; and a variety of industrial operations. Thus, the control of ozone is complicated by the variety of sources and the distances that can occur between high-ozone areas and the sources. Suburban and rural areas downwind of urban sources will often have higher ozone levels than source areas because of the transport that occurs while ozone is being formed. Both ozone and PAN cause serious injury to vegetation, but PAN does so at much lower concentrations.

PARTICULATE MATTER

"Fine particles" are less than 2.5 μm in size and require electron microscopy for detection; nevertheless, they are much larger than molecules such as ozone and other gaseous pollutants, which are thousands of times smaller and cannot be seen even with electron microscopy. Fine particles are formed by the condensation of molecules into solids or liquid droplets, whereas larger particles are mostly formed by mechanical breakdown of material. "Coarse particles" are between 2.5 and 10 μm in diameter and cannot penetrate as readily as fine particles; nevertheless, they have been found to cause serious deterioration of health. The severity of effects will vary with the chemical nature of the particles; however, since their nature can be so varied and difficult to determine, coarse and fine particles are considered in terms of what epidemiological studies have shown.

The inhalation of particles has been linked with illnesses and deaths from heart and lung disease as a result of both short- and long-term exposures. People with heart disease may experience chest pain, palpitations, shortness of breath, and fatigue when exposed to particulate-matter pollutants. Exposures have been linked to cardiac arrhythmias and heart attacks. Inhalation of particulate matter can increase susceptibility to respiratory infections such as asthma and chronic bronchitis. The EPA has found that nearly 100 million people in the United States live in areas that have not met the standard for particulate matter with a diameter less than 2.5 μm. It estimates that compliance by 2010 will prevent 15,000 premature deaths, 75,000 cases of chronic bronchitis, 20,000 cases of acute bronchitis, 10,000 hospital admissions for respiratory and cardiovascular disease, and the loss of 3.1 million days worked.

Emissions from diesel-fuel combustion in vehicles and equipment are a special problem, especially for those individuals breathing in close proximity to the exhausts. Cars, trucks, and off-road engines emit more than half a million tons of diesel particulate matter per year. Emissions of 2.5-μm particles have decreased in the United States from 2.3 million tons in 1990 to 1.8 million tons in 2003.

SULFUR DIOXIDE

The combustion of sulfur-containing fuels is the main source of sulfur-dioxide air pollution. The oil and coal burned to heat homes and water and to produce electrical power are the main sources that affect the general population, but individuals who live near metal smelting and other industrial processes can be heavily exposed. Sulfur-dioxide exposures are usually accompanied by exposures to particulate matter, which together exacerbate the effects.

Emissions of sulfur compounds from motor vehicles have increased in importance as those from oil and coal burning have been reduced. The diesel fuel used in vehicles can contain up to 500 ppm by weight of sulfur. California, which has the unfortunate combination of high emissions and poor atmospheric ventilation, hopes to reduce the allowable sulfur content of fuels to 15 ppm by 2007. It must be noted that California is the only state that is not preempted by the federal government in controlling pollution, because its efforts anteceded those of the federal government. Emissions of sulfur dioxide in the United States decreased from 31 million tons in 1970 to 16 million tons in 2003.

The defense mechanisms of the lung are challenged by sulfur dioxide; however, its rapid solution in water irritates tissues but reduces the concentrations that reach the deeper parts of the lung. Inhalation of particulate matter together with sulfur dioxide increases the hazard to the lungs. Asthmatic children and active adults can experience breathing difficulties in high concentrations of sulfur dioxide, and individuals with cardiovascular disease can have their symptoms exacerbated. The conversion in the atmosphere of sulfur dioxide into sulfite and sulfate acidic aerosol particles increases its threat to health.

Sulfur dioxide harms the body's defense system against particulate pollution and the ingress of bacteria into the body through the respiratory system. It also increases the harmful effects of ozone when both of these gases are present. Asthmatics, the elderly, and those already suffering from respiratory problems are affected at lower concentrations than the general population. Studies have shown that in the 1950s and 1960s, when ambient concentrations were sometimes higher than 1 ppm and mixed with particulate matter, the occurrence of lasting atmospheric inversions resulted in thousands of excess deaths.

CARBON MONOXIDE

Carbon monoxide has afflicted the human race since the discovery of fire. Nature contributes very significant quantities, but it does so in such a highly dispersed fashion that human exposures from this source are insignificant. Nature has provided sinks for this insoluble, relatively unreactive gas; otherwise background concentrations would rise much more rapidly as human contributions added their burden. The oceans, which at one time were believed to be a major sink, are now considered to be a source, because certain marine organisms release enough carbon monoxide to supersaturate the surface layer. The important removal mechanism is believed to be the action of microorganisms that live in soils and plants and the reaction of carbon monoxide with hydroxyl radicals in the atmosphere.

The rapid growth in the use of internal combustion engines has created an outdoor problem as indoor problems were decreased by improvements in space-heating equipment. The problem is concentrated in urban areas where traffic congestion is combined with canyonlike streets. Emissions of carbon monoxide in the United States decreased from 197 million tons in 1970 to 94 million tons in 2003.

With the exception of exposures resulting from the breakdown or misuse of indoor heating equipment that produces fatalities or serious injuries, carbon-monoxide exposures of significance occur in the vicinity of congested traffic. People whose occupation requires them to be near such traffic receive the highest exposures, as do those who jog or bicycle in these areas. Malfunctions in the exhaust system of vehicles also can result in high exposures to their occupants. Exposure to carbon monoxide results in the buildup of carboxyhemoglobin in the blood, which will interfere with the transport of oxygen to cells in the body.

Carbon-monoxide molecules attach themselves to the hemoglobin molecules in the blood with much greater tenacity than do oxygen molecules. The Haldane equation attempts to approximate this competition.

$$\frac{(\mathrm{HbCO})}{(\mathrm{HbO_2})} = 210\,\frac{\mathrm{PCO}}{\mathrm{PO_2}}$$

(HbCO) and (HbO_2) are the concentrations of carboxyhemoglobin and oxyhemoglobin, and PCO and PO_2 are the partial pressures of carbon monoxide and oxygen. Inspiration of air containing high concentrations of carbon monoxide results in its preferential absorption in the blood, thereby interfering with oxygen delivery to the cells in the body. Exposure to carbon monoxide causes a gradual increase in the percentage of carboxyhemoglobin in the blood until an equilibrium value dependent upon the ambient air concentration is reached. The rate of intake is dependent upon the breathing rate; therefore, equilibrium is reached more quickly the greater the exertion. Up to 50 ppm, the equilibrium values of carboxyhemoglobin corresponding to different concentrations of inspired carbon monoxide can be estimated from the equation

$$\%\mathrm{HbCO} = 0.4 + \frac{\mathrm{PPM\ CO}}{7}$$

The 0.4 constant is in the equation to account for the endogenous carbon monoxide, that is, the carboxyhemoglobin that results from the body's own production of carbon monoxide.

Graphic representations of the conversion of hemoglobin to carboxyhemoglobin in the presence of different concentrations of ambient carbon monoxide and the effect of various levels of activity on the rate of uptake are presented in Figure 2 and Figure 3.

The level of HbCO in the blood (Table 2) is the important measurement in the evaluation of carbon-monoxide pollution. High levels of HbCO are associated with cigarette smokers, firemen, garage workers, foundry workers, and individuals who spend extended periods of time in heavy congested traffic or in vehicles with faulty exhaust systems. Ambient carbon-monoxide measurements at a monitoring site can be very misleading as an index of exposure, because study populations are usually mobile and carbon-monoxide concentrations can vary significantly, both horizontally and vertically, throughout an urban area.

Exposures to the high concentrations of carbon monoxide sometimes encountered in community atmospheres, even those well above the national standards, are not believed to be sufficient to initiate cardiopulmonary disease; however, individuals whose pulmonary functions are already significantly impaired because of anemia or damage to the heart, vascular system, or lungs can suffer adverse health effects from such exposures.

In order to maintain normal function, the tissues of the body must receive oxygen at a rate that depends upon their nature and functions. Those with a high rate of oxygen demand are more susceptible to the oxygen-depriving action of carbon monoxide. For example, studies of the brain and liver show a decrease in oxygen pressure at those sites even at levels as low as 2% carboxyhemoglobin. Cardiopulmonary-system abnormalities, such as shunts that have developed that allow venous blood to mix directly with arterial blood, cause the individuals affected to be explicitly sensitive to carbon monoxide. Angina-pectoris patients who experienced exposures that raised their carboxyhemoglobin level to 2.5%—that is, approximately to the level produced by an 8-hour exposure at the concentration set as the air-quality standard—suffered the onset of chest pain from exercise significantly sooner than did other angina patients not similarly exposed. The reduction in risk of heart attack that is observed soon after the cessation of the cigarette-smoking habit indicates that carbon monoxide may be an important factor in precipitating heart attacks. The inhalation of carbon monoxide during pregnancy is a special concern because a higher concentration of carboxyhemoglobin is generated in the fetus than in the mother, and the elimination of carbon monoxide after exposure is slower in the

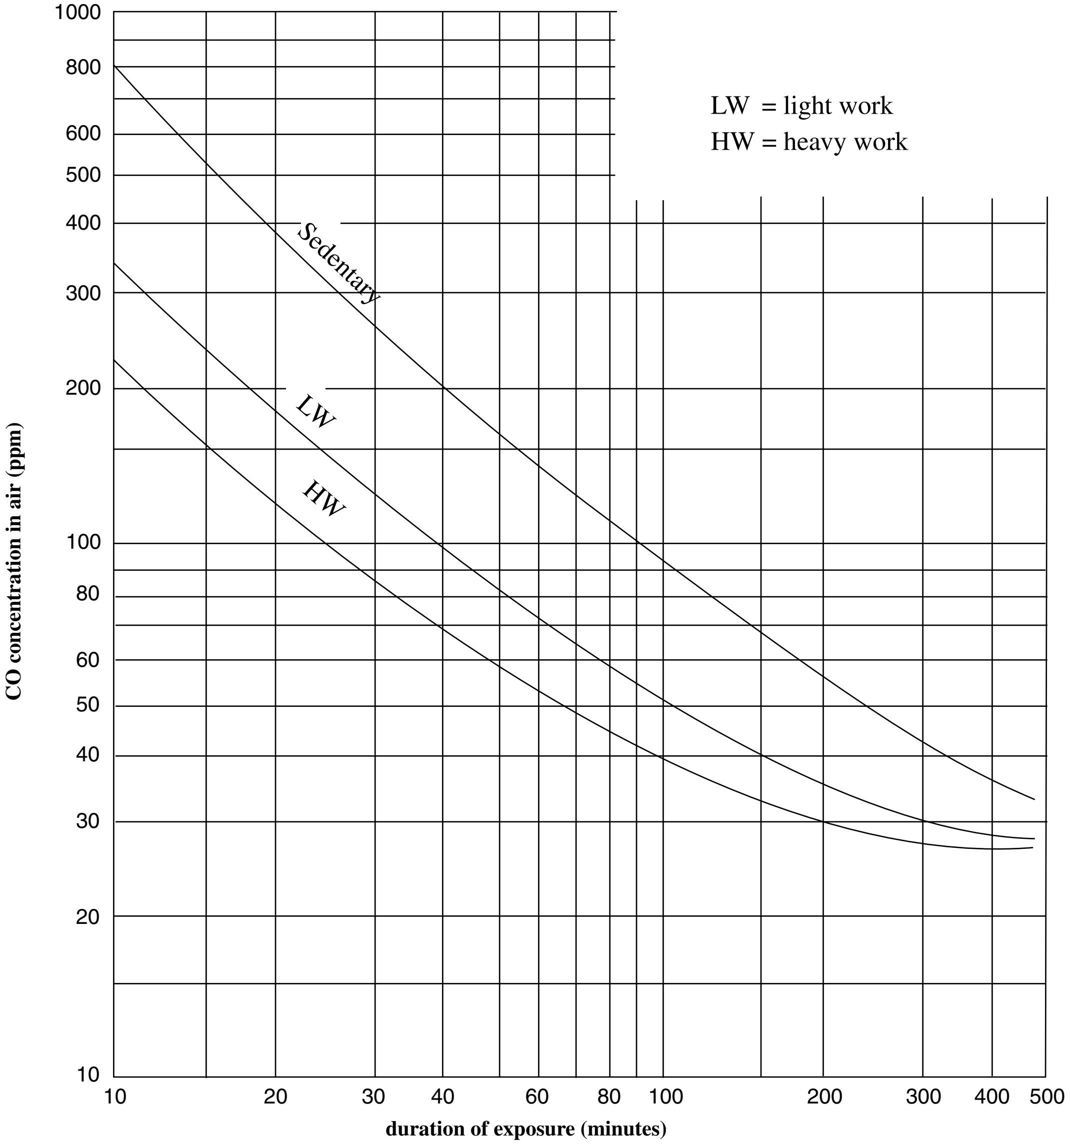

FIGURE 2 Criteria for a Recommended Standard Occupational Exposure to Carbon Monoxide. NIOSH, 1972.

fetus. The effects of combining exposure to carbon monoxide with sudden significant changes in altitude or the intake of drugs or alcohol upon the performance of body functions should be considered and avoided.

NITROGEN OXIDES (NO_x)

"Nitrogen oxides" refers to the mixtures of nitric oxide and nitrogen dioxide that are formed when combustion causes the nitrogen and oxygen in the atmosphere to combine to form nitric oxide, some of which then oxidizes further to nitrogen dioxide; combustion gases contain about 5 to 10% nitrogen dioxide mixed with nitric oxide. The mechanism for the process is believed to be

$$O_2 = 2O$$
$$N_2 + O = NO + N$$
$$N + O_2 = NO + O$$
$$N + OH = NO + H$$

The overall reaction for the formation of nitrogen dioxide is

$$2NO + O_2 = 2NO_2$$

Nitric oxide is oxidized rapidly by ozone; therefore, ozone levels tend to be lower in the vicinity of nitric-oxide sources, such as the tailpipes of vehicles.

Nitrogen dioxide, the most toxic of the nitrogen oxides, causes damage to lung tissues at concentrations higher than usually found in ambient atmospheres. Exposures above the

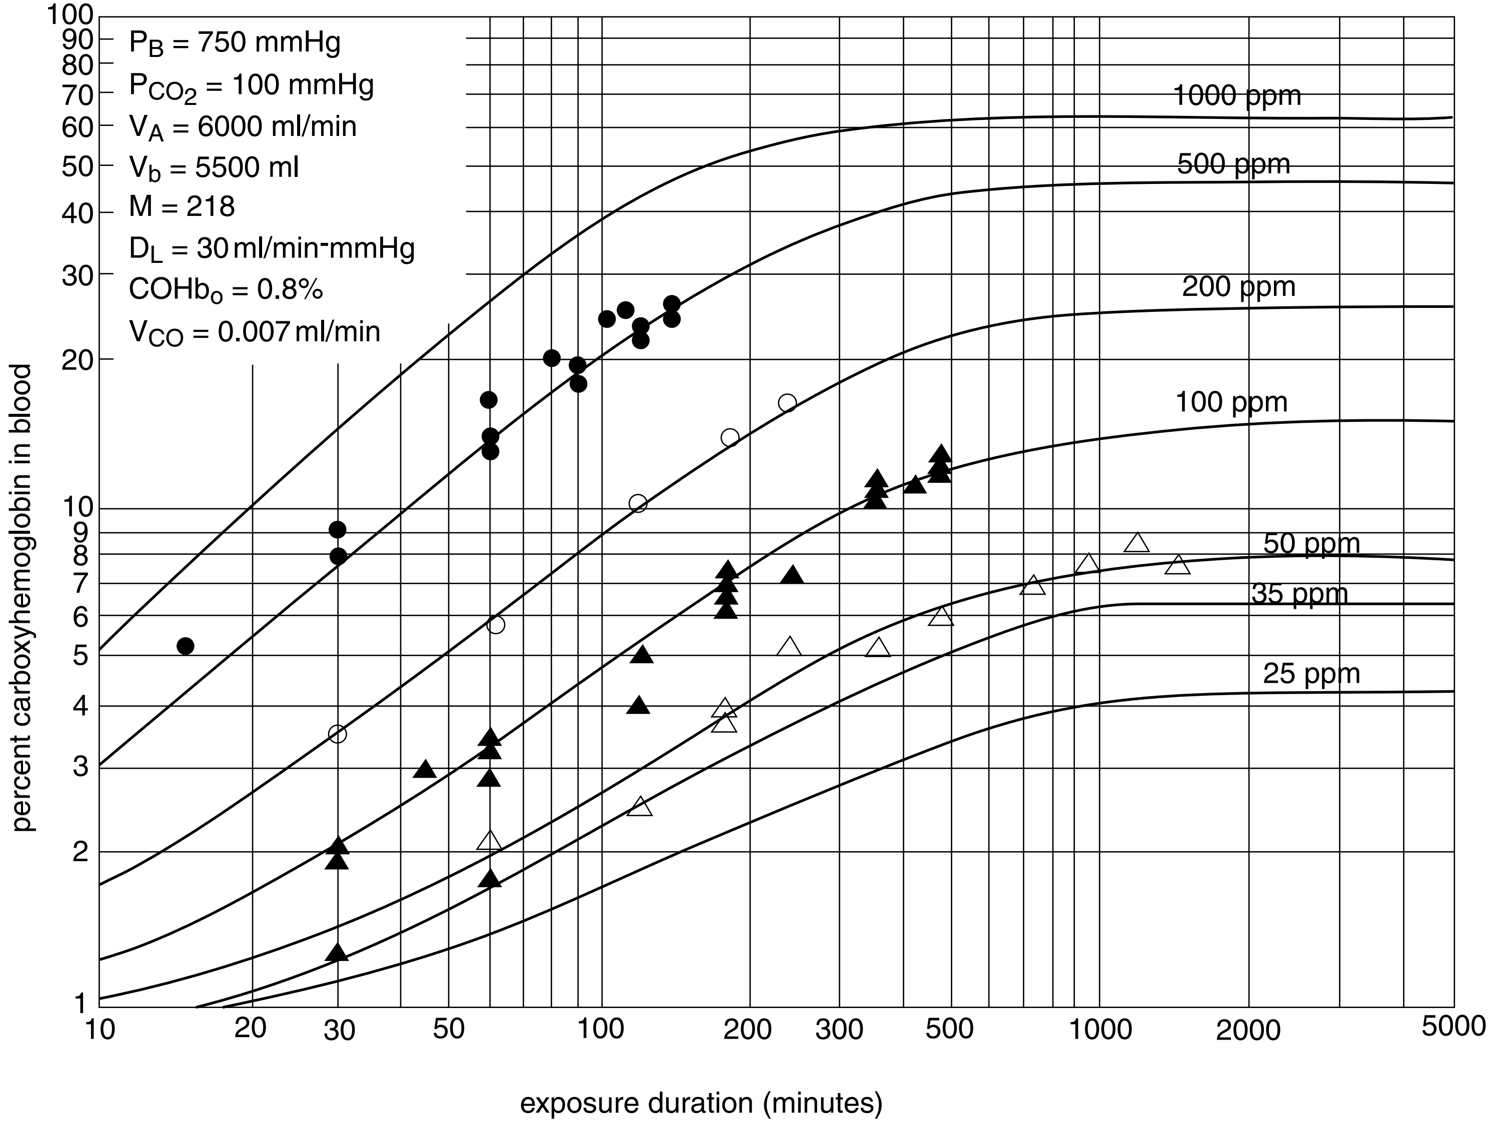

FIGURE 3 Criteria for Recommended Standard Occupational Exposure to Carbon Monoxide. NIOSH, 1972.

TABLE 2
Carboxyhemoglobin levels resulting from steady-state exposure to increasing concentrations of CO in ambient air

CO in Atmosphere (ppm)	COHb in Blood (%)	Signs and Symptoms
10	2	Asymptomatic
70	10	No appreciable effect, except shortness of breath on vigorous exertion; possible tightness across the forehead; dilation of cutaneous blood vessels
120	20	Shortness of breath on moderate exertion; occasional headache with throbbing in temples
220	30	Headache; irritable; easily fatigued; judgment disturbed; possible dizziness; dimness of vision
350–520	40–50	Headache; confusion; collapse; fainting on exertion
800–1220	60–70	Unconsciousness; intermittent convulsion; respiratory failure; death if exposure is long continued
1950	80	Rapidly fatal

Source: Ellenhorn's Medical Toxicology, 2nd Ed, Baltimore, MD: Lippincott Williams & Wilkins.

national standard of 0.053 ppm are rare; therefore, with the exception of activities in the vicinity of industrial sources, nitrogen oxides have not been found to be a cause for community concern. An important consideration in the case of significant exposures is the delay that can occur between exposure and sensations of distress, which may delay prompt treatment. An important effect is the increased susceptibility to pathogens that may result from the destruction of macrophages and general injury to the lung's defense mechanisms.

LEAD

The major source of lead in the air environment has been motor vehicles; therefore, levels have decreased dramatically as regulations have mandated the elimination of lead from gasoline because of its health effects and its detrimental action on the catalytic converters in vehicles. Metal processing, such as in lead smelters, is currently responsible for most of the lead in the air, but waste incinerators and lead-acid-battery manufacturing also contribute.

The chief cause of concern about lead is its effect on children. Lead damages the brain, particularly the cerebellum, and the kidneys, liver, and other organs, and can lead to osteoporosis and reproductive disorders. Its effects upon fetuses and young children produces learning disabilities and lowers IQ. Lead exposures result in high blood pressure and can lead to anemia.

The exposure of children occurs not only through the air but also through accidental or intentional eating of paint chips and contaminated food or water.

TOXIC AIR POLLUTANTS

The Clean Air Act of 1977 required that emission standards be imposed upon air pollutants considered hazardous because they have been found to increase illness or mortality. The complexities encountered in attempts to control pollutants by declaring them to be criteria pollutants and setting air-quality standards resulted in the choice of emission controls instead of air-quality standards for toxic materials. The EPA has listed 188 pollutants whose emissions must be reduced. Examples are benzene (gasoline), perchlorethylene (used in dry cleaning), and methylene chloride (a solvent and paint stripper), as well as toluene, dioxin, asbestos, cadmium, mercury, and chromium.

The effects of significant exposures to toxic pollutants may be cancer, neurological effects, damage to the immune system, and reproductive effects. The risk of cancer associated with exposure to toxic pollutants in the air for a population is calculated on the basis of two factors. One describes the potency of the air contaminant, the other the magnitude and duration of the exposure, which is commonly assumed to be a lifetime of 70 years. The potency of a hazardous material can be expressed as a unit risk value. The unit risk value for an air pollutant is the increased lifetime cancer risk occurring in a population in which all individuals are exposed continuously from birth (70 years). The following discussion is based on a relatively simple version of risk assessment compared to the more sophisticated methods that are now in use.

The unit risk values are used to compare the potency of carcinogens with each other and to make crude estimates of the risk to populations whose exposures are known or assumed. The unit risk values are calculated so as to represent plausible upper bounds that are unlikely to be higher but could be appreciably lower. The units of unit risk values are $(\mu g/m^3)^{-1}$. The product of the unit risk value and the ambient concentration is the individual risk, and the product with the population exposed is the aggregate risk. Division of the individual or aggregate risk by 70 results in the corresponding annual risks. The maximum average concentration of the hazardous material in the ambient atmosphere is used in order to be conservative. Thus, if a maximum value of cadmium in the atmosphere in the vicinity of a copper smelter is $0.3\ \mu g/m^3$, and the unit risk value of cadmium is $2.3 \times 10^{-3}\ (\mu g/m^3)^{-1}$, then the probability of cancer (i.e., the maximum individual risk from the inhalation of cadmium) is

$$2.3 \times 10^{-3} \times 0.3 = 0.69 \times 10^{-3}$$

and the aggregate risk is

$$1000/70 = 14.3$$

Risk assessment has become increasingly important but also more complex as the basis for the management of exposures. The EPA issues guidelines for assessing the risks of carcinogens, mutagens, developmental toxicants, and chemical mixtures together with guidelines for estimating exposures. The Integrated Risk Information System (IRIS) is an electronic database maintained by EPA that contains information on the human health effects that can result from exposure to hazardous pollutants. The EPA provides telephone, fax, and e-mail contacts for obtaining information about hazardous pollutants.

DIOXIN

The term "dioxin" refers to a group of compounds that cause similar adverse health effects. They belong to three classes of chemicals: chlorinated dibenzo-p-dioxins (CDDs), chlorinated dibenzofurans (CDFs), and polychlorinated biphenyls (PCBs). Studies to date indicate that the compound 2,3,7, 8-tetrachlorodibenzo-p-dioxin (TCDD) is the more toxic substance. CDDs and CDFs are not created on purpose but result as by-products of certain activities; PCBs were produced for use in transformers and other purposes, but their use has now been prohibited. Combustion of certain materials, chlorine bleaching of pulp and paper, and certain chemical manufacturing processes all may create small amounts of dioxins.

Dioxins are characterized as likely human carcinogens, with the compound TCDD considered a human carcinogen on the basis of available human and animal data. The cancer risk to the population from exposures to dioxins is estimated to be 1 in 1000, with the likelihood that the risk may be much lower. Adverse health effects have been associated with personnel exposed to Agent Orange in Vietnam because of its dioxin content. Based upon available data, there is no clear indication that the general population is suffering health diseases from exposure to dioxins.

INDOOR AIR

Indoor air quality became important to those responsible for protection against adverse health effects caused by the inhalation of pollutants when it was realized that most individuals spend 90% of their time indoors and that indoor air quality is deteriorated by a large variety of sources. Four organizations—the American Lung Association, EPA, Consumer Product Safety Commission, and American Medical Association—prepared a document titled *Indoor Air Pollution* in 1989 that presents a summary of information for health professionals about the causes and effects of indoor air pollution. Figure 4 from this document provides an overview of the effects of air pollutants and their causes.

From a practical standpoint, the most important factor in the control of indoor air pollution is the quality of the ventilation of occupied space. The reduction of energy costs by cutting down on forced ventilation can lead to "sick building syndrome," the term applied to outbreaks of complaints as a result of poorly ventilated indoor spaces. The National Institute for Occupational Safety and Health has investigated many cases of indoor air-quality health hazards and has published guidelines for such investigations.

In certain cases, air-quality standards are met outdoors but not indoors. For example, an investigator who measured indoor versus outdoor levels of suspended particulate matter found that he spent 84% of his time indoors, and that 82.3% of his exposure was attributable to indoor air. The average indoor levels of nitrogen dioxide of 95 homes in rural Wisconsin was higher than the outdoor level, sometimes exceeding the ambient air-quality standard.

SECONDHAND SMOKE

The mixture of combustion products from the burning end of tobacco products and the smoke exhaled by smokers is referred to as "environmental tobacco smoke" or "secondhand smoke." It contains more than 4,000 chemicals, more than 50 of which are cancer-causing agents. It is associated with an increase in lung cancer and coronary heart disease and is particularly dangerous to the not yet fully developed lungs of young children, increasing their risk for sudden infant death syndrome, asthma, bronchitis, and pneumonia. An estimated 3,000 lung-cancer deaths and 35,000 coronary-heart-disease deaths occur annually among adult nonsmokers in the United States as a result of exposure to secondhand smoke. In children it is estimated that 8,000 to 26,000 new asthma cases and 15,000 to 300,000 new cases of bronchitis and pneumonia for those less than 18 months are the result of inhaling secondhand smoke.

INDOOR RADON LEVELS

Next to cigarette smoking, the inhalation of radon gas and the products of its radioactive disintegration are considered the most significant cause of lung cancer. The EPA has estimated that 20,000 of the lung-cancer deaths expected annually can be ascribed to radon, and the surgeon general has attributed 85% of lung-cancer deaths to smoking.

Radon-222, an odorless, colorless radioactive gas, is one of the products in the chain of decay of elements starting with uranium-238 in the soil, which after radon goes on to produce polonium isotopes 218 and 214. Their alpha-particle emissions dissipate their energy while destroying lung tissue,

which leads to lung cancer. The radioactivity attributable to radon in the air is measured in picocuries per liter, which correspond to two atoms decaying per liter per minute. The concentration of the decay products is measured in "working level units," where 1 working level unit of decay products is released from approximately 200 pCi/l of radon.

The only certain method of determining the presence of radon is by testing, which should be performed whenever a dwelling is brought or sold. The EPA has prepared the "Home Buyer's and Seller's Guide to Radon," which provides information about what can be done to protect against this problem.

BIOLOGICAL CONTAMINANTS

The New York Academy of Medicine issued a resolution in 1983 (Health Aspects of Indoor Air, New York Academy of Medicine [1981] 57, No.10) expressing its concern about the damage to health caused by the inhalation of biologic agents that points out that "by far the most important substances in indoor air that affect human health are infectious agents, primarily viruses and bacteria in the form of aerosols or as part of droplets or particles. These cause more than 60,000 deaths and 250 million disabling illnesses in the United States each year." In addition to viruses and bacteria, the indoor air can be contaminated with pollens, fungal sores, algae, amoebas, actinomycetales, arthropod fragments, and droppings and dander from humans and animals. The airborne transfer of disease can involve pathogenic, toxicogenic, or allergenic agents via short-range direct person-to-person transfer or long-range dispersion throughout rooms sharing a common ventilation system. An important preventive strategy is to isolate other rooms from contamination by the air from rooms containing sources of microbial pollution.

Secondary sources of biological contamination can be established indoors by viable organisms that find friendly environments and sources of nourishment in soils, plants, and stagnant water. Pathogens, toxins, and allergens can be brought indoors through air intakes and shoes, clothing, or tools. The human body—mainly from the nose and mouth but also from other parts of the body—is a primary source of biological air contaminants and of nourishment for the growth of microorganisms. For example, it has been reported that the body sheds skin scales at a rate, dependent upon activity level, that averages 7 million scales per minute with an average of four bacteria per scale. Dust mites, dermatophagoides, feed on these scales and in turn produce fecal pellets in the respirable size range that can strongly affect sensitive individuals.

Almost all surfaces containing organic material such as cloth fabrics, paper, wood, leather, adhesive ceiling tiles, paint, soaps, and greases under proper conditions can sustain the growth of fungi, bacteria, acarids, and other microbes. Locations indoors where water can stagnate or cause continuous dampness of surfaces—for example, chilled-water air-conditioning systems, refrigerator drip pans, bathrooms, flooded basements, hot tubs, and saunas—are possible sources of biological pollutants.

Aerosol formation originating from water reservoirs is an important mechanism for airborne transmission of disease. The "jet-drop" phenomenon that occurs in washbasins, bathtubs, toilet bowls, and urinals can generate aerosolized microorganisms, as can the high-speed water-cooled drills used by dentists. Humidifiers that generate steam by other than thermal means can be dangerous sources of microorganisms that have grown inside the reservoirs; therefore, they should be sterilized before use and will always form droplets containing the minerals in the water being used. Filters in ventilating systems, if not properly cleaned and maintained, can also become significant sources of infectious diseases.

Some organisms are not able to survive for long periods outside a host and thus require rapid person-to-person transfer to cause serious problems, but others can remain viable for long periods and thus carry the diseases that are recognized as transmittable through air. The following are some of the major diseases that are classified as human airborne infections.

Tuberculosis
Rheumatic fever
Scarlet fever
German measles
Smallpox
Chicken pox
Hemolytic streptococci
Pneumococcus pneumonia
Mycoplasma pneumonia
Influenza
Diphtheria
Meningococcus meningitis
Psittacosis
Measles
Whooping cough
Poliomyelitis
Systemic mycosis
Mumps
The common cold

Certain lesser-known diseases have been brought into focus by investigators of illnesses attributed to indoor air pollution. Some of these have been associated with contaminated water reservoirs in humidifiers, chilled-water air-conditioning systems, and other adjuncts to indoor ventilation and climatization.

The most notable infection is Legionnaires' disease, which has caused a number of epidemics, including the one at the Legionnaires Convention in Philadelphia in 1977, which resulted in 182 cases, 25 of which were fatal. The infection is caused by a not-uncommon soil bacterium, *Legionella pneumophilia,* which survives very well in water and can thus contaminate cooling towers, air conditioners, and other potential sources of aerosols. Drinking water in a hospital has also been implicated in the transmission of this infection. Since its discovery, studies have claimed that 10 to 15% of pneumonia cases in hospitals are attributable to legionella.

A milder, self-limiting disease with flulike symptoms called Pontiac fever is also attributed to legionella.

Tuberculosis is caused by a virulent microorganism, mycobacterium tuberculosis, which can survive for long periods is encapsulated form and has been shown to be readily transmitted through ventilation systems. The gradual disappearance of this disease has been reversed in areas where AIDS is prevalent, therefore, its importance as a public-health problem is increasing.

Hypersensitivity pneumonitis and humidifier fever also are associated with aerosols from contaminated water. The former, which is the more serious, is an interstitial lung disease that in its acute form causes fever, chills, cough, and dyspnea 4 to 6 hours after exposure. The more commonly blamed agents are the thermoactinomycetes or the thermophylic micropolyspora. Humidifier fever is self-limited, with symptoms resembling the flu.

FUNGAL DISEASES

Fungi can cause disease and can also generate highly potent toxins. Treating the diseases is a special problem because available drugs are few in number because of the difficulty of finding ones that will preferentially attack fungal cells in the presence of mammalian cells.

Histoplasma capsulatum and other molds and yeast organisms such as blastomyces, cryptococcus, and coccidiodes are pathogenic to humans. The latter is responsible for valley fever, which is causing concern in hot, dry areas such as the Southwest, where it thrives. Cryptococcus, often found in soil contaminated by pigeon droppings, is a killer of AIDS patients, attacking the central nervous system and causing meningitis. *Aspergillus fumigatus* is a common fungus that invades the lung. When the spores are stirred up and inhaled they can grow fungus balls in the lung. One condition is called “farmer’s lung,” but in hospitals where transplant or AIDS patients have suppressed immune systems, the fungus can produce severe infections that must be treated rapidly. Detection of the fungus is difficult because instead of using the bloodstream it attacks by traveling from tissue to tissue. *Aspergillus flavus* produces aflatoxin, one of the most potent carcinogens known.

As in the case of tuberculosis, immuno-compromised individuals are readily susceptible to the acquisition of disease via inhalation. *Nosocomial aspergillosis* from sources such as contaminated air conditioners should be a special concern in hospitals.

ASBESTOS

“Asbestos” is the generic term for silicate materials that occur in fibrous form. A fibrous form that is classified as a serpentine is called “chrysotile” and is the type of asbestos most common in the United States. The length and flexibility of its fibers allow it to be spun and woven. Other types of asbestos are amphiboles that include amosite, crocidolite, tremolite, antophyllite, and actionide. Their fibers do not lend themselves to weaving, but in general they have higher heat resistance than chrysotile. Asbestos is used in many products, but most of it is used in construction—in floor tiles, cements, roofing felts, and shingles—and was used in very large quantities to protect steel structures from weakening during fires.

Measurements made of asbestos concentrations in the ambient air of New York City led to its banning in 1971 in sprayed material, a ban rapidly adopted nationally and worldwide. Nevertheless, many tons of asbestos will have to be handled with great care when the many buildings that used it to protect their steel structure from fire are finally demolished.

A study by Selikoff et al. of mortality among 17,800 asbestos workers from 1967 to 1976 found 675 excess deaths from cancer out of a total of 995. The ratio of observed to expected deaths in such a population was 3.11 for all cancers, 4.60 for lung cancers, and greater than 1 for several other

types of cancer. They found 175 deaths from mesothelioma, a cancer rarely found in the general population, and 168 from asbestosis, a form of pneumoconiosis characterized by fibrosis of the lung that often continues after exposure ceases.

Cigarette smoking was found to have a strong multiplicative effect when combined with exposure to asbestos. Based upon a mortality rate of 1 for a nonsmoking, nonexposed comparison group, the mortality ratio for nonsmoking asbestos workers, nonexposed cigarette smokers, and workers exposed to asbestos who also smoked were 5, 11, and 53.

The methods of asbestos analysis differed in that occupational exposures were originally measured by counting the number of fibers longer than 5 μm in a given volume of air using optical microscopy. In the ambient air the submicroscopic fibers, called "fibrils," which are the ones that can penetrate deeply into the respiratory system, had to be measured; therefore, the Environmental Science Laboratory, led by Irving Selikoff, at Mount Sinai School of Medicine developed an electron-microscopy method that measured the mass of fibrils per cubic meter of air.

Asbestos air concentrations are now reported in terms of nanograms per cubic meter—asbestos background concentrations are usually in the range of 0 to 10 ng/m^3.

Asbestos in schools has been a major concern because of the prevalence of its use and the nature of the population involved. A study of chrysotile asbestos in schools known to contain damaged asbestos insulation measured 9 to 1950 ng/m^3. Measurements in schools selected at random found a mean of 179 ng/m^3, compared to average outdoor concentrations of 6. The excess risk of death from lung cancer caused by asbestos exposure is proportional to the intensity of the exposure and its duration. One estimate of the cancer-incidence rate from asbestos reported by the EPA was that continuous exposure to 0.01 fibrils per ml (about 300 ng/m^3) will cause 28 mesotheliomas per million females and 19 per million males, and 5 excess lung cancers per million females and 17 per million males.

PLANT EFFECTS

The effects upon the plant surfaces of the contact of vegetation by suspended particulate matter via dry or wet deposition are not well documented. Direct entry of sulfur-dioxide gas molecules through the plant stomata, on the other hand, produces effects that are better understood and appear to depend, to a great extent, upon the rate of conversion to sulfate, a natural plant nutrient. As might be expected, the response of a plant to a particular exposure incident is dependent upon the concentration and duration of exposure and, because of the opening and closing patterns of stomata, also on the time in its daily cycle that exposures occur. Data on the injury threshold of 31 species of forest and agricultural plants were plotted to show their relative sensitivity to

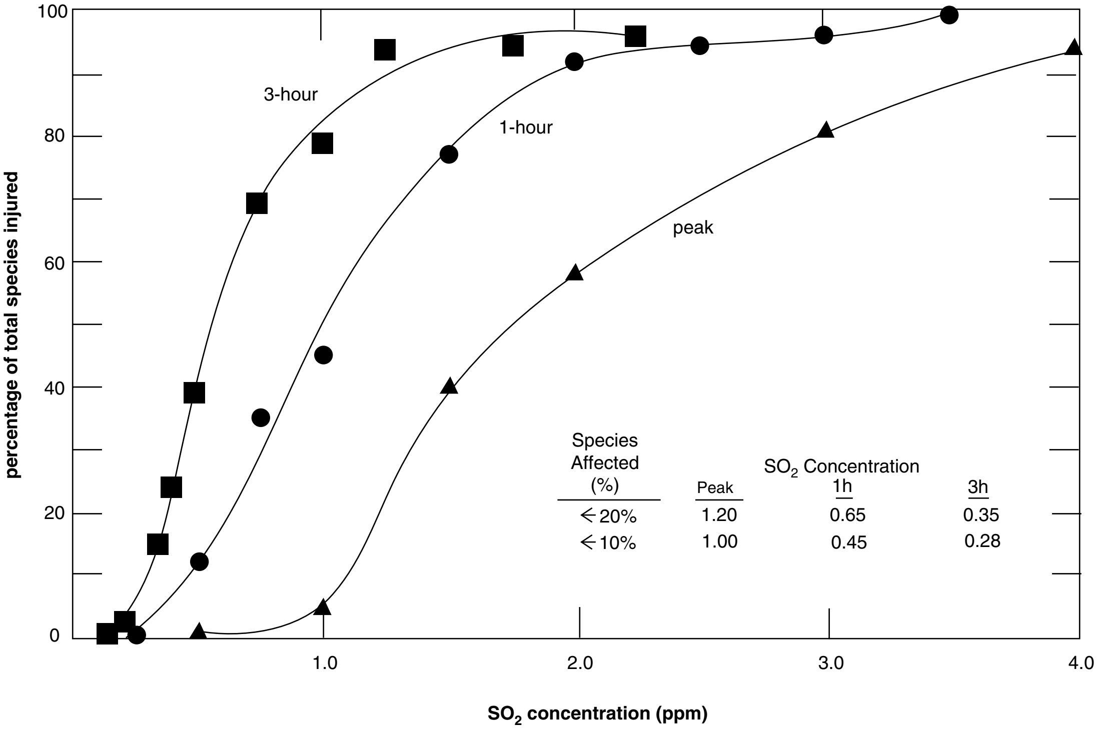

FIGURE 5 Percentage of plant species visibly injured as a function of peak 1-hour and 3-hour SO$_2$ concentrations. *Source:* McLaughlin and Lee (1974); McLaughlin (1980). (Air Quality Criteria for Particulate Matter and Sulfur Oxide, 1981.)

sulfur dioxide (Figure 5). The relative sensitivity of specific plants to SO_2 is indicated in Table 3.

AIR POLLUTANT REMOVAL: see ELECTROSTATIC PRECIPITATION; INDOOR AIR POLLUTION; PARTICULATE REMOVAL; MOBILE SOURCE POLLUTION

AIR POLLUTION INSTRUMENTATION: see also STACK SAMPLING; REMOTE SENSING

AIR POLLUTION INSTRUMENTATION

Advances in pollutant monitoring techniques and instrumentation have progressed significantly in the past several years to the point where noteworthy confidence in instrumentation-generated data has been established. Most systems, whether manual or automatic, have been designed to determine the quality of pollutants present per unit volume of air. These determinations can be made either in a duct/stack or in the outside atmosphere for the purpose of either ensuring adherence to published air quality regulations or for defining air pollution control device design criteria.

Air pollution instrumentation is utilized in the two major air quality areas of source and ambient monitoring with a further breakdown in the source monitoring category to the manual, and continuous type of instrumentation. Each of the three categories presents various types of monitoring problems which must be overcome, and each program is performed for a different reason.

MANUAL MONITORING—SOURCE INSTRUMENTATION

Instrumentation is utilized in this type of monitoring to provide a means to determine compliance with existing regulations and for developing design criteria for control of air pollution. The systems must be durable and allow for a certain amount of flexibility due to the many different situations which are encountered during the evaluations of stationary sources. This is emphasized by the fact that there are more than 25 different Environmental Protection Agency (EPA) sampling methods which, all except Method 9, require some type of instrumentation to complete the evaluation. (See *Stack Sampling.*) The most familiar procedure, "Method 5," has been the basis for the development of most of the other procedures. Method 5, shown in Figure 1, utilizes the basic equipment and sampling procedures (i.e., impingers, dry gas meter, pump, etc.) which with minor modifications or additions can be utilized to perform other EPA methods. As an example, Method 17 shown in Figure 2, utilizes the same components from the EPA 5 "sampling train" with a change in the filter location, and Method 8 for sulfuric acid mists presents even other changes. The EPA methodology and equipment were developed specifically to improve the accuracy of the source testing programs, and supplement the "ASME Train" (the "ASME" or American Society of Mechanical Engineers Train was developed to allow the determination of stack gas concentrations primarily in the electric utility area). The major reason for the testing methodology change (ASME to EPA) was to improve the capture efficiency of smaller (submicron) particles, and allow for gaseous concentration determinations. Due to thimble porosity the alundum thimble utilized in the "ASME Train" did not allow for the determination of representative data when sampling after a control device for either the determination of regulatory compliance or control efficiency. In addition, the use of an entirely glass-lined sampling system ("EPA Five Train") minimized the introduction of outside contamination to the samples being collected.

Such theories as isokinetic sampling for particulates ≥ 1.0 micron and proportional testing for gaseous determinations remain unchallenged. Only the equipment for manual monitoring has changed and will continue to change as improvements are made.

Manual source testing (stack sampling) equipment is available through several manufacturers, some of which are presented in the "Product Line Profiles" developed by *Pollution Equipment News*.

CONTINUOUS MONITORING—SOURCE INSTRUMENTATION

There are two basic types of source emission monitoring instrumentation—opacity monitors and gaseous emission monitors. Opacity monitors, which measure the transmittance of light through the gas stream, are called transmissometers, and are of two basic types; single-pass systems and double pass systems. Gaseous emission monitors on the other hand, are utilized to measure the concentration of specific gaseous components of the exhaust gas, such as O_2, CO, SO_2, NO_2, NO_x, etc. These instruments are divided into three basic types: extractive systems, *in-situ* systems, and remote systems. The *in-situ* systems can be further sub-divided into either in-stack or cross-stack monitors.

Opacity Monitors

Opacity monitors, also known as transmissometers, serve the purpose of providing information relative to combustion conditions, or control device efficiency. Transmissometers, although required by the EPA for various stationary sources

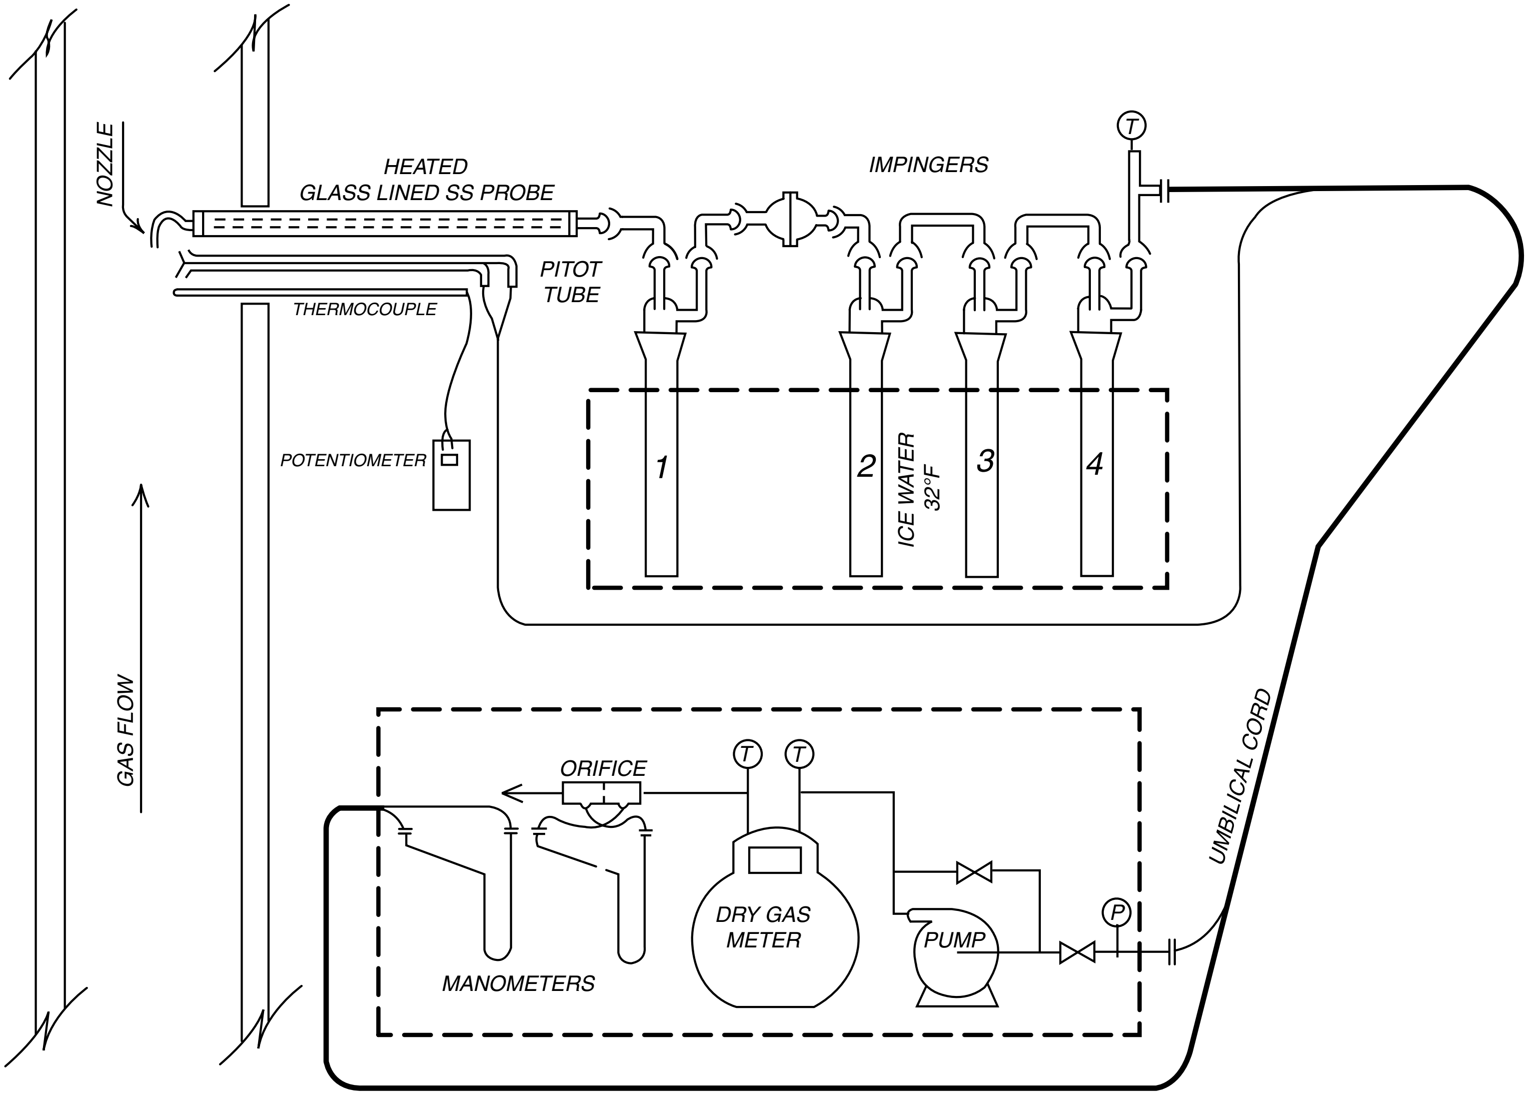

FIGURE 1 Method 5 schematic.

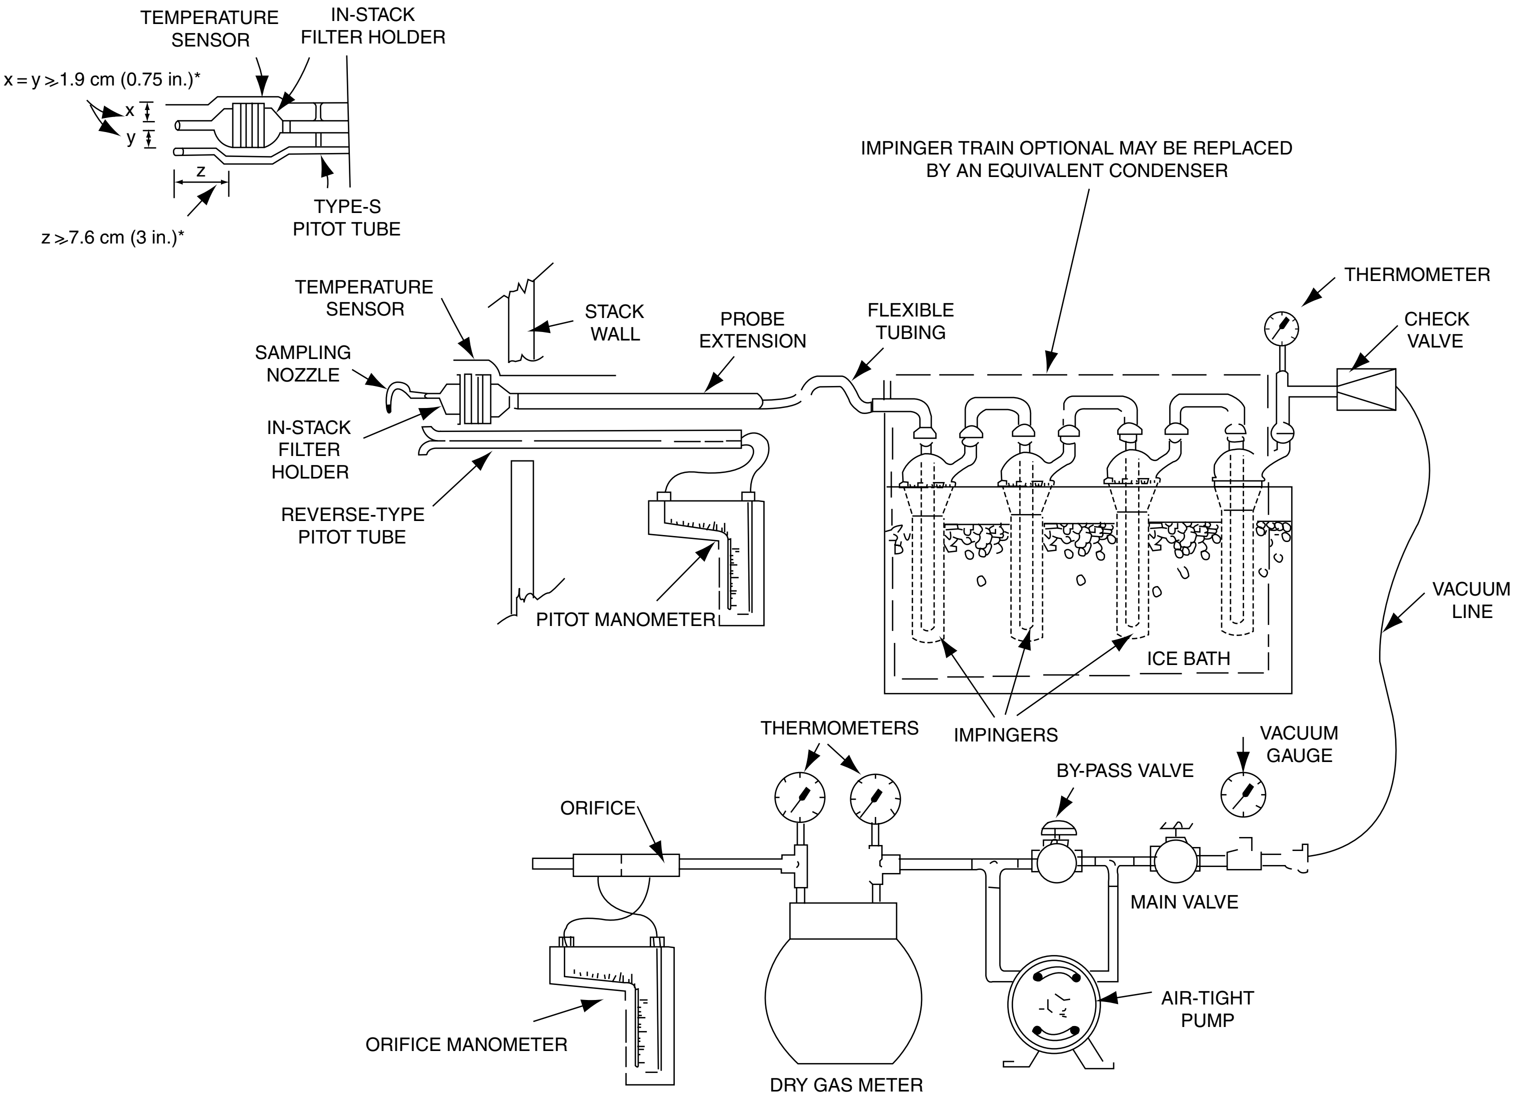

* SUGGESTED (INTERFERENCE-FREE) SPACINGS

FIGURE 2 Method 17 schematic.

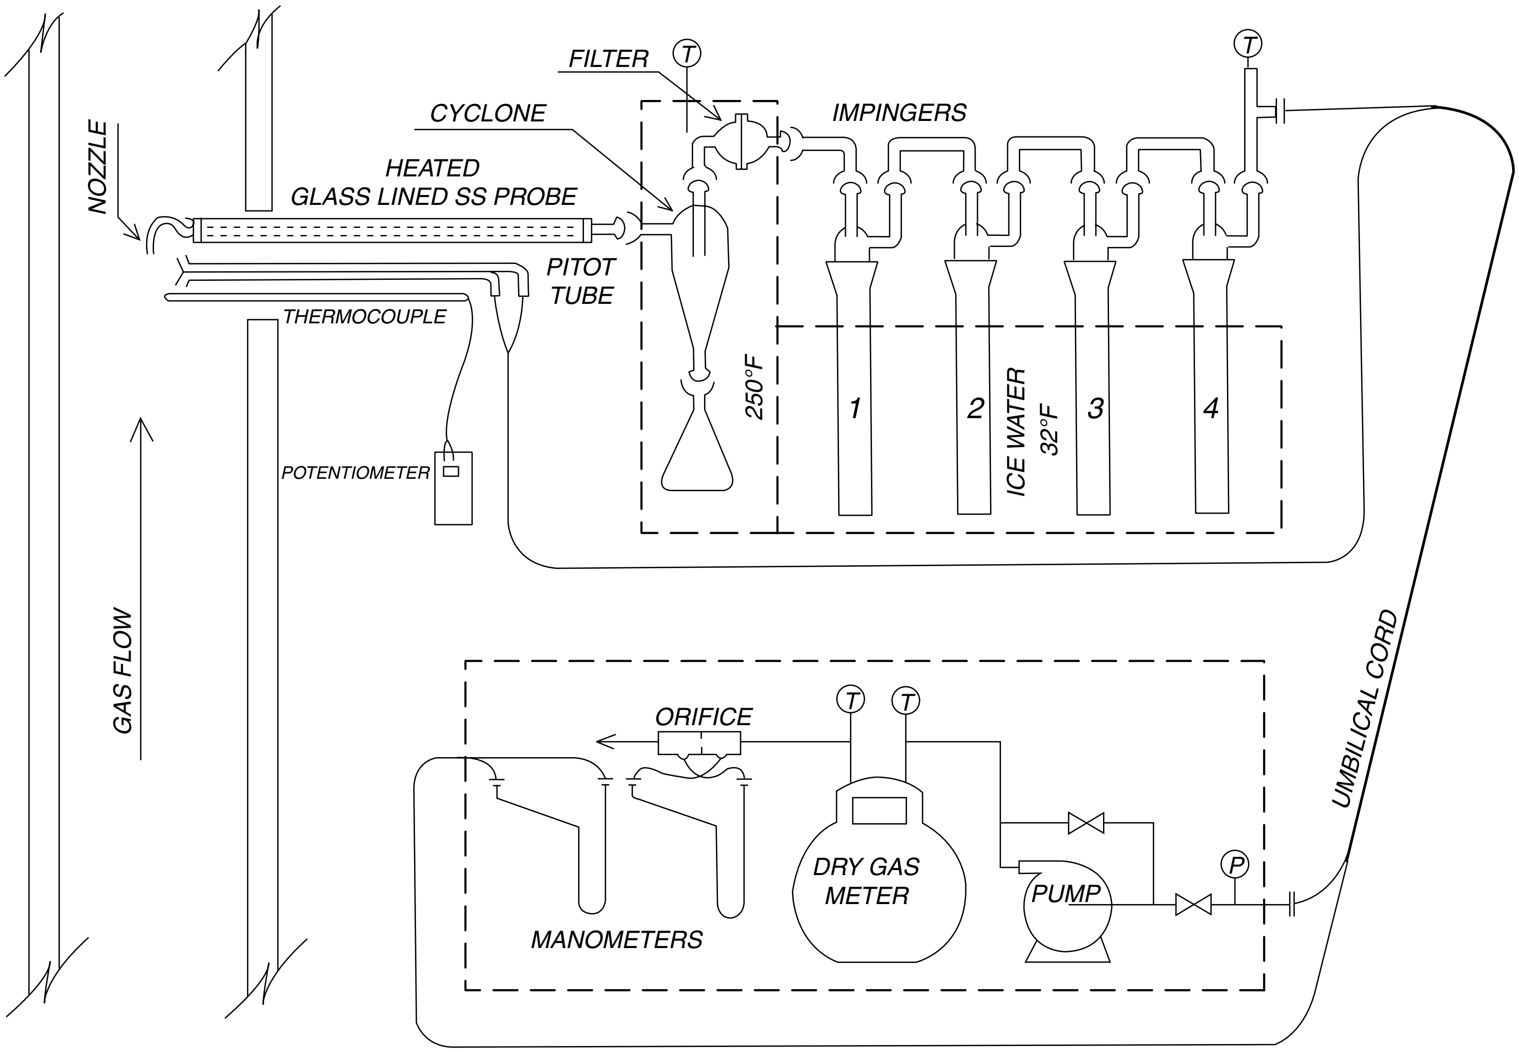

FIGURE 3 Method 8 schematic.

for the above-described purpose, are not considered to be enforcement tools. This requirement is fulfilled by the EPA certified Visual Emissions Observer as is specified in EPA Reference Method 9.

There are two basic types of transmissometers, single-pass and double-pass systems. The single-pass system incorporates a light source on one side of the stack and a detector on the opposite side. Although this is the more economical of the two systems, it does not meet the EPA requirements for system zero and calibration checks without complete process shutdown every 24-hours. It is better applied in a situation where direct compliance with the EPA criteria is not a factor, such as process control or baghouse filter bag breakage detection.

The double-pass system houses both the light source and detector with attendant calibration and zero-check instrumentation on the same side of the stack with only a reflecting mirror on the opposite side. Therefore, most of the double-pass systems satisfy the EPA design criteria. Refer to Table 1 for a list of vendors of either single-pass or double-pass transmissometers. The fraction of light lost in crossing the stack is used to calculate opacity and its value is related to the amount of dust or smoke passing through the light path. The cost per unit including control options is about $20,000–40,000 (1996$). The lower figure is for a quantity of more than 30 units; the higher figure is for a single installation.

An acid dew point meter is a related instrument produced by Land Combustion (see address above). It is useful in estimating SO_3/H_2SO_4 concentration.

Gaseous Emissions Monitoring

Stationary sources that are required by the EPA to install a continuous gaseous emissions monitor must match their specific process, and source emissions to the capabilities of the continuous monitor types available. Most instrumentation will fall into two categories, extractive systems and *in-situ* systems. A third category, remote monitors, utilizes concepts such as lasers and advanced spectroscopic methods to monitor gaseous emissions at distances from 500 to 100 meters away from the source.

EXTRACTIVE MONITORS

The basic principle behind an extractive monitor is the withdrawal of a gas sample from the main exhaust stream into the analyzer. This withdrawal must be conducted such that a representative sample is selected, and then appropriate interferents (particulates, water vapor, etc.) must be removed dependent upon analytical methodology. Extractive monitor types can be subdivided into three general categories: absorption spectrometers, luminescence analyzers, and electroanalytical monitors. Specialized extractive methods that do not fit into these three categories include paramagnetism and thermal conductivity.

Absorption Spectrometers

Spectroscopic analyzers utilized as continuous emissions monitors include two basic types: non-dispersive infrared analyzers (NDIR), and non-dispersive ultraviolet analyzers (NDUV).

NDIR detectors can monitor SO_2, NO_x, CO, CO_2 and hydrocarbons. As the gas travels through the instrument and is exposed to the infrared light source, light energy absorption occurs which is subsequently detected in comparison with a reference gas. Different gases are characterized by differing absorption characteristics, and are thereby identified and quantified.

NDUV detectors are used primarily to monitor SO_2 and NO_2. These instruments use light in the ultraviolet and visible portions of the spectrum. They are similar to NDIR monitors except that they do not use a reference gas for comparison. Instead, they use a reference wavelength with minimal absorption capabilities. NDUV analysis, also known as differential absorption, is also utilized in *in-situ* and remote sensing systems.

Luminescence Analyzers

Luminescence analyzers measure the emission of light from an excited molecule. Dependent on the mode of molecule excitement, molecules can exhibit photoluminescence (fluorescence), chemiluminescence or flame luminescence. Fluorescence occurs when a molecule is excited by light energy of a given wavelength, and light energy of a second wavelength is emitted. Fluorescence analyzers are utilized for SO_2 analysis.

Chemiluminescence analyzers are used for NO_x and NO_2 determinations, and operate on the principle of the emission of light energy resulting from a chemical reaction. In the case of chemiluminescence analyzers, the reaction involves ozone (O_3) and nitric oxide (NO).

Flame photometric analyzers use the principle of luminescence through molecule/flame interaction. These analyzers detect sulfur compounds, and are specific to sulfur alone.

Electroanalytical Monitors

Four distinct types of electroanalytical monitors are used in continuous source monitoring. These instruments rely on the methods of polarography, electrocatalysis, amperometric analysis, and conductivity.

Polarographic analyzers, also known as voltametric analyzers or electrochemical transducers, are capable of detecting SO_2, NO_2, CO, O_2, H_2S and other gases dependent on instrument setup. The analytical basis is a self-contained electrochemical cell in which a chemical reaction takes place involving the pollutant molecule. As a result of the chemical reaction, a current change through a specific electrode indicates pollutant concentration.

Electrocatalytic analyzers are utilized for O_2 determinations. These analyzers use a solid catalytic electrolyte and are available in both extractive and *in-situ* models.

Amperometric analyzers, also called coulometric analyzers, measure the current in an electrochemical reaction. They are susceptible to various interferents; however, they are useful for SO_2, H_2S, and mercaptan analyses.

Conductimetric analyzers for SO_2 determinations measure the change in the electrical conductivity in water after a soluble substance is dissolved in it. This is a non-specific method, therefore interfering gases must be removed prior to introduction to the monitor.

Extractive Analyzers—Other Methods

There are a few special methods that do not fit into the three general classifications of absorption spectrometers, luminescence analyzers or electroanalytical methods. Paramagnetism is used in some O_2 analyzers, and thermal conductivity is used in some SO_2 continuous monitors.

Paramagnetic analyzers rely on the fact that O_2 molecules are attracted by a magnetic field, and this attraction can be quantified. However, it should be noted that NO and NO_2 are also paramagnetic, and in high enough concentrations can interfere in the analysis.

Thermal conductivity analyzers utilize a heated wire which undergoes resistance changes as gases flow over it. CO_2, SO_2 and other gases may be continuously monitored by thermal conductivity.

Please refer to Table 2 for list of some extractive instrument manufacturers.

IN-SITU ANALYZERS

Unlike an extractive monitor, an *in-situ* monitoring system will directly measure gas concentrations in the stack without

modifying the flue gas composition. This can even be accomplished in the presence of particulate matter. Three techniques, differential absorption, gas filter correlation and second derivative spectroscopy, eliminate the problems associated with a reduction in light transmission due to the presence of particulates.

Two types of *in-situ* monitors exist: cross-stack and in stack. Cross-stack monitors, which can either be single-pass or double-pass systems (like transmissometers), measure the gas concentration across the entire, or a majority, of the stack diameter. In-stack systems (or short-path monitors) have a shorter path length of 5 centimeters to a meter.

In-Situ *Cross-Stack Analyzers*

Cross-stack analyzers use either the principle of differential absorption spectroscopy or gas-filter correlation spectroscopy. Differential absorption analyzers utilize a technique similar to that used by NDUV extractive analyzers; however, they operate *in-situ* and eliminate the particulate matter interference. CO_2, SO_2, and NO can be monitored in this manner.

Gas-filter correlation spectroscopy, used for CO, CO_2, SO_2, and NO analysis, is an NDIR *in-situ* method which, like the differential absorption technique, eliminates particulate interference.

In-Situ *In-Stack Analyzers*

In-stack analyzers utilize second-derivative spectroscopy to measure NH_3, SO_2, and NO concentrations. They are also known as in-stack point, or short-path monitors. Ultraviolet light is transmitted through the probe and the sensing area, to a reflector and back.

Please refer to Table 3 for a list of some of the manufacturers of the various *in-situ* instruments available.

AMBIENT INSTRUMENTATION

Ambient monitoring requires the use of instrumentation ranging in sophistication from the standard high volume particulate sampler to electronic systems incorporating several different gaseous detectors and data loggers all maintained in a temperature and humidity controlled remote sampling station. The reasons for performance of an ambient monitoring program are presented below:

1. Collection of background air quality data for preparation of air permits.
2. Verification of the reduction of specific air quality impacts resulting from emission control programs.
3. Verification of groundlevel downwind concentrations as determined by computer modeling.
4. To validate and refine models.

In each of the above cases, instrumentation is selected based on the requirements and the length of the program. Monitors are available for all parameters for which the National Ambient Air Quality Standards (NAAQS) have been set.

1. Suspended Particulates
2. Sulfur Dioxide
3. Oxides of Nitrogen (as NO_2)
4. Total Hydrocarbons (Non Methane)
5. Photochemical Oxidants
6. Carbon Monoxide

In each case, an EPA reference test method has been established and to monitor for any of the above, an instrument employing that approved reference method must be utilized. If a parameter is chosen and no reference method is available, then direct contact with the EPA or the governing regulatory body is highly recommended before proceeding with the monitoring program.

The identification of continuous Reference or Equivalent Methods for NAAQS parameters can be obtained by writing the Environmental Monitoring and Support Laboratory, Department E, US Environmental Protection Agency, Research Triangle Park, NC 27711.

In addition to the NAAQS parameters, selected meteorological data will also be required for the analysis and unless the proposed test site is near a National Climatic Recording Station, a meteorological recording station must also be established to collect at a minimum, wind speed and direction, humidity, and temperature. This can be accomplished through the use of a highly portable compact system or very sophisticated meteorological monitoring system employing such items as a 30 meter tower with monitors at different heights, daily weather balloon releases, etc.

Please refer to the “Product Line Profiles” included in this chapter for a brief description of the equipment provided by some of the equipment manufacturers.

PRODUCTION LINE PROFILES

Anderson Samplers, Inc. EPA Method 5 and ASME In-Stack Filter Method) stack sampler equipment is available. Full compliance, double pass opacity monitors are also available. A complete line of cascade impactors may be used for in-stack and ambient particle-sizing applications. Alarm systems are produced which detect faulty control equipment performance or broken bags in a baghouse. Anderson Samplers Inc., 4215-C Wendell Drive, Atlanta, GA 30336, 404-691-1910 or 800-241-6898.

BGI Inc. Samplers have been developed for airborne particulates, liquid droplet clouds, volatile gases and toxic materials. Cascade impactors are featured with four stages, 2 × 5 in. binderless glass fiber filters, wind vanes, suction pumps and still air adaptors. High volume air samplers are continuous or intermittent. Cascade centripeters accommodate flowrates of 30 l/min. Detector tubes have protective holders and continuous pumps. BGI Inc., 58 Guinan Street, Waltham, MA 02154, 617-891-8380.

Baird Corp. Instrumentation is available for measuring sodium concentrations in ambient air for gas turbine applications. Continuous Model LSM-30 ean detect and record ppm concentrations in gas turbine inlet air and fuel. Baird Corp., 125 Middlesex Turnpike, Bedford, MA 01730, 617-276-6131.

Beckman Instruments, Process Instrument Division Air quality monitoring instrumentaion includes a chemiluminescence O_3 analyzer, a fluorescence SO_2 analyzer, an infrared CO analyzer, and an NO_2 analyzer. These four instruments have received reference or equivalent method designation from the EPA. Each instrument is a totally self-contained system that offers precise interference-free measurement, convenient interface with peripherals, minimum expendables for ease of maintenance and choice of mounting options. Beckman Instruments PID, 2500 Harbor Blvd., Fullerton, CA 92634, 714-871-4848.

Bendix Corp. Chemiluminescent, chromatographic, infrared, and photometric apparatus may be specified for ambient and stack analysis of NO, NO_2, NO_x, CO, CO_2, SO_2, H_2S, TRS, THC, benzene, and other gases associated with the environmental and process industries. Bendix Environmental and Process Instrument Division, Box 831, Lewisburg, WV 24901, 304-647-4358.

Berkeley Controls Series 300 and 3300 semiportable continuous stack monitoring systems can be applied to source monitoring, ambient air monitoring, scrubber development, combustion studies, pollution research and OSHA standards. The cartridge sensor is an electrochemical membrane type polarographic gas detector. The 3300 series provides a complete integral sampling system consisting of filters, condensate removal and heat trace line controls. Berkeley Controls, 2825 Laguna Canyon Road, Laguna Beach, CA 92652, 714-494-9401 or 800-854-2436.

Byron Instruments Air quality instruments analyze hydrocarbons, organics, methane, carbon monoxide and carbon dioxide at source and ambient levels. The total emission analyzer oxidation/reduction system insures accurate readings. The analyzer gives part-per-million carbon readings on non-methane hydrocarbons from 10 ppmc full scale to 50,000 ppmc (5%) full scale. The instrument also provides readings on total hydrocarbons, methane, carbon monoxide, and carbon dioxide each analytical cycle. Byron Instruments Inc., 520-1/2 S. Harrington Street, Raleigh, NC 27601, 919-832-7501.

CEA Instruments Inc. The model 555 air monitor provides for the analysis of acrylonitrile, ammonia, bromine, chlorine, fluorine, formaldehyde, hydrazine, hydrogen chloride, hydrogen cyanide, hydrogen fluoride, hydrogen sulfide, nitrogen dioxide, oxides of nitrogen sulfur dioxide, and total oxidants. The RI 550 single channel IR analyzer provides for the analysis of CO, CO_2, methane, ethylene, ethane, propane, and butane or total hydrocarbons in the 0–2 up to 0–100% range, CEA Instruments Inc., 15 Charles Street, Westwood, NJ 07675, 201-664-2300.

Climatronics Corp. Equipment includes portable instruments and turn-key systems for meteorological testing. Units can be specified with sensors, data transmission and acquisition equipment, and upper air sounding systems. Climatronics Corp., 1324 Motor Parkway, Hauppauge, NY 11787, 516-234-2772.

Columbia Scientific Chemiluminescent laboratory and on-site automated apparatus measure NO, NO_2, NO_x, and ozone. Performance specifications are guaranteed over the range of +10 to +40°C. The equipment is capable of at least seven days of unattended operation for prolonged on-site monitoring. Columbia Scientific Inds., Box 9908, Austin, TX 78766, 412-258-5191 or 800-431-5003.

Contraves-Goerz Corp. Infrared electronic equipment can be selected for monitoring stationary source emissions. Total source control packages are offered for power generation and process industries. Portable and *in-situ* instruments are available. Contraves-Goerz Corp., 610 Epsilon Drive, Pittsburgh, PA 15238, 412-782-7700.

D and S Instruments Sampling cannisters are precleaned and prepared for part per trillion level sampling. Another product is a cryotrap suitable for EPA Method 25 sampling of volatile hydrocarbons. D and S Instruments Ltd., SE 1122 Latah Street, Pullman, WA 99163. 509-332-8577.

Daco Products Inc. Wet impingement samplers can be specified for gases, fumes, and vapors. Custom packages are available for sampling toxic substances. Colorimetric, electrochemical, photometric, and wet chemical analyzers are available. Daco Products Inc., 12 S. Mountain Avenue, Monclair, NJ 07042, 201-744-2453.

Datametrics Hot-wire anemometer-type air velocity and flow meters are used in conjunction with air sampling. The instrumentation is used to determine sample size. Other equipment analyzes air composition. Datametrics, 340 Fordham Road, Wilmington, MA 01887, 617-658-5410.

Datatest Inc. Instruments are designed for the continuous monitoring of particulate emissions. The instruments use photometric techniques and are *in-situ.* The emission is continuously recorded on a strip chart or circular recorder. Relay contacts are provided for controlling external equipment such as dampers and air flow valves. Datatest Inc., 1410 Elkins Avenue, Levittown, PA 19057, 215-943-0668.

Davis Instrument Manufacturing Co. Stack monitoring devices include optical probes for smoke density measurement and dust samplers for quantitative analysis of particulate emissions. Davis Instrument Manufacturing Company, Inc., 513 E. 36th Street, Baltimore, MD 21218, 301-243-4301.

Delta F. Corp. Factory calibrated oxygen analyzer is capable of monitoring oxygen in gas streams containing "acid" gases as well as combustibles. Trace and percent analyzers are available in panel mount configurations, battery operated models and remove sensor versions. Delta F Corp., One Walnut Hill Park, Woburn, 01801, 617-935-6536.

Digicolor Inc. Automatic and manual analyzers are available for the determination of ammonia, halogens, acidic sulfur, as well as most organic gases. Samplers may be specified as grab samplers, intermittent samplers, or continuous samplers. All have the option of filtration, or wet or dry impingement separation techniques. Metering is either rate or volume control. Digicolor Inc., 2770 E. Main Street, Columbus, OH 43209, 614-236-1213.

Dionex Corp. The ion chromatograph is used in a variety of air quality applications. Among these are ambient aerosols and SO_2 levels, carbon dioxide analysis, ammonia, sulfur species, halogens and nitrogen oxides in auto exhausts and other sources. Flue gas desulfurization analysis is also done by ion chromatograph. Toxicology applications include sulfate and oxalate ions in industrial environments, chloroacetyl chloride and formaldehyde at trace levels, and ambient levels of SO_2. The ion chromatograph is also extensively used in acid rain analysis. Dionex Corp., 1228 Titan Way, Sunnyvale, CA 94086, 408-737-0700.

Dupont Company Source monitoring equipment may be specified for the determination of SO_2, NO_x, H_2S, and ammonia as well as halogens and aromatics. All equipment features photometric detectors and has the ability to measure multiple sources. Dupont Company, Scientific and Process Instrument Division, Concord Plaza, Wilmington, DE 19898, 302-772-5500.

Dynasciences Continuous electrochemical apparatus may be used for EPA compliance monitoring for inspection and testing. Instrumentation monitors oxides of nitrogen, sulfur, and oxygen. Turn-key installations, as well as engineering assistance and field support are offered. Dynasciences Env. Products Division, Township Line Road, Blue Bell, PA 19422, 215-643-0250.

Dynatron Inc. Air pollution monitoring systems include a complete line of *in-situ* stack gas measurement and analysis equipment. Opacity monitoring systems offer digital displays, automatic EPA calibration, and direct optical density readout. Dynatron Inc., Box 745, Wallingford, CT 06492, 203-265-7121.

Edwards Engineering Hydrocarbon vapor analyzer is used for the continuous check of operation and emission percentage from hydrocarbon vapor recovery units. It is designed to mount directly within the vapor recovery control room. It features automatic replenishing of charcoal absorption chambers and a constant meter indicator with a strip chart recorder. Edwards Engineering Corp., 101 Alexander Avenue, Pompton Plains, NJ 07444, 201-835-2808.

Energetics Science Instruments are available for measurement of toxic gas, combustible gas/oxygen and oxygen deficiency in ambient air and in process control. Toxic gas capability includes the measurement of carbon monoxide, hydrogen sulfide, nitric oxide, nitrogen dioxide, hydrazine, and sulfur dioxide. The combustible gas detector is a catalytic filament type and the oxygen sensor uses a polarographic sensor. Energetics Science Inc., 85 Executive Blvd., Elmsford, NY 10523, 914-572-3010.

Enmet Corp. Monitors are offered for detecting dangerous levels of toxic or combustible bases. Monitors can be specified with meters as well as integral lights and audible alarms, with external signal capabilities, actuated when gas concentrations exceed safe levels. Portable O_2 deficiency detectors are available, featuring push-button checks for alarms and batteries. Automatic CO respiratory air line monitors may be specified for detection of concentrations as low as 10 ppm. Enmet Corp., 2308 S. Industrial Highway, Ann Aror, MI 48104, 313-761-1270.

Environmental Measurements Ambient air sampling systems are designed to collect and store pollutant and tracer gases in sampling bags for their subsequent analysis. Also available are heavy and regular duty Tedlar air sampling bags. These sampling bags are available in sizes from 0.5 to 300 liters. An automatic sequential or radon bag sampler designed for unattended gas collection may be programmed by the user to collect up to 8, 12, 16, or 24 hourly samples over a 96-hour period. This self-contained battery operated system is operated in real time and is designed for use in harsh environments. Environmental Measurements, 215 Leidesdorff Street, San Francisco, CA 94111, 408-734-0713.

GCA Environmental A fibrous aerosol monitor provides a real-time count of airborne fibers in the presence of large concentrations of nonfibrous particles. A respirable dust monitor tells how much respirable dust is in the air being breathed. A recording dust monitor is designed for short and extended time monitoring of respirable dust. GCA/Environmental Instruments, Burlington Road, Bedford, MA 01730, 617-275-9000.

Gastech Inc. Portable and fixed detectors and alarms measure combustible and toxic gases, oxygen deficiency, hydrocarbons, and airborne halogens. Calibration kits are also available for a variety of gases. Gastech, Inc., Johnson Instrument Div., 331 Fairchild Drive, Mountain View, CA 94043, 415-967-6794.

General Metal Works High-volume filtration samples feature continuous flow controllers and recorders, weatherproof housings, and stainless steel inlet tubing materials. Integrated packages can be ordered which comply with federal and state monitoring regulations. Related equipment which can be specified includes timers, flowmeters, impactors, and calibration units. General Metal Works Inc., 8368 Bridgetown Road, Cleves, OH 45002, 513-941-2229.

General Monitors Single-channel system for continuous monitoring of combustible gas concentrations consists of a remote sensing assembly and a solid state controller. Control electronics include an analog meter scaled from 0–100% LEL and four vertically arranged LEDs. The LEDs indicate high and low alarm status, normal operation and any malfunction conditions. A digital display from 0–99% LEL is one of many user-selected options available. Relay options include a choice of normally energized or de-energized high and low alarms, latching or non-latching high and low alarms, or sealed relays. General Monitors Inc., 3019 Enterprise Street, Costa Mesa, CA 92626, 714-540-4895.

Horiba Instruments Instruments and integrated single or multi-gas monitoring systems are for stack gas and ambient air applications. Sampling and continuous equipment is available. Instruments include NDIR gas analyzers free of interference from water vapor and carbon dioxide, and flame ionization analyzers for measuring total hydrocarbons. Systems are custom designed and may include remote computerized operation and automatic calibration. Horiba Instruments Inc., 1021 Duryea Avenue, Irvine, CA 92714, 714-540-7874.

Interscan Corporation Toxic gas monitors available from pocket alarm units and dosimeters to complete plant-scale multipoint systems. The line includes analyzers for CO, SO_2, H_2S, $NO/NO_2/NO_x$, and Cl_2. Additionally, systems which may use products manufactured by others, specified by the customer, are available. Examples of this are multi-gas and source monitoring systems. Interscan Corp., 9614 Cozycroft Avenue, Chatsworth, CA 91311, 213-882-2331.

Kurz Instruments Constant flow air samplers are produced for low volume air sampling, for sampling of organics or particulates. Flow ranges are available from 30 sccm to 150 slpm. They are mass flow controlled and referenced to EPA standards of 25°C and 760 mmHG. Vacuum capability as high as 20″ Hg and control accuracy of ±3% reading over a wide temperature range are standard. Higher sampling requirements are handled by the high volume air samplers, which sample from 20–60 scfm. Kurz Instruments Co., Box 849, Carmel Valley, CA 93924, 408-659-3421.

Lamotte Chemical Portable air quality sampling and measurement outfit provides individual tests for 14 major contaminants. Tests are provided for ammonia, bromine, cadmium, carbon monoxide, chlorine, cyanide, hydrogen peroxide, hydrogen sulfide, iodine, lead, nitrogen dioxide, ozone, phenols, and sulfur dioxide. The outfit features a portable air sampling pump with calibrated flowmeter. The absorbing solutions, which are contained in the impinger, collect the air to be tested. Driven by 4 standard "D" cell batteries, the pump will sample up to 2.5 liters per minute at 6 volts and is capable of maintaining flow rate for 48 hours of continuous sampling. An adjustable flow-meter regulates and indicates the air sampling rate. The sampling pump is furnished with flow-meter, impinger holder, batteries, and connection tubing. Lamotte Chemical Products Co., Box 329, Chestertown, MD 21620, 301-778-3100.

Mast Development Company Portable and online instruments measure ambient and work place TLV levels of ozone, chlorine, fluorine, bromine, and iodine. Appropriate calibration devices are also available, including automatic bubble meter for the determination of low air flow in devices using miniature pumps. Mast Development Co., 2212 E. 12th Street, Davenport, IA 52803, 319-326-0141.

Met One Equipment, systems, technical, and engineering assistance provided for complete meterological environmental monitoring, measuring, and control. Systems provide statistics on wind direction and velocity, ambient air temperatures, relative humidity, precipitation and solar radiation. Portable and permanent systems available. Met One, Box 60279, Sunnyvale, CA 94088, 408-733-9100.

Mine Safety Appliances Analyzers and sampling systems are supplied for the measurement of contaminants such as SO_2, NO_2, CO, CO_2, hydrocarbons, and oxygen. Applications include monitoring power plant stacks, metallurgical processes, combustion control, and solvent recovery beds. Mine Safety Appliance Company, 600 Penn Center Boulevard, Pittsburgh, PA 15235, 412-273-5101.

Monitor Labs Ambient air analyzers, calibrators, data loggers, telemetry systems, and computer-based monitoring networks are offered for ozone, sulfur dioxide, total sulfur, and oxides of nitrogen. Calibration sources for nitrogen dioxide and sulfur dioxide are supplied with certificates of traceability to NBS. Data loggers accept up to 20 parameters. Monitor Labs Inc., 10180 Scripps Ranch Boulevard, San Diego, CA 92131, 714-578-5060.

Napp Inc. Model 31 manual stack sampling system is lightweight, modular equipment designed for compliance testing and performance evaluation of industrial stack emissions. The molecular design allows selection of equipment for sampling all EPA Methods (1–17) except 7, 9, 14, and 16. A standard Method 7 system is also offered. Method 16 is constructed for individual applications. Napp. Inc., 8825 N. Lamar, Austin, TX 78753, 512-836-5110.

National Draeger Portable personnel monitors are used for the determinations of TLV levels of over 140 different gases and vapors. Grab sampling is available. National Draeger Inc., 401 Parkway View Drive, Pittsburgh, PA 15205, 412-787-1131.

Nutech Corp. Assay, chromatographic and wet chemical equipment may be used in the determinations of most organic gases, as well as oxides of nitrogen and solid and liquid particulates. Grab samplers can be specified for aerosols, gases or particulates. Nutech Corp., 2806 Cheek Road, Durham, NC 27704, 919-682-0402.

Pollution Measurement Corp. Non-absorbent sample bags of Tedler, Teflon or Mylar are available in eight sizes from 0.4 to 70 liter. Gas sample spheres are available in sizes from 0.5 to 14.5 liter with vacuums of 22 inches of mercury. Special packages are available for meeting EPA and OSHA requirements. Pollution Measurement Corp., Box 6182, Chicago, IL 60680, 312-383-7794.

Rader Company High-volume samplers measure solid particulates emitted from stacks and other stationary sources. Equipment is for manual or automatic operation, and can be specified with a variety of accessories. Rader Company Inc., Box 20128, Portland, OR 97220, 503-255-5330.

Research Appliance Company RAC designs, manufactures and supplies diversified lines of precision environmental instruments and laboratory apparatus. The product mix includes instruments and systems that sample/monitor ambient air and process emissions, laboratory and testing apparatus, certified reagents for wet chemical gas sampling/analyzing, meteorological indicating/recording instruments and a broad range of related accessories. Research Appliance Company, Moose Lodge Road, Cambridge, MD 21613, 301-228-9505.

Sierra Instruments Instruments are available for particulate sampling and size fractionating in ambient air quality monitoring, stack sampling, OSHA applications, and aerosol research. Instruments include dichotomous samplers, cascade impactors, cyclone samplers, flow-controlled high volume air samplers, flow-controlled low volume air samplers, hi-vol size selective inlets, and cotton-dust samplers. Sierra Instruments Inc., Box 909, Carmel Valley, CA 93924, 408-659-3177.

Sierra Misco Inc. Grab, intermittent, and continuous samplers are available for the sampling of aerosols, particulates and gases. Glass, stainless steel, and Teflon inlet tubing are also available. Samplers are AC or battery operated. Separation collection techniques include filtration, charcoal, and wet and dry impinging. Sierra Misco Inc., 1825 Eastshore Highway, Berkeley, CA 94710, 415-843-1282.

Teledyne Analytical Equipment is suitable for continuous interference free monitoring of such pollutants as H_2S, SO_2 and hydrocarbons. Analyzers are designed for permanent location and continuous operation with minimal maintenance. Teledyne Analytical, Box 70, San Gabriel. CA 91776, 213-576-1633. www.teledyne-api.com

Thermo Electron Air pollution monitoring instrumentation can be specified for NO_x and SO_2 in ambient air, stack gases, and automotive emissions. The chemiluminescence principle is used for NO_x, while SO_2 is determined by pulsed fluorescence. All instrumentation meets or exceeds federal and state performance requirements. Thermo Electron Corp., Environmental Instruments, 27 Forge Parkway, Franklin, MA 02038, USA Tel +1 (508) 520 0430, Toll free +1 (866) 282 0430.

Varian Associates Gas chromatographs are offered for research as well as monitoring applications, and may be specified with special options for total hydrocarbon, vinyl chloride, and ppb sulfur gas analyses. Atomic absorption devices, with optical microsamplers, are also available and are especially useful for measuring trace levels of metal pollutants. Varian Associates, Instruments Group, 611 Hansen Way, Palo Alto, CA 94303, 415-493-4000.

VICI Metronics H_2S detection system is based upon card mounted, sensitized pads that visibly change color when exposed to H_2S. Applications range from odor surveys and area wide transport studies to worker dosage monitoring and work area testing. VICI Metronics, 2991 Corvin Drive, Santa Clara, CA 95051, 408-737-0550.

Wedding & Associates Critical Flow Device A high volume sampler and volumetric flow controller is offered which meets federal standards of volumetric flow rate at ambient conditions. Size specific inlets such as PM_{10} systems employing fractionating devices whose performance depends on air velocity may experience substantial variations in sampler performance values if operated using mass flow controllers. Also, the value for total sampled volume of air used in the denominator when calculating ambient concentration levels will bear little resemblance to the actual volume sampled if the ambient sample does not utilize a volumetric flow controller.[9]

R. M. Young Company The portable recording wind set provides continuous analog chart records of wind speed and wind direction side by side on a single 6″ wide chart. The windvane and 3 cup anemometer are generally used where analog records of wind speed and wind direction are required. A wind run anemometer can be substituted where a record of total wind passage is desired. The propvane provides signal characteristics in the range of 0–10 mph. R. M. Young Company, 2801 AeroPark Drive, Traverse City, MI 49684, 916-946-3980.

For additional monitoring and testing sources, including those outside the US, the reader is referred to the environmental expert home page.[10]

AIR POLLUTION METEOROLOGY

EFFECTS OF WEATHER ON POLLUTION

Introduction

As the world's population and industrialization grow, air pollution (Figure 1) becomes a progressively more serious problem. The control of air pollution requires the involvement of scientists from many disciplines: physics, chemistry and mechanical engineering, meteorology, economics, and politics. The amount of control necessary depends on the results of medical and biological studies.

The state of the atmosphere affects, first, many types of pollution. For example, on a cold day, more fuel is used for space heating. Also, solar radiation, which is affected by cloudiness, has an influence as smog production. Second, atmospheric conditions determine the behavior of pollutants after they leave the source or sources until they reach receptors, such as people, animals, or plants. The question to be answered is: given the meteorological conditions, and the characteristics of the source or sources, what will be the concentration of the pollutants at any distance from the sources? The inverse question also is important for some applications: given a region of polluted air, where does the pollution originate?

Finally, the effect of the pollution on the receptor may depend on atmospheric conditions. For example, on a humid day, sulfur dioxide is more corrosive than on a dry day.

Meteorological information is needed in three general areas of air pollution control:

(1) In planning control measures, wind climatology is required. Pollution usually must be reduced to a point where the air quality is substantially better than the existing quality. In order to assure improved quality, certain standards are set which prescribe maximum concentrations of certain pollutants.

In order to reach such standards, the points of origin of the pollution must first be located; traditionally, everybody blames everybody else for the unsatisfactory air quality. Given possible pollution sources, tracing of air trajectories coupled with estimates of atmospheric dispersion will give the required answers. Once the relative importance of different pollution sources is known, strategies have to be developed to determine the degree to which each source must reduce its effluent.

FIGURE 1 Air pollution in New York City prior to SO_2 and particulate restriction.

The most economical way to cut concentration of some pollutant may not be to cut the effluent of each emitter by the same amount. In order to find the best strategy, city models must be constructed, separately for each pollutant and for different meteorological conditions, which show how the air pollution climate of an urban region is affected by the existing distribution of sources, and what change would be produced when certain sources are controlled. The construction of such models will be discussed later, and requires a fairly sophisticated handling of meteorological data. The same models then also help in planning future growth of housing and industry.

Of course, not all problems of air pollution meteorology are as complex as those involving urban areas. The planning of individual plants, for example, must be based in part on the air pollution to be expected from the plant under various atmospheric conditions; meteorological calculations may show whether expensive techniques for cleaning the effluent before leaving the stack may be required.

(2) Meteorological forecasts can be used to vary the effluent from day to day, or even within a 24 hour period. This is because at different times the atmosphere is able to disperse contaminants much better than at other times; purer fuels must be used, and operation of certain industries must be stopped completely in certain areas when the

mixing ability of the atmosphere is particularly bad.

(3) Meteorological factors have to be taken into account when evaluating air pollution control measures. For example, the air quality in a region many improve over a number of years—not as a result of abatement measures, but because of gradual changes in the weather characteristics. If the effects of the meteorological changes are not evaluated, efforts at abatement will be relaxed, with the result of unsupportable conditions when the weather patterns change again.

Effects Between Source and Receptor

The way in which the atmospheric characteristics affect the concentration of air pollutants after they leave the source can be divided conveniently into three parts:

(1) The effect on the "effective" emission height.
(2) The effect on transport of the pollutants.
(3) The effect on the dispersion of the pollutants.

Rise of Effluent

To begin with the problem of effluent rise, inversion layers limit the height and cause the effluent to spread out horizontally; in unstable air, the effluent theoretically keeps on rising indefinitely—in practice, until a stable layer is reached. Also, wind reduces smoke rise.

There exist at least 40 formulae which relate the rise of the meteorological and nonmeteorological variables. Most are determined by fitting equations to smoke rise measurements. Because many such formulae are based only on limited ranges of the variables, they are not generally valid. Also, most of the formulae contain dimensional constants suggesting that not all relevant variables have been included properly.

For a concise summary of the most commonly used equations, the reader is referred to a paper by Briggs (1969). In this summary, Briggs also describes a series of smoke rise formulae based on dimensional analysis. These have the advantage of a more physical foundation than the purely empirical formulae, and appear to fit a wide range of observed smoke plumes. For example, in neutrally stable air, the theory predicts that the rise should be proportional to horizontal distance to the 2/3 power which is in good agreement with observations. The use of dimensionally correct formulae has increased significantly since 1970.

Given the height of effluent rise above a stack, an "effective" source is assumed for calculation of transport and dispersion. This effective source is taken to be slightly upwind of a point straight above the stack, by an amount of the excess rise calculated. If the efflux velocity is small, the excess rise may actually be negative at certain wind velocities (downwash).

Transport of Pollutants

Pollutants travel with the wind. Hourly wind observations at the ground are available at many places, particularly airports. Unfortunately, such weather stations are normally several hundred kilometers apart, and good wind data are lacking in between. Further, wind information above 10 meters height is even less plentiful, and pollutants travel with winds at higher levels.

Because only the large-scale features of the wind patterns are known, air pollution meteorologists have spent considerable effort in studying the wind patterns between weather stations. The branch of meteorology dealing with this scale—the scale of several km to 100 km—is known as mesometeorology. The wind patterns on this scale can be quite complex, and are strongly influenced by surface characteristics. Thus, for instance, hills, mountains, lakes, large rivers, and cities cause characteristic wind patterns, both in the vertical and horizontal. Many vary in time, for example, from day to night. One of the important problems for the air pollution meteorologist is to infer the local wind pattern on the mesoscale from ordinary airport observations. Such influences are aided by theories of sea breezes, mountain-valley flow, etc.

In many areas, local wind studies have been made. A particularly useful tool is the tetroon, a tetrahedral balloon which drifts horizontally and is followed by radar. In some important cities such as New York and Chicago, the local wind features are well-known. In general, however, the wind patterns on the mesoscale are understood qualitatively, but not completely quantitatively. Much mesoscale numerical modeling is in progress or has been completed.

Atmospheric Dispersion

Dispersion of a contaminant in the atmosphere essentially depends on two factors: on the mean wind speed, and on the characteristics of atmospheric "turbulence." To see the effect of wind speed, consider a stack which emits one puff per second. If the wind speed is 10 m/sec, the puffs will be 10 m apart; if it is 5 m/sec, the distance is 5 m. Hence, the greater the wind speed, the smaller the concentration.

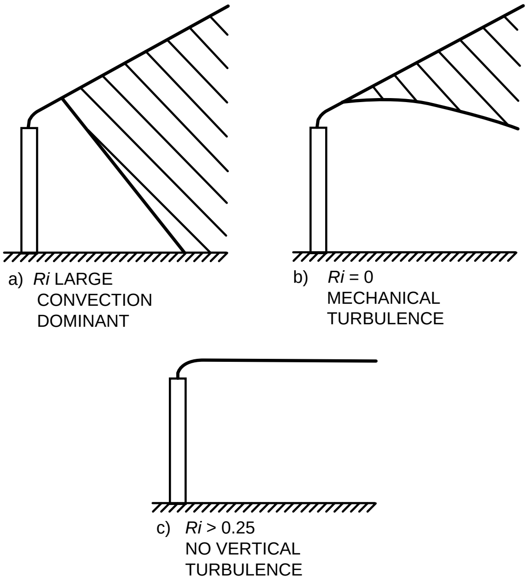
Atmospheric "turbulence" consists of horizontal and vertical eddies which are able to mix the contaminated air with clean air surrounding it; hence, turbulence decreases the concentration of contaminants in the plume, and increases the concentration outside. The stronger the turbulence, the more the pollutants are dispersed.

There are two mechanisms by which "eddies" are formed in the atmosphere: heating from below and wind shear. Heating produces convection. Convection occurs whenever the temperature decreases rapidly with height—that is, whenever the lapse rate exceeds 1°C/100 m. It often penetrates into regions where the lapse rate is less. In general, convection occurs from the ground up to about a thousand meters elevation on clear days and in cumulus-type clouds.

The other type of turbulence, mechanical turbulence, occurs when the wind changes with height. Because there is no wind at ground level, and there usually is some wind above the ground, mechanical turbulence just above the ground is common. This type of turbulence increases with increasing wind speed (at a given height) and is greater over rough terrain than over smooth terrain. The terrain roughness is usually characterized by a "roughness length" z_0 which varies from about 0.1 cm over smooth sand to a few meters over cities. This quantity does not measure the actual height of the roughness elements; rather it is proportional to the size of the eddies that can exist among the roughness elements. Thus, if the roughness elements are close together, z_0 is relatively small.

The relative importance of heat convection and mechanical turbulence is often characterized by the Richardson number, *Ri.* Actually, –*Ri* is a measure of the relative rate of production of convective and mechanical energy. For example, negative Richardson numbers of large magnitude indicate that convection predominates; in this situation, the winds are weak, and there is strong vertical motion. Smoke leaving a source spreads rapidly, both vertically and laterally (Figure 2). As the mechanical turbulence increases, the Richardson number approaches zero, and the angular dispersion decreases. Finally, as the Richardson number becomes positive, the stratification becomes stable and damps the mechanical turbulence. For Richardson numbers above 0.25 (strong inversions, weak winds), vertical mixing effectively disappears, and only weak horizontal eddies remain.

Because the Richardson number plays such an important role in the theory of atmospheric turbulence and dispersion, Table 1 gives a qualitative summary of the implication of Richardson numbers of various magnitudes.



a) *Ri* LARGE CONVECTION DOMINANT

b) *Ri* = 0 MECHANICAL TURBULENCE

c) *Ri* > 0.25 NO VERTICAL TURBULENCE

FIGURE 2 Average vertical spread of effluent from an elevated source under different meteorological conditions (schematic).

It has been possible to describe the effect of roughness length, wind speed, and Richardson number on many of the statistical characteristics of the eddies near the ground quantitatively. In particular, the standard deviation of the vertical wind direction is given by an equation of the form:

$$\sigma_\theta = \frac{f(Ri)}{ln\ z/z_0 - \psi(Ri)}. \tag{1}$$

Here z is height and $f(Ri)$ and $\psi(Ri)$ are known functions of the Richardson number which increase as the Richardson number decreases. The standard deviation of vertical wind direction plays an important role in air pollution, because it determines the initial angular spread of a plume in the vertical. If it is large, the pollution spreads rapidly in the vertical. It turns out that under such conditions, the contaminant also spreads rapidly sideways, so that the central concentrations decrease rapidly downstream. If σ_θ is small, there is negligible spreading.

Equation 1 states that the standard deviation of vertical wind direction does not explicitly depend on the wind speed, but at a given height, depends only on terrain roughness and Richardson number. Over rough terrain, vertical spreading is faster than over smooth terrain. The variation with Richardson number given in Eq. (1) gives the variation of spreading with the type of turbulence as indicated in Table 1: greatest vertical spreading with negative *Ri* with large numerical values, less spreading in mechanical turbulence ($Ri = 0$), and negligible spreading on stable temperature stratification with little wind change in the vertical.

An equation similar to Eq. (1) governs the standard deviation of horizontal wind direction. Generally, this is somewhat larger than σ_θ. For light-wind, stable conditions, we do not know how to estimate σ_θ. Large σ_θ are often observed, particularly for $Ri > 0.25$. These cause volume meanders, and are due to gravity waves or other large-sclae phenomena, which are not related to the usual predictors.

In summary, then, dispersion of a plume from a continuous elevated source in all directions increases with increasing roughness, and with increasing convection relative to mechanical turbulence. It would then be particularly strong on a clear day, with a large lapse rate and a weak wind, particularly weak in an inversion, and intermediate in mechanical turbulence (strong wind).

TABLE 1

Turbulence characteristics with various Richardson numbers

$0.24 < Ri$	No vertical mixing
$0 < Ri < 0.25$	Mechanical turbulence, weakened by stratification
$Ri = 0$	Mechanical turbulence only
$-0.03 \leq Ri < 0$	Mechanical turbulence and convection but mixing mostly due to the former
$Ri < -0.04$	Convective mixing dominates mechanical mixing

Estimating Concentration of Contaminants

Given a source of contaminant and meteorological conditions, what is the concentration some distance away? Originally, this problem was attacked generally by attempting to solve the diffusion equation:

$$\frac{d\chi}{dt} = \frac{\partial}{\partial x} K_x \frac{\partial \chi}{\partial x} + \frac{\partial}{\partial y} K_y \frac{\partial \chi}{\partial y} + \frac{\partial}{\partial z} K_z \frac{\partial \chi}{\partial z}. \tag{2}$$

Here, χ is the concentration per unit volume; *x, y,* and *z* are Cartesian coordinates, and the *K*'s are diffusion coefficients, not necessarily equal to each other.

If molecular motions produced the dispersion, the *K*'s would be essentially constant. In the atmosphere, where the mixing is produced by eddies (molecular mixing is small enough to be neglected), the *K*'s vary in many ways. The diffusion coefficients essentially measure the product of eddy size and eddy velocity. Eddy size increases with height; so does *K.* Eddy velocity varies with lapse rate, roughness length, and wind speed; so does *K.* Worst of all, the eddies relevant to dispersion probably vary with plume width and depth, and therefore with distance from the source. Due to these complications, solutions of Eq. (2) have not been very successful with atmospheric problems except in some special cases such as continuous line sources at the ground at right angles to the wind.

The more successful methods have been largely empirical: one assumes that the character of the geometrical distribution of the effluent is known, and postulates that effluent is conserved during the diffusion process (this can be modified if there is decay or fall-out), or vertical spread above cities.

The usual assumption is that the distribution of effluent from a continuous source has a normal (Gaussian) distribution relative to the center line both in the vertical direction, *z* (measured from the ground) and the direction perpendicular to the wind, *y.* The rationalization for this assumption is that the distributions of observed contaminants are also nearly normal.[†] Subject to the condition of continuity, the concentration is given by (including reflection at the ground).

$$\chi = \frac{Q}{2\pi V \sigma_y \sigma_z}\left(\exp - \frac{y^2}{2\sigma y^2}\right) \times \left(\exp - \frac{(z-H)^2}{2\sigma_z^2} + \exp \frac{-(z+H)^2}{2\sigma_z^2}\right). \tag{3}$$

Here, *H* is the "effective" height of the source, given by stack height plus additional rise, σ is the standard deviation of the distribution of concentration in the *y* and *z*-direction, respectively, and *V* is the wind speed, assumed constant. *Q* is the amount of contaminant emitted per unit time.

The various techniques currently in use differ in the way σ_y and σ_z are determined. Clearly, these quantities change with downwind distance *x* (Figure 3) as well as with roughness and Richardson number.

Quantitative estimation of the Richardson number requires quite sophisticated instrumentation; approximately, the Richardson number can be estimated by the wind speed, the time of the day and year, and the cloudiness. Thus, for example, on a clear night with little wind, the Richardson number would be large and positive, and σ's in Eq. (3) are small; on the other hand, with strong winds, the Richardson numbers are near zero, and the dispersion rate as indicated by the σ would be intermediate.

For many years, standard deviations were obtained by Sutton's technique, which is based on a very arbitrary selection for the mathematical form of Lagrangian correlation functions. More popular at present is the Pasquill–Gifford method in which σ_y and σ_z as function of *x* are determined by empirical graphs (Figure 4). Note that the dependence of the standard deviations on *x* varies with the "stability category" (from A to F). These categories are essentially Richardson number categories, judged more or less subjectively. Thus, A (large dispersion) means little wind and strong convection; D is used in strong winds, hence strong mechanical turbulence and less dispersion; F applies at night in weak winds.

One drawback of the Pasquill–Gifford method is that it does not allow for the effect of terrain roughness; the empirical curves were actually based on experiments over smooth terrain, and therefore underestimate the dispersion over cities and other rough regions. Some users of the method suggest allowing for this by using a different system of categories over rough terrain than originally recommended.

This difficulty can be avoided if fluctuations of wind direction and vertical motion are measured. Taylor's diffusion theorem at right angles to the mean wind can be written approximately,

$$\sigma_y = \sigma_0 \times F\left(\frac{t}{T_L}\right). \tag{4}$$

Here *F* is a function which is 1 for small diffusion time, *t.* For larger *t, F* decreases slowly; its behavior is fairly well known. T_L is a Lagrangian time scale which is also well known.

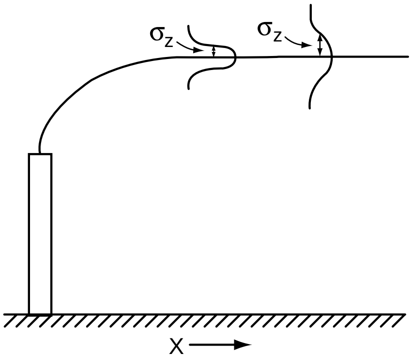


FIGURE 3 Change of vertical effluent distribution downstream.

[†] Note added in proof: It now appears that this assumption is not satisfactory for vertical dispersion, especially if the source is near the surface.

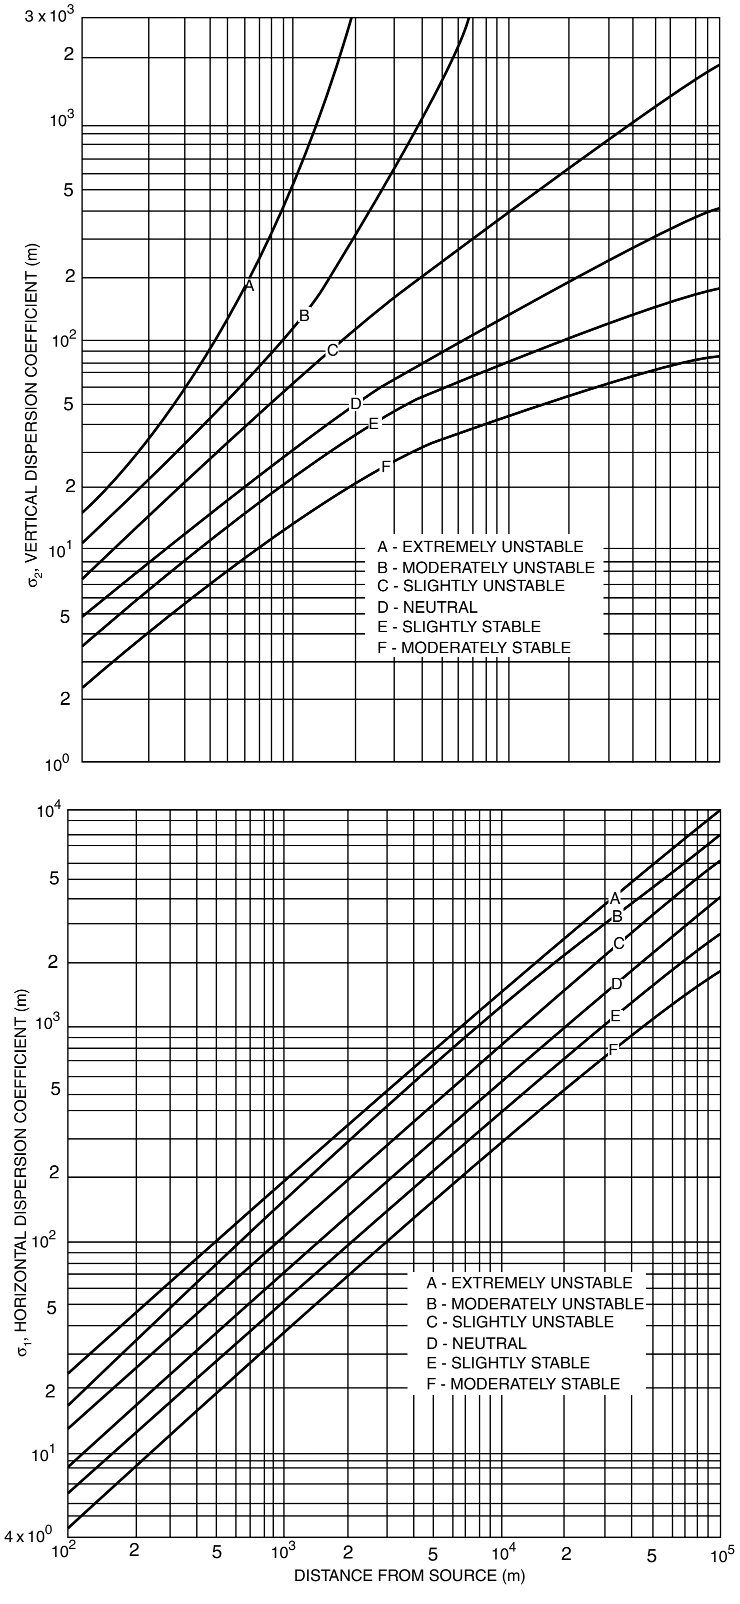

FIGURE 4 Pasquill–Gifford scheme for estimating vertical and lateral plume width as function of downwind distance and meteorological conditions.

An equation similar to (4) also exists for vertical spreading; however, it is theoretically less valid, since turbulence is not homogeneous in the vertical.

As the plume expands vertically, the vertical distribution cannot remain normal indefinitely. At the bottom, the plume is limited by the ground. At the top, the plume will be limited by an elevated inversion layer. Eventually, the vertical distribution becomes uniform. In that case, the concentration is given by the equation:

$$x = \frac{Q}{\sqrt{2\pi}VD\sigma_y}\exp - \frac{y^2}{2\sigma_y^2} \tag{5}$$

where *D* is the height of the inversion layer, which is also the thickness of the "mixed layer." Note that the concentration is inversely proportional to *VD,* the "ventilation factor," which is the product of *D,* and *V,* the average wind in the mixed layer.

The lateral spread is often limited by topography. In a valley of width *W,* the factor $(\exp - y^2/2\sigma_y^2)/(\sqrt{2\pi}\sigma_y)$ in Eqs. (3) and (5) is replaced by 1/*W,* after the contaminant concentration fills the valley uniformly in the *y*-direction (the direction perpendicular to the valley). The effect of this change is that relatively large concentrations are maintained at large distances from the sources.

Although the Pasquill–Gifford graphs are still popular in practical applications, evaluation in diffusion experiments have suggested serious deficiencies. Thus, the research community is groping for alternate methods. In particular, vertical distributions are far from Gaussian, particularly for ground sources. Significant progress has been made only for the important case of light-wind, sunny conditions. Then, the basic predictors are the thickness of the planetary boundary layer (PBL), z_i; another important predictor is a vertical-velocity parameter, $w*$ which is proportional to $(z_i H)^{1/3}$ where *H* is the vertical heat flux at the surface. *H* is not usually measured, but must be estimated independently; fortunately, it is raised to the 1/3 power. Lateral dispersion is still Gaussian, but with σ_y given by

$$\sigma_y/z_i = f(tw*/z_i) = f(X) \qquad \text{where } X = tw*/z_i$$

f is presumably universal and fairly well known.

The vertical distribution is definitely not Gaussian; for example, the center line of the plume rises for ground sources. More important, the center line comes down toward the surface for elevated sources, unless the sources are buoyant.

If vertical diffusion is normalized by the new variables, it depends on z/z_i, *X* and h/z_i where *h* is stack height. The distributions have been measured for different h/z_i, and complicated formulas exist to fit the observations. The results are believed to be quite reliable, because numerical models, laboratory experiments and full-scale observations are all in satisfactory agreement.

The results of this research should be used in practical applications, but have not been. For more detail, see Panofsky and Dutton, 1984.

City Models

These different methods give the pollutant concentrations downwind from a single source. In order to obtain the total picture of air pollution from a city, the concentrations resulting from all sources must be added together, separately for all different wind directions, different meteorological conditions, and for each contaminant. Such a procedure is expensive, even if carried out with an electronic computer, and even if, as is usually done, all small sources in square-mile areas are combined. Therefore, complete city models of air pollutant concentrations have only been constructed for very few locations. It is necessary, however, to have city models in order to understand the distribution of contaminants; only then it is possible to determine the most economical strategy to reduce the pollution, and to evaluate the effects of expansion of housing and industry.

Because the construction of a complete city model is so expensive, city models are often simplified. For example, if the city is represented by a series of parallel line sources, the computations are greatly reduced. Many other simplifications have been introduced; for a summary of many city models now in existence, see Stern (1968).

Diurnal Variation of Air Pollution

Equation (5) which shows that concentrations at considerable distances from individual sources are inversely proportional to the ventilation factor (*VD*), can be used to explain some of the variations in air pollution caused by meteorological factors. First, we shall consider the diurnal variation of air pollution. Of course, the actual variation of pollution may be different if the source strength varies systematically with time of day. The diurnal variation is different in cities and in the country. Consider typical vertical temperature distributions as seen in Figure 5. During the day, both over cities and country, the ground temperature is high, giving a deep mixed layer. After sunset, the air temperature near the surface in the country falls, producing an inversion reaching down to the ground. After air moves from the country out over the relatively warmer and rougher city, a thin mixed layer is formed near the ground. The thickness of this mixed

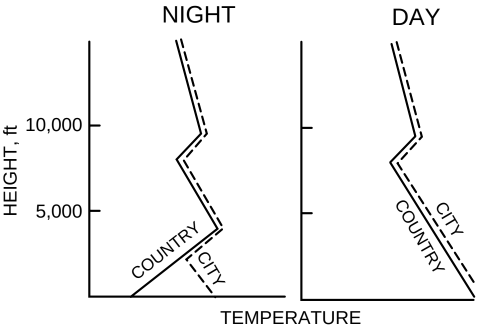

FIGURE 5 Vertical temperature distribution (schematic) over city and country, day and night.

layer varies with the size of the city, and depends on how long the air has moved over the city. In New York, for example, the mixed layer is typically 300 m thick; in Johnstown, Pa., an industrial valley city with just under 100,000 population, it is only a little over 100 m.

Figure 6 indicates how the temperature changes shown in Figure 5 influence the diurnal variation of pollution due to an elevated source in the country; at night, vertical mixing is negligible and the air near the ground is clean. Some time shortly after sunrise, the mixed layer extends to just above the source, and the elevated polluted layer is mixed with the ground air, leading to strong pollution (also referred to as "fumigation"), which may extend many kilometers away from the source. Later in the morning and early afternoon, the heating continues and thickens the mixed layer. Also, the wind speed typically increases, and the pollution decreases.

In the city, many sources usually exist in the thin nighttime mixed layer. Since this layer is so thin, and the wind usually weak, dense pollution occurs at night. Right after sunrise, the pollution at first increases somewhat, as the effluent from large, elevated sources is brought to the ground. As the mixed layer grows, the concentrations diminish, and, in the early afternoon, they are often less than the nighttime concentrations (see Figure 7).

Thus, the main difference between air pollution climates in the city and country is that country air near industrial sources is usually clean at night, whereas the city air is dirtier at night than in the middle of the day. These differences are most pronounced during clear nights and days, and can be obliterated by diurnal variations of source strengths. Figure 7 shows the characteristic behavior only because the sources of pollution at Johnstown, Pa., are fairly constant throughout.

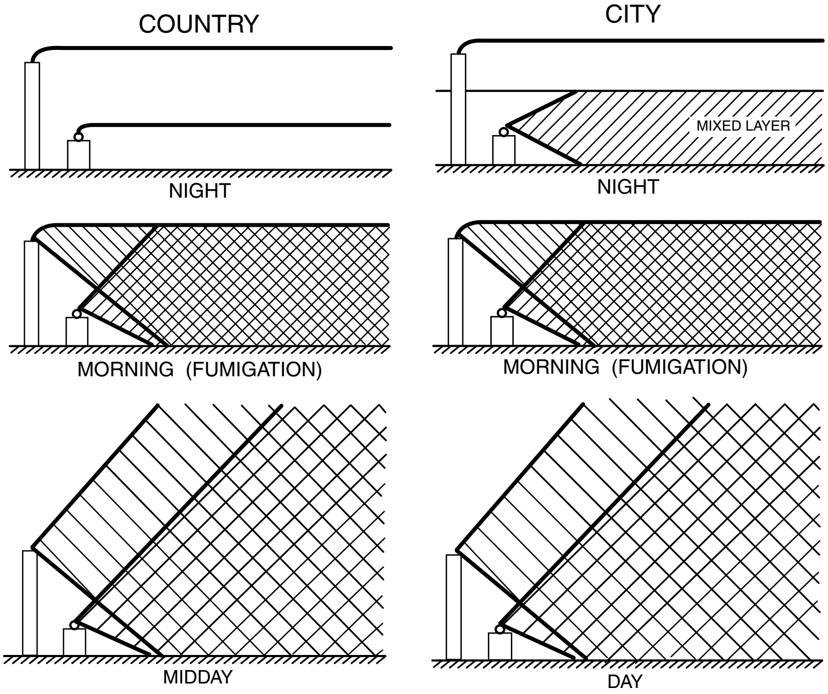

FIGURE 6 Concentrations of effluent (schematic) as function of time of day, over city and country.

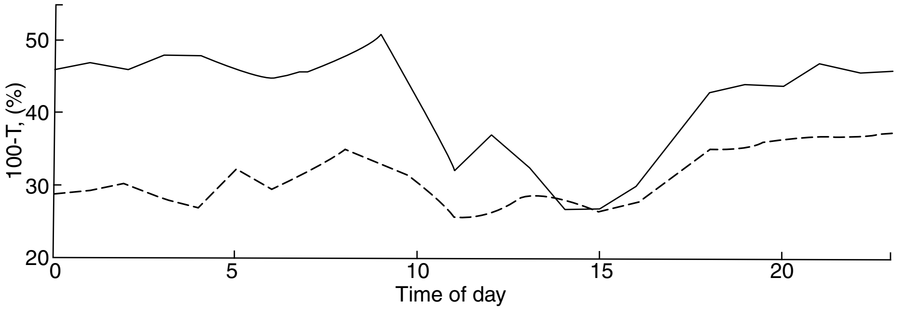

FIGURE 7 Concentrations of air pollution (100-T%), as function of time of day, on clear day (solid line) and cloudy day (dashed line), at Johnstown, Pa.

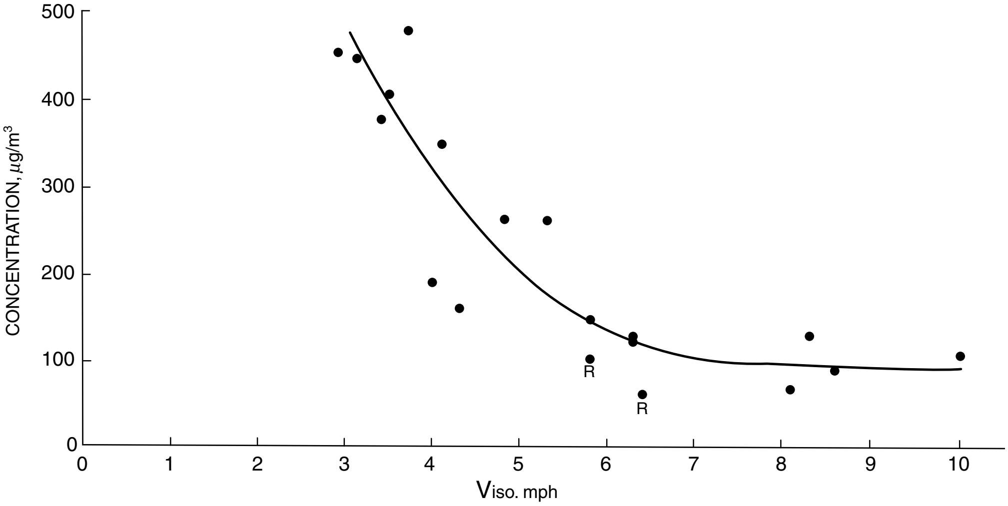

FIGURE 8 Dependence of 24-hour average particle concentrations at Johnstown on wind speed at 150 ft. R denotes rain.

Day-to-day Variations in Air Pollution

Equation (5) shows that, other things being equal, the concentration of contaminants is inversely proportional to the wind speed. Figure 8 shows this effect on 24-hr total particulate concentration at Johnstown, for cases where the source strengths were roughly the same, during the fall of 1964.

Conditions of particularly bad air pollution over wide areas and for extended periods are accompanied not only by light winds and calms, but also by unusually small mixing depths (*D*) so that the ventilation factor is usually small. Such conditions occur within large high-pressure areas (anticyclones). In such areas, air is sinking. Sinking air is warmed by compression. Thus, in an anticyclone (high-pressure area), an elevated warm layer forms, below which there is room only for a relatively thin mixed layer (Figure 9). The inversion on top of the mixed layer prevents upward spreading of the pollution, and when mountains or hills prevent sideways spreading the worst possible conditions prevail. A particularly bad situation arose in the industrial valley town of Donora, Pa., in which many people were killed by air pollution in 1948.

Cities in California, like Los Angeles, are under the influence of a large-scale anticyclone throughout the summer, and an elevated inversion at a few hundred meters height occurs there every day; that is why Los Angeles had air pollution problems as soon as pollutants were put into the atmosphere to any large extent. In the United States outside the West Coast, stagnant anticyclones occur only a few times per year, usually in the fall.

So far, relatively little use has been made in the USA of forecast changes in air pollution potential from day to day. As air pollution problems become more severe, more use will be made of such forecasts. Already, this type of information has proved itself in air pollution management in some European countries.

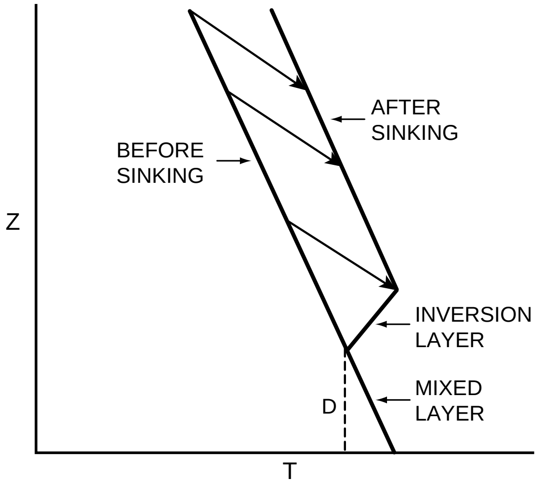

FIGURE 9 Effect of sinking on vertical temperature distribution (schematic).

Not much has been said about the influence of wind direction on air pollution. When pollution is mainly due to many, relatively small sources, as it is New York, the pollution is surprisingly insensitive to changes in wind direction. Even in Johnstown, Pa., wind direction is unimportant except for the case of easterly winds, when a single, huge steel plant adds significantly to the contaminant concentration.

In contrast, wind direction plays a major role when most of the pollution in a given area is due to a single or a few major plants or if an industrial city is nearby. Also, there are special situations, in which wind direction is particularly important; for example, in Chicago, which has no pollution sources east of the city, east winds bring clean air.

The main difference between the effects of lapse rate, mixing depth, and wind speed on the one hand, and wind direction on the other, is that the wind direction has different effects at various sites, depending on the location of the sources; the other factors have similar effects generally.

EFFECT OF AIR POLLUTION ON LOCAL AND REGIONAL WEATHER

Visibility

The most obvious effect of air pollution is to reduce visibility. This effect has been studied frequently by comparing visibility in different parts of a city, or the visibility in a city with visibility in the country. For a summary of many such investigations, see Peterson, 1969.

To give some examples: Around London and Manchester, afternoon visibility less than 6¼ miles occurs on more than 200 days; in Cornwall in SW England, the number is less than 100. In central London, there are 940 hours a year with visibilities less than ⅝ mile; in SE England, only 494.

In many cities, visibilities have recently improved probably due to control of particle emissions; however, as mentioned before, some of this change may be due to changes in large-scale weather patterns.

Although decreased visibility is usually associated with industrial or automobile pollution, considerable attention has been paid recently to decreased visibilities due to the "contamination" of the atmosphere by water droplets by industry. This problem arises because many processes generate excess heat; if this is added to streams and lakes, undesirable effects ensue; hence, progressively more and more heat is used to evaporate water which is then emitted into the atmosphere, and later condenses to form water plumes.

There are many unpublished studies estimating the effect of cooling towers on visibility. This varies greatly with meteorological conditions, but is particularly serious in winter, then the air is nearly saturated and little additional vapor is required to produce liquid drops. Under those conditions, water plumes from industries produce clouds and fog which may reach over a hundred miles from the sources. Automobile accidents have been blamed on such fogs, particularly when the particles freeze and make roads slippery, adding to the visibility hazard.

Sunshine Intensity

"Turbidity" is an indicator of the reduction of light due to haze, smoke and other particles. Turbidity is now being monitored at many places in the world. It is quite clear that it is larger over cities than over the country; it has been suggested that the average decrease of sunshine over cities is 15 to 20% due to pollution. The effect is even larger if only ultraviolet light is considered.

Control of smoke emission in cities such as London has caused a very noticeable increase of sunshine intensity: for example the hours of "Bright sunshine" increased by 50% after control measures had become effective. Again, for a summary of some of these studies, the reader is referred to Peterson, 1969.

Precipitation Amount

There have now been several studies suggesting that precipitation is increased downstream of industrial centers. The investigations are of a statistical nature, and it is not known whether the effects are due to increased convection (increased heat), increased condensation nuclei or increased water vapor. Further, the reliability of the statistics has been questioned.

For example, Changnon (1969) found a large precipitation anomaly at La Porte (Indiana) just downwind of large industrial complexes of Northwestern Indiana. But change in observational techniques of rainfall and other uncertainties have thrown doubt on the results. Hobbs *et al.* (1970) have compared rainfall distribution in Western Washington before and after the construction of industries and found an increase by 30% or so; but some of this increase may have been due to "normal" climatic change. For a summary of these and other studies see Robinson (1970). It becomes quite clear from this summary that more, careful investigations of this type are needed before effects of air pollution on precipitation patterns can be definitely proven.

A large study (Metromex) found strong enhancement of precipitation downwind of St Louis. But this may be due to the St Louis heat sources rather than to pollution.

Acid Rain

There is no question that acid rain is produced by atmospheric pollution. The acidity of rainfall is large only when the wind direction suggests industrial or urban sources. Most important is sulphuric acid, produced by power plants or smelters, the effluent from which contains SO_2. Also important is nitric acid, which is formed mostly from nitrogen oxides in car exhausts. Acid rain has done important damage to lakes and forests; but there is controversy how to deal with the problem. For example, the relation between acidity and SO_2 may be nonlinear, so that substantial reduction of SO_2 may not effect acid rain significantly.

GLOBAL EFFECTS OF AIR POLLUTION

Natural Climatic Changes

We will assess the effect of some atmospheric pollutants as to their ability to change the earth's climate. In doing so, we are hampered by the fact that the present climate is produced by a multitude of interacting factors; if one factor is changed, others will too, and a complex chain reaction will ensue. These reactions can be studied by complex mathematical models of the atmosphere, which so far have been quite successful in describing the existing climate. But, as yet these models contain assumptions which make it impossible at this time to assess accurately the effects of changes in some of the factors affecting climate. Until such models are improved, then, we cannot really estimate quantitatively climatic changes produced by pollutants.

The concentration of CO_2 is about 340 parts per million (ppm). According to observations at Mauna Loa in Hawaii, over the last forty years or so, it has increased at the rate of 0.7% per year. This is less than half the amount put into the atmosphere by industry. The other half goes into the ocean or into vegetation; but it is not known how much goes into each. Further, we do not know whether the same fraction can disappear out of the atmosphere in the future—e.g., the amount going into the ocean is sensitive to temperature, and the amount going into vegetation may be limited by other factors. However, a reasonable guess is that the fraction of CO_2 in the atmosphere will double in the middle of the 21st century.

The basic effect of CO_2 on climate is due to the fact that it transmits short-wave radiation from the sun, but stops a part of the infrared radiation emitted by the earth. Hence, the more CO_2, the greater the surface temperature. This is known as the greenhouse effect. Also, since CO_2 increases the radiation into space, the high atmosphere is cooled by increasing CO_2.

The heating rate at the ground expected with a doubling of CO_2 has been calculated by many radiation specialists. The answers differ, depending on how many other variables (such as cloud cover) are allowed to change as the CO_2 changes. The best current estimates are that doubling CO_2 would increase the surface temperature about 2°C, and decrease the temperature aloft a little more. But these estimates do not treat changes of cloud cover and oceanic effects realistically, and these estimates may yet be corrected. Still, if we expect only a 20% change in CO_2 by the end of the century, the climatic change due to this factor should be small. However, a serious problem could arise in the next century, particularly because it is difficult to see how a trend in CO_2 concentration can be reversed. It is therefore of great importance to continue monitoring CO_2 concentration accurately.

As of 1987, it appears likely that increases of concentration of other trace gases (e.g. fluorocarbons) may, in combination, have as strong a warming effect at the surface as CO_2. So far, no significant warming has been detected.

Ozone

Ozone (O_3) is an important part of photochemical smog; originating mostly from the effect of sunlight on automobile exhaust. The concentration is critically dependent on chemical reactions as well as on diffusion. Chemistry is beyond the scope of this paper as O_3 and ozone pollution near the ground will not be discussed further.

More important, 90% of the ozone exists in the stratosphere (above about 11 km). Its concentration even there is small (usually less than 10 ppm). If all ozone were to be brought to the surface of the ground, its thickness would average about 0.3 cm.

Most of the ozone occurs at high latitudes, and there is a spring maximum. The great importance of stratospheric ozone is due to its ability to absorb ultraviolet (UV) light, particularly in the UVB region (290–320 μm) where human skin is extremely sensitive. Thus, decreased ozone would increase skin cancer.

We now realize that small fractions (10^{-9}) of certain gases can destroy ozone by catalytic reactions. The most important are oxides of nitrogen and chlorine. Nitrogen oxides could originate for example, from supersonic transports. However calculations show that, unless the number of SSTs is increased significantly, this problem is not serious.

More important is the problem of chlorofluoromethanes (CFM) the use of which has been rapidly increasing. They are used in sprays, foams and refrigeration, CFMs are so stable that most of them are still in the atmosphere. Eventually, however, CFMs will seep into the stratosphere (about 1%/year). In the high stratosphere, UV will dissociate CFMs producing chlorine, which destroys ozone.

A slow decrease of ozone in the stratosphere has indeed been indicated by recent satellite observations. For total ozone, the results are much more controversial. Chemical–meterological models show only a very small decrease so far, too small to isolate from the "noisy" observations. However, the accuracy of the models can be questioned, particularly since new relevant reactions have been discovered every few years, so that model results have varied.

Of special interest has been the recognition of an "ozone hole," centered at the South Pole, and lasting a month or so in the Southern Spring. Total column ozone falls to about half its normal value. The phasing out of chlorofluorocarbons, or CFCs began in 1989 with the implementation of the Montreal Protocol.

Editors Notes: Scientists at NASA and various U.S. universities have been studying satellite data taken over the past 2 decades. They found the rate of ozone depletion in the upper stratosphere is slowing partially as a result of a reduction in the use of CFCs (see Newchurch, et al., 2005).

In the troposphere, aerosol formation from the combustion of fossil fuels and biomass is a precursor to the formation of brown clouds, which are intricately linked to climate changes (Ramanathan and Ramana, 2003). Ozone, a component of smog, also forms in the troposphere, when NO_x combines with volatile organic compounds in the presence of sunlight. There is growing scientific evidence that the intercontinental transport (ICT) of aerosols and ozone influences surface air quality over downwind continents (Fiore, *et al.*, 2003). For example during the dust storm events in Asia in April of 2001, the ground level aerosol concentrations in the western U.S. and Canada increased by as much as 40 μg/m^3 resulting from the ICT of aerosols. Fiore, *et al.* found there are global dimensions to the aerosol and ozone problems.

It has also been suggested that ozone changes can produce climate changes, but these appear rather unimportant at present, except that they may worsen slightly the CO_2 greenhouse effect.

Summary

In summary, increasing air pollution can modify the climate in many ways. There is no evidence that any significant change has occurred so far; but eventually, large effects are likely.

AIR POLLUTION MODELING—URBAN: see URBAN AIR POLLUTION MODELING

AIR POLLUTION SOURCES

Air pollution may be defined as the presence in the atmosphere of any substance (or combination of substances) that is detrimental to human health and welfare; offensive or objectionable to man, either externally or internally; or which by its presence will directly or indirectly adversely affect the welfare of man. ("Air Pollution," Homer W. Parker, 1977.) The substances present in the atmosphere which cause this detriment to health and welfare are the air pollutants.

A considerable quantity of air pollution occurs naturally as a consequence of such processes as soil erosion and volcanic eruptions. However, those pollutants which pose a threat to human health and cause extensive damage to property are primarily derived from activities associated with the development of community living, as well as with the growth of affluence and living standards in industrial societies. These activities include the burning of fuel for heat and power, the processing of materials for food and goods, and the disposal of wastes.

Much of the materials which pollute our atmosphere represent valuable resources which are being wasted. We have available today the technological means of controlling most sources of air pollution. The cost of control however has been estimated on the order of 10 to 20 percent of the world's gross national product. Moreover, full implementation of the control measures that would be necessary to achieve healthful air quality in many of our large centers of population would require significant changes in lifestyle in those areas.

POLLUTANT CLASSIFICATIONS

Air pollutants are numerous, each with its own peculiar characteristics. Therefore it is usual to have these pollutants classified by some design. Classification allows for the study of pollutants in subgroups on the basis of some characteristic of interest or concern and also provides an ordering which makes it easier to formulate air pollution control programs. Accordingly, the classification of air pollutants may be based on:

1. How the pollutants are borne into the atmosphere.
2. The physical state of the pollutant.
3. The molecular composition of the pollutants.
4. The nature of the problem or health threat associated with the pollutants.

Classification According to the Method of Entry into the Atmosphere

This classification contains two categories: (1) Primary and (2) secondary.

Primary Pollutants Primary air pollutants are emitted into the atmosphere directly from identifiable sources whether from mechanical or chemical reaction processes. Examples of such direct discharge from an identifiable source into the atmosphere include the complete and incomplete combustion of carbonaceous fuels from industrial processes and automobile engines yielding carbon monoxide and carbon dioxide.

Secondary Pollutants These pollutants are those which are formed as a result of some reaction in the atmosphere. This reaction may occur between any combination of air pollutants (including primary pollutants) and natural components of the atmosphere. Some of these reactions require the presence of sunlight and are called photo-chemical reactions. An example of such a reaction is the formation of ozone from the interaction of organic and nitrous compounds in the presence of sunlight.

Classification According to the Physical State of the Pollutant

According to their state of matter, pollutants may be classified as: (1) gaseous and (2) particulate.

Gaseous Pollutants Most air pollutants exhibit gaseous properties in that they tend to obey gas laws, for example, there is a predictable interrelationship between their pressure, volume and temperature. In many ways these pollutants behave like air itself and do not tend to settle out or condense over long periods.

However, they almost always undergo some form of chemical transformation while resident in the atmosphere. Approximately 90% of air pollutants are gaseous.

Particulate Pollutants Any pollutant that is not gaseous is defined as a particulate pollutant or particulate whether they exist in the form of finely divided solids or liquids. The larger particulates after having been introduced into the air tend to settle out quickly and affect lives and property near the source. The smaller and lighter particles travel further away, and eventually settle out great distances from the source. The very smallest particulates exhibit certain gaseous characteristics, remaining suspended in the atmosphere for long periods of time and are readily transported by wind currents.

Classification According to Chemical Composition

Pollutants may also be classified according to their chemical structure. The basic classifications are (1) organic and (2) inorganic.

Organic Pollutants Organic compounds may be defined as those which contain carbon, hydrogen, and may contain other elements. By this definition we exclude the very simple carbon monoxide and carbon dioxide. These contain carbon, but no hydrogen.

Inorganic Pollutants Inorganic pollutants may be defined as compounds which do not contain compounds of carbon, with the exception of carbon oxides, like CO and CO_2, and carbon disulfide. Many of the most commonly encountered pollutants are inorganic. You might be asking yourself why CO_2 is considered a pollutant. Isn't CO_2 beneficial in the maintenance of the earth's ecological system by providing a source of energy for manufacturing plants? The answer is yes, but the earth's ecosystem can utilize only so much carbon dioxide. The surplus of CO_2 in the atmosphere is believed to be one of the contributors to the "Greenhouse Effect." Excesses of this gas are believed to cause the global heating that is now being experienced. The long-term outlook for this phenomenon is the melting of the polar icecaps resulting in the oceans' levels rising and threatening population areas that are located at the coastline.

Classification According to the Nature of the Problem or Health Threat Posed by the Pollutant

Under the Clean Air Act, the Congress of the United States established a classification system which recognized two distinct categories of air pollutants: those air pollutants which because of their universal nature or ubiquity, presented a threat to public health and welfare (called criteria pollutants); and those pollutants, while not widespread, contribute to higher mortality rates in humans (called hazardous pollutants).

Criteria Pollutants These are air pollutants for which a national ambient air quality standard has been established. In the selection of these standards, certain criteria are established using observed levels of air pollution and the associated impacts on human health, vegetation and materials relating air quality level to health and welfare effects. Six specific

TABLE 1
Classification of Pollutants

Major Classes	Sub-classes	Typical Members of Sub-classes
Organic	Alkanes	Ethane
Gases	Alkenes	Ethylene
(Hydrocarbons)	Alkynes	Acetylene
	Alkyl Halides	Ethylenedichloride
	Aldehydes	Formaldehyde
	Ketones	Acetone
	Amines	Methyl Amine
	Alcohols	Ethanol
	Aromatics	Benzene
Inorganic	Photochemical Oxidants	Ozone
Gases	Oxides of Nitrogen	Nitrogen Dioxide, Nitric Oxide
	Oxides of Sulfur	Sulfur Dioxide, Sulfur Trioxide
	Oxides of Carbon	Carbon Monoxide, Carbon Dioxide
	Halides	Chlorine, Flourine
	Miscellaneous	Ammonia, Hydrogen Sulfides
Particulates	Solid Particulates	Dust, Smoke
	Liquid Particulates	Mist, Spray
		Heavy Metals

Other Pollutants Include:

—Radioactive Substances
—Pesticides
—Aeroallergens

pollutants (nitrogen dioxide, sulfur dioxide, hydrocarbons, carbon monoxide, particulate matter and ozone) were identified in 1971 as the most "universal" within the United States and the most significant pollutants contributing to the degradation of the lower atmosphere or troposphere. Once national air quality standards were established each state was given the responsibility to make sure that emissions from sources of air pollution in that state and neighboring states do not violate these air quality standards by developing and implementing creative plans for reducing source emissions. Recognizing that hydrocarbons in the atmosphere did not, as a class of pollutants, create a singular and internally consistent ambient air quality problem, the class term was dropped and lead was added as a new pollutant class.

Hazardous Pollutants These are air pollutants for which no air quality standard has been established but nevertheless cause or contribute to an increase in the mortality rate or serious irreversible or incapacitating illness. The hazardous pollutants listed by January 1988 are: asbestos, beryllium, mercury, vinyl chloride, radionuclides, coke oven emissions, benzene and inorganic arsenic.

In November of 1990, the U.S. Congress passed Clean Air Act amendments (CAAA) into law which greatly expand the list of regulated chemicals—Hazardous Air Pollutants (HAPs)– to about 190. The EPA's mandate is to promulgate standards for the control of HAP emissions from about 100 source categories, employing maximum achievable control technology (MACT). To date greater than 95% of MACT standards have been published.

SOURCE CLASSIFICATIONS

The management and control of air pollution is generally achieved through the regulation and control of air pollution sources. For convenience, sources of air pollutants may be classified according to the size or the nature of the pollutant activity and source type characteristics.

Classification According to Magnitude

For convenience of analysis, air pollution sources are divided into two classes (1) major sources and (2) minor sources.

Major sources are sources whose emissions quantities are large enough to cause them to have a dominant role in the pollution potential of an area. Prior to the 1990 CAAA, the U.S. Environmental Protection Agency classified all sources that emitted or had the potential for emitting 100 tons/year of any single pollutant as a major source.

Today, the definition has been revised and made more stringent. Depending upon an area's air quality, emissions of as little as 10 tons/year would constitute a major source.

Major sources are fixed (stationary) and commonly occupy a limited area relative to a community. They include:

1. Major industrial and manufacturing plants.
2. Steam—Electric power plants.
3. Industrial and Municipal Incinerators.
4. Facilities that use solvents (surface coating, degreasing, dry cleaning, plastics manufacture, rubber manufacture) and lose petroleum products by evaporation.
5. Facilities that lose petroleum product from storage and marketing (tank farms, service stations) operations.
6. Motor vehicles, aircraft, ships and railroads in which the combustion of fuels for transportation occurs.
7. Dumps, incinerators, etc. in which combustion of wastes occur.
8. Facilities or units in which the decomposition of organic wastes occur.
9. Sewage treatment plants.

Industrial plants constitute a highly varied and complex chemical system, each industry presenting a unique air pollution problem. The characteristics of the emissions produced are directly related to the peculiarities of the operation in question, that is, on the raw materials, the fuels, the process method, the efficiency of the chosen process, the method and the type of air pollution control measures applied.

Minor sources are those which cannot be cataloged practically on a source-by-source basis. They may be stationary or mobile and are commonly spread throughout the community. These sources are associated with:

1. Combustion of fuels in residences and commercial buildings and institutions for personal comfort and convenience.
2. Service industries such as laundries, dry-cleaning plants, repair services, etc.
3. Animal processing.
4. Handling and use of paints, lacquers and other surface coatings containing organic solvents.
5. Food processing in restaurants, grills, coffee roasting, etc.

Classification According to Nature of Emissions

The U.S. Environmental Protection Agency classifies sources depending on both the quantitative and qualitative nature of the emissions. The source categories are:

1. NSPS (New Source Performance Standard) sources. These are sources for which national emissions standards have been established. All sources built subsequent to the date of establishment of these emissions standards must meet NSPS requirements.
2. SIP (State Implementation Plan) sources. These are sources built prior to the establishment of the new source standards. These older SIP sources have no national emissions standards to follow per se, but rather their level of emissions is determined on a source-by-source basis and depend on the air quality of the area in which they are located. If the

air quality is particularly poor, stricter operating requirements are imposed.

3. NESHAP (National Emission Standards for Hazardous Air Pollutants) sources. These are sources which emit any of the nine hazardous pollutants which were discussed in the section on air pollutant classification. These sources also have operating standards imposed on the equipment.
4. Transportation sources. These are sources of air pollution which do not necessarily remain stationary but are mobile, and include cars, trucks, buses, airplanes, railroad locomotives and marine vessels. These sources' main emissions are carbon monoxide, carbon dioxide, nitrogen dioxide and lead and result from the internal combustion of fuel in their engines.

TABLE 2

Summary of National Emissions (thousand short tons, 1.1 million short tons equals 1 million metric tons)

Note(s):

* Fugitive dust emissions not estimated prior to 1985. They include miscellaneous-agriculture and forestry, miscellaneous-fugitive dust, and natural sources-wind erosion.

** NAPAP historical emissions.[3,4]

*** NA denotes not available.

**** Combination of revised transportation values and NAPAP historical emissions.

***** There is a change in methodology for determining on-road vehicle and non-road sources emissions (see chapter 6).

****** There is a change in methodology in all sources except on-road vehicles and non-road sources and all pollutants except lead, as reflected by the dotted line.

******* 1990 through 1994 estimates are preliminary. The emissions can be converted to metric tons by multiplying the values by 0.9072.

The NSPS, SIP and NESHAP sources are further classified depending on their actual and potential emissions.

Presuming that a certain area's major-source cutoff is 100 tons/year, for that area:

1. Class A sources are sources, which actually or potentially, can emit greater than 100 tons per year of effluent.
2. Class SM sources, can emit less than 100 tons per year of effluent, if and only if the source complies with federally enforceable regulations.
3. Class B sources are sources, which at full capacity, can emit less than 100 tons per year of effluent, products, and by-products.

Miscellaneous

The group is used to include such air environmental problems as aeroallergens, biological aerosols, odorous compounds, carbon dioxide, waste heat, radioactive emissions, and pesticides. In many cases they are not normally characterized as air pollutants.

The remainder of this chapter is divided into two parts.

Part 1 deals with emissions from three major classes of pollutants: hydrocarbons, inorganic gases and particulates. Typical pollutants in these major classes are described, along with their sources and the method of abatement or control.

Part 2 discusses the nature of the activity and the types of air pollutant problems associated with sources identified under standard categories of industries.

Part 1. Pollutant Emissions

Pollutant types	Sources and abundance	Abatement and control
A. HYDROCARBONS: Hydrocarbons are compounds containing the elements of carbon and hydrogen. The gaseous compounds of carbon found in nature and polluted atmospheres make up a broad spectrum of the compounds of organic chemistry. Carbon atoms bond readily to one another to form the stable carbon–carbon link. It is this link which forms the great number of organic molecules in existence (>1,000,000). By linking together in various ways, carbon atoms form a great assortment of chain and ring molecules (Aliphatics and Aromatics). The most significant hydrocarbons when considering air pollutants are known as volatile compounds (VOCs), that exist in the atmosphere primarily as gases because of their low vapor pressures. However, it is important to note that solid hydrocarbons can cause an environmental and health threat as well. For example, Benzo-(a)-pyrene, a well known carcinogen, exists in the air as a fine particulate. Hydrocarbons by themselves in air have relatively low toxicity. They are of concern because of their photochemical activity in the presence of sunlight and oxides of nitrogen (NO_x). They react to form photochemical oxidants. The primary pollutant is ozone, however, other organic pollutants like peroxyacetal nitrate (PAN) have been identified as the next highest component. Table 11 shows ozone levels generated in the photochemical oxidation of various hydrocarbons with oxides of nitrogen. The immediate health effects associated with ozone is irritation to the eyes and lungs. Long-term health effects include scarring of the lung tissue. The long-term welfare effects include damage to architectural surface coatings as well as damage to rubber products. Ozone can also damage plants and reduce crop yields.	More hydrocarbons (HC) are emitted from natural sources than from the activities of man. The one in greatest abundance is methane which has an average background concentration of 1.55 ppm. This is produced in the decomposition of dead material, mostly plant material. Methane is joined by a class of compounds of a more intricate molecular structure known as terpenes. These substances are emitted by plants, and are most visible as the tiny aerosol particulates or the "blue haze" found over most forested areas. Other hydrocarbons found in large concentrations in the ambient air besides methane (CH_4), are Ethane (C_2H_6), Propane (C_3H_8), acetylene (C_3H_4), butane and isopentane. Methane gas is one of the major greenhouse gases See Greenhouse Gases Effects, B.J. Mason. As can be inferred from Table 3, landfill emissions are the primary source of methane. About 15 percent of all atmospheric hydrocarbon is due to man's activity. However, the impact of man-made hydrocarbons to human health is out of proportion to their abundance since they are emitted in urban areas which have a high population concentration.	FROM MOBILE SOURCES: Emissions resulting from the evaporation of gasoline from fuel tanks and carburetors can be limited by storage of the vapors (within the engine itself or in a carbon canister which absorbs the fuel vapors) and then routs the vapors back to the tanks where they will be burned. Controls also exist in the refueling of automobiles and other mobile sources. These controls usually involve pressurized vacuum hoses and tighter seals at the filler pipe. FROM STATIONARY SOURCES: a) Design equipment to use or consume completely the processed material. b) In the surface coating industry, use a higher percent solids paint to reduce the amount of VOC. c) Use materials which have a higher boiling point or are less photochemically active. d) Use control equipment and recycling or organic solvents to reduce emissions. e) Control by adsorption, absorption and condensation.

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
1. *Oxygenated Hydrocarbons:* Like hydrocarbons, these compounds make up an almost infinite array of compounds which include alcohols, phenols, ethers, aldehydes, ketones, esters, peroxides, and organic acids, like carboxylic acids. Oxygenated hydrocarbons are very commonly used in the paint industry as solvents, and in the chemical industry as reactants for many chemical products and intermediates. Oxygenated hydrocarbons have a two-fold environmental problem. First, they are very reactive thus readily form photochemical oxidants in the presence of sunlight (light energy) and oxides of nitrogen; thus adding to the tropospheric ozone problem.	Small amounts of oxygenated hydrocarbons are emitted by industrial processes such as spray paint coating, chemical and plastics industry. The large majority of emissions of these chemicals are associated with the internal combustion engine. Table 6 shows some typical concentrations, (parts per million), of simple hydrocarbon fuels. The aldehydes are the predominant oxygenates (these compounds will be discussed in greater detail in the following section) in emissions, but are emitted in minor amounts when compared to aliphatics and aromatics, carbon dioxide, carbon monoxide, and nitrogen oxide emissions.	FROM MOBILE SOURCES: Emissions resulting from the evaporation of gasoline from fuel tanks and carburetors can be limited by storage of the vapors (within the engine itself or in a carbon canister which absorbs the fuel vapors) and then routs the vapors back to the tanks where they will be burned. Controls also exist in the refueling of automobiles and other sources. These controls usually involve pressurized vacuum hoses and tighter seals at the filler pipe.

TABLE 3

Summary of U.S. Methane Emissions by Source Category, 1990 to 1994 Preliminary Estimates (thousand short tons)

Source Category	1990	1991	1992	1993	1994
WASTE					
Landfills	10,900	11,100	10,900	11,000	11,200
Wastewater	200	200	200	200	200
AGRICULTURE					
Cattle	6,000	6,000	6,100	6,200	6,300
Other	300	300	300	300	300
Animal Waste					
Dairy	900	900	900	900	1,000
Beef	200	200	200	200	200
Swine	1,100	1,100	1,200	1,100	1,300
Poultry	300	300	300	300	200
Other	40	40	40	40	40
Agricultural Waste Burning	100	100	100	100	100
Rice Cultivation	500	500	500	500	600
Total Agriculture	9400	9,500	9,700	9,700	10,200
FUGITIVE FUEL EMISSIONS					
Coal Mining	4,900	4,700	4,500	4,000	4,400
Oil and Gas Systems	3,600	3,600	3,600	3,600	3,600
MOBILE SOURCE COMBUSTION	300	300	300	300	100
STATIONARY COMBUSTION	700	800	800	700	700
Total Emissions	29,900	30,100	30,000	29,500	30,600

Note(s): Totals presented in this table may not equal the sum of the individual source categories due to rounding.

1994 emission estimates are preliminary and will be updated in the next report.
Tier 1 source categories and emissions are shaded.

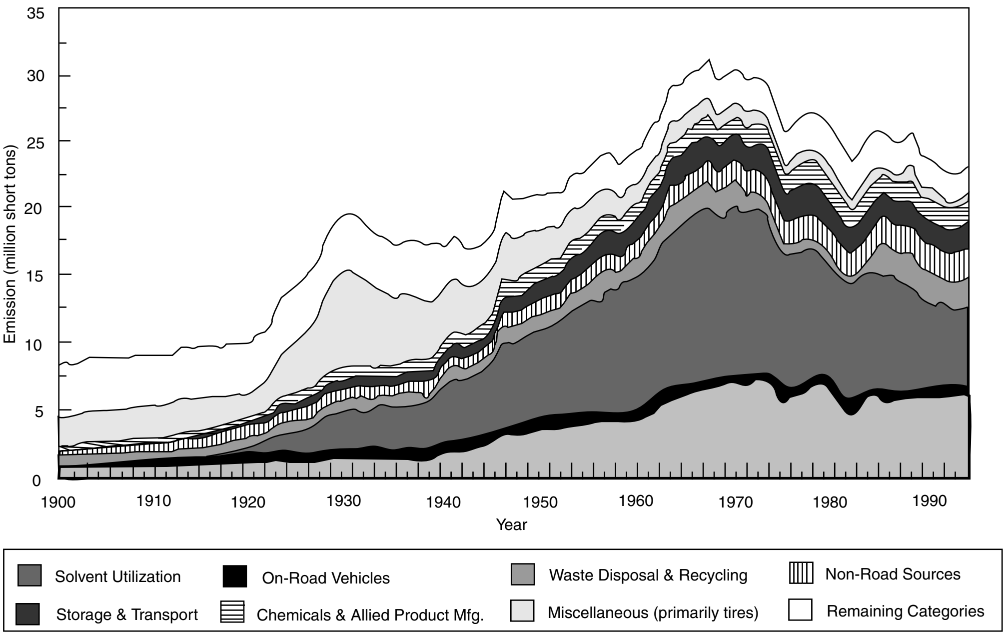

FIGURE 1 Trend in volatile organic compound emissions by seven principal source categories, 1990 to 1994.

TABLE 5
Oxygenates in Exhaust from Simple Hydrocarbon Fuel*

Oxygenate	Concentration range (ppm)
Acetaldyde	0.8–4.9
Acrolein	0.2–5.3
Benzaldehyde	<0.1–13.5
Tolualdehyde	0.1–2.6
Acetone (+ propionaldehyde)	2.3–14.0
Methyl ethyl ketone	0.1–1.0
Methyl vinyl ketone (+ benzene)	0.1–42.6
Acetophenone	<0.1–0.4
Methanol	0.1–0.6
Ethanol	<0.1–0.6
Benzofuran	<0.1–2.8
Methyl formate	<0.1–0.7
Nitromethane	<0.8–5.0

*Reference 3

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
Many of the oxygenated hydrocarbons are themselves toxic, many of them are known human carcinogens and some, especially esters, ketones, and alcohols are known to cause central nervous system disorders (narcosis, etc…)		FROM STATIONARY SOURCES: a) Design equipment to use or consume completely the processed material. b) In the surface coating industry, use a higher percent solids paint to reduce the amount of VOC.

(*continued*)

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
2. *Aldehydes*: Aldehydes are one of a group of organic compound with the general formula R-CHO which yield acids when oxidized and alcohols when reduced. They are products of incomplete combustion of hydrocarbons and other organic materials. Formaldehyde and Acrolein-Acetaldehyde cause irritation to the mucous membranes of the eyes, nose, and other portions of the upper respiratory tract. Formaldehyde has also been cited as a potential human carcinogen.	One of the most popular aldehydes used in the chemical process industry is formaldehyde. This is because of its relatively low cost, high purity, and variety of chemical reactions. Among its many uses are as an intermediate in the production of phenolic and amino resins and also in the production of slow release fertilizers. Annual worldwide production capacity now exceeds 12 × 10^6 metrics tons (calculated as 37% solution). In general, aldehydes are produced by the combustion of fuels in motor vehicles, space heating, power generation, and in other combustion activities (such as the incineration of wastes). In addition aldehydes are formed in photochemical reactions between nitrogen oxides and certain hydrocarbons. Natural sources of aldehydes do not appear to be important contributors to air pollution. Some aldehydes are found in fruits and plants.	c) Use materials which have a higher boiling point or are less photochemically active. d) Use control equipment and recycling of organic solvents to reduce emissions. e) Control by absorption, adsorption and condensation. Control methods include more effective combustion as may be obtained in direct flame and the use of catalytic afterburners.
3. *Ethylene:* Ethylene ($H_2C = CH_2$) is the largest volume organic chemical produced today. Ethylene is a colorless hydrocarbon gas of the olefin series, it is generally not toxic to humans or animals, but it is the only hydrocarbon that has adverse effects on vegetation at ambient concentrations of 1 ppm or less. It therefore represents a considerable air pollution problem, for two reasons: 1. it is significantly harmful to plants,	Ethylene may form as a by-product of incomplete combustion of hydrocarbons and other organic substances. Thus, ethylene has been found to be one of the components of automobile and diesel combustion emissions (exhaust and blow by emissions), incinerator effluents, and agricultural waste combustion gases. Ethylene is not normally found in deposits of petroleum or natural gas.	Ethylene poses no peculiar control problem in these emissions and this can be controlled by methods generally used for hydrocarbons. These methods include combustion techniques, absorption techniques, absorption methods, and vapor recovery systems.

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
2. it contributes to photochemically produced air pollution. Ethylene is the most abundant (based on mole volume) of the photoreactive hydrocarbons in the lower atmosphere.	In the chemical process industry, virtually all ethylene is consumed as feedstock for a variety of petrochemical products. Ethylene has been known to be used as a ripening agent for fruits and vegetables	
4. *Organic Carcinogens*: These are carbon compounds which cause cancer in experimental animals and are therefore suspected of playing a role in causing human cancer, particularly cancer of the lungs. There is some question as to the carcinogenicity of selected compounds. Polynuclear aromatic hydrocarbons (PAH) in our environment evolve from high-temperature reactions under pyrolytic conditions during incomplete combustion contained in some air pollution source effluents in automobile exhaust fumes, and in moderate concentrations in the air. The major classes of organic carcinogens are as follows: 1. Polynuclear aromatic hydrocarbons (PAH); Benzo-(a)-pyrene (BAP)-substance found in cigarette smoke. Benzo(e)pyrene Benzo(a)anthracene Benzo(e)acetophenthrylene Benzo(b)fluoranthene Chrysene 2. Polynuclear azo-heterocyclic compounds; Dibenz(a,h)acridine Dibenz(a,j)acrydine 3. Polynuclear imino-heterocyclic compounds 4. Polynuclear carbonyl compounds 7H-Benz(de)anthracene-7-one 5. Alkylation agents Aliphatic and alifinic epoxides Peroxide Bactones	The incomplete combustion of matter containing carbon. Heat generation (burning coal, oil and gas) accounts for more than 85%. Sources of heat generation that were tested ranged in size from residential heaters to heavy industrial power plant boilers. Municipal incinerators produce about 5% of emissions. Industrial processes also account for 5%. Organic carcinogens are primarily unwanted by-products of incomplete combustion. However, a few sources of organic carcinogens might be defined as naturally occurring. Bituminous coal contains certain organic carcinogens.	From Motor Vehicle Sources: (Same Controls as Hydrocarbons) From Stationary Sources: 1. Design equipment to use or consume completely the processed material. 2. Use of materials which have a higher boiling point or are less photochemically reactive. 3. Use of control equipment to reduce emissions. 4. Stop open burning of waste by use of multiple-chamber incinerators or disposing of waste in sanitary landfills.
5. *Halogenated Hydrocarbons*: Halogenated hydrocarbons are carbon and hydrogen compounds with one or more of the halide elements of fluorine, chlorine, bromine, or iodine. Of these elements, the most common halogenated hydrocarbons are those containing fluorine and chlorine. Halogenated hydrocarbons were once thought to solve the ozone problem because of their low reactivity. However, many of these compounds are very toxic and thus cause a more immediate threat to human health. Also, there is a great concern of damage caused by these compounds to the stratospheric ozone layer which protects us from the harmful ultraviolet radiation of the sun. These compounds tend to degrade into their elemental components, which include radical alogen, which have a great affinity for ozone.	Halogenated hydrocarbon solvent vapors include those of chloroform ($CHCl_3$), carbon tetrachloride (CCl_4), trichloroethylene (C_2HCl_3), perchloroethylene (C_2Cl_4), etc. From vapors ($CFCl_3$, C_3FCl_3) are very widely used as refrigerants and were once used as propellants. Except for the vicinity of major urban areas, atmospheric halogen concentrations are very low.	The same controls apply for halogenated hydrocarbons as for non-halogenated hydrocarbons. These are adsorption, absorption, etc. However, combustion may be undesirable since free halogen radical combining with water vapor may cause an acid problem. This may damage equipment as well as create a serious environmental problem.
6. *Pesticides*: Pesticides are economic poisons used to control or destroy pests that cause economic losses or adverse human health effects. These chemicals can be grouped as insecticides, herbicides (weed and brush killers, defoliants, and desiccants), fungicides, iscaricides, nematocides, repellants, attractants, and plant growth regulators. In the United States, 300–400 pesticides are registered for use in the production of food. These chemicals	The primary source of pesticides in air is from the application process; a certain amount of drift is unavoidable, even under normal conditions. Pesticides can evaporate into the air from soil, water and treated surfaces. Pesticides contained in dust from the soil can enter the air and be transported for considerable distances before falling back to the earth. Chemical plants manufacturing pesticides also produce pollutant emissions.	Improved application equipment and methods: Improved formulas for pesticides (higher density or use water soluble oils) Wider distribution and use of weather data in area where pesticides are used.

(*continued*)

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
have served quite well in the past years in the prevention of famine and disease. However, it must be realized that some pesticides, especially chlorinated hydrocarbons, are metabolized very slowly thus, accumulate in adipose tissue. DDT for example, has been shown to cause tumors in laboratory animals.	Production of pesticides is estimated at 1.1×10^9 lbs.	Control and abatement during production: Venting of solid emissions through bag houses and cyclones Venting of liquid emissions through liquid scrubbers.

Tier 1 source categories and emissions are shaded.

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
B. INORGANIC GASES: The chemistry of the lower atmosphere is controlled by the reactivity of oxygen. In the presence of molecular oxygen (O_2), the stable forms of almost all of the elements are oxides, with the notable exception of nitrogen. Thus, many of the major pollutants are oxides (i.e., CO, SO_2, SO_3, NO, NO_2) and their associated reactive by-products. 1. *Carbon Oxides* Significant amounts of carbon oxides, carbon monoxide (CO) and carbon dioxide (CO_2), are produced by natural and anthropogenic (man made) sources. CO is considered a major atmospheric pollutant because of its significant health effects, whereas, CO_2 is a relatively non-toxic, normal tropospheric (lower atmospheric) constituent and is, therefore, not usually described as a major atmospheric pollutant. However, anthropogenic emissions of CO_2 are of significant concern since large amounts of CO_2 may contribute to global climatic warning. a. *Carbon Monoxide*:	Carbon monoxide (CO) is a colorless, odorless, tasteless gas formed by the incomplete combustion of fossil fuels and other organic matter. During combustion, carbon is oxidized to CO by the following reactions: $$2C + O_2 \longrightarrow 2CO \qquad (1)$$ $$2CO + O_2 \longrightarrow 2CO_2 \qquad (2)$$ CO, formed as an intermediate in the combustion process, is emitted if there is insufficient O_2 present for reaction (2) to proceed. CO is produced naturally by volcanic eruptions, forest fires, lightning and photochemical degradation of various reactive organic compounds. Biologically, CO is formed by certain brown algae, decomposition of chlorophyll in leaves of green plants, various micro-organisms and microbial action in the oceans. Major anthropogenic sources include transportation, industrial processing, solid waste disposal and agricultural burning. it also is present in high concentrations in cigarette smoke. Background concentrations of CO average 0.1 ppm, with peak concentrations in the northern hemisphere during the autumn months due to the decomposition of chlorophyll associated with the color change and fall of leaves. The residence time for CO in the atmosphere is estimated to be 0.1 to 0.3 years. Because CO has a higher affinity (approximately 200 × greater) for blood hemoglobin than oxygen, and also tends to remain more tightly bound, oxygen transport throughout the body	CO can be removed from the atmosphere by the actions of soil micro-organisms which convert it to CO_2. The soil in the U.S. alone is estimated to remove approximately 5×10^8 tons of CO per year, which is far in excess of the anthropogenic emission rate. However, little CO is removed in urban areas since emissions of CO are large and soil is scarce. In automobiles, catalytic convertors are used to reduce CO emissions by combusting the exhaust gases over a catalyst. This catalyst aided reaction combines O_2 with CO to produce CO_2 and water. Similar after-burner processes are used in controlling emissions from stationary sources.

(*continued*)

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
	of an individual exposed to CO can be greatly reduced. CO is highly toxic at concentrations greater than 1000 ppm. Death results from asphyxiation since body tissues, especially the brain, are deprived of a sufficient supply of oxygen. Because it is colorless, odorless and tasteless, individuals exposed to toxic concentrations are unaware of its presence. However, the concentrations of CO commonly encountered in urban environments are usually only a fraction of those levels which cause asphyxiation. Low-level CO exposure affects the central nervous system with typical behavioral changes including decreased time interval recognition, impairment of brightness, delayed reaction time to visual stimuli, decrease in drying performance and, at concentrations of 100 ppm, dizziness, headache, fatigue and loss of coordinatation. Cigarette smoke contains especially high levels of CO (15,000 to 55,000 ppm) which bind to approximately 3 to 10% of a smoker's hemoglobin. The effects of these high levels would be extremely harmful if it were not for the intermittent nature of the exposure. The inhalation of air between drags greatly reduces the toxic dose. The major effect of CO in cigarette smoke appears to be to increase the risk of angina pectoris patients to myocardial infarcation and sudden death. However, cigarette smoke contains many harmful substances and it is difficult to specifically assess the harmful effects of CO and its exact role in cardiovascular diseases.	
b. *Carbon Dioxide*:	Carbon dioxide (CO_2 is the most commonly emitted air contaminant. It is a product of the complete combustion of carbon in the presence of O_2 as shown in reactions (1) and (2) previously. CO_2 is produced naturally through the decomposition, weathering and combustion of organic matter. Human and animal respiration also contribute CO_2 to the atmosphere. The combustion of coal, oil and natural gas in both stationary and mobile sources is responsible for 90% of anthropogenic CO_2 emissions throughout the world. Solid waste disposal and agricultural burning account for the remaining 10%. Coke ovens and smelters emit significant amounts of CO_2 on a localized basis.	The oceans absorb approximately 50% of anthropogenic CO_2 emissions since CO_2 is highly soluble in water. Green plants also consume large amounts of CO_2 for use in photosynthesis. The use of alternate sources of energy such as nuclear, solar or chemically derived energy is the preferred method to control emissions of CO_2.

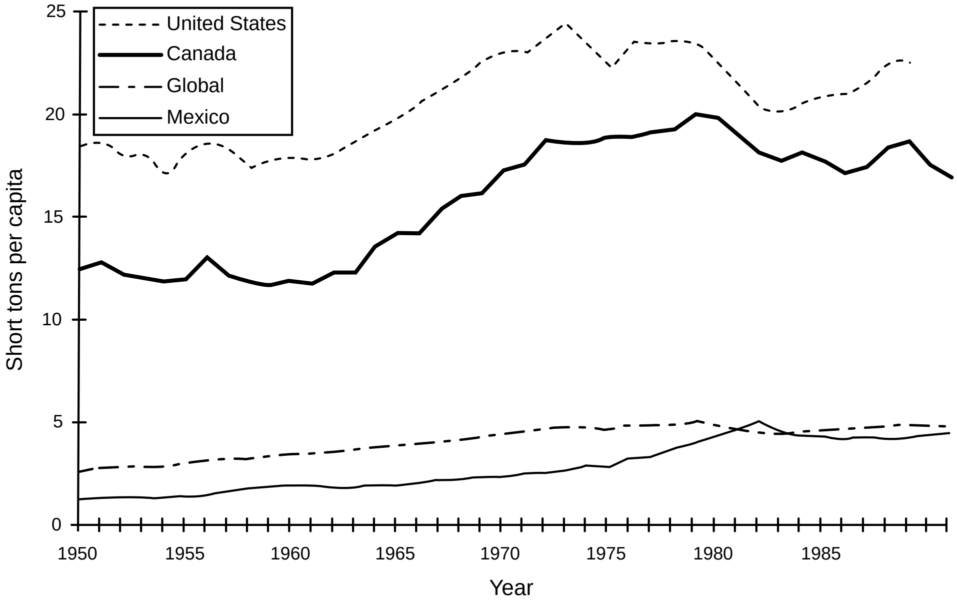

FIGURE 2 Comparison of Per Capita Carbon Dioxide emissions.

Note(s): U.S. per capita emissions data is not presented for 1990 or 1991. See section 10.1 for a discussion of 1990 to 1994 national CO_2 emission estimates.

Sources(s): Marland, G., R.J. Andres, and T.A. Boden 1994. Global, regional and national CO_2 emissions, pp. 9–88. In T.A. Boden, D.P. Kaiser, R.J. Sepanski, and F.W. Stoss (Eds.), *Trends '93: A Compendium of Data on Global Change.* ORNL/CDIAC-65. Carbon Dioxide Information Analysis Center, Oak Ridge National Laboratory, Oak Ridge, Tenn., U.S.A.

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
	CO_2 is not typically considered a pollutant in air pollution regulations, however, its role in the global heat balance is well recognized. CO_2 can heat up the earth's surface by a phenomenon commonly called the "greenhouse effect." This "greenhouse effect" is caused primarily by water vapor and CO_2, both of which are strong absorbers of infrared radiation. When radiation is absorbed by CO_2 and water, it is reemitted in all directions with the net result being that part of the radiation returns to the earth's surface and raises the temperature. Since 1890, atmospheric CO_2 levels have increased from about 290 to 322 ppm. 25% of this increase has occurred in the past decade. Since 1958, the atmospheric CO_2 levels have increased at a rate of approximately 0.7 ppm per year. If this trend continues, atmospheric CO_2 levels could double by the year 2035A.D. This doubling could result in the warming of surface temperatures by 2.4°C in the midlatitudes, with a greater warming in the polar regions.	
Sulfur Oxides a. *Sulfur Dioxide*:	Sulfur dioxide (SO_2) is a colorless gas whose odor and taste can be detected in the concentration range of 0.3 to 0.1 ppm. Above 3 ppm, it has a pungent, irritating odor. Although SO_2 emissions may occur from volcanic eruptions, most SO_2 (and sulfur trioxide, SO_3) is due to the burning of	In order to reduce the levels of sulfuric acid aerosols in urban air, power plants are often built with tall smokestacks which disperse the SO_2 over a wide area. This reduces the local problem but increases the problem for areas

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
	coal and crude oils for electric power and heating. The sulfur content of refined petroleum is usually quite low. At the high temperatures of combustion, the sulfur in these fuels is converted to SO_2 by the reaction: $S + O_2 = SO_2$ (3) Background levels of SO_2 are very low, about 1 ppb. In urban areas maximum concentrations vary from less than 0.1 to over 0.5 ppm. SO_2 itself is a lung irritant and is known to be harmful to people who suffer from respiratory disease. However, it is the sulfuric acid aerosol formed from the oxidation of SO_2 and SO_3 that causes the most damaging health effects in urban areas. The sulfuric acid aerosol is formed by the following reactions which in the atmosphere are photochemically and catalytically accelerated: $2SO_2 + O_2 = 2SO_3$ (4) $SO_3 + H_2O = H_2SO_4$ (5) The sulfuric acid aerosols formed are usually less than 2 microns in diameter and can quite effectively penetrate the innermost passages of the lung, known as the pulmonary region. This is the region where O_2 is exchanged with CO in the blood. Sulfuric acid aerosols irritate the fine vessels of the pulmonary region, causing them to swell and block the vessel passages. Severe breathing impairment may occur. The effect is cumulative, with older people suffering the most severe respiratory problems. SO_2 can also severely damage crops such as spinach, turnip, beets, alfalfa and oats. Trees such as the white pine, white birch and trembling aspen, as well as, ornamental plants such as gladiolus, tulip and sweet pea, can also be damaged.	which are far from the source of the pollutant. The sulfuric acid aerosol is washed out in either rain or snowfall and increases the acidity of local waters downwind from the plant. This condition is known as acid rain. Another approach to SO_2 abatement is to substitute low sulfur coal, sulfur free coals (produced by screening crushed coal) and other sulfur free fuels for high sulfur to low sulfur fuels. This can be seen in urban areas where coal has largely been displaced by petroleum and natural gas. An alternative approach is to remove the SO_2 from the stack gases of the plant by using chemical scrubbers. In the chemical scrubber, the stack gas is passed through a slurry of limestone (calcium carbonate, $CaCO_3$) which removes the SO_2 and produces calcium sulfite which can be collected and disposed of. More commercially valuable abatement processes include catalytic oxidation to produce usable sulfuric acid and reaction with alkalized alumina which allows the recovery of usable sulfur.

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
b. *Hydrogen Sulfide*:	Hydrogen sulfide (H_2S) is a colorless gas known by its characteristic rotten egg odor. Natural sources of H_2S include volcanic eruptions, geothermal wells and chemical or bacteriological decomposition of mineral sulfates in springs and lakes. In these natural occurances, other sulfur compounds are nearly always present with the H_2S. Anthropogenic sources include the combustion of coal, natural gas and oil. The refining of petroleum products, coke production, sulfur recovery operations and the kraft process for producing chemical pulp from wood are all major sources of H_2S. The typical rotten egg odor can be detected at very low concentrations, 0.025 to 0.2 ppm, but at these concentrations it has little or no effect upon human health. However, at higher concentrations, H_2S is extremely toxic. Above 150 ppm, the human olfactory apparatus becomes paralyzed, effectively preventing any olfactory warning signal. H_2S is life threatening at 300 ppm since it causes pulmonary edema. At 500 ppm, there is strong stimulation to the nervous system. Above 1000 ppm, there is immediate collapse and respiratory paralysis.	Most removal system for H_2S scrub the gas streams with a suitable absorbent and then remove the absorbed gas from the absorbent for disposal by burning or conversion to usable by-products. Different types of scrubbers can be used such as spray towers, plate towers and venturi scrubbers. Natural removal of H_2S occurs by atmospheric conversion to SO_2 which is subsequently removed from the atmosphere through precipitation and absorption by surfaces and vegetation.
3. *Nitrogen Compounds*: There are five major gaseous forms of nitrogen in the atmosphere: nitrogen gas (N_2), ammonia (NH_3), nitrous oxide (N_3O), nitric oxide (NO), and nitrogen dioxide (NO_2). N_2 is the major gaseous component in the atmosphere and counts for 78% of the atmosphere's mass. NO and NO_2 are important pollutants of the lower atmosphere and because of their interconvertibility in photochemical reactions, are usually collectively grouped as NO_x.	Nitrous oxide (N_2O) is a colorless, slightly sweet, non-toxic gas. It is probably best known as the "laughing gas" which is widely used as an anesthetic in medicine and dentistry. Bacterial action which produces N_2O is the largest single source of any nitrogen oxide on a worldwide basis. It is present in the atmosphere at an average concentration of 0.27 ppm. It is quite inert in the lower atmosphere, but it can react with oxygen atoms that are available in the stratosphere to produce nitric oxide.	
a. *Nitrous Oxide*:		
b. *Nitric Oxide*:	Nitric oxide (NO) is a colorless, odorless, tasteless, relatively non-toxic gas. Natural sources include anaerobic biological processes in soil and water, combustion processes and photochemical destruction of nitrogen compounds in the stratosphere. On a worldwide basis, natural emissions of NO are estimated at approximately 5×10^8 tons per year. Major anthropogenic sources include automobile exhaust, fossil fuel fired electric generating stations, industrial boilers, incinerators, and home space heaters. All of these sources are high temperature combustion processes which follow the reaction: $N_2 + O_2 = 2NO \qquad (6)$ This reaction is endothermic, which means that the equilibrium shifts to the right at high temperatures and to the left at low temperatures. Therefore, as the combustion temperature of a process increases, so will the amount of CO emitted. Background concentrations of NO are approximately 0.5 ppb. In urban areas, one hour average concentrations of NO may reach 1 to 2 ppm. Atmospheric levels of CO are related to the transportation and work cycle, with the highest	

(*continued*)

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
	concentrations observed during the morning and evening rush hours. Emissions of NO are also greater in the winter months since there is an increase in the use of heating fuels. NO is a relatively non-irritating gas and is considered to pose no health threat at ambient levels. It is rapidly oxidized to nitrogen dioxide, which has a much higher toxicity.

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
c. *Nitrogen dioxide*:	Nitrogen dioxide (NO_2) is a colored gas which is a light yellowish orange at low concentrations and reddish brown at high concentrations. It has a pungent, irritating odor. It is relatively toxic and has a rapid oxidation rate which makes it highly corrosive as well. The oxidation of NO to NO_2 follows the reaction: $2NO + O_2 \rightarrow 2NO_2 \quad (7)$ This reaction is slow at low atmospheric levels and accounts for about 25% of all NO conversion. The major NO conversion processes are photochemical, involving hydrocarbons, ozone, aldehydes, carbon monoxide, and other compounds. Background concentrations of NO_2 are approximately 0.5 ppb with one hour average concentrations in urban areas of 0.5 ppm. Peak morning concentrations of NO are followed several hours later by peak levels of NO_2 produced by the chemical and photochemical oxidation of the NO. Since the conversion of NO to NO_2 is related to solar intensity, more NO_2 is produced on warm, sunny days.	In the atmosphere, NO_2 can be photochemically oxidized to nitrates which are subsequently removed by precipitation, dry deposition and surface absorption. In motor vehicles, current methods for controlling NO_x emissions include retardation of spark timing, increasing the air/fuel ratio (i.e., less fuel to air), injecting water into the cylinders, decreasing the compression ratio, and recirculating exhaust gas. All these methods reduce the combustion chamber temperature (which reduces NO_x emissions) without greatly increasing the emissions of hydrocarbons and CO. Catalytic convertors which reduce NO to elemental nitrogen (N_2) can also be used. The use of alternative fuels, such as methyl and ethyl alcohol, which combust at a lower temperature than gasoline can also be used to lower NO_x emissions. For stationary sources, one abatement method is to use a lower NO_x producing fuel; emissions are highest from coal, intermediate with oil and lowest with natural gas. For the numerous methods of control see the article "Nitrogen Oxides" in this Encyclopedia.
4. *Photochemical Oxidants*: Photochemical oxidants are secondary pollutants which result from a complex series of atmospheric actions involving organic pollutants, NO_x, O_2 and sunlight. The main photo-chemical oxidants are ozone, NO_2 (covered in the section on nitrogen compounds) and, to a lesser extent, peroxyacetylnitrate.	Ozone (O_3) is the most important and widely reported of the photochemical oxidants. It is a bluish gas that is 1.6 times heavier than oxygen and is normally found at elevated levels in the stratosphere where it functions to absorb harmful ultraviolet radiation. Ground level ozone is one of the major constituents of photochemical "smog" which is a widespread, urban phenomenon. It is formed when nitrogen dioxide absorbs ultraviolet light energy and dissociates into nitric oxide and an oxygen atom: $NO_2 + h\nu \rightarrow O + NO \quad (8)$	Abatement is achieved through the control of hydrocarbons and nitrogen oxides as discussed in other sections of this chapter.

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
	These oxygen atoms, for the most part, react with oxygen to form ozone: $O + O_2 \rightarrow O_3 \quad (9)$ In addition, the oxygen atoms can react with certain hydrocarbons to form free radical intermediates and various products such as peroxyacetylnitrate (PAN). Since photochemical oxidants are secondary pollutants formed in the atmosphere as the result of primary pollutants reacting, their concentration in the atmosphere will vary proportionally to the amount of hydrocarbons and NO_2 in the air and the intensity of sunlight. PAN is a very potent eye irritant in addition to being a strong lung irritant like O_3. O_3 is relatively insoluble in respiratory fluids and can be transported into the pulmonary system where it can damage the central airways and terminal pulmonary units such as the respiratory bronchioles and alveolar ducts. Exposure in excess of ambient levels affects lung function causing increased respiratory rates and decreased lung capacity. These effects are more pronounced in smokers and during exercise. Prolonged low-level exposure may result in decreased lung elasticity. Studies on micro-organisms, plants mutagenic, that is, it can cause permanent, inheritable changes in genes. Since mutagens and carcinogens appear to be related, it is possible that O_3 is also carcinogenic.

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
Halides a. *Chlorine*:	Chlorine (Cl_2) is a dense, greenish-yellow gas with a distinctive irritating odor. The major anthropogenic sources of chlorine emissions include the chemical decomposition of chlorofluorocarbons (CFCs) used as a refrigerant and propellant in consumer goods, the liquifaction of chlorine cell gas, the loading and cleaning of tank cars, barges and cylinders, dechlorination of spent brine solutions and power or equipment failure. Due to the high reactivity of Cl_2 with many substances, natural emissions of Cl_2 gas are very rare. Volcanic gases contain very small amounts of Cl_2. Low concentrations of Cl_2 may, however, be formed by atmospheric reactions. Since chlorine has strong oxidizing and bleaching properties, it is extremely hazardous to all life forms, as well as corrosive to metals and other materials. Chlorine atoms can destroy ozone	The use of propellants which do not contain CFCs. Industrial emissions can be controlled by the use of scrubbing systems, i.e., water scrubbers, alkali scrubbers and carbon tetrachloride scrubbers.

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
	molecules and, thus, deplete the earth's protective ozone layer. This stratospheric ozone depletion is a result of the photolytic destruction of CFCs and, subsequent, release of chlorine atoms in the middle stratosphere. Chlorine and ozone react by the reactions: $\mathrm{Cl} + \mathrm{O}_3 \rightarrow \mathrm{ClO} + \mathrm{O}_2 \quad (10)$ $\mathrm{ClO} + \mathrm{O} \rightarrow \mathrm{Cl} + \mathrm{O}_2 \quad (11)$ In these reactions, chlorine acts as a catalyst since it is rapidly regenerated by reaction 11. Estimates have shown that one chlorine atom has the potential to destroy 100,000 ozone molecules before the chlorine atom reacts with hydrogen to form hydrochloric acid and be removed from the cycle.	
b. *Fluorides:*	Fluorine is the 13th element in order of abundance and exists in nature primarily as fluorospar and fluorspatite which contain 49% and 3–4% fluorine, respectively. Fluorospar is the source of nearly all commercially used fluorine. Fluorspatite is also known as phosphate rock and is used in the manufacture of phosphate fertilizers and elemental phosphorous compounds comprising of fluorine. It may occur in extremely low concentrations in the atmosphere as solid particles (sodium and calcium fluoride) or highly irritating and toxic gases (hydrofluoric acid). The processing of fluorospar and fluorspatite are the predominate sources of fluorine air pollutants. Industrial plants manufacturing steel, glass, brick and tile, are among the major emitters. The combustion of coal is another source.	Scrubbers, electrostatic precipitators or baghouses can be used to remove particle emissions while scrubbers can be used to clean gaseous emissions. Most industrial processes require the use of both.

1994 emission estimates are preliminary and will be updated in the next report.
Tier 1 source categories and emissions are shaded.

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
C. PARTICULATES: Particulates are dispersed solid or liquid matter in which the industrial aggregates are larger than single small molecules (about 0.0002 microns in diameter) but smaller than 500 microns. Particulates in the atmosphere range from about 0.1 microns to 10 microns. In general, the smaller particles are quite abundant while the larger particles exist in the atmosphere in very low concentrations. Particulates can remain airborne from a few seconds to several months. Typically, the particulate pollutant category is made up of the products of incomplete fuel combustion, metals, large ions or salts, mists, fumes fugitive dusts and various other solid or liquid particles, for example, acid mist. Small particulates can cause lung irritation and reduce respiratory efficiency by inhibiting the transport of	Sources due to the activities of man include factories such as kraft pulp paper mills, steel mills, and power plants. Mobile sources include the incomplete combustion of fuel in the internal combustion engine, primarily the diesel engine. In many rural areas the wood-burning stove has made a large contribution to airborne particulates. This category includes some compounds which are gaseous while contained, but which condense when they enter into the atmosphere. Included are: aerosols (solids and liquids of microscopic size which are dissolved in gas, forming smoke, fog or mist), large particles and dust, soot (carbon particles impregnated with tar), oil and grease.	Stationary Sources: a) Use of air cleaning techniques and devices by industry and power plants to remove particulate: — Inertial separations or gravitational settling chambers. — Cyclones. — Baghouses and fabric filters. — Electrostatic precipitators. — Scrubbers and venturi scrubbers. b) Control of construction and demolition in the grading of earth, paving roads and parking lots, sand blasting, spray-painting. Techniques include hooding and venting, to air

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
oxygen from the lungs through the circulatory system. Small particulates are also detrimental to health by having adsorbed toxic materials on their surfaces; the particulates are then inhaled into the body. Particulates are also responsible for soiling of materials and reduced visibility. In July 1987, the U.S. Environmental Protection Agency promulgated revised national ambient air quality standard for particulate matter. The new standard placed emphasis on particles less than10 microns in diameter. This revision was based on the finding that fine particulates of less than 10 microns (also known as PM-10) pose a greater hazard to human health than larger particles, because it is these smaller particles that penetrate deep into the lungs. In addition, because of their ability to remain airborne and their refractive properties, the smaller particles also have a greater impact on visibility. In July 1997, based on studies which indicated adverse health effects from the inhalation of very fine particles, the U.S. EPA promulgated a PM-2.5 standard.	Naturally occurring sources of particulates are due to forest fires and windblown dust. Mechanical processes such as wind erosion, grinding, spraying, demolition, industrial activity and salt also contribute to particulate problems. Most of these particulates are in the 1–10 micron range and generally predominate very near the source. Electricity generation, forest product industries, agriculture and its related operations, the crushed stone industry, the cement industry, the iron and steel industry and asbestos mining are other important examples. Surface coating sources emit spray and mist pollutants. These pollutants include organic solvent bases that are used in paints. These volatile organic solvents become airborne during the application of paints to their intended surface.	pollution control equipment and the wetting down of working surfaces with water or oil. c) Disposal of solid waste by sanitary land fill, composting, shredding and grinding rather than incineration. Mobile Sources: The aim is to develop methods of achieving complete combustion. If this is accomplished, particulates (like soot and smoke) would be minimal. To achieve maximum combustion, vehicles in the United States are equipped with catalytic converters which help to completely incinerate unburned fuel. In the U.S. and in many other countries like Canada, Britain and Germany unleaded gasoline is available for use in automobiles. Less lead in the gasoline means less lead particles being emitted into the air. The following are examples of some typical particulate pollutants.

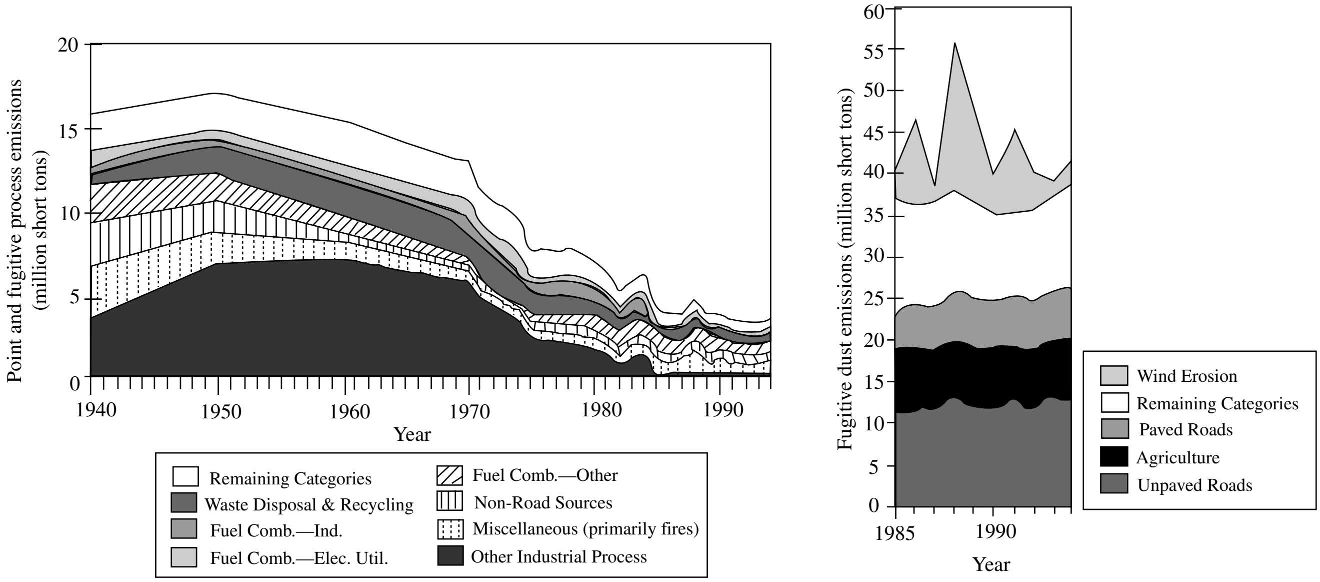

FIGURE 3 Trend in particulate Matter (PM-10) by point and fugitive process sources (1940 to 1994), and by fugitive dust sources (1985 to 1994).

Pollutant types	Sources and abundance	Abatement and control
1. *Aeroallergens*: Aeroallergens (pollens) are airborne materials that elicit a hypersensitivity or allergic response in susceptible individuals. The most common aeroallergens are the pollens of wind-pollinated plants—especially ragweed pollen, which is the main cause of hay fever. In addition to the pollens, aeroallergens include molds, danders, house, cosmetics, and others. It has been estimated that	Most aeroallergens are produced by natural causes, although some may be produced through man-made interferences 1) *Natural sources*. The aeroallergens encompass a wide variety of materials, but pollens are the most important member of this group.	Abatement and control measures for aeroallergens have been directed primarily at the ragweed. Since ragweed grows quickly in areas where the soil has been disturbed, it is not controlled by pulling it up when noticed, since the soil is thus disturbed and the growth may be heavier the following year.

(*continued*)

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
between 10 and 15 million people in the United States are affected by seasonal allergic (hay-fever).	a) *Ragweed*—has been found in all 50 states, it produces large quantities of pollen, and the grains are especially adapted for aerial dissemination by virtue of their size (20 μ), shape, and density. It has been estimated that an acre of giant ragweed may produce as much as 50 lbs of pollen during a single season. b) *Fungi*—(molds) usually habitating in soil and dust, can become a menace when airborne. Their concentration in the air is dependent upon the magnitude of the source, their death rate in the air, humidity, temperature and other factors. c) *Danders*—(small particulate organic materials), including feathers of fowl and hair of animals and house dust. 2) *Man-made sources*: a) Flour mills—grain dusts produced in flour-milling plants (have been identified as a cause of asthma). b) Castor bean dust-oil processing plants. Most sources of biological aerosols are natural.	*Herbicide* (*plant killers*)—are sometimes used, but they are not only to ragweed, but to all plants. For eradicating molds, a number of disinfectants have been utilized. Man-made sources are subject to normal particulate control methods as well as good housekeeping practices in plants.
2. *Asbestos*: General name given to a variety of fibrous minerals found in rock masses. The value of asbestos ensues from the indestructible nature of products fabricated from the various grades of mineral fibers. *The major asbestos minerals are*: (Pyroxenes) chrysolite (amphiboles—), crocidolite, amosite, and anthophyllite. Tremolite and actinolite are considerably less important. Over 90% of the asbestos is chrysolite.	*Major sources are*: a) Asbestos mines and factories. b) The wearing of brake linings, roofing insulation and shingles. c) Fireproofing of buildings with sprayed asbestos applications. d) Road surfacing. e) Asbestos cement. f) Asbestos removal.	a) IN MANUFACTURING: Ventilation through fabric sleeve filters carrying out some operations (such as spinning and weaving of asbestos fabrics) as wet processes to eliminate dust. b) IN TRANSPORTATION: Use of plastic-coated bags to transport asbestos. c) IN CONSTRUCTION REMOVAL: Use of insulators to enclose the work area when asbestos fire-proofing is blown onto steel frames. Wetting of asbestos prior to removal.
3. *Non metallic elements*: a. BORON: A non-metallic chemical element which occurs only in combination with other elements as with sodium and other elements (as with sodium and oxygen in borax). Most important pollutants are boron dust and borane fuel. The borones are the most highly toxic of the boron compounds, consists chiefly of pentaborane, decaborane, and diborane.	*Major sources are*: Rocket motor or jet engines which use borane, a compound of boron, for a high energy fuel; combination of petroleum fuels which contain boron as an additive; burning of coal containing boron; manufacturing processes employed to produced boron compounds which are used as wastes softness. *Natural abundance*: Boron is widely distributed in nature, but constitutes only an estimated in 0.001% of the earth's crust. It is present in sea water, and is an essential constituent of a number of rock-forming silicate minerals, such as datolite and tourmaline. Boron occurs naturally only in combined forms, usually as air alkaline earth borate or as boric acid.	1) Prevention of accidental spilling of fuels. 2) Reduction or elimination of boron additives in vehicle fuels.
b. PHOSPHORUS: A solid non-metallic element existing in at least two allotropic forms, one yellow (poisonous, inflammable, and luminous in the dark), the other red (less poisonous, and less inflammable). Elemental phosphorus (yellow) is a protoplasmic poison. Some of its compounds, especially organic phosphates, can also be lethal to man and animal in the case of exposure to high air concentrations.	The compounds known to be emitted in appreciable quantities into the ambient air are phosphorus oxides, phosphoric acid, mostly in agricultural chemicals. Other organic phosphorus compounds are very probably emitted into the ambient air by the chemical industry from processes in which phosphorous products are intermediate or final outputs.	*Major control methods*: Scrubbers cyclones, fiber mist eliminators, high energy wire-mesh contactors and electrostatic precipitators are used in the control of phosphorus emissions.

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
	Major sources: 1) Oil-fired boilers—0.9% phosphorus in fly ash. 2) Iron and steel industry—phosphorus pentoxide accounts for an average of 0.2% of the total weight of fume from furnances. 3) Transportation sources: Organophosphorus compounds used as fuel additives. *Natural abundance*: Natural phosphates are divided into three classes on the basis of the metal or metals to which it is bound. The three major classes are aluminium (iron) phosphates, calcium-aluminum (iron) phosphates, and calcium phosphates.	
c. SELENIUM: This is a non-metallic element chemically resembling sulfur and tellurium, occurring in several allotropic forms. The soils of the midwestern U.S. are particularly high in selenium content. Selenium has also been found to be an essential nutrient for animals and may be necessary for humans.	*Major sources*: The sources of atmospheric selenium are believed to be terrestrial, such as fuels and ores used by industry (copper refinery), or possibly the burning of trash, particularly paper. *Natural abundance*: In nature, selenium is widely distributed in the earth's crust at a concentration of about 0.09 ppm. Selenium can also be found in coal and igneous rock. Approximately 0.001 $\mu g/m^3$ of selenium has been found in samples of rain, snow, and air.	No study has been made of the methods for control of selenium and its compounds. However, based on the properties and on the methods of recovery and purification of selenium wet scrubbers and high-voltage electrostatic precipitators should be effective.
4. *Heavy metals*. These are the chemically inert electronegative metals with densities of 5 gm/cm^3 and greater. They are chemically inert because their electrons are tightly bound to the metal's nuclei and are unable to readily combine with other elements. However, heavy metals are toxic to the human physiology in that the heavy metals try to bond with enzymatic sulfur atoms in the body. They also attack free amino ($-NH_2$) and organic acid (–COOH) groups found in proteins. A few heavy metals combine with and precipitate some of the body's vital phosphate compounds; other heavy metals catalyze the decomposition of phosphates. Mercury, lead, cadmium, copper combine with all membranes and interfere with the transport of chemicals in and out of the cell. As a result of this heavy metal combination with the tissue, a variety of diseases ranging from cancer to heart disease occurs. The following is a list of metals that are considered to be most detrimental to human health. a. MERCURY: A high density, silver-white metal, is liquid at normal ambient temperatures. Although it is contained in at least 25 minerals, the chief source is cinnabar (HgS).	*Major sources*: The combustion of coal was the largest source of mercury emissions in the United States in 1968. The paint industry was the source of more than 25% of lead emissions in the U.S. in 1968. Marine anti-fouling paints contain mercurial compounds as a toxicant; latex paints use mercurial compounds as a preservative. The third largest source of mercury emissions is the combustion of wastes which accounted for almost 17% of all mercury emissions in 1968. Other sources of mercury include mining and processing of ore. In industrial applications mercury is used in rectifiers, mercury precision lighting, batteries (mercury cell and alkaline energy cell). Laboratory equipment and instruments—such as barometers, thermometers, flow meters, pressure-sensing devices, switches and relays all contain mercury (spillage creates droplets which vaporize). Electrolytic preparation of chlorine. Agricultural use of mercury compounds as pesticides (now declining).	For applications which use mercury at normal temperatures: 1) Proper ventilation in work areas. 2) Cleaning up spilled mercury (sweeping with special vacuum cleaners or chemical treatment). 3) Use of non-porous material for floors, working surfaces and protective clothing. 4) Conventional control of pesticides. For applications which use mercury at high temperatures: Condensing mercury vapors by: Cold-water jacketed condensers, impregnated charcoal. Water scrubbers.
b. LEAD: Lead is a heavy, soft malleable, bluish-gray metallic element. It is the sulfide ore, galena, soil, water, vegetation and animal. It is introduced into the body with the intake of water and in air. Most lead air pollution is in the form of aerosols, fume, and sprays. The largest use of lead 39% of the total in 1968 is in the construction of storage batteries. The second largest use is in the manufacture of gasoline and tetramethyl lead. Approximately 1.30 million tons of lead were consumed in the United States in 1968.	*Major sources*: The *major source* of airborne lead in urban areas is the exhaust from gasoline powered vehicles. Other man-made sources are manufacturing of lead additives for gasoline, processing and manufacture of lead products, the combustion of coal.	1) *From vehicle sources*: Reduction or elimination of lead in fuel; use of particulate traps on vehicle exhausts. 2) *From lead processing and the manufacture of lead products*: Control of operating conditions (temperature and timing): Use of oconventional air cleaning techniques (bag house filters, scrubbers, electrostatic precipitators).

(*continued*)

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
		3) *From coal combustion*: use of electrostatic precipitators. 4) *From manufacture of lead additives for gasoline*: Use of water scrubbers and bag house filters. 5) *From transfers and transportation of lead gasoline*: Use of vapor recovery systems; reduction or elimination of lead in gasoline. 6) *From use of pesticide*: Use of pesticides which do not contain lead; improved techniques of pesticide use. 7) *From incineration of refuse*: Use of conventional air cleaning techniques or sanitary land fills instead of incinerators.
c. NICKEL: A grayish white metallic element—hard, rough partially magnetic resistant to oxidation and corrosion. Nickel forms a variety of alloys with other metals. It is very important in making steel alloys and particularly stainless steel. Major pollutants are nickel dust and vapours.	*Major sources*: The processing of nickel to produce various alloys is the major source of emissions: See Table 16: This includes: 1) PLANT producing nickel alloys (including stainless steel) contains anywhere between 3–65% nickel in the alloys. 2) Nickel plating facilities via, electro-plating, electroless plating (chemical plating), electoforming (nickel can on mold) etc.	a) Use of conventional air cleaning devices: 1) Bag filters 2) Precipitators 3) Scrubbers b) Decomposition of gaseous emissions at high temperature forming nickel (which can be removed as a particulate) and carbon monoxide. c) No control methods currently available for vehicle engine exhausts.

TABLE 13

Sources and Health Effects of Some Prominent Heavy Metals[a]

Element	Sources	Health Effects
Mercury	Coal electrical batteries, other industrial	Kidney damage, nerve damage and death
Lead	Auto exhaust, paints	Brain, liver, and kidney damage; convulsions, behavioral disorders, death
Cadmium	Coal, zinc mining, water mains and pipes, tobacco smoke, burning plastics	High blood pressure and cardiovascular disease, interferes with zinc and cooper metabolism
Nickel	Diesel oil, residual oil, coal, tobacco smoke, chemicals and catalysts, steel and nonferrous alloys	Lung cancer
Arsenic	Coal, petroleum, detergents, pesticides, mine tailings	Hazard disputed, may cause cancer
Germanium	Coal	Little innate toxicity
Vanadium	Petroleum (Venezuela, Iran), chemicals and catalysts, steel and nonferrous alloys	Probably no hazard at current levels
Antimony	Industry	Shortened life span in rats

[a] Data from *Chemical & Engineering News 49* (July 19, 1971), 29–33, and other sources.

TABLE 14
National Anthropogenic Mercury Emissions (short tons/year)

Source Category	Mercury	Activity Year
Area Sources		
Electric Lamp Breakage	1.5	1989
Laboratory Use	0.8	1992
Dental Preparations	0.8	1992

Primary Lead Smelting	9.0	1990
Primary Cooper Smelting*	0.7	1992
Lime Manufacturing	0.7	1992
Fluorescent Lamp Recycling*	0.006	1993
Subtotal	32.0	
TOTAL	244.3	

* Emissions are estimated for only one source, which is scheduled to cease operations by March 31, 1995; nationwide estimates are expected to be higher.

Note(s): Mercury was phased out of paint use in 1991.

Insufficient information was available to estimate emissions for the following source categories:

- Mobile sources;
- Agricultural burning (one study estimates 0.04 tons/year from preharvest burning of sugarcane in Florida everglades area);
- Landfills;
- Hazardous waste incinerators;
- Mercury compounds production;
- By-product coke production; and
- Petroleum refining.

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
	3) Nickel is used extensively as a catalyst (for i.e. Raney Nickel) used in hydrogenation of organic compounds, dehydrogenation of organic compounds, aging of liquors, etc. 4) Aviation and automobile engines burning fuels containing nickel concentrations range from 1 to 10% nickel. 5) Burning coal and oil-nickel in ash varies from 3 to 10,000 μg/g 6) Incineration of nickel products.	
d. CADMIUM: Is a relatively rare metal which is not found in a free natural state. It is obtained from zinc, lead, copper and other ores that contain zinc minerals. Pollution exists as fumes, and vapors. The major use of cadmium is for electroplating iron and steel. The most common cadmium compounds and their uses are: 1) Electroplating—cadmium cyanide, $Cd(CN_2)$, and cadmium acetate, $Cd(CH_3COO)_3$. 2) Photography and dyeing—cadmium chloride, $CdCl_3$. 3) Manufacture of phosphors, glass in nuclear reactor controls. 4) Manufacture of electrodes for storage batteries—cadmium hydroxide $Cd(OH)_3$. 5) Cadmium iodide, CdI_2, electrode-position of Cd, manufacturing of phosphors. 6) Cadmium oxide—CdO. In phosphores, semi-conductors, manufacture of silver alloys. 7) Cadmium selenide—CdSe. In Photoconductors. 8) Cadmium sulfate—$CdSO_4$. In electrodeposition Cd, Cu, and N. 9) Dimethylcadmium $Cd(H_3)_2$ In organic synthesis.	*Major sources are*: (See Table 17) 1) Mining—Since no ore is mined solely for cadmium recovery, emissions of cadmium dust ore vapors are those that occur during mining and concentration of zinc-bearing ores. 2) Metallurgical processing—most of the atmospheric emissions occur during the roasting and sintering of zinc concentrates as impurities are removed. Cadmium is volatized and condensed to be collected as dust in baghouses or electrostatic precipitators. Lead and copper smelters also process concentrates containing cadmium. 3) Reprocessing—emissions occur during electroplating, manufacturing. 4) Consumptive uses—include use of rubber tires, motor oil, fungicides and fertilizers. 5) Incineration and ether disposal gaseous emissions will occur when scrap metal is melted to make new steel. 6) Cadmium used in plastics and pigments. NATURAL OCCURRENCE: The concentration of cadmium is almost always in direct proportion to that of zinc. The cadmium to zinc ratio varies from about 0.0002 to 0.002. With respect to the cadmium concentration percentage of the earth's crust, it is roughly 0.000055. Small concentrations of cadmium have been estimated in soil and sea water. MAN-MADE OCCURRENCE Mining—2 lbs are emitted per ton of cadmium mined usually as wind loss from tailings. Metallurgical processing.	General control procedures for the prevention of air pollution by dust, fumes, and mists applicable to the metal refinery alloying, and machining industries are considered suitable to these processes in the cadmium industry. —Copper mining and smelting: addition of bag filters and cyclones added to increase the recovery of cadmium. —Use of flue systems to direct the flow of gases to proper receptacles.
e. ARSENIC: a brittle, very poisonous chemical element, found widely distributed over the earth's crust. It is most often found with copper, lead, cobalt, nickel, iron, gold and silver. Arsenic is commonly found as a sulfide, arsenide, arsenite, or arsenate.	*Major sources*: (See Table 18) a) Smelters processing copper, zinc, lead and gold—arsenic is recovered as by product. b) Cotton ginning and the burning of cotton trash. c) Use as a pesticide (DDT). d) Combustion of coal. e) Incineration. Possible sources are: (See Table 18) manufacturing of glass—arsenic pentoxide, As_2O_3, arsenic trisulfide. As_2S_3 manufacturing of ceramics—arsenic trichloride, As_2Cl_3	a) Use of air cleaning devices to remove particulates from smelters and cotton gins. Equipment must operate at temperatures low enough to condense arsenic fumes ($<100°C$) —Electrostatic precipitators —Cooling flues —Bag houses, especially those using wet scrubbing vacuum pumps instead of fabric filters. b) No methods available to control emissions produced by burning cotton trash.

Pollutant types	Sources and abundance	Abatement and control
f. VANADIUM: A grayish malleable ductile element found combined in many materials. Vanadium is used primarily to form alloy. Vanadium is also found in coal and oil as an impurity. The consumption of vanadium in 1968 was reported as 5495 tons. Of this total about 80% was used in making various steels. More than 65 vanadium-bearing minerals have been identified. The most important: a) patronite (V_2S_3S) b) Bravoite ($(FeNi)(S_2)$) c) Sulvanite ($3Cu_2S \cdot V_2S_3$)	*Major sources*: Almost all emissions of vanadium in the United States are derived from the combustion of fuel oil and coal both of which contain small amounts of metal. Fuel oil is by far the largest contribution (almost 90% of total emissions). In oil, the concentrations of vanadium pentoxide vary from 0.01% (Continental crude) to 0.06% (Venezuelan crude). The ash from combustion of residual oil varies from 0.002 to 0.3% (by weight). In coal, there is a small contribution of vanadium in the lignite deposit and the ash	*Use of additives*: Use of magnesium oxide in oil-fired burners, resulting in the reduction of fine particulate and amounts of vanadium escaping to the atmosphere. Use of conventional devices to remove particulates. Use of centrifugal collectors to gather ash emissions. Use of efficient fly-ash control equipment such as cyclones, electrostatic precipitators.

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
d) Davidite—titanium ore e) roacoelite ($CaO\cdot 3V_2\cdot S_3\cdot 9H_3O$)	emitted. Vanadium percentages in ash can range anywhere between 0.001 to 0.11%. Other minor sources are the processing of steel, cast iron and nonferrous alloys. Some additional emissions result from the manufacture of glass and ceramics and the use of vanadium as a catalyst.	
g. BERYLLIUM: is a light-weight, grayish metal that has a high strength-to-weight ratio, great stiffness and valuble nuclear properties. A hard metallic element which forms strong, hard alloys with several metals, including copper and nickel. Almost all the presently known beryllium compounds are acknowledged to be toxic in both the soluble and insoluble forms: —beryllium sulfate soluble —beryllium chloride —metallic beryllium insoluble —beryllium oxide In concentrated form, it is found in relatively few minerals, and there are basically compounds of beryllium oxide. The most important such minerals are as follows: Principal ore: Beryl—$3BeO\cdot Al_2O_3\cdot 6SiO_2$ Beryllium is used in nuclear reactors, gas turbines, airplane brakes, optical devices, springs, bellows, diaphragms, electrical contacts especially in high voltage insulation.	*Major sources*: Beryllium is commonly found as an atmospheric pollutant within the confines and in the proximity of industrial plants producing or using beryllium substances. Such plants engage in the extraction, refining, machining and alloying of the metal. b) Combustion of coals and oil containing of on the average 1.9 ppm and 0.08 ppm of beryllium respectively. c) Use of beryllium as additive in rocket fuels. d) During the 1930s, use of beryllium in production of fluorescent lamps was a major source of pollution. NATURAL ABUNDANCE: Beryllium makes up a small portion of the earth's crust (10 ppm) or 0.006%.	1) a) Use of conventional air cleaning devices: scrubbers, venturi scrubbers packed towers, organic wet collectors, wet cyclones. b) For dry processes; conventional bag collectors, reverse-jet bag collectors, electrostatic precipitators, cyclones, unit filters. 2) Discontinuance of the use of beryllium in fluorescent lamp tubes.
h. CHROMIUM: Chromium is a lustrous brittle metallic element usually occurring in compound form with other elements. Most of the chromium ore produced is used in the production of stainless and austenite steels. Chromium (Cr) is commonly known for its use as a decorative finish in chrome plating.	*Major Sources*: Chromium concentrations in urban air average 0.015 $\mu g/m^3$ and range as high as O. 3SO $\mu g/m^3$. Although a complete inventory of sources of ambient chromium has not been made some possible sources are metallurgical industry, chromate-producing industry, chrome plating, the burning of coal, and the use of chromium chemicals as fuel additives, corrosion inhibitors, pigments, tanning agents, etc. *Natural occurrence*: Elemental chromium is not found in nature. The only important commercial chromium mineral is chromite ($FeOCr_2O_3$) which is also never found in the pure form. Most soils and rocks contain small amounts of chromium usually as chromic oxide (Cr_2O_3). The continental crust averages 0.037% by weight, of chromium. In addition, most animal and plant tissues contain small amounts of chromium.	Chromium air pollution usually occurs as particulate emissions, which may be controlled by the usual dust-handling equipment, such as bag filters, precipitators, and scrubbers. *Chrome-plating facilities*: Moisture-extractor vanes in hood-duct systems have been used to break up bubbles in the exhaust gases. *Mist emissions*: Mist emissions from a decorative-chrome plating tank with problems can be substantially eliminated by adding a suitable surface-active agent to the plating solution.

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
i. IRON: A ductile, malleable silver-white metallic element, scarcely known in a pure condition, but abundantly used in its crude or impure forms containing carbon. Although inhalation of iron oxide is believed to cause a benign pneumoconiosis, there is growing concern about its synergistic effects with sulfur dioxide and carcinogens. Iron particulates may also act to reduce visibility.	*Major sources*: Iron and steel industry, sintering plant, blast furnaces, gray iron cupolas (used to melt gray iron), fuel sources (coal and oil), and incineration. *Natural occurrence*: Iron abounds in nature and is an essential element for both animals and plants. The iron content of the earth's crust has been calculated at 5.6%.	Control of emissions from the iron and steel industry is being accomplished through improvements in steel processing. Dust removal is accomplished by high-efficiency electrostatic precipitators, venturi type scrubbers, or filters.
j. MANGANESE: A hard, brittle grayish-white metallic element whose oxide (MnO_2) is a valuable oxidizing agent, used as alloying agent in steel to give it toughness. Although manganese (Mn) is one	*Major sources*: Air pollution by manganese arises almost entirely from the manganese and steel industries. Fumes from welding rods and organic manganese compounds may also contribute to	Control of manganese from furnaces is accomplished by various types of collectors, including electrostatic

Part 1. Pollutant Emissions (*continued*)

Pollutant types	Sources and abundance	Abatement and control
of the elements essential to the human body, a high atmospheric concentration may result in poisoning and disease of several types.	air pollution. The organic compounds that have been tested as additives in gasoline, fuel oil, and diesel oil for use in both internal combustion engines and turbine engines may become an increasingly important source of pollution. *Natural occurrence*: Manganese is widely distributed in the combined state, ranking 12th in abundance (100 μg/m^3) among the elements in the earth's crust. Almost all of the manganese in the atmosphere enters as manganese oxides, such as MnO, Mn_3O_3 or Mn_3O_4.	precipitators, high-efficiency scrubbers, and fabric filters.
k. ZINC: A bluish-white metallic element occurring combined as the sulfide, oxide, carbonate, silicate etc. resembling magnesium in its chemical reactions. Although zinc is an essential element of the human and animal body, zinc and its compounds have been found to be toxic under certain conditions.	*Natural occurrence*: Zinc, widely distributed in the earth's crust, occurs in small quantities in almost all igneous rocks. The primary sources of emissions of zinc compounds into the atmosphere are zinc, lead, and copper smelting operations, secondary processing to recover scrap zinc, and possibly the incineration of zinc-bearing materials. Zinc oxide fumes are the zinc compounds most commonly emitted from these sources.	*Zinc gores*—can be collected by electrostatic (rod-curtain-type) precipitates and then further treated in cyclone scrubbers. *Zinc particles*—can be collected by use of electrostatic precipitators, a central cloth-bag collector system, or soil efficient filtering device.
l. BARIUM: A silvery white malleable, active, divalent, metallic element occurring in combination chiefly as barite. Inhalation of barium compounds can cause Baritosis a non-malignant lung disease. Characterized by fibrous hardening.	*Major sources are*: (1) Industrial process involved in mining, refining and production of barium and barium-based chemicals. 2) Use of barium compounds as a fuel additive for the reduction of black smoke emissions from diesel engines. (This is accomplished by the production in vehicle exhaust of micron-sized particles which have minimal effects on visibility.) Concentration of about 0.075 per cent *barium* by weight of additive is most effectively used. *Natural abundance*: Barium frequently appears as gangne in lead and zinc ore deposits. The two main minerals are barite (barium sulfate, $BaSO_4$) and witherite (barium carbonate, $BaCO_3$).	The conventional methods for removal of barium are the same as those for solids, and include bag filters, electrostatic precipitators, and wet scrubbers.

Part 2. Major Air Pollution Sources

Chemicals manufacturing industry	Nature of activity	Type of air pollution problems
ADIPIC ACID	Adipic Acid, COOH × $(CH_2)_4$ × COOH, is a dibasic acid used in the manufacture of synthetic fibers. Adipic acid is produced by the oxidation of cyclohexane by air over a catalyst and then purified by crystallization.	Emissions: The only significant emissions from the manufacture of adipic acid are nitrogen oxides. In oxidizing the cyclohexanol, nitric acid is reduced to nonrecoverable N_2O and potentially recoverable NO and NO_2 emitted into the atmosphere.
AMMONIA	The manufacture of ammonia (NH_3) is accomplished primarily by the catalytic reaction of hydrogen and nitrogen at high temperatures and pressures.	Emissions: Range from CO, HC, to NH_3 gases. Wet scrubbers and water can be utilized to reduce the atmospheric emissions.
CARBON BLACK	Carbon black is produced by reacting a hydrocarbon fuel such as oil and/or gas with a limited supply of air at temperatures of 2500–3000°F. Part of the fuel is burned to CO_2, CO and water, thus generating heat for combustion of fresh feed. The unburnt carbon is collected as a black fluffy particle.	Emissions: A high percentage of the emissions are carbon monoxide and hydrocarbons. The particulate and hydrogen sulfide problem are not as prevalent but do occur at amounts warranting attention. NO_2 emissions are relatively low due to the lack of available oxygen in the reaction.

Part 2. Major Air Pollution Sources (*continued*)

Chemicals manufacturing industry	Nature of activity	Type of air pollution problems
CHARCOAL	Charcoal is generally manufactured by means of pyrolysis, or destructive distillation of wood waste from members of the deciduous hardwood species. Four tons of hardwood are required to produce one ton of charcoal. In the pyrolysis of wood, all the gases, tars, oils, acids, and water are driven off leaving virtually pure carbon.	During pyrolysis of wood, carbon monoxide, hydrocarbons, particulate crude methanol, and acetic acid are emitted into the atmosphere. Some of these gases can be recovered by utilizing a chemical recovery plant.
CHLOR-ALKALI	Chlorine and caustic are produced concurrently by the electrolysis of brine in either the diaphragm or mercury cell.	Emissions from diaphragm and mercury cell chlorine plants include chlorine gas, carbon dioxide, carbon monoxide, and hydrogen. Other emissions include mercury vapor, chlorine, wet scrubbers (alkaline) can be utilized for emission reduction.
EXPLOSIVES	An explosive is a material which, under the influence of thermal or mechanical shock, decomposes rapidly and spontaneously with the evolution of large amounts of heat and gas.	Emissions: Sulfur oxides and nitrogen oxides emissions from processes which produce some of the raw materials for explosives production can be considerable.
HYDROCHLORIC ACID	Hydrochloric acid is manufactured by a number of different chemical processes. Approximately 80% of the hydrochloric acid is produced by the by-product hydrogen chloride process. By-product hydrogen chloride is produced when chloride is added to an organic compound such as benzene, toulene, and vinyl chloride.	The recovery of the hydrogen chloride from the chlorination of an organic compound is the major source of hydrogen chloride emissions. The exit gas from the absorption or scrubbing system is the actual source of the hydrogen chloride emitted.
HYDROFLUORIC ACID	All hydrofluoric acid in the United States is currently produced by reacting acid grade fluorspar with sulfuric acid for 30–60 minutes in externally fired rotary kilns at a temperature of 400–500°F.	The exist gases from the final absorber contain small amounts of HF, silicon tetrafluoride (SiF_4), CO_2, and SO_4 and may be scrubbed with a caustic solution to further reduce emissions. Dust emissions may also result from raw fluorspar grinding and drying operations.
NITRIC ACID	The ammonia oxidation process (AOP) is the principal method of producing commercial nitric acid. It involves high temperature oxidation of ammonia with air over a platinum catalyst from nitric oxide. The nitric oxide air mixture is cooled, and additional air water added to produced nitric acid.	The main source of atmosphere emissions from the manufacture of nitric acid is the tail gas from the absorption tower, which contains unabsorbed nitrogen oxides. These oxides are largely in the form of nitric oxide and nitrogen dioxide.
PAINT AND VARNISH	The manufacture of paint involves the dispersion of a colored oil or pigment in a vehicle, usually an oil or resin, followed by the addition of an organic solvent for viscosity adjustment.	Particulate emissions amount to 0.5 to 1% of the pigment handled; 1 to 2% of the solvent are lost. Hydrocarbons are the pollutant of primary concern.
PHOSPHORIC ACID	Phosphoric acid is produced by two principal methods, the wet process and the thermal process. In the wet process finely-ground phosphate rock is fed into a reactor with sulfuric acid to form phosphoric acid and gypsum. In the thermal process phosphate rock, siliceous flux, and coke are vaporized and placed in contact with water to produce phosphoric acid.	Emissions from the wet process are primarily gas fluorides, consisting mostly of silicon tetrafluoride and hydrogen fluoride. The principal emissions from the thermal process acid are P_2O_2 acid and acid mist. Particulates are also emitted in fairly large quantities.
PHTHALIC ANHYDRIDE	Phthalic anhydride is produced primarily by oxidizing naphthaline vapors with excess air over a catalyst, usually V_2O_5. The phthalic anhydride is then purified by a chemical soak in the sulfuric acid.	The major source of emissions is the excess air from the production system which contains some uncondensed phthalic anhydride, maleic anhydride, quinines, and other organics.
PLASTICS	The manufacture of most resins or plastics begins with the polymerization or linking of the basis compound (monomer) usually a gas or liquid, into high molecular weight noncrystalline solids.	The air contamination from plastics manufacturing are the emissions of raw material or monomer, emissions of solvents or other volatile liquids during the reaction, emissions of sublimed solids such as phthalic anhydride in alkyd production, and emissions of solvents during storage and handling of thinned resins.

(*continued*)

Part 2. Major Air Pollution Sources (*continued*)

Chemicals manufacturing industry	Nature of activity	Type of air pollution problems
PRINTING INK	Printing ink is produced by adding dyes to water and then flushing it with an ink vehicle.	Particulate emissions result from the addition of pigments to the vehicle while gases like terpenses, carbon dioxide, and aldehydes are emitted into the atmosphere, during the preliminary stages of ink production.
SOAP AND DETERGENTS	Soap is manufactured by the catalytic hydrolysis of various fatty acids with sodium or potassium hydroxide to form a glycerol-soap mixture. This mixture is separated by distillation, neutralized and blended to produce soap. In the manufacture of detergents, a fatty alcohol is sulfated, neutralized, and then sprayed dry to obtain the product.	The main atmospheric pollution problem in the manufacture of soap is odor from the spray drying operation, storage of mixing tanks and particulate emissions from the spray drying tower.
CHEMICAL INDUSTRY SODIUM CARBONATE	The Solvay process is used to manufacture over 80% of all soda ash. In this process, the basic raw materials of ammonia, cake, lime-stone (calcium carbonate) and salt (sodium chloride) are purified inabsorbent using ammonia and CO$_2$, to produce sodium bicarbonate as a by-product.	The major emissions from the manufacture of soda ash is ammonia. Small amounts of ammonia are emitted in the vent gases from the brine purification system. Traces of particulate emissions can result from rotary drying, dry solids handling and processing of lime.
SULFURIC ACID	The contact process is responsible for producing 90% of all the sulfuric acid in the United States. In this process sulfuric acid is produced from the contact of SO$_2$ and SO$_3$ with water.	The waste gas contains unreacted sulfur dioxide, unabsorbent sulfur trioxide, as well as sulfuric acid mist and spray. When the waste gas reaches the atmosphere, sulfur trioxide is converted to acid mist.

Food and agricultural industry	Nature of activity	Type of air pollution problems
	This section deals with the manufacture of food and agricultured products and the intermediate steps which present an air pollution problem.	
ALFALFA DEHYDRATING	An alfalfa dehydrating plant produces an animal feed from alfalfa. The dehydrating and grinding of alfalfa constitute the bulk of the manufacturing process of alfalfa meal. It is a very dusty operation most commonly carried out in rural areas.	Sources of dust emissions are the primary cyclone, grinders and air-meal separators. Overall dust loss has been reported as high as 7% by weight of the meal produced. The use of a bag house as a secondary collection system can greatly reduce emissions.
COFFEE ROASTING	Coffee, which is imported in the form of green beans, must be cleaned, blended, roasted and packaged before being sold.	Dust, chaff, coffeebean oils (as mists), smoke, and odors are the principal air contaminants emitted from coffee processing. The major source of particulate emissions and practically the only source of aldehydes, nitrogen oxides and organic acids is the roasting process.
COTTON GINNING	In separating the seed from the lint in raw seed cotton, a large amount of trash is left over. From one ton of cotton approximately one 500 pound bale of cotton can be made, the rest is discarded as trash.	The major sources of particulates from cotton ginning are the unloading fan, the cleaner and the stick and bur machine. When cyclone collectors are used emissions have been reported to be about 90% less.
FEED AND GRAIN MILLS AND ELEVATORS	Grain elevators are primarily transfer and storage units of various sizes. At grain elevator locations the following might occur: recewing, transfer and storages, cleaning, drying and milling or grinding.	Almost all emissions emanating from grain mills are dust particulates (minute grain particulates). The emissions from grain elevator operations are dependent on the type of grain, the moisture content of the grain, amount of foreign material, and the loading and unloading areas.
FERMENTATION	Fermentation occurs when various organisms (as molds, yeast, certain bacteria, etc.) agitate or excite substances into another form. The fermentation industries include the food, beer, whiskey, and wine categories.	Emissions from fermentation process are nearly all gases and primarily consist of carbon dioxide, hydrogen, oxygen, and water vapor, none of which present an air pollution problem. However, particulate emissions can occur in handling of the grain used as raw material, while gaseous hydrocarbons can be emitted during the drying of spent grains.
FISH PROCESSING	The canning, dehydrating, smoking of fish, and the manufacture of fish oil are the important segments of fish processing.	The biggest problem from fish processing is emissions of odors such as hydrogen sulfide and trimethylamine. Some of the methods used to control odors include activated carbon adsorbers, scrubbing with some oxidizing solution and incineration.

Part 2. Major Air Pollution Sources (*continued*)

Food and agricultural industry	Nature of activity	Type of air pollution problems
MEAT SMOKEHOUSES	Smoking is a diffusion process in which food products are exposed to atmosphere of hardwood smoke, causing various organic compounds to be absorbed by the food.	Emissions from smokehouses are generated from the burning hardwood, and included particulates, carbon monoxide, hydrocarbons (CH_4), aldehydes (HCH) and organic acids (acetic).
NITRATE FERTILIZERS	Nitrate fertilizers are the product of the reaction of nitric acid and ammonia to form ammonia nitrate solution or granules.	The main emissions from the manufacture of nitrate fertilizers are the ammonia and nitric oxides lost in the neutralization and drying operation.
PHOSPHATE FERTILIZERS	Nearly all phosphate fertilizers are made from naturally occurring phosphorous-containing minerals such as phosphate rock. The phosphorous content of these minerals is not in a form that is readily available to growing plants so that the minerals must be treated to convert the phosphorous to a plant-available form.	Emissions from manufacturing phosphate fertilizers include vent gases containing particulates ammonia, silicon tetrafluoride, carbon dioxide, steam and sulfur oxides. The sulfur oxides emissions arise from the reaction of phosphate rock and sulfuric acid.
STARCH MANUFACTURING	Starch is obtained through the separation of coarse starch in corn to a fine dry powder form ready for marketing.	The manufacture of starch from corn can result in significant dust emissions from cleaning, grinding, and screening operations.
SUGAR CANE PROCESSING	The processing of sugar cane starts with harvesting crops, then through a series of processes (washing, crushing, milling, diffusing) into the final sugar product.	The largest sources of emissions from sugar cane processing are the open burning in the harvesting of the crop and the burning of bagasse as fuel. Emissions include particulates, CO usually large, HC and nitrogen oxides.

Wood processing industry	Nature of activity	Type of air pollution problems
WOOD PULPING INDUSTRY	Wood pulping involves the production of cellulose from wood by dissolving the lignin that binds the cellulose fiber together. The three major chemical processes for pulp production are the kraft or sulfate process, the sulfite process and the neutral sulfite semi chemical process. The kraft process involves cooking wood chips in sodium sulfide and sodium hydroxide to dissolve the lignin. The excess pulp and impurities are washed away and the remaining clean pulp pressed and dried into the finished product.	Particulate emissions from the kraft process occur primarily from the recovery furnace, the lime kiln and smelt dissolving tank. This characteristic kraft mill odor is principally due to the presence of a variable mixture of hydrogen sulfide and dimethyl disulfide. Some sulfur dioxide emissions result from the oxidation of the sulfur compounds. CO emissions may occur from the recovery furnaces and klins.
PULPBOARD	Pulpboard manufacturing includes the manufacture of fibrous boards from a pulp slurry. After the pulp is washed, it is entered into a board machine and subsequently, dried and ready for fabrication.	Emissions from the paper board machine consist of only water vapor. Little or no particulates are emitted from the dryers.

METALLURGICAL INDUSTRY

The metallurgical industries can be broadly divided into primary and secondary metal production operations. Primary metal industry includes the production of the metal from ore; among these industries are the nonferrous operations involved in aluminum ore reduction, copper smelters, lead smelters, zinc smelters, iron and steel mills, ferro alloys and metallurgical coke manufacture. The secondary metals industry includes the recovery of the metal from scrap and salvage, the production of alloys from ingot, secondary aluminum operations, gray iron foundries, lead smelting, magnesium smelting, steel foundries, and zinc processing.

Metals industry	Nature of activity	Type of air pollution problems
ALUMINUM ORE REDUCTION	Bauxite, a hydrated oxide of aluminum associated with silicon, titanium, and iron, is the base ore for aluminum production. After preliminary purification using the (Boyer) process, the new oxide (Al_2O_3) is reduced in the Hall-Heroult process and pure aluminum is produced. Four tons of bauxite are required to make 1 ton of aluminum.	During the reduction process, the effluent released contains fluorides particulate and gaseous hydrogen fluoride. Particulate matter such as aluminum and carbon from the anodes are also emitted.

(*continued*)

Part 2. Major Air Pollution Sources (*continued*)

Metals industry	Nature of activity	Type of air pollution problems
METALLURGICAL COKE MANUFACTURE	Coking is the process of heating coal in an atmosphere of low oxygen content, i.e., destructive distillation. During the process organic compounds in the coal break down to yield gases and a relatively non-volatile residue.	Visible smoke, hydrocarbons, carbon monoxide, sulfur dioxide, nitrogen oxide and ammonia originate from by-product coking operations.
COPPER SMELTERS	Copper is produced primarily from low-grade sulfide ores, which are concentrated by gravity and subjected to melting and purifying procedures.	The raw waste gases from the process contain significant amounts of dust and sulfur oxides.
FERRO ALLOY PRODUCTION	Ferro alloys is the generic term for alloys consisting of iron and one or more other metals. The major method used to produce ferro alloy for steel making is the electric furnace process. In this process suitable oxides are reduced to the appropriate metals.	Most of the emissions of carbon monoxide and particulates (dust) are a direct result of the electric furnace, which uses carbon as the reducing agent.
BRASS AND BRONZE INGOTS (COPPER ALLOYS)	Obsolete domestic and industrial copper-bearing scrap is the basic raw material of the brass and bronze ingot industry. The ingots are produced from a number of different furnaces through a combination of melting, smelting, refining, and alloying of the process scrap materials.	The exit gas from the furnaces may contain fly ash, soot and smoke and some zinc oxides. Other particulate emissions include the preparation of raw materials and the pouring of ingots.
GRAY IRON FOUNDRY	The major type of furnace used to produce gray iron castings is the cupola, which uses an extremely hot bed of coke to melt the iron.	Emissions from cupola furnaces include CO dust and fumes, smoke, and all vapors.
SECONDARY LEAD SMELTING	Furnaces similar to the ones mentioned above are used to melt impure leaded scraps into desirable products (hard-lead, semi-soft lead, and pure lead).	The primary emissions from lead smelting are particulates, lead oxides, and carbon monoxides.
SECONDARY MAGNESIUM SMELTING	Magnesium smelting is carried out in crucible or pot type furnaces charged with magnesium scraps, melted and poured into perspective molds.	Emissions from magnesium smelting include particulate magnesium (MgO), oxides of nitrogen, sulfur dioxide and chloride gases.
IRON AND STEEL MILLS	To make steel, iron ore is reduced to pig iron, and some of its impurities are removed in a blast furnace. The pig iron is further purified in other processes (open hearth, Bessemer converters, basic oxygen furnaces, or electric furnaces).	Particulates and carbon monoxide are the major pollutant emissions resulting from the various furnace reactions.
LEAD SMELTERS	The ore from primary lead produced contains both lead and zinc. After melting, the metals are concentrated.	Effluent gases from the various concentrating processes include considerable particulate matter and sulfur dioxide.
ZINC SMELTERS	Most domestic zinc comes from zinc and lead ores. Another important source of raw material for zinc metal has been zinc oxide from fuming furnaces, the roasted are electrolytically purified.	Dust, fumes, and sulfur dioxide are evolved from zinc concentrate roasting.
SECONDARY ALUMINUM OPERATIONS	Secondary aluminum operations involve making lightweight metal alloys for industrial castings and ingots. Copper, magnesium, and silicon are the most common alloying constituents.	Emissions from secondary aluminum operations include fine particulate matter and small quantities of gaseous chlorides and fluorides.
STEEL FOUNDRIES	Steel foundries produce steel castings by melting steel metal and pouring it into molds. The basic melting process operations are furnace charging, melting, tapping the furnace into a ladle and pouring the steel into molds.	Particulate emissions from steel foundry operations include iron oxide fumes, sand fires, graphite and metal dust. Gaseous emissions from foundry operations include oxide of nitrogen, oxides of sulfur, and hydrocarbons.
SECONDARY ZINC PROCESSING	Zinc processing includes zinc reclaiming (separation of zinc from the scrap), zinc oxide manufacturing (distilling metallic zinc into dry air stream), and zinc galvanizing (flux cover over zinc).	A potential for particulate emissions, mainly zinc oxide, occur, if the temperature of the furnaces is very high (100°F). Small quantities of ammonia chloride, nitrogen oxides, and carbon monoxides are also emitted into the atmosphere.

Part 2. Major Air Pollution Sources (*continued*)

Mineral products industry	Nature of activity	Type of air pollution problems
	This section involves the processing and production of various minerals. Mineral processing is characterized by particulate emissions in the form of dust. However, most of the emissions from the manufacturing process conventional in this section can be reduced by conventional particulate control equipment such as cyclones, scrubbers, and fabric filters.	
ASPHALT BATCH PLANTS	Hot-mix asphalt paving consists of a combination of aggregates, coarse or fine, uniformly mixed and coated with asphalt cement. The coarse aggregates are usually crushed stone, crushed slag or crushed gravel, while the fine aggregates are usually natural sand and finely crushed stones.	The largest pollutant type is dust, emanating from the rotary dryers and filtering systems, normally used in producing asphalt.
ASPHALT ROOFING	The manufacture of asphalt roofing felts and shingles involves saturating a fiber media with asphalt by means of dipping and/or spraying.	The major pollutants are particulate emissions from asphalt roofing plants during the asphalt blowing operations and the felt saturation. Common methods of control at asphalt saturation plants include complete enclosure of the spray area and saturation followed by good ventilation through one or more collection devices. Some traces of carbon monoxide and hydrocarbons are also present in the emissions from this asphalt process.
BRICKS AND RELATED CLAY PRODUCTS	The manufacture of brick and related products such as clay pipe, pottery and some types of refraction brick involves the grinding, screening, blending of the raw materials, forming, drying or curing, firing and ferial cutting or shaping.	Particulate emissions similar to those obtained in clay processing are emitted from the materials handling process in refractory and brick manufacturing. Gaseous fluorides and nitrogen oxides are also emitted from brick manufacturing operations.
CALCIUM CARBIDE	Calcium carbide is manufactured by heating a mixture of quick-lime (CaO) and carbon in an electric arc furnace when the lime is reduced by the coke to calcium carbide and carbon monoxide. About 1990 pounds of lime and 1300 pounds of coke yield 1 ton of calcium carbide.	Particulates, acetylena, sulfur compounds and some carbon monoxide are emitted from calcium carbide plants.
CASTABLE REFRACTORIES	Castable or fused-cast refraction are manufactured by carefully blending such components as alumina, zirconia, silica, chrome, and magnesium, melting the mixture, pouring into molds, and slowly cooling to the solid state.	Particulate emissions occur from drying, crushing and handling procedures while gaseous fluoride occurs during melting operations.
PORTLAND CEMENT MANUFACTURING	Lime (calcareous), silica (siliceous), alumina (argillaceous) and iron (ferriferous) are the four major components used to manufacture cement. The various substances are crushed in exact proportions, fired in a klin, and then ground in gypsum to be bagged for shipment as cement.	Particulate matter is the primary emission in the manufacture of portland cement and is emitted primarily from crushing operations and rotary kilns. Control systems usually include multicyclones, electrostatic precipitators or combinations of these types of control.
CERAMIC CLAY MANUFACTURE	The manufacture of ceramic clay involves the conditioning of the basic ores, coolinate and mont-morillonite (aluminous-silicate materials), into dry clay products.	Emissions consist primarily of particulates, but some fluorides and acid gases are also emitted in the drying process.
CLAY AND FLY ASH SINTERING	Both the sintering clay and fly ash involve the firing and burning off of residual matter to desirable product. In fly ash, carbon is burned off while in clay, entrained volatile matter is driven off.	Dust is the major pollutant emitted from the screening and sintering process.
COAL CLEANING	Coal cleaning is the process by which undesirable materials are removed from both	Particulates in the form of coal dust constitute the major air pollution problem from coal clearing plants.

(*continued*)

Part 2. Major Air Pollution Sources (*continued*)

Mineral products industry	Nature of activity	Type of air pollution problems
	bituminous and authorite coal. The coal is screened, classified, washed and dried at coal preparation plants.	
CONCRETE BATCHING	Concrete batching involves the proportioning of sand, gravel, cement, and water by means of weight hoppers and conveyors into a mixing receiver.	Particulate emissions consist primarily of cement dust, but some sand and aggregate dust emissions do occur during batching operations.
FIBERGLASS MANUFACTURING	Fiberglass manufactured by melting various raw materials to form glass, drawing the molten glass into fibers, and coating the fibers with an organic material.	The major emissions from fiberglass manufacturing processes are particulates from the glass melting furnace and the product coaling line.
FRIT MANUFACTURING	Raw materials such as borax, feldspar, sodium fluoride and soda ash are melted and then quenched with water to produce shattered small glass particles—called frit. The frit particles are then ground into fine particles used in enameling iron and steel or in glazing porcelain or pottery.	The major emissions from frit-smelting operations are dust and fumes (usually condensed metallic oxide fumes) from the molten charge. A small quantity of hydrogen fluoride also can be detected in the emissions.
GLASS MANUFACTURE	Nearly all glass produced commercially is either soda-lime, lead, fused silica, borasilicate, or 96% silicate. Soda lime glass, being of the largest type, is produced on a massive scale in large, direct fired, continuous melting furnaces in which the blended raw materials are melted at 2700 to form glass.	Emissions from the glass melting operation consist primarily of particulate (only a few microns in diameter) and fluorides, if fluoride-containing fluxes are used in the process.
GYPSUM	Gypsum or hydrated calcium sulfate is a naturally occurring mineral which hardens when in contact with water to form a solid crystalline hydrate. Gypsum is an important building material, and if it loses its water of hydration, becomes plaster of paris.	Gypsum rock dust and partially calcined gypsum dust are emitted into the atmosphere from the grinding and mixing of the gypsum material.
LIME MANUFACTURING	Lime (CaO) is the high temperature product of the calcination of limestone ($CaCO_3$). Lime is manufactured in vertical or rotary kilns fired by coal, oil, or natural gas.	Atmospheric emissions in the lime manufacturing industry include the particulate emissions from the mining, handling, crushing, screening, and calcining of the limestone and the combustion products from the kiln.
MINERAL WOOL	The product mineral wool is made by firing charge material (slag wool and rock wool) in a furnace with silica rock and coke, into long fibrons tails for a “blanket” of wool.	Gases such as sulfur oxides and fluorides are major emissions from cupolas or furnace stacks. Minor particulate emissions are found in existing fumes.
PERLITE MANUFACTURE	Perlite is a glassy, volcanic rock consisting of oxides of silicon and aluminum combined as a natural glass by water of hydration. By a process called exfolication, the material is slowly heated to release water of hydration and thus expand the spherules into low-density particles used primarily as aggregate in plaster and concrete.	A fine dust is emitted from the outlet of the last product collector in a perlite expansion plant. In order to achieve complete control of these particulate emissions a bag-house is needed.
PHOSPHATE ROCK PROCESSING	Phosphate rock preparation involves the benefication to remove impurities, drying to remove moisture, and grinding to improve reactivity.	Emissions in the form of fine rock dust may be expected from drying and grinding operations.
SYNTHETIC FIBERS	Synthetic fibers are classified into two major categories—semi-synthetic, or “True synthetic.” Semi-synthetics, such as viscose rayon and acetate fibers, result when natural polymeric materials such as cellulose are brought into a dissolved or dispersed state and then spun into fine filaments. True synthetic polymers, such as nylon, orlon and dacron result from addition and polymerization reaction to form long chain molecules.	In the manufacture of viscose, rayon, carbon disulfide are the major gaseous emissions. Some examples of minor pollutants emitted from the drying of the finished fiber are hydrocarbons and oil vapor (mist).

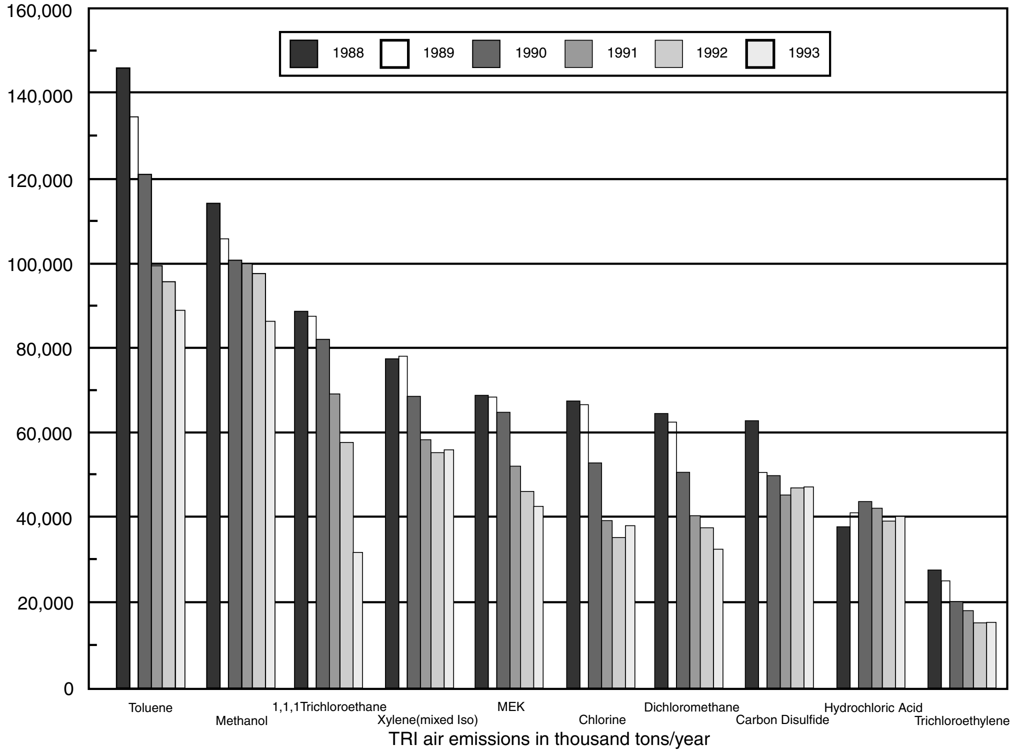

FIGURE 4 Top 10 Hazardous Air Pollutants—1988 Basis.

Part 2. Major Air Pollution Sources (*continued*)

Mineral products industry	Nature of activity	Type of air pollution problems
TEREPHTHALIC ACID	Terephthalic acid is an intermediate in the production of polyethylene terephthalate, which is used in polyester films and other miscellaneous products and by oxidizing paraxylene by nitric acid.	The NO in the off gas from the reactor is the major air contaminant from the manufacture of terephthalic acid.
STONE QUARRYING AND PROCESSING	Rock and gravel products are looosened by drilling and blasting from their deposit beds and removed with the use of heavy equipment. Further processing includes crushing, regrinding, and removal of fines.	Dust emissions occur from many operations in stone quarrying and processing.
Petroleum industry	Nature of activity	Type of air pollution problems
PETROLEUM REFINING	The operations of a petroleum refinery can be divided into four major steps: separation, conversion, treating, and blending. The crude oil is first separated into selected fractions (e.g., gasoline, kerosine, fuel oil, etc.). Some of the less valuable products such as heavy naphtha, are converted to products with a greater sale value such as gasoline. This is done by splitting, uniting, or rearranging the original molecules. The final step is the blending of the refined base stocks with each other and various additives to meet final product specifications.	The major pollutants emitted are sulfur oxides, nitrogen oxides, hydrocarbons, carbon monoxide and malodorons materials. Other emissions of lesser importance include particulates, aldehydes, ammonia, and organic acids. Most of the above mentioned emissions come from boiling process heaters, and catalytic cracking unit regenerators.

Table 19 shows trends of estimated emissions of criteria pollutants from 1970 through 2003. (note: VOCs are precursors to ozone, a criteria pollutant).

Source: http://www.epa.gov/airtrends/econ-emissions.html

Notes:

1. In 1985 and 1996 EPA refined its methods for estimating emissions. Between 1970 and 1975, EPA revised its methods for estimating particulate matter emissions.
2. The estimates for 2003 are preliminary.
3. NO_x estimates prior to 1990 include emissions from fires. Fires would represent a small percentage of the NO_x emissions.
4. PM estimates do not include condensable PM, or the majority of PM2.5 that is formed in the atmosphere from "precursor" gases such as SO_2 and NO_x.
5. EPA has not estimated PM2.5 emissions prior to 1990.
6. The 1999 estimate for lead is used to represent 2000 and 2003 because lead estimates do not exist for these years.
7. PM2.5 emissions are not added when calculating the total because they are included in the PM10 estimate.

AIR POLLUTION SOURCES: see ATMOSPHERIC CHEMISTRY, GREENHOUSE GASES EFFECTS

AQUATIC PRIMARY PRODUCTION

Primary productivity in aquatic systems, like the same process in terrestrial environments, provides the base of the food web upon which all higher levels of an ecosystem depend. Biological productivity is the increase in organic material per unit of area or volume with time. This addition of organic matter is the material from which the various plant and animal communities of an ecosystem are made, and is dependent on the conversion of inorganic matter into organic matter. Conversion is accomplished by plants through the photosynthetic process. Plants are therefore considered to be the *primary producers*, and in an aquatic ecosystem these plants include algae, bacteria, and sometimes higher plants such as water grasses and water lilies. *Primary productivity*, the first level of productivity in a system, can be measured as the rate of photosynthesis, addition of biomass per unit of time (yield), or indirectly by nutrient loss or a measure of respiration of the aquatic community.

METHODS OF STUDY

Standing crop refers to the part of biological production per unit area or per unit volume that is physically present as biomass and that is not lost in respiration. Standing crop measurements over a period of time give an indirect measure of productivity in terms of yield. Plankton, microscopic floating plants and animals, can be collected in a plankton net and may be counted under a microscope or weighed. Aquatic biologists have used standing crop measurements to estimate productivity longer than any other method (e.g. Lohman, 1908). This method is still also used for periphyton (attached algae) or rooted plants.

Only within the past few decades have biologists progressed from merely counting numbers of organisms to calculating biomass, and more recently, to expressing biomass *yield.* Fishery biologists, like farmers, for many years have measured fish productivity in terms of tons produced per acre of water surface per year. Calculating biomass and biomass yield is an important step forward since changes in standing crop reflect the net effect of many biological and physical events and therefore are not directly proportional to productivity. For example, the standing crop of a phytoplankton community may be greatly diminished by predation and water movement, while photosynthetic rates of the survivors may remain high.

The measurement of plant pigments such as chlorophyll *a* is also a standing crop measurement that is frequently used and may now be done through remote sensing by aircraft or satellites.

UPTAKE OF NUTRIENTS

Another early attempt at measuring the rate of production in aquatic ecosystems was to measure the inorganic nutrients taken up in a given system and to calculate the amount of biological production required to absorb this amount. Atkins (1922, 1923) studied the decrease in carbon dioxide and phosphate in measuring production in the North Sea, and Steel (1956), also working in the North Sea, estimated the annual cycle of plant production by considering changes in the inorganic phosphate in relation to vertical mixing of the water mass. Many biologists consider phosphorus to be a difficult element to study in this respect because organisms often store it in excess of their requirements for optimum growth.

Measuring nutrient uptake in an indirect method of determining the rate of productivity in an aquatic ecosystem and is influenced by various other biological activities. Nevertheless, it has been important in the development toward more precise measurements of the dynamic aquatic ecosystem.

MEASUREMENTS OF OXYGEN AND CARBON DIOXIDE

The net rate at which the phytoplankton community of a given ecosystem incorporates carbon dioxide may be estimated in moderately to highly productive aquatic environments by direct measurement of the short-term fluctuations in the dissolved oxygen it produces. The calculations are based on the assumption that a mole of oxygen is released into the environment for each mole of carbon dioxide reduced in photosynthesis. This method precludes the necessity of enclosing the phytoplankton in a bottle. If measurements are made at regular hourly intervals over a 24-hour period, the average hourly decrease in oxygen during times of darkness when no photosynthesis is occurring can be determined. It is assumed that respiration removes this amount of oxygen each hour throughout the day thus giving a measure of the gross rate at which the community incorporates carbon dioxide.

An analogous method exists for recording fluctuations in carbon dioxide.

The pH meter, which measures acidity, has been successfully employed to measure these carbon dioxide changes in the aquatic ecosystem since the removal of carbon dioxide from the water for photosynthesis is accompanied by a proportional rise in pH. This pH shift has been used to estimate both photosynthesis and respiration. The sea and some fresh waters are too buffered against changes in pH to make this method useful in all environments, but it has been employed with success in lakes and for continuously monitoring the growth of cultures. Carbon dioxide may also be directly measured by standard volumetric or gasometric techniques.

Although carbon dioxide and oxygen can be measured with relative precision, the overall precision of productivity measurements made by these techniques is not generally great because of uncertainties in the corrections for diffusion, water movements, or extended enclosure time. Some of the oxygen produced by higher aquatic plants may not be immediately released thus causing a lag period in the evolution of oxygen into the environment. The primary advantage this method has over the more sensitive ^{14}C method is the added benefit of an estimate of community respiration.

Some of the uncertainties of the previous method can be reduced by enclosing phytoplankton samples just long enough in glass bottles for measurable changes in the concentration of oxygen and carbon dioxide to occur, but not long enough for depletion of nutrients or the growth of bacteria on the inside bottle surface. This method is called the *light and dark bottle* method. The name is derived from the fact that identical samples are placed in a transparent "light bottle" and an opaque "dark bottle." Gross and net productivity of the plankton community from which the samples were taken can be estimated by calculating the difference in the oxygen content between the two bottles after a predetermined period of incubation and with that present initially.

Productivity determinations that are dependent on measurements of oxygen are based on some estimated photosynthetic quotient (moles O_2 liberated/moles CO_2 incorporated). For the photosynthesis of carbohydrates the ratio is unity. For the synthesis of an algal cell, however, the expected ratio is higher, and presumably varies with the physiological state of the algae and the nutrients available.

Oxygen methods in general have rather poor sensitivity and are of no use if the gross incorporation of inorganic carbon during the test period is less than about 20 mg of carbon per cubic meter. Several days may be required in many of the less productive aquatic environments for this much photosynthesis to occur and bacteria may develop on the insides of the container during this time, invalidating the results.

Photosynthetic rates can be measured in light and dark bottles also by determining the amount of carbon fixed in particulate form after a short incubation. This can be done by inoculating the bottles with *radioactive carbon* ($Na_2{}^{14}CO_3$). Sensitivities with this method are much greater than the standard method and much shorter periods of incubation are possible. It is possible to obtain easily measurable amounts of ^{14}C in particulate form after only two hours by adjusting the specific activity of the inoculums. However, unlike the oxygen method, the dark bottle results do not provide an estimate of community respiration thus giving the ecologist less information with which to work.

The ^{14}C method has been widely used because it is sensitive and rapid. One outcome of its popularity is that a great deal of scrutiny has been devoted to the method itself. After 18 years of use, however, it is still not clear whether the ^{14}C is measuring gross productivity, net productivity, or something in between. The results probably most closely estimate net productivity, but it may be that this method applies only to a particular set of experimental conditions.

Already mentioned is the evidence that some of the ^{14}C that is fixed during incubation may seep out of the algal cells in the form of water-soluble organic compounds. This material is presumably utilized by bacteria rather than passed on directly to the next higher trophic level as is the remainder of the consumed primary productivity. The amount of primary production liberated extracellularly is large enough to be measured with precision and a number of workers are now routinely including quantitative studies of extracellular products of photosynthesis as part of the measurements of primary productivity.

Calibration of radioactive sources and instruments for measuring radioactivity pose a serious technical problem for the ^{14}C method. In order to calculate productivity in terms of carbon uptake it is necessary to know accurately the amount of ^{14}C added in microcuries and the number of microcuries recovered in particulate form by filtering the sample through a membrane filter.

Further it has been found that phytoplankton cells may become damaged during filtration and calculations based on these conditions will show lower productivity rates than are actually the case.

A point deserving emphasis is that those of us measuring primary productivity are still attempting to determine more precisely what is being measured, and generalizations about the transfer of energy through aquatic food-webs should be made continuously. Neither this nor any other practical technique adequately measures the change in oxidation state of the carbon that is fixed. The subsequent ecological role of newly fixed carbon is even more difficult to measure because of the various ways the photosynthate may be used.

USE OF PRIMARY PRODUCTIVITY MEASUREMENTS IN AQUATIC ECOSYSTEMS

Lindeman (1942) developed a trophic-dynamic model of an aquatic ecosystem and introduced the concept of "energy flow," or the efficiency of energy transfer from one trophic level to the next, to describe its operation. A certain value derived from the measured primary productivity represented the input of energy into the next grazing level, and so forth up the food chain. It was consistent with Lindeman's purpose to express his data as energy units (calories). Subsequent workers have continued to probe the concept of energy flow. However, advances in biochemistry, physiology, and ecology require such a complex model of energy flow that it is difficult to relate it to the natural world. In an imaginary world or model of a system in which the function units are discrete trophic levels, it is not only possible but stimulating to describe the flow of energy through an ecosystem. But when the functional units of the system being investigated are conceived of as macromolecules it is difficult to translate biomass accumulation into energy units.

Besides requiring a portion of their autotrophic production for respiration, phytoplankton communities must also reserve a portion for the maintenance of community structure. In terms of information theory, energy expended for community maintenance is referred to as "*information*." Energy information cost has never been measured directly but there is indirect evidence that it must be paid. For example, when an aquatic ecosystem is altered artificially with the aim of increasing the production of fish, zooplankton and fish may increase in greater proportion than the phytoplankton (McConnell, 1965; Goldman, 1968). Perhaps a large amount of primary production remains with the phytoplankton as information necessary for the maintenance or development of community structure. Grazers then have access only to the production in excess of this threshold level. If the magnitude of the information cost is high relative to primary production, then a small increase in the rate of growth of the primary producers will provide a relatively larger increase in the food supply of grazers and in turn the fish that consume them.

There are difficulties that must be met in the course of fitting measurements of primary productivity to the trophic-dynamic model. A highly variable yet often significant portion of primary production, as measured by ^{14}C light-and-dark bottle experiments, is not retained by the producers but instead moves into the environment in soluble form. It is difficult to measure the absolute magnitude of such excretion by a community of natural plankton because the excreta can rapidly serve as a substrate for bacterial growth and thus find its way back to particulate or inorganic form during the incubation period. Although this excrement is part of the primary productivity and eventually serves as an energy source for organisms at the higher trophic levels, the pathway along which this energy flows does not follow the usual linear sequence modeled for the transfer of energy from phytoplankton to herbivorous zooplankton. There is evidence that the amount of energy involved may sometimes be of the same order of magnitude as that recovered in particulate form in routine ^{14}C productivity studies.

The role of allochthonous material (material brought in from outside the system) in supporting the energy requirements of consumer organisms must also be considered in studies of energy flow. No natural aquatic ecosystem is entirely closed. Potential energy enters in the form of organic solutes and debris. Organic solutes undergo conversion to particulate matter through bacterial action. Sorokin (1965) in Russia found this type of production of particulate matter to be the most important in producing food for crustacean filter-feeders. Particulate and dissolved organic matter may also arise in the aquatic environment through chemosynthesis. This is a form of primary production not usually considered and therefore not usually measured. Although its magnitude may not be great in many systems, Sorokin found it to be very important in the Rybinsk reservoir and in the Black Sea.

PRIMARY PRODUCTION AND EUTROPHICATION

The process of increasing productivity of a body of water is known as eutrophication and in the idealized succession of lakes, a lake would start as oligotrophic (low productivity), becoming mesotrophic (medium productivity) eventually eutrophic (highly productive) and finally dystrophic, a bog stage in which the lake has almost been filled in by weeds and the productivity has been greatly decreased. The concept of eutrophic and oligotrophic lake types is not a new one. It was used by Naumann (1919) to indicate the difference between the more productive lakes of the cultivated lowlands and the less productive mountain lakes. The trophic state of five different aquatic environments will be discussed below.

The general progression from an oligotrophic to an eutrophic and finally to a dystrophic lake (lake succession) is as much a result of the original basin shape, climate, and such edaphic factors as soil, as it is of geologic age. It is unlikely that some shallow lakes ever passed through a stage that could be considered oligotrophic, and it is just as unlikely that the first lake to be considered here, Lake Vanda, will ever become eutrophic. It is also possible that the "progression" may be halted or reversed.

Lake Vanda, located in "dry" Wright Valley near McMurdo Sound in Antarctica, is one of the least productive lakes in the world. The lake is permanently sealed under 3 to 4 meters of very clear ice which transmits 14 to 20% of the incident radiation to the water below. This provides enough light to power the photosynthesis of a sparse phytoplankton population to a depth of 60 meters (Goldman *et al.*, 1967). Lake Vanda can be classified as ultraoligotrophic, since its mean productivity is only about 1 mg $C \cdot m^{-2} \cdot hr^{-1}$.

Lake Tahoe in the Sierra Nevada of California and Nevada is an alpine lake long esteemed for its remarkable clarity. Although it is more productive than Lake Vanda, it is still oligotrophic. The lake is characterized by a deep euphotic (lighted) zone, with photosynthesis occurring in the phytoplankton and attached plants to a depth of about 100 m. Although the production under a unit of surface area is not small, the intensity of productivity per unit of volume is extremely low. Lake Tahoe's low fertility (as inferred from its productivity per unit volume) is the result of a restricted watershed, whose granitic rocks provide a minimum of nutrient salts. This situation is rapidly being altered by human activity in the Tahoe Basin. The cultural eutrophication of the lake is accelerated by sewage disposal in the basin and by the exposure of mineral soils through road building and other construction activities. Since Lake Tahoe's water is saturated with oxygen all the way down the water column, the decomposition of dead plankton sinking slowly towards the bottom is essentially complete. This means that nutrients are returned to the system and because of a water retention time of over 600 years the increase in fertility will be cumulative.

Castle Lake, located at an elevation of 5600 feet in the Klamath Mountains of northern California, shows some of the characteristics of Lake Tahoe as well as those of more productive environments. It, therefore, is best classified as mesotrophic. Although it has a mean productivity of about 70 mg $C{\cdot}m^{-2}{\cdot}hr^{-1}$ during the growing season, it shows a depletion in oxygen in its deep water during summer stratification and also under ice cover during late winter.

Clear lake is an extremely eutrophic shallow lake with periodic blooms of such bluegreen algae as *Aphanizomenon* and *Microcystis* and inorganic turbidity greatly reducing the transparency of the water. The photosynthetic zone is thus limited to the upper four meters with a high intensity of productivity per unit volume yielding an average of about 300 mg $C{\cdot}m^{-2}{\cdot}hr^{-1}$ during the growing season. Because Clear Lake is shallow, it does not stratify for more than a few hours at a time during the summer, and the phytoplankton which sink below the light zone are continuously returned to it by mixing.

Cedar Lake lies near Castle Lake in the Klamath Mountains. Its shallow basin is nearly filled with sediment as it nears the end of its existence as a lake. Numerous scars of similar lakes to be found in the area are prophetic of Cedar Lake's future. Terrestrial plants are already invading the lake, and higher aquatic plants reach the surface in many places. The photosynthesis beneath a unit of surface area amounts to only about 6.0 mg $C{\cdot}m^{-2}{\cdot}hr^{-1}$ during the growing season as the lake is now only about four meters in depth and may be considered a dystrophic lake. Some lakes of this type pass to a bog condition before extinction; in others, their shallow basins may go completely dry during summer and their flora and fauna become those of vernal ponds.

In examining some aspects of the productivity of these five lakes, the variation in both the intensity of photosynthesis and the depth to which it occurs is evident. The great importance of the total available light can scarcely be overemphasized. This was first made apparent to the author during studies of primary productivity and limiting factors in three oligotrophic lakes of the Alaskan Peninsula, where weather conditions imposed severe light limitations on the phytoplankton productivity. The average photosynthesis on both a cloudy and a bright day was within 10% of being proportional to the available light energy.

Nutrient limiting factors have been reviewed by Lund (1965) and examined by the author in a number of lakes. In Brooks Lake, Alaska a sequence of the most limiting factors ranged from magnesium in the spring through nitrogen in the summer to phosphorous in the fall (Goldman, 1960). In Castle Lake potassium, sulfur, and the trace element molybdenum were found to be the most limiting. In Lake Tahoe iron and nitrogen gave greatest photosynthetic response with nitrogen of particular importance. Trace elements, either singly or in combination, have been found to stimulate photosynthesis in quite a variety of lakes. In general, some component of the phytoplankton population will respond positively to almost any nutrient addition, but the community as a whole will tend to share some common deficiencies. Justus von Liebig did not intend to apply his law of the minimum as rigidly as some have interpreted it, and we can best envision nutrient limitation from the standpoint of the balance and interactions of the whole nutrient medium with the community of organisms present at any given time. Much about the nutrient requirements of phytoplankton can be gleaned from the excellent treatise of Hutchinson (1967).

It must be borne in mind that the primary productivity of a given lake may vary greatly from place to place, and measurements made at any one location may not provide a very good estimate for the lake as a whole.

Variability in productivity beneath a unit of surface area is particularly evident in Lake Tahoe, where attached algae are already becoming a nuisance in the shallow water and transparency is often markedly reduced near streams which drain disturbed watersheds. In July, 1962, the productivity of Lake Tahoe showed great increase near areas of high nutrient inflow (Goldman and Carter, 1965). This condition was even more evident in the summer of 1967 when Crystal Bay at the north end of the lake and the southern end of the lake showed different periods of high productivity. This variability in productivity may be influenced by sewage discharge and land disturbance. Were it not for the great volume of the lake (155 km^3), it would already be showing more severe signs of eutrophication.

In the foregoing paper I have attempted to sketch my impressions of aquatic primary productivity treating the subject both as a research task and as a body of information to be interpreted. I believe that biological productivity can no longer be considered a matter of simple academic interest, but of unquestioned importance for survival. The productivity and harvest of most of the world's terrestrial and aquatic environments must be increased if the world population is to have any real hope of having enough to eat. This increase is not possible unless we gain a much better understanding of both aquatic and terrestrial productivity. Only with a more sound understanding of the processes which control productivity at the level of the primary producers can we have any real hope of understanding the intricate pathways that energy moves and biomass accumulates in various links of the food chain. With this information in hand the productivity of aquatic environments can be increased or decreased for the benefit of mankind.

ATMOSPHERIC CHEMISTRY

INTRODUCTION

Atmospheric chemistry is a broadly based area of scientific endeavor. It is directed at determining the quantities of various chemicals in the atmosphere, the origin of these chemicals, and their role in the chemistry of the atmosphere. Many atmospheric chemists are involved in the development of techniques for the measurement of trace quantities of different chemicals in the atmosphere, in emissions, and in depositions. Other atmospheric chemists study the kinetics and mechanisms of chemical reactions occurring in the atmosphere. Still other atmospheric chemists are involved in the development of chemical models of the processes occurring in the atmosphere. Atmospheric chemists work closely with other disciplines: engineers in characterizing anthropogenic emissions; biologists and geologists in characterizing natural emissions and in evaluating the effects of air pollution; physicists in dealing with gas-to-particle conversions; and meteorologists, physicists, computer scientists, and mathematicians in dealing with model development. Atmospheric chemistry plays a key role in maintaining the general well-being of the atmosphere, which is extremely important for maintaining the health of the human race.

In recent years, there has been a growing concern about a number of atmospheric environmental problems, such as the formation of photochemical oxidants, acid deposition, global-scale effects on stratospheric ozone, the sources and fates of toxic chemicals in the atmosphere, and urban and regional haze issues and the presence and effects of fine particulate matter in the atmosphere. These problems are affected by a wide variety of complex chemical and physical processes. Atmospheric chemistry is the broad subject area that describes the interrelationships between these chemical and physical processes.

The principal components of the atmosphere are nitrogen and oxygen. These molecules can absorb a portion of the high-energy solar ultraviolet radiation present in the upper atmosphere and form atoms. These atoms may react with a variety of other species to form many different radicals and compounds. For example, the short-wavelength ultraviolet radiation present in the upper atmosphere can photolyze molecular oxygen to form oxygen atoms. These oxygen atoms may react with molecular oxygen to form ozone. These reactions are only of importance at high altitudes, where the short-wavelength ultraviolet radiation is present. In the lower regions of the atmosphere, only light of wavelengths greater than about 300 nm is present. Table 1 lists the relative concentrations of a number of species present in the atmosphere, near the Earth's surface. The chemistry that is most important at lower altitudes is initiated by a variety of compounds or trace species, which are present in the atmosphere at concentrations of much less than 1 ppm.

One of the most important reasons to understand atmospheric chemistry is related to our need to understand and control air pollution. The air-pollution system, shown in Figure 1, starts with the sources that emit a variety of pollutants into the atmosphere. Those pollutants emitted directly into the atmosphere are called *primary pollutants.* Once these primary pollutants are in the atmosphere, they are subjected to meteorological influences, such as transport and dilution, in addition to chemical and physical transformations to secondary pollutants. *Secondary pollutants* are those formed by reactions in the air. The pollutants in the air may be removed by a variety of processes, such as wet and dry deposition. An ambient-air-monitoring program is used to provide detailed information about the compounds present in the atmosphere.

TABLE 1
Relative composition of the atmosphere near the Earth's surface

Species	Concentration (ppm)
N_2	780,840
O_2	209,460
H_2O	<35,000
Ar	9,340
CO_2	335
Ne	18
He	5.2
CH_4	1.7
Kr	1.14
H_2	0.53
N_2O	0.30
CO	<0.2
Xe	0.087
O_3	0.025

One of the principal goals of air-pollution research is to obtain and use our detailed knowledge of emissions, topography, meteorology, and chemistry to develop a mathematical model that is capable of predicting concentrations of primary and secondary pollutants as a function of time at various locations throughout the modeling domain. These model results would be validated by comparison with ambient-air-monitoring data. Model refinement continues until there is acceptable agreement between the observed and predicted concentrations. This type of air-quality model, on an urban scale, is called an *airshed model.* Airshed models treat the effects of a set of stationary and mobile sources scattered throughout a relatively small geographical area (~100 km^2). These models are intended to calculate concentrations of pollutants within this geographical area and immediately downwind.

It is also necessary to develop a detailed knowledge of the impacts of pollutants on the various important receptors, such as humans, plants, and materials. This impact information is used to identify the pollutants that need to be controlled. An airshed model can be used to predict the effectiveness of various proposed control strategies. This information can be passed on to legislative authorities, who can evaluate the costs and benefits of the various strategies and legislate the best control measures.

Unfortunately, there are significant gaps in our knowledge at every step throughout this idealized air-pollution system.

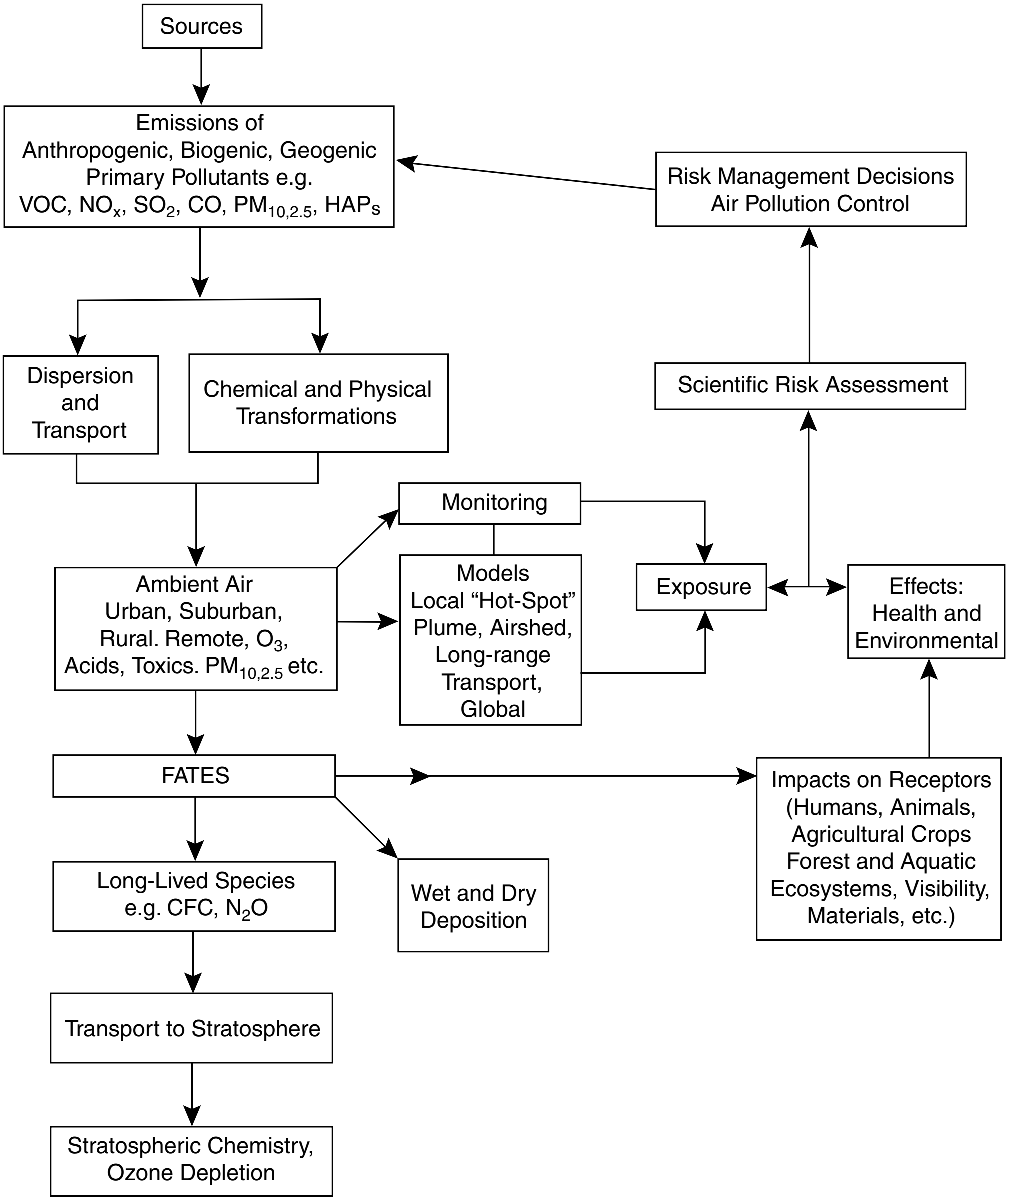

FIGURE 1 The atmospheric air-pollution system. From Finlayson-Pitts and Pitts (2000). (HAPs—hazardous air pollutants). With permission.

Hence, there is considerable room for continued research. Atmospheric chemistry is involved in several steps through the air-pollution system. First is chemically characterizing and quantifying the emissions of primary pollutants. Second is understanding the chemical and physical transformations that these primary pollutants undergo. Third is measuring the quantities of the various pollutants in the ambient air. Fourth is quantifying the deposition processes for the various pollutants. Finally, a mathematical formulation of the sources, chemical and physical transformations, and removal processes must be incorporated into the atmospheric model.

The chemistry of the formation of secondary pollutants is extremely complex. It requires the identification of all of the important reactions contributing to the chemical system. There must be a thorough investigation of each specific reaction, which can be achieved only when the reaction-rate constant has been carefully determined for each elementary reaction involved in the properly specified reaction mechanism. Because of the large number of important reactions that take place in the atmosphere, the rapid rates of many of them, and the low concentrations of most of the reactants, the experimental investigations of these atmospheric chemical kinetics is an enormously large and complex task.

In the United States, a set of National Ambient Air Quality Standards (NAAQS) have been established, as shown in Table 2. The primary standards are designed to protect the public health of the most susceptible groups in the population. Secondary NAAQS have also been set to protect the public welfare, including damage to plants and materials and aesthetic effects, such as visibility reduction. The only secondary standard that currently exists that is different from the primary standard is for SO_2, as shown in the table. For comparison purposes, Table 3 shows recommended limits for air pollutants set by the World Health Organization and various individual countries.

To illustrate the importance and complexity of atmospheric chemistry, a few examples will be presented and discussed: (1) urban photochemical-oxidant problems, (2) secondary organic aerosols, (3) chemistry of acid formation, and (4) stratospheric ozone changes in polar regions. These examples also illustrate the differences in the spatial scales that may be important for different types of air-pollution problems. Considering urban problems involves dealing with spatial distances of 50 to 100 km and heights up to a few kilometers, an urban scale or mesoscale. The chemistry related to acid formation occurs over a much larger, regional scale, extending to distances on the order of 1000 km and altitudes of up to about 10 km. For the stratospheric ozone-depletion problem, the chemistry of importance occurs over a global scale and to altitudes of up to 50 km. Secondary organic aerosol formation can be an urban to regional scale issue.

TABLE 2

U.S. National Ambient Air Quality Standards

Pollutant	Primary	Averaging Times	Secondary
Carbon monoxide	9 ppm	8-hour[1]	None
	35 ppm	1-hour[1]	None
Lead	1.5 $\mu g/m^3$	Quarterly average	Same as primary
Nitrogen dioxide	0.053 ppm	Annual (arith. mean)	Same as primary
Particulate matter (PM_{10})	50 $\mu g/m^3$	Annual[2] (arith. mean)	Same as primary
	150 $\mu g/m^3$	24-hour[1]	
Particulate matter ($PM_{2.5}$)	15 $\mu g/m^3$	Annual[3] (arith. mean)	Same as primary
	65 $\mu g/m^3$	24-hour[4]	
Ozone	0.08 ppm	8-hour[5]	Same as primary
	0.12 ppm	1-hour[6]	Same as primary
Sulfur oxides	0.03 ppm	Annual (arith. mean)	—
	0.14 ppm	24-hour[1]	—
	—	3-hour[1]	0.5 ppm

[1] Not to be exceeded more than once per year.

[2] To attain this standard, the expected annual arithmetic mean PM_{10} concentration at each monitor within an area must not exceed 50 $\mu g/m^3$.

[3] To attain this standard, the 3-year average of the annual arithmetic mean $PM_{2.5}$ concentrations from single or multiple community-oriented monitors must not exceed 15 $\mu g/m^3$.

[4] To attain this standard, the 3-year average of the 98th percentile of 24-hour concentrations at each population-oriented monitor within an area must not exceed 65 $\mu g/m^3$.

[5] To attain this standard, the 3-year average of the fourth-highest daily maximum 8-hour average ozone concentrations measured at each monitor within an area over each year must not exceed 0.08 ppm.

[6] *(a)* The standard is attained when the expected number of days per calendar year with maximum hourly average concentrations above 0.12 ppm is ≤ 1.

(b) The 1-hour NAAQS will no longer apply to an area one year after the effective data of the designation of that area for the 8-hour ozone NAAQS.

URBAN PHOTOCHEMICAL OXIDANTS

The photochemical-oxidant problems exist in a number of urban areas, but the Los Angeles area is the classic example of such problems. Even more severe air-pollution problems are occurring in Mexico City. The most commonly studied oxidant is ozone (O_3), for which an air-quality standard exists. Ozone is formed from the interaction of organic compounds, nitrogen oxides, and sunlight. Since sunlight is an important factor in photochemical pollution, ozone is more commonly a summertime problem. Most of the ozone formed in the troposphere (the lowest 10 to 15 km of the atmosphere) is formed by the following reactions:

$$NO_2 + h\nu\ (\lambda \leq 430\text{ nm}) \rightarrow NO + O(^3P) \qquad (1)$$

$$O(^3P) + O_2 + M \rightarrow O_3 + M \qquad (2)$$

Nitrogen dioxide (NO_2) is photolyzed, producing nitric oxide (NO) and a ground-state oxygen atom (designated as $O(^3P)$). This oxygen atom will then react almost exclusively with molecular oxygen to form ozone. The M in reaction (2) simply indicates that the role of this reaction depends on the pressure of the reaction system. NO can also react rapidly with ozone, reforming NO_2:

$$NO + O_3 \rightarrow NO_2 + O_2 \qquad (3)$$

These three reactions allow one to derive the photostationary state or Leighton relationship

$$[O_3]\,[NO]/[NO_2] = k_1/k_3 \text{ or } [O_3] = k_1[NO_2]/k_3[NO]$$

This relationship shows that the O_3 concentration depends on the product of the photolysis rate constant for NO_2 (k_1) times the concentration of NO_2 divided by the product of the rate constant for the NO reaction with O_3 (k_3) times the NO concentration. This photolysis rate constant (k_1) will depend on the solar zenith angle, and hence will vary during the day, peaking at solar noon. This relationship shows that the concentration of ozone can only rise for a fixed photolysis rate as the $[NO_2]/[NO]$ concentration ratio increases. Deviations from this photostationary state relationship exist, because as we will see shortly, peroxy radicals can also react with NO to make NO_2.

Large concentrations of O_3 and NO cannot coexist, due to reaction (3). Figure 2 shows the diurnal variation of NO, NO_2, and oxidant measured in Pasadena, California. Several features are commonly observed in plots of this type. Beginning in the early morning, NO, which is emitted by motor vehicles, rises, peaking at about the time of maximum automobile traffic. NO_2 begins rising toward a maximum value as the NO disappears. Then the O_3 begins growing, reaching its maximum value after the NO has disappeared and after the NO_2 has reached its maximum value. The time of the O_3 maximum varies depending on where one is monitoring relative to the urban center. Near the urban center, O_3 will peak near noon, while further downwind of the urban center, it may peak in the late afternoon or even early evening.

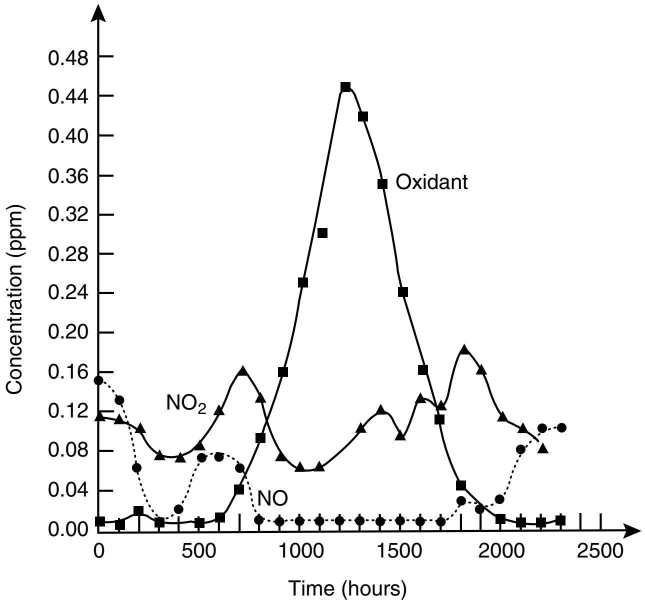

FIGURE 2 Diurnal variation of NO, NO_2, and total oxidant in Pasadena, California, on July 25, 1973. From Finlayson-Pitts and Pitts (2000). With permission.

Hydrocarbon Photooxidation

The chemistry of O_3 formation described thus far is overly simplistic. How is NO, the primary pollutant, converted to NO_2, which can be photolyzed? A clue to answering this question comes from smog-chamber studies. A smog chamber is a relatively large photochemical-reaction vessel, in which one can simulate the chemistry occurring in the urban environment. Figure 3 shows a plot of the experimentally observed loss rate for propene (a low-molecular-weight, reactive hydrocarbon commonly found in the atmosphere) in a reaction system initially containing propene, NO, and a small amount of NO_2. The observed propene-loss rate in this typical chamber run was considerably larger than that calculated due to the known reactions of propene with oxygen atoms and ozone. Hence, there must be another important hydrocarbon-loss process.

Hydroxyl radicals (OH) react rapidly with organics. Radicals, or free radicals, are reactive intermediates, such as an atom or a fragment of a molecule with an unpaired electron. Let's look at a specific sequence of reactions involving propene.

The hydroxyl radical reacts rapidly with propene:

$$OH + CH_3CH{=}CH_2 \rightarrow CH_3CHCH_2OH \qquad (4a)$$

$$OH + CH_3CH{=}CH_2 \rightarrow CH_3CHOHCH_2 \qquad (4b)$$

These reactions form radicals with an unpaired electron on the central carbon in (4a) and on the terminal carbon in (4b). These alkyl types of radicals react with O_2 to form alkylperoxy types of radicals.

$$CH_3CHCH_2OH + O_2 \rightarrow CH_3CH(O_2)CH_2OH \qquad (5a)$$

$$CH_3CHOHCH_2 + O_2 \rightarrow CH_3CHOHCH_2(O_2) \qquad (5b)$$

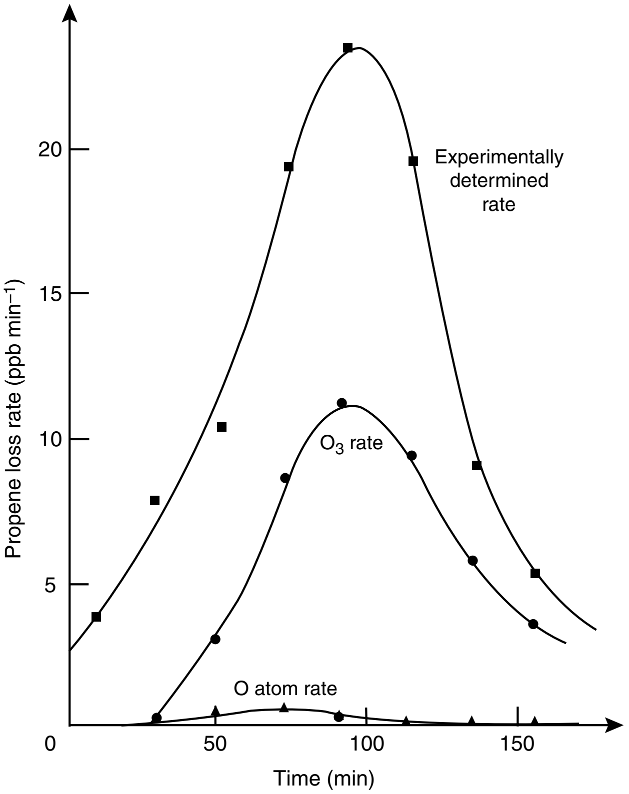

FIGURE 3 Experimentally observed rates of propene loss and calculated loss rates due to its reaction with O_3 and O atoms. From Finlayson-Pitts and Pitts (1986).

In both cases the unpaired electron is on the end oxygen in the peroxy group (in parentheses). These peroxy radicals react like all other alkylperoxy or hydroperoxy radicals under atmospheric conditions, to oxidize NO to NO_2:

$$\begin{aligned}&CH_3CH(O_2)CH_2OH + NO \rightarrow\\ &\qquad CH_3CH(O)CH_2OH + NO_2 &(6a)\\ &CH_3CHOHCH_2(O_2) + NO \rightarrow\\ &\qquad CH_3CHOHCH_2(O) + NO_2 &(6b)\end{aligned}$$

The resulting oxy radicals are then expected to dissociate to

$$CH_3CH(O)CH_2OH \rightarrow CH_3CHO + CH_2OH \quad (7a)$$
$$CH_3CHOHCH_2(O) \rightarrow CH_3CHOH + CH_2O \quad (7b)$$

Forming CH_3CHO (acetaldehyde or ethanal) and a new, one-carbon radical (7a) and HCHO (formaldehyde or methanal) and a new, two-carbon radical (7b). These new radicals are expected to react with O_2 to form the appropriate aldehyde and a hydroperoxy radical, which can oxidize NO to NO_2.

$$CH_2OH + O_2 \rightarrow HCHO + HO_2 \quad (8a)$$
$$CH_3CHOH + O_2 \rightarrow CH_3CHO + HO_2 \quad (8b)$$
$$HO_2 + NO \rightarrow OH + NO_2 \quad (9)$$

So far in this hydrocarbon oxidation process, two NO molecules have been oxidized to two NO_2 molecules, a formaldehyde and an acetaldehyde molecule have been formed, and the hydroxyl radical that initiated the reaction sequence has been re-formed. This mechanism shows the importance of the hydroxyl radical in explaining the excess removal rate of propene observed in smog-chamber studies. In addition, it provides a clue about how NO is converted to NO_2 in the atmosphere.

Hydroxyl radicals are present in the atmosphere at very low concentrations. Since the hydroxyl radical is reformed in the atmospheric photooxidation of hydrocarbons, it effectively acts as a catalyst for the oxidation of hydrocarbons. Figure 4 illustrates the role of the hydroxyl radical in initiating a chain of reactions that oxidize hydrocarbons, forming peroxy radicals that can oxidize NO to NO_2 and re-form hydroxyl radicals. The NO_2 can photolyze, leading to the formation of ozone.

PAN Formation

Acetaldehyde may react with hydroxyl radicals, forming the peroxyacetyl radical ($CH_3C(O)O_2$) under atmospheric conditions:

$$CH_3CHO + OH \rightarrow CH_3CO + H_2O \quad (10)$$
$$CH_3CO + O_2 \rightarrow CH_3C(O)O_2 \quad (11)$$

The peroxyacetyl radical may react with NO:

$$CH_3C(O)O_2 + NO \rightarrow CH_3C(O)O + NO_2 \quad (12)$$
$$CH_3C(O)O + O_2 \rightarrow CH_3O_2 + CO_2 \quad (13)$$

oxidizing NO to NO_2 and producing a methylperoxy radical. The methylperoxy radical can oxidize another NO to NO_2, forming a HO_2 (hydroperoxy) radical and a molecule of formaldehyde:

$$CH_3O_2 + NO \rightarrow CH_3O + NO_2 \quad (14)$$
$$CH_3O + O_2 \rightarrow HCHO + HO_2 \quad (15)$$

Alternatively, the peroxyacetyl radical may react with NO_2 to form peroxyacetyl nitrate ($CH_3C(O)O_2NO_2$, or PAN):

$$CH_3C(O)O_2 + NO_2 \leftrightarrow CH_3C(O)O_2NO_2 \quad (16)$$

Which reaction occurs with the peroxyacetyl radical depends on the relative concentrations of NO and NO_2 present.

PAN, like ozone, is a member of the class of compounds known as photochemical oxidants. PAN is responsible for much of the plant damage associated with photochemical-oxidant problems, and it is an eye irritant. More recent measurements of PAN throughout the troposphere have shown that PAN is ubiquitous. The only significant removal process for PAN in the lower troposphere is, as a result of its thermal decomposition, the reverse of reaction (16). This thermal decomposition of PAN is both temperature- and pressure-dependent. The lifetime for PAN ranges from about 30 minutes at 298 K to several months under conditions of the upper troposphere (Seinfeld and Pandis, 1998). In the upper troposphere, PAN is relatively stable and acts as an important reservoir for NO_x. Singh *et al.* (1994) have found that PAN is the single most abundant reactive nitrogen-containing compound

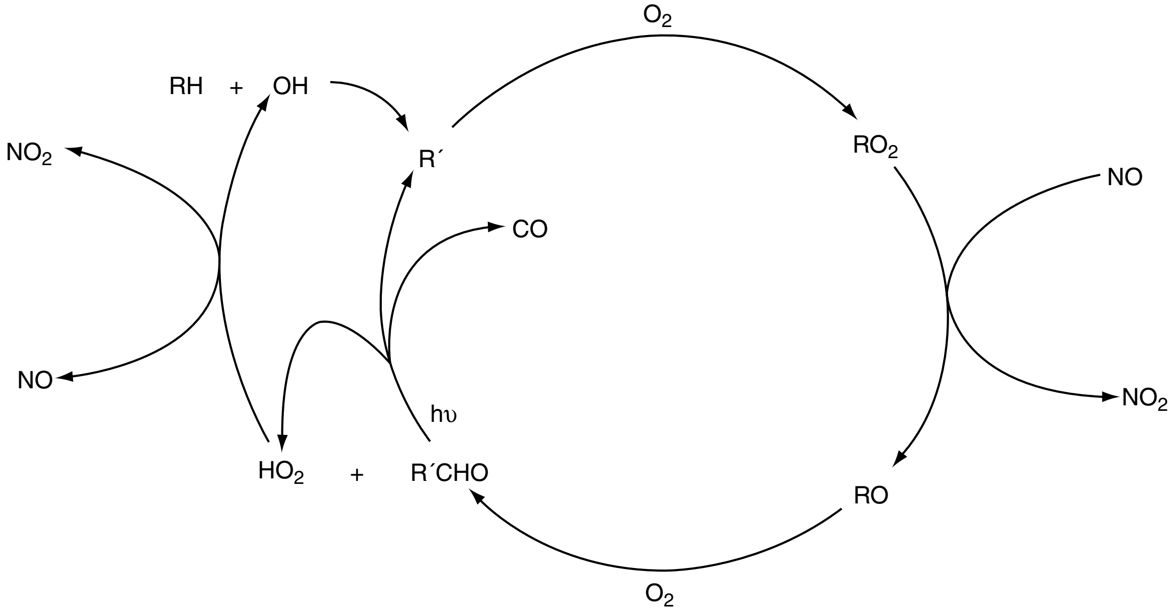

FIGURE 4 Schematic diagram illustrating the role of the hydroxyl-radical-initiated oxidation of hydrocarbons in the conversion of NO to NO_2.

in the free troposphere. Talukdar *et al.* (1995) have found that photolysis of PAN can compete with thermal decomposition for the destruction of PAN at altitudes above about 5 km. The reaction of the hydroxyl radical with PAN is less important than thermal decomposition and photolysis throughout the troposphere.

The oxidation of hydrocarbons does not stop with the formation of aldehydes or even the formation of CO. It can proceed all the way to CO_2 and H_2O. CO can also react with hydroxyl radicals to form CO_2:

$$OH + CO \rightarrow H + CO_2 \qquad (17)$$
$$H + O_2 + M \rightarrow HO_2 + M \qquad (18)$$

The chain of reactions can proceed, oxidizing hydrocarbons, converting NO to NO_2, and re-forming hydroxyl radicals until some chain-terminating reaction occurs. The following are the more important chain-terminating reactions:

$$HO_2 + HO_2 \rightarrow H_2O_2 + O_2 \qquad (19)$$
$$RO_2 + HO_2 \rightarrow ROOH + O_2 \qquad (20)$$
$$OH + NO_2 + M \rightarrow HNO_3 + M \qquad (21)$$

These reactions remove the chain-carrying hydroxyl or peroxy radicals, forming relatively stable products. Thus, the chain oxidation of the hydrocarbons and conversion of NO to NO_2 are slowed.

Radical Sources

This sequence of hydrocarbon oxidation reactions describes processes that can lead to the rapid conversion of NO to NO_2. The NO_2 thus formed can react by (1) and (2) to form O_3. In order for these processes to occur, an initial source of hydroxyl radicals is required. An important source of OH in the nonurban atmosphere is the photolysis of O_3 to produce an electronically excited oxygen atom (designated as $O(^1D)$):

$$O_3 + h\nu\ (\lambda \leq 320\ \text{nm}) \rightarrow O(^1D) + O_2 \qquad (22)$$

The excited oxygen atom can either be quenched to form a ground-state oxygen atom or react with water vapor (or any other hydrogen-containing compound) to form hydroxyl radicals:

$$O(^1D) + H_2O \rightarrow 2OH \qquad (23)$$

Other possible sources of hydroxyl radicals include the photolysis of nitrous acid (HONO), hydrogen peroxide (H_2O_2), and organic peroxides (ROOH):

$$HONO + h\nu\ (\lambda \leq 390\ \text{nm}) \rightarrow OH + NO \qquad (24)$$
$$H_2O_2 + h\nu\ (\lambda \leq 360\ \text{nm}) \rightarrow 2OH \qquad (25)$$

The atmospheric concentration of HONO is sufficiently low and photolysis sufficiently fast that HONO photolysis can only act as a radical source, in the very early morning, from HONO that builds up overnight. The photolysis of H_2O_2 and ROOH can be significant contributors to radical production, depending on the quantities of these species present in the atmosphere. Another source of radicals that can form OH radicals includes the photolysis of aldehydes, such as formaldehyde (HCHO):

$$HCOC + h\nu\ (\lambda \leq 340\ \text{nm}) \rightarrow H + HCO \qquad (26)$$
$$HCO + O_2 \rightarrow HO_2 + CO \qquad (27)$$

forming HO_2 radicals in (27) and from H atoms by reaction (18). These HO_2 radicals can react with NO by reaction (9) to form OH. The relative importance of these different sources for OH and HO_2 radicals depends on the concentrations of the different species present, the location (urban or rural), and the time of day.

Organic Reactivity

Atmospheric organic compounds have a wide range of reactivities. Table 4 lists calculated tropospheric lifetimes for selected volatile organic compounds (VOCs) due to photolysis and reaction with OH and NO_3 radicals and ozone (Seinfeld and Pandis, 1998). All of the processes identified in the table lead to the formation of organic peroxy radicals that oxidize NO to NO_2, and hence lead to ozone production. But we can see that in general the reaction of the organic molecule with the hydroxyl radical is the most important loss process.

The most important chain-terminating process in the urban atmosphere is the reaction of OH with NO_2. Hence, comparing the relative rates of the OH reaction with VOCs to that of OH with NO_2 is important for assessing the production of ozone. Seinfeld (1995) found that the rate of the OH reaction with NO_2 is about 5.5 times that for the OH reactions with a typical urban mix of VOCs, where NO_2 concentrations are in units of ppm and VOC concentrations are in units of ppm C (ppm of carbon in the VOC). If the VOC-to-NO_2 ratio is less than 5.5:1, the reaction of OH with NO_2 would be expected to predominate over the reaction of OH with VOCs. This reduces the OH involved in the oxidation of VOCs, hence inhibiting the production of O_3. On the other hand, when the ratio exceeds 5.5:1, OH preferentially reacts with VOCs, accelerating the production of radicals and hence O_3. Different urban areas are expected to have a different mix of hydrocarbons, and hence different reactivities, so this ratio is expected to change for different urban areas.

TABLE 4

Estimated tropospheric lifetimes for selected VOCs due to photolysis and reaction with OH and NO_3 radicals and ozone

	Lifetime Due to Reaction with			
	OH[a]	O_3[b]	NO_3[c]	hν
n-Butane	5.7 days	—	2.8 yr	
Propene	6.6 h	1.6 days	4.9 days	
Benzene	12 days	—	—	
Toluene	2.4 days	—	1.9 yr	
m-Xylene	7.4 h	—	200 days	
Formaldehyde	1.5 days	—	80 days	4 h
Acetaldehyde	11 h	—	17 days	5 days
Acetone	66 days	—	—	38 days
Isoprene	1.7 h	1.3 days	0.8 h	
α-Pinene	3.4 h	4.6 h	2.0 h	
β-Pinene	2.3 h	1.1 days	4.9 h	
Camphene	3.5 h	18 days	1.5 days	
2-Carene	2.3 h	1.7 h	36 min	
3-Carene	2.1 h	10 h	1.1 h	
d-Limonene	1.1 h	1.9 h	53 min	
Terpinolene	49 min	17 min	7 min

[b] 24-hour average O_3 concentration of 7×10^{11} molecules cm^{-3} (30 ppb).

[c] 12-hour average NO_3 concentration of 2.4×10^7 molecules cm^{-3} (1 ppt).

Carter and Atkinson (1987) have estimated the effect of changes in the VOC composition on ozone production by use of an "incremental reactivity." This provides a measure of the change in ozone production when a small amount of VOC is added to or subtracted from the base VOC mixture at the fixed initial NO_x concentration. The incremental reactivity depends not only on the reactivity of the added VOC with OH and other oxidants, but also on the photooxidation mechanism, the base VOC mixture, and the NO_x level. Table 5 presents a table of maximum incremental reactivities (MIR) for several VOCs. The concept of MIR is useful in evaluating the effect of changing VOC components in a mixture of pollutants.

TABLE 5

Maximum incremental reactivities (MIR) for some VOCs

VOC	MIR[a] (grams of O_3 formed per gram of VOC added)
Carbon monoxide	0.054
Methane	0.015
Ethane	0.25
Propane	0.48
n-Butane	1.02
Ethene	7.4
Propene	9.4
1-Butene	8.9
2-Methylpropene (isobutene)	5.3
1,3-Butadiene	10.9
2-Methyl-1,3-butadiene (isoprene)	9.1
α-Pinene	3.3
β-Pinene	4.4
Ethyne (acetylene)	0.50
Benzene	0.42
Toluene	2.7
m-Xylene	8.2
1,3,5-Trimethylbenzene	10.1
Methanol	0.56
Ethanol	1.34
Formaldehyde	7.2
Acetaldehyde	5.5
Benzaldehyde	−0.57
Methyl *tert*-butyl ether	0.62
Ethyl *tert*-butyl ether	2.0
Acetone	0.56
C_4 ketones	1.18
Methyl nitrite	9.5

[a] From Carter (1994).

This concept of changing the VOC mixture is the basis for the use of reformulated or alternative fuels for the reduction of ozone production. Oxygenated fuel components, such as methanol, ethanol, and methyl t-butyl ether (MTBE), generally have smaller incremental reactivities than those of the larger alkanes, such as n-octane, which are more characteristic of the fuels used in automobiles. The use of these fuels would be expected to reduce the reactivity of the evaporative fuel losses from the automobiles, but the more important question is how they will change the reactivity of the exhaust emissions of VOCs. The data that are currently available suggests that there should also be a reduction in the reactivity of the exhaust emissions as well.

Ozone Isopleths

Ozone production depends on the initial amounts of VOC and NO_x in an air mass. Ozone isopleths, such as those shown in Figure 5, are contour diagrams that provide a convenient means of illustrating the way in which the maximum ozone concentration reached over a fixed irradiation period depends on the initial concentrations of NO_x and the initial concentration of VOCs. The ozone isopleths shown in Figure 5 represent model results for Atlanta, using the Carbon Bond 4 chemical mechanism (Seinfeld, 1995). The point on the contour plot represents the initial conditions containing 600 ppbC of anthropogenic controllable VOCs, 38 ppbC of background uncontrollable VOCs, and 100 ppb of NO_x. These conditions represent morning center-city conditions. The calculations are run for a 14-hour period, as chemistry proceeds and the air mass moves to the suburbs, with associated changes in mixing height and dilution. The air above the mixing layer is assumed to have 20 ppbC VOC and 40 ppb of O_3. The peak ozone concentration reached in the calculation is about 145 ppb, as indicated at the point. The isopleths arise from systematically repeating these calculations, varying the initial VOC and initial NO_x with all other conditions the same.

The base case corresponds to the point, and the horizontal line represents a constant initial NO_x concentration. At a fixed initial NO_x, as one goes from the point to a lower initial VOC, the maximum O_3 decreases, while increasing the initial VOC leads to an increase in the maximum O_3 concentration until the ridge line is reached. The ridge line represents the VOC-to-NO_x ratio that leads to the maximum ozone production at the lowest concentrations of both VOC and NO_x. The region of the isopleth diagram below the ridge line is referred to as the NO_x-limited region; it has a higher VOC:NO_x ratio. The region of the diagram above the ridge line is referred to as the VOC-limited region; it has a lower VOC:NO_x ratio. In

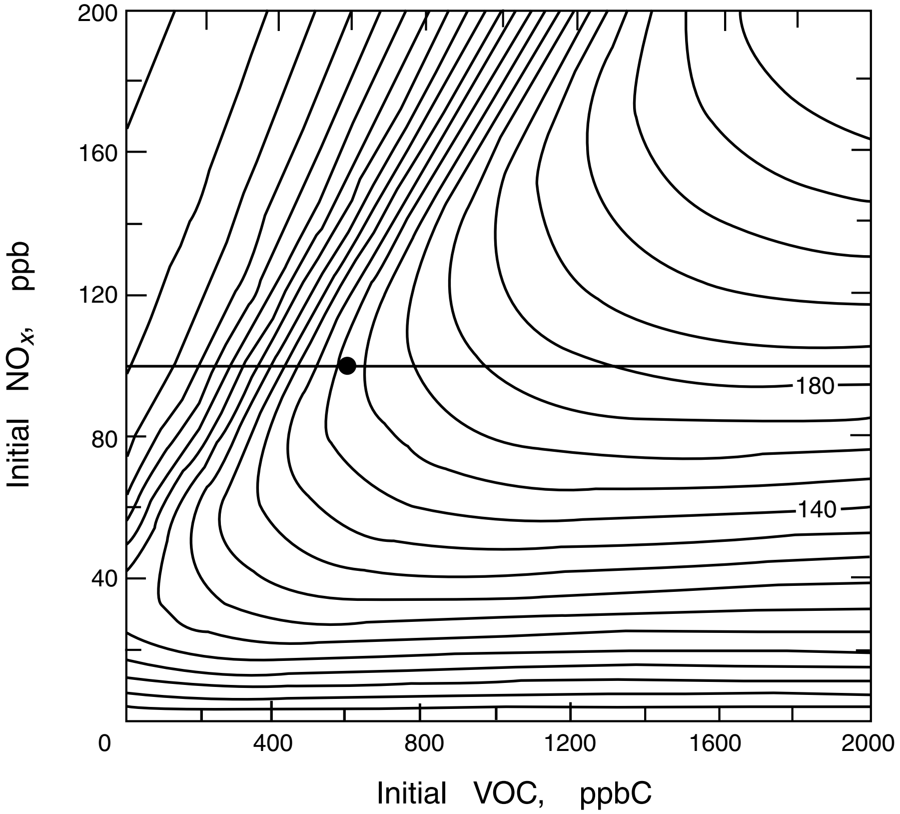

FIGURE 5 Ozone isopleth diagram for Atlanta, Georgia. Adjacent ozone isopleth lines are 10 ppb different. The point on the constant NO_x line represents the base case. From Seinfeld (1995). With permission.

the NO_x-limited region, there is inadequate NO_x present to be oxidized by all of the peroxy radicals that are being produced in the oxidation of the VOCs. Adding more NO_x in this region increases ozone production. The base-case point in Figure 5 is located in the VOC-limited region of the diagram. Increasing NO_x from the base-case point actually leads to a decrease in the maximum ozone that can be produced.

Nighttime Chemistry

At night, the urban atmospheric chemistry is quite different than during the day. The ozone present at night may react with organics, but no new ozone is formed. These ozone reactions with organics are generally slow. Ozone can react with alkanes, producing hydroxyl radicals. This hydroxyl-radical production is more important for somewhat larger alkenes. The significance of this hydroxyl-radical production is limited by the available ozone. Besides reacting with organics, ozone can react with NO_2:

$$O_3 + NO_2 \rightarrow O_2 + NO_3 \tag{28}$$

forming the nitrate radical (NO_3). NO_3 radicals can further react with NO_2 to form dinitrogen pentoxide (N_2O_5), which can dissociate to reform NO_3 and NO_2:

$$NO_3 + NO_2 + M \rightarrow N_2O_5 + M \tag{29}$$

$$N_2O_5 \rightarrow NO_3 + NO_2 \tag{30}$$

establishing an equilibrium between NO_3 and N_2O_5. Under typical urban conditions, the nighttime N_2O_5 will be 1 to 100 times the NO_3 concentration. These reactions are only of importance at night, since NO_3 can be photolyzed quite efficiently during the day.

NO_3 can also react quickly with some organics. A generic reaction, which represents reactions with alkanes and aldehydes, would be

$$NO_3 + RH \rightarrow HNO_3 + R \tag{31}$$

The reactions of NO_3 with alkenes and aromatics proceed by a different route, such as adding to the double bond. NO_3 reacts quite rapidly with natural hydrocarbons, such as isoprene and α-pinene (Table 4), and cresols (Finlayson-Pitts and Pitts, 2000). Not much is known about the chemistry of N_2O_5, other than it is likely to hydrolyze, forming nitric acid:

$$N_2O_5 + H_2O \rightarrow 2HNO_3 \tag{32}$$

Summary

The discussion of urban atmospheric chemistry presented above is greatly simplified. Many more hydrocarbon types are present in the urban atmosphere, but the examples presented should provide an idea of the types of reactions that may be of importance. In summary, urban atmospheric ozone is formed as a result of the photolysis of NO_2. NO_2 is formed by the oxidation of the primary pollutant NO, which accompanies the hydroxyl-radical-initiated chain oxidation of organics. Hydroxyl radicals can be produced by the photolysis of various compounds. Ozone formation is clearly a daytime phenomenon, as is the hydroxyl-radical attack of organics.

SECONDARY ORGANIC AEROSOLS

With the implementation of air-quality standards for fine (or respirable) particulate matter in the atmosphere, there has been increasing interest in the composition and sources of this fine particulate matter. It has long been recognized that particles in the atmosphere have both primary (direct emission) and secondary (formed in the atmosphere) sources. Among the secondary particulate matter in the atmosphere are salts of the inorganic acids (mostly nitric and sulfuric acids) formed in the atmosphere. It has been found that there is a significant contribution of carbonaceous particulate matter, consisting of elemental and organic carbon. Elemental carbon (EC), also known as black carbon or graphitic carbon, is emitted directly into the atmosphere during combustion processes. Organic carbon (OC) is both emitted directly to the atmosphere (primary OC), or formed in the atmosphere by the condensation of low-volatility products of the photooxidation of hydrocarbons (secondary OC). The organic component of ambient particles is a complex mixture of hundreds of organic compounds, including: n-alkanes, n-alkanoic acids, n-alkanals, aliphatic dicarboxylic acids, diterpenoid acids and retene, aromatic polycarboxylic acids, polycyclic aromatic hydrocarbons, polycyclic aromatic ketones and quinines, steroids, N-containing compounds, regular steranes, pentacyclic triterpanes, and iso- and anteiso-alkanes (Seinfeld and Pandis, 1998).

Secondary organic aerosols (SOAs) are formed by the condensation of low-vapor-pressure oxidation products of organic gases. The first step in organic-aerosol production is the formation of the low-vapor-pressure compound in the gas phase as a result of atmospheric oxidation. The second step involves the organic compound partitioning between the gas and particulate phases. The first step is controlled by the gas-phase chemical kinetics for the oxidation of the original organic compound. The partitioning is a physicochemical process that may involve interactions among the various compounds present in both phases. This partitioning process is discussed extensively by Seinfeld and Pandis (1998).

Figure 6 (Seinfeld, 2002) illustrates a generalized mechanism for the photooxidation of an n-alkane. The compounds shown in boxes are relatively stable oxidation products that might have the potential to partition into the particulate phase. Previous studies of SOA formation have found that the aerosol products are often di- or poly-functionally substituted products, including carbonyl groups, carboxylic acid groups, hydroxyl groups, and nitrate groups.

A large number of laboratory studies have been done investigating the formation of SOAs. Kleindienst *et al.* (2002)

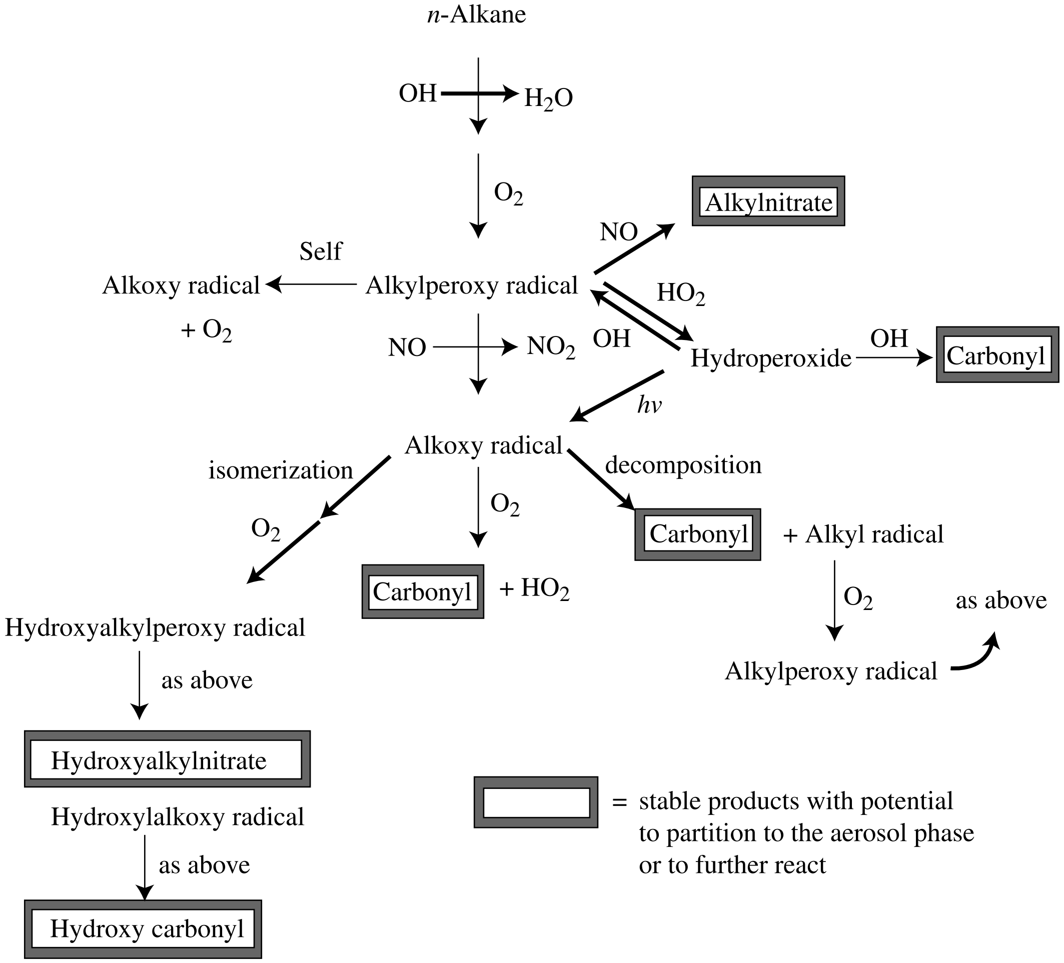

FIGURE 6 Generalized mechanism for the photooxidation of an n-alkane. The products shown in boxes are expected to be relatively stable organic products that might be able to partition into the particulate phase, if they have sufficiently low vapor pressures. From Seinfeld (2002). With permission.

have shown significant SOA formation from the irradiation of simulated auto exhaust. Griffin *et al.* (1999) have shown that the oxidation of biogenic hydrocarbons can also be important contributors to SOAs. This work also investigated the role of individual oxidation pathways, by ozone, nitrate radicals, and hydroxyl radicals. It was found that each of these oxidants can be quite important depending on the biogenic hydrocarbon with which they are reacting. Figure 7 (Seinfeld, 2002) shows an example of the partitioning of products of the ozone reaction with α-pinene between the gas and particulate phases. From this figure it is clear that the partitioning can change a lot between the various poly-functional products of the oxidation of α-pinene.

Jang *et al.* (2002) suggested that acidic aerosol surfaces may catalyze heterogeneous reactions that could lead to the formation of additional SOAs. As we will see in the next section, there is considerable potential for having acidic aerosols present in the atmosphere. The authors present data that suggests larger secondary-aerosol yields in the presence of an acid seed aerosol than occurs in the presence of a non-acid seed aerosol. The suggestion is that the acid is capable of catalyzing the formation of lower-volatility organic products, maybe through polymerization.

Pandis *et al.* (1991) have found no significant SOA formation from the photooxidation of isoprene, due to its small size and the high volatility of its oxidation products. Significant SOAs are formed from biogenic hydrocarbons larger than isoprene. Claeys *et al.* (2004) suggest that the yield of SOAs from the photooxidation of isoprene in the Amazonian rain forest, where NO_x is low (<100 ppt), is about 0.4% on a mass basis. Even with its low particulate yield, since the global annual isoprene emissions are about 500 Tg per year, the SOAs from isoprene photooxidation alone could account for about 2 Tg/yr. This is a significant fraction of the Intergovernmental Panel on Climate Change (Houghton *et al.*, 2001) estimate of between 8 and 40 Tg/yr of SOAs from biogenic sources. The oxidation of the other biogenic hydrocarbons are expected to have much higher SOA yields.

CHEMISTRY OF ATMOSPHERIC ACID FORMATION

Acid deposition has long been recognized to be a serious problem in Scandinavian countries, and throughout Europe, much of the United States, and Canada. Most of the concerns about acid deposition are related to the presence of strong inorganic acids, nitric acid (HNO_3) and sulfuric acid (H_2SO_4), in the atmosphere. Sulfur dioxide (SO_2) and nitrogen oxides (NO_x) are emitted from numerous stationary and mobile combustion sources scattered throughout the industrialized nations of the world. As this polluted air is transported over large distances, 500 km and more, the sulfur and nitrogen oxides can be further oxidized, ultimately to the corresponding acids. The 1990 Clean Air Act Amendments require significant reductions in SO_2 from power plants in the eastern portion of the United States. Less significant reductions of NO_x emissions are also required.

As was suggested earlier, one of the primary goals of air-pollution research is to take information about emissions, topography, meteorology, and chemistry and develop a mathematical model to predict acid deposition in the model area. The type of model used to do this is known as a long-range transport (LRT) model, where the dimensions are on the order of 1000 km or more. The acid deposition that is observed is produced by the chemical processes occurring in the atmosphere during the transport. Prediction of the effects of any reduction in emissions of sulfur and nitrogen oxides requires a detailed understanding of the atmospheric reactions involved in the oxidations.

Pollutant emissions are transported by the winds for hundreds of kilometers within the boundary or “mixing” layer of the atmosphere. This layer is approximately 1000 m deep and well mixed, allowing pollutants to be dispersed both horizontally and vertically throughout this layer. In the boundary layer, a variety of chemical and physical processes affect the concentrations of the pollutants. To form the acids, the sulfur and nitrogen oxides must react with some oxidants present in the atmosphere. The most important gas-phase oxidants were discussed above. These oxidation processes may occur in the gas phase, or they may occur as aqueous phase reactions in clouds. The gas-phase oxidations of sulfur and nitrogen oxides are better quantified than are the aqueous-phase oxidations.

Gas-Phase Processes

There are three potentially important gas-phase oxidation processes for producing nitric acid. These processes were identified earlier: the reaction of hydroxyl radicals with NO_2 (21), hydrogen abstraction reactions from organics by NO_3 (31), and the reaction of N_2O_5 with water (32). During the day, the dominant process leading to the formation of HNO_3 is reaction (21). At night, the N_2O_5 reaction with water vapor (32) is important. The hydrogen atom abstraction reaction of NO_3 with organics is expected to be of relatively minor importance. The 24-hour averaged rate of NO_2 conversion to HNO_3 during the summer at 50% relative humidity is expected to be between 15%/hour and 20%/hour.

Calvert and Stockwell (1983) have shown that the gas-phase oxidation of sulfur dioxide is primarily by the reaction of the hydroxyl radical with SO_2:

$$HO + SO_2 + M \rightarrow HOSO_2 + M \quad (33)$$

$$HOSO_2 + O_2 \rightarrow HO_2 + SO_3 \quad (34)$$

$$SO_3 + H_2O \rightarrow H_2SO_4 \quad (35)$$

In this sequence of reactions, the OH radical initiates the oxidation of SO_2. The bisulfite radical ($HOSO_2$) product reacts rapidly with oxygen to form sulfur trioxide (SO_3) and HO_2. The HO_2 radical can be converted back to OH by reaction (9), and the SO_3 can react with water to form sulfuric acid. The details of the kinetics of these processes have been presented by Anderson *et al.* (1989). This sequence of reactions can be simplified for modeling purposes to the reaction

$$OH + SO_2 \ (+ \ O_2, H_2O) \rightarrow H_2SO_4 + HO_2 \quad (36)$$

The modeling suggests that for moderately polluted and mildly polluted cases described above, the maximum SO_2 oxidation rates were 3.4%/hour and 5.4%/hour. These maximum conversions occurred near noon, when the OH concentration was a maximum. The conversion of SO_2 to H_2SO_4 for a clear summertime 24-hour period was 16% and 24% for the moderately and mildly polluted conditions. The gas-phase oxidation of both NO_2 and SO_2 vary considerably, depending on the concentrations of other species in the atmosphere. But the gas-phase oxidation of SO_2 is always going to be much slower than that for NO_2.

Aqueous-Phase Chemistry

Aqueous-phase oxidations of nitrogen oxides are not believed to be very important in the atmosphere. On the other hand, the aqueous-phase oxidations of sulfur dioxide appear to be quite important. Sulfur dioxide may dissolve in atmospheric water droplets, to form mainly the bisulfite ion (HSO_3^-):

$$SO_2 + \text{Cloud} \rightarrow SO_2{\cdot}H_2O \rightarrow HSO_3^- + H^+ \quad (37)$$

The concentration of the bisulfite ion in the droplet is dependent on the Henry's law constant (H), which determines the solubility of SO_2 in water, the equilibrium constant (K) for the first dissociation of the hydrated SO_2, the gas-phase SO_2 concentration, and the acidity of the solution.

$$[HSO_3^-] = KH\,[SO_2]_{gas}/[H^+]$$

$SO_2{\cdot}H_2O$, HSO_3^-, and SO_3^{2-} are all forms of sulfur (IV) (S(IV)). At normal pH levels, the bisulfite ion is the predominate form of sulfur (IV) in aqueous systems, and the form that needs to be oxidized to the sulfate ion (SO_4^{2-}), sulfur (VI). HSO_3^- can be oxidized by oxygen, but this process is very slow. The reaction may be catalyzed by transition metal ions, such as manganese (Mn^{2+}) and iron (Fe^{3+}). The importance of these metal-catalyzed oxidations depends strongly on the concentration of metal ions present. This may be enhanced by passing through heavily industrialized areas, where there might be sources of these metals for the atmosphere.

Ozone and hydrogen peroxide are likely to be more important catalysts for the oxidation of S(IV). The rate of ozone-catalyzed oxidation of S(IV) decreases as the pH of the solution decreases (or as the solution becomes more acidic). Since the HSO_3^- concentration depends inversely on $[H^+]$, the rate of oxidation of S(IV) slows down considerably as the pH decreases ($[H^+]$ increases). This reaction is likely to be of importance at pH $\geqslant$ 4.5.

Hydrogen peroxide, on the other hand, is much more soluble than ozone. Hence, even though the gas-phase concentrations are much lower than ozone, the aqueous concentrations can be high. The rate constant for the hydrogen-peroxide-catalyzed reaction increases as the pH decreases, down to a pH of about 2.0. At a pH of 4.5, the oxidation catalyzed by 1 ppb of gaseous H_2O_2 in equilibrium with the aqueous phase is about 100 times faster than the ozone-catalyzed oxidation by 50 ppb of gaseous O_3 in equilibrium with the aqueous phase. Figure 8 shows a comparison of aqueous-phase

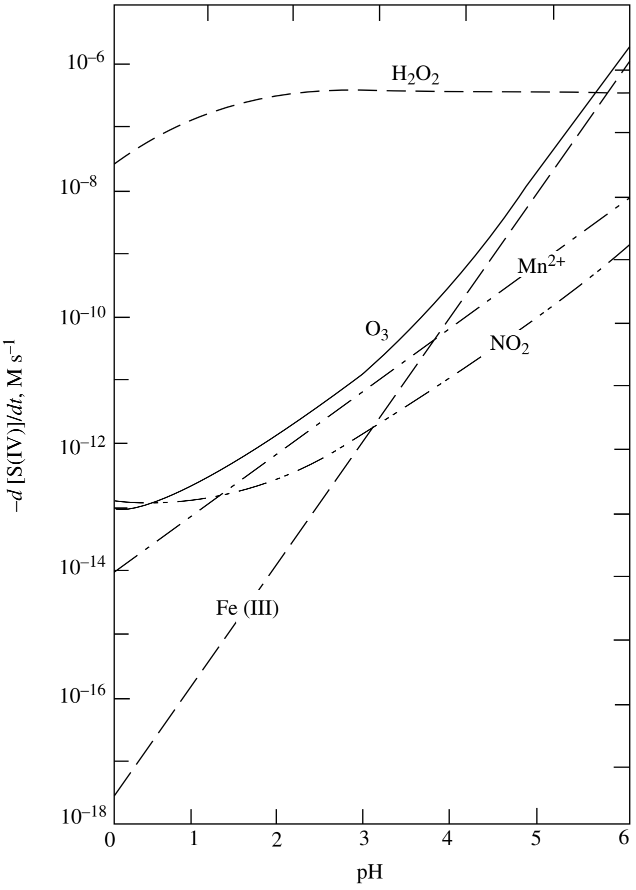

FIGURE 8 Comparison of aqueous-phase oxidation paths; the rate of conversion of S(IV) to S(VI) as a function of pH. Conditions assumed are: $[SO_2(g)] = 5$ ppb; $[NO_2(g)] = 1$ ppb; $[H_2O_2(g)] = 1$ ppb; $[O_3(g)] = 50$ ppb; $[Fe(III)] = 0.3$ µM; and $[Mn(II)] = 0.03$ µM. From Seinfeld and Pandis (1998). With permission.

catalyzed SO_2 oxidation paths as a function of pH. In the case of the H_2O_2-catalyzed oxidation of S(IV), the rate of oxidation will be limited by the H_2O_2 present in the cloud or available to the cloud. This leads to the rate of S(IV) conversion to S(VI) being limited by the rate at which gaseous H_2O_2 is incorporated into the aqueous phase of the clouds by updrafts and entrainment.

Natural Sources of Acids and Organic Acids

There are a variety of potential natural sources of acids in the atmosphere. Dimethyl sulfide (DMS) is one of the most important natural sulfur compounds emitted from the oceans (Cocks and Kallend, 1988). Hydroxyl radicals may react with DMS by either of two possible routes:

$$OH + CH_3SCH_3 \rightarrow CH_3S(OH)CH_3 \qquad (38)$$

$$OH + CH_3SCH_3 \rightarrow CH_3SCH_2 + H_2O \qquad (39)$$

addition to the sulfur or abstraction of a hydrogen atom from one of the methyl groups. For the first case, the product is proposed to react with oxygen:

$$CH_3S(OH)CH_3 + 2O_2 \rightarrow CH_3SO_3H + CH_3O_2 \qquad (40)$$

eventually forming methane sulfonic acid (CH_3SO_3H, or MSA). Many organic S(IV) compounds are easily hydrolyzed to inorganic S(IV), which can be oxidized to S(VI). For the second path, the alkyl-type radical is expected to react with molecular oxygen to form a peroxy-type radical, followed by the oxidation of NO to NO_2:

$$CH_3SCH_2 + O_2 \rightarrow CH_3SCH_2O_2 \qquad (41)$$

$$CH_3SCH_2O_2 + NO + 2O_2 \rightarrow NO_2 + HCHO + SO_2 + CH_3O_2 \qquad (42)$$

The details of this mechanism are not well established, but the suggestion is that DMS, which is produced by biogenic processes, can be partially oxidized to SO_2, hence contributing to the SO_2 observed in the atmosphere. This SO_2 would be oxidized by the same routes as the anthropogenic SO_2. Several of the papers included in the volume by Saltzman and Cooper (1989) have presented a much more complete discussion of the role of biogenic sulfur in the atmosphere.

In recent years, it has become increasingly obvious that there are substantial contributions of organic acids (carboxylic acids) in the atmosphere (Chebbi and Carlier, 1996). It has been found that formic acid (HCOOH) and acetic acid (CH_3COOH) are the most important gas-phase carboxylic acids identified in the atmosphere. Concentrations in excess of 10 ppb of these compounds have been observed in polluted urban areas. Concentrations of these acids have been observed in excess of 1 ppb, in the Amazon forest, particularly during the dry season. A very wide range of mono- and dicarboxylic acids have been observed in the aqueous phase, rain, snow, cloud water, and fog water. Dicarboxylic acids are much more important in aerosol particles, since they have much lower vapor pressures than do monocarboxylic acids. Carboxylic acids have been observed as direct emissions from biomass burning, in motor-vehicle exhaust, and in direct biogenic emissions. Carboxylic acids are also produced in the atmosphere. The most important gas-phase reactions for the production of carboxylic acids are as a product of the ozone oxidation of alkenes. Aqueous-phase oxidation of formaldehyde is believed to be a major source of formic acid, maybe more important than the gas-phase production. Carboxylic acids are, in general, relatively unreactive; their primary loss processes from the atmosphere are believed to be wet and dry deposition.

Summary

Much of the atmospheric acidity results from the oxidation of nitrogen oxides and sulfur oxides. In the case of nitrogen oxides, this oxidation is primarily due to the gas-phase reaction of OH with NO_2. In the case of sulfur oxides, the comparable reaction of OH with SO_2 is much slower, but is likely to be the dominant oxidation process in the absence of clouds. When clouds are present, the aqueous-phase oxidation of SO_2 is expected to be more important. At higher pH, the more important aqueous oxidation of SO_2 is likely to be catalyzed by ozone, while at lower pH, the H_2O_2-catalyzed oxidation is likely to be more important. Organic acids also contribute significantly to the acidity observed in the atmosphere.

POLAR STRATOSPHERIC OZONE

In 1974, Molina and Rowland proposed that chlorofluorocarbons (CFCs) were sufficiently long-lived in the troposphere to be able to diffuse to the stratosphere, where effects on ozone would be possible. They shared in the 1995 Nobel Prize in chemistry for this work.

More recently an ozone "hole" has been observed in the stratosphere over Antarctica, which becomes particularly intense during the Southern Hemispheric spring, in October. This led attention to be shifted to the polar regions, where effects of CFCs on stratospheric ozone content have been observed. Before dealing with this more recent discovery, it is necessary to provide some of the background information about the stratosphere and its chemistry.

The stratosphere is the region of the atmosphere lying above the troposphere. In the troposphere, the temperature of the atmosphere decreases with increasing altitude from about 290 K near the surface to about 200 K at the tropopause. The tropopause is the boundary between the troposphere and the stratosphere, where the temperature reaches a minimum. The altitude of the tropopause varies with season and latitude between altitudes of 10 and 17 km. Above the tropopause, in the stratosphere, the temperature increases with altitude up to about 270 K near an altitude of 50 km. In the troposphere, the warmer air is below the cooler air. Since warmer air is less dense, it tends to rise; hence there is relatively good vertical mixing in the troposphere. On the other hand, in the stratosphere the warmer air is on top, which leads to poor vertical mixing and a relatively stable atmosphere.

Stratospheric Ozone Balance

In the stratosphere, there is sufficient high-energy ultraviolet radiation to photolyze molecular oxygen:

$$O_2 + h\nu\ (\lambda \leq 240\ \text{nm}) \rightarrow 2O(^3P) \tag{43}$$

This will be followed by the oxygen-atom reaction with O_2 (2) forming ozone. These processes describe the ozone production in the stratosphere. They are also the processes responsible for the heating in the upper stratosphere. This ozone production must be balanced by ozone-destruction processes. If we consider only oxygen chemistry, ozone destruction is initiated by ozone photolysis (22), forming an oxygen atom. The oxygen atom can also react with ozone, re-forming molecular oxygen:

$$O(^3P) + O_3 \rightarrow 2O_2 \tag{44}$$

Reactions (43), (2), (22), and (44) describe the formation and destruction of stratospheric ozone with oxygen-only chemistry. This is commonly known as the Chapman mechanism.

Other chemical schemes also contribute to the chemistry in the natural (unpolluted) stratosphere. Water can be photolyzed, forming hydrogen atoms and hydroxyl radicals:

$$H_2O + h\nu\ (\lambda \leq 240\ \text{nm}) \rightarrow H + OH \tag{45}$$

The OH radical may react with ozone to form HO_2, which may in turn react with an O atom to reform OH. The net effect is the destruction of odd oxygen (O and/or O_3).

$$OH + O_3 \rightarrow HO_2 + O_2 \tag{46}$$
$$HO_2 + O \rightarrow OH + O_2 \tag{47}$$
$$O + O_3 \rightarrow 2O_2 \tag{Net}$$

These reactions form a catalytic cycle that leads to the destruction of ozone. An alternative cycle is

$$H + O_3 \rightarrow OH + O_2 \tag{48}$$
$$OH + O \rightarrow H + O_2 \tag{49}$$
$$O + O_3 \rightarrow 2O_2 \tag{Net}$$

Other catalytic cycles involving HO_x species (H, OH, and HO_2) are possible. Analogous reactions may also occur involving NO_x species (NO and NO_2),

$$NO + O_3 \rightarrow NO_2 + O_2 \tag{3}$$
$$NO_2 + O \rightarrow NO + O_2 \tag{50}$$
$$O + O_3 \rightarrow 2O_2 \tag{Net}$$

and ClO_x species (Cl and ClO),

$$Cl + O_3 \rightarrow ClO + O_2 \tag{51}$$
$$ClO + O \rightarrow Cl + O_2 \tag{52}$$
$$O + O_3 \rightarrow 2O_2 \tag{Net}$$

These processes are some of the ozone-destruction processes of importance in the stratosphere. These types of processes contribute to the delicate balance between the stratospheric ozone production and destruction, which provide the natural control of stratospheric ozone, when the stratospheric HO_x, NO_x, and ClO_x species are of natural origin.

Ozone plays an extremely important role in the stratosphere. It absorbs virtually all of the solar ultraviolet radiation between 240 and 290 nm. This radiation is lethal to single-cell organisms, and to the surface cells of higher plants and animals. Stratospheric ozone also reduces the solar ultraviolet radiation up to 320 nm, wavelengths that are also biologically active. Prolonged exposure of the skin to this radiation in susceptible individuals may lead to skin cancer. In addition, stratospheric ozone is the major heat source for the stratosphere, through the absorption of ultraviolet, visible, and infrared radiation from the sun. Hence, changes in the stratospheric ozone content could lead to significant climatic effects.

Stratospheric Pollution

Over the past 30 years, there has been considerable interest in understanding the ways in which man's activities might be depleting stratospheric ozone. Major concerns first arose from considerations of flying a large fleet of supersonic aircraft in the lower stratosphere. These aircraft were expected to be a significant additional source of NO_x in the stratosphere. This added NO_x could destroy stratospheric O_3 by the sequence of reactions (3) and (50) and other similar catalytic cycles. The environmental concerns, along with economic factors, were sufficient to limit the development of such a fleet of aircraft.

More recently, environmental concern has turned to the effects of chlorofluorocarbons on the stratospheric ozone. These compounds were used extensively as aerosol propellants and foam-blowing agents and in refrigeration systems. The two most commonly used compounds were $CFCl_3$ (CFC-11) and CF_2Cl_2 (CFC-12). These compounds are very stable, which allows them to remain in the atmosphere sufficiently long that they may eventually diffuse to the stratosphere. There they may be photolyzed by the high-energy ultraviolet radiation:

$$CFCL_3 + h\nu\ (\lambda \leq 190\ \text{nm}) \rightarrow CFCl_2 + Cl \tag{53}$$

This reaction, and similar reactions for other chlorinated compounds, leads to a source of chlorine atoms in the stratosphere. These chlorine atoms may initiate the catalytic destruction of ozone by a sequence of reactions, such as reactions (51) and (52). Numerous other catalytic destruction cycles have been proposed, including cycles involving combinations of ClO_x, HO_x, and NO_x species.

In recent years, our ability to model stratospheric chemistry has increased considerably, which allows good comparisons between model results and stratospheric measurements. Based upon our improved understanding of the stratosphere and the continuing concern with CFCs, about 45 nations met during the fall of 1987 to consider limitations on the production and consumption of CFCs. This led to an agreement to freeze consumption of CFCs at 1986 levels, effective in September 1988, and requirements to reduce consumption by 20% by 1992 and by an additional 30% by 1999. In November 1992, the Montreal Protocol on Substances That Deplete the Ozone Layer revised the phase-out schedule for CFCs to a complete ban on production by January 1, 1996. In November 1995, additional amendments were adopted to freeze the use of hydrogen-containing CFCs (HCFCs) and methyl bromide (CH_3Br) and eliminate their use by 2020 and 2010, respectively. These agreements were very important steps to addressing the problem of CFCs in the atmosphere. This has also led to major efforts to find environmentally safe alternatives to these compounds for use in various applications.

Antarctic Ozone

Farman *et al.* (1985) observed a very significant downward trend in the total ozone column measured over Halley Bay, Antarctica (Figure 9). Solomon (1988) has reviewed this and other data from Antarctica, and has concluded that there has been a real decrease in the ozone column abundance in the South Polar region. Other data suggest that the bulk of the effect on ozone abundance is at lower altitudes in the stratosphere, between about 12 and 22 km, where the stratospheric ozone concentrations decrease quickly and return to near normal levels as the springtime warms the stratosphere. The subsequent discussion will outline some of the chemical explanations for these observations. Some atmospheric dynamical explanations of the ozone hole have been proposed, but these are not believed to provide an adequate explanation of the observations.

Figure 10 shows plots of results from flights in the Antarctic region during August and September 1987 (Anderson *et al.*, 1991). Ozone- and ClO-measurement instrumentation was flown into the polar stratosphere on a NASA ER-2 aircraft (a modified U-2). This figure shows a sharp increase in ClO concentration as one goes toward the pole and a similar sharp decrease in stratospheric ozone. On the September 16th flight, the ClO concentration rose from about 100 to 1200 ppt while the ozone concentration dropped from about 2500 to 1000 ppb. This strong anticorrelation is consistent with the catalytic ozone-destruction cycle, reactions (51) and (52).

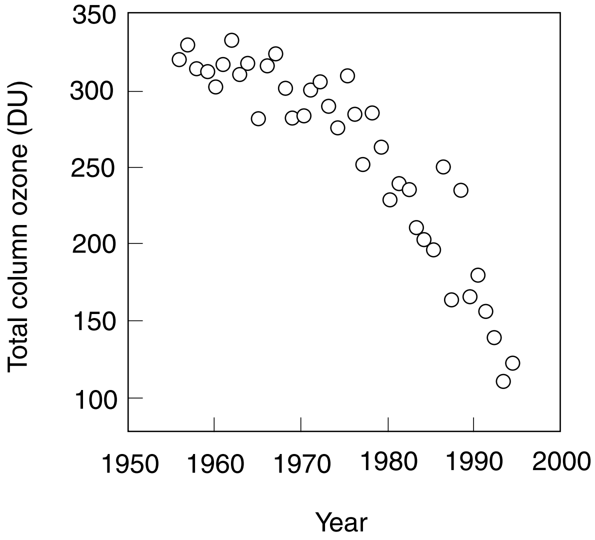

FIGURE 9 Average total column ozone measured in October at Halley Bay, Antarctica, from 1957 to 1994. Ten additional years of data are shown in this plot beyond the period presented by Farman *et al.* (1985). From Finlayson-Pitts and Pitts (2000). With permission.

Solomon (1988) has suggested that polar stratospheric clouds (PSCs) play an important role in the explanation of the Antarctic ozone hole. PSCs tend to form when the temperature drops below about 195 K and are generally observed in the height range from 10 to 25 km. The stratosphere is sufficiently dry that cloud formation does not occur with water-forming ice crystals alone. At 195 K, nitric acid-trihydrate will freeze to form cloud particles, and there is inadequate water alone to form ice, until one goes to an even lower temperature. Significant quantities of nitric acid are in the cloud particles below 195 K, while they would be in the gas phase at higher temperatures. PSCs are most intense in the Antarctic winter and decline in intensity and altitude in the spring, as the upper regions of the stratosphere begin warming. It was proposed that HCl(a) ((a)—aerosol phase), absorbed on the surfaces of PSC particles, and gaseous chlorine nitrate, $ClONO_2(g)$, react to release Cl_2 to the gas phase:

$$ClONO_2(g) + HCl(a) \rightarrow Cl_2(g) + HNO_3(a) \qquad (54)$$

Subsequent research identified several other gas-surface reactions on PSCs that also play an important role in polar stratospheric ozone depletion

$$ClONO_2(g) + H_2O(a) \rightarrow HOCl(g) + HNO_3(a,g) \qquad (55)$$
$$HOCl(g) + HCl(a) \rightarrow Cl_2(g) + H_2O(a) \qquad (56)$$
$$N_2O_5(g) + H_2O(a) \rightarrow 2HNO_3(a,g) \qquad (57)$$

Reactions (55) and (56) have the same net effect as reaction (54), while reaction (57) removes reactive nitrogen oxides from the gas phase, reducing the rate of ClO deactivation by

$$ClO + NO_2 \rightarrow ClONO_2 \qquad (58)$$

Webster *et al.* (1993) made the first *in situ* measurement of HCl from the ER-2 aircraft. These results suggested that HCl is not the dominant form of chlorine in the midlatitude lower stratosphere, as had been believed. These results suggested that HCl constituted only about 30% of the inorganic chlorine. This has led to the belief that $ClONO_2$ may be present at concentrations that exceed that of HCl.

Figure 11 shows a chronology of the polar ozone-depletion process. As one enters the polar night, $ClONO_2$ is the dominant inorganic chlorine-containing species, followed by HCl and ClO. Due to the lack of sunlight, the temperature decreases and polar stratospheric clouds form, permitting reactions (54), (55), and (56) to proceed, producing gaseous Cl_2. Both HCl and $ClONO_2$ decrease. As the sun rises, the Cl_2 is photolyzed, producing Cl atoms that react

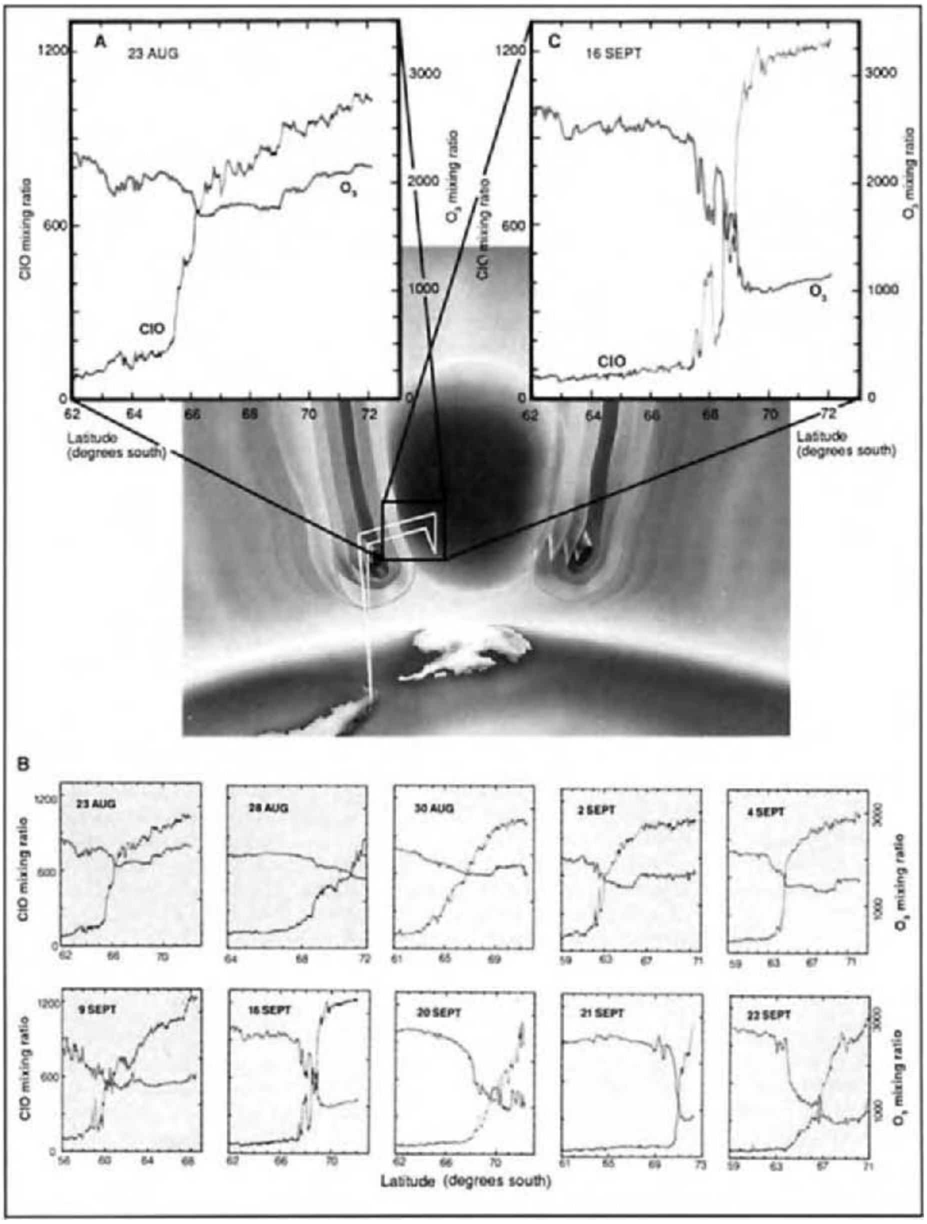

FIGURE 10 Rendering of the containment provided by the circumpolar jet that isolates the region of highly enhanced ClO (shown in green) over the Antarctic continent. Evolution of the anticorrelation between ClO and O_2 across the vortex transition is traced from: (A) the initial condition observed on 23 August 1987 on the south-bound log of the flight; (B) summary of the sequence over the ten-flight series; (C) imprint on O_3 resulting from 3 weeks of exposure to elevated levels of ClO. Data panels do not include dive segment of trajectory; ClO mixing ratios are in parts per trillion by volume; O_3 mixing ratios are in parts per billion by volume. From Anderson *et al*. (1991). With permission.

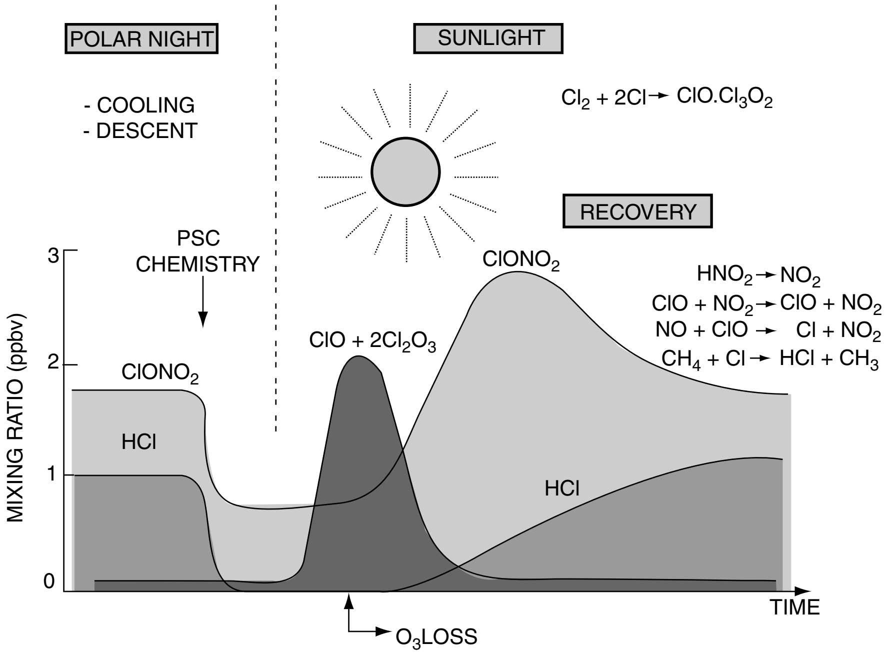

FIGURE 11 Schematic of the time evolution of the chlorine chemistry, illustrating the importance of the initial HCl/$ClONO_2$ ratio, the sudden formation of ClO with returning sunlight, the way in which $ClONO_2$ levels can build up to mixing ratios in excess of its initial values, and the slow recovery of HCl levels. From Webster *et al.* (1993). With permission.

with ozone to form ClO. This ClO may react with itself to form the dimer, $(ClO)_2$:

$$ClO + ClO + M \rightarrow (ClO)_2 + M \qquad (59)$$

Under high-ClO-concentration conditions, the following catalytic cycle could be responsible for the destruction of ozone:

$$\begin{aligned} 2 \times (Cl + O_3 &\rightarrow ClO + O_2) && (51)\\ ClO + ClO + M &\rightarrow (ClO)_2 + M && (59)\\ (ClO)_2 + h\nu &\rightarrow Cl + ClOO && (60)\\ ClOO + M &\rightarrow Cl + O_2 && (61)\\ 2O_3 &\rightarrow 3O_2 && (\text{Net}) \end{aligned}$$

This ClO-driven catalytic cycle can effectively destroy O_3, but it requires the presence of sunlight to photolyze Cl_2 and $(ClO)_2$. The presence of sunlight will lead to an increase in temperature that releases HNO_3 back to the gas phase. The photolysis of HNO_3 can release NO_2, which can react with ClO by reaction (58) to re-form $ClONO_2$. This can terminate the unusual chlorine-catalyzed destruction of ozone that occurs in polar regions.

Anderson (1995) suggests that the same processes occur in both the Arctic and Antarctic polar regions. The main distinction is that it does not get as cold in the Arctic, and the polar stratospheric clouds do not persist as long after the polar sunrise. As the temperature rises above 195 K, nitric acid is released back into the gas phase only shortly after Cl_2 photolysis begins. As nitric acid is photolyzed, forming NO_2, the ClO reacts with NO_2 to form $ClONO_2$ and terminate the chlorine-catalyzed destruction of ozone. Anderson (1995) suggests that the temperatures warmed in late January 1992, and ozone loss was only 20 to 30% at the altitudes of peak ClO. The temperatures remained below 195 K until late February 1993, and significantly more ozone will be lost. The delay between the arrival of sunlight and the rise of temperatures above 195 K are crucial to the degree of ozone loss in the Arctic.

Summary

The observations made in the polar regions provided the key link between chlorine-containing compounds in the stratosphere and destruction of stratospheric ozone. These experimental results led to the Montreal Protocol agreements and their subsequent revisions to accelerate the phase-out of the use of CFCs. A tremendous amount of scientific effort over many years has led to our current understanding of the effects of Cl-containing species on the stratosphere.

CLOSING REMARKS

Our knowledge and understanding has improved considerably in recent years. Much of the reason for this improved knowledge is the result of trying to understand how we are affecting our environment. From the foregoing discussion, it is clear that atmospheric chemistry is quite complex. It has been through the diligent research of numerous individuals, that we have been able to collect pertinent pieces of information that can be pulled together to construct a more complete description of the chemistry of the atmosphere.

BIOLOGICAL TREATMENT OF WASTEWATER

1. INTRODUCTION

Biological treatment is the most widely used method for removal, as well as partial or complete stabilization of biologically degradable substances present in waste-waters. Most often, the degradable substances are organic in nature and may be present as suspended, colloidal or dissolved matter. The fraction of each form depends on the nature of wastewater. In the operation of biological treatment facilities, the characteristics of wastewater are measured in terms of its chemical oxygen demand, COD, biochemical oxygen demand, BOD, total organic carbon, TOC, and volatile suspended solids, VSS; concepts of which have been discussed elsewhere.[1]

Most of the conventional biological wastewater treatment processes are based on naturally occurring biological phenomena, but are carried out at accelerated rates. These processes employ bacteria as the primary organisms; however, certain other microorganisms may also play an important role. Gates and Ghosh[2] have presented the biological component system existing in the BOD process and it is shown in Figure 1. The degradation and stabilization of organic matter is accomplished by their use as food by bacteria and other microorganisms to produce protoplasm for new cells during the growth process. When a small number of microorganisms are inoculated into a bacteriological culture medium, growth of bacteria with time follows a definite pattern as depicted in Figure 2 by plotting viable count and mass of bacteria against time.[3] The population dynamics of bacteria in biological treatment processes depends upon various environmental factors including pH, temperature, type and concentration of substrate, hydrogen acceptor, availability and concentration of essential nutrients like nitrogen, phosphorous, sulfur, etc., and essential minerals, osmotic pressure, toxicity of media or by-products, and degree of mixing.[4] In recent years, cultures have been developed for biological treatment of many hard-to-degrade organic wastes.

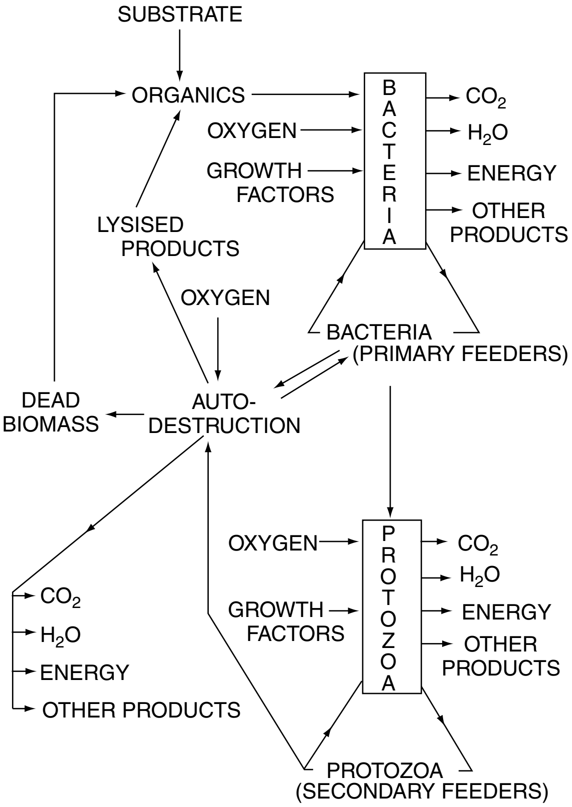

FIGURE 1 Biological component system existing in BOD process.

2. METABOLIC REACTIONS

The metabolic reactions occurring within a biological treatment reactor can be divided into three phases: oxidation, synthesis and endogenous respiration. Oxidation–reduction may proceed either in the presence of free oxygen, aerobically, or in its absence, anaerobically. While the overall reactions carried out may be quite different under aerobic and anaerobic conditions, the processes of microbial growth and energy utilization are similar. Typical reactions in these three phases are formulated below:

- Organic Matter Oxidation (Respiration)
  $C_xH_yO_z + O_2 \rightarrow CO_2 + H_2O + \text{Energy}$
- Inorganic Matter Oxidation (Respiration)
  $NH_4^+ 2O_2 \rightarrow NO_3^- + H_2O + 2H^+ + \text{Energy}$
- Protoplasm (Cell Material) Synthesis
  $C_xH_yO_z + NH_3 + O_2 + \text{Energy} \rightarrow C_5H_7NO_2 + H_2$
  $C_xH_yO_z + H^+ + NO_3^- + \text{Energy} \rightarrow C_5H_7NO_2 + CO_2 + H_2O$
- Protoplasm (Cell Material) Oxidation
  $C_5H_7NO_2 + 5O_2 \rightarrow 5CO_2 + 2H_2O + NH_3 + \text{Energy}$

Therefore, bacterial respiration in living protoplasm is a biochemical process whereby energy is made available for endothermic life processes. Being dissimilative in nature, respiration is an important process in wastewater treatment practices. On the other hand, endogenous respiration is the internal process in microorganisms that results in auto-digestion or self-destruction of cellular material.[3] Actually, bacteria require a small amount of energy to maintain normal functions such as motion and enzyme activation and this basal-energy requirement of the bacteria has been designated as endogenous respiration. Even when nutrients are available, endogenous metabolism proceeds with the breakdown of protoplasm.[5] According to Bertalanffy's hypothesis,[6] the microbial growth is the result of competition between two opposing processes: Aufban—assimilation, and Abban—endogenous metabolism. The rate of assimilation is proportional to the mass of protoplasm in the cell and the surface area of the cell, whereas the endogenous metabolism is dependent primarily on environmental conditions.

In the presence of enzymes produced by the living microorganisms, about 1/3 of the organic matter removed is oxidized into carbon dioxide and water in order to provide energy for synthesis of the remaining 2/3 of the organic matter into the cell material. Metabolism and process reactions occurring in typical biological wastewater treatment processes are explained schematically by Stewart[7] as shown in Figure 3. Thus, the basic equations for biological metabolisms are:

Organic matter metabolized
= Protoplasm synthesized + Energy for synthesis

and

Net protoplasm accumulation
= Protoplasm synthesized − Endogenous respiration.

"Growth Kinetics"

Irvine and Schaezler[8] have developed the following expression for non-rate limited growth of microorganisms in logarithmic phase:

$$\frac{dN}{dt} = k_0 N \qquad (1)$$

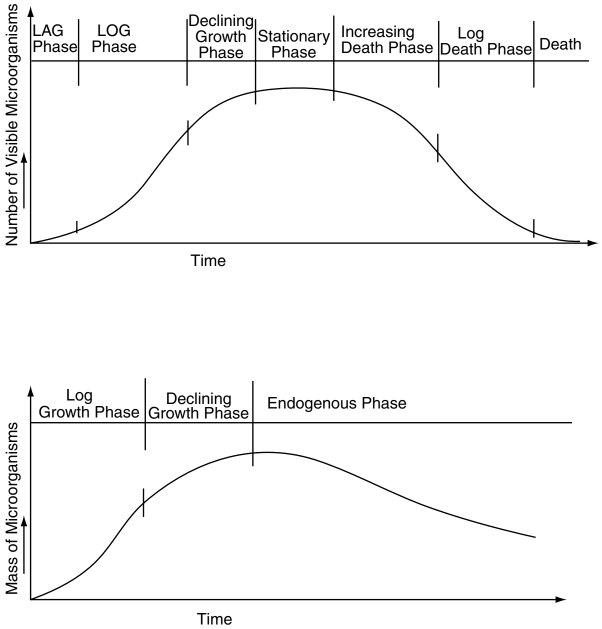

FIGURE 2 Growth pattern of microorganisms.

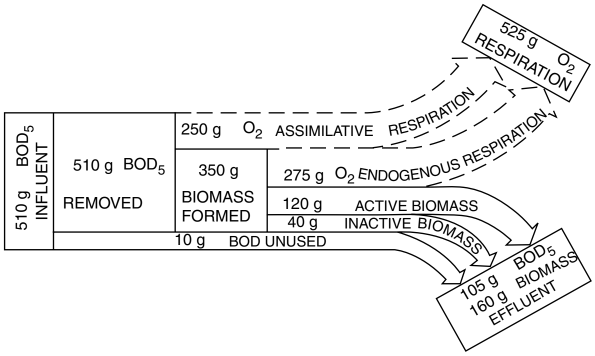

SYSTEM METABOLISM FOR SOLUBLE WASTES

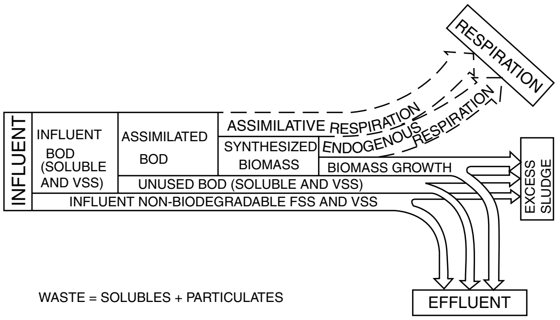

FIGURE 3 Metabolism and process reactions.

or

$$N_t = N_o e^{k_o t}$$

where:

N_0 = Number of viable microorganisms per unit volume at time $t = 0$
$N_t = N$ = Number of viable microorganisms per unit volume at time t

and

k = Logarithmic growth rate constant, time^{-1}.

In wastewater treatment practices, the growth pattern based on mass of microorganisms has received more attention than the number of viable microorganisms. If each microorganism is assumed to have an average constant mass, then N in Eq. 1 can be replaced with X, the mass of active microorganisms present per unit volume to obtain:

$$\frac{dX}{dt} = k_0 X. \tag{2}$$

The growth of bacterial population may become limited either due to exhaustion of available nutrients or by the accumulation of toxic substances. The growth rate of bacteria starts slowing down, and Eq. 1 changes to the form:

$$\frac{dN}{dt} = k_t N \tag{3}$$

where growth rate factor k_t, varies with time and becomes a function of temperature, T, pH, substrate concentration, S, and concentration of various nutrients, C_{n1}, C_{n2}, etc., i.e.:

$$k_t = V_1\,(T, \text{pH}, C_s, C_{n1}, C_{n2}, \ldots).$$

Figure 4 shows variation in growth rate k_t with change in nutrient concentrations, assuming that T and pH are held constant and substrate concentration, S, is greater than the critical substrate concentration, S^*, above which k_t, is independent of S. Several interesting observations are made from these curves.[8] First, the maximum value of k_t is essentially constant. Second, the shape of the curve and the limiting concentration is different for each nutrient. Third, k_t is shown to be zero when any of the nutrients is missing. Fourth, as the biological reaction proceeds, all nutrients are consumed. Thus, even if all nutrients are initially in excess, the growth may eventually become limited. Finally, as the concentration drops to zero, a stationary phase is reached, i.e., dN/dt becomes zero.

In case of a substrate limited system, rate of growth is given by:

$$\frac{dN}{dt} = \mu N \tag{4}$$

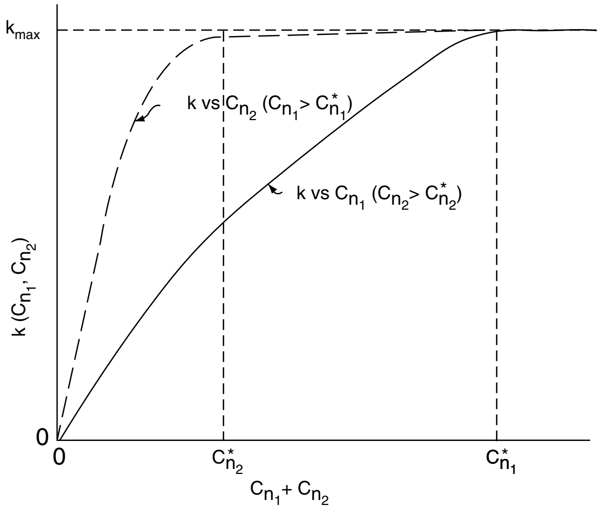

FIGURE 4 k vs nutrient concentration.

or

$$\frac{dX}{dt} = \mu X.$$

The following simple relationship between specific growth rate of microorganisms, μ, and substrate concentration, S, was developed by Monod[9] and has been widely accepted:

$$\mu = \frac{dN}{N dt} = \frac{dX}{X dt} = \mu_{\max} \frac{S}{K + S} \tag{5}$$

where K is a constant called half velocity coefficient and $\mu_{\max}$ is maximum specific growth rate.

It is postulated that the same amount of substrate is incorporated in each cell formed. Therefore, the rate of increase in number or mass of microorganisms in logarithmic growth phase, dN/dt, or dX/dt, is proportional to the rate of substrate consumption, dS/dt, or dL/dt, if the substrate concentration is measured in terms of its BOD, L, and the following relationship can be stated:

$$\frac{dX}{dt} = Y \frac{dS}{dt} \tag{6}$$

or

$$\Delta X = Y \Delta S$$

where Y is called the growth yield coefficient, ΔX is the cell mass synthesized in a given time, and ΔS is substrate removed in the same time. The substrate utilization rate, q, per unit biomass has been defined as:

$$q = \frac{dS}{X dt} \tag{7}$$

Combining Eqs. 4, 6 and 7 yields:

$$q = \frac{\mu}{Y} \tag{8}$$

and

$$q = q_{\max} \frac{S}{K + S}. \tag{9}$$

Under conditions of rate limited growth, i.e., nutrient exhaustion or auto-oxidation, Eq. 6 becomes:

$$\frac{dX}{dt} = Y \frac{dS}{dt} - bX \tag{10}$$

where b is the auto-oxidation rate or the microbial decay rate. In absence of substrate, this equation is reduced to:

$$\frac{dX}{dt} = -bX. \tag{11}$$

Several kinetic equations have been suggested for analysis and design of biological wastewater treatment systems and the following have been applied frequently:[10–13]

$$\frac{dS}{dt} = \frac{q_{\max} SX}{(K + S)} \tag{12}$$

$$\frac{dS}{dt} = qSX \tag{13}$$

$$\frac{dS}{dt} = qX \frac{S^2}{S_0} \tag{14}$$

where S_0 is the initial substrate concentration. Combining Eqs. 10 and 12 gives the net specific growth rate:

$$\mu = \frac{dX}{X dt} = \frac{q_{\max} YS}{K + S} - b \tag{15}$$

A similar kinetic relationship can be obtained by combining Eq. 10 with Eqs. 13 and 14.

Effect of Temperature

One of the significant parameters influencing biological reaction rates is the temperature. In most of the biological treatment processes, temperature affects more than one reaction rate and the overall influence of temperature on the process becomes important. The applicable equation for the effect of temperature on rate construct is given by:

$$k_T = k_{20} \theta^{T-20} \tag{16}$$

where θ is the temperature coefficient. This equation shows that reaction rates increase with increase in temperature.

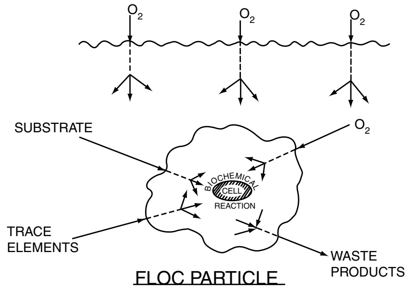
Methods of BOD Removal

In wastewater treatment processes, the microorganisms are not present as isolated cells, but are a collection of microorganisms such as bacteria, yeast, molds, protozoa, rotifers, worms and insect larvae in a gelatinous mass.[13] These microorganisms tend to collect in a biological floc, called biomass, which is expected to possess good settling characteristics. The biological oxidation or stabilization of organic matter by the microorganisms present in the floc is assumed to proceed in the following sequence:[13,14]

(a) An initial high rate of BOD removal from wastewater on coming in contact with active biomass by adsorption and absorption. The extent of this removal depends upon the loading rate, the type of waste, and the ecological condition of the biomass.
(b) Utilization of decomposable organic matter in direct proportion to biological cell growth. Substances concentrating on the surface of biomass are decomposed by the enzymes of living cells, new cells are synthesized and end products of decomposition are washed into the water or escape to the atmosphere.
(c) Oxidation of biological cell material through endogenous respiration whenever the food supply becomes limited.
(d) Conversion of the biomass into settleable or otherwise removable solids.

The rates of reactions in the above mechanisms depend upon the transport rates of substrate, nutrients, and oxygen in case of aerobic treatment, first into the liquid and then into the biological cells, as shown in Figure 5.[15] Any one or more of these rates of transport can become the controlling factors in obtaining the maximum efficiency for the process. However, most often the interfacial transfer or adsorption is the rate determining step.[14]

In wastewater treatment, the biochemical oxygen demand is exerted in two phases: carbonaceous oxygen demand to oxidize organic matter and nitrogenous oxygen demand to oxidize ammonia and nitrites into nitrates. The nitrogenous oxygen demand starts when most of the carbonaceous oxygen demand has been satisfied.[15] The typical progression of carbonaceous BOD removal by biomass with time, during biological purification in a batch operation, was first shown by Ruchhoft[16] as reproduced in Figure 6. The corresponding metabolic reactions in terms of microorganisms to food ratio, M/F, are shown in Figure 7. This figure shows that the food to microorganisms ratio maintained in a biological reactor is of considerable importance in the operation of the process. At a low M/F ratio, microorganisms are in the log-growth phase, characterized by excess food and maximum rate of metabolism. However, under these conditions, the settling characteristic of biomass is poor because of their dispersed



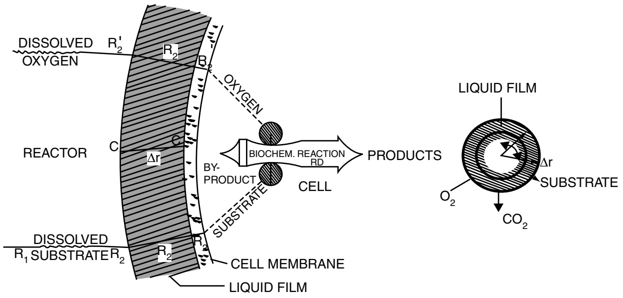


FIGURE 5 Mass transfer in biofloc.

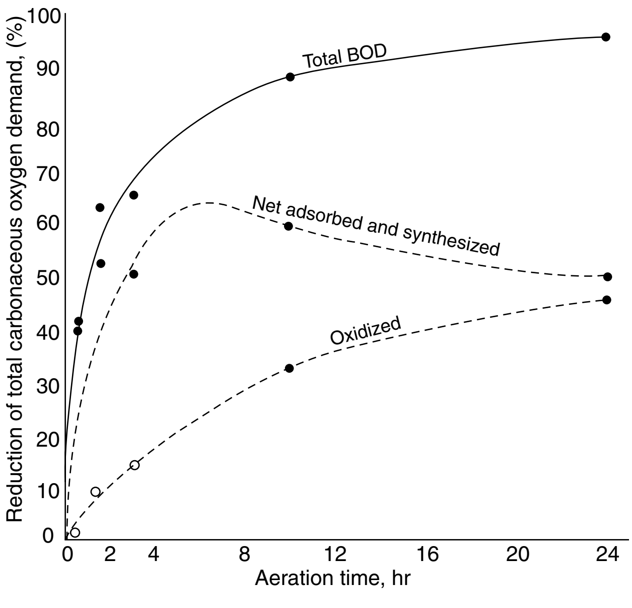

FIGURE 6 Removal of organic inbalance by biomass in a batch operation.

growth; also, the BOD removal efficiency is poor as the excess unused organic matter in solution escapes with the effluent. On the other hand, high M/F ratio means the operation is in the endogenous phase. Competition for a small amount of food available to a large mass of microorganisms results in starvation conditions within a short duration and continued aertion under these conditions results in auto-oxidation of biomass. Although the rate of metabolism is relatively low at high M/F ratio, settling characteristics of biomass are good and BOD removal efficiency is high.

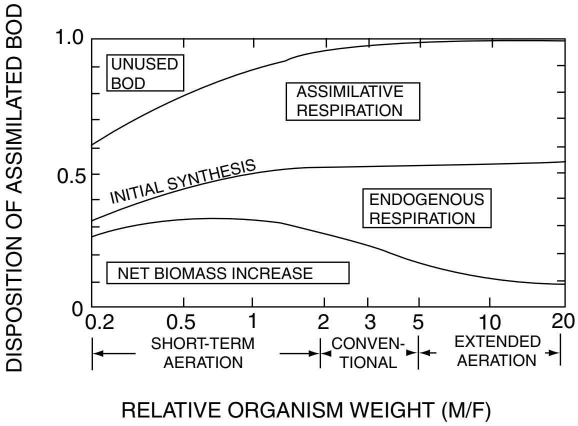

FIGURE 7 Metabolic reactions for the complete spectrum.

Goodman and Englande[17] have suggested that the total mass concentration of solids, X_T, in a biological reactor is composed of an inert fraction, X_i, and a volatile fraction, X_v, which can be further broken down into an active fraction, X, and non-biodegradable residue fraction, X_n, resulting from endogenous respiration, i.e.:

$$X_T = X_i + X_v = X_i + X + X_n. \qquad (17)$$

The total mass concentration of solids in wastewater treatment is called suspended solids, whereas its volatile fraction is called volatile suspended solids, X. In a biological reactor, volatile suspended solids, X, is assumed to represent the mass of active microorganisms present per unit volume.

3. TOXICITY

Toxicity has been defined as the property of reaction of a substance, or a combination of substances reacting with each other, to deter or inhibit the metabolic process of cells without completely altering or destroying a particular species, under a given set of physical and biological environmental conditions for a specified concentration and time of exposure.[18] Thus, the toxicity is a function of the nature of the substance, its concentration, time of exposure and environmental conditions.

Many substances exert a toxic effect on biological oxidation processes and partial or complete inhibition may occur depending on their nature and concentration. Inhibition may result from interference with the osmotic balance or with the enzyme system. In some cases, the microorganisms become more tolerant and are considered to have acclimatized or adapted to an inhibitory concentration level of a toxic substance. This adaptive response or acclimation may result from a neutralization of the toxic material produced by the biological activity of the microorganisms or a selective growth of the culture unaffected by the toxic substance. In some cases, such as cyanide and phenol, the toxic substances may be used as substrate. Rates of acclimation to lethal factors vary greatly. Thus, the toxicity to microorganisms may result due to excess concentrations of substrate itself, the presence of inhibiting substances or factors in the environment and/or the production of toxic by-products.[19–23]

The influence of a toxicant on microorganisms depends not only on its concentration in water, but also on its rate of absorption, its distribution, binding or localization in the cell, inactivation through biotransformation and ultimate excretion. The biotransformations may be synthetic or nonsynthetic. The nonsynthetic transformations involve oxidation, reduction or hydrolysis. The synthetic transformation involve the coupling of a toxicant or its metabolite with a carbohydrate, an amino acid, or a derivative of one of these. According to Warren[19], the additive interaction of two toxic substances of equal toxicity, mixed in different proportions, may show combined toxicity as shown in Figure 8. The combined effects may be supra-additive, infra-additive, no interaction or antagonism. The relative toxicity of the mixture is measured as the reciprocal of median tolerance limit.

Many wastewater constituents are toxic to microorganisms. A fundamental axiom of toxicity states that all compounds are toxic if given to a text organism at a sufficiently high dose. By definition, the compounds that exert a deleterious influence on the living microorganisms in a biological treatment unit are said to be toxic to those microorganisms. At high concentrations, these substances kill the microbes whereas at sublethal concentrations, the activity of microbes is reduced. The toxic substances may be present in the influent stream or may be produced due to antagonistic interactions.

Biological treatment is fast becoming a preferred option for treating toxic organic and inorganic wastes in any form;

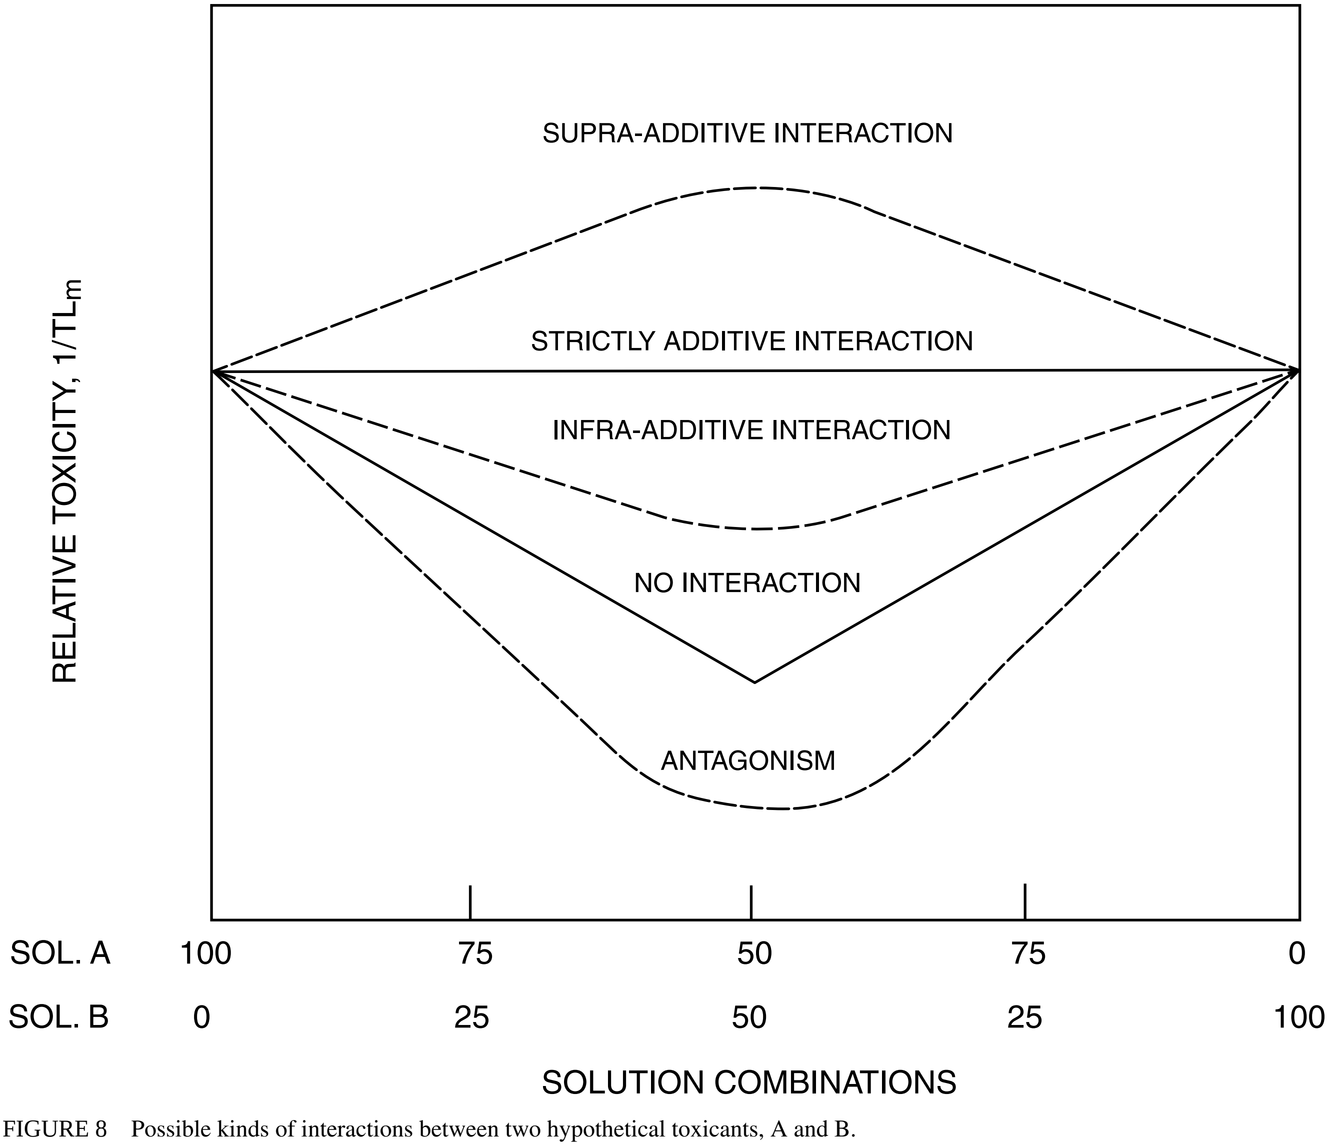

FIGURE 8 Possible kinds of interactions between two hypothetical toxicants, A and B.

solid, liquid or gaseous. The application of biological processes in degradation of toxic organic substances is becoming popular because (i) these have an economical advantage over other treatment methods; (ii) toxic substances have started appearing even in municipal wastewater treatment plants normally designed for treating nontoxic substrates; and (iii) biological treatment systems have shown a resiliency and diversity which makes them capable of degrading many of the toxic organic compounds produced by the industries.[24] Grady believes that most biological treatment systems are remarkably robust and have a large capacity for degrading toxic and hazardous materials.[25] The bacteria and fungi have been used primarily in treating petroleum-derived wastes, solvents, wood preserving chemicals and coal tar wastes. The capability of any biological treatment system is strongly influenced by its physical configuration.

As mentioned previously, the Michelis–Menten or Monond equation, Eq. 5, has been used successfully to model the substrate degradation and microbial growth in biological wastewater treatment process. However, in the presence of a toxic substance, which may act as an inhibitor to the normal biological activity, this equation has to be modified. The Haldane equation is generally accepted to be quite valid to describe inhibitory substrate reactions during the nitrification processes, anaerobic digestion, and treatment of phenolic wastewaters.[24,26,27]

$$\text{Haldane Equation} \quad \mu = \frac{\mu_{\max} S}{S + K + S^2/K_i} \qquad (18)$$

where K_i is the inhibition constant.

In the above equation, a smaller value for K_i indicates a greater inhibition. The difference between the two kinetic equations, Monod and Haldane, is shown in Figure 9, in which the specific growth rate, μ, is plotted for various substrate concentrations, *S*. The values for $\mu_{\max}$, K_s and K_i are assumed to be 0.5 h^{-1}, 50 mg/L and 100 mg/L, respectively.

Behavior of Biological Processes

The behavior of a biological treatment process, when subjected to a toxic substance, can be evaluated in three parts:

1. Is the pollutant concentration inhibitory or toxic to the process? How does it affect the biodegradation rate of other pollutants?
2. Is the pollutant concentration in process effluent reduced to acceptable level? Is there a production of toxic by-products?
3. Is there an accumulation of toxic substances in the sludge?

The above information should be collected on biological systems that have been acclimated to the concerned toxic substances. Pitter[28] and Adam *et al.*[29] have described the acclimation procedures.

Generally, biological processes are most cost-effective methods to treat wastes containing organic contaminants. However, if toxic substances are present in influents, certain pretreatment may be used to lower the levels of these contaminants to threshold concentrations tolerated by acclimated microorganisms present in these processes. Equalization of toxic load is an important way to maintain a uniform influent and reduce the shock load to the process. Also, various physical/chemical methods are available to dilute, neutralize and detoxicate these chemicals.

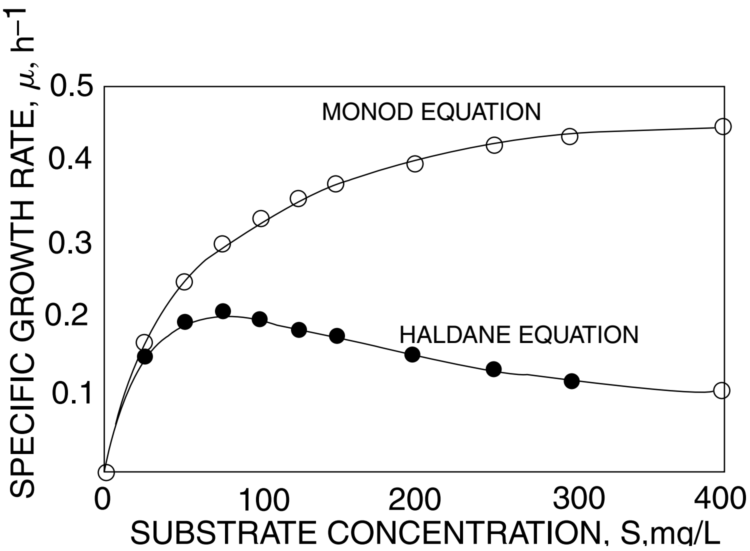

FIGURE 9 Change of specific growth rate with substrate concentration (inhibited and uninhibited).

Genetically Engineered Microorganisms

One of the promising approaches in biodegradation of toxic organics is the development of genetically engineered microorganisms. Knowledge of the physiology and biochemistry of microorganisms and development of appropriate process engineering are required for a successful system to become a reality. The areas of future research that can benefit from this system include stabilization of plasmids, enhanced activities, increased spectrum of activities and development of environmentally safe microbial systems.[30]

4. TYPES OF REACTORS

Three types of reactors have been idealized for use in biological wastewater treatment processes:

(a) Batch Reactors in which all reactants are added at one time and composition changes with time;
(b) Plug Flow or Non-Mix Flow Reactors in which no element of flowing fluid overtakes another element; and
(c) Completely Mixed or Back-Mix Reactors in which the contents are well stirred and are uniform in composition throughout.

Most of the flow reactors in the biological treatment are not ideal, but with negligible error, some of these can be considered ideal plug flow or back-mix flow. Others have considerable deviations due to channeling of fluid through the vessel, by the recycling of fluid through the vessel or by the existence of stagnant regions of pockets of fluid.[31] The non-ideal flow conditions can be studied by tagging and following each and every molecule as it passes through the vessel, but it is almost impossible. Instead, it is possible to measure the distribution of ages of molecules in the exit stream.

The mean retention time, $\bar{t}$ for a reactor of volume V and having a volumetric feed rate of Q is given by $\bar{t} = V/Q$. In non-ideal reactors, every molecule entering the tank has a different retention time scattered around $\bar{t}$. Since all biological reactions are time dependent, knowledge on age distribution of all the molecules becomes important. The distribution of ages of molecules in the exit streams of both ideal and non-ideal reactors in which a tracer is added instantaneously in the inlet stream is shown in Figure 10. The spread of concentration curve around the plug flow conditions depends upon the vessel or reactor dispersion number, *Deul,* where D is longitudinal or axial dispersion coefficient, u is the mean displacement velocity along the tank length and l is the length dimension.[32] In the case of plug flow, the dispersion number is zero, whereas it becomes infinity for completely mixed tanks.

Treatment Models

Lawrence and McCarty[11] have proposed and analyzed the following three models for existing continuous flow aerobic or anaerobic biological wastewater treatment configurations:

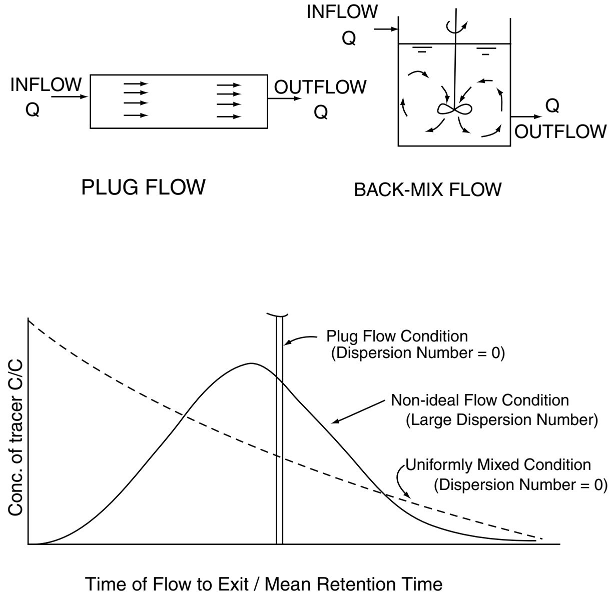

FIGURE 10 Hydraulic characteristics of basins.

(a) a completely mixed reactor without biological solids recycle,
(b) a completely mixed reactor with biological solids recycle, and
(c) a plug flow reactor with biological solids recycle.

These configurations are shown schematically in Figure 11. In all these treatment models, the following equations can be applied in order to evaluate kinetic constants,[33] where Δ indicates the mass or quantity of material:

- *Solid Balance Equation*

$$\begin{bmatrix}\Delta\text{Cells}\\ \text{Reactor}\end{bmatrix} = \begin{bmatrix}\Delta\text{Cells}\\ \text{Growth}\end{bmatrix} - \begin{bmatrix}\Delta\text{Cells}\\ \text{Decay}\end{bmatrix} - \begin{bmatrix}\Delta\text{Cells}\\ \text{Effluent Loss}\end{bmatrix} \tag{19}$$

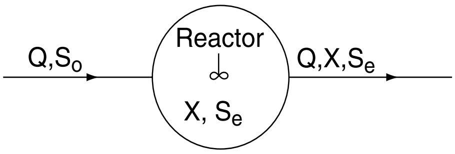
- *Substrate Balance Equation*

$$\begin{aligned}\begin{bmatrix}\Delta\text{Substrate}\\ \text{Reactor}\end{bmatrix} &= \begin{bmatrix}\Delta\text{Substrate}\\ \text{Influent}\end{bmatrix} - \begin{bmatrix}\Delta\text{Substrate}\\ \text{Growth}\end{bmatrix}\\ &\quad - \begin{bmatrix}\Delta\text{Substrate}\\ \text{Effluent Loss}\end{bmatrix}\end{aligned} \tag{20}$$

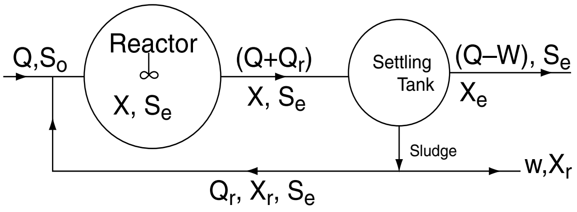
Parameters for Design and Operation

Various parameters have been developed and used in the design and operation of biological wastewater treatment processes and the most significant parameters are:

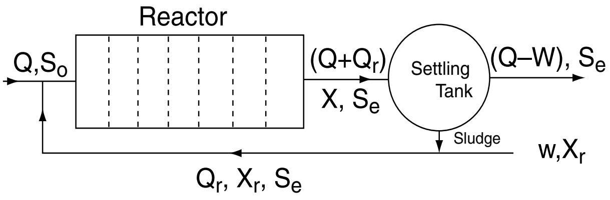
θ_x– Biological Solids Retention Time, or Sludge Age, or Mean Cell Retention Time, is defined



I- Completely Mixed-No biological solids recycle



II- Completely Mixed-Biological solids recycle



III- Plug Flow-Biological solids recycle

FIGURE 11 Treatment models.

as the ratio between total active microbial mass in treatment system, X_T, and total quantity of active microbial mass withdrawn daily, including solids wasted purposely as well as those lost in the effluent, $\Delta X_T/\Delta t$. Regardless of the fraction of active mass, in a well-mixed system the proportion of active mass wasted is equal to the proportion of total sludge wasted, making sludge age equal for both total mass and active mass.

U– Process Loading Factor, or Substrate Removal Velocity, or Food to Microorganisms Ratio, or Specific Utilization, is defined as the ratio between the mass of substrate utilized over a period of one day, $\Delta S/\Delta t$, and the mass of active microorganisms in the reactor, X_T.

$\bar{t}$– Hydraulic Retention Time or Detention Time, or Mean Holding Time, is defined as the ratio between the volume of Reactor, V, and the volumetric feed rate, Q.

B_V– Volumetric Loading Rate or Hydraulic Loading Rate is defined as the ratio between the mass of substrate applied over a period of one day, $S_T/\Delta t$ and the volume of the reactor, V.

E– Process Treatment Efficiency or Process Performance is defined as percentage ratio between the substrate removed, $(S_0 - S_e)$, and influent substrate concentration, S_0.

A desired treatment efficiency can be obtained by control of one or more of these parameters separately or in combination.

5. BIOLOGICAL TREATMENT SYSTEMS

The existing biological treatment systems can be divided into the following three groups:

(a) Aerobic Stationary-Contact or Fixed-Film Systems: Irrigation beds, irrigation sand filters, rotating biological contactors, fluidized bed reactors, and trickling filters fall in this group. In these treatment processes, the biomass remains stationary in contact with the solid supporting-media like sand, rocks or plastic and the wastewater flows around it.

(b) Aerobic Suspended-Contact Systems: Activated sludge process and its various modifications, aerobic lagoons and aerobic digestion of sludges are included in this group. In these treatment processes, both the biomass and the substrate are in suspension or in motion.

(c) Anaerobic Stationary-Contact and Suspended Contact Systems: Anaerobic digestion of sludges and anaerobic decomposition of wastewater in anaerobic lagoons fall in this category.

A typical layout of a wastewater treatment plant incorporating biological treatment is shown in Figure 12. Primary sedimentation separates settleable solids and the aerobic biological treatment is designed to remove the soluble BOD. The solids collected in primary sedimentation tanks and the excess sludge produced in secondary treatment are mixed together and may be digested anaerobically in digesters. Trickling filter and activated sludge processes are most common secondary treatment processes for aerobic treatment and are discussed in detail. Discussion of sludge digestion by anaerobic process and use of biological nutrient removal as a tertiary treatment have also been included.

In addition to conventional pollutants present in municipal and industrial wastewaters, significant concentrations of toxic substances such as synthetic organics, metals, acids, bases, etc., may be present due to direct discharges into the sewers, accidental spills, infiltration and formation during chlorination of wastewaters. It is import to have a knowledge of both the scope of applying biological treatment and the relevant engineering systems required to achieve this capability. Thus, the kinetic description of the process and the deriving reactor engineering equations and strategies for treatment of conventional and toxic pollutants are essential for proper design and operation of biological waste treatment systems.[24]

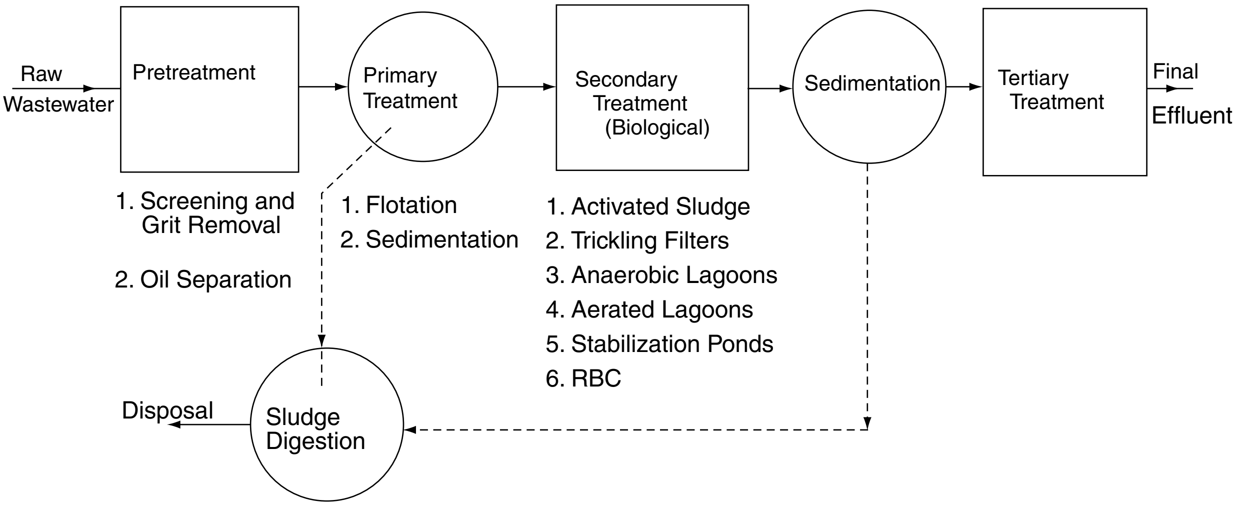


FIGURE 12 Typical wastewater treatment sequence.

The available information strongly indicates that immobilized biological systems are less sensitive to toxicity and have a higher efficiency in degrading toxic and hazardous materials.[34] Fixed-film wastewater treatment processes are regarded to be more stable than suspended growth processes because of the higher biomass concentration and greater mass transfer resistance from bulk solution into the biofilm in fixed-films.[35] The mass transfer limitation effectively shields the microorganisms from higher concentrations of toxins or inhibitors during short-term shock loads because the concentrations in biofilms change more slowly than in the bulk solution. Also, since the microorganisms are physically retained in the reactor, washout is prevented if the growth rate of microorganisms is reduced.[34,35] The biofilm systems are especially well suited for the treatment of slowly biodegradable compounds due to their high biomass concentration and their ability to immobilize compounds by adsorption for subsequent biodegradation and detoxification.[34]

Trickling Filters

Wastewater is applied intermittently or continuously to a fixed bed of stones or other natural synthetic media resulting in a growth of microbial slime or biomass on the surface of this media. Wastewater is sprayed or otherwise distributed so that it slowly trickles through while in contact with the air. For maximum efficiency, food should be supplied continuously by recirculating, if necessary, the treated wastewater or settled sludge or both. Oxygen is provided by the dissolved oxygen in influent wastewater, recirculated water from the air circulating through the interstices between the media to maintain aerobic conditions.

Active microbial film, biomass, consisting primarily of bacteria, protozoa, and fungi, coats the surface of filter media. The activity in biological film is aerobic, with movement of oxygen, food and end-products in and out of it as shown in Figure 13. However, as the thickness of the film increases, the zone next to the filter medium becomes anaerobic. Increased anaerobic activity near the surface may liquify the film in contact with the medium, resulting in sloughing or falling down of the old film and growth of a new film. The sloughed solids are separated in a secondary settling tank and a part of these may be recirculated in the system. Two types of trickling filters are recognized, primarily on the basis of their loading rates and method of operation, as shown in Table 1. In low-rate trickling filter, the wastewater passes through only once and the effluent is then settled prior to disposal. In high-rate trickling filter, wastewater applied

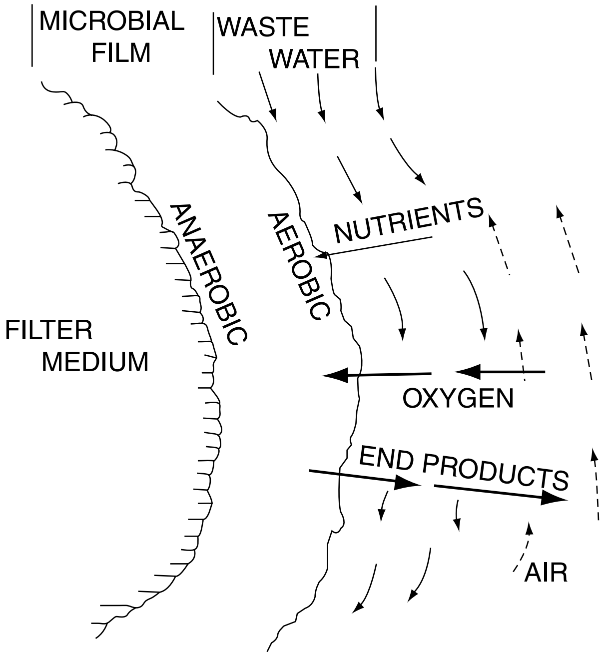

FIGURE 13 Process of BOD removal in trickling filters.

TABLE 1

Comparison of low-rate and high-rate filters

Parameters	Low-Rate Filters	High-Rate Filters
Hydraulic Loading		
US gallons per day per square foot	25 to 100	200 to 1000
Million US gallons per day per acre	1.1 to 4.4	8.7 to 44
Cubic metre per day per square metre	1.0 to 4.1	8.1 to 40.7
Organic Loading (BOD)		
Pounds of BOD per day per 1000 cubic feet	5 to 25	25 to 300
Pounds of BOD per day per acre-foot	220 to 1100	1100 to 13000
g of BOD per day per cubic metre	80 to 400	400 to 4800
Recirculation	Generally absent	Always provided R = 0.5 to 3
Effluent Quality	High nitrified, lower BOD	Not fully nitrified, higher BOD

to filters is diluted with recirculated flow of treated effluent, settled effluent, settled sludge, or their mixture, so that it is passed through the filter more than once. Several recirculation patterns used in high-rate filter systems are shown in ASCE Manual.[36] Sometimes two filter beds are placed in series and these are called Two-Stage Filters.

The advantages and disadvantages of recirculation are listed below:

Advantages of Recirculation

(a) Part of organic matter in influent wastewater is brought into contact with growth on filter media more than once.

(b) Recirculated liquid contains active microorganisms not found in sufficient quantity in raw wastewater, thus providing seed continually. This continuous seeding with active microorganisms and enzymes stimulates the hydrolysis and oxidation and increases the rate of biochemical stabilization.

(c) Diurnal organic load is distributed more uniformly. Thus, when plant flow is low, operation is not shut off. Also, stale wastewater is freshened.

(d) Increased flow improves uniformity of distribution, increases sloughing and reduces clogging tendencies.

(e) Higher velocities and continual scouring make conditions less favourable for growth of filter flies.

(f) Provides for more flexibility of operation.

Disadvantages

(a) There is increased operating cost because of pumping. Larger settling tanks in some designs may increase capital cost.

(b) Temperature is reduced as a result of number of passes of liquid. In cold weather, this results in decreased biochemical activity.

(c) Amount of sludge solids to digesters may be increased.

The *ACE Manual*[36] lists the following factors affecting the design and operation of filters:

(a) composition and characteristics of the wastewater after pretreatment,
(b) hydraulic loading applied to the filter,
(c) organic loading applied to the filter,
(d) recirculation, system, ratio and arrangement,
(e) filter beds, their volume, depth and air ventilation,
(f) size and characteristics of media, and
(g) temperature of wastewater.

Assuming that the flow through the packed column could be approximated as plug flow, and if BOD removal rate occurs by first order reaction, Eq. 13, then the formula to use in trickling filters will become:

$$\frac{\mathrm{d}S}{\mathrm{d}t} = qSX = k_f S$$

or

$$\frac{S_e}{S_0} = \mathrm{e}^{-k_f t}. \tag{21}$$

Another equation suggested for application in trickling filters[13] is:

$$\frac{S_e}{S_0} = \frac{1}{1+qXt} = \frac{1}{1+k_f}t \tag{22}$$

where trickling filter rate coefficient, k_f, is a function of active film mass per unit volume and remains constant for a given specific area and uniform slime layer. Contact time, t, is related to filter depth, H, volumetric rate of flow per unit area, Q_a, and specific surface area of filter media, A_v. Sinkoff, Porges, and McDermott[37] have proposed the following relationship based on their experiments:

$$t = c_1 H \left[\frac{A_v}{Q_a} \right]^n \tag{23}$$

c_1 is assumed to be a constant and exponent n ranges between 0.53 and 0.83 depending upon the type of filter medium and the hydraulic characteristics of the system. Substitution of this value of t in Eq. 21 gives:

$$\frac{S_e}{S_0} = \exp - k_f \left[\frac{A_v}{Q_a} \right]^n Hc_1 = \mathrm{e}^{-k'_f H/Q_a^n}. \tag{24}$$

Eckenfelder[13] suggests that the amount of active surface film covering the filter medium decreases with depth H; therefore, combining Eqs. 22 and 23 and substituting $c_1 \propto 1/H^m$, gives:

$$\frac{S_e}{S_0} = \frac{1}{1 + k_f A_v^n H(1-m)/Q_a^n} = \frac{1}{1 + k''_f H(1-m)/Q_a^n}. \tag{25}$$

For treatment of domestic wastewater on rock filters, Eckenfelder has obtained the values of $n = 0.5$, $m = 0.33$ and $k''_f = 2.5$ with H in ft and q in MGD/acre. Several empirical relationships for process efficiency in trickling filters have been proposed and successfully applied. Most significant of these are the National Research Council Formula and Rankin's Formula which have been described in detail in ASCE Manual.[36] Eckenfelder and O'Connor[13] have reported a value of 1.035 for overall temperature coefficient, θ, in Eq. 16. An adjustment in process efficiency due to variation in temperature should be provided.

Activated Sludge Process

It is a biological treatment process in which biologically active mass, called activated sludge, is continuously mixed with the biodegradable matter in an aeration basin in the presence of oxygen. The combination of wastewater and activated sludge is called the mixed liquor. The oxygen is supplied to the mixed liquor either by diffusing compressed air or pure oxygen into the liquid or by mechanical aeration. The activated sludge is subsequently separated from the mixed liquor by sedimentation in a clarifier and a part of this sludge is recirculated to the aeration basin. The rest of this sludge, indicating net excess production of biological cell material, is disposed of. Activated sludge treatment plants vary in performance due to variation in unit arrangements, methods of introducing air and wastewater into the aeration basin, aeration time, concentration of active biomass, aerator volume, degree of mixing, etc. Some important types of activated sludge processes are discussed below and their operating parameters are summarized in Table 2.

TABLE 2
Activated sludge process parameters

Parameters	Conventional	Step Aeration	Short Term	Biosorption	Pure Oxygen	Complete Mixing	Extended Aeration	Aerated Lagoons
Organic Loading Rate—B_v 1b BOD_5 per day per 1000 cubic feet	30–40	50–150	100–400	30–70	150–250	125–180	10–20	5
g BOD_5 per day per cubic metre	480–640	800–2400	1600–6400	480–1120	2400–3200	2000–2880	160–320	80
Process Loading Factor, U 1b BOD_5 per day per 1b 1b MLVSS								
or								
kg BOD_5 per day per kg MLVSS	0.2–0.5	0.2–0.5	2–5	0.2–0.5	0.4–1.0	0.6–1.0	0.05–0.2	0.2
Sludge Age, days, θ_x	3–4	3–4	0.2–0.5	3–4	0.8–2.3		14–∞	3–5
Aeration Time, hours, $\bar{t}$	6–7.5	6–7.5	2–4	0.5–1.5 (aeration)	1–3	3–5	20–30	70–120

Primary Settling Required	Yes	Yes	No	Optional	Yes	Optional	No	No

*Provision in design should be made for these maximum and minimum values.

Kinetic Rate: Depending upon the design and operating conditions, one or more of the kinetic rate Eqs. 10, 12, 13 and 14 for BOD removal can be applied to different types of the activated sludge processes.

Oxygen Requirement: Oxygen is used to provide energy for synthesis of biological cells and for endogenous respiration of the biological mass. The total oxygen requirement, ΔO_2, can be expressed with the following equation;

$$\Delta O_2 = a'\Delta S + b'X_T \tag{26}$$

where a' is the fraction of BOD removed that is oxidized for energy and b' is the oxygen used for endogenous respiration of the biological mass, per day. In conventional aeration basins, an hourly oxygen demand of 50 to 80 mg/L per 1000 mg/L of VSS is exerted near the beginning of the tank and is reduced to 20 mg/L per 1000 mg/L of VSS in the course of 4 to 6 hours.[14]

Excess Sludge Yield: By applying material balance for volatile suspended solids in activated sludge system, and using the concept shown in Figure 3:

Excess solids in activated sludge system = Non-biodegradable suspended solids in influent + Biomass Synthesized during BOD removal – Biomass broken down by endogenous respiration
or

$$\Delta X = fX_0 + a\Delta S - bX_T \tag{27}$$

where:

ΔX = Net accumulation of volatile suspended solids, g/day

f = Fraction of volatile suspended solids present in the influent which are non-degradable

X_0 = Influent volatile suspended solids, g/day

Temperature Effect: According to Eckenfelder and O'Connor,[13] the value of temperature coefficient in Eq. 12 varies between 1.0 for low loading rates to 1.04 for high loading rates. Friedman and Schroeder[38] have studied in detail the effect of temperature on growth and the maximum cell yield occurred at 20°C.

Elements of a conventional activated sludge system are shown in Figure 14. In this system, the settled waste is mixed with the return sludge at the inlet end of the aeration tank. The microorganisms receive the full impact of any shock load and respond accordingly with sudden increase in oxygen demand during growth. By the time microorganisms leave the aeration tank, the organic matter has been stabilized and the microorganism population starts dying off. Thus, the microbial population undergoes a continual shifting and never reaches a relatively constant equilibrium.[7]

A mass of activated sludge of three to four times the mass of the daily BOD load must be kept in the system in order to consume all the new food and also acquire good settling properties. These types of plants have been used for treating domestic wastewaters of low biochemical oxygen demands. In conventional activated sludge plants

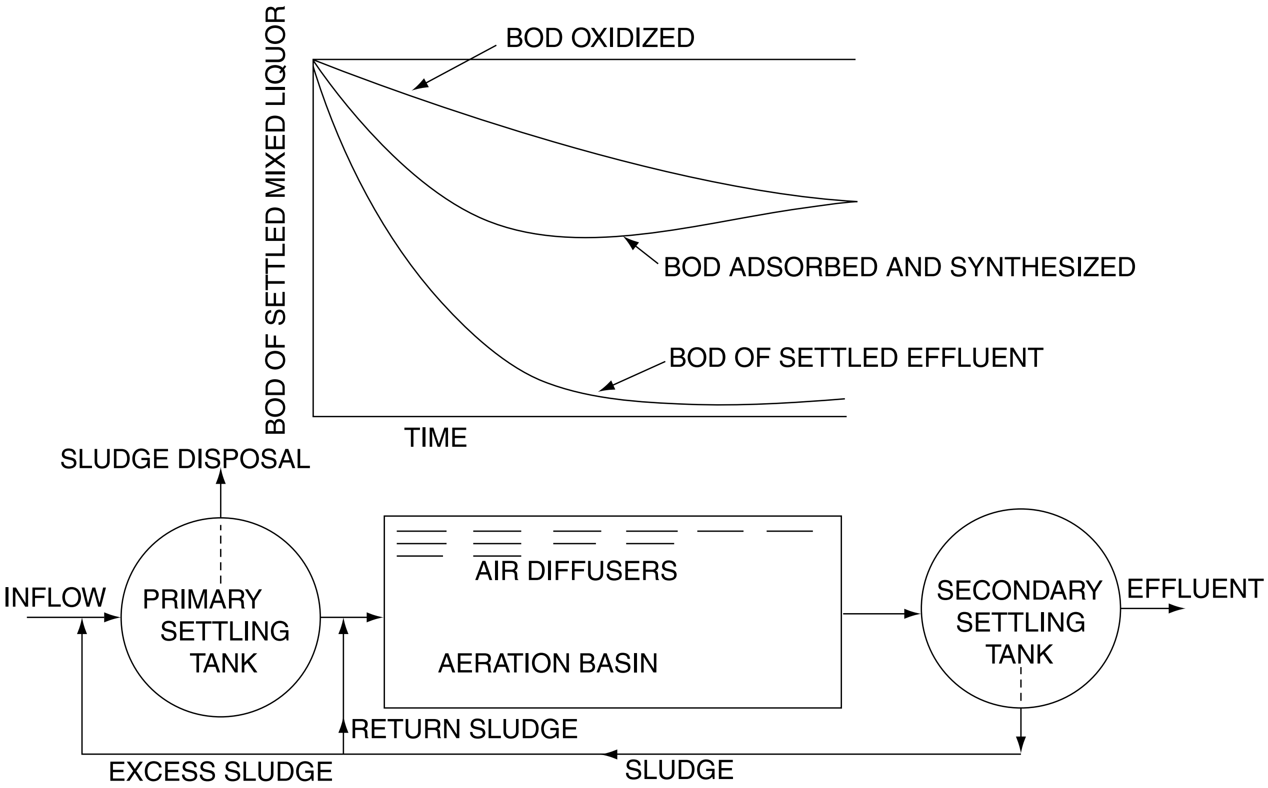

FIGURE 14 Conventional activated sludge.

that have plug flow design, high BOD in influent causes higher oxygen demand at that point in the mixed liquor and this oxygen demand diminishes as the flow passes down the aeration tank. Most of the plants designed these days are provided with tapered aeration, with highest air supply near the inlet end and lowest near the outlet end of the aeration tank.

Modifications of the Conventional Activated Sludge Process

A. Step Aeration Activated Sludge

Step aeration process, developed by Gould[39] at New York City, offers more flexibility than the conventional activated sludge process. In this process, wastewater is introduced at four or more points along the aeration tank in order to maintain a uniformly distributed loading. In addition to evening out the oxygen demand, this also keeps sludge reaerated in the presence of substrate. This process remains biologically more active instead of reaching the endogenous phase near the end of the conventional aeration tank. Step aeration system layout and fluctuations in BOD in aeration tank are shown in Figure 15. This method has been successfully employed in the treatment of domestic wastewaters and industrial wastewaters of similar nature.

B. Short Term Aeration or High Rate or Modified Activated Sludge

These systems have very high loading rates, both in terms of organic and volumetric loading, and low mixed liquor volatile suspended solids, thus requiring small aeration tank capacities and reduced air requirements. Because of shorter aeration time and lower mass of organisms, this process provides an intermediate degree of treatment. Organic matter is removed largely by synthesis, thus exerting a high rate of oxygen demand and producing a relatively large volume of sludge per unit mass of BOD removed. Since the sludge still contains certain unstabilized organic matter, the settled sludge in secondary settling tanks should be removed rapidly in order to avoid its anaerobic decomposition and floatation. The flow diagram is similar to the conventional system as shown in Figure 14.

C. Contact Stabilization or Biosorption

The elements of this type of plant are shown in Figure 16. This system is ideally suited to the treatment of wastewaters in which a large portion of BOD is

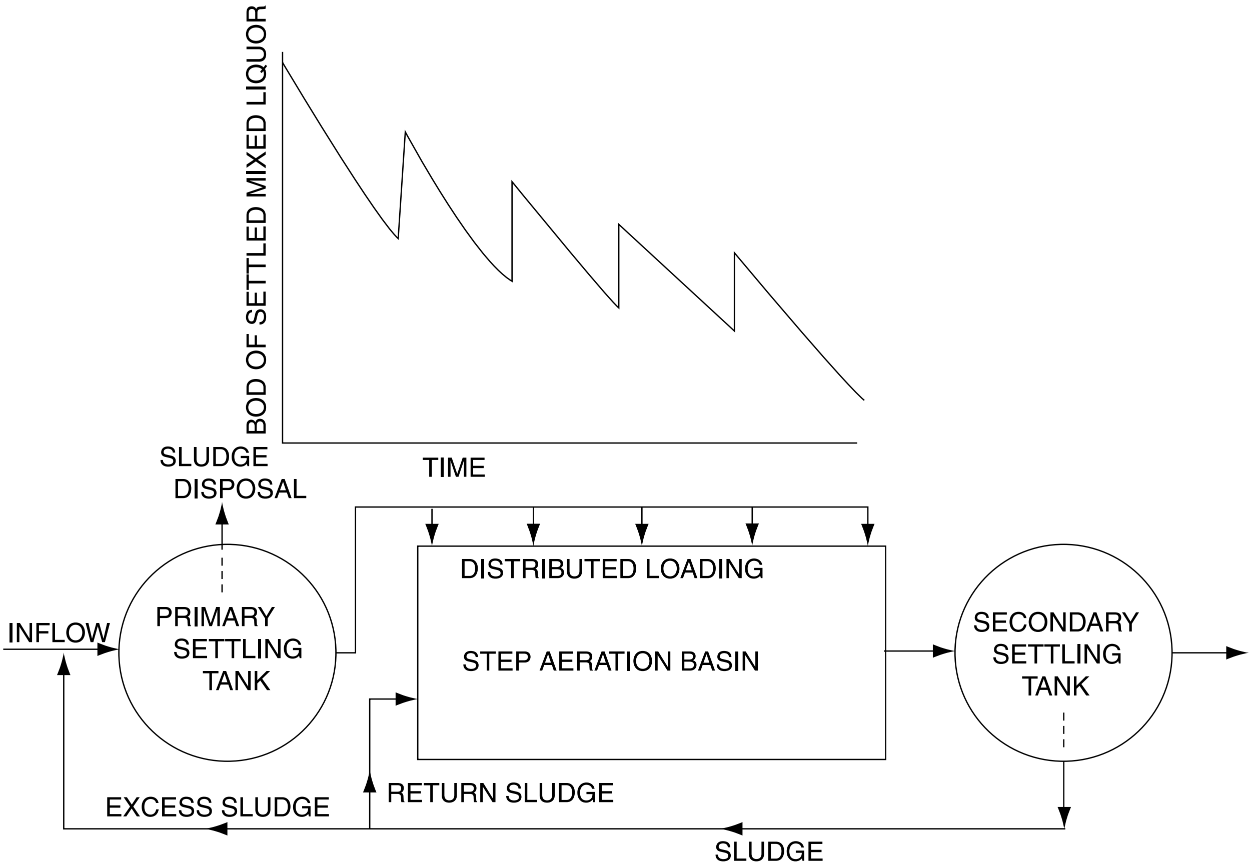

FIGURE 15 Step aeration activated sludge.

present in suspended or colloidal form. The suspended BOD is rapidly absorbed in a short period, ½ to 1½ hours, by the well-activated organisms and a part of soluble BOD is metabolized. In the activation tank, the sludge is reaerated for bio-oxidation and stabilization of adsorbed food; and when returned to the aeration tank, it is activated for higher BOD removal as compared to the conventional plant where sludge has become lean and hungry in the absence of a food supply. The additional advantage of this process is the reduced overall tank volume required as compared to the conventional system. However, the operation of such plants is more complex and less flexible than conventional ones.

D. Completely Mixed Activated Sludge

"Complex mix" approach is with respect to combining the return sludge and wastewater in order to maintain the entire contents of the aeration chamber in essentially a homogenous state. Wastewater introduced into the aeration basin is dispersed rapidly throughout the mass and is subjected to immediate attack by fully developed organisms throughout the aeration basin. Biological stability and efficiency of the aeration basin is enhanced by this design. Layout of a completely-mixed activated sludge plant and variation in BOD are shown in Figure 17.

In this mathematical analysis, McKinney[5] considered the complete mixing activated sludge process as the one in which the untreated wastes are instantaneously mixed throughout the aeration tank. In effect, the organic load on the aeration tank is uniform from one end to the other end and consequently a uniform oxygen demand and a uniform biological growth are produced. It is assumed to reduce the effect of variations in organic loads that produce shock loads on conventional units, retain a more biological population and hence, produce a more uniform effluent, and be able to treat organic wastes of any concentration and produce an effluent of any desired concentration.[5] Using Treatment Model II, Figure 11, as an example of a completely mixed system, Lawrence and McCarty[11] have shown analytically that although the complete-mixing will reduce the shock loads due to variations in organic loads, plug flow type conventional units, Treatment Model III, are more efficient.

Assuming that Eq. 13 is applicable for BOD removal rate, and since the BOD in a completely mixed aerator, S, is equal to the effluent BOD, S_e, therefore under steady state conditions:

$$\frac{\mathrm{d}S}{\mathrm{d}t} = \frac{S_0 - S_e}{t} = qXS_e$$

or

$$\frac{S_e}{S_0} = \frac{1}{1 + qXt}. \tag{28}$$

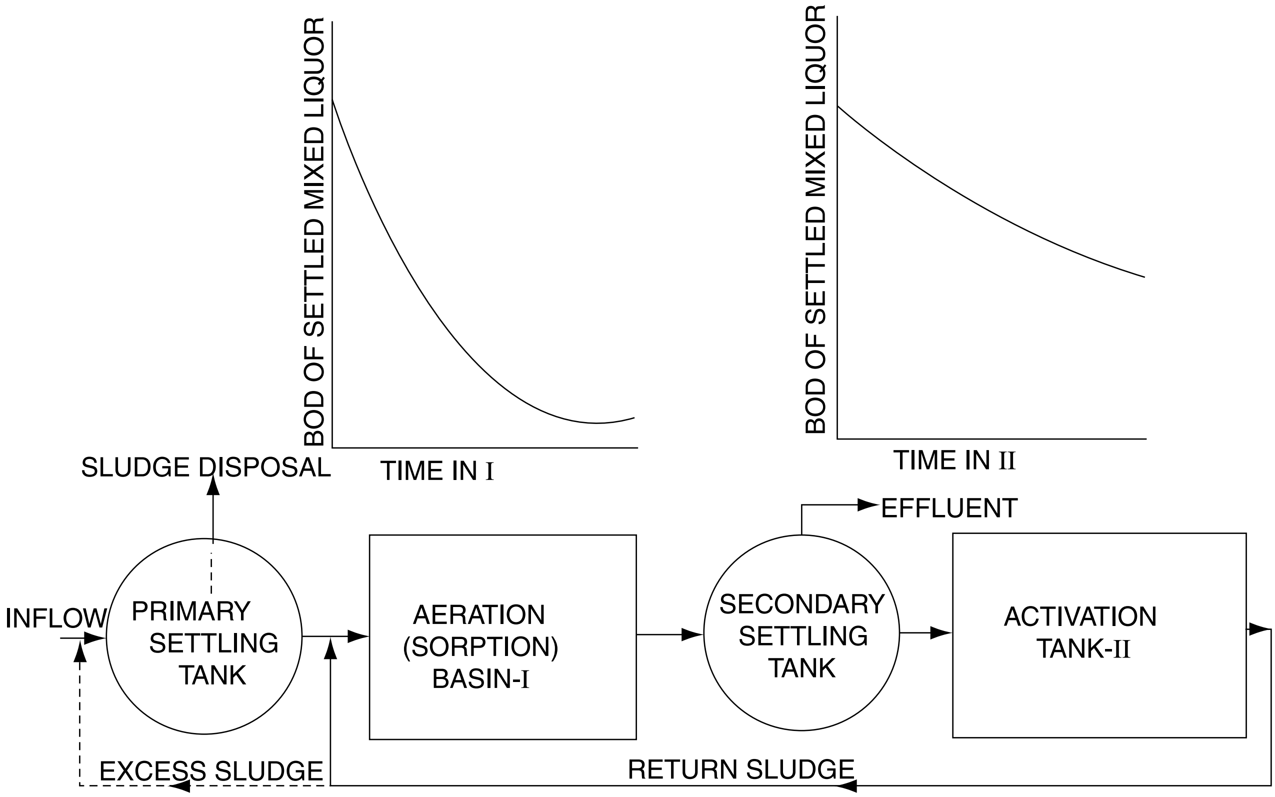

FIGURE 16 Biosorption (contact stabilization) activated sludge.

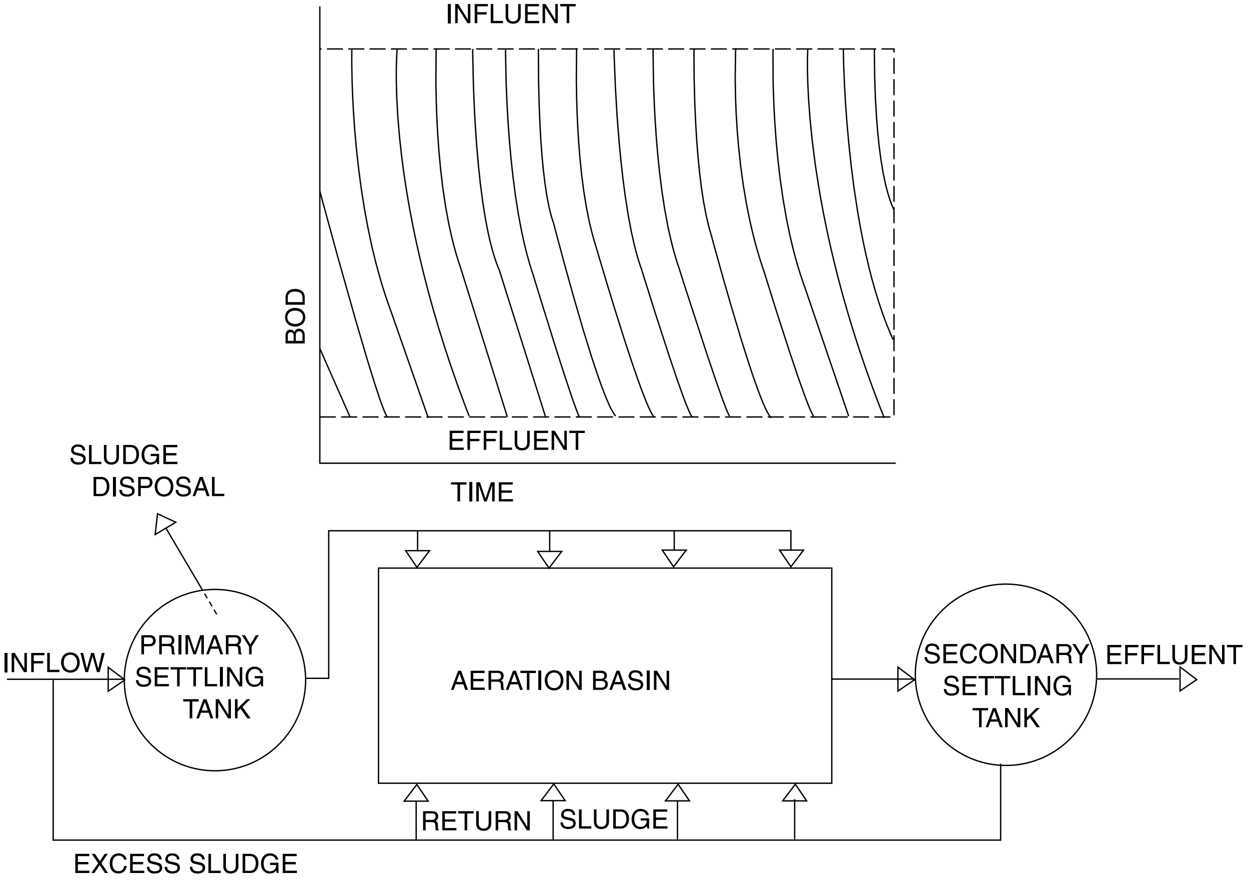

FIGURE 17 Complete mixing activated sludge.

E. In recent years, several wastewater treatment plants have been designed to operate with pure oxygen instead of conventional use of air in activated sludge treatment process. The obvious advantage of pure oxygen aeration is the higher oxygen concentration gradient maintained within the liquid phase, and this condition permits higher concentration of biomass in the aeration tank. This process has been shown to be more economical due to less energy requirements and in some cases has produced a better quality effluent. Significant increase in volumetric loading rate, reduction in sludge production, elimination of foaming problems and decrease in treatment costs are claimed to be advantages.[40]

A pure oxygen activated sludge system developed by Union Carbide Corporation is shown in Figure 18. This process is operated at MLSS values between 3000–10000 mg/L and the settling rate of sludge is considerably improved.

F. Extended Aeration

Extended aeration plant is the one where the net growth rate is made to approach zero, i.e., rate of growth becomes approximately equal to rate of decay. This is achieved by increasing the aeration time in order to keep the sludge in the endogenous growth phase for a considerable time. In practice, it is impossible to operate an extended-aeration system without sludge accumulation, because certain volatile solids, mainly polysaccharides in nature and inert organisms in activated sludge process, accumulate in the plant. Excess sludge is not generally wasted continuously from an extended aeration, but instead, the mixed liquor is allowed to increase in suspended solids concentration and a large volume of the aeration tank content or return sludge is periodically pumped to disposal. Oxidation ditch plants are designed and operated on this principle. Layout of a typical extended-aeration plant and variation in BOD in aeration tank are shown in Figure 19.

G. Aerated Lagoons

These are similar to the activated sludge system but without recirculation of sludge. Mechanical or diffused aeration devices are used for supplying oxygen and also providing sufficient mixing. All suspended solids may or may not be kept in suspension, depending upon the degree of mixing. Deposited solids may undergo anaerobic decomposition. Mathematically, the BOD removal rate in aerated lagoons is given by Eq. 13 and assuming the aerated lagoon to be a completely mixed system, without recycle and maintaining sufficient turbulence,

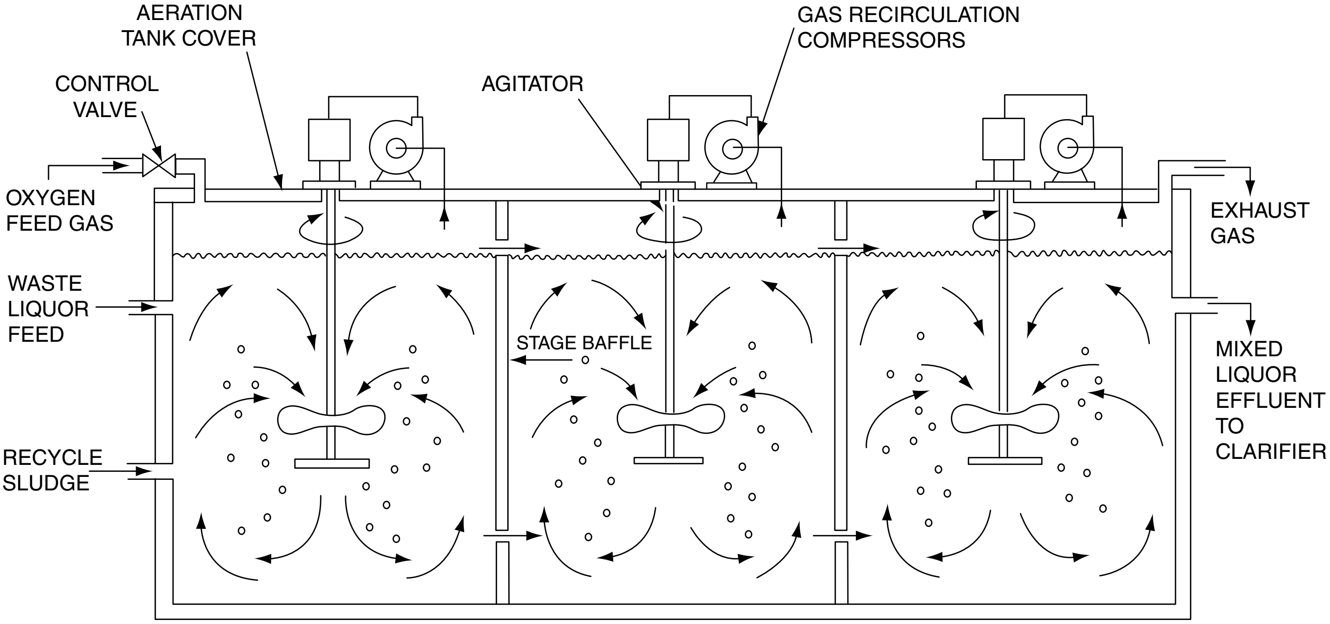

FIGURE 18 Schematic diagram of "unox" system with rotating sparger.

this equation becomes similar to Eq. 28. In practice, this equation has proven to represent a generalized response function for design of most aerated lagoons.[33]

The exact solid level in an aerated lagoon can be approximated by applying a material balance around the lagoon, under equilibrium conditions:

Solids In + Net Synthesis In Basin = Solids Out

or

$$X_0 + (Y\Delta S - b\,X_e t) = X_e$$

or

$$X_e = \frac{X_0 + Y\Delta S}{1 + bt} \tag{29}$$

Because of a very low solid concentration, the detention time in aeration basins is very high and a large volume of aeration basins is required. Therefore, the temperature variation exerts a profound effect on the rate of BOD removal. Eckenfelder and Ford[10] have given a relationship for estimating the lagoon temperature at both extreme conditions. Once this temperature is established, a corrected k_T value should be obtained from Eq. 16, using θ equal to 1.035 and then adopted in the kinetic Eq. 28.

Several other modifications in the activated sludge process have been discussed elswhere;[41] but most of these modifications are similar in concepts to one or more of the types discussed above. For example, in Hatfield and Kraus systems the supernatant from digestion tanks or even digested sludge are added to the reaeration tank to provide nutrients. Similarly, an Activated Aeration Plant is a combination of a conventional activated sludge process and the short-term aeration process.

Rotating Biological Contactors

As mentioned earlier, the traditional aerobic biological wastewater treatment processes have been divided into two groups: fixed film or stationary contact systems like trickling filters and suspended contact systems like activated sludge process. Rotating biological contactors, RBC, are more like trickling filters in operation, but adopt certain characteristics of suspended growth systems. In this process, large lightweight plastic disks of 2–4 m diameter are half submerged in the wastewater flowing continuously through cylindrical bottomed tanks. The disks are rotated slowly at a speed of 1–2 rpm. The biomass grows on the plastic disks and the substrate is absorbed by this biomass while it is submerged in the wastewater. The oxygen absorption occurs when the biomass is in direct contact with air, generally at a rate higher than that obtained in trickling filters.

These units have been operated successfully at extreme temperature conditions both for municipal and industrial wastewaters having very high BOD values. Antoine and Hynek[42] have concluded that RBC are stable, versatile and competitive with the activated sludge process.

In Canada, an important parameter regulating the pulp and paper wastewater treatment is toxicity reduction, measured by rainbow trout standard bioassay tests. The results of bioassay tests conducted by Antoine[43] showed RBC was effective in treating the toxic paper mill wastewater, when

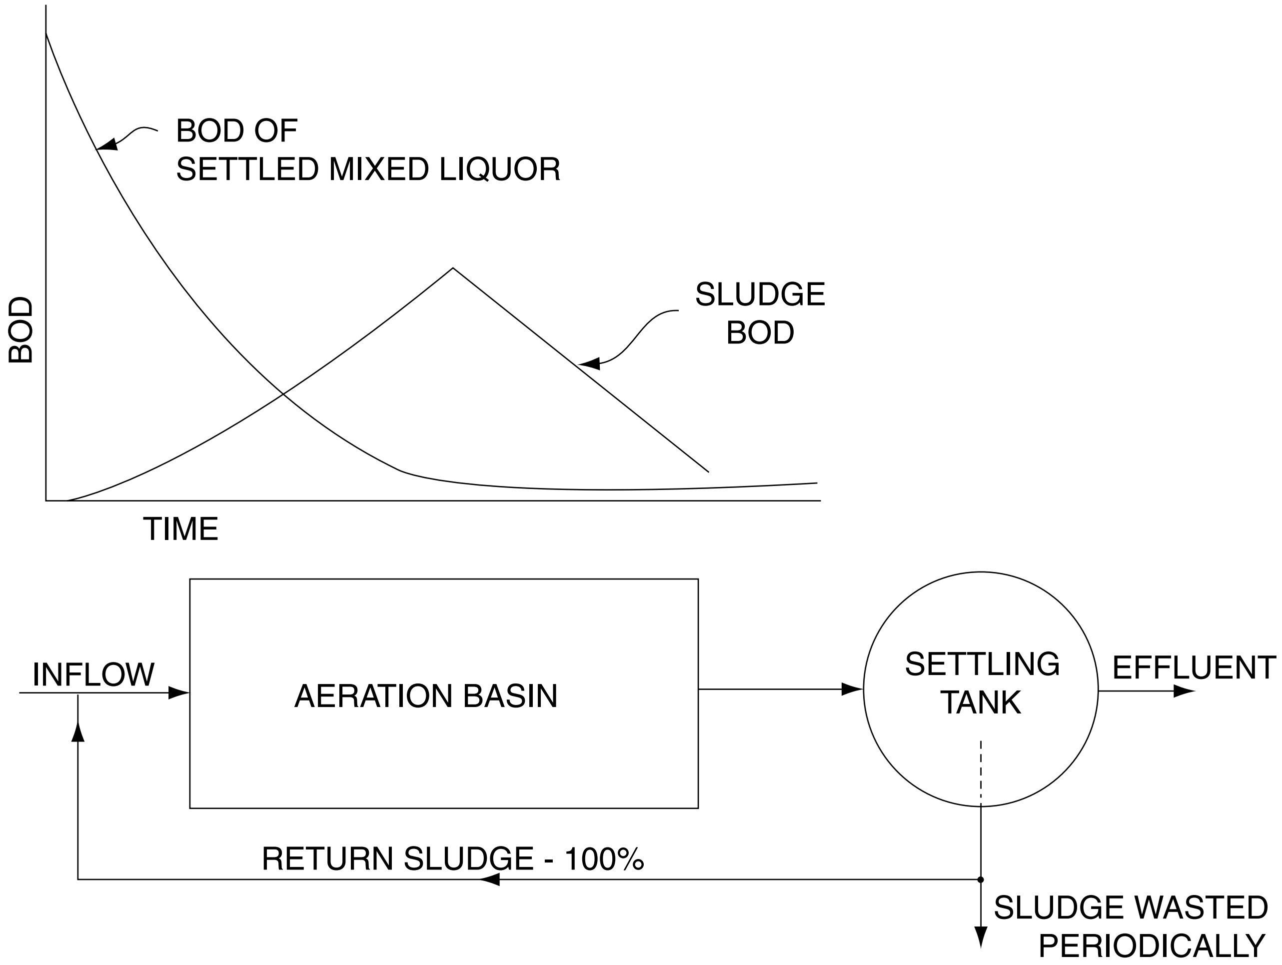

FIGURE 19 Extended aeration activated sludge.

it was operated at disk speeds of 13 and 17 rpm and flow rates of 1.9 to 2.5 LPM (0.5 to 0.65 USGPM). Similarly, Antoine observed that the RBCs were able to produce acceptable effluents for boardmill, kraft and sulfite wastewaters. For sulfite wastewater, the loading rate had to be reduced to increase the detention time. On the other hand, the suspended growth treatment of pulp and paper wastes has not consistently produced effluents of an acceptable level. B.C. Research had conducted tests on the use of the rotating biological contactor process for refinery waste containing phenols and observed it to be an effective method with proper control on operation.[43]

Anaerobic Treatment

In this process, anaerobic bacteria stabilize the organic matter in absence of free oxygen. Anaerobic treatment has been used widely for stabilization of sludges collected from primary and secondary settling tanks and recently is being adopted for treatment of soluble wastes in anaerobic lagoons, anaerobic filters, etc. One of the important advantages of anaerobic processes over aerobic processes is a high percentage conversion of organic matter to gases and liquid and a low percentage conversion to biological cells. McCarty[44] has mentioned that efficient anaerobic treatment of soluble wastes with BOD concentration as low as 500 mg/L is now feasible. Wastes with lower BOD can also be treated anaerobically, although the waste treatment efficiency will not be of the same magnitude as expected from aerobic treatment.

Anaerobic treatment of wastewaters takes place in two stages as shown in Figure 20. In the first stage, complex organic materials like protein, fats, carbohydrates, are converted into simple organic acids by acid forming bacteria, but with little change in BOD or COD value. In the second stage, these fatty acids are converted to carbon dioxide and methane, thereby stabilizing the BOD or COD.

In a conventional anaerobic treatment process, the substrate is fed into the digester continuously or intermittently. In most of the existing digesters, the contents are mixed, mechanically or with compressed gas collected from digesters. There is no recirculation of digested sludge and the system is a typical flow through system. The hydraulic detention time, $\bar{t}$ in

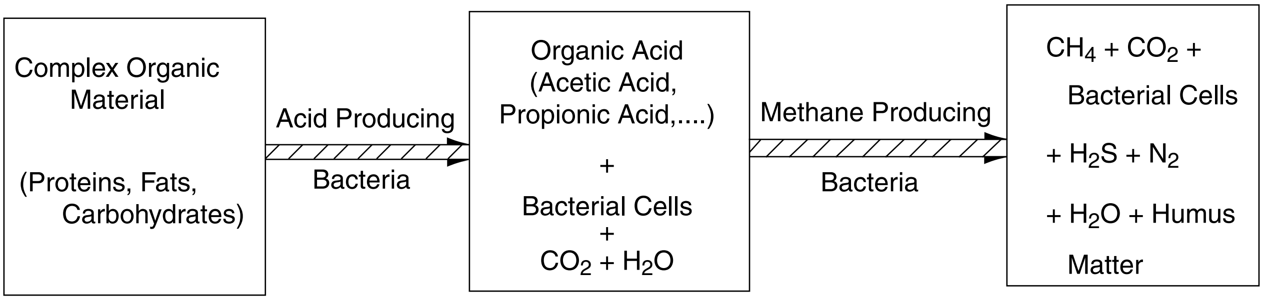

FIGURE 20 Sequential mechanism of anaerobic waste treatment.

the conventional process becomes equal to the solid retention time, θ_x. Recently, several modifications have been made in the conventional anaerobic treatment process. McCarty[44] has grouped the basic anaerobic process designs into Conventional Process, Anaerobic Activated Sludge Process, and Anaerobic Filter Process. Operating conditions of these process designs are shown in Figure 21. It is suggested that the conventional process be used for concentrated wastes like sludges where economical treatment can be obtained by keeping hydraulic detention time, $\bar{t}$ equal to the desired solid retention time, θ_x. The economic treatment of diluted wastes, however, requires hydraulic detention time, $\bar{t}$, much below the desired solid retention time, θ_x, and thus, anaerobic contact processes become more applicable.[44]

Anaerobic treatment processes are more sensitive to operating parameters and their environments as compared to aerobic processes. The best parameter for controlling the operation of anaerobic treatment is the biological retention time or solid retention time, SRT. A minimum SRT exists below which the critical methane producing bacteria are removed from the system faster than they can reproduce themselves. In practice, SRT values of two to ten times this minimum value are used. Thus, the hydraulic detention time and solid retention time maintained in anaerobic treatment processes are very high and the net growth of biological solids becomes very low due to significant decay as given by Eq. 12.

Mixing of the digester content is becoming a common practice. The advantages of mixing are better contact between food and microorganisms, uniform temperature, reduction in scum formation, accelerated digestion and distribution of metabolic inhibitors.

Certain cations, such as sodium, potassium, calcium, or magnesium show a toxic or inhibitory effect on anaerobic treatment when present in high concentrations, as shown in Table 3.[45]

Soluble sulfides exhibit toxicity because only they are available to the cells. If the concentration of soluble sulfides exceeds 200 mg/L, then the metabolic activity of methanogenic population will be strongly inhibited leading to the process failure.[21] Concentrations up to 100 mg/L can be tolerated without acclimation and sulfide concentrations between 100 and 200 mg/L can be tolerated after acclimation.

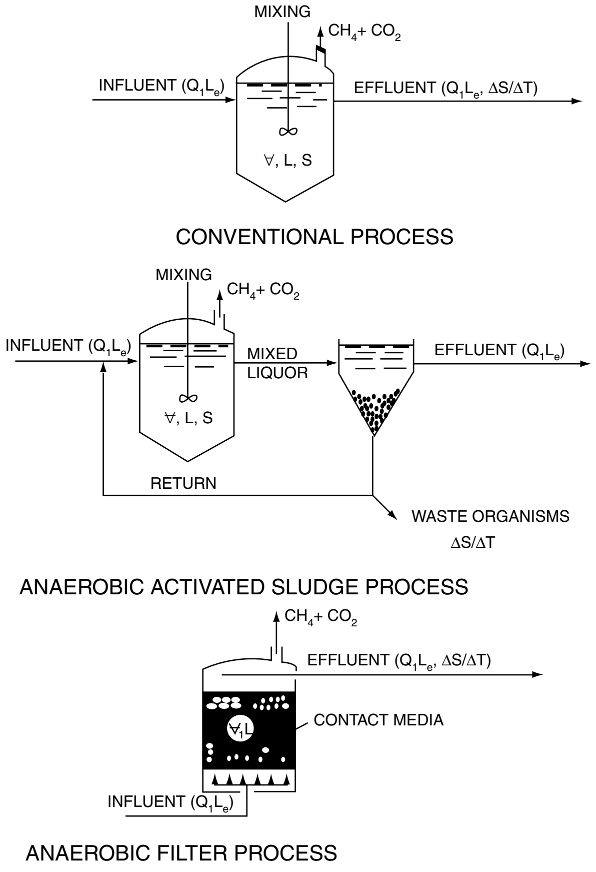

FIGURE 21 Basic anaerobic process designs.

TABLE 3
Stimulatory and inhibitory concentrations of light metal cations to anaerobic processes

Cation	Stimulatory Con., mg/L	Strong Inhibitory Con., mg/L
Sodium	100–200	8000
Potassium	200–40	12000
Calcium	100–200	8000
Magnesium	75–150	3000

Depending on pH, ammonia can be toxic to anaerobic bacteria and free ammonia is more toxic. If concentration of free ammonia exceeds 150 mg/L, severe toxicity will result, whereas the concentration of ammonium ions must be greater than 3000 mg/L to have the same effect. At a concentration of 1600 mg/L as *N*, ammonia can upset the process.[20] The volatile acids cause little inhibition in anaerobic reactors at neutral pH.[21] Operating parameters of conventional anaerobic digesters are shown in Table 4.

6. NUTRIENT REMOVAL

Biological nitrification and denitrification is one of the common methods for nitrogen removal from wastewaters. In warmer climates, nitrification may occur to a considerable degree in conventional aerobic biological treatment processes, followed by serious adverse effects of denitrification in settling tanks and/or the receiving bodies of water. In northern cold climates, below 18°C, a three-stage biological system as shown in Figure 22 is considered necessary for nutrient removal.[46] In the first stage, carbonaceous BOD is reduced to a level below 50 mg/L. In the second stage, the ammonia, present in effluent from the first stage, is oxidized to nitrites and nitrates by nitrosomonas and nitrobacters, respectively, as shown below:

$$2NH_4^+ 3O_2 \xrightarrow{\text{Nitrosomonas}} 2NO_2^- + 2H_2O + 4H^+$$
$$2NO_2^- + O_2 \xrightarrow{\text{Nitrobacter}} 2NO_3^-$$

The third stage accomplished denitrification–conversion of nitrites and nitrates to atmospheric nitrogen under anaerobic conditions:

$$3NO_3^- + CH_3OH \rightarrow 3NO_2^- + CO_2 + 2H_2O$$
$$2NO_2^- + 2CH_3OH \rightarrow N_2 + CO_2 + H_2O + 2OH^-$$

TABLE 4
Operating parameters of conventional anaerobic digesters

	Parameters	Unmixed	Mixed
B_v	– Loading Rate,	0.02–0.05	0.1–0.3
	1b VSS/day/cubic ft	0.32–0.80	1.6–3.2
	kg VSS/day/cubic metre		
$\bar{t}$	– Detention time, days	30–90	10–15
E	– Volatile Solids	50–70	50
	Reduction percent		
Mixing		Absent	Present
pH		6.8–7.4	6.8–7.4
Temperature, °C		30–35	30–35

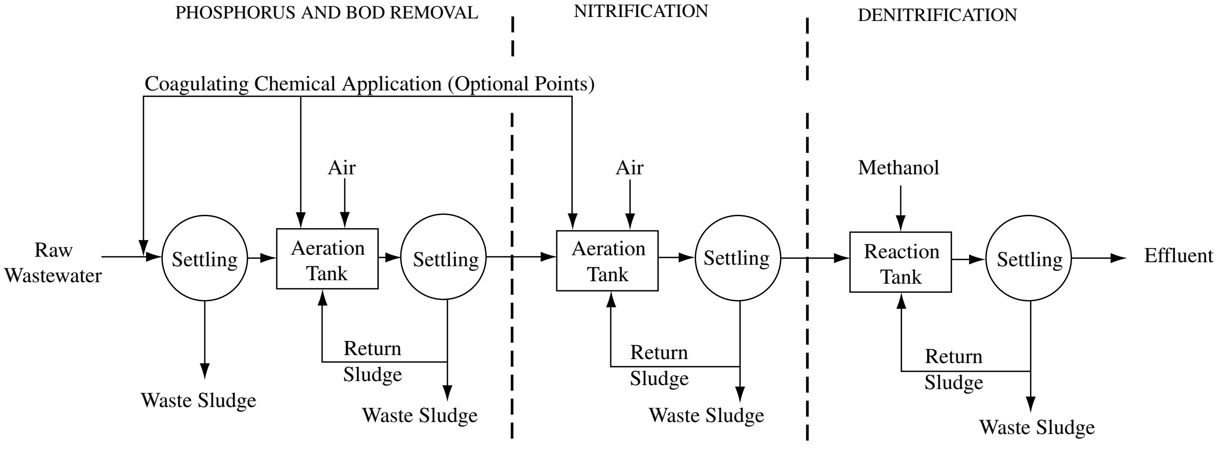

FIGURE 22 Typical three-stage treatment process for nutrient removal.

A supplemental source of carbonaceous BOD must be added in this stage to reduce the nitrates to nitrogen gas in a reasonable period of time. This has been accomplished either by adding a cheap organic substrate like methanol or by bypassing a part of the wastewater containing carbonaceous BOD in the first stage. In some cases, the carbonaceous and nitrogeneous oxidation steps are combined in a one-stage aerobic biological system. Another system uses fixed-film reactors, such as gravel beds, separately for nitrification and denitrification stages. Effluent nitrogen concentrations of 2 mg/L have been proposed as the upper limit in a biological process. Many full scale biological nitrogen removal facilities are now in operation. Nitrifying bacteria are subject to inhibition by various organic compounds, as well as by inorganic compounds such as ammonia. Free ammonia concentrations of 0.1 to 1.0 mg/L and free nitrous acid concentrations of 0.22 to 2.8 mg/L, start inhibiting *Nitrobacters* in the process.[20]

The majority of phosphorus compounds in wastewaters are soluble and only a very small fraction is removed by plain sedimentation. The conventional biological treatment methods typically remove 20 to 40 percent of phosphorus by using it during cell synthesis. A considerably higher phosphorus removal has been achieved by modifying the processes to create "luxury phosphorus uptake." Factors required for this increased phoshorus removal are plug-flow reactor, slightly alkaline pH, presence of adequate dissolved oxygen, low carbon dioxide concentration and no active nitrification.[46] However, the most effective method of phosphate removal is the addition of alum or ferric salts to conventional activated sludge processes.

Nomenclature

A_v = Specific surface area of filter media, Length^{-1}

B_v = Volumetric loading rate; mass per unit volume per unit time

D = Longitudinal dispersion coefficient, (Length)^2 per unit time

E = Process treatment efficiency, ratio

H = Filter depth, length

K = Half velocity coefficient = substrate concentration at which rate of its utilization is half the maximum rate, mass per unit volume

K_i = Inhibition constant, mass per unit volume

L = Substrate concentration around microorganisms in reactor, measured in terms of BOD, mass per unit volume

N_0 = Number of microorganisms per unit volume at time $t = 0$

N_t = N = Number of microorganisms per unit volume at time t

ΔO_2 = Amount of oxygen requirement, mass per unit time

Q = Volumetric rate of flow, volume per unit time

Q_a = Volumetric rate of flow per unit area, Length per unit time

Q_r = Volumetric rate of return flow, volume per unit time

R = Recycle ratio

S = Substrate concentration, mass per unit volume

ΔS = Substrate removed, mass per unit time

S_e = Effluent BOD or final substrate concentration, mass per unit volume

S_0 = Influent BOD or in the initial substrate concentration, mass per unit volume

T = Temperature, °C

U = Process loading factor, time^{-1}

V = Volume of the reactor, volume

X = Mass of active microorganisms present per unit volume

ΔX = Cell mass synthesized, mass per unit time

X_e = Effluent volatile suspended solids, mass per unit volume

X_0 = Influent volatile suspended solids, mass per unit volume

X_r = Volatile suspended solids in return sludge, mass per unit volume

X_T = Total mass of microorganisms in the reactor, mass

Y = Growth yield coefficient, dimensionless

a' = Fraction of BOD removed that is oxidized for energy

b = Microorganisms decay coefficient, time^{-1}

b' = Oxygen used for endogenous respiration of biological mass, time^{-1}

c_1 = Constant

f = Fraction of volatile suspended solids present in the influent which are non-degradable

k_f, k'_f, k''_f = Rate coefficient in filters, time^{-1}

k_0 = Logarithmic growth rate constant, time^{-1}

k_t = Growth rate factor, time^{-1}

k' = Growth rate factor, (time)$^{-1}$ (mass per unit volume)$^{-1}$

l = Length dimension in reactor, Length

m = Constant

n = Trickling filter exponent

q = dS/Xdt = Substrate utilization rate per unit biomass

$q_{\max}$ = Maximum substrate utilization rate per unit biomass

t = Contact time in filter or any other reactor, time

$\bar{t}$ = V/Q = Mean retention time, time

u = Mean displacement velocity in reactor along length, length per unit time

w = Volumetric rate of flow of waste sludge, volume per unit time

θ = Temperature coefficient for microbial activity

θ_x = Mean cell retention time, time

μ = dx/Xdt = Specific growth rate of microorganisms, time^{-1}

$\mu_{\max}$ = Maximum specific growth rate of microorganisms, time^{-1}

D/ul = Reactor dispersion number, dimensionless

M/F = Microorganisms to food ratio in a reactor

$\mathrm{d}L/\mathrm{d}t$ = Rate of waste utilization measured in terms of BOD, mass per unit volume per unit time

$\mathrm{d}N/\mathrm{d}t$ = Rate of growth in number of microorganisms, Number per unit volume per unit time

$\mathrm{d}S/\mathrm{d}t$ = Rate of substrate consumption, mass per unit volume per unit time

$\Delta S/\Delta t$ = Mass of substrate utilized over one day, mass per unit time

$S_T/\Delta t$ = Total mass of substrate applied over a period of one day, mass per unit time

$\mathrm{d}X/\mathrm{d}t$ = Rate of growth of mass of active microorganisms, mass per unit volume per unit time

$\Delta X_T/\Delta t$ = Total quantity of active biomass withdrawn daily, mass per unit time

BROWNFIELDS

The American Society for Testing and Materials (ASTM) defines *brownfields* as “abandoned, idled, or underutilized properties where expansion or redevelopment is complicated by the potential or confirmed existence of chemical(s) of concern.” The U.S. Environmental Protection Agency (EPA) Web page states, “Brownfields are abandoned, idled, or under-used industrial and commercial facilities where expansion or redevelopment is complicated by real or perceived environmental contamination.”

In the mid-twentieth century, *brownfield* was a planners’ term for urban blight. Brownfields had existed for decades, perhaps centuries, but a strong focus on cleaning up these properties did not happen until the 1970s (see Table 1). Concurrent with the federal use of *brownfields,* several local and state governments adopted the term for their efforts to bring about economic revitalization. Most governments have adopted specific legal definitions of brownfields. These definitions reflect differing environmental and economic conditions but have strong similarities to the federal definition.

In everyday language, a brownfield is an area that is contaminated or perceived to be contaminated. Most brownfields can be redeveloped, revitalized, and reused after assessment and cleanup. The EPA’s brownfields program helps communities work together to create jobs and put abandoned properties back into productive use. The EPA, together with other federal, state, and local agencies, provides funds, coordination, and advice for the cleanup of brownfields.

Politically, brownfields have been contrasted to “greenfields.” Greenfields are rural areas that are in danger of being converted to industrial areas. The goals of many brownfield programs include saving farmland and open spaces in addition to putting brownfields back into industrial use. Development of greenfields can be economically and environmentally problematic, because it means building shipping and utility infrastructures that are essential for most industrial development. Development of brownfields can be economically and environmentally more desirable because they often have utility connections like water, sewer, and electricity as well as train access with sidings. Further, cities and counties can regain or enhance their tax base by cleaning and redeveloping brownfields.

This article discusses the history of brownfields, lists some common and legal definitions, discusses the associations with social justice and banking issues, and gives a case study of a showcase community that demonstrates creative successes. It does not discuss the associated new urbanism movement within architecture and urban planning.

HISTORY

The history of brownfields is intertwined with the history of hazardous-waste cleanups and the EPA. In the 1960s the United States grappled with the challenge of many unused and contaminated facilities. These properties were across the United States, from the shuttered steel mills in Pennsylvania and Cleveland to mining operations in Montana and Arizona to closed timber mills in Washington and Oregon. The facilities represented many industries, including closed smelters, metal-plating factories, machine shops, and chemical plants. Many facilities had complied with the few environmental regulations of the early 1900s.

In response to a fire on the Cuyahoga River, President Richard Nixon created the EPA in 1969 by presidential directive. The new EPA was faced with such media disasters as Love Canal, the Valley of the Drums, and Bridgeport. The EPA began regulatory efforts with the Clean Air Act and Clean Water Act, closely followed by regulations to control hazardous substances. In 1976, the Resource Conservation and Recovery Act (RCRA) and Toxic Substance Control Act (TSCA) initiated cleanup regulations. In 1980, the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, or Superfund) ushered in two decades of federal Superfund cleanups. Many states created analogous legislation and regulations. From 1984 to 1995, Superfund cleanups were financed by a tax on the industries that synthesized or manufactured chemicals.

In response to the widespread economic-development obstacles posed by urban brownfields, the EPA announced its original Brownfields Action Agenda in January 1995. Brownfields were an adaptation from the EPA cleanup-enforcement-driven pattern over to economic and environmental local collaboration with support from the EPA. The impetus to bring about this change came from several large Midwest and East Coast cities that led the movement to revitalize their abandoned industrial areas with funding from federal and private sources. Initially, both the EPA and the John D. and Catherine T. MacArthur Foundations funded a series of brownfield forums in Chicago in the early 1990s. These forums developed a set of brownfield redevelopment principles that have been adopted, adapted, and standardized.

Nationwide movement to clean up abandoned grayfields—2003																												

Some of these principles have become engineering practice in the "Standard for Process of Sustainable Brownfields Redevelopment" from the ASTM.

In association with the forums, the Chicago Brownfield Initiative began with a pilot cleanup and redevelopment program in 1993. The Chicago Department of Environmental Protection, in partnership with the mayor's office and the Chicago Departments of Planning and Development, Buildings, and Law, coordinated the brownfields pilot program. The pilot program involved the cleanup up of five abandoned polluted industrial sites and initiated redevelopment. The five pilots resulted in new construction activity and the creation of jobs. The city's experience with these sites became a national model for continued innovation at large-scale cleanups.

Chicago shared its experiences by hosting another brownfield forum to discuss the legal, financial, and ethical issues related to urban disinvestments. The forum, which included business leaders, industrialists, environmentalists, bankers, regulators, and city officials, generated a list of recommended actions to facilitate brownfield cleanups and redevelopments. Cities across the United States began to use the successful Chicago-recommended actions. Chicago revisited its forum recommendation in late 1997 to assess local and national progress. This conference increased national attention and validated the work since the first conference. More urban areas took the model and made it theirs.

One city that took the model and made it theirs is St. Louis, Missouri. St. Louis, like many older cities, had deteriorated commercial districts that imposed a blighting effect on surrounding residential neighborhoods. St. Louis began one of the earliest brownfields programs in the mid-1990s. By 2000, St. Louis had cleaned up many sites using the brownfields approach. Mayor Freeman Bosley detailed the experiences at several sites in congressional testimony. In one targeted area, the city paid to assemble, clear, and clean a corner site critical to the shopping district's viability. According to the mayor, the owners of this area had not been able to command sufficient rent to maintain their property. When cleanup was accomplished, a private company invested in what is now a thriving commercial business district that provides employment, generates sales, and helps to attract patrons to other retail and eating establishments in the area.

On May 13, 1997, Vice President Al Gore announced the Brownfields National Partnership Action Agenda (National Partnership), outlining the EPA's activities and future plans to help states and communities implement and realize the benefits of the brownfields initiative. The National Partnership brings together federal agencies to address brownfield cleanups and redevelopments in a more coordinated approach.

AGENCIES, CITIES, AND UNIVERSITIES INVOLVED IN BROWNFIELDS

The other seven federal agencies involved are: the Department of Housing and Urban Development (HUD), the Department of Transportation (DOT), the General Services Administration (GSA), the National Oceanic and Atmospheric Administration (NOAA), the Department of Health and Human Services (DHHS), the Department of Labor (DOL), and the Department of Energy (DOE). HUD administers the Brownfields Economic Development Initiative (BEDI) as the key competitive grant program to stimulate and promote economic- and community-development activities under Section 108(q) of the Housing and Community Development Act of 1974. Through BEDI, HUD administers these grants to stimulate local governments and private-sector parties to redevelop or continue phased redevelopment efforts on brownfield sites where environmental conditions are known and redevelopment plans exist. The DOT has multiple approaches to support transportation-related brownfields by funding cleanups as part of its infrastructure development, work with other agencies on brownfields for transportation-related uses, encourage consideration of transportation access in redevelopment planning, and identify policies that discourage transportation-related brownfields redevelopment. With thousands of federal properties located throughout the country, the GSA is partnering with communities to ensure that underutilized federal properties are an active component in the redevelopment of our nation's urban centers. NOAA has a signed agreement with the EPA to lay the groundwork for revitalizing aging port-city waterfronts. The DHHS specifies essential services to be provided by its health-related agencies and the larger public-health community that must be applied to each brownfields project to assure public-health protection. The DOL, through its Office of Environmental Management, Office of Intergovernmental and Public Accountability, has developed an electronic access (Internet-based) system to provide technical assistance and increase community members' capacity to understand and resolve environmental issues related to brownfields. The DOE provides technical assistance in brownfield efforts from its Headquarters Program Offices and the National Laboratories and Technology Centers.

Many major urban areas, through both cities and counties, have associated with the federal brownfields, and some have continued their own brownfields efforts. Pittsburgh, Pennsylvania, is a city that develops brownfields innovations in association with Carnegie Mellon University while it continues to work with the EPA. Another city with a strong university affiliation is Cincinnati, Ohio, where collaboration with the University of Cincinnati provides training and environmental-justice support and broadens community affiliations.

COMMON AND LEGAL DEFINITIONS

The EPA and other environmental- and health-protection agencies base their regulations and implementation on science. Most often they adapt technical definitions that are measurable and science-based into regulations. The terms surrounding brownfields do not follow this pattern. Brownfields definitions bring a community-based sensibility. The complexity and plasticity of brownfields begins in the definitions and continues through implementation.

Legally, the EPA uses the definition of brownfield in Public Law 107-118 (HR 28869), the Small Business Liability Relief and Brownfields Revitalization Act, signed into law January 11, 2002. This definition says that "within certain legal exclusions, the term 'brownfield site' means real property, the expansion, redevelopment, or reuse of which may be complicated by the presence or potential presence of a hazardous substance, pollutant, or contaminant." Following the definition are pages of exclusions that primarily detail sections of other laws with priority. The primary statutory authorities citied are: the Clean Water Act, as amended in 1977; CERCLA of 1980, commonly called Superfund; the RCRA, as amended in 1984; the Superfund Amendments and Reauthorization Act (SARA) of 1986; the Medical Waste Tracking Act of 1988; the Great Lake Critical Programs Act of 1990; the Clean Air Act of 1990; the Clean Water Act of 1990; and the Housing and Community Development Act of 1992.

On many publications and Web pages on brownfields, the EPA discusses them as "abandoned, idled or underused industrial and commercial facilities where expansion or redevelopment is complicated by real or perceived environmental contamination." This definition facilitates the EPA's Brownfields Economic Redevelopment Initiative in empowering states, communities, and other stakeholders involved in brownfield revitalization to work together on redevelopment.

The definitions of brownfields by states are varied, as are the patterns of implementation. They vary from Missouri, with one of the oldest and most defined brownfields programs; to Washington, with an operating program without a definition; to Alaska, with no definition or program.

Missouri's complex definition of brownfields comes from its 1995 brownfields legislation in Chapter 447 of the Revised Statutes of Missouri (commonly known as the Brownfields Redevelopment Program). The Missouri Department of Natural Resources (MDNR) and the Missouri Department of Economic Development jointly have the following definition. To be a brownfield in Missouri, a project must meet two criteria:

1. All projects must enter and be accepted into the MDNR Voluntary Cleanup Program which provides property owners with oversight of and concurrence with all cleanup activities.
2. A project will be considered eligible if it meets the following criteria:

   (a) The property must have been abandoned for at least three years or underutilized. Real property is underutilized if less than 35% of its commercially usable space is used for its most commercially profitable and economically productive use.

   (b) The property is owned by a local, state, or federal governmental agency, or by a private party who is to the potential responsible party, and the project is endorsed by the local municipality;

   (c) The property is contaminated, or perceived to be contaminated, by a hazardous substance; and,

   (d) The property is planned to undergo redevelopment for a commercial, mixed-use, or industrial use that is expected to create at least 10 jobs or retain at least 25 jobs, or some combination thereof.

The state of Washington discusses brownfields as "the shorthand term for historically contaminated and underutilized or vacant industrial property" on its Web page. In some literature it defines brownfields as "properties that are abandoned or underused because of environmental contamination for past industrial or commercial practices." However, there is not a definition in any state statute or regulation. If the public thinks a site is a brownfield—it is. Nevertheless, Washington maintains an active brownfields program, with a showcase project in Seattle and King County as its model. That project is discussed in the case study below.

ASSOCIATED ISSUES: ENVIRONMENTAL JUSTICE AND BANKING

Many contaminated properties are located in areas such as older urban centers, where a high proportion of the residents are minorities, have low incomes, or do not have English as their first language. These common problems reflect the economic limitations faced by disadvantaged individuals. Therefore, disadvantaged communities must overcome special barriers to effectively advocate for their community interests during the review and permitting of projects with potential environmental impacts. This created environmental injustice. In 1982, Warren County was the poster child for environmental injustice and documented racism. That year, citizens banded together and made the Warren County PCB landfill protest a seminal event for the environmental-justice movement. The North Carolina Environmental Justice Network (NCEJN) was formed, and it became a catalyst that galvanized people of color in the fight for environmental justice. The struggle in Warren County was the spark that lit that national environmental-justice movement in the 1980s.

In its most basic interpretation, environmental justice (EJ) is the principle that all people have the right to be protected from environmental pollution and to receive a fair share of environmental benefits. It combines environmental protection with considerations of nondiscrimination and civil rights. Many organizations have been formed on the model of the NCEJN to support these principles locally. Additionally, governments have provided support through agencies such as the Oregon Governors Environmental Justice Advisory Board.

EJ policies seek to level the playing field by providing disadvantaged communities with technical and organizational support, by providing special scrutiny for proposed projects in EJ communities that might result in significant environmental impact, and by offering incentives for certain desirable types of development, including brownfields. EJ policies go beyond brownfields. However, brownfields are an effective means for advancing EJ principles.

When HUD administers brownfields grants, it has EJ requirements. HUD works with community organizations, the private sector, local and state governments, and other federal agencies to provide equitable reinvestment in communities with fair employment opportunities. Other agencies, such as the Agency for Toxic Substance and Disease Registry's Office of Urban Affairs, are actively involved in issues such as public-health issues that are linked to EJ.

Bankers make lending decisions that affect brownfields. Initially, bankers chose to lend on greenfields, rather than brownfields, because brownfields bring unpredictable expense and liability—this despite the fact that greenfields may be more expensive because of the infrastructure that needs to be built. The unpredictable expense and liability of brownfields came from the wide variability in cleanup and associated legal costs. Without some predictability for cleanup and liability costs, banks were biased toward the more predictable greenfields without infrastructures, like rail connections, sewer, water, electricity, and nearby communities to provide. The EPA's brownfield program brought predictability through its multiagency collaborative approach. This approach, combined with funding, often overcame the reluctance of bankers to fund the development of brownfields. Additionally, bankers rely on technical standards developed by other fields to make decisions. With the engineering standards that have been developed in the 1990s such as the "Standard for Process of Sustainable Brownfields Redevelopment" from the ASTM, banks have reliable technical standards. Finally, banks are members of the community and are positively influenced by brownfields because of the community support and process.

From the success of the brownfield cleanups, an associated movement to clean up grayfields has developed. "Grayfields" are defined as blighted or obsolete buildings sitting on land that is not necessarily contaminated. Grayfields range from aging shopping malls in the suburbs to mining reclamation across the Pennsylvania countryside. Many regions hope to have grayfield successes using some of the partnerships and methods developed by brownfield programs.

SEATTLE AND KING COUNTY CASE STUDY

Case studies are written discussions of a topic containing an applied example of the topic. Case studies are used in legal, business, and environmental studies. There are many case studies to select from, because from 1993 to 2000, the EPA has provided over $250 million in brownfields funding in the form of grants and loans. More that 50 brownfield-related job-training and redevelopment demonstration projects have been funded. Projects have ranged from innovative test pilots for heavily contaminated areas in large cities to small communities with a large brownfields.

The case study below discusses a brownfield showcase community initiative in Seattle, Washington, that uses differing levels of technology and different levels of private–public cooperation at several sites. The Seattle and King County Brownfields Initiative was one of the 11 initially funded under the EPA Brownfields Showcase Communities Initiative. The funding comes through the King County and Seattle Offices of Economic Development and has been renewed because of a track record of successes.

This initiative has two tracks. First, several small businesses have received assistance from the brownfields program that has enabled them to return contaminated industrial properties to productive businesses. Second, area-wide projects have made cleanups more attainable for all businesses under their umbrellas.

One of the businesses receiving funding was an auto-wrecking yard, All City Wrecking, that has been cleaned up and redeveloped as a neighborhood store and gas station. This 2-acre site supported a family-owned auto wrecking yard for 30 years. As the owners neared retirement, they ceased operating their business with the hopes of selling their property. The presence of contamination posed challenges to that sale. The site was contaminated with oil, petroleum products, and heavy metals. The Environmental Extension Service (EES), a contractor under the grant, was able to help this business overcome the difficulties of addressing the contamination.

The EES provided free assistance at every stage of the project. The EES helped the owners properly dispose of liquid wastes on the site, and obtained a local matching grant to defray disposal costs. The EES then assisted in selecting and hiring consultants to perform both the assessment and cleanup on the property, reviewed and interpreted consultant reports for the owners, and made recommendations for how to proceed with assessment and cleanup. Within approximately 8 months, the All City Wrecking site underwent environmental testing, cleanup, and compliance monitoring. This process ended with a "No Further Action" designation by the Washington Department of Ecology and has enabled this property to be sold, redeveloped, and recycled for a new productive use as a neighborhood store and gas station. There were many such cleanups that were facilitated by the umbrella projects described below.

Two wide-ranging projects facilitated the cleanup of all properties in their respective ranges. The largest, Washington's newly established risk-based cleanup standards for total petroleum hydrocarbons (TPH), was statewide. The other project was the localized Duwamish Corridor Groundwater Study. This study characterized the groundwater in a heavily industrial area that has been created with material dredged from the river and washed from the hills and documented that the groundwater was not a drinking-water aquifer. Both of these government efforts had the effect of streamlining projects and reducing the cleanup costs. The more flexible TPH cleanup standards enabled this project to clean the soil up to a commercial, rather than a residential, cleanup level. The groundwater study, funded by King County from state and federal grants, helped to streamline the evaluation and regulatory process for each site. Both reduced the time needed to collect background information on sites, thereby lowering the costs of site evaluation.

This and other brownfield cleanups in Seattle and King County were facilitated by:

1. A 5-year project to improve the science for characterizing and guiding the cleanup of petroleum-contaminated sites statewide. The changes to state law recommended by this project were ecological as part of the revisions to Washington's Model Toxics Control Act Regulation.
2. An interagency project that provided the Duwamish Corridor Groundwater Study of an industrial area by a river that is important to shipping. The area included parts of south Seattle and adjacent King County.
3. The creation of a technical-assistance center (the EES) run by the nonprofit Environmental Coalition of South Seattle (ECOSS), which provides direct, door-to-door assistance to manufacturing and industrial businesses in environmental cleanup and pollution-prevention practices.
4. A revolving loan fund for environmental cleanup for which a partnership among King County, the city of Seattle, the city of Tacoma, and the state of Washington manage the EPA grant money.

CONCLUSION

Brownfield programs are a highly successful phase of environmental cleanups in the United States. The first phase was science-based and regulation-driven cleanups. That phase began in 1976 and continues to this day. Occasionally, these cleanups involve economically viable properties that go right back into use. More often, the cleaned-up sites involve abandoned, idled, or underutilized properties. In those cases, the expansion or redevelopment is complicated because of the potential or confirmed contamination. Therefore, the brownfield approach was added in 1993 as a phase that ideally works with the cleanup and then continues through redevelopment. The two approaches continued concurrently. When the federal tax to fund Superfund cleanups was sunsetted in 1995, the number of cleanups began to decline. As Superfund monies run out, brownfield funding will become more important. Brownfield programs coordinate agency and private-sector interests to work together to create jobs and put abandoned properties back into productive use. Problems may arise when the brownfield cleanups are underfunded, the local economy is weak, or cooperation is not achieved. Despite these obstacles, brownfield pilots and projects have been documenting success stories for over a decade. Brownfields have sparked social economic movements such as EJ and economic revitalization of grayfields.

The next phase of environmental cleanups has not yet arrived. Currently, brownfield programs are active across the United States. Their goal is to have all contaminated sites cleaned cooperatively and put back into use. If cleanup and brownfield sites remain clean and no further sites are created, cleanup programs may work themselves into obsolescence. Related movements like EJ and grayfields begun from brownfields will separate as their goals differ. However, brownfields are likely to remain at a smaller and increasingly more sophisticated level for decades.

COAL GASIFICATION PROCESSES

In spite of temporary oil "gluts," elements of a new coal-based synthetic fuels industry are slowly emerging in oil importing nations. This coal conversion activity involves the commercial integration of process and power systems. Overcoming both process engineering and environmental problems will be crucial factors in the development of coal liquefaction and gasification plants. Depending upon project size and complexity, the associated expenditures for the total compliance effort could require multimillion dollar budgeting.

The concept of gasification of coal is not a new one. John Clayton proved conclusively that gas could be obtained from coal in the early 1680s. His initial experiments were observations of the products formed upon heating coal. In the presence of air, heat will invariably be generated by burning a portion of the coal. In order to increase the yield of secondary fuels with higher hydrogen to carbon (H/C) ratio than that of coal, it is required to gasify the coal in the presence of steam and an oxygen containing gas. The products formed during high yield gasification are typically hydrogen, carbon monoxide, and variable amounts of light hydrocarbons, especially methane. Carbon dioxide may be scrubbed from the product. The coal, steam, air mixtures are contacted at temperatures above 700°C in fluidized, entrained flow or moving bed configurations.

Liquefaction of coal may be accomplished by reacting with heavy oil derivative hydrocarbons at temperatures of 400 to 500°C. Contaminants are typically hydrogenated to gases which may be absorbed (sulfur to H_2S, nitrogen to ammonia and oxygen to water).

According to Quig and Granger (1983), a coal conversion facility impacts the environment through the handling of large amounts of coal, and discharges from the conversion process and associated facilities. Also, there will be impacts related to the construction and operation of any large industrial complex. The major health concerns for both occupational and offsite populations include potential exposure to particulates, sulfur compounds, trace elements, aromatic amines, and other nitrogenous compounds and radioactive nuclides.

Considerations of these issues and concerns for this facility will begin with the coal handling facilities. Fugitive dust, consisting mainly of coal fines, is generated by the disturbance of the coal in the unloading, transfer and storage facilities. Particulates can remain airborne and be transported from the site under certain meteorological conditions and therefore must be evaluated in terms of their potential impacts and control mechanisms. Coal pile runoff and coal wetting wastewater contain varying amounts of coal fines and dissolved constituents depending on variables such as rainfall intensity and duration, contact time, coal storage configuration and coal pile sealing techniques. Values of over 2000 mg/l total suspended solids and 10,000 mg/l total dissolved solids have been reported by EPA and TVA for runoff from coal piles. The magnetic separation of metallic materials from the coal during preliminary coal cleaning operations will generate a variable quantity of pyretic solid waste which must be addressed. The coal processing facilities, that is coal grinding and slurry preparation, include controls which minimize the discharges from these operations.

Some of the more important coal gasification processes include those of Texaco, Shell, Dow & British Lurgi. These are carried out at high temperature 600 to 3000°F and high pressure 25 to 80 atmospheres. The most developed process is Cool Water integrated gasification/combined cycle (IGCC) described by Holt (1988) and Spencer *et al.* (1986) which uses a Texaco gasifier. Makansi (1987) compares the performance of various systems. Important emissions data for IGCC projects are presented at the end of the current review.

Additional information is presented below on the status of coal gasification environmental effects. A comparison of the impacts on water streams of various processes is given in Table 1.

Pruschek *et al.* (1995) discusses the removal of pollutants from a coal gasification plant in a more efficient and economical manner than in previous designs by conserving energy in the cleaning sections of the plant. A zinc titanate catalyst is being tested for hot (1000°F) gas cleanup potential at Tampa Electric's 260 MW coal gasification power plant in Lakeland, Fla.

Waste gas emissions are reduced by scrubbing the raw gases leaving the gasifier in an acid gas removal system and converting the H_2S (via a modified Claus process) to sulfur. Sulfur dioxide is thus drastically reduced in the final stack emissions. NO_x levels are reduced by saturating the gas prior to gas turbine combustion (see Spencer 1986) or Makansi (1987). Advances in process efficiency are possible, through the use of a combined cycle configuration and by reducing gasifier energy losses. Figure 1 illustrates the Shell Coal gasification process. The product gas would typically be fired in a combustion turbine followed by an HRSG and a steam turbine (i.e., combined cycle) to complete the IGCC. Heitz (1985) presented data on end uses of various gasifier process streams (see Table 2). The analysis of a typical product gas stream appears in Table 3.

From an economic point of view it is desirable to construct an IGCC in phases, Le *et al.* (1986). In the typical scenario the first phase would be installation of simple cycle gas turbines for peaking power. As of 1989 the maximum single gas turbine output is about 150 MW. In the second phase a heat recovery boiler is used to generate steam for either cogeneration or to power a steam turbine (i.e., ordinary combined cycle). Zaininger Engineering (Lewis, 1988) indicate that there is an optimum time at which the gasifier plant could be added as fuel cost/availability would dictate. Normal combined cycle efficiency can be approximately 50% (LHV) whereas IGCC values range from 37 to 42%. However, new hot gas cleanup processes (such as limestone throwaway or metal oxide catalyst) are being developed which may increase IGCC efficiency to about 48%.

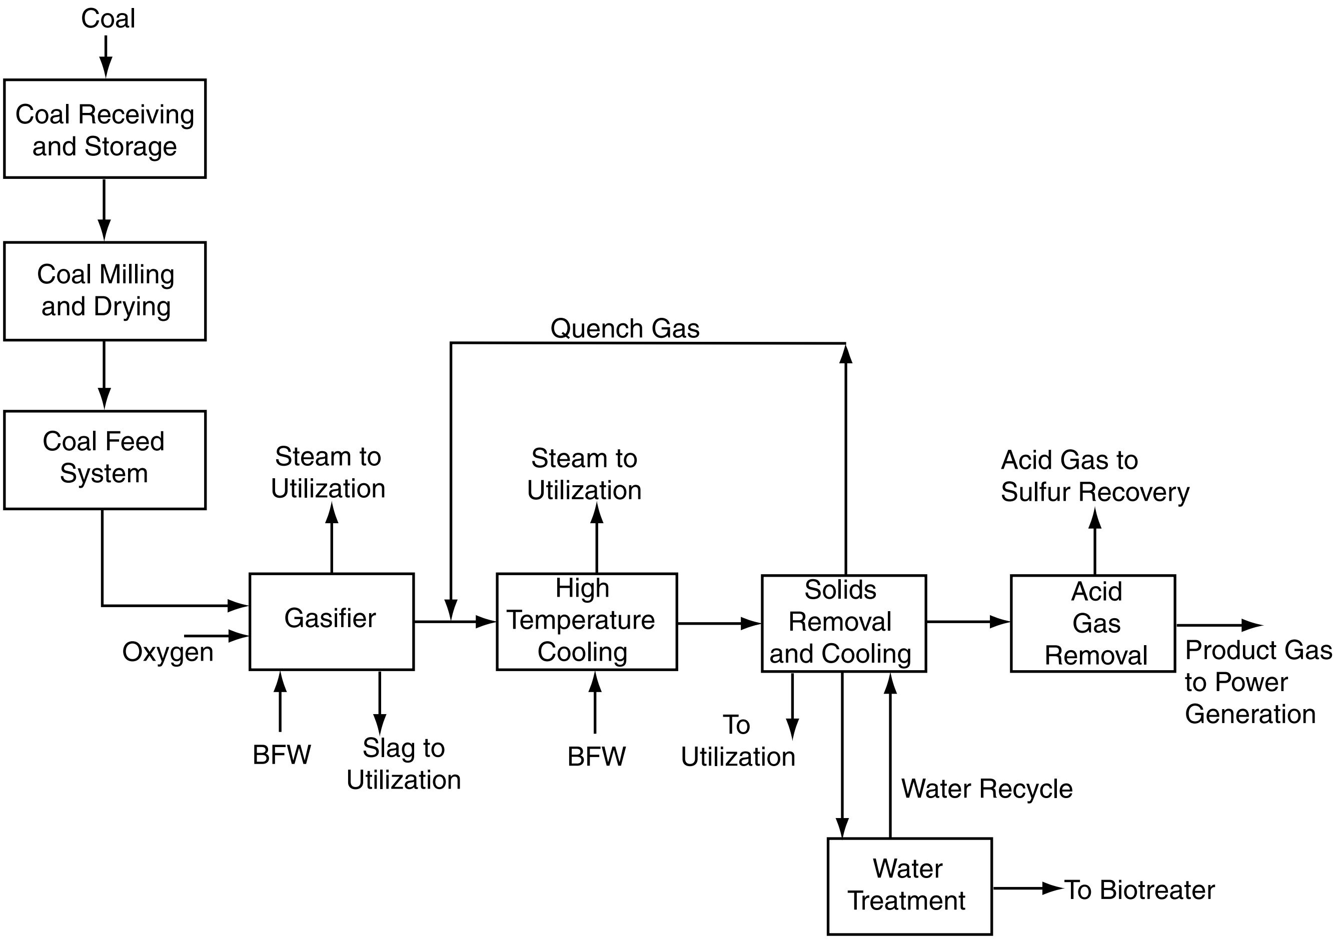

FIGURE 1 Shell coal gasification process block flow diagram for SCGP-1.

The stack emission values presented in Table 4, as per Holt's (1988) review of Cool Water data, are impressively low for a coal-based plant. Sulfur dioxide in the gases leaving the tail gas incinerator is about one fifth the quantity leaving in the turbine exhaust stream. The turbine exhaust did not contain sulfur compounds other than SO_2.

A typical gasification process will generate both solid and liquid wastes. The solid waste retains the natural impurities inherent in the coal such as heavy metals, chlorides as well as organic compounds formed by the combustion of coal in the reactor. Testing, as defined in rules and regulations under Section 3001 of the 1976 Resource Conservation and Recovery Act RCRA, must be conducted to determine the nature of the solid waste generated by the gasification of the particular coal with the specified process. The wastewater stream exiting the carbon-ash scrubbers may contain dissolved and suspended fly ash and unconverted carbon trapped in the scrubber. The treatment of this process wastewater for discharge will generate sludge which will have to be controlled and assessed.

A gasification process may not have any atmospheric emissions during normal operating conditions. Gases are processed and recirculated so that the desired discharge from the system is product gas alone. During upset conditions, however, venting will occur causing releases of gaseous wastes.

TABLE 2
Uses of products, co-products and effluents (from Heitz, 1985)

Product gas	Power generation
Steam	General steam system
Acid gas	Sulfur plant/sulfur sales
Slag and ash	Roads, fill, other products
Runoff and stripped	Biotreater

Sources of non-gasifier liquid wastes which must be evaluated include blowdown from clarifiers and cooling towers, drainage from equipment and floor areas, demineralizer wastes and sanitary wastes. Contaminants in these streams are generally a function of the intake water quality and any chemical additives.

TABLE 3
Typical treated product gas composition. (Adapted from Heitz, 1985 for SCGP-1)

Component	% Volume (N_2 Free)
Hydrogen	30
Carbon monoxide	69
Carbon dioxide	<0.1
Hydrogen sulfide	<0.01
Carbonyl sulfide	<0.01
Hydrogen cyanide	<0.001
Ammonia	<0.001
Hydrogen chloride	<0.001
Hydrogen fluoride	<0.001
Methane	0.03
Water	0.6
Argon	0.2

Cool water stack emissions. (adapted from Holt 1988)

	HRSG Emissions (Lbs/Million Btu)			
Pollutant	U.S. EPA NSPS	Cool Water Permits*	Cool Water Test Results**	Incinerator combustion products
NO_x	0.60	0.13	0.056	140 ppmv
SO_2	0.24	0.034	0.017	116 ppmv
Particulates	0.03	0.01	0.008	0.18 g/m^3

* Cool Water Permit for Low Sulfur Coal Operation (Low sulfur coal is defined in the permit as coal containing less than 0.7 wt.% sulfur).

** 1987 EPA Performance Test Results for SUFCo Coal, Holt (1988).

The main problems found with sulfur sorbents involve mechanical property degradation and/or loss of sulfur capacity over many sulfidation-regeneration cycles. The sorbents receiving the most attention are all zinc based. Building on the Cool Water technology, various zinc titanate formulations and proprietary materials were developed by the U.S. Department of Energy (DOE)/Morgantown Energy Technology Center (METC) and used at Tampa Electric—Swisher *et al.* (1995). A hot gas pilot scale desulfurization is currently operating at METC. It uses a simulated coal gas mixture at volumetric flow rates of up to 120,000 standard cubic feet per hour and 400 psia and up to 1200°F. Fluidized bed technology is ideal for reactors that continuously circulate reactive and regenerated adsorbent. For further information and updates the reader is referred to the following publication and the DOE websites:

http://www.netl.doe.gov/publications/proceedings/96/96ps/ps_pdf/96ps1_5.pdf, and http://www.netl.doe.gov/publications/proceedings/02/GasCleaning/1.05paper/pdf

One of the world's largest coal gasification plants for electricity generation, a 253 MWe power plant based on the Shell IGCC process, was built and started-up in Buggenum, in the Netherlands, in 1994. Since October 2001, the installation has been owned and operated by NUON Power as a fully commercial electric generating unit. Pulverized coal is gasified at about 400 psi and 2700°F using pure oxygen rather than air. Fly ash bearing raw gas exiting the gasifier is passed through cyclones to remove the larger particles. The remaining fines are collected in a hot gas ceramic candle filter. The filter treats about 1 million cubic feet per hour of syngas at about 500°F and 380 psia. The filter contains tube modules with elements made from a structure of silicon carbide supporting a porous Mullite grain membrane with a pore size of about 4×10^{-4} inch. Future plans include co-gasifying waste materials such as biomass chicken litter, wood products and sewage sludge.

Further cleanup of the syngas involves removal of acid gases such as COS, H_2S and chlorides as well as a process to recover sulfur (see Fig. 1). Also removal of ammonia compounds is included in the water treatment process.

Sources of non-gasifier solid wastes include sludge from raw water treatment and spent bauxite catalyst from the Claus unit, spent cobalt/molybdenum catalyst from the tail gas treatment, silica gel from the air separation plant, and various resins from the water treatment plant.

Sources of non-gasifier atmospheric emissions are cooling tower evaporation and drift, and the gas turbine. The cooling tower releases will cause salt deposition in the surrounding area. The nature and extent must be determined and evaluated using intake water quality data, design information and mathematical modeling. The on-site gas turbine will emit low levels of NO_x, SO_2 and particulates which will have to be considered.

Other impacts associated with any large scale project are those related to the construction of the plant. There will be an increase in traffic by the construction work force on the existing roads. There are potential construction work force impacts related to workers immigration, shortage of certain skilled labor categories, etc. which must be assessed. In addition, there is a potential for noise impacts during the construction or operation of the facility.

The increase in traffic on the roads, rails and rivers near a proposed site due to coal deliveries will create additional demands on the system. The construction of a facility will have unavoidable impacts on the land use at the site.

Construction and operation may impact on the surface water bodies and the potable aquifers in the area but due to the current state of waste water treatment technology, minimal impact on water quality is expected after control measures are applied.

COMMUNITY HEALTH

GENERAL

Health is the ability to cope with activities of daily living, ever a norm yet always relative.[1] Most people enjoy and expect good health, boast of their abilities to perform but resent being unhealthy. Health is valued most highly after it has been impaired.

Health and sickness are two contrasting aspects of our world's life. Sickness is a deviation from normal healthy functioning, much like any other system breakdown. Each attracts a legion of helpers ready to aid ailing persons return to their diverse pre-illness states. So it is with a community's health.[2]

Evaluations of community health must consider many factors. In addition to specialized and general medical care, variables include housing availability and ownership, transportation adequacy for work or pleasure, entertainment and recreation, severity of usual weather conditions, educational opportunities, and social and religious factors, among others. Whereas a plethora of medical and surgical options contribute to what are sometimes claimed as miraculous recoveries from a personal illness, environmental engineering quietly strives to create basic healthy living conditions and protect communities from potential physical dangers, widely ranging in severity and in size from small to large.

Environmental health of a community is rated by the degrees of satisfaction that result from engineering works and organized community efforts that improve the physical freedom, comfort, and efficiency of residents. Cities and towns are judged on the numbers and quality of existing recreation opportunities, schools and colleges, and transportation routes, and fiscal services. Yet, while the processes that caused those amenities to be developed are important, the systems and organizations that currently maintain growth or stability must also be carefully noted and weighed. A community's health is not static and must be cared for continually, much like the health of any resident.

For millennia, communities have depended on engineering skills to install, maintain and improve necessities and amenities of life that contribute to the well being of citizens, animals, and plant life. Ancient Crete used conical terra cotta pipes to keep sewage flowing, an early example of the venturi principle, and for centuries massive aqueducts provided ample supplies of fresh water to Roman communities. Excellent roads and transport brought foodstuffs from farms to imperial cities and helped speed commerce and communications between businesses and governments. Cities around the world before and after Rome have turned to engineers to solve urban problems of drainage, flooding, and crowding while at the same time pyramids and temples, cathedrals and castles, universities and markets were being built, all designed to maintain good health and integrity of communities.

Today, efficient land, sea, and air rapid transport networks help deliver farm products promptly to processors, relying heavily on refrigeration to maintain freshness and nutritional quality. Water supplies, a vital element in human health as well as a basic unit of industry, no longer depend on insanitary streams or cisterns but are collected behind large dams, delivered over great distances through well-engineered conduits to filtration plants and there purified, chlorinated and fluoridated for safe consumption. Epidemic diseases like typhoid fever and cholera, amoebiasis, malaria and yellow fever no longer threaten communities in developed nations, thanks to engineering that provides potable water, free from harmful parasites and available for human waste disposal.

Evaluation of any community's health is both quantitative and qualitative. Planners need to know how many hospitals exist within the city limits, where they are in relation to centers of population, and whether transportation for patients, staffs, and visitors is adequate. Numbers of primary and secondary schools, technical training centers and universities, each with details of the students being served are important data in judging community ambience. Local governments want to know how many of the people who work in a city actually reside there, how many residents rent apartments or own their own homes and in what direction these numbers are changing, measures of migration in and out of the jurisdiction.

Businesses and factories that are seeking new locations look closely at pertinent employment rates and skills of available workers that can support general manufacturing, or contribute to growth or modification of an enterprise. Other statistics reflect the fire safety of a community, like the numbers of residential or business fires, annual dollar losses due to conflagrations, or the average response times of fire apparatus to alarms. Law enforcement is rated by numbers and categories of crimes, numbers of crimes solved and the convictions that result. Social health indices would include the numbers of persons on public welfare or assistance, and the numbers and rates of out-of-wedlock school-age pregnancies.

When a community's ability to provide effective sickness care is weighed, the ratios of total population to physicians and other health professions, the number, size, accessibility, and types of hospitals, with attention to emergency services and rehabilitation care are important. Slightly different studies for evaluation of care must be given to rural areas where hospital accessibility, highway networks, and estimated transit times for ambulance services, become critical elements in area's health study.

Residents and visitors, businesses and news media, continually assess the health of a community by studying reports that describe adherence to or departures from desired norms of community living. Governmental publications provide estimates and statistical analyses of regularly collected data about commerce, industry, and banking. Visitors fairly accurately sense or rate a community's ambience by noting the frequency and types of cultural activities for residents or visitors, the numbers and quality of public and private schools, and available recreational facilities. Competent urban planning encourages and supports neighborhoods that have identity and local pride, perhaps with islands of green park land, all served by excellent roads and public mass transit that make for easy access to cultural and recreational areas. Community health depends upon diverse activities, many that result from excellent engineering and some directly related to personal health or sickness care of citizens.

The central official health authority for a community is its public health department, a major health agency under direct control of the mayor or county executive. The health department is established by statute, and its chief health officer is a legal guardian of community health with an authority that includes subpoena power to enforce applicable health codes and regulations. Sizes and complexity of official health agencies range from two or three persons in a town or village to major departments of states and territories, or the national U.S. Department of Health and Human Services (DHHS) and the international World Health Organization (WHO).

Health agencies or departments have a tradition of professional knowledge and compassionate service, two characteristics that usually provide a modest freedom from administrative interventions. This varies somewhat in proportion with budget allocations but it allows health departments a certain flexibility to design their services as needed to carry out community health tasks. Child health care in an affluent suburb will be patterned differently from clinics for expectant mothers and infants and family planning in low income or poverty areas. Centers for treatment of drug abuse and addictions or patients recently discharged from state mental health hospitals need to be close to where those conditions are frequently encountered.

Basic services of most health departments include the epidemiology of infectious diseases; treatment clinics with emphases on sexually transmitted diseases and tuberculosis; family planning services, often a euphemism for contraception but they may also include advice on abortions in the first trimester of a pregnancy; child health care in well-baby clinics where newborn infants and preschoolers are followed closely with childhood immunizations and school health services; pediatric dentistry; services for drug and alcohol abusers who want relief from these personal burdens; and special clinics or services when needed by special communities, such as victims of AIDS or chronic psychiatric ailments. Health education, once a major activity in a local health department, now is carried out by schools and numerous single-focus volunteer organizations, like those for heart disease or cancer. Health promotion, too, has received much attention in the public press and from an increase in general awareness of the advantages of stopping smoking tobacco, weight control, cholesterol levels, and balanced diets.

Environmental control services, a major division of any health department, include restaurant inspection and food services control, with added concerns for area-wide sanitation, housing, industrial hygiene, and animal control. Control and abatement of environmental hazards vary as an emphasis shifts from human health effects to a general community salubriousness, pushed by legislative actions that reflect the relative effectiveness of lobbyists for human health adherents or environmental activists.

Concentrations of population and their needs vary among cities, towns, or counties whose geographies, ethnic compositions, and industrial bases differ sufficiently so that each health unit needs flexibility in designing services. Many health departments have citizen or legislative oversight through various boards of health, and functional tasks vary with the problems that confront the individual jurisdictions. Malaria control, for example, is a prime concern for tropical and some developing countries while the energies of urban health agencies may be heavily invested in tuberculosis detection and treatment. Each is governed by regulations or distinct health codes that have been written to implement laws enacted by respective legislatures. Although occasional conflicts can arise between neighboring communities when confusion or contradiction exist in regulations or information flows, relatively consistent scientific and engineering standards developed by professional societies or governmental experts are available to make health codes more uniform, despite restrictions of jurisdictional boundaries.

Public health responsibilities were once synonymous with local and urban health departments and a few public health schools that were based in major universities. Since about 1960, however, many other community agencies have assumed much of traditional public health's former activities and have blurred the previously clear image of official health departments.

Federal funds to carry out public health programs once were limited to health departments but have been made available as grants to groups such as voluntary associations, hospitals, medical schools, neighborhood associations, and Indian tribes or ethnic groups. Interested community health care provider groups now provide needed auxiliary services such as health education and promotion, medical services to disadvantaged groups, and family planning. They also carry out limited data collection and disease specific epidemiology that support their ongoing research activities. Coordination of numerous separate and isolated studies and consolidation of focused findings can be difficult for local health departments who may not have had a role in the investigations. William Foege, a former director of the Centers for Disease Control, has described the environment for public health practice as changing beyond any predictions and urged support of government for health monitoring systems and interventions.[3]

Private health care has gradually become part of the greater public health system, largely due to change in funding and demands from the public and its elected officers for better quality control of health services. These interests have led to closer supervision of medical services delivery. Licensing boards and related quality assurance organizations have increased their efforts to assure that the professionals who provide health care are fully qualified to practice the disciplines for which they were trained. Terminology like licenses, certificates, or permits tend to be specific for each profession even though a general public may use the names interchangeably. Commonly, physicians and dentists are licensed, nurses are registered, midwives are certified, and physician assistants receive permits from specific state boards.

Each board evaluates the training that its applicants have received and administers a licensing examination that must be passed before permission to practice is awarded. Licenses or certificates can be withdrawn when the specific board has, always by careful legal action, determined that the holder of that license has breached its standards for quality performance. Sanctions of licensees or permit holders vary and may include a written admonition or reprimand, suspension for brief periods, requirement that the professional undergo special training or medical treatment, or even complete withdrawal of the permit to practice. Failure to perform in accordance with accepted standards may result in disciplinary action by hospitals as well, and the results of such decisions are shared with all agencies that have official public responsibility for quality care, consistent with existing standards of confidentiality. Categories of other health care practitioners who must possess licenses vary slightly from state to state but often include dental hygienists, psychologists, social workers, physician assistants, chiropractic, physical therapists, and acupuncturists.

Personal health care services, once known as the "private practice" of physicians and nurses, are gradually shifting from solo practitioners to corporate or group practices. Remuneration has also shifted from personal payments by the patient or a guardian to public payments from sources like Medicare, Medicaid, and insurance programs. Some of the new groups of health providers are independent practice organizations (IPAs) in which physicians are separate providers but relate to a central management group; preferred provider organizations (PPOs) where physicians retain independence but engage in contractual services; and health maintenance organizations (HMOs) in which physicians and other professionals may be contractual employees of a public or private entrepreneurial organization, rather than independent professionals.

Free-standing medical centers provide initial care for relatively minor illnesses or prompt referral of more serious conditions, sometimes known as "urgicenters," have arisen to care for persons who have no regular medical attendant or whose physicians are not immediately available. Free-standing non-governmental medical clinics are often located at vacation resorts or in busy shopping malls and are part of a community's medical resources. These are also known as walk-in clinics or colloquially as "doc in a box" services of various complexity and usually meant to suffice only for short-term care.

Mergers of smaller health care groups create progressively larger corporations which control wide-ranging delivery sites with well-equipped outpatient clinics for initial care and specialty consultations of medical and surgical illnesses, ambulatory surgical centers for one-day surgery, as well as more complex invasive and diagnostic procedures, similar to those provided in hospitals. Pharmacies and laboratories and rehabilitation centers may be part of major health care groups. Special medical units have been created to provide general care services for entire families at university medical centers with their own professional schools, or by major hospital groups or industries whose employees might otherwise lack quality medical care.

Urban and rural US communities have always had cadres of health care providers or "healers" who were considered by traditional licensed physician groups as being less well trained and to whom medical licensure was denied. Some of these care givers in remote or isolated communities were folk medicine healers who had received instruction from older practitioners or even been self-taught. These indigenous healers and a large number of other allied health care providers have been roughly designated as complementary or alternative health care.

Complementary and alternative are general terms applied loosely to more than a hundred or so unrelated healing methods whose adherents believe each is effective. Complementary health care refers to those skills or systems that will support customary medical or surgical care directed by a licensed physician. Acupuncture is a complementary system, an insertion of needles in parts of the body in accord with a complex system to relieve pain or cure ailments.[4] The practice of chiropractic, also, is increasingly accepted as complementary to physician directed care. In contrast, alternative health care is a term to denote a therapy or system that is meant to supplant regular medical care of a physician. Iridology, the diagnosis of human disorders by examining the ocular iris, and naturopathy are two of many alternative care systems.

Homeopathy and chiropractic practitioners, for example, are recognized as healers to be licensed by their own boards in many states, thus subjecting them to a degree of oversight and legal responsibility. Several popular journals now exist in which the various supportive health care modalities are featured. Meanwhile, any of the other alternative care practitioners may be found in local jurisdictions with little or no official supervision or control, unless medical licensure laws are violated or use of a specific method causes harm to a subject under care.[5] Quiet controversy or open disagreement exists about the value of any one system in these two fields, but a federal office has been created in the Department of Health and Human Services (DHHS) to study and evaluate efficacy and safety in complementary or alternative health care practice.

One school of fully qualified healers, the osteopathic physicians, were once considered as having a discipline that was distinctly different from allopathic physicians. Today, osteopathic physicians graduate from osteopathic medical schools that have full governmental certification and provide training of equivalent quality to other U.S. medical schools. Osteopathic physicians are licensed in all states and osteopathic specialty certifications are acceptable for full practice privileges and positions on hospital medical staffs.

Modern socialized health care that began in Germany in 1876 has spread in one form or another to almost all of the world's developed nations, notably excepting the United States of America. Socialized health systems have varied from care that is nearly totally government controlled to that which is delivered by independent practitioners whose patients have freedom to select their caregivers. Payment systems also differ, with mixtures of public pay from government directed services to private pay for personal services to individuals.

In the U.S., mixtures of private or public insured care and public entitled care exists. Health care insurance is available to many workers as part of their employment obtained through union efforts or purchased by employers. Federal Medicare is available to persons over 65 years of age and those who receive Social Service disability payments. Public entitlements include military personnel, certain categories of persons in need, such as pregnant mothers, children, prisoners, and Medicaid for persons receiving governmental subsistence aid.

Federal grants were given to medical schools during WW I to speed the training of medical students and produce the physicians needed by an expanding military establishment. Funding for medical education and research increased regularly during World War II and continued to escalate after hostilities ceased. Medical school enrollments grew and new schools were opened to accommodate the soldiers who were returning to seek new careers. Premedical courses were expanded to provide basic instruction to prepare medical school candidates, and hospital residency programs expanded rapidly to provide training after medical school in the burgeoning medical specialties.

Concurrently, efforts were under way to make sure that patients and entire communities that once suffered tragically from diseases like acute poliomyelitis and chronic tuberculosis would no longer be threatened by these scourges. Protective oral and injectable vaccines have nearly eliminated polio, and effective antituberculosis drugs have rendered sanitoria for very long-term care no longer necessary. The severe late effects of sexually transmitted diseases [STDs], like cardiac complications of syphilis and its severe central nervous system damage, or late complications of gonorrhea that resulted in sterility, pelvic abscesses, or purulent arthritis, are now forestalled by early treatment with antibiotics. Scarlet fever, child-bed fever or puerperal sepsis, rheumatic fever, and erysipelas, streptococcal infections are nearly medical rarities. However, drug-resistant forms of all common bacteria are viewed as major therapeutic dangers, and new diseases like those of the Ebola and Hanta viruses begin to challenge infectious disease specialists, leading to a surging interest in global infectious diseases.

Major advances occurred in basic health care technology and pharmaceutical products manufacturing but also in the engineering skills and sciences that produced computed tomography, magnetic resonance imaging, molecular biology, laparoscopic surgery, and rapid, convenient laboratory methods. A current view of these fields has been described by N.P. Alazraki.[6]

Medical divisions of all major universities and large private hospitals compete vigorously for federal funding for basic and advanced research in health sciences, and insurance reimbursements and private bequests or donations of money to enable the expansion of existing facilities and structures needed for new health technologies and the related technical staffs.

Much controversy exists over rising costs of medical care, specialized equipment, laboratory procedures, and growing numbers of professional personnel. Efforts to remedy the large U.S. medical care system and reduce expenditures met much opposition from organized caregivers and thwarted the efforts of the Clinton administration to carry out sweeping changes in the way that health care would be delivered. Perhaps paradoxically, much attention is now being given to curbing excessive or elaborate care through better organization, shorter hospital stays, living wills and durable powers of attorney that help patients to terminate useless care under predetermined conditions, and even a medical concept of "futility care" that attempts to deal with hopeless cases. Despite many condemnations of modern medical practice that has grown rich, the balance of curative efforts has been positive. Abel Wolman, the famed water and sanitation engineer, once summed up the progress that federal and other monies have supported by saying, "Money is the root of all … good!"

HEALTH AGENCIES

The health department of any political subdivision is the governmental unit that enforces the health code and the sanitary ordinances and regulations that follow. Its director is a governmental officer for health sworn to uphold the laws that relate to health and sanitation and to recommend new measures to counter any recognized dangers to the public's health. No other licensed physician group or hospital or voluntary health agency has this key legal authority to maintain health in a political jurisdiction. Each health department is responsible for guarding the health of its entire assigned geographic and political subdivision, a legal commitment to abate any health hazard that is as broad as the political units to which they belong. Contrasted to the border-to-border obligations of a health officer, the wall-to-wall scope of hospitals is limited to medical events within its buildings or in contractual obligations of outreach programs. Physicians and other healthcare providers are more or less limited in their concerns to person-to-person duties in the care of individual patients.

Official public health services provide some sickness care but are legally charged to assure that all citizens have safe and healthy environments in which to live and work. Health departments must respond to complaints from anyone within their jurisdiction, and their officers are expected to act promptly to abate health dangers. These agencies have a duty to intervene and a right to enter whenever a hazard exists that threatens the community's health. Although actual physical entry can legally be obtained only by permission or by warrant, health departments have long been considered to have a right to enter any dispute that involves community health. In this respect, official health departments are truly safety agencies equal to fire or police departments.

In addition to this unique legal status, the health officer is a member of the central staff or cabinet of the chief elected official and provides advice on health matters. The mayor, county executive, or governor can direct that health officer to begin appropriate corrective actions whenever the public health is endangered. To help in fulfilling statutory and directed functions, health departments have four essential community functions: Epidemiology, disease prevention, needed services, rescue and protection.

EPIDEMIOLOGY

The importance of epidemiology, or the knowledge of a disease that exists in a community, was clearly stated as early as 1879 in a Baltimore City health ordinance that began with this statement: "It shall be the duty of the Commissioner of Health, from time to time to make a circuit of observation to the several parts of the city and its environs" to detect dangers to health and promptly order their correction. This legal charge codified the duty of the health officer personally or through delegated agents to gather information about the healthiness of the community or its inhabitants. Often known as "shoe leather epidemiology," this direction is similar to a military axiom that tells commanders to "go to the sound of the guns," to go where troubles exists. Further, the Baltimore ordinance directed the health commissioner to take immediate steps to correct noxious conditions and to report to the mayor with advice on further actions needed to maintain a healthy city.

All of these steps are a part of epidemiology, or wisdom "among a people." Health departments collect information about communicable diseases, analyze reports of births and deaths, follow trends in accidental injuries and childhood development, and provide annual summaries of the health of a community. Possibly the earliest example of modern measurement of health statistics occurred in 1882 when vital records of Baltimore, MD, and Washington, DC, were analyzed by sensing punch cards. John Shaw Billings, who would later design the Johns Hopkins Hospital and the New York Public Library, asked an electrical engineer, Herman, Hollerith, to devise a means of electrically sensing and counting the holes in a series of punch cards that contained census information about the respective populations. This venture was successful and the information obtained is listed in the annual reports of the 1880 U.S. census for the two cities. Gathering health facts and analyzing them is such a distinctive health department function that a well-known national health officer once urged that they be named "Departments of Epidemiology" to emphasize this importance.[7]

The discipline of epidemiology determines and analyzes the distribution and dynamics, or changing characteristics, of diseases in human populations. Physical health in a community is measured inversely by the incidence of a disease or injury over time or its prevalence at any given moment or time period.[8] The lower the incidence or prevalence, the better the community's epidemiologic health. Health officers utilize epidemiology to determine where, how and why disease exists in their communities. Other measures of the impact of diseases on community health are found in statistics of morbidity and mortality, as well as a disease intensity in a neighborhood, where a disease is spreading, and any deaths as noted by gender, age, and race. Epidemiology is a basic tool for allocation of departmental protective and preventive resources and services.

Health departments gather and analyze data supplied in reports to central agencies received from physicians and health care workers who are required by law to so report on official forms each occurrence of certain human diseases, at least 52 of which must be reported to the U.S. Centers for Disease control. Reporting enables health officials to deploy public health workers and resources who can act to limit the spread of infection to susceptible inhabitants. A health officer can require that patients with certain communicable diseases can be isolated in a single household, or order a community-wide investigation of food poisoning or a measles outbreak in local schools that is preliminary to focused prevention. When spread of a disease can be minimized by vaccination, localized or mass specific inoculation programs are offered to all persons at risk, some of whom may also require specific antibiotic therapy as prophylactic against infection.

DISEASE PREVENTION

The first case of an infectious disease, the "index case," is the well-spring of epidemiology (Sartwell). Certain diseases spread rapidly in a community and cause severe economic loss if workers are incapacitated or children are disabled by severe complications. Infections like measles and rubella (German measles), are no longer accepted as unavoidable risks to children but have been markedly reduced by protective vaccines. Poliomyelitis has nearly been eliminated in the Americas and small pox has in fact been eliminated from the world by mass immunizations.[9] Epidemic cholera appeared in Peru in the last decade and spread through neighboring countries, and Lyme disease was identified several decades ago in New England; recent findings show that it also has a world-wide distribution. Diseases are spread easily by tourists and business people who return to homes by air, unwittingly carrying early infections of exotic diseases. These may include malaria, typhus, hemorrhagic dengue fever, and others, many of which require prompt public health attention to minimize or eliminate transmission to U.S. residents.

An initial report of a case of tuberculosis, for example, will require that all persons who have contacted the patient be skin tested (tuberculin test) several times for evidence of existing tuberculosis; those persons who test positive must be further examined to determine if active or progressive disease is present. Prophylactic treatment with isoniazid can be safely offered to persons with positive skin tests if they are under the age of 35 or 40 years, but full therapeutic courses of antibiotic drugs are recommended for those with clearly evident pulmonary or extra-pulmonary infection. Some strains of tuberculosis germs (mycobacteria) have arisen that are resistant to several of the four customary therapeutic drugs. The specific type of mycobacterium responsible for a patient's disease must be determined so that the initial drug regime will be effective from the beginning, not after months of partially effective therapy have elapsed and the infection has not been controlled. To prevent the spread of drug resistant mycobacteria, initial courses of multiple antituberculosis drugs are individually administered by nurses who see to it at each scheduled dosing that an infected patient ingests the total amount of drugs that have been prescribed. This mode of anti-tuberculosis therapy is "Directly Observed Treatment" (DOT) and, while costly in staff time, it has resulted in effective control of a dangerous disease. In many political jurisdictions, when a patient with tuberculosis is judged to be a public danger because of failure to cooperate in treatment and control of the spread of infection, public health officers can request courts to incarcerate that patient so that treatment can be carried out under close supervision to protect the public.

Reported tuberculosis has increased as a complication of the human immunodeficiency virus (HIV), the causative agent of the AIDS epidemic. Because of this, the Centers for Disease Control (CDC) in Atlanta have advised state and local health departments to tuberculin skin test all persons with HIV infection.[10] Conversely, persons with tuberculosis are urged to be tested for HIV, and the registries of patients with these two diseases should be matched at least annually.[11]

When many cases of enteric diseases are reported, either localized as endemics or widespread as epidemics, health departments mount intensive searches to determine the nature and source of infections. Control measures to prevent further spread can include mass vaccination, provision of safe food supplies and potable water, official quarantine or isolation of sick persons and their excreta, evacuation of critically ill persons for definitive therapy, and vigorous public information programs to help uninfected persons at risk take appropriate steps to avoid the disease.[12]

Infectious disease outbreaks can result in heavy loads of sick or injured persons that may overwhelm community resources and require help from allied governmental or voluntary health providers for the short term as in disasters or damage to water supplies, or over the long term to remedy the ill effects of continued poverty or devastation.

Rats and mice, the animals chiefly regarded as signs of environmental deterioration, easily find homes and food in the debris customarily associated with poverty housing. Rat urine spreads leptospirosis, an infection that results in jaundice and occasionally renal impairment or aseptic meningitis, but small children who must live in rat infested neighborhoods are also at risk of rat bites. Major control projects strive to teach communities to deny rats an access to food in accumulated garbage, and eliminate easy harborage in piles of casually discarded trash or poorly maintained, dilapidated residential structures. Rats have proved to be courageous adversaries and survive despite major attempts to eliminate them with poisons, traps, gases, high frequency sound, and education of human residents. Yet, the dangers from rat bites are intolerable and health departments continue to war on rat populations.

ENVIRONMENTAL HAZARDS

Huge plumes of dark smoke billowing from industrial stacks was once a sign of a community's prosperity, but no longer. Oil and electricity heat have replaced coal as fuels for residences, industry, locomotives, and ships. Municipalities have banned or severely curbed the operations of home and apartment incinerators, and those that remain must have stack scrubbers and other equipment to drastically reduce emissions of particulates into the atmosphere. Half a century ago, the dark, gray lungs of city dwellers that resulted from inhalation of coal dusts and other particulates were easily distinguished at autopsies from the pinkish gray ones of rural citizens. Funded by federal grants, states are now well equipped to measure gaseous atmospheric pollutants and gather the data needed to support limiting toxic gaseous emissions by motor vehicles and major industries, and human pulmonary health has markedly improved.

Control of hazardous materials (HAZMATs) may be divided between health and other agencies yet emphasize safe storage and transport to protect neighborhoods and safe usages for workers. Local fire departments and state fire marshals or departments of environment are charged with the responsibility for containing spills and subsequent decontamination. Fire officials, for example, at all times carry handbooks and catalogs of toxic substances in their vehicles, and have been trained in the appropriate responses to hazardous spills. Frequent reconnaissance inspections of known locations where hazardous materials are stored helps to insure safe management of toxic materials. Departments of public works, health, and police may also be called upon to assist in management of spills.

Official health agencies now participate as consultants for community health in air pollution management, or advisors on the health aspects of building construction when toxic substances are used incorrectly. When lines of authority are not clear, duplication of municipal or county services and conflicting regulations may result in failure to respond promptly to early warning signs of environmental hazards. Health officials may be called after a chemical spill has been abated to counsel communities about possible delayed hazardous effects on humans.

Health sanitarians and technical inspectors of other agencies investigate complaints made by workers, nearby residents, or the general public about unsafe workplace environments. Officials inspect sites where alleged infractions of regulations have occurred, interview complainants and workers, and take samples or measurements of gases, dusts, or other possible toxic agents. Corrections may be made on the scene, or the respective departments will initiate official regulatory actions or seek legal sanctions. Airborne particles of asbestos, silica, metallic dusts, chemical gases or fumes, and organic fibers can pose dangers to workers or the general public and must be promptly abated.

Once widely used in fireproofing, building construction, and insulation, asbestos, if inhaled, results in fibrosis or chronic scarring of lungs with moderate to severe respiratory disability. Late effects include cancer (mesothelioma) of the lining membranes of the pleura (chest) or the peritoneum (abdominal wall) and is uniformly fatal. Abatement of existing asbestos-containing material from limited building areas that do not involve major razing must be sealed off to prevent dusts from spreading to unaffected areas; workers engaged in asbestos removal must be carefully garbed in protective clothing and equipped with approved protective respiratory equipment. All asbestos demolition activities, and the debris containing asbestos must be handled with strict attention to federal and local laws and regulations.

Inhaled coal dusts result in coal miner pneumoconiosis or black lung disease, a disabling condition more often seen in mines producing anthracite or hard coal. Unprotected inhalations of dusts from the floors of factories that produce pottery or electrical insulators has resulted in silicosis, a severe pulmonary fibrosis that may be associated with recurrences of old pulmonary tuberculosis.

Control of known toxic volatile inhalants is also spread among several agencies at all governmental levels, occasionally with no clear delineation of regulatory boundaries or with control and enforcement distributed among several departments. Urged by insurance companies and pressured by legal actions to improve worker and community safety, industries strive to provide healthy workplace environments and still achieve satisfactory manufacturing profits.

Federal funding remains for lead paint poisoning prevention, rodent control in cities, water fluoridation, air pollution control, protection against hazardous materials, and staff education or training. The blood lead level that is considered to be toxic in children and adults continues to decrease, but the problems of plumbism (lead poisoning) associated with chipped and worn lead paint in homes persist. Although paints containing lead were banned in Baltimore city by an ordinance more than half a century ago, walls and woodwork of old homes retain lead paints under successive covers of new lead-free paint. Nevertheless, children continue to suffer from plumbism, albeit lower levels, because they inhale lead dusts in homes or eat lead paint chips that fall from old painted surfaces. Adults who are unaware of the toxic effects of lead paint dust may suffer from a more acute form of plumbism when they fail to wear protective masks of industrial-quality in de-leading homes.

To correct environmental hazards, officials benefit from epidemiologic data to locate where toxic wastes have been dumped and to measure the effects of toxic substances on community health. After chemically damaged land has been identified, reclamation or redevelopment as prime commercial and residential sites is often difficult without costly decontamination. States have established official registries of toxic substances that include listings of associated cancer cases. Toxic substance registries are valuable in the long run but high initial costs, operational difficulties, and challenges from local industries have hampered their development.

Air pollutants may merely annoy residents in a neighborhood because of unpleasant odors but, when residents suspect that pollution can be hazardous, high levels of general community anxiety can result. Persons who work or dwell in a polluted area cannot avoid breathing the air that may cause acute or chronic respiratory difficulties. When pollutants are known to have serious short-term or long-term effects, citizens or workers demand that regulatory action be taken to reduce or eliminate the offending pollutants. However, if threats of job losses occur should the cost of controls cause major industries to move away, low level pollution may be tolerated. Detection, accurate measurement and clearly defined pathologic effects of fumes and dusts on human and animal health have been recorded, as well as toxic damage to fabrics or delicate machinery and other personal or industrial equipment.

Air pollution from industrial processes or solvents used in manufacturing is closely monitored by most industries but small, non-union or inexperienced producers may be unaware that hazards exist in a workplace. In some cases, managers will ignore or defy governmental regulatory control. Health department inspection staffs may be too small to carry out regular inspections of the thousands of small industries in their jurisdictions and complaints from citizens or workers may be needed to give the earliest warnings of serious small-factory air pollutions. Health inspectors may be called upon to test and measure for toxicity of fumes in workplaces from chemical processes, spills or misuse of dangerous mixtures, or emanations from treated fabrics, compressed wood products, and other finished products. Local health departments, however, are no longer responsible for water supply, sewage treatment, and trash and garbage disposal.

The emphases of governmental air pollution control efforts range from entire geographic areas, such as area-wide ambient levels of industrial stack pollutants and motor vehicle emissions, to residences that may be contaminated with radon emissions from soils or rocks. Although state or federal governments are responsible for monitoring large area contaminations, toxic emissions control in local industries is often a community task.

Water pollution results when surface contaminants from industry spills or runoffs from soil fertilizers and pest control agents enter streams and reservoirs or filter into an area's aquifer and wells. Water filtration plants carefully monitor bacterial and chemical contaminants of inflows and outflows to assure that pleasantly tasting potable water and low mineral content is delivered to a community. This is a major task when a downstream community depends on river water to supply its needs while upstream another community dumps its sewerage and industrial wastes. Water potability and safety must meet national standards but water qualities for drinking, food preparation, and industrial uses may vary widely. Adequate water supplies are vital to community health, recreation and cleanliness, but also to industry and related employment. Carefully controlled use of low mineral content non-potable water can be used carefully for garden plots and residential lawns and general use in irrigation technologies for agriculture.

National dental societies have urged that minimum levels of fluoride be added to residential water supplies because of the protective action of this chemical against tooth decay. However, opposition has arisen in some communities because high fluoride levels may cause annoying dental discoloration. Effects of chlorination, also, has been reported to be remotely associated with malignant conditions in humans but the net value of better control of intestinal diseases is believed to far outweigh any possible small toxic effect of chlorinated water. Water with high mineral content, known as “hard water,” even though potable, may require water softening equipment in homes to make it satisfactory for laundry and food preparation or manufacturing.

Anti-smoking campaigns have emphasized documented tragic ill effects from tobacco smoke produced by burning tobacco products, both for the smoker and for persons who are breathing “second hand smoke,” a mixture of exhaled smokes and that which rises from the tips of lit cigarettes. Increased mortality from lung cancer, emphysema, and cardiovascular disease has been thoroughly documented and other cancers of the gastrointestinal and genitourinary tracts are believed to result in part from the swallowing of saliva that contains nicotine and other constituents of tobacco smoke, and the urinary excretion of tobacco-associated chemicals through those channels. Bans on indoor use of smoking tobacco have been promulgated by many local and state governments to protect non-smokers from immediate or long-term effects of noxious chemicals in tobacco smoke. Existing efforts to restrict the purchase of tobacco products to adults and prevent sales to adolescents have been increased. So-called smokeless tobacco (snuff) has been shown to cause precancerous lesions of oral structures and ultimately to lead to localized cancer, even in young adults.

Carbon monoxide (CO) emissions are highly toxic because the CO radical bonds tightly to hemoglobin in circulating blood cells, markedly reducing their oxygen-carrying capacity and resulting in serious impairment of cerebral or cardiovascular function and death. Poisonings have occurred from CO in motor vehicle exhausts in home garages or poorly maintained underground parking garages with deficient ventilation, in homes that use fossil fuels for heating when flues have been obstructed, and when unvented space heaters are used in small, closed spaces and room oxygen has been markedly diminished or exhausted. Poorly maintained mufflers or exhaust systems may leak CO into automobile or passenger compartments at any time, even when driving through traffic. Slow and quiet development of this highly toxic gas can result in unrecognized but fatal levels of CO in vacation cabins, recreational boating, and private airplanes.

Radon is a radioactive gaseous chemical element formed as a first product in the atomic disintegration of radium. Rather frequently encountered in homes of what is known as the “Reading Prong,” a geographic area around the city in Pennsylvania, radon levels vary from home to home. This radioactive gas may be an environmental hazard when high levels exist in confined human habitations that are surrounded by radioactive soils or rocks. Ambient atmospheric levels can usually be reduced to safe levels by adequate ventilation.

Additional disease prevention activities of community health departments include sanitary control of food production and distribution, large-scale childhood vaccination programs, strict quarantine or relative isolation of persons with infectious diseases, and animal control to minimize animal bites or rabies and other zoönoses (diseases spread by animals to humans). In Baltimore, for example, when animal control was transferred to the health department and the collection of all stray dogs was emphasized, reported animal bites of humans decreased from over 8000 to under 1500 in a period of four years. Feral animals are dangers to all humans, to each other, as well as their excreta being a major source of area insanitation. Increasingly, local laws provide improved community protection by requiring that animals be leashed and that owners collect and dispose of animal feces in a sanitary fashion.

NEEDED SERVICES

Governments, large and small, provide health care services in many bureaus other than the official health department, and often with little or no coordination. For example, a county may operate jail medical care, a personnel system for employees, fire fighters and police, school health programs, health units in a department of social service, care for indigent elderly, ambulance services, a public general hospital, and more. The totality of community health services operated by a government is generally poorly comprehended, frequently underestimated and understated.

Rescue and protection require health departments to work with police, fire and other rescue agencies where human health is endangered. When local sickness care units refuse to care for ill or injured persons, for whatever reasons, health departments are expected to supply medical care. Because treatment of homeless or abandoned indigent persons can be costly for diseases such as tuberculosis or complex conditions such as AIDS (acquired immunodeficiency syndrome), these tasks may fall to health departments when other health providers fail to meet their obligations or are overwhelmed by patient loads of epidemics.

Official health departments in cities and counties operate personal health clinics for special populations. Although these services vary with local needs, they have been categorized by one local health officer as traditionally treating “unwashed patients with dirty diseases, who live in hard to reach places and can’t pay.”[13] These groups of patients constitute indigent or needy citizens with ailments like tuberculosis, leprosy, sexually transmitted diseases, or AIDS.

Major health problems that confront community health departments include teen-age pregnancies and inadequate child health care, homicides that are highest among young males, substance abuse (drugs and alcohol) that lead to severe personal and community deterioration and high crime rates in any community, and AIDS with its costly and complex terminal care. The total number of cases since first reporting in 1981 of AIDS worldwide in 1995 was 436,000, with 295,493 deaths. In one state alone, namely Maryland, the total number of cases was 13,082 since 1981, with 7,507 deaths. This epidemic of a terrible new disease has been devastating. The disease is transmitted via body fluids, in heterosexual as well as homosexual contacts, by inadequately screened blood transfusions, and by the use of inadequately sterilized parenteral equipment such as shared needles in illicit drug use.

An office of the state medical examiner, often incorrectly identified as the coroner, is a public health agency that is closely allied with the judiciary. Directed by a physician who is a specialist in forensic pathology, this department operates a morgue to which is taken a person who has been found dead under suspicious circumstances or who died without medical attention. A medical examiner performs an autopsy to determine the cause of death, and may be called upon to testify to this fact in criminal cases. A medical examiner should have immediately available a complete forensic or criminal laboratory to examine human tissues, clothing stains, and body fluids that might relate to or explain a crime. The skills of these pathologists are often called upon to identify bodies from comparison of oral structures to dental records, or even by sending specimens or entire parts of a body to federal crime laboratories for analysis. Although often a grisly business, a prime function of medical examiners is to assure that justice is served and diverse community concerns are assuaged.

Public general hospitals (PGHs) are owned by the political subdivision and have major fiscal support from any of several governments. The PGH reports directly to the chief executive officer (CEO) of the respective jurisdiction or the hospital is supervised by an appointed or elected board. The future of this once important resource of a city or county medical system is in jeopardy, threatened by growth of voluntary, not-for-profit, and profit-making hospitals. Funding equivalent to that of private hospitals has not readily reached public city and county hospitals perhaps for many reasons. It may have been that inexperienced or inattentive elected officials, medically unskilled appointed governing boards, serious budgetary limitations or other critical but unmet needs have all been responsible for the decrease in public hospital care efforts. Whatever the reasons for poor support of these public hospitals that were often the major care centers for immediate and long-term care of needy citizens, many of them have closed and some have been sold to voluntary groups or medical schools. Some have simply been closed, leaving communities with inadequate sickness care.

Others remained in central city locations, inadequately funded, surrounded by blighted areas and required to serve large populations with major health problems. These hospitals are still unable to accomplish easily their missions of helping critically and chronically ill needy residents. Often located in population centers where per capita income and insurance payments are low, public general hospitals serve patients who, for whatever reasons can find no other medical resource. Their populations also present with severe illnesses, chronic conditions, and with multiple complications of various addictions, poverty lifestyles, and AIDS. Obsolescent or convoluted governmental policies set by local, state and federal statutes can hamper smooth operations of these municipal or county hospitals. Employment practices, budgeting, purchasing and plant maintenance may be insensitive to the needs of hospitals. Medical care demands rapid response by all persons involved if services must adapt to changing professional practices.

For better patient care, larger PGHs may be linked with nearby professional schools to help train graduate physicians, medical students and other health care workers. In this exchange, the teaching and research staffs of medical schools bring with them a bevy of talented professionals who supervise patient care and prepare physicians for a life of learning and service. It remains to be seen whether the fresher and better funded investor-owned and corporately managed HMOs and hospitals will find it possible before the end of the century to assume a sizable portion of the heavy load of poverty patients with complex problems, and still make the profits demanded by their stockholders.

Hospitals in the U.S. struggle to maintain fiscal stability in a health care system that is undergoing rapid change. Some may not easily or willingly accept indigent patients suffering from complex medical and social problems. Maryland and several other states in the USA, however, have enacted legal requirements to ease fiscal burdens of hospitals by mandating that private and public patient care costs be shared by all hospitals and all payers in an equitable fashion.

Fiscal support for any general hospital is derived in part from local taxes, federal grants for disease management, and private philanthropy for specified tasks. Considerable income is also generated by fees for service charged to and paid by Medicare (elderly persons), Medicaid (indigent patients), payments from Blue Cross and other insurance companies, and from direct self-payments.

Any community that operates a jail or prison faces a growing need to provide quality medical care to its prisoners. Penal systems, once condemned for their inattention to the medical needs of inmates, have instituted policies to expand services while shortening sick-call lines, improve staff and prisoner morale, and reduce risky transport of prisoners to hospitals for medical or surgical consultations. Large jail populations, also regarded as a class of "regulated communities," include inmates who suffer from drug abuse, alcoholism, mental illness and behavioral disorders. Some jails have created obstetrical and infant care facilities to serve female populations, or special care units for geriatric prisoners.

Designers of new jails must also consider special handling of two major illnesses among prisoners when health units are being planned—pulmonary tuberculosis and AIDS (acquired immunodeficiency syndrome). Patients with tuberculosis infections may ascribe a chronic cough to smoking, or be nearly free of symptoms yet spread the infection to other inmates via sputum droplets that contain live tuberculosis bacteria. The customary elements (volume, rate of change, direction, etc.) in ventilation and air flow in prison cells, hospital suites, recreation and dining areas, need careful attention to minimize the spread of tuberculosis and other respiratory infections from patients with unrecognized disease to other inmates. Health suites should provide for temporary isolation of tuberculosis patients in the early phase of therapy. Longer term isolation may be required rarely but can be needed if the disease is advanced. Moreover, some tuberculosis infections are being increasingly recognized as due to "multiple drug resistant" (MDR) bacilli and the usual anti-tuberculosis drug regimes are not effective. New and expensive drugs, carefully administered, are needed to achieve successful treatment of stubborn MDR infections.

Although AIDS is believed transmissible only through body fluids like blood or semen, isolation may be needed to provide special care for persons who are critically ill with AIDS. These patients are at high risk of severe illnesses from "opportunistic" infections due to organisms that opportunistically take advantage of AIDS patients whose resistance to infections is compromised. These organisms may be bacteria, viruses, or even fungi and other parasites that are normally part of a prison environment. Management of patients with advanced HIV disease can be difficult and requires that the health staff be aware of the continuing advances in therapy that may be available. Medical or administrative protective isolation may be needed to remove AIDS patients from cell blocks where they might be exposed to physical danger from other inmates.

Health services for governmental employees are similar to those of industry and vary in size and complexity with the jurisdiction served. Pre-employment examinations and on-the-job injury care follow customary standards, and worker's compensation claims are processed in accord with state or federal regulations. Medical advisory programs (MAPs) for employees whose on-the-job performances are thought to be due to emotional disorder or substance abuse helps guide affected workers to appropriate care and permit continued employment. If existing buildings are to be altered for use as employee health clinics to include a wide range of health services, special attention must be given to shielding staff workers from x-radiation. A surgical suite should be available for initial care and follow-up of injured workers, and adequate soundproofing provided for rooms where psychiatric counseling is to be delivered.

RESCUE AND PROTECTION

Ambulance services have become an important part of any medical care system, with marked expansion after the mid 1970s. Although turn-of-the century horse-drawn ambulances had long been replaced by hospital-based motor vehicles, only major cities provided this vital emergency transport. The city of Baltimore, for example, had provided a crude transport that used canvas litters in police patrol wagons (paddy wagons) until 1928. At that time several limousine-type ambulances were purchased to be based in and operated by the Fire Department. Fire fighters who volunteered for this duty received basic first aid training and were assigned permanently to this service for better patient care of citizens who could not afford a private ambulance. Commercial ambulance services, many being operated by funeral directors who used converted hearses and personnel with little or no training in patient care, were not supervised or licensed until federal funding was assured with the passage of Medicare in 1965. Local governments developed regulations to assure that patients being transported would have emergency care immediately available and that they would be secure. Regulations specified the training that should prepare ambulance attendants, as well as the medications and patient care equipment to be carried in ambulance vehicles.

Today, municipal or county ambulance services are usually based in fire departments, to take advantage of a communication network that is already in place. Fire houses provide ambulance bases that are open around the clock, staffed by fire fighters who are a uniformed and disciplined corps, and who have a tradition of rapid response to emergencies. Air ambulance services using helicopters are operated by state police departments, in the absence of functioning fire departments. Some local governments may contract with private ambulance companies to provide both emergency and routine medical transport, and hospitals may also be used both as bases and to provide quick and ready access to medical critical care specialists for urgent consultations.

An ambulance is a sick-room on wheels for urgent care. Whereas once these emergency vehicles and staff operated simply in a "scoop and run" format, providing rapid transit for critically ill or injured persons, today's ambulances have state-of-the-art design and equipment, and their crews have expert training in the provision of immediate and effective responses to life-threatening conditions. Communities have quickly recognized the value of highly trained attendants who can stabilize critically ill or injured persons prior to careful transport to hospital centers for definitive care. Radio two-way communications for voice and electronic equipment, like electrocardiographs, enable attendants to administer initial medical care beyond usual first aid, and provide hospitals with information that helps them have ready any special equipment or staff for prompt attention on arrival of the ambulance.

Ambulance attendants, or emergency medical technicians, ambulance (EMT-As), are the first-responders in any emergency transport system. To be designated an EMT-A, each applicant must undergo special training, pass a stringent examination, and be certified by an official body of the local or state jurisdiction before being permitted to care for patients with medically emergent conditions. Ambulances dedicated to critical emergency care are stocked with approved medications for use by EMT-As in the field. Technical equipment is readily available to reestablish damaged airways or stop dangerously irregular heart action by electrical defibrillation,[14] immobilize fractured bones, or provide intravenous fluids. All ambulance equipment and EMT-A training is approved by official boards of physicians and other health care professionals; it is used in accord with tested protocols and the support of hospital physicians via radio communication when needed.

Helicopter emergency transport of patients, first used by several municipal ambulance systems in the early 1960s, was proven of value in military use. Helicopters and emergency technicians provide rapid patient evacuation over difficult terrain or locations that wheeled vehicles can reach only with difficulty. Helicopters are dispatched from a central location and radio communication provides directions to the helicopter pilot and continuous medical consultation for the medical attendants. As in any other ambulance, expert patient care is provided both initially on the ground and then in the air en route to a designated hospital center, thus avoiding rough highway carries. Vital data for on-going patient care is supplied by electrocardiograms (ECGs) and other clinical information is transmitted directly to a base hospital trauma center where a skilled physician is in direct voice radio contact and guides the prompt resuscitation of patients. Additional electronic support for advanced mobile sick care, including image transmission and limited or special laboratory services can be expected to be developed in this decade.

Regional hospital-based trauma centers receive casualties according to protocols that have been developed by regional emergency medical service committees. Each is staffed and equipped to provide complete skilled care for critically injured or severely ill patients. Trauma centers are regulated by a state agency and based at hospitals after a careful selection process that considers need, existing transport networks, and available staffing. Each must agree to maintain superior medical and surgical staff capability, and be ready to receive patients with urgent medical problems or extensive injuries around the clock. Critical care support must be extended in hospitals allied with the trauma center to provide patients needed long-term care through expected periods of recovery and initial rehabilitation. A trauma center concept best fits hospitals that are closely allied with medical schools, and it relieves small community hospitals of legal and economic burdens of severe trauma. Trauma centers may also accept urgent transfers from efficient community hospitals when severe injuries have been stabilized sufficiently for transport.

A community hospital need not operate an emergency care department but, if it does, all persons seeking medical, surgical, or psychiatric help must be accepted. Each patient must receive prompt and appropriate treatment and disposition, even if continued care is accomplished elsewhere. Although residents of a community may view a nearby emergency department as a walk-in clinic for the management of minor ailments, each of these special departments must be fully equipped and adequately staffed for critical care conditions. Physicians should be qualified for advanced life support care (ALS) and the nurses for basic life support (BLS), as a minimum. Emergency physicians preferably are certified by an appropriate emergency specialty board. The high costs of hospital emergency care is offset by assured payments for a wide range of costly services to patients with full insurance coverage who are admitted.

COMPUTERS AND TELEMEDICINE

Computer storage and transmission of information in clinical practice has lagged behind industrial usage, largely due to the confidential nature of patient data. A relative inadequate computer literacy of older, experienced physicians who must learn to enter data according to prescribed formats may account for some continued reluctance in the acceptance of electronic clinical data systems. Despite more general availability of more compact personal computers and electronic bookkeeping systems now installed in the offices of most physicians and clinics, maintaining patient records in computerized systems has advanced slowly.

In 1991, the Institute of Medicine (IOM) released a report that urged adoption of a computer-based patient record as standard medical practice in the United States.[15] In 1995, Beverly Woodward discussed many aspects of computer use in medical care.[16] Attempts to design algorithms that replicate complex thought processes a trained physician uses to probe the history of a patient's illness or solve a clinical problem have not been uniformly commercially successful. Generation, storage, and easy retrieval of clinical records expose the data to improper use by persons who are not entitled to confidential information. Data that include treatment for AIDS or psychiatric illnesses, for example, are particularly sensitive because of their possible misuse by employers, insurance companies, or legal systems.

Computers have proven useful in hospitals to store and have readily available cumulative information that records hourly and daily patient care data and provides easy review of a patient's progress. But start-up costs are high and training of hospital staffs includes nursing personnel, administrators, and other care givers, such as visiting personal physicians and consultants. Lindberg and Humphreys of the National Library of Medicine (NLM) have discussed other uses for computers in medicine that are now being explored.[17]

Boards in each state that license physicians and national professional specialty societies regularly use computers to store data and track careers of individual physicians and other regulated health care professionals. State licensing boards that need to research a physician's application for medical licensure can access information in the National Practitioner Data Bank that briefly describes pertinent disciplinary experiences in any of the 50 states.[18] National specialty societies have computerized the credits earned in cumulative continuing medical education (CME), critical information that each member can access when applying for license or specialty certification renewals.

Telemedicine and related modem technology provide access through e-mail or the World Wide Web to specialists and the National Library of Medicine in Bethesda, MD for instant consultations, making it possible for distant and isolated communities quickly to obtain needed expert medical and surgical advice and guidance.

Telemedicine is the transmission of laboratory information, radiologic interpretations, and clinical information, including actual examination of patients, by audio-visual communication via fiber optic telephone line or satellite transmission between isolated areas and medical specialists in urban teaching hospitals. Begun in Scotland in the 1960s to provide medical consultations to explorer units in Antarctica, telemedicine is now established as a medical subspecialty with its own journals.[19] Telecare refers to the delivery of health care by means of telecommunications technology, and is relevant to community care.

An early example of telemedicine in the United States was a cable linkage that provided one-way transmission of black-and-white video and two-way audio between a medical facility at Logan Field, the major airport of Boston, MA, and physicians several miles away at the Massachusetts General Hospital. Patients could be interviewed and even their urines and simple blood stains examined microscopically through this electronic hook up. More complex equipment and communication alternatives helped to increase use of telemedicine in the U.S., and $85 million in federal funds was made available in 1995 for this field. Several states established telemedicine networks to link hospitals and clinics with correctional facilities for more readily available medical consultations, and to join universities for mutual support of medical student education.

Quick and accurate transfer of information between primary care physicians, the "gatekeepers" in health care nets, with tertiary care centers hundreds of miles away has resulted in telemedicine expansion especially in states with large rural populations or great distances between medical centers.[20] Telemedicine also enables the Cancer Treatment Center at the University of Kansas to follow-up patients undergoing medicinal treatment but who have returned home. When U.S. troops were deployed to Bosnia in 1996, telemedicine interchange between medical commands in field hospitals and their home bases in Landstuhl, Germany, and various military medical facilities in the U.S. was arranged through facilities at Fort Detrick, Maryland.

J.H. Sanders has described telemedicine services established in 1991 at the Medical College of Georgia to provide continuing medical education and consultations for rural practitioners, using a system described as "totally distance-insensitive." A digital communication link integrates modalities from twisted pair 56 k copper wire to cable, fiber, microwave, or to satellite in series or in parallel, Sanders notes.[21,22]

The efficacy of telemedicine in supervising continued care and patient education has been proven. Efforts are now underway to extend its value to medicine and personal health, including improved sensors that substitute for palpation of a tumor mass or body parts, electronic stethoscopes, cardiac ultrasound, and radiographs. Distant physicians can visualize the ocular retina and the tympanic membrane of the ear by scopes that have been adapted for telemedicine use.

Ethical and legal concerns also have arisen, given that telemedicine transmits patient data over publicly accessible lines to physicians in another state or country. Privacy and confidentiality are not yet fully protected, even though several varieties of patient consent forms have been used. Current requirements that physicians be licensed by the state or nation in which they practice must be modified to permit effective telemedicine examinations of patients in another state, as well as consultations between physicians similarly located in different jurisdiction, must be resolved.

DISASTER CARE

All health units are important when disasters such as floods, tornadoes, hurricanes, earthquakes, train derailments, major air crashes, or major acts of terrorism strike a community. Disasters of any size are accompanied by varying degrees of incoordination in rescue operations, and complicated by stress and fatigue of both trained and volunteer personnel who have responded to the emergency. Roads that are usually available for patient transport may be obstructed by fallen buildings, large trees, and other debris. Water supply, sewerage, communication, and power lines may have been damaged so that hospitals that respond to unusual casualty loads find that equipment may be inoperable, lighting inadequate, telephones out of order, and water supplies for cleansing or sterilization impaired.

Although many calamities are relatively small and localized, each community must prepare plans for rapid responses and quick resolutions. Relatively simple planning brings together the several agencies that will respond to disasters to discuss staffing and organization for recovery, define available resources, list locations of supplies and equipment, determine the availability of outside help in rescue work, clarify usable radio frequencies, and work out the multitude of other elements of a disaster plan. Ideally, representatives of community physicians, hospital information officers, and many other health care workers, even morgue attendants, should be brought into disaster drills to share information with fire and police units. As a plan develops, each department or agency should become familiar with the others' capabilities because in the throes of an emergency it may not be possible to refer to a written plan, page by page. "Planning is everything, the plan is nothing," General Dwight Eisenhower is reported to have said. In regional disaster planning, Eisenhower's dictum applies.

First responder agencies strive to develop a radio communication network with compatible radio frequencies that will link rescue units whose usual work does not require regular exchange of on-the-scene communications. Rescuers must learn to know where community supply depots and equipment pools are located, who owns or manages the materiel, plus knowledge of what is available in civilian depots. Responsibilities for establishing refugee centers with food and shelter, and locations of emergency medical sites should be defined. Repeated drills prepare a community's disaster workers for their duties in response to a disaster, and are the key to rescue and rapid resolution of disorder.

Training of health and allied workers begins with standard courses prepared for firefighters and police officers who, along with public works personnel, are often known as "first responders." Training is available from state agencies and the U.S. Federal Emergency Management Administration (FEMA), based at Emmitsburg, Maryland, who provide control and coordination of disaster relief efforts. Analysis of responses to previous disasters is also a major effort of governments in all of the Americas where an international networking exists to share information and prepare or a wide range of mutual support efforts by communities in emergencies. Easily accessible first aid stations provide initial care for injured and ailing persons and transfer critically ill persons to hospitals via designated medical transport. When catastrophes occur in limited areas, well-defined routes into and out of the disaster area must be defined for ambulances that are to be used to evacuate patients. Dispatchers should maintain accurate lists of patients and their destinations to provide timely information to communities of relatives and friends. Supplies of special protective clothing and personal equipment that support workers in the rescue operations must also be in the planning calculus. Schultz, Koenig, and Noji have described a modified simple triage and rapid treatment system aimed at reducing immediate mortality after earthquake.[23]

Hospitals may not be able to use telephone lines in some areas, for example, and should become part of the radio net for disasters. If hospitals are liable to be damaged by earthquakes, floods, or major neighborhood fires, all staff persons should be trained in rapid and safe patient evacuation techniques. When even modest numbers of casualties are expected, hospitals must prepare to receive worried relatives and curious friends as well as patients. Hospitals should be assured of effective highway traffic control for ambulances in addition to their own internal management of patient flow and necessary restriction of visitors. Administrators plan to meet needs of hospital personnel who may have difficulty in reaching the hospital, and may have to be housed and fed until the emergency has subsided.

Continued supplies of medications and surgical material, food, and laundry are additional concerns of municipal departments that support the hospital community. During early recovery and mop up periods, community health planners should anticipate that a disturbed environment may be a seed-bed for enteric diseases due to several bacteria, such as salmonella or staphylococci, and other pathogens that contaminate damaged water supplies and foodstuffs that lack refrigeration or safe storage. Increased numbers of respiratory diseases can be expected among the very young and old survivors, as well as exacerbated severity of many existing chronic diseases that require a continuous supply of remedies, like diabetes, heart or kidney disease, and seizure disorders.

A natural disaster or major industrial calamity often calls out the best in a community and may reveal unsuspected leadership strengths. Nonetheless, each jurisdiction should be prepared by careful community planning to meet the abrupt challenges of a flood, tornado, earthquake, building collapse, explosion, or fire.

CONCLUSIONS

Community health care is more than what is provided by an official public health department. It includes manifold basic structures and services that give a community an identity and allow it to serve the needs of its citizens. A catalog of core services would include both governmental and non-governmental agencies and range from police, fire, health and public works to housing, food supply and safety, sickness care, education, and entertainment—and more. A healthy community is a vital organization, continually growing by systematic or irregular alterations and adjustments to meet continuing challenges. Not all of its activities are planned by a central agency but each contributes to some degree to the general good. Whether hamlet or major city, a community must form friendly liaisons with its neighbors and eschew bitter relations if they are to prosper as a region. Councils of governments can bring together the elected officials of adjoining subdivisions conjointly to solve selected administrative problems such as fire and police protection along borders, trash disposal, recreation and entertainment, and public health. To keep a community in good health, the chief executive officer directs that each of its elements be alert to changes and any resultant needs to adjust, as well as continuing to be secure financially. A healthy community, like a healthy body, needs constant care even when it appears to be functioning almost automatically and with little direction.

COMPOSTING

INTRODUCTION

Composting is the biological decomposition of semi-dry organic waste by microorganisms under controlled conditions. During the process, a succession of microbial attacks by bacteria, fungi, and actinomycetes physically and chemically alters the character and structure of the organic material. The volume of the original material is reduced by 30 to 40% as the microorganisms convert the organic waste to nutrient-rich, nuisance-free soil-like humus resistant to further decomposition.

In nature, composting is a continually occurring, ubiquitous process. It is a soil-based, ecological system that recycles mineral plant nutrients in organic form[1] wherever residues of vegetation accumulate and whenever favorable environmental conditions (appropriate temperature and moisture) exist. In agriculture, composted green waste and manures have been applied to tilled soil to increase crop yield since land was first cultivated. While compost is still most widely used to improve soil fertility, its application also helps provide erosion control, restore wetlands and purify toxic sites through bioremediation.[2]

In the last half century, growth of the United States population and improvements in the country's standard of living, coupled with changing product consumption habits, has led to a massive solid waste stream. At present, nearly 2.25 tons of municipal solid waste (MSW) are generated per capita each year in the United States[3]—630 million tons per year for the country as a whole (figures cited do not include tonnage for industrial or agricultural wastes). Traditionally, this mountain of waste has been landfilled or incinerated; indeed, for the last forty years, efforts to produce a soil amendment or low grade fertilizer from composted MSW have been largely unsuccessful. Poor quality and higher than acceptable costs of the finished product have contributed to this failure.[4] Lack of public acceptance of composting as a valuable recycling method, nuisance problems and perceived but unfounded health concerns have also played a part in the closing of some composting facilities.

Over the course of the last 10 years, the study of the science and engineering of composting has intensified. The reconsideration of composting as an alternative disposal method is due, in part, to landfill shortages, rising transportation costs and tipping fees, and tougher federal and state regulations for siting and operating landfills and incinerators. This reconsideration has also been generated by significant improvements made in the design of facilities, equipment and process controls, and of equal importance, the wider dissemination and application of the mechanisms and best practices involved in successful composting. In communities throughout the country, large scale composting has begun to play a significant part in county and municipal integrated solid waste planning and management.

Renewed interest in composting began specifically with sewage sludge, expanded to yard wastes, and has now made inroads into the entire organic fraction of the municipal solid waste stream.[5] Yard waste composting, with a feedstock of leaves and yard/park debris mixed with animal manures, has become the most prevalent form of composting in the United States. Diverting yard waste from MSW reduces the waste stream—with seasonal fluctuations—on average, up to 30%. Several states now permit supermarket and/or restaurant organics to be included in yard waste composting.[6,7] As of 1992, 2,981 yard waste composting facilities and 12 source-separated (food, paper and other organics) composting facilities are in operation; as of 1993, 182 waste water sludge composting facilities are in operation; and as of 1994, 17 MSW composting facilities are in operation with 2 additional plants in the pilot stage and 3 facilities under construction.[8] While there are many biochemical, functional and operational similarities between various compost operations, this discussion will be limited to the fundamentals, the process mechanics and end products of MSW, source-separated and yard waste composting.

FUNDAMENTALS

Almost any solid waste with an organic component (e.g., vegetable matter, fats, leaves, grass-clipping, sawdust, wood chips, waste water sludges) can be composted by one of a variety of process modifications as long as an environment suitable for microbial growth on a particular feedstock is maintained. All composting regardless of the facility design or type of feedstock (substrate) share similar process and microbiological fundamentals. Figure 1 shows an overview of the composting process.

Substrate/Mixing and Blending

Composting begins with the substrate. Over the past decade, recycling and recovery requirements for municipal refuse have altered the composition of the waste being diverted to compost facilities. With much of the metal, plastic and glass

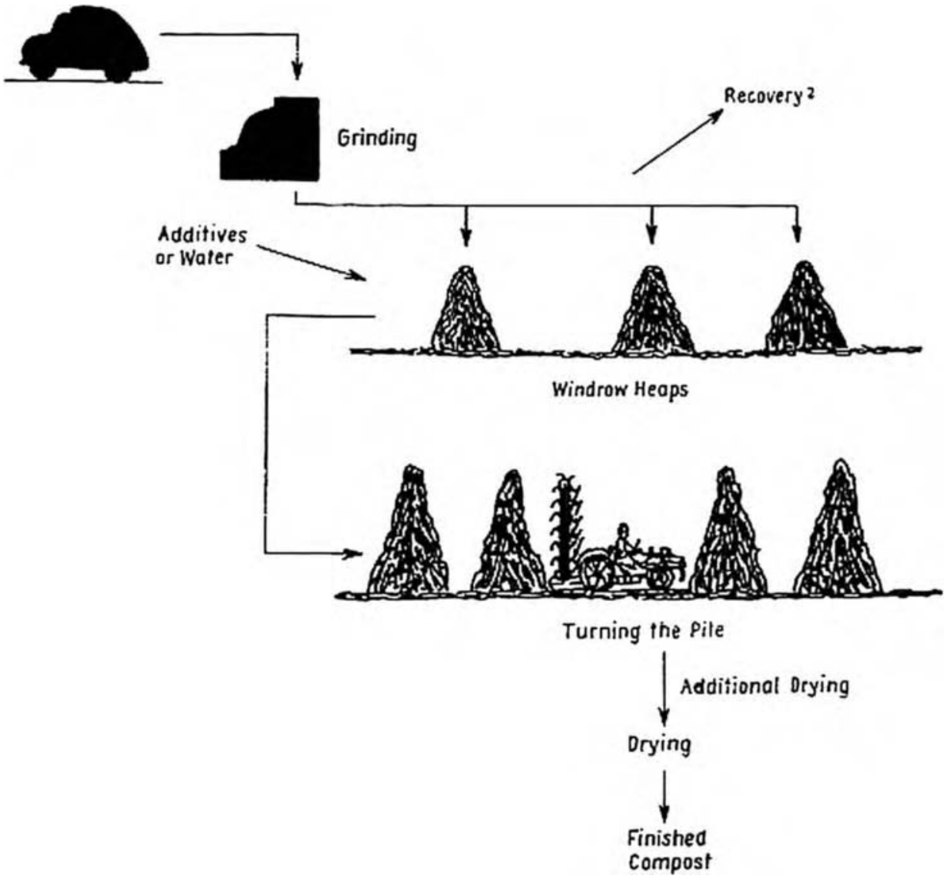

FIGURE 1 Batch composting using windrows.

now removed, the resulting source-separated organic waste (SSOW) is nutritionally richer, yet, because of increased consumption of paper products and packaging, it has a higher cellulosic content.

Most often, a number of different wastes are combined to achieve the nutrient balance necessary to sustain the microbial population. In general terms, the balance depends on nutritive waste fractions like food wastes, manures and waste water sludges (biosolids) combined with bulking agents like wood chips, leaves, bark, light paper and waxed cardboard. If necessary, adjustments are made to the substrate to achieve the proper balance of nutrients (e.g., adding ammonium or nitrate salts boosts nitrogen levels). Biosolids—because of their high moisture content (up to 98%), available nitrogen and an indigenous microbial population—are ideal for mixing (cocomposing) with MSW and SSOW. It must be noted, however, that potential problems characteristic of biosolids (e.g., the presence of pathogens, toxic metals and organics, and odor) must be recognized before beginning the co-composting process and producing an end product.

Preparation

Shredding, chopping or grinding reduces particle size and increases surface area, exposing more of the substrate to microbial attack. It also produces a uniform mass that facilitates mixing and aeration. Typically, the resulting particle size is smaller than one inch. Such preparation is not essential to all compost operations. For example, composting biosolids and leaves does not call for much preparation—equipment is needed only for mixing blending and moving the materials—while MSW and SSOW and yard wastes are routinely shredded. Optimal preparation of the feedstock includes front-end separation and recovery of ferrous metals, glass, plastic, textile and other recyclable materials (resource recovery and screening to remove recyclables and large objects may occur at any point in the process).

Environment and Supplements

In large scale composting operations, efficient decomposition and odor control are determined by the dependent relationship between moisture, oxygen, temperature and bulk density. The moisture content of the mixture is a key parameter in composting because the biochemical reactions that drive the compost process (providing nutrients that support microbial population growth) take place in the film of water enveloping each particle (hence the importance of particle size and surface area). Oxygen also plays a key role. It must be available in sufficient amounts to microorganisms throughout the composted feedstock in order to sustain the microbial attack under aerobic conditions. At least one investigator recommends 10–30 cubic feet of air per day per pound of volatile solids initial charge[9] while oxygen utilization was found to be 0.0244 parts of oxygen per minute per 100 parts of dry weight.[10]

Moisture content of a combined feedstock is determinant of the oxygen supply: If it's too dry, insufficient moisture exists for metabolism; if it's too moist, the pore spaces are filled with water, blocking oxygen from metabolic sites and causing the process to become anaerobic.[11] The optimal range for moisture content is 40–65% depending on the feedstock. Composting MSW and yard waste often requires the addition of water; it can be added at the beginning of the process (as noted, biosolids are an ideal source of moisture) and/or during biological stabilization. During this later stage, moisture content must be monitored on an on-going basis as particle size reduction from microbial and physical decomposition increases the density of the substrate.[12]

For metabolism and growth of microorganisms to occur in substrate, the macro-nutrients, carbon and nitrogen, should be present at an optimum ratio (C:N ratio, 30:1). Some municipal solid waste streams require the addition of nitrogen (in the form of ammonium sulfate, urea or protein) to bring the nutrient levels of the feedstock into balance (see Compost Microbiology).

The bulk density of a mixed feedstock is important in large scale windrow operations especially where food waste is a large fraction of the compost mix. A recent pilot study of grocery waste composting found that air-filled, macro pore space volume is the single most important component of the initial mix.[12] The more dense the mixture, the less oxygen, the more likely odor-producing anaerobic conditions will develop. The study concluded that ideal density is less than 900 pounds of SSOW per cubic yard.

The pH of composting material is another important parameter for microbial growth. While composting will occur with broad pH limits of 5 to 9, no one pH assures success. Rather, the pH changes during the process, reflecting the sequential decomposition of the substrate. Stated simply, at first, as carbohydrates present in the raw feedstock are degraded to organic acids and carbon dioxide, the pH drops; as the carbohydrate fraction is depleted, and the protein substrate falls to microbial attack, the pH, in turn, rises. The pH is seldom controlled during the process unless levels remain depressed due to low moisture content or other process upsets. In such situations, lime or caustic, carefully added, since buffers are characteristic of composting materials, is used to readjust the pH.

Biological Stabilization

The heart of the compost process is biological decomposition and stabilization of the substrate. Whether the feedstock is heaped into windrows (long haystack-shaped piles) or "digested" in-vessel (within an enclosed container or system), decomposition proceeds because of the metabolic activities of a diverse microbial flora. Compost stability (i.e., the point at which no further microbial attack will occur unless new feedstock is introduced) is measured by respirometric methods focusing on oxygen uptake, heat output and carbon dioxide evolution. These measurements give a good indication of microbial activity and odor potential.[13] Depending on facility operations and processes (see sections on Batch Composting and Continuous/Intermittent Composting) and the biological availability of the substrate, the time needed for stabilization (retention time) can be a matter of days, several weeks or several months.

Temperature is another critical parameter of the compost process. During decomposition, heat is generated by microbial metabolism. Due to the insulating capacity of the composted materials, the heat accumulates and temperatures rise rapidly to well above ambient. The temperature rise enhances the succession of microbial attack on the substrate; and the temperatures attained, typically 55–60°C, destroy weed seeds and fecal pathogens that may be present. Many reports have shown that 37°C to be within the optimal temperature range for activity of compost microorganisms,[13] while excessively high temperatures limit growth. Aerating the decomposing material by mechanized turning and mixing, forced aeration or some combination of the two methods moderates temperature and provides oxygen necessary for aerobic metabolism. Temperatures can rise more than once during the process: It is possible to induce a temperature cycle *de novo* if, for example, additional moisture is added to a substrate drying out too quickly, or if the materials are remixed and aerated thereby exposing new surfaces to microbial attack.

Eventually, the biological processes run their course; the temperature of the pile returns to ambient levels. In theory, as long as the moisture content is adequate, decomposition in a compost pile can go on indefinitely, or until no organic material remains. From an operational standpoint, however, when the temperature of the compost falls to about 2°C over ambient, the stabilization phase is complete. This final drop in temperature is probably the most reliable test for the compost's stability.

Biological availability refers to how readily a substrate can be used as food by microorganisms (i.e., how fast it degrades). When composting a municipal solid waste stream, the biological availability of the substrate will be as diverse as the incoming materials. Because of the variety of MSW and SSOW, it is difficult to estimate availability of even the most prevalent macro-nutrient, organic carbon; however, a first order approximation can be made on the basis of a BOD test (as used in testing waste waters). In general terms, decomposition proceeds sequentially with the most readily available substances: soluble carbohydrates, proteins and fats, attacked first. Polysaccharides, proteins and materials high in cellulose, hemi-cellulose and lignin (e.g. paper, cardboard, wood) only become available after a succession of microbial attacks breaks down compounds into their constituent units. Enzymes, synthesized by the microorganisms themselves, are the catalysts that enable these biochemical reactions to occur[14] (see section on Compost Microbiology).

It should be noted that decomposition can proceed in either aerobic (excess oxygen) or anaerobic (lack of oxygen) conditions. All large-scale facilities go to great lengths to maintain aerobic conditions throughout the composting process, for anaerobic conditions in decomposing organic matter can produce foul-smelling odors. A number of compost operations have failed solely because of nuisance problems with odors. Waste water sludge composting facilities often include a controlled anaerobic step in the processes, but further discussion of the anaerobic composting process is beyond the scope of this entry.

Compost Microbiology

The microorganisms that decompose MSW, SSOW and yard waste substrates are generally indigenous to the soil and refuse environment. Successful composting depends on a variety of organisms: bacteria, fungi, actinomycetes and to some extent, protozoa, attacking the substrate in successive waves of metabolic activity. In this succession, one group of organisms paves the way for a succeeding group with the metabolic end products produced by the first organism serving as starting nutrients for the second. It is thought that some microorganisms excrete small amounts of vitamins or amino acids that are essential for other's growth.[15] This cycle of microbial attack, characterized by a synergistic, nutritional and metabolic interaction between a variety of organisms, continues until the available organic material is virtually exhausted.

In the first wave, initiated by bacteria, the most available substrate (soluble carbohydrates, etc.) is consumed. The temperature of the composted material rises quickly, and bacteria and yeasts, multiplying at exponential rates, become the dominant population. At peak activity, they number as many as 10^8–10^9 per gram of compost. As decomposition continues and the pH rises, spore-forming fungi and actinomycetes, undergoing a succession of their own, become the predominant population. During each successive wave of metabolic activity, microorganisms synthesize and release specific enzymes, breaking down complex molecules through enzymatic reactions.[14] A variety of microbial species needs to be present in the composting mixture for complete "digestion" of the substrate as each group of microorganism produces only specific enzymes; i.e., it takes the combined metabolic activities of different types of organisms in the feedstock to produce finished compost.

The majority of microorganisms present in the compost environment are saprophytic (i.e., capable of living on dead organic matter), aerobic and facultatively anaerobic. Among the bacteria are aerobic, spore-forming rods, *Bacillus* spp., as well as *Achromobacter, Enterobacter, Pseudomonas* and *Xanthomona* spp., and numerous small gram-negative rods (coliforms, etc). Among the fungi are *Aspergillus, Fusarium, Penicillium, Rhizopus* and *Trichoderma.* Among the actinomycetes are *Steptomyces, Nocardia, Micromonospora* and *Streptosporangium.* These microorganisms exhibit optimal growth at different temperature ranges and, indeed, flourish at different times during the stabilization temperature cycle. They are mesophilic (thriving in 20°C to 45°C range) or thermophilic microorganisms (thriving in the 45°C to 70°C range). While mesophilic bacteria are more efficient than thermophilic groups for organic decomposition, thermophilic temperatures are necessary to kill pathogenic microorganisms and weed seeds. Operators strive to maintain temperatures in the decomposing material at an ideal range of 35°C to 55°C, enabling both types of microorganisms to flourish.

As noted, the most important microbial nutrients (macronutrients) are organic carbon and nitrogen. Available carbon is the major energy source for microorganisms, nitrogen is essential to microbial growth and reproduction. Phosphorous, and other minor nutrients (sulfur, iron, calcium) and trace elements (manganese, zinc, copper, cobalt, and molybdenum) are normally found in appropriate quantities in municipal refuse and are not usually determining factors. The optimum ratio of carbon to nitrogen is 30:1. However, this is an ideal ratio; the biological processes of composting will occur if the ratio is somewhat higher or lower. If the ratio of carbon to nitrogen is too great, reproduction and growth decline; and when nitrogen is unavailable, the compost process slows to a halt:[15] it is, in a sense, one of the limiting factors in composting. With a C:N ratio lower than 30:1 (e.g., organic grocery debris has an extremely high nitrogen content), the microorganisms eliminate unused nitrogen as ammonia, producing increased odors, reducing the available nitrogen content of the finished compost product and creating a potential health hazard.

While composting operations have occasionally added microbial "seed" to a composting unit, special inocula are not needed for composting. As mentioned above, the microorganisms responsible for decomposition are already present in the raw material: MSW, SSOW, yard wastes, waste water sludges, etc., and, in general, the microbial population most suited for substrate attack will develop on its own. On the other hand, seed recycle (i.e., adding microorganisms grown previously on the same substrate under the same environmental conditions) can help sustain continuous processes at peak activity, it can serve to shorten the retention time for batch processes (see sections on Continuous/Intermittent Composting and Batch Composting).

THE PROCESS

Two methods of large scale composting are in use in the United States: batch operations and continuous (or semi-continuous) operations. But methods require some degree of mechanization depending on facility siting, volume of incoming material, recovery operations and desired finished product. Community yard waste composting is a typical batch composting process; municipal solid waste composting is a typical continuous flow composting process. Three general steps are common to both operations: 1. Feedstock preparation, including particle size reduction and nutrient balancing; 2. Aeration and moisture content adjustment to maximize decomposition by microorganisms; 3. Curing and screening.

Batch Composting

In batch composting, solid waste materials are heaped into windrows. As noted, the feedstock is usually a combination of wastes chosen to provide the appropriate environment and ensure active decomposition within the windrow. Waste water sludges are often added to "seed" the pile with microorganisms (abundant in waste water sludges) and/or raise the moisture content of the mixture; water is often added to bring the moisture content up to optimum levels; and nutrients may be added, specifically nitrogen amendments, if it's necessary to balance the mixture's C:N ratio.

Periodically, the windrows are turned. In the first weeks after the feedstock has been windrowed, the piles are turned frequently (e.g., every fifth day), thereby aerating the interior sections of the pile. Adequate oxygen supply maintains aerobic conditions and ensures the microbial population reaches peak metabolic activity. After 1–2 months, the piles are turned less frequently. At some facilities, forced aeration helps keep the pile aerobic and speeds decomposition: Windrows are heaped on a composting pad constructed with a build-in ventilation system or, at more rudimentary facilities, simply piled over a ventilator pipe. Negative aeration pulls air down through the pile; positive aeration forces air up through the pile from below.

In batch operations, windrows are monitored for moisture content; long retention times are required to stabilize the feedstock. Kept in windrows for several months, the waste material undergoes a substantial change in character, becoming a dark, earthy, soil-like humus.

Continuous/Intermittent Composting

Continuous-flow or intermittently-fed composting processes (Figure 2) have been used as a method of processing MSW since the 1920s. Many European plants built since the 1950s are continuous flow operations. In the United States, a number of continuous-flow, in-vessel processes are currently

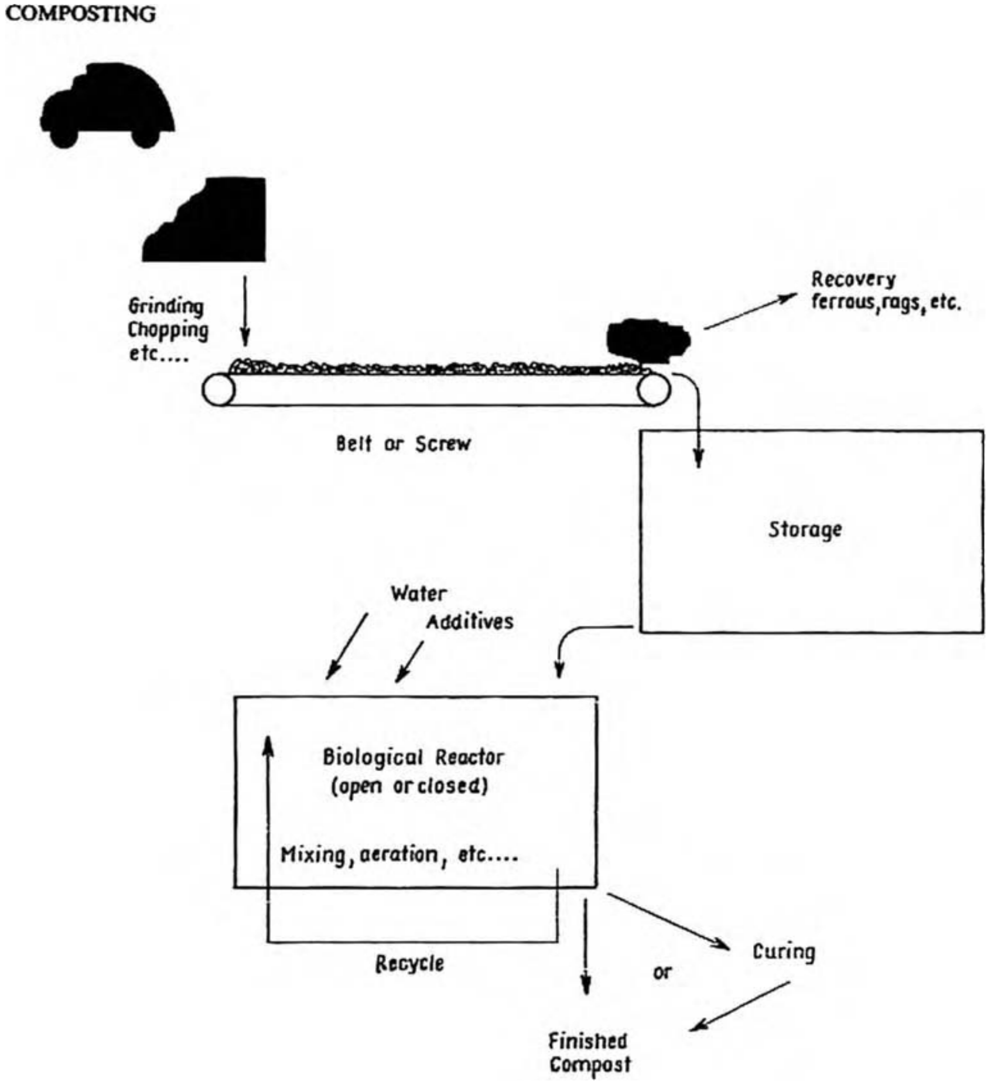

FIGURE 2 Continuous (or intermittently fed) compoting using biological reacter.

in use or under construction. The largest, a tunnel reactor in Baltimore, Maryland, has a throughput of 2,500 tons per week. Another facility, in Sevier County, Tennessee, using a continuous flow rotating tunnel digester, processes 1,100 tons of MSW per week; in St. Cloud, Minnesota, a digester with an agitated bed, processes 250 tons of MSW per week; in Easthampton, New York, a recently opened facility uses an in-vessel, agitated-bed digester to process 180 tons of source-separated and mixed MSW per week.[16,17]

Continuous flow operations have a number of common unit processes: feedstock preparation, storage, biochemical activation/stabilization and curing. After preparation (see Fundamentals: *Preparation,* above), the feedstock is transported to a storage vessel via mechanized conveyors; from there it is fed into the biological digester on a more or less continuous basis. The biochemical reactions that take place in-vessel are the same as those in batch operations (see Fundamentals): a succession of microorganisms attack the substrate, temperatures rise to 55–65°C, and the initial material undergoes chemical and physical transformation. At some facilities, the in-coming waste material is seeded with microorganisms from compost produced on site; in others, waste water sludges or animal manures provide the necessary microbial culture to maintain peak-activity within the digester. Nutritional supplements may also be added to accelerate the process or to supply a nutrient that can be used in the finished product.

The amount of time the feedstock remains in the digester depends on the design of the system and the incoming flow of the waste stream. For example, the Baltimore tunnel system (65' × 18' d.) "digests" material for 12–20 days; at the Sevier Country facility, the rotating digester (185' × 12' d.) stabilizes the MSW feedstock in 3 days; in Easthampton, the agitated-bed system (6' × 6' × 250' troughs) stabilizes waste materials in 21 days.[14] In continuous operations, the accelerated rates of microbial attack characteristic of in-vessel systems, require that moisture, temperature and oxygen be monitored carefully and maintained at as close to optimal levels as possible, and most process controls are now run by computer. It should also be noted that in the higher temperatures sustained in the digester, thermophilic microorganisms are the predominant population.

Curing and Final Processing

In continuous flow operations, biological stabilization is normally followed by some type of aerated curing. The curing lets the compost mature to a point where significant microbial activity has subsided. During this stage, phytotoxicity (characteristic of immature compost) disappears and available nitrogen (mostly nitrate-N) rises to higher levels. At the Baltimore facility, stabilized material is cured in static, negatively-aerated piles, while at the St. Cloud facility, stabilized material matures in mechanically turned, positively-aerated, 200' trenches; at the Easthampton plant, negatively aerated windrows are used.[17]

After a period of 1–3 months of curing, ambient temperatures are regained, and the finished compost is ready for application. Using a mechanized rotary drum screens, finished compost is screened to various particle sizes for use in agricultural, horticultural or landscape applications. While most field agricultural application does not require final processing, screening compost to a 3/4 inch size is common for landscaping; while a 1/4 inch screened compost product is more likely to be bagged and marketed at gardening centers. Generally, high in available nitrogen, low in ammonia and heavy metal concentrations, top-grade compost intended for use as a soil amendment, conditioner or fertilizer can be customized during the latter stages of the curing process to suit the users' needs. The parameters most commonly balanced for specific use are the NPK ratio (nitrogen, phosphorous, potassium) and soluble salt content (i.e., the conductivity of the finished product).

UTILIZATION

The recent growth of MSW composting facilities in the U.S. can be attributed to the necessity, in communities all over the country, to minimize the volume of waste being landfilled and incinerated. As composting takes a larger and larger bite out of the solid waste stream, and as a wider spectrum materials are composted, greater quantities of compost are being produced. To ensure product marketability and continued industry growth, solid waste managers and facility operators will now have to place greater emphasis on quality control, customer satisfaction and product utilization.[18,19] They will have to approach composting as a manufacturing process: The biodegradability of the incoming material must be well understood; systems and processes designed to maximize consistency and maturity; markets developed for a range of compost applications based on user's needs and product benefits (e.g., water conservation, fertilizer savings, increased yield/acre, stronger plants, pesticide savings, disease suppression[20] bioremediation of hazardous sites and land reclamation).

Quality

Currently, compost producers, Departments of Agriculture in a number of states and the Composting Council (a nonprofit industry association) are working together to develop compost quality standards and application (i.e., product use) guidelines. These standards will draw on the U.S. Environmental Protection Agency's Part 503 biosolids rule which established health, safety and environmental standards for composts from waste water sludges. When implemented these standards will enable operators to improve process design; they will provide end users with quantitative and qualitative data on specific parameters of a compost product and in general further awareness of the interrelationship of the composting process and the quality of the end product.[21] Quantitative standards will include: pH, soluble salt content, water holding capacity, bulk density, moisture content, organic matter content and particle size. Qualitative and unspecified standards will include concentrations of trace elements/heavy metals and compost stability (see Fundamentals: *Biological Stabilization*) and maturity.[19]

While compost maturity is a key parameter for end use applications, it is important to note that unlike other parameters, standard testing methods for stability and maturity do not yet exist.[19] Efforts by compost producers and scientists to devise a standard measurement for compost maturity are underway in a number of countries including the United States, Japan and Italy. Areas of consideration include a measure of the degree of humification via fractionation of organic carbon (i.e., the ratio between humified fractions—humic and fulvic acid—and total extractable carbon),[22] magnetic resonance scanning and kinetic modeling of the composting process.

Recent work on a kinetic model for commercial yard waste composting has enabled researchers, with some limitations, to better predict the biochemical behavior of different waste mixtures. With a further researched kinetic model in hand, producers will be able to adapt processes for a seasonally changing waste stream and design systems which reduce odor release, leachate production and other localized environmental problems. By optimizing the process, operators can produce a higher quality, more marketable finished product (e.g., a product that is more likely to function as a substitute for peat moss—a nonrenewable resource)[23,24] and, avoiding nuisance problems, gain greater public acceptance for the facility.

Application

Top quality composts from a variety of feedstocks are marketed to the agricultural, horticultural and landscaping industries as a soil amendments and low grade fertilizers for use in row crops, nursery stock, container plants, commercial sod production, tree farms, etc. Lesser quality composts (i.e., with some contamination by inerts or borderline heavy metal concentrations) are used for excavation and forest reclamation, hazardous waste bioremediation, DOT landscaping and landfill cover. Such composts are often products of co-composting facilities where an MSW waste stream is combined with biosolids (waste water sludges). It is widely known that in some MSW, as well as in biosolids from urban areas (i.e., where automotive contaminants enter waste water facilities through run-off into storm drains) heavy metal concentrations in the finished product will exceed unrestricted use criteria, limiting application to land reclamation and landfill cover.

Using compost to suppress soilborne plant diseases may be one of the most valuable, beneficial effects of compost application.[24] Agricultural scientists, plant pathologists and compost operators are currently field testing composts as biocontrol agents with specific applications in the nursery container plant and tree-farming industries.[25] Research over the past two decades has identified large numbers of microorganisms, isolated from mature composts, that induce suppression to soil-borne disease. There is now sufficient information available on compost's disease-suppressive properties that predictable, effective biological control can now be practiced. The mechanics of suppression, in the simplest terms, can be described as a competition between beneficial microbes and their disease-causing counterparts for the nutrients delivered to the soil by the plant's root system. In mature compost with a robust microbial population, the beneficial microbes dominate the nutrient source; biological control prevails; the disease is suppressed.[26,27]

Compost with its resident microorganisms is also useful for bioremediation of hazardous wastes (*in situ* as well as off-site). Recent tests and pilot programs have found that composts successfully degrade pesticide-contaminated soils[28] and crop residues; remediate oil field wastes (benzene, toluene, xylene) and petroleum sludges;[29] and detoxify other hydrocarbon pollutants such as PCBs and chlorinated aliphatic solvents. Composting hazardous wastes has distinct advantages to incineration: lower capital and operating costs, and it's safer in terms of impact on water, land and air resources. However, there are disadvantages as well: for instance, the preparatory work and precautionary measures (e.g., enclosing the site or facility) that might be required to compost a particular hazardous material can be economically prohibitive.[30]

Public Health Concerns/Environmental Impact

As composting gains wider acceptance, and becomes a part of more communities' integrated solid waste management plans, certain health and environmental issues have been raised and will continue to be raised by concerned facility neighbors and end users. The most common concerns are the fate of pathogenic organisms, bioaersol exposure, odors and cumulative loading of contaminants to soil groundwater. To ensure a continued role for composting in MSW disposal, producers are currently addressing, monitoring and managing these concerns more aggressively than ever before.

Questions often arise about the survival or reproduction of pathogenic organisms shown to be present in some MSW and waste water sludges: what happens to microorganisms such as *Salmonella,* enteric bacteria, flagellated and amebic protozoans and enteric viruses at a composting facility; can compost produced from the other pathogenic microorganisms do not compete well in enriched environments such as soil or waste water sludges, nor can they withstand for even short periods of time the elevated temperatures (140°F to 160°F) produced during the composting process. Under existing Federal regulations for handling sludges—and considering the temperature reached in composters for extended periods of time wastes can be safe for agricultural uses. In general, these from finished compost, is negligible. To meet EPA top quality, Class A criteria, compost must be maintained at 55°C (130+°F) for three days. This is referred to as PFRP (process to further reduce pathogens). The second EPA category, Class B, requires that compost be kept at 40°C for five days or 55°C for three hours. Class B is referred to as PSRP (process to significantly reduce pathogens).

Another public health concern often linked to compost facilities is aspergillosis, an infection of the lung caused by an invading fungus of the same genus name, mostly *Aspergillus fumigatus.* Although this organism is common in composting materials—its spores are small, buoyant bioaerosols—investigators have been unable to establish a causal relationship between compost operations and the disease.[31,32] With background levels of this ubiquitous fungus found in most households and backyards in the country, compost proponents state unswervingly that there has never been a case of *a. fumigatus* infection associated with composting facilities, either in workers or in the surrounding public.[33] By way of caution, however, it should be noted that any microorganism can become an invading opportunist given the right circumstances; and immunocompromised individuals, the elderly and workers with unprotected wounds should not risk exposure to microbial infection where microbiological processes are taking place.

Though the odors that can be generated during composting are more likely to be nuisance problems than health risks, offensive odors from poorly controlled compost operations have resulted in the closing of more facilities than any other health or environmental factor. The groups of odorous compounds that have been identified at composting facilities are reduced sulfur compounds, ammonia and amine compounds, fatty acids, terpenes, acetone, phenol and toluene.[34] The most common odors are for the most part the result of the formation, release and reactivity of hydrogen sulfide (i.e., a reduced sulfur compound), a natural end product of anaerobic decomposition. Hydrogen sulfide in itself is fairly malodorous, but in its reactions with available organic matter, a class of compounds are formed, called mercaptans or thioorganics, that are even more disagreeable. Typical mercaptans are dimethylsulfide (DMS) and dimethyldisulfide (DMDS). These compounds can then further combine with the natural odors of composting such as ammonia, or the alcohols, acids and aldehydes associated with fermentation, or with other vegetable-based hydrocarbons such as limonene to produce serious odor problems.

Odor control now plays a significant role in large and small composting operations alike. Aeration systems, discussed previously, are in use in many facilities, and the newer, enclosed facilities have odor control/treatment systems in place. The most common and effective treatment systems are multistage chemical scrubbers and biofilters. Both packed-tower adsorption and misting are operated in stages to allow different chemical reactions to remove different groups of compounds from the air stream. Gaining in popularity, biofilters are now used in over two dozen biosolids and MSW composting facilities in the U.S.[34] It should be noted that, in the near future, facilities' air treatment technology may have to have the capacity control VOC emissions. With the enactment of 1990 Clear Air Act Amendments, regulations are being developed to limit VOC emissions in nonattainment areas for the pollutant ozone, and such regulations would most likely have an impact on the operations of large scale MSW compost facilities.[34]

While virtually all land application of mature compost supports plant growth and improves soil properties, environmental concerns specific to compost use in field and horticultural crops have been raised by industry researchers and farmers. These concerns involve the cumulative loading of trace amounts of heavy metals to soils, the cumulative effect of nitrate leachate on ground water,[35] and to a lesser degree, the potential presence of lawn-care pesticide residues in finished yard waste compost.[36]

Despite the use of top quality compost and standard agricultural practices, trace amounts of heavy metals can accumulate in field soil if compost is applied at rates high enough to supply fertilizer requirements. After a 3–5 year period, the concentration of a specific metal in the soil could be toxic to certain agricultural or horticultural crops. It is interesting to note that some fruit tree farmers can repeatedly use compost with higher metal concentrations with benefits from the cumulative effect, for the longevity of some species of fruit trees depletes the surrounding soil of the necessary inorganic trace nutrients. Research into the concerns of nitrate-N contamination of ground water from compost amended field test plots indicates that after three consecutive years there is a cumulative effect in the soil. Because of the effect, it is suggested that lower rates should be applied in subsequent years to lessen nitrate leaching.[35] However, to date, there has been no indication of ground water contamination. Samples analyzed beneath several different test sites were in one case, well below 10 ppm drinking water standard, and in another case, showed no significant difference from ground water flowing under control plots.[37]

It is generally agreed that with rigorous monitoring, quality assurance and pH management to limit bio-availability, the use of compost containing low levels of trace minerals can be safely applied for an indefinite period of time without risk to agriculture or the environment. These concerns underscore the push for quality and utilization guidelines in the composting industry.

CONCLUSION

With the potential to divert millions of tons of MSW from landfills and incinerators and to provide beneficial end-products for horticultural and agricultural uses, composting is an obvious and natural method for recycling, reusing and conserving the organic fraction of the solid waste stream.

DESALINATION

INTRODUCTION

Our planet, the earth or gaia, is a water place. Water occupies 70% of the total earth's area, about 360×10^{12} m^2, and the total water volume that covers the earth's surface is about 1.40×10^{18} m^3. This makes the planet earth a very large water reservoir, nevertheless practically, these huge amounts of water are not directly usable, as 97% of this water is the seawater of the open seas and oceans and only 3% consist of fresh and brackish water, i.e., 0.042×10^{18} m^3. From these 3.0% fresh water reserves only a portion (0.014%) is in liquid form in rivers, lakes and wells directly available to us for immediate use, the rest can be found as glacier, icebergs and very deep water of geological reservoirs.

Fresh water, for all of historical times has been an uncontrollable happening of nature wherever and however found. In the Bible "good land" is described as one "of brooks of water, of fountains, and depths that spring out of valleys and hills," for water is a precious source of development and civilization, because water and civilization are two inseparable conceptions.

From antiquity up to our times, rivers, seas, oases, and oceans have attracted man to their shores. As a rule, towns and countries have grown along rivers. Egypt for example was considered as "the gift of the river." Egypt is a typical historical example of the influence of water to the birth and development of a civilization.

As a largely developed agricultural country, Egypt was able to master the river and had most of the time such an abundant harvest, that it became the main wheat-exporting country in the whole Mediterranean. The Egyptians learned to determine the seasons of the year by the behaviour of the river. Inundation, Emergence of the fields and Drought were their seasons. The first calendar was created in this way and out of this was derived the modern calendar.

Unfortunately, fresh water, and even seawater has not had our proper attention, respect and treatment. Due to the increase of population, especially in certain regions, and the increase of living standards, water demand increased exponentially, and wells or other fresh water sources run dry. The great population increase multiplies the total withdrawal. In some areas twice or more as much water is being drawn out of the ground as sank into it, thus the water table drops every year a few meters and water shortage increases dramatically, especially in dry years.

In modern large civic centers, opening of the tap provides us with as much fresh water as we are able to waste. The notion of lack of water is usually a matter we very seldom think of. However, at the same time there are places where water is so scarce that there are serious problems of existence, as is the case these days in many places in Africa. Generally it is not realized that fresh water represents only 3% of the total reserves in the world and that 75% of it is immobilized as ice. Modern agriculture also requires considerable amounts of good water to meet increasing food requirements. There is a tremendous requirement of water to run industrial plants, to produce all kinds of goods but also all kinds of polluting effluent.

The quantity of water used varies from location to location throughout the day and throughout the year, as many factors influence this variation. The more important factors include the economics of a community, its geographic location, and the nearby availability of the water source or the transportation distance from the source.

Climate is the most common cause of water lack or of water insufficiency. Sparse rainfall to feed streams, wells and the soil for agricultural production of crops exhausts water reserves. The most arid areas are the deserts, where no rain exists and some underground waters most of the time are salty or brackish. About 19% of the total land surface of the earth on all continents but Europe, is covered by deserts, which are surrounded by semi-arid lands where existing water is insufficient.

Coastal deserts, where the lack of water is as high as in the interior deserts, cover about 33,000 km^2 around the world, the greatest part of which is found in the Middle East, along the Persian Gulf, adjoining parts of the Arabian Sea and the Indian Ocean. The coastal deserts are divided into four main categories, according to their climatic conditions.

The tropical regions, where the temperature is about 30°C in summer and 22°C during winter. The subtropical regions, where in warm periods the temperature is about 30°C, and it ranges between 10 and 22°C in the cold months. The regions, as in the Mediterranean coasts, where during warm periods the temperatures are 22 to 33°C, and in cold months 10 to 22°C. The cool coastal deserts have in summer temperatures under 22°C and in winter time 10 to 22°C. The last desert regions are the cold places where summer is under 22°C and winter under 10°C. The largest single coastal desert of the third type, with the moderate climatic conditions, is that of the Mediterranean Sea and covers about 2650 km^2.[1]

Coastal deserts have an advantage over the interior deserts. They are climatically more pleasant, because they are cooler in summer and warmer in winter. Further, they have advantages over the interior deserts from the desalination point of view. Coastal deserts are surrounded by abundant sea water supply which is in the same level as the desalting installation, and thus the intake of water can be pumped with less power consumption than the deep well salty or brackish waters of the inland deserts. The brine disposal is also easy, without problems, as it is discharged directly into the sea, whereas the disposal of brine in inland deserts may create serious problems. Also, coastal deserts are in favour over the inland ones concurring the transportation of the equipment and all other necessary supplies for a desalination plant. Figure 1 shows a modern desalination plant in Saudi Arabia.

Some of the most attractive areas and beaches of the world are almost devoid of water. Not only is this living space, and space for resort hotels lost, but, in some cases, profitable resources cannot be exploited. Thus, known minerals on Egypt's Red Sea coast cannot be mined, and fishing industries on South America's Pacific coast, and other places around the world, cannot be expanded for lack of water. These present major losses in the world supplies of minerals and foods.

WATER DEMAND AND USAGE

The water cycle leaves about 9000 km^3 of water worldwide per year. This amount is enough to provide, with good quality water, about 20 billion people, but this water is far from evenly divided, with major shortages in some regions and abundant quantities in other places.

In a modern urban agglomeration, supply of water may satisfy domestic, municipal and industrial demand, as well as agricultural needs. There are no standards of general acceptance for the quality of water required by each group of users. Domestic demand includes all water consumed in housekeeping and gardening. A limit of 500 mg/L (ppm) for total dissolved solids with a maximum of 250 mg/L for chloride and sulphate ions, respectively, is recommended by the World Health Organization (WHO).[2] Nevertheless, there is a large number of communities, which are still consuming water containing up to 1000 mg/L total dissolved solids and sometimes more. Physiological changes may result from the intake of large amounts of the main ions, as well as of some trace elements.

Municipal requirements, beside the supply of water for domestic use, include all water needed by offices, public and commercial establishments, fire-fighting and irrigation of municipal parks. Although the standards for the latter uses are not strictly the same, as for drinking water, in practice all municipal water requirements are identical to drinking water since it is nearly always supplied by the same piping system.

A large variety of quality standards is involved in the use of industrial water, depending on its specific use. They may vary from high-quality drinking water for food processing to completely demineralized water for specific uses. Limitations of salt content may be imposed in some cases for process water. Boiler feed water needs special treatment to minimize salt content and eliminate dissolved gases. Cooling water also needs some treatment to meet the process requirements. River water and sea water can be used for cooling purposes and this is the usual practice in plants located on a river or near the seashore.

About 70% of water withdrawn from the earth goes for agriculture purposes and the balance, 30%, for various uses, as household and industrial process water. Overirrigation the last years, brought salinization of the nearby water resources, affecting the soil and crop quality, as salts are accumulating in the soil.

Irrigation water quality, which includes also drinking water for animals, depends to a large extent on the nature of the soil, the crops and the climate. The yield and quantity of some crops can be affected, not only by the total amount of dissolved solids, but also by the presence of certain specific salts. Thus if desalinated water is to be used in certain places the make-up of the product water will be necessary.

The water withdrawn per year and per capita, concerning industry and agriculture is increasing by 8.5%, the main increase in the developed countries. The USA consumes 2500 m^3 per year per capita, Switzerland 500 and Ghana, a very poor African country, only 40 m^3.[3]

Meanwhile, the majority of fresh water streams are severely polluted, decreasing the quality water reserves. Self decontamination is not feasible in many cases and, thus, treatment methods have to be applied to degrade at least some of the pollutants in the water. On the other hand, sea water exist in huge amounts, given free. Although also polluted to some extent, it is a future source of fresh water as desalination is the future process to produce this valuable good quality water.

SEA WATER

The seas and oceans are great sources of material available to mankind, though their destiny is very low to be exploited, but high enough to make the water salty, unsuitable for drinking or processing purposes. Not all the seas around the world have the same amount of total dissolved solids, the amount of which range from 20,000 to 50,000 ppm.

FIGURE 1 Panoramic view of the Al-Jubail Saudi Arabia, phase II, MSF desalination plant. It is up to now the World largest desalination installation totaling a capacity of 947,000 m^3/d (250 Mgd) fresh water production. Each unit has a capacity of 23,500 m^3/d (6.2 Mgd). The plant was built for the Saline Water Conversion Corporation, of Saudi Arabia by the Japanese Companies of Sasakura and Mitsubishi. (Courtesy Sasakura Engineering Co., Japan)

Table 1 gives the total dissolved salt of various oceans and closed seas. Over seventy elements have been detected in seawater, some in very small to trace amounts. Their proportion in all oceans, independent of their concentration, is almost stable.[4]

The four main metals—sodium, magnesium, calcium and potassium—and their combining ions, chlorides, including the other halogens and bicarbonates, are presented in amounts beyond comprehension. In Table 2 are given the major and the minor elements in seawater.

TABLE 1
Total Dissolved Solids in Various Seas

Ocean/Sea	g/kg	ppm	Ocean/Sea	g/kg	ppm
Baltic Sea	7.0	7,000	Pacific Ocean	33.6	33,600
Caspian Sea	13.5	13,500	Atlantic Ocean	36.0	33,600
Black Sea	20.0	20,000	Mediterranean Sea	39.0	39,000
White Sea	28.0	28,000	Red Sea	43.0	43,000
Northern Adriatic	29.0	29,000	Kara Bogar (Caspian)	164.0	164,000
			Dead Sea	270.0	270,000

TABLE 2
Ionic Composition of Main Elements in Seawater[6]

Ions		g/kg	Ions		g/kg
Chlorides	Cl^-	18.980	Copper	Cu	0.003×10^{-3}
Sodium	Na^+	10.560	Uranium	U	0.003×10^{-3}
Sulfates	SO_4^{2-}	2.560			
Magnesium	Mg^{2+}	1.270	Total TDS	—	34.482
Calcium	Ca^{2+}	0.400	Water	H_2O	965.518
Potassium	K^+	0.380			
Hydrogen				Seawater characteristics	
Carbonates	HCO_3	0.143	Salinity	g/kg	34,330
Bromides	Br^-	0.065	Chlorinity	g/kg	19,000
Boric acid	H_3BO_3	0.026	Chlorocity	g/kg	19,950
Strondium	Sr^{2+}	0.014	Specific weight	N/m^3	10,243
Fluorides	F	0.001			

Desalination eliminates the main elements from seawater, producing fresh water and concentrated brine, almost saturated in the main salts, which are withdrawn to the sea. There are two main reasons that these salts are not exploited. The brine volumes are huge and cannot be handled easily. The present extraction technology is expensive for the relatively cheap materials. Nevertheless, there is some industry exploiting, in part, the concentrated brine.

Today throughout the world more than 1,900,000 m^3/d (500 MUSGPO) of fresh water is produced by the various desalination processes.[5] Usually twice to 2½ as much seawater is processed, so that the solids concentration of the brine is doubled. It is estimated that the recovery from the withdrawn brine can be:

Magnesium	2,306.000 t/y	Bromine	116.100 t/y
Calcium	728.000 t/y	Copper	5.385 t/y
Potassium	659.000 t/y	Uranium	5.385 t/y
Sulfate	4,855.000 t/y	Gold	7.2 kg/y

Calcium and magnesium are the main elements that cause scale formation. Scales are formed and precipitate inside desalination equipment simultaneously with other suspended solids content in the feed water sea or brackish. These materials precipitate in areas favored for deposition. In distillation plants these are the heat exchangers and, in reverse osmosis, the semipermeable membranes, cause the problems. These deposits are categorised in two main types, the sludge which is soft and can be easily washed out, and the scale which is hard, adheres to heat transfer surfaces and can be removed only by plant shutdown.

Brackish waters are classified as waters with total dissolved solids content ranging from 3,000 ppm to 20,000 ppm. The elements vary widely, depending on the rocks and soil coming in contact with the water. In some brackish waters large amounts of calcium sulfate are present up to saturation conditions, making the water bitter and unsuitable for any use.

DESALINATION PROCESSES

When all other possibilities to use existing natural water resources are exhausted or to augment fresh water supply by conventional methods fail, then desalting of seawater, or brackish water and/or of polluted water reserves might give the answer to local water problems. The cost of desalting has been drastically reduced over the past several years. This is the result of the combined effort of scientists and engineers. However, it should not be forgotten that desalted water is an industrial product and its cost can never compete with the cost of natural fresh water supplies.

The largest desalination plant is Nature. The hydrological cycle on earth begins by desalination of surface waters. As the sun's energy evaporates the water from the oceans and the land surface waters, the vapors condense again on the earth's surface, as desalted water, stored as snow, ice or through the soil returns to the rivers and seas. This water is the vital liquid for all creatures on the earth.

The importance of water, as a matter of life, is quoted as far back as there are records in history. We read in the Old Testament: "Moses brought the sons of Israel from the Red Sea and they went into the desert of Shur. They marched three days in the wilderness and could not find water to drink. And when they arrived to Merra they could not drink the waters of Merra, for they were bitter. Therefore, he named this place 'bitterness.' And the people murmured against Moses, saying: What shall we drink? And Moses cried onto the Lord. And the Lord sweded a wood, which when he had cast into the waters, the waters were made sweet."[7] Nobody has guessed what kind of wood this could be, but is the first known in history, technical desalination.

The effort of a desalination process is to separate one of the most common, and most useful and yet most unusual material—the water from the one of the next common material, the salt. Hundreds of processes have been proposed, based on the various properties of water and its saline solutions. Nevertheless only a few of these methods have reached such an advanced state of technology to be considered as safe processes for the commercial conversion of saline waters into fresh. Distillation processes, reverse osmosis and electrodialysis or in some cases combination of two processes. The expectations, connected with freezing processes, could not be met with current freezing technology in large scale industrial application.

The required separation may be of water from salt, or of salt from water. Thus the desalination processes can be classified, according to the operation reference parameter as follow:

1: Methods that separate water from salts
  1.1: All distillation methods
  1.2: Reverse osmosis
  1.3: Crystallization (freezing and hydrates)

2: Methods that separate the salts from the water
  2.1: Electrodialysis
  2.2: Ion-exchange
  2.3: Piezodialysis
  2.4: Osmionic methods

3: Methods with phase change
  3.1: All distillation methods
  3.2: Crystallization

4: Methods without phase change
  4.1: Reverse osmosis
  4.2: Electrodialysis

From the energy point of view, the methods are classified as follow:

5: Methods using heat (thermal methods)
  5.1: All distillation methods except mechanical vapor compression

6: Methods using mechanical energy
  6.1: Mechanical vapor compression
  6.2: Reverse-osmosis

7: Methods using electrical energy
  7.1: Electrodialysis

8: Methods depending on chemical energy
  8.1: Ion-exchange

The methods which found practical applications in large scale industrial plants are:

Distillation methods: which comprise the following modifications:

1:	Multiple-Effect Evaporation	ME
2:	Multi-Stage-Flash Evaporation	MSF
3:	Vapor-Compression methods	VC
4:	Solar distillation method	SD

Distillation is the most developed process of removing water from a saline solution. It is applied up to very large capacities with various types of evaporators and accounts for about 59.4% of the total world plant capacity.[5]

The latent heat of changing phase is an important factor in the overall process economics, but the degree of salinity of the raw water is of no importance. Multistage flash distillation and multi-effect evaporation are reducing considerably the economic effect of the latent heat of vaporization.

Reverse osmosis uses mechanical energy, as pressure, to drive the water out of the solution through semipermeable membranes. The applied pressure must be higher than osmotic pressure, its value depending from the salt content of the brackish or seawater solution. The necessary counterpressure in reverse osmosis depends greatly upon the salt content of the raw water and imposes constraints on membrane life and performance, but also varying energy consumption according to the salinity of the raw water. Membrane life is an important cost factor.

Today reverse osmosis plants account, worldwide, for 32.6% for plants having a capacity 100 to 4000 m^3/d and 19.5% for capacities over 4000 m^3/d.

Electrodialysis is the most developed process for eliminating salts from aqueous solutions. The economics depend closely on the salt content of the raw water, as the consumption of electric energy is related to the total dissolved solids removed from the solution. Electrodialysis may, therefore, preferably be applied for the purification of brackish waters. Reversal electrodialysis is a modification, by which poles are reversing every 20′ and which assures the production of high-quality water and minimizes the rejection of brine.

Today electrodialysis accounts for 5.7% of plants with capacities 100 to 4000 m^3/d and 2.5% for capacities over 4000 m^3/d.

Freezing processes found no commercial application though the simplicity of the method. They failed because the size of produced ice was very small and half of the fresh water was used to wash out the salt from ice surface, rendering the method uneconomical.

Independently from the method or procedure for sea or brackish water desalination the operation of a desalination plant includes some general steps to be followed. Figure 2 gives the procedures before and after the main desalination step.

ENERGY SOURCES

Running a desalination plant many expenses arise, the highest of which is energy cost. In a normal chemical plant energy cost is low, only 1 to 5% and, in some extreme occasion, 10% of the total operation cost. On the contrary, desalination is a high energy consuming procedure and the cost of necessary minimum energy to run the plant is 40% of the total cost.

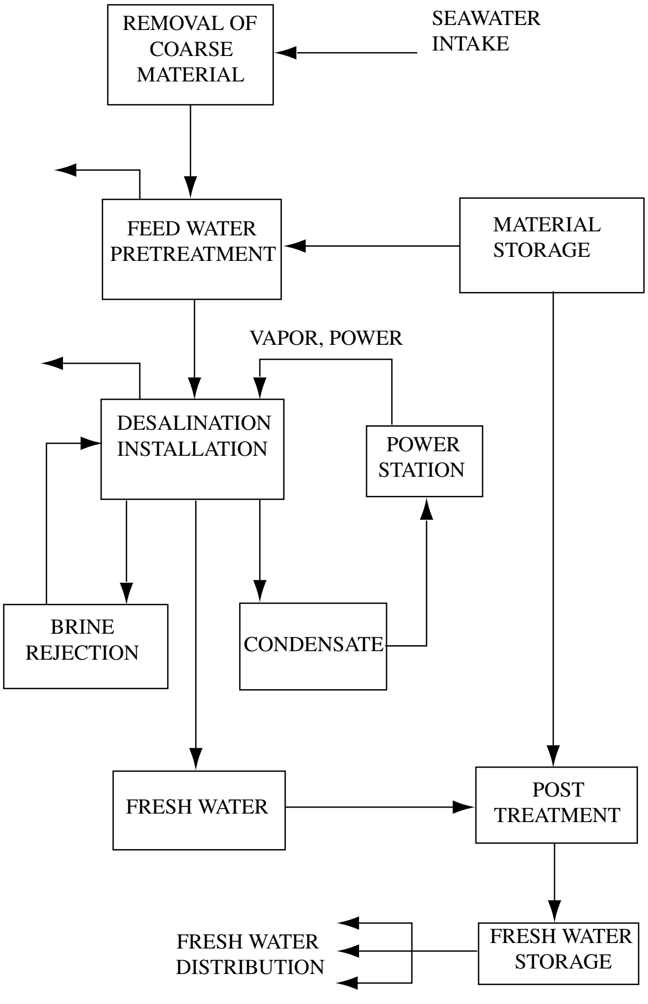

FIGURE 2 Flow diagram of the main procedures to be followed in the operation of a desalination plant.

The main energy sources, depending on the method, are low pressure stream and electricity, two energy sources easily available in any industrialized region. Few other energy sources are given at lower cost or free of charge. These alternative energies are suitable for small capacity plants and/or for remote and arid regions, where fuel and electricity are not available or the cost of fuel transportation renders its use uneconomic.

Alternative energy sources include geothermal energy when and where is available, all kinds of waste heat and waste heat from nuclear plants.

Renewable energy sources include wind energy, tidal energy, Ocean Thermal Energy Conversion (OTEC) and, above all, the abundant solar energy.

Waste heat is available from chemical industry, power plants and nuclear power plants in large amounts, but in low heat content. Wind and tidal energy are available in certain specified regions, transforming the corresponding energy into electricity. OTEC takes advantage of the temperature difference between the ocean surface and about the 500 m depth of the tropical regions. Solar energy is for the time being the most promising renewable energy. In the earth's sunny regions solar radiation is very intensive though also very spread out, thus the capture of solar energy depends on large areas.

Although solar, wind and tidal energy are natural forces given free, the corresponding equipment for transformation of these energies into a usuable form are yet very expensive and the yield very low.

DISTILLATION PROCESSES

Aristotle, the ancient Greek philosopher, wrote: "Salt water, when it turns into vapor, becomes sweet, and the vapor does not form salt water again when it condenses." Sailors have used simple evaporation apparatus to make drinking water for almost 400 years, and ocean going ships have traditionally used evaporators, often multiple-effect, as an accessory to steam boilers.

The simplest way to evaporate water is the natural one, using solar heat. Sun is a free inexhaustible source of energy. However, this energy has not been captured and stored at its most concentrated form as yet. The way to use solar energy for desalination purposes depends on the desalination process. The simplest and most common method is the direct use of the solar energy in specific equipment called "solar stills" which act simultaneously as converters of solar energy to heat and as distillers.[8]

Indirect use of solar energy, called "solar assisted" or "solar driven" desalination, captures the solar radiation using one of the modern procedures which transform the energy into either heat or electrical power. Horizontal tube, multiple-effect (HTME), multi-stage-flash (MSF) and thermal vapor compression (TVC) distillation methods are coupled to the heat source, though reverse osmosis (RO), electrodialysis (ED) and mechanical vapor compression (MVC) to the electrical power produced from the sun's radiation.[9]

As the incidence of solar radiation varies over the day, the time of the year, the degree of cloudy weather and the geographic location, conventional solar evaporation can never be a steady state operation. Moreover, convectional solar distillation is a single effect process and is characterized by the thermal disadvantages of single stage operation.

The intensity of solar radiation reaching the earth varies from zero to about 1047 W/m^2. Part of this radiation may come directly from the sun, but sometimes as much as 10% of it comes as scattered light, even when the atmosphere is unobstructed by clouds. In cloudy weather the total radiation is greatly reduced and most of the light that passes through may be scattered light.

The solar radiation striking a horizontal surface is greatest at noon, as the sun's rays pass through the atmosphere with a minimum length of passage through the air. In the morning and the afternoon the rays are subject to increased absorption and scattering. Considering the latitude, maximum radiation is at the equator. Hence the radiation intensity depends on the hour of the day, the day of the year, and the clarity of the atmosphere for a given location, as well as of the latitude of the earth at the point of observation. These limitations of the solar radiation render solar distillation method and solar driven desalination a nonsteady state operation except if solar energy storage is provided, which in general increases installation costs.

The daily production of conventional solar distillation is low, due to low performance of the stills. Depending on the intensity of solar radiation, the day of the month and the month of the year the fresh water production ranges from 1.5 to 5.51/m^{2}d (0.036 to 0.130 gal/ft^{2}d).[10]

Increasing feedwater temperature the daily productivity increases as well. This can be done by connecting a solar still with a solar collector or by using the condensate from low pressure steam. Many other methods have been proposed, to augment the efficiency of solar stills, nevertheless without any success due to increase of the corresponding costs.

To calculate the efficiency or the daily productivity of the solar stills have been proposed many mathematical models. Here two general equations are given: One concerns the operation of a conventional solar still and the second the productivity of a solar still connected to a solar collector.

The daily output of a stagnant solar still is given by the equation:[11]

$$M_{out} = F_1 H_d + F_2(T_{ad} - T_{wd}) + F_3 \tag{1}$$

and the daily output of a solar still connected to a solar collector is:[12]

$$M_{out} = F_p H_d + F(\overline{T}_{swd} - \overline{T}_{ad}) + F_2. \tag{2}$$

Both equations depend on construction and operational parameters.

Much material is required to construct a solar still: glass or plastic for the cover, black basin surface to absorb the solar radiation, material for the basin, usually concrete or plastic, pumps and piping—metal or preferably plastic, for the feed water and the fresh water distribution.[13,14,15]

Total cost of installation and operation of solar distillation plants is not very high if land is given free. They need large condensing areas and are vulnerable to storms. However, energy is free, except pumping, operation is simple, and maintenance cost very low.

Although the advantage of cost-free energy is partly offset by increased amortization cost and the large installation area, distillation with solar energy remains a favorable process for small-capacity water desalting at remote locations where there is considerable solar radiation. Most solar distillation plants are being (or will be) erected in less developed countries or in areas where there are limited maintenance facilities.

Solar energy for evaporation was first used on a major scale about 1872 in Chile, where a glass-roofed unit had 4,400 m^2 to make 22.4 m^3/d ($\sim$6000 gpd) in a mining camp.[16] Today many units, glass covered or plastic ones, are installed in small capacities world wide, mainly in arid and remote areas. Figure 3 is the photograph of a solar distillation plant, glass covered, yet in operation, in Porto Santo (Madeira) Portugal, with an installation area of 1200 m^2.[17]

It seems to be very simple as a method, and really it is, because theoretically solar energy can replace any other energy source. From a technical point of view this is not yet totally feasible because either the corresponding technology is not fully developed or the market is still very expensive.

Both procedures, solar distillation and solar driven desalination, depend on local insolation rates which vary from site to site for the same region, from the time of the day, the time of the year and the cloudy weather making desalination an unsteady state operation. Heat storage, if possible, improves productivity by extending operation during the nighttime or during cloudy days but also affects directly the economics of the method. However, for certain locations as remote, arid or semi-arid regions, where the small communities are poor and where the techniques and tools of water production and distribution developed in industrialized areas are not always appropriate to be used, solar desalination is admitted as the most suitable process.

The other way of using solar energy for desalination purposes is the collection of solar energy by solar collectors or concentrators, with subsequent conversion of the solar energy to heat or electricity. This solar assisted desalination is expanding rapidly and many installations have been erected in commercial but as yet small capacity sizes.

The simplest thermal conversion type of collector is a solar pond. A solar pond is a shallow body of water in which a stabilizing salinity gradient prevents thermal convection, thereby allowing the pond to act as a solar trap. The merit of solar ponds lies in their ability to collect solar energy in large scale and provide long-term heat storage. This long-term storage provides also increased flexibility of heat use. They can operate at all latitudes and are estimated to be less

FIGURE 3 Photograph of the Solar distillation plant in Porto Santo, Madeira, Portugal. It is the only solar plant in operation in Europe. Has a total evaporating area of 1,200 m^2, and consists from two different kinds of solar stills, of the assymetrical type. The Greek design developed at the T.U. of Athens and the design developed by the university of Berlin.

expensive than flat plate collectors per unit area installed and per unit of thermal energy delivered. Solar ponds, being low-grade heat source, can be competitive with convectional heat sources in many applications.

Flat-plate collectors, evacuated tube collectors and focussing collectors are used to produce hot water or steam as the heat medium for the distillation units. For reverse osmosis or electrodialysis units, photovoltaic devices are used or thermal conversion systems, e.g., central receivers, to drive the turbine generator.

A very important aspect of the solar assisted desalination process is the cost of energy and water produced. However, experience has shown that cost estimates are different everywhere. Labour, material cost, etc. depend on local circumstances, so the cost of water is not the same at all places.

Solar assisted desalination capacity is only a very small percentage, about 0.80%, of the total world capacity of convectional-fossil fuel fired desalination plants. A part, 0.60% is coupled to collectors or photovoltaic devices and 0.13% are wind-driven plants. The total capacity of worldwide solar-driven desalination plants is only about 15,250 m^3/d, and wind driven as low as 2,530 m^3/d.[5]

Figure 4 presents the first known sketch for solar distillation equipment.[18]

Distillation process, operated with conventional energy sources, i.e., low pressure steam, are applied up to very large capacities by using various types of evaporators and are classified accordingly as follow:

Multiple-effect evaporator (ME)

Vertical tube evaporators VTE, falling or climbing type
Horizontal tube evaporators HTE

Multi-stage-flash evaporator (MSF)

Vapor compression evaporator (VC)

Thermal vapor compression TVC
Vacuum vapor compression VVC
Mechanical vapor compression MVC

The term "evaporation" in the desalination refers especially to the vaporization of water from an aqueous saline solution, as brackish or seawater, where the solid constituents are practically nonvolatile, in the range of working

FIGURE 4 The first historically known solar distillation equipment, according to Giovanni Batista De La Porta. The sun evaporates the water inside the glass vessels and distilled water is collected beneath the vessels. "De distillations," Libri IX, Rome 1608.

temperatures and pressures. Thus, water alone is vaporized, which is the main product, and the dissolved solids remain in the residual liquid, the brine.

In the chemical industry, when an evaporation process is applied, the water vapors are usually discarded and the emphasis is given to the recuperation of the dissolved solids. In desalination the term "distillation" predominates over the correct term "evaporation." The process is performed in evaporators, where heat is supplied to the solution, to change phase.

The productivity is expressed either as the net evaporation or "gain output ratio" (GOR), i.e., the kilos of produced distilled water per kilo of boiler steam used, (kg/kg) or as performance ratio R. It is usually prefered, instead of the GOR, to use the term performance ratio which defines the mass of distillate produced per 2326 kJ (gal/1000 BTU) of heat input to the brine heater in case of MSF distillation or to the first effect in case of multiple-effect evaporators. The latter definition is thermodynamically more accurate, as it refers to the enthalpy of the steam instead to the mass.

Thermodynamic considerations lead to a common characteristic of all distillation process, that the percentage of evaporated water with respect to the circulating seawater is as much larger as is the difference between the maximum and minimum temperature of the saline solution. As the minimum temperature is defined by the temperature of the incoming seawater, enlarging of the temperature difference can only be obtained by increasing the initial maximum temperature of the salt water feed. Limitations due to the appearance of phenomena like scale formation and corrosion, which are becoming more important at higher temperatures, define an allowable maximum temperature for each distillation process. An appropriate pretreatment of the salt water is necessary to make an increase of the feed water temperature possible.

The economics of the distillation process might be affected by the following parameters:

- The chemical additives for feed water pretreatment
- Scale formation which decreases performance
- Increase of maintenance costs due to corrosion

Corrosion may increase fixed changes, when more expensive materials of construction must be used.

Multiple-Effect Distillation (ME)

Theoretically, in single-effect distillation 1 kg of distillate will be produced for every kg of steam consumed and the gain output ratio of the plant will be 1. In fact, despite preheating of the feed, a large part of the enthalpy of the vapors, evolved in the single-effect evaporator, is lost in the condenser. A better heat recuperation would be obtained if the heat, released by the condensing vapor, is not rejected in a condenser, but is used to heat the brine of a second evaporator and so on.

This leads to the concept of multiple-effect distillation, where the vapors from one effect are used as the heat source of the next effect, as long as the difference in temperature between the condensing vapor and the solution is high enough to act as the driving force in the evaporation process, each effect being at progressively lower temperature and pressure. Vapor condensing because of lower boiling temperature, in each effect, produces fresh water as distillate, whereas the vapor from the final effect is condensed by a circulating seawater cooling stream.

Theoretically, an additional kg of distillate would be obtained in each consecutive effect for the same kg of steam initially introduced into the first effect and the plant gain output ratio would be equal to the number of effects in operation. However, this is not true in practice. Part of the condensation heat to be recovered is lost to the atmosphere, in design features and in the differences of temperature used as the plant's driving force.

Multiple-effect distillation process uses evaporators which are modified successors of evaporators that have been used in sugar and other process industries for more than 100 years and have been in use for seawater distillation about 90 years. The latter were originally built for shipboard use, the main requirements being for compactness, simplicity in operation and reliability. In land based industrial evaporator plants the requirements are mainly directed to the cost of product water with emphasis on cheaper materials of construction, high boiling temperatures, efficient descaling methods and the use of the cheapest type of evaporator.

Previously multiple-effect distillation was second in importance of the distillation process, as medium capacity plants but day hardly is applied. Worldwide capacity of ME plants for units producing more than 100 m^3/d of fresh water, is only 765,143 m^3/day or 4.1% of total world capacity.[5]

Long Tube Vertical Evaporator, LTVE Long tube evaporators consist of a series of long tubes arranged vertically inside the evaporator shell. Seawater feed may be from the top or from the bottom, called respectively falling or rising film LTV evaporators.

In the falling film evaporator seawater is introduced at the top and the incoming seawater flows across an upper tube plate and is equally distributed to the tubes, and flows downward by gravity as a thin film. The principal advantage of the VTE process is that high heat-transfer can be achieved, which considerably reduces the required heat-transfer surface area. This forward feed is the usual method of feeding a multiple-effect-evaporator.

The VTE rising film is similar to falling film evaporator except that seawater is introduced at the bottom of the first effect, thus reducing the overall pumping requirements. Heat transfer in the VTE evaporators is increased by using fluted tubes, which enhance heat transfer.

Steam condenses outside the tubes, forming also a thin film of distillate. Surface tension forces are created, which are inversely proportional to the flute radius. This causes the condensate film to drain from the crests to the grooves, so that a very thin condensate layer is remaining on the crests, which promotes heat transfer.

The flow sheet of a typical multiple-effect vertical tube distillation plant is shown in Figure 5. In each effect is adapted a feed heater C which uses the product vapors as heating medium in the form of distilled water or vapor condensate. Vapors produced in the first effect condense outside the tubes of effect 2 and the brine is pumped from each effect to the top of the next. The average efficiency K of each effect is usually between 0.85 and 0.95. Concerning N effects in a LTE system, as in Figure 5, the GOR is given by the equation:

$$\mathrm{GOR} = K(1 - K)^N/(1 - K) \tag{3}$$

Thus when $K = 0.95$ and the number of effects N is 15, GOR = 10 kg/kg. Doubling the effects to 30, the GOR is only 14.9, and it will attain a maximum of 19.0 for an infinite number of effects, when $K = 0.95$.

There are some economic limitations increasing the number of effects. The investment costs and consequently the fixed charges are increasing almost linearly with the number of effects. The costs of steam and water fall off rapidly at first, but the savings diminish progressively. The total cost of operating an evaporator leads to an optimum number of effects, at the point where the sum of fixed costs and the cost of utilities shows a minimum. The most probable number of effects will be between 10 and 20.

The Multiple-Effect Horizontal-Tube Evaporator The (MEHT) type of evaporator operates on the same principle as the VTE evaporator, but the steam condenses on the inside of the horizontal tubes imparting its latent heat of condensation to the brine, which cascades and evaporates over the outside of the tubes. The brine falls to the next effect by gravity and the vapors formed in one effect are used in the next effect. The horizontal-tube evaporator eliminates the pumps required for each effect of the VTE brine circulation, by an arrangement in which the effects are stacked vertically on the top of each other. This compact arrangement of the ME evaporators, called also multiple-effect stack (MES), is constructed in low capacity units and though there are many advantages, it accounts for only 1% of the world capacity. In Figure 6 a typical HTE evaporator is presented.[19] Multiple-effect-horizontal-tube evaporators are suitable to operate with solar energy plants.

VAPOR COMPRESSION (VC)

Vapor compression (VC) distillation takes advantage of the latent heat of the vapors produced in the process. Vapor produced by evaporation from a salt solution is superheated because of the boiling point elevation of the solution and

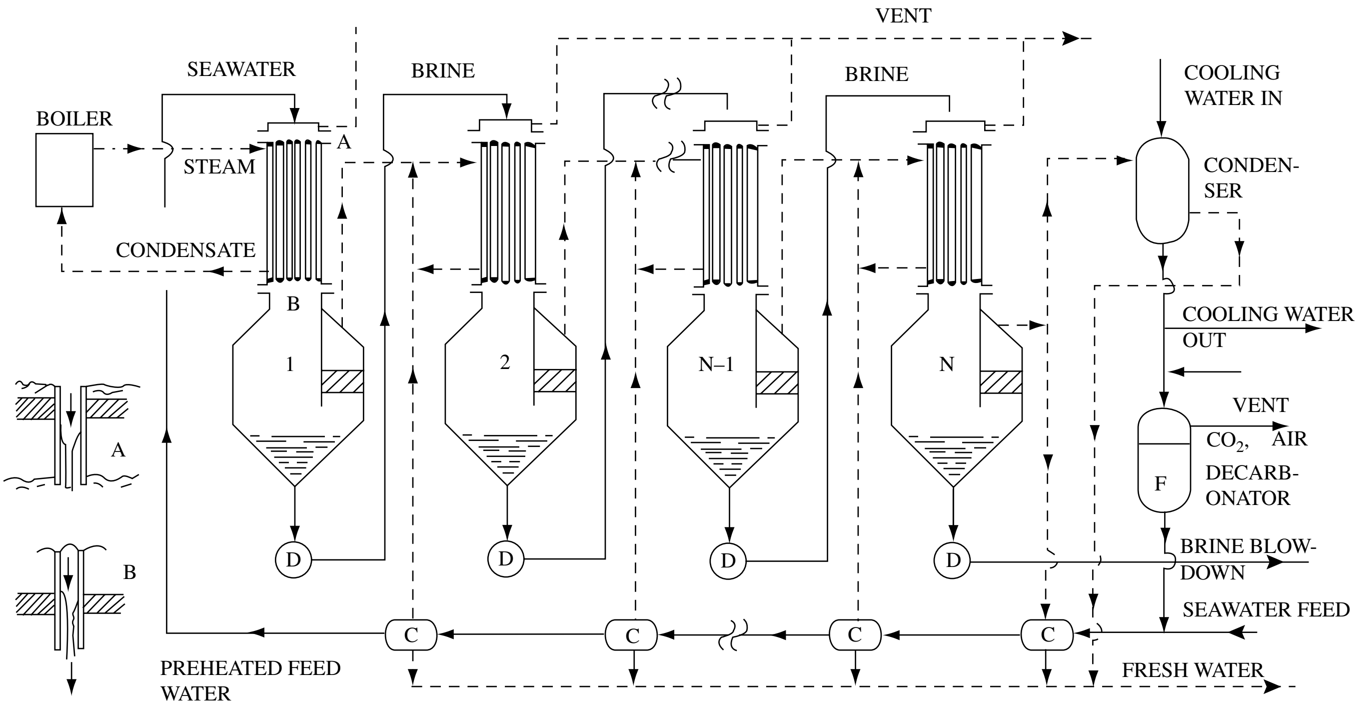

FIGURE 5 Flow diagram of a multiple-effect-evaporator for seawater desalination, of the falling type. Seawater is preheated in the heaters C and pumped on the top of the first evaporator No. 1, from where falls down inside the vertically oriented tubes B. A thin film of brine is formed inside (detail A and B). In the first effect steam from the boiler forms a thin film of condensate outside the tubes. In the following effects the vapors of each effect condenses outside the tubes of the next effect. The rest of the space of the evaporator is then filled with water vapors. The brine accumulates in the bottom of the evaporator from where is fed to the next effect by the pumps D. A distributor cap is fitted on each tube to ensure even distribution of the brine. The produced fresh water is used to preheat the seawater fed in the heaters C. Part of the seawater is acid treated and a decarbonator F, is used for the removal of air and CO_2.

has a lower pressure than the saturation pressure of pure water. It will, therefore, in losing the superheat, condense at a lower temperature than the boiling point of the solution. If this vapor is compressed to a higher pressure, the energy input results in a rise in temperature. With sufficient rise in pressure and temperature, the recompressed vapor might be used as a source of heat for evaporating the same salt solution.

Heat needs to be supplied to the system only at the start-up for elevating the temperature of the solution to the boiling point. Once boiling has started, it is maintained by the external supply of power and no more by the addition of heat as the cycle is repeated.

Vapor compression distillation accounts only 3.7% of total world wide desalination capacities and about 6.2% of distillation processes, for units producing 100 m^3/d or more fresh water. Daily productivity is 686,500 m^3/d.[5]

The energy source may be mechanical or electrical power to drive the compressors for mechanical vapor compression. Thermal vapor compression, or “thermocompression,” uses high pressure steam to compress the vapors to higher temperatures. Vacuum vapor compression uses electric or waste heat to reheat the vapors, circulating by the use of a blower.

Mechanical Vapor Compression (MVC) The MVC process uses compressors to reheat the vapors to higher temperatures. High or low pressure compressors are used, depending on the capacity of the system. As high capacity plants have many stages, the necessary temperature is higher and they are high pressure compressors. Low capacity plants use low pressure compressors. The higher the compression pressure, the smaller is the volume of the compressor and that of the vapor. Due to high temperatures, high capacity MVC plants are prone to scale formation.

Figure 7 presents the flow-sheet of a four-stage mechanical vapor compression evaporator and the T-S diagram of the thermodynamic operation.[20]

Thermocompression Thermocompression uses high pressure steam ejector to re-heat the vapors released from the last stage. Figure 8 gives a typical two stage thermal vapor compression diagram.

Another type of thermal vapor compression operates under vacuum inside the evaporation chamber. The low pressure vapors are circulated by a vapor blower and heated by electric heater, hot water or hot gas, according to the available heat source. A suitable adaptor for the various heat sources is necessary.

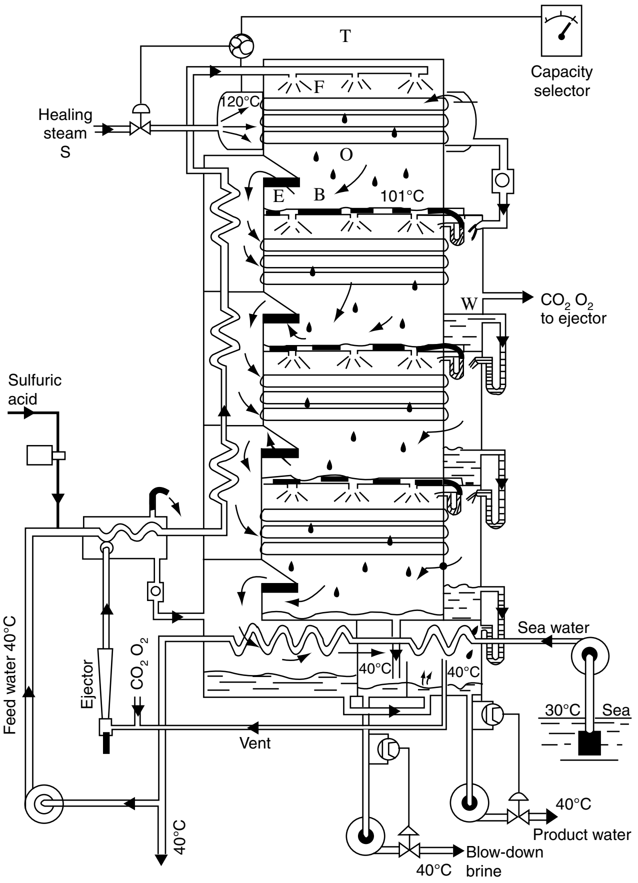

FIGURE 6 Flow-diagram of a multiple-effect-horizontal tube evaporator. The effects are vertically oriented, one on top of the other. This arrangement is compact and is called multiple-effect-stack type (MES) distillation equipment.[19] Preheated seawater feed is sprayed, F, onto the outer surface O of the evaporator tubes in the first effect at the top of the column, T, where a portion of seawater is evaporated by the heating steam S. The remaining seawater is collected at the bottom B, of the first effect and then sprayed onto the outer surfaces of the second effect where another portion of seawater is evaporated, being heated by the vapor generated in the first effect. The generated vapor is delivered through a mist eliminator section, E. The vapor itself condenses into fresh water in the side section W. The cycle is repeated in each successive effect up to the last one. Vapors generated in the last effect is condensed in a heat rejection condenser C.

Multi-Stage-Flash (MSF) Distillation

When saline water is heated to a temperature slightly below its boiling point at a given pressure and then introduced into a chamber where a sufficiently lower pressure exists, explosive boiling will occur. Bubbles are evolving from the whole mass of the liquid and part of the water will evaporate until equilibrium with its vapor at the prevailing pressure is reached.

This evaporation lowers the temperature of the remaining brine. The liquid may then be passed into another chamber at an even lower pressure, where it flashes again to vapor. If a higher rate of saline water circulation is supplied, an increased proportion of flash will occur. The increased flow rate may be considered as a means of obtaining increased evaporative yield in a system without increasing the evaporating surface. It is, therefore, equivalent to diminishing the evaporating surface.

Flashing of vapor requires a finite residence time of the liquid in the evaporation chamber in order to achieve near equilibrium conditions. For a given flow rate the residence time is determined by the chamber length. Mass-transfer rates in two-phase flow depend on the interfacial geometry of the two phases and on the degree of turbulence. They accordingly determine the residence time required and thus the size of the flashing chamber.

On the other hand, the length of the flashing chamber must be sufficient to achieve the required temperature rise of the incoming seawater under the acceptable maximum velocity inside the condensing tubes. As there are limitations for both brine and feed-water flow rates, the width of the flashing chamber becomes the important determinant for increasing the plant size. Figure 9 presents a flow diagram of a vacuum vapor compression unit.

MSF is the most widely applied distillation process, especially for large units, and despite the thermodynamic advantages of ME evaporation, all major plants installed are of the MSF principle because of the simplicity and reliability of the process. It accounts for 51.5% of the world desalination capacity and 86.9% of total distillation processes. The capacity of MSF plants capable of producing 100 m^3/d per unit or more fresh water was, by the end of 1993, about 9,640,000 m^3/d, 51.5% and 8,960,000 m^3/d, or 71.7% of world desalination capacity for desalting plants producing more than 4,000 m^3/d unit fresh water.

Multi-stage-distillation process, as applied in large scale desalting of seawater, may be considered as consisting of three sections in handling heat: the heat input section, usually named brine heater, by condensing external steam; the heat recovery section, in which the heat of the evaporation is recovered in the condensers at the various stages; and the heat rejection section, which maintains the thermodynamic process by reducing temperature and pressure and accounts for the last stages of the plant.

MSF distillation plants operate with recirculation part of the brine. Recirculation can be applied so far as the concentration of the scale-forming compounds does not reach, after the evaporation, the critical point. It is a disadvantage of this design that the brine concentration at the hottest stages of the plant is much higher than the concentration of dissolved solids in the seawater. The fact limits the maximum brine temperature of the process.

Operating with this cycle arrangement, the maximum operating temperature with acid injection is limited to 121°C (250°F), with brine concentration 1.5 times. The number of stages is usually limited by 2°C flashdown per stage, because of the low pressure differential available at the deep vacuum conditions prevalent in the last stages.

The total number of stages is affected by the initial and final brine temperatures, as well as by the necessary

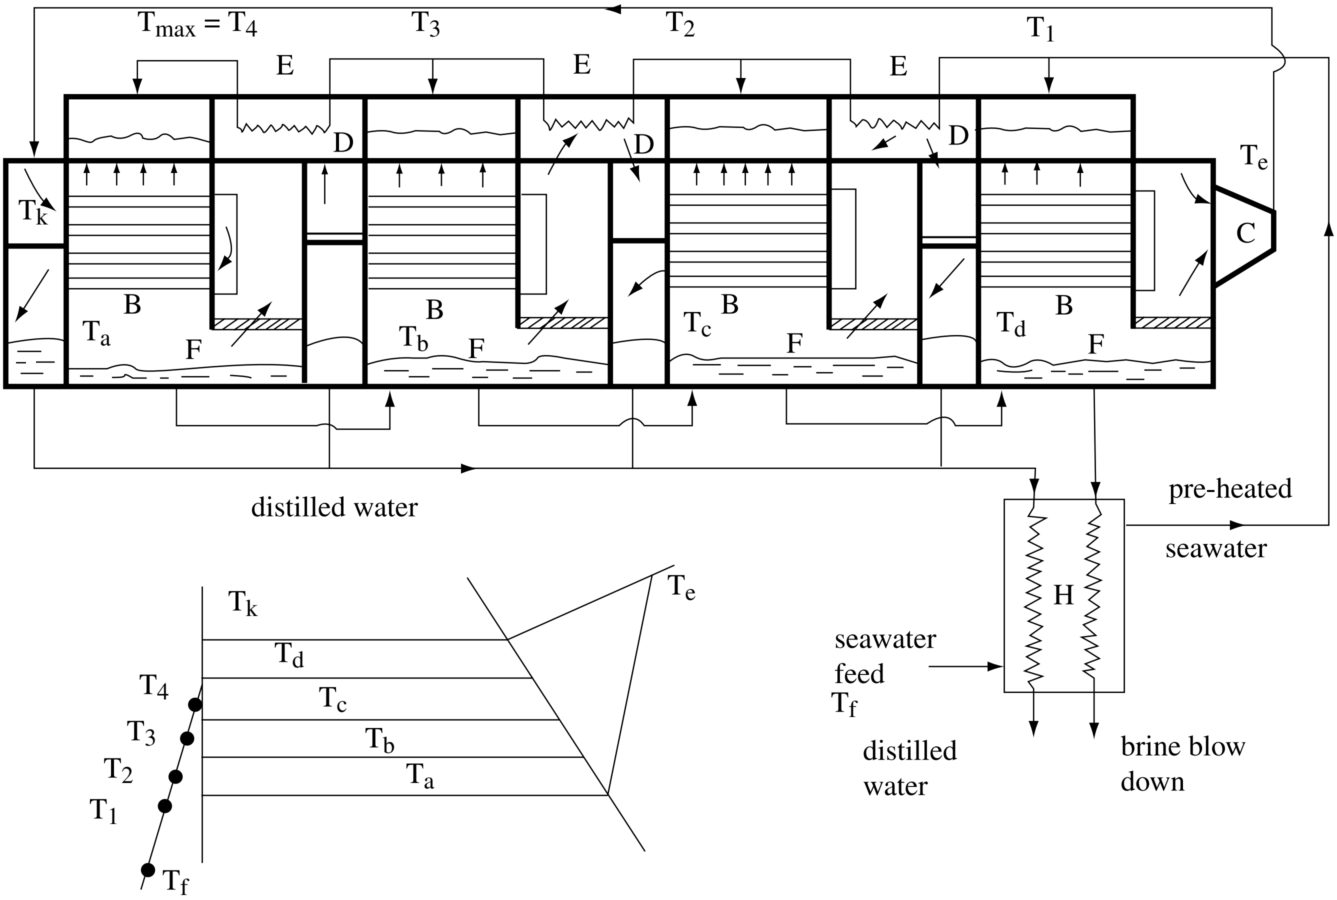

FIGURE 7 Flow diagram of a typical 4-stage, mechanical vapor compression plant. Incoming seawater feed is preheated in the heat-exchanger H, by the produced freshwater and the blowdown brine. The vapors released in the first stage are flashing to the second stage and so go on up to the 4th (or to the nth stage). The vapor from the last stage is compressed in the compressor C. Electric power is generated in a turbine to drive the compressor C. Compressed steam is circulated through the tubes of the condenser B, where it condenses, giving the heat to the evaporating seawater. Released vapors are used as heating medium in the second stage, etc. The condensate, i.e., the produced freshwater, leaving the flashing chambers F is collected after further cooling in the heat-exchanger H and brine is rejected.

temperature gradient between stages, to maintain the thermodynamic cycle. However, there are practical limits in the excessive increase of the number of stages. The additional investment to provide further stages to the plant should be reasonable with respect to the savings of heat obtained by the same stages. In large multi-stage flash evaporators for desalting of seawater, the cost of the heat transfer tubes is a very important part of the total construction cost. The temperature drop in each stage and the difference between brine-inlet temperature at the first stage and the discharge temperature at the last stage are the main controlling parameters of the MSF distillation process. In a cascading flashing stream of an MSF evaporator, the combined heat capacity of the flashing brine and distillate streams equals that of the recirculating brine and the temperature rise of the recirculating brine equals the temperature drop of the flashing stream.

The number of stages in an MSF distillation plant is related to the performance of ratio. An increase in the number of heat-recovery stages will generally result in a higher performance ratio for a given product-water output and in a decrease of steam consumption at the brine heater.

The performance ratio R can be correlated to the number of stages by the following relation:

$$R = \frac{\text{no recovery stages}}{\text{no reject stages}} = \frac{T_{max} - T_f}{T_o - T_F}\,\frac{\text{kg}}{2326\ \text{kJ}}. \tag{4}$$

Vapor bubbles almost explode to carry entrained brine to the product. Demisters D (Figure 5) reduce this but give additional temperature losses up to 0.11°C (0.2°F) per stage. Low flash temperatures per stage reduces flash violence and entrainment but this increases the number of stages to 40 or more and also increases equipment costs and inefficiency, which increase capacity and material costs.

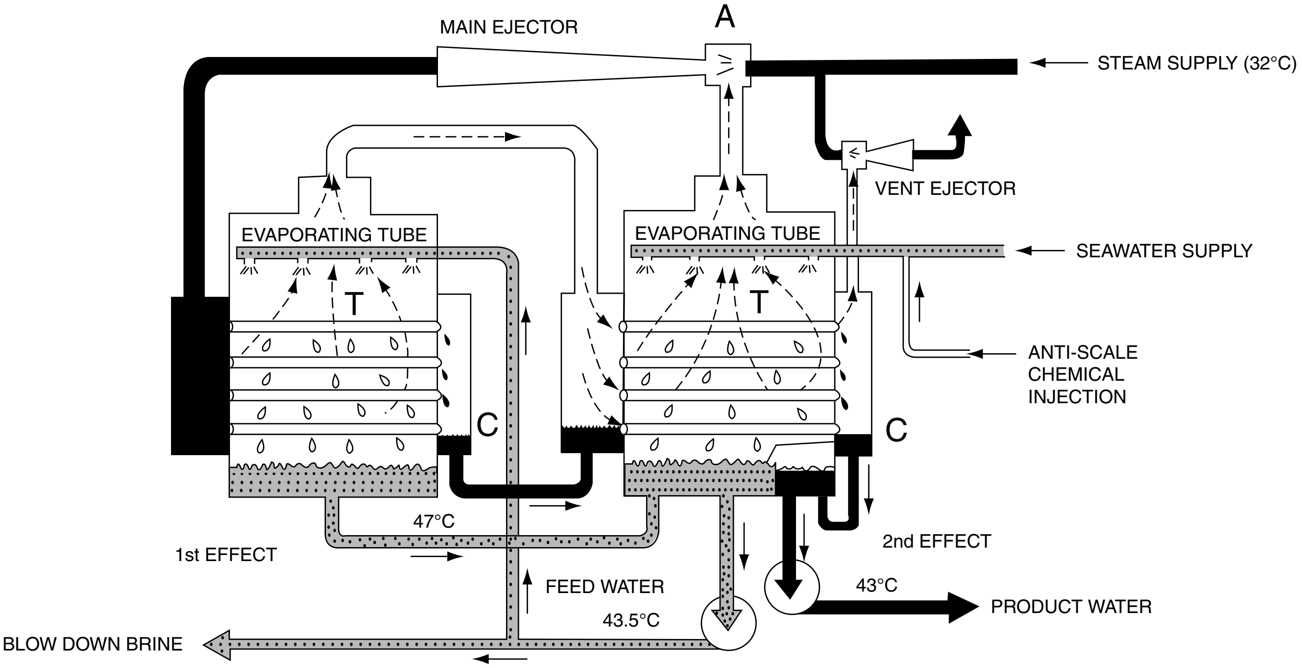

FIGURE 8 A two effect reheat or thermal compression unit. The low pressure, low temperature vapors from the second effect are sucked by the steam jet ejector A, driven by a small quantity of high pressure boiler steam, and delivers a hotter compressed mixture of stream and vapors to the condenser tubes T of the first effect. The seawater feed is sprayed onto the outside of the horizontal condenser tubes T. Part of the rejected brine from the last stage is used as feed to the first stage. Condensate, or product fresh water is collected in the last stage chamber C and distributed through the pump P. (Courtesy Sasakura Engineering Co., Ltd., Japan.)

Temperature differences between brine and vapor streams leaving stages may be from 0.45 to 1.7°C (~3/4 to 3°F) besides boiling point elevation.

In Figure 10 the flow diagram is given of a multi-stage-flash evaporator and the temperature profile across the plant. Figure 11 gives the two arrangements of the multi-stage-flash chambers. Configuration No. 1, with long tubes is preferred by American construction companies. The cross type No. 2, is usually preferred by European contractors.

Combined Distillation Plants

Significant economic advantages may be expected from combining different distillation processes, especially where desalting plants are designed with large capacities. Studies and design experience indicate that the combined system possesses substantial advantages in cost compared with the unit form of multi-stage plant of the same capacity. The savings in cost are due primarily to lower capital investment, and lower operational and maintenance costs. A further advantage of the combined plant is its high operational stability at varying loads.

Many designs have been proposed and many combinations have been tried, mainly for small capacity or pilot size plants. Commercial application used the vertical tube-multi-stage-flash (VTE/MSF) and the vertical tube-vapor compressor processes. Tubes with fluted surfaces are used in the vertical tube evaporator plants to obtain enhanced heat transfer performance. The heat recovery section of the multi-stage-flash plant is used as feed preheater of the vertical tube plant, which is the main evaporator for the distillate production. The combined vapor compression-vertical tube evaporator process uses the heat recovery section of the multi-stage-flash as preheater for the vapor compression plant as it is more efficient than the heat-exchangers in the single vapor compression process.

Scale Formation and Its Prevention

Formation of scale deposits on and fouling of heat transfer surfaces is one of the most serious problems of distillation equipment operating with sea or brackish water. As the scale deposits lower the efficiency of heat transfer surfaces and increase the pressure drop, pretreatment of feed water is necessary to prevent the deposition of scale.

As the salt concentration increases during progressive evaporation, the critical point may be reached at which the solubility limit of scale-forming compounds contained in the feed water, is exceeded and formation of scale occurs. The term scale is applied particularly to describe hard, adherent, normally crystalline deposits on the heat transfer

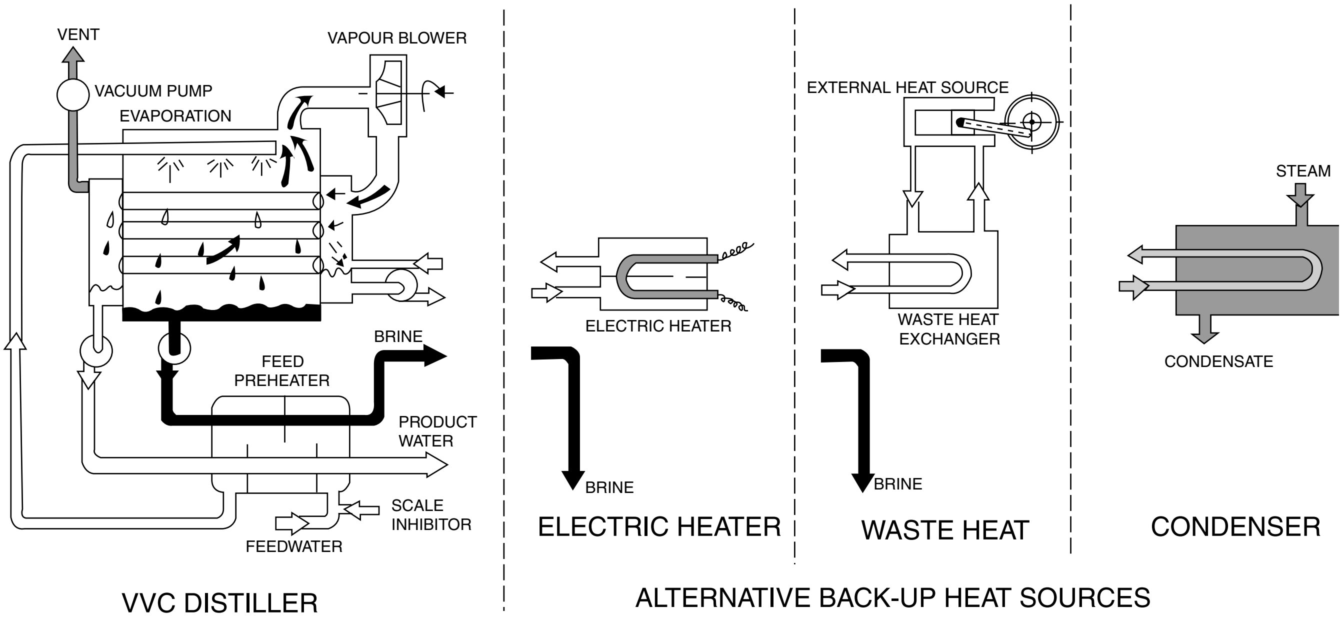

FIGURE 9 Flow diagram of a vacuum vapor compression (VVC) unit. The vacuum vapor compression distillers are small capacity units, and can produce fresh water from any kind of water, as dirty waters, with low energy consumption. It operates without acid treatment at 70°C (158°F) and uses, as heat source, electricity or can be combined with hot gas or hot water 80°C. The salt water feed is preheated and sprayed to the top of the evaporator A, where it is distributed as a thin film over the outside of the tubes T. The thin film boils at the tube surface due to condensation of the hotter vapor inside the tubes. The vapor thus created is compressed in the blower B and its temperature is raised, before it passes to the inside of the tubes T, where it condenses to form fresh water. Most of the heat is thus effectively recycled. C, D, E, represent the auxilliary parts of heating which can be adapted to the main distillation unit U, according to their availability. (Courtesy Sasakura Engineering Co., Ltd., Japan.)

surfaces. Three simultaneous factors are required for the formation of the scale:

1. Local supersaturation of the solution.
2. Nucleation, which when formed includes the rate of further scale deposition.
3. Sufficient contact time of the solution and the nucleus.

Under certain conditions a soft, amorphous material, called sludge, may be deposited or remain suspended in the brine and is generally more easily removed than hard scale.

If the ions contained in seawater are combined in the form in which they usually deposit, the resulting compounds will be approximately:

$CaCO_3$	109 mg/L
$CaSO_4 \cdot 2H_2O$	1,548 mg/L
$MgCl_2$	3,214 mg/L
$MgSO_4$	2,233 mg/L
NaCl	26,780 mg/L

assuming that hydrogen carbonate decomposes to carbonate before precipitation occurs. Alkaline scale, $CaCO_3$ and $Mg(OH)_2$, results from the decomposition of the hydrogen carbonate ion. On heating seawater up to 82°C (180°F), the hydrogen carbonate ion decomposes and calcium carbonate is formed.

A second type of scale, called acid scale, is due to three forms of calcium sulfate: the anhydrite $CaSO_4$, the hemihydrate and the dihydrate $CaSO_4 \cdot 2H_2O$, or gypsum. While the precipitation of $CaCO_3$ and $Mg(OH)_2$ is mainly affected by CO_3^{2-} concentration, pH and temperature affect the solubility of calcium sulfates in addition to the concentrations of other ions present. $CaSO_4$ has as well decreasing solubility in the temperature ranges of interest. The solubility increases in chloride solutions, as the concentration approaches 4 to 5% chloride and then decreases to values comparable to those in chloride free water as the chloride concentration becomes 10 to 15%.

Maximum brine temperature provided in the design, maximum allowable brine concentration and brine recirculation rate are also affected by the formation of scale. These operating variables and the plant availability are closely tied to the economics of the process as the production rate is generally lowered. Periodic plant shutdowns for descaling would be required either by an acid clean or, in extreme cases, by mechanical cleaning of the tubes. Incrustation allowances to reduce the frequency of shut-downs are made in designing evaporators, which are provided with a sufficient larger heat-exchange surface in order to maintain the design capacity. The term fouling is often extended to this type of admissible scaling.

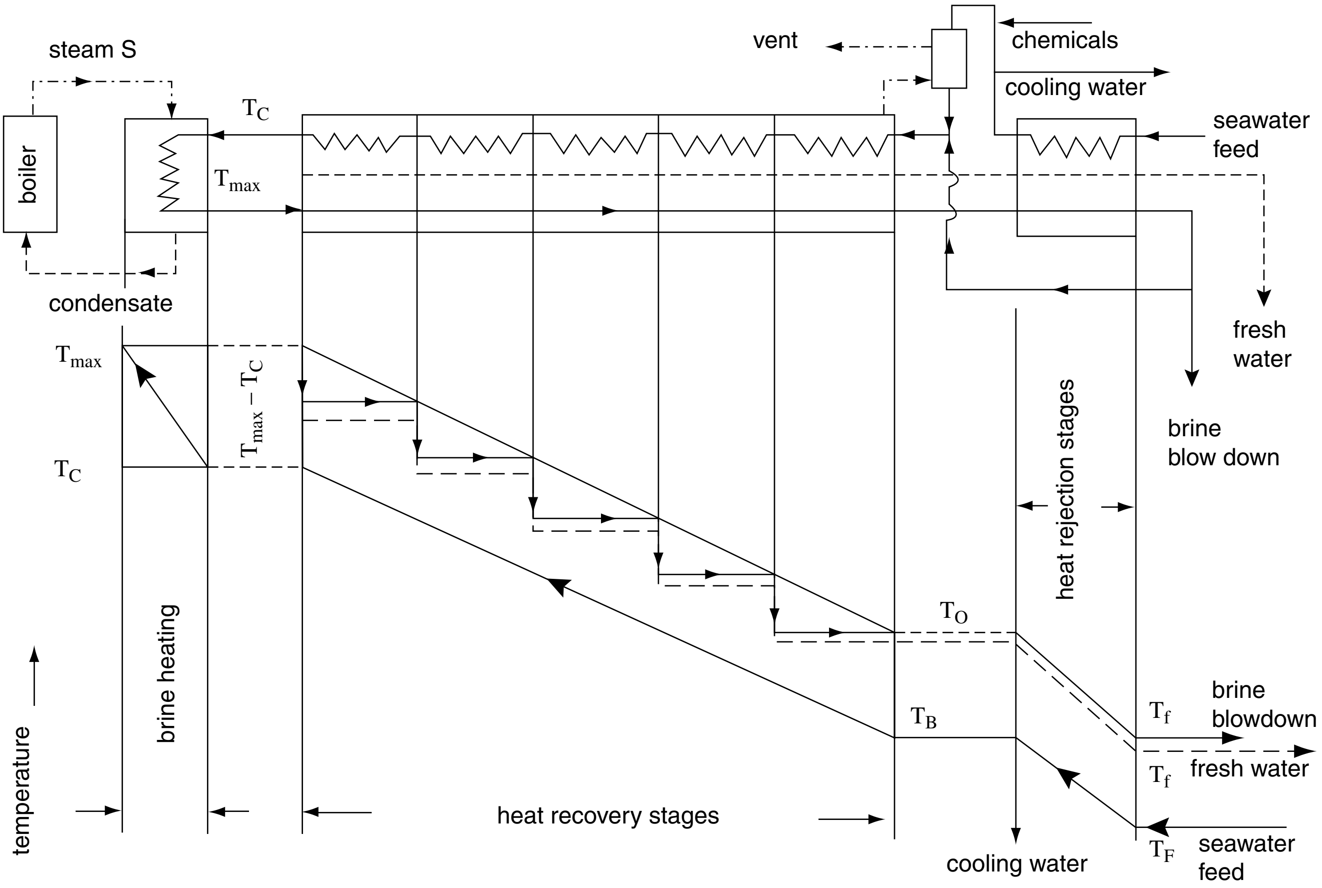

FIGURE 10 Flow diagram of a multi-stage-flash evaporator with brine recirculation, and temperature profile across the plant. Cold water feed is pre-heated inside the condenser tubes of the heat rejection stage A, then circulating through the condensers of the recovery stages, is heated to temperature T_c. Finally is heated by steam and reaches the highest temperature in the process T_{max}. By this temperature is fed to the 1st stage of the recovery section. The recovery and the rejection sections are enclosed in a single long vessel. The rejection stage removes excess heat from the flashing brine. Each stage is operating at a lower pressure than the preceding stage, with temperature fall from stage to stage. The vapor generated in the flash chambers condenses on the tubes of the condenser giving its latent heat of condensation to the heated seawater into the tubes. Leaving the heat rejection stage, brine is blow-down. Usually 50% to 75% of the brine recirculates after mixing with cold seawater. In the temperature profile, the stepped line shows the temperature fall at each stage of the heat recovery and heat rejection sections. T_{max} is the maximum temperature to which the seawater feed is heated. T_f is the discharge temperature of the brine in the last stage and T_o is the outlet temperature from the recovery stage to the rejection stage. T_F is the temperature of cold seawater feed. These temperatures are correlated to the performance ratio R.

There are several techniques used to avoid deposition of scale. Calcium carbonate and magnesium hydroxide formation can be controlled by acid injection and pH adjustment or by the addition of polyphosphates. Sulphuric acid transforms the carbonates to sulphates so that only one type of scale-forming salt remains present. Phosphates precipitate calcium and magnesium as sludge, minimizing the effects on the heat transfer surfaces. Either of the chemicals is introduced into seawater before its entry into the deaerator. In the deaerator the dissolved gases, together with carbon dioxide evolved during acidification, are eliminated. The pH of the treated seawater is controlled by the addition of dilute caustic soda, which binds the remaining carbon dioxide.

Calcium sulphate scale is more difficult to control. When formed on heat transfer surfaces, removal is difficult, if not impossible. To prevent deposits two methods may be applied. Seed crystals are injected into the hot seawater to promote precipitation of scale-forming compounds on these seeds, which then form a sludge rather than a deposit on the heat transfer surfaces. Ion exchange treatment is applied to eliminate completely both calcium and magnesium ions from the solution.

A technique of seawater pretreatment is the LMC or lime-magnesium carbonate process. 70 to 80% of the calcium originally present in seawater is removed and this permits operation at higher temperatures and concentration

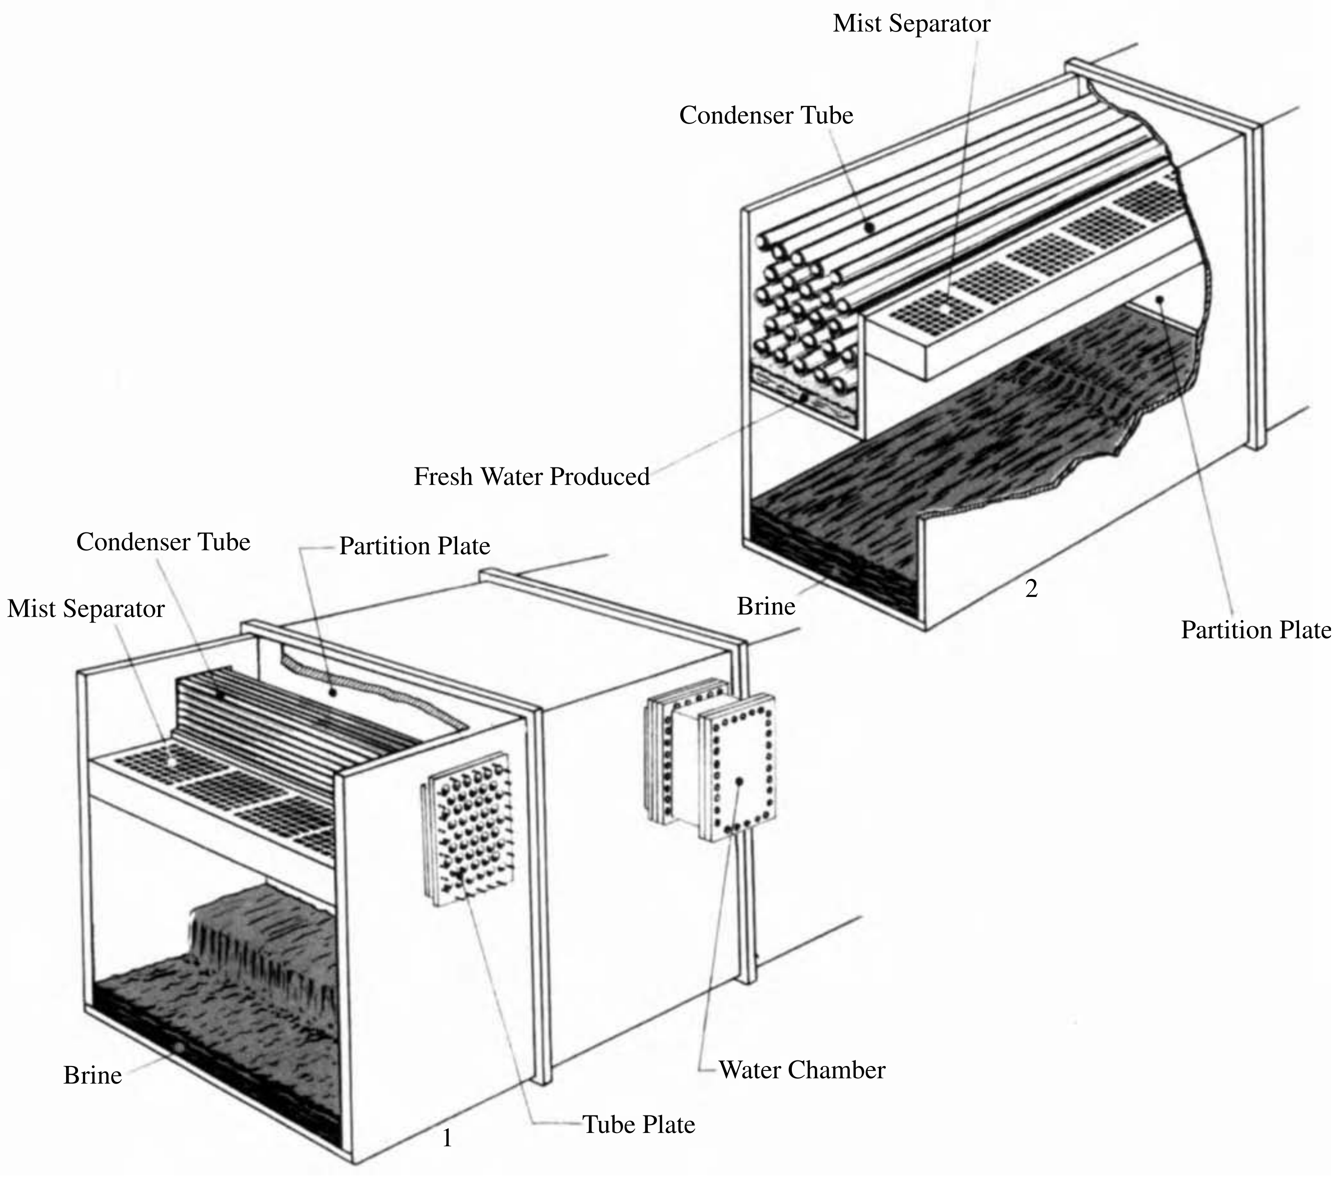

FIGURE 11 Drawing of a long tube multi-stage-flash (No. 1) and a cross tube multi-stage-flash chamber. The long tube configuration has a condenser running through each stage and the tubes are parallel to the flow direction of the flashing brine. High technical skill is necessary to seal the partition plates where the condenser runs through the partition plate. Long tube MSF plants are adopted for larger desalination plants. The cross tube type desalination units have the tubes across the top of the flash chamber and at right angles to the flow direction of the flashing brine. The cross tube configuration has condensers independent of each other and is mainly used for smaller desalination plants. (Courtesy of Sasakura Engineering Co., Ltd., Japan).

factors, thereby increasing the water recovery ratio for saline solutions and favourably affecting the economics of the desalting process. Treatment of the seawater with H_2SO_4, on the other hand, reduces the corrosiveness of the water by eliminating dissolved oxygen and carbon dioxide in the deaerator.

Acid treatment converts bicarbonate to carbon dioxide gas, whereas caustic treatment yields the carbonate ion, which combines with the calcium ion present in seawater to precipitate calcium carbonate. Nucleation of scale on the heat transfer surfaces is inhibited and precipitation of solids is dispersed in suspension by the addition of small amounts of certain commercial preparations. The sludge formed is then removed in the blowdown.

The first commercially available scale control compound was Hagevap, a mixture of sodium tripolyphosphate lignin sulfonic acid derivatives and various esters of polyalkylene glycols. Polyphosphates act as sequestrants for calcium and magnesium ions. Lignin sulfonic acid, starch, tannin, etc. act as dispersants in coating surfaces such that scale adherence and crystal growth are inhibited. Polyalkylene-glycols are surface active agents which tend to retard foaming of the seawater.

The use of polyphosphate based additives is limited to temperatures below 90°C (190°F). Above this temperature, polyphosphates undergo chemical changes which restrict their effectiveness as antiscaling agents. Other additives are low molecular weight polyacrylic acid or 10% ethyl acrylate-acrylic acid copolymer. An optimum polymer concentration of about 2 mg/L was observed to be most effective.

Materials of Construction: Corrosion

The selection of suitable metals to construct desalination plants is of prime importance as the use of inadequate materials may lead to shutdowns, increased replacement and maintenance costs and affect the overall economics of the plant.

The optimization of a distillation process has as a first object the minimization of the amounts of thermal or mechanical energy and of the amount of equipment and, hence, the amounts of materials used. Quite often, in such optimization studies, as energy goes down equipment goes up, and vice versa. Thus the most economical balance must be struck. Often this is at a point where the energy cost and the capital cost of the equipment are about equal.

Of the billion dollars per year to be spent for plants, materials for the equipment might be regarded as at least 50%, with costs of engineering, fabrication, transportation, installation, etc. accounting for the rest. Of materials used in equipment by far the largest amount will be for metals, particularly those metals which are least corroded by seawater. These are not the most abundant or least expensive. The specification of these metals for equipment—those which are suitable for withstanding the corrosion and other deleterious effects of this service—are of greatest importance. Their fabrication into sheets, tubes, shapes, and then finished vessels and parts and accessories will be a great test of the skill of the metallurgist, the chemical engineer, and the mechanical engineer.

Membrane Processes

Membrane processes are classified in two main categories:

- Methods which separate salts from the water, in their ionic form, called ionic processes. Electrodialysis and ion-exchange are the separation processes for desalination.
- Methods which separate water from a salt solution. Reverse osmosis, nanofiltration, ultrafiltration and microfiltration are the main processes of this type of separation which are applied to desalination or to water purification.

Ionic Processes Common salt, and other salts as well as acids and bases, are ionized in solution into the positive (for example, sodium ions) and the negative (for example, chlorine ions). Whereas in distillation processes the amount and kind of salts dissolved in the raw feed water are of no importance to the process and do not affect the economics, in all ionic processes the amount of dissolved salts is of primary importance. In electrodialysis, the amount of salts to be removed affects the consumption of electrical energy and in ion-exchange affect the amount and the cost of regenerant. Thus, ionic processes are much too expensive to use with the higher salt concentration of seawater, as compared with brackish, river or estuary water. In general ionic processes depend on specially developed polymeric resins in the form of membrane in the case of electrodialysis and as granules for ion exchange.

Ion Exchange The chemical system for removal of the ions of salt is called ion exchange and has long been used in the reverse process in which, for example, the sodium ion of salt is used to replace calcium ions to “soften” hard water. In this case the “bed,” of ion-exchanging material consists of granules of resin which have the property of removing positive or metal ions from a circulating aqueous solution by displacing them by a chemical bond with the resin of the bed. This replaces them with ions which are loosely bound in the molecular structure of the resin. When the positive ions of the resin are completely replaced, an aqueous solution, relatively concentrated in the other positive ion, is cycled, and the process is reversed. Other beds of resin have the properties of exchanging negative ions.

Similarly the sodium ion of a salt solution such as seawater passing through a suitable first bed may be interchanged with a hydrogen ion from the resin to leave the sodium ion in a loose combination with the resin and a resulting hydrochloric acid in the effluent solution. This solution is then passed through a second resin bed, in which a hydroxyl ion interchanges with the chlorine ion to give a resin chloride combination and an equivalent amount of chemically formed water which is added to the aqueous stream.

When the two resin beds have interchanged all of their respective hydrogen and hydroxyl ions, their activity ceases and they must be generated. This is done by stopping the flow and adjusting valves to take the beds off-stream and to pass through the first bed a dilute solution of sulfuric acid and then to pass through the second bed a dilute solution of caustic soda. The hydrogen ions of the sulphuric acid displace the sodium ions on the resin of the first bed to give sodium sulphate in its effluent which is run to waste and the hydroxyl ions of the caustic soda displace the chlorine ions on the second resin to give sodium chloride (salt) in the effluent of the second bed, which also runs to waste. Again, the ions on the beds are completely interchanged, the beds are thus generated and the controlling valves are adjusted, with those allowing the sequential flow of the original seawater being opened to allow the process to be repeated.

This process thus required both sulphuric acid and caustic soda in amounts which are chemically equivalent to the amount of salt present. Usually, at least 50 to 100% excess of each is used. This will represent a very high and impossible cost for large-scale desalination of seawater.

In special cases, particularly for desalinating brackish water, ion-exchange beds have been used, since only a relatively smaller amount of chemicals is required to interchange ionically with the salt in the feed solution. Thus water containing 1750 ppm of salt would be regarded as non-potable, but it would require only about 5% of the chemicals that seawater would require. On the other hand, the energy cost for its desalination by evaporation or RO would not be so greatly different from that required for seawater because in these processes it is the water which is being separated.

For emergency kits, packages of ion-exchange resins have been made to have only a single use, e.g. by aviators downed at sea. Seawater is passed through these small "beds" to make a small amount of drinking water. Provision for regeneration of the resins would be complicated and the resins are discarded when charged with sodium and chlorine, respectively.

The simplicity of ion exchange has attracted much effort to finding less expensive methods of generation of the ion-exchange resins. Carbon dioxide is a weak but cheap acid, as lime is a cheap alkali, and special resins and processes have been developed to use them and also to use the major differences of ion exchange equilibria at 80°C as compared to those at room temperature.

Ion exchange processes depend upon good resins. Excellent resins are available and they are not the limiting factor. The major cost is that of the chemicals required for the much less than stoichiometric replacement of salt by two chemicals. In desalination the ion-exchange process is used mainly for pre-treatment of brackish water for electrodialysis or reverse osmosis.

Electrodialysis, ED

Electrodialysis is the transport of ions through ion-selective membranes as a result of an electrical driving force. The process takes advantage of the ability of these membranes to discriminate between differently charged ions, allowing for free passage to either cations or anions and being impermeable to ions of the opposite charge. Electrodialysis is a desalination process of brackish water and, under certain circumstances for seawater as well.

The electrical mechanism of ion removal is much more complicated, and much cheaper, than ion exchange since it uses electrical energy rather than chemical equivalence to replace the two ionic changes of a molecule salt, since an electric current assists greatly the dialysis or movement of the ions through membranes permeable to the positive ions and to the negative ions, respectively. A membrane which is permeable to sodium ions forms the wall on the side of a channel of flowing saline water and a membrane permeable to chlorine ions forms the wall on the other side. The deionized water flows between the two membranes, and the electric current may be regarded as flowing at right angles. The other aqueous streams on the other side of the respective membranes may flow out counter-currently in the other direction (Figure 12).

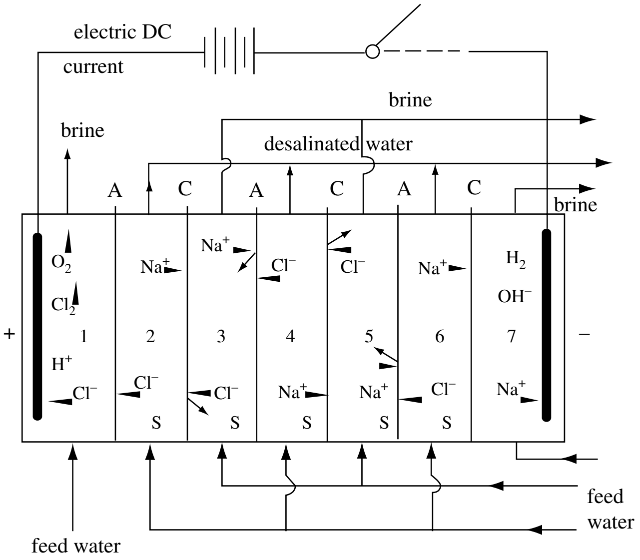

FIGURE 12 Flow diagram of a multicomponent electrodialysis cell, with 7 compartments showing the principle of the process operation. The saline water feed is pumped through the compartments, s, of the membrane stack and, when a direct current potential is applied, cations pass easily through the cation-permeable membrane and are stopped when they reach an anion-permeable membrane. Similarly anions have free passage through the anion-permeable membrane and are stopped at the cation-permeable membrane. The ion concentration increases in the alternate compartments.[3,5] Simultaneously the compartments between them become depleted of ions.[2,4] Hence two streams of water are extracted from the electrodialysis stack: one stream with low ion concentration, which is the product water, and one stream with high salt concentration, which is the reject brine. Separate feed and brine blowdown is provided for the first and last compartments containing the anode and cathode respectively, since corrosive oxygen, chloride and hydrogen gases are released.

The electrodialysis process is performed in cells consisting of many compartments formed alternatively by an anion and a cation exchange membrane placed between an anode and a cathode (Figure 12). Multicompartment electrodialysis cells are usually termed as electrodialysis stacks. A membrane pair is called a "cell pair" and consists of a:

- Cation transfer membrane
- Anion transfer membrane
- Demineralized water flow spacer
- Concentrate water flow spacer

A typical membrane stack contains 300 to 500 cell pairs, depending on feed salinity. If the feed water has a low salinity, it is possible to obtain an acceptable potable water in a single pass through the electrodialysis stack. If the feed water is high in salinity this is not normally practical. Feed velocities have to be maintained above a certain minimum value and this requirement is handicapped by the necessity to provide also for a minimum residence time of the fluid in the compartment. An increase of the current density may lead to concentration polarization, a phenomenon that can stop process operation.

Figure 13 is a view of an electrodialysis stack before assembly, that shows the main components. Typically the design is based on the configuration used in the plate and frame filter press. The end frames have provisions for holding the anode or cathode and are usually made relatively thick and rigid that pressure can be applied to hold the stack components together. The inside surfaces of the end frames are recessed to form an electrode-rinse compartment and provisions are made for introducing and withdrawing the solutions. Spacer frames with gaskets at the edges and ends are placed between membranes to form the solution compartments when ion exchange membranes and spacer frames are clamped together.

These are various electrodialysis systems:

- The conventional batch-type which was the first commercially developed system.
- The continuous-type unidirectional electrodialysis system.

Both types of the electrodialysis systems have some operation disadvantages and limitations. Ionic movement is unidirectional. In such systems cations are moving toward a fixed cathode and anion toward a fixed anode. Sealing forming salts, colloidal particles or slimes, slightly electronegative are accumulated on the surface of the anion-exchange membrane causing membrane fouling.

- Electrodialysis reversal (EDR) is a system designed for continuous operation. The polarity of the electrodes is reversed 3 to 4 times per hour.

This operation system reverses the direction of ion movement within the membrane stack, controlling thus scale formation and fouling.

To day almost all electrodialysis cells are constructed to operate with the reversal arrangement. Figure 14, gives a flow diagram of a reversal electrodialysis system, in a vertical arrangement.

The electrodialysis process is related to Faraday's law which states that the passage of 96,500 Ampere-s transfers theoritically one gram-equivalent of salt. The needed current for transferring a specific quantity of salt is given by the equation:

$$I = \frac{Fm_d \Delta c}{eN}. \tag{5}$$

If current efficiency e is 100%, 96,500 A-s will transfer one gram-equivalent of sodium ions, or 23 g Na^+, to the cathode and one gram-equivalent of chloride ions, or 35.5 g Cl^- to the anode.

Electrodialysis is applied usually to brackish water desalination up to 7 g/kg salinity. Sea water can be used also to produce water around 0.50 g/kg or less but energy consumption is very high. In reversal electrodialysis scaling is very low, almost zero, but in conventional ED pretreatment of feed water is necessary.

Energy input for electrodialysis depends on feed water salinity and varies from 19 to 20 kWh/m^3 (72 to 76 kWh per 1000 gallons) for seawater feed. For brackish waters the required energy is 2.4 kWh/m^3 (9 kWh per 1000 gallons) for

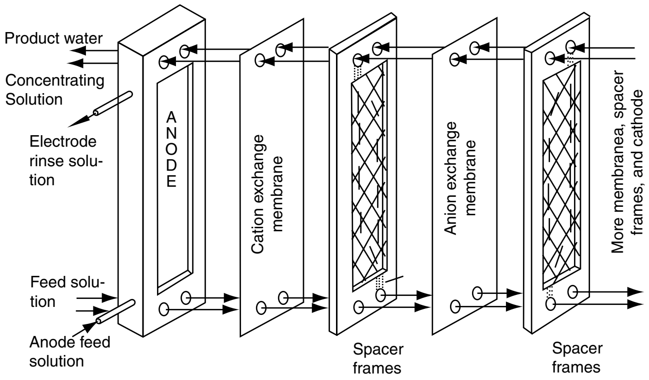

FIGURE 13 View of part of an electrodialysis stack before assembly. Component 1 is the one end frame, each of which holds an electrode and has opening for feeding and withdrawal of the depleting, the concentrating and the electrode rinse solutions. Compartments 3 and 5 are spacer frames which have gaskets at the edges and ends and form solution compartments with the membranes when they are clamped together. Many membranes and spacers clamped together form an electrodialysis unit.

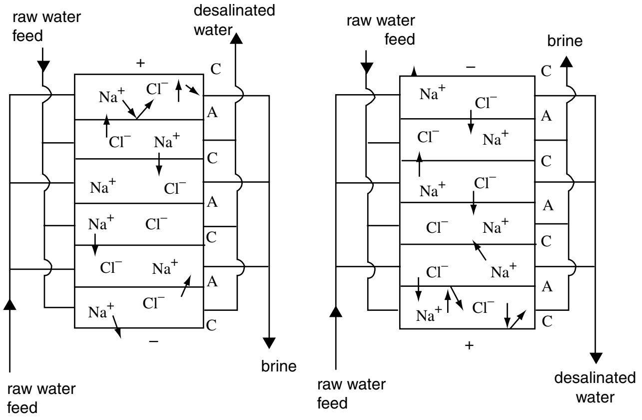

FIGURE 14 Flow diagram of an electrodialysis reversal cell. B represents the one-way operation and D the operation after the reversing of the polarity. Cathode or anode are reversing and become anode and cathode respectively. Ion movement reverses as well and concentration compartment acts as dilution compartment. Blowdown brine circulates in fresh water tubes and vice-versa.

feed water having 2,500 ppm and about 3.9 kWh/m^3 (14.8 kWh per 1000 gallons) for feed water containing 4,500 ppm total dissolved solids. The pumps operate at low pressure of 350 to 700 kPa (51 to 101 psi).

Electrodialysis has a variety of applications, in addition to that of fresh-water production, i.e., for the treatment of wastes, for the recovering of trace elements from effluents and for concentration of various solutions, such as fruit juices.

To the end of 1993 world capacity of electrodialysis plants producing more than 100 m^3/d/unit was 1,070,005 m^3/d covering only 5.7% of the total desalination capacity, and 14.8% of the membrane processes.

Ion Exchange Membranes The ion-exchange membranes are membranes selective either to cations or to the anions. When a cation-selective membrane is immersed in an electrolyte solution the cations in solution will enter in the resin matrix and replace the cations present. The anions are prevented from entering the matrix by the repulsion of the anions affixed to the resin. The opposite phenomenon takes place when an anion-selective membrane is immersed in an electrolyte solution. Ion exchange membranes are essentially ion-exchange resins cast in sheet form.

Membranes of synthetic resins have been developed which are highly selective to the passage of positive ions, and others have been developed which are highly selective to the passage of negative ions. Hundreds of membranes form passages in parallel between somewhat like a plate and frame filter press., which is the electrodialysis stack. A stack is presented in Figure 15.

Counter-ions within an ion exchange resin or membrane are ions with a charge opposite to the charges affixed to the membrane matrix. Co-ions are ions with the same charge as the fixed charge of the matrix. Hence, ion selective membranes are selectively permeable to counter-ions and selectively impermeable to co-ions. The selectivity, which might be expressed in terms of the transference number of counter-ions in the membranes, is not generally restricted to all ions of the charge. Membranes may well be more selective to some ionic species than to others. There are commercially available membranes that will selectively transport univalent ions in electrodialysis. With these membranes not only the concentrations but also the composition of electrolyte solutions can be altered. A membrane possessing specific selectivity between divalent and univalent ions would be useful for removing sulfate from a solution of chloride and sulfate, or to fractionate a mixture of the ions into two solutions, each one containing only one of the ions.

Transport numbers of ions in the ion exchange membrane are different from those in the solutions on both sides of the membrane. Because of the lower transport number of ions in the solution, the number of ions transported to the membrane surface by the electrical current is in deficiency to the ions removed from that surface and transferred through the membrane. The opposite phenomenon occurs on the other side of the membrane. A greater number of ions are transferred from the entering to the outgoing membrane surface than can be carried away by the electrical current. Two boundary layers with the opposite concentration gradients are formed at both sides of the membrane. This tendency for concentration and depletion is opposed by diffusion and physical mixing. Hence, the thickness of the boundary layers depend on hydrodynamic conditions and on the degree of turbulence. However, there remain layers adjacent to the membrane in which the solutions are completely static.

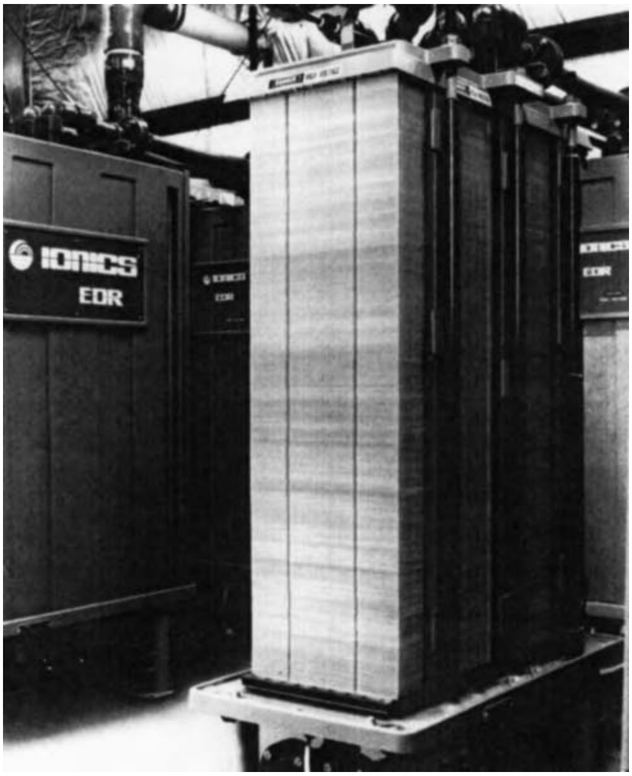

FIGURE 15 Photograph of an electrodialysis reversal stack with 500 cell pairs in vertical arrangement. (Courtesy Ionics Inc., Watertown, Mass. USA.)

Increasing the current density has the effect of increasing the concentration gradients at both surfaces of the membrane and the point may be reached at which the concentration of ions at the entering side of the membrane approaches zero. This is the limiting current density. When the limiting current density is exceeded, hydrogen and hydroxyl ions are transported through the solution and the membrane causing changes of pH inside the membrane and at the boundary layers of the solutions, as well as an increase in the overall electrical resistance. The desired ions participate with only a small amount in the transport. The phenomenon is termed concentration polarization and is the major limitation of the production rates achievable by electrodialysis.

The increase in the pH of the solution associated with polarization promotes the formation of alkaline precipitates such as calcium carbonate and magnesium hydroxide on the membrane surface. Membrane scaling causes additional electrical and flow resistance, a decrease in electrodialysis efficiency and an increase in pumping power requirement and mechanical damages in some occasions.

Ion exchange membranes are very thin, about 0.5 mm (0.020 inches), and they are supported by spacers as shown in Figure 13. Spacers are made usually from two layers of low density polyethylene having manifold cutouts which match the membrane cuts as it is shown in Figure 16.

Membrane life is short, from 3 to 6 years, depending on scale formation, fouling and the poisoning of the membranes. Poisoning of the membranes occurs from chemical agents such as chemicals for pre-treatment. The membranes lose their characteristic properties, their volume is increased, their water content decreased and they deteriorate easily. Scaling, fouling and poisoning of the membranes have influence not only on membrane life but also on membrane efficiency, which drops considerably after long period use.

Reverse Osmosis, RO Reverse osmosis separates pure water molecules from a salt containing solution through a semipermeable membrane having extreme fine pores.

Osmotic flow, direct or reversed, depends on the selective properties of some membranes to allow certain components of a solution, usually the solvent, to pass through the membrane. This intrinsic property of the membrane is termed as semipermeability. If two solutions of different concentration, or a pure solvent and a solution, are separated by a semipermeable membrane, the solvent will flow under normal conditions from the less concentrated department through the membrane into the concentrated solution, with the tendency that both solutions reach the same concentration. This flow is known as osmosis. Osmotic flow through the membrane will stop when the concentrated solution reaches a sufficiently higher pressure than prevailing in the less concentrated solution or the solvent compartment. The equilibrium pressure difference between solvent and solution, or the two solutions, known as osmotic pressure, is a property of the solution. Equilibrium can also be reached by applying an external pressure to the concentrated salt solution equal to the osmotic pressure. Further increase of the pressure on the concentrated solution, beyond the osmotic pressure, causes reversal of the osmotic flow. Pure solvent passes from the solution through the membrane into the solvent compartment. By applying a pressure higher than the osmotic the phenomenon is reversed and water flows from the concentrated solution to the dilute. This is the basis of reverse osmosis, the major attractions of which, from an economic point of view are its simplicity and the relatively low energy consumption.

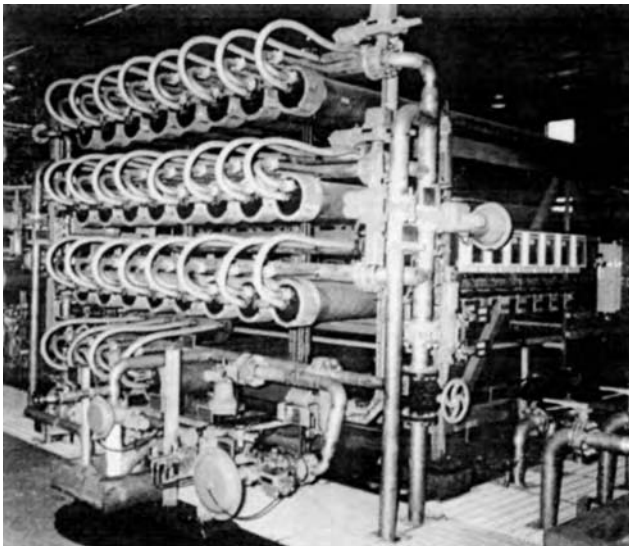

FIGURE 16 A cell pair spacers and anion and cation membranes with the corresponding manifolds. Water is circulating through the paths of the spacer. (Courtesy Ionics Inc., Watertown, Mass, USA).

Reverse osmosis has some analogies with filtration in that both remove substances from a liquid. As matter, removed by reverse osmosis is in solution, the process previously was termed "hyperfiltration," when the membranes used were highly semipermeable with respect to low molecular weight solutes. On the contrary, when the membranes used have little or no selectivity for such solutes but they may be applied for the separation of colloids or macromolecules from low molecules solutes, the method is called "ultrafiltration." In fact ultra, a Latin word, is identical to the Greek word hyper. Today high pressure, low molecular matter separation is called "reverse osmosis" and lower pressure low molecular separation is called "nanofiltration." By chemical engineering point of view reverse osmosis, nano-, ultra- and micro-filtration can replace, in some extent other unit-operation separation methods as these are shown in Figure 17. These four methods can be applied for the purification of water of solutions related or not to desalination methods and reverse osmosis and nanofiltration for desalination of seawater brackish or natural waters, as well.

Applied pressures are higher for the reverse osmosis method and low for microfiltration and, on the other hand, porosity of membranes is decreasing from micro-filtration to reverse osmosis as follow:

	Applied pressure, bars	Porosity
Reverse Osmosis, RO	30 to 70	5 to 20 Å
Nanofiltration, NF	20 to 40	10 to 20 Å
Ultrafiltration, UF	5 to 15	20 Å to 0.1 μm
Microfiltration, MF	1 to 4	0.1 to 2 μm

Reverse osmosis, for desalination of sea or brackish water, by the end of 1993 had a world capacity of 6,109,250 m^3/d per unit or 32.7% of total world capacity. This capacity gives RO second place in fresh water production worldwide.

The vapor gap osmotic distillation process is a forerunner of the reverse osmosis process. It is based upon the difference between the water vapor pressures over a saline solution and that over pure water.

Reverse osmosis as a process was developed first with the plate and frame concept, using the filter-press principle. This

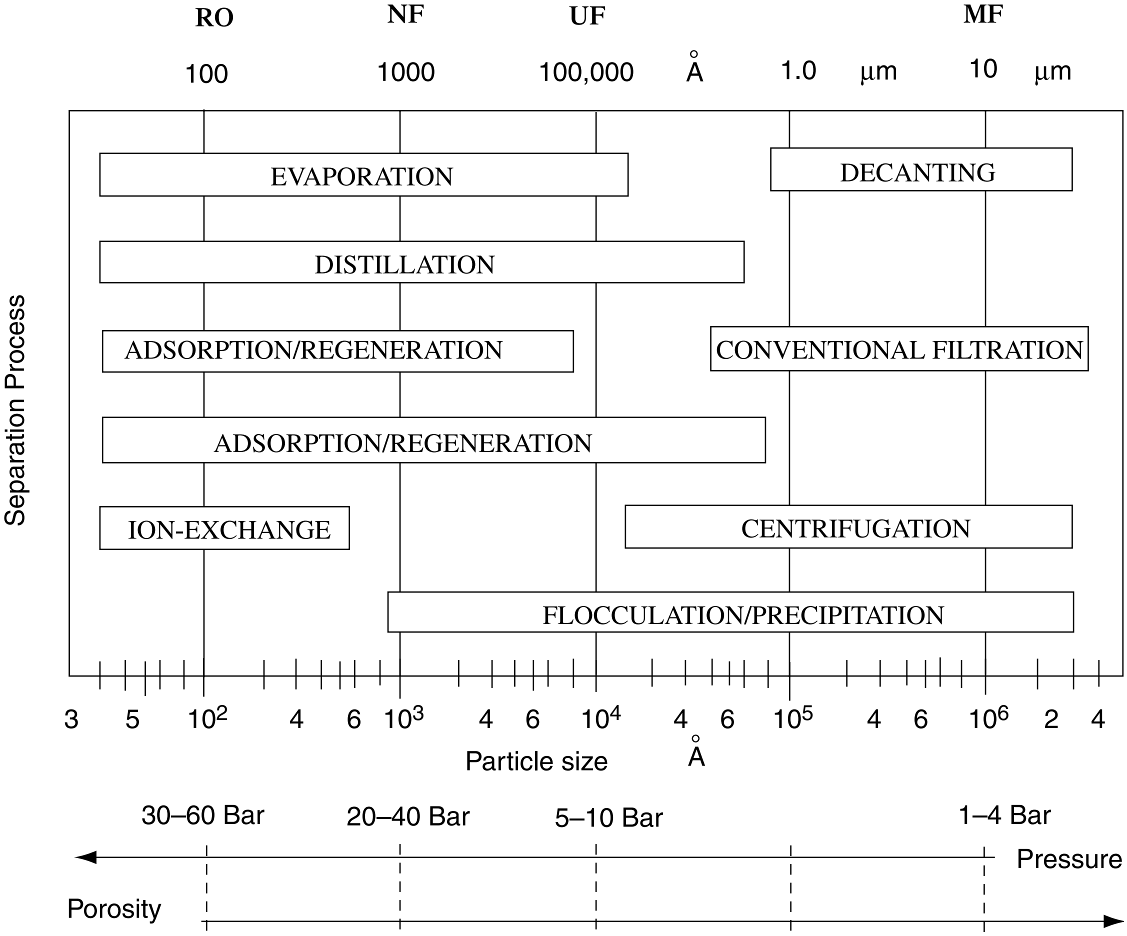

FIGURE 17 Particle size separation by various membrane and the range where they can replace the conventional chemical engineering separation methods. The particle size range for each membrane separation method depends on the porosity of the membrane, increasing with the particle size, and on the pressure which is decreasing proportionally with porosity increase.

configuration is now coming back, having many improvements and makes use of a rigid plate with the membranes mounted on opposite sides and sealed to the plate. Salt water under pressure is following on the outer side of the membrane and the product water is forced through the membranes into the interior of the porous plate, which serves as membrane support.

Two other configurations, are in use: The tubular and the spiral wound. Both, as the plate and frame concept, use flat sheet membranes, and another concept uses membranes in the form of hollow fibers.

All membranes are assembled in units called modules. Each module is self-contained and can be used as an independent reverse osmosis unit. Most often, many modules connected in series are used to increase capacity. Semipermeable membranes are very thin, as are ion-exchange membranes and fragile, and they need special support to withstand the pressure applied for the separation. Assembling the various types of modules special care must be taken to support the membranes properly. The fact that water flow through a membrane is proportional to the membrane area and inversely proportional to its thickness renders a module a device requiring the maximum possible area per unit volume of water passing through the membrane. The membranes are vulnerable to mechanical damage, fouling and scaling as well as to concentration polarization phenomenon. A perfect module has the following advantages.

- Minimizes the effects of concentration polarization.
- Has high resistance in seawater corrosion and in the cleaning chemicals.
- Continuous operation at high pressure.
- Almost constant quality of freshwater produced.

Reverse osmosis is a method used not only for desalination of sea or brackish water, but also for the purification of a large variety of various solutions in the chemical industry by using suitable semipermeable membranes.

Ultrafiltration and microfiltration do not desalinate waters directly but are used for pretreatment of various kinds of solution and water, depending on the molecular weight of the dissolved or suspended matter previous to reverse osmosis treatment.

Reverse Osmosis Membranes The reverse osmosis membranes are the main and more delicate component of the method. They are usually permeable to some species, as water and impermeable to other, as salts. They are characterized by two important parameters: The water flux, or water permeability and the salt rejection. Concentration polarization plays a significant role and influences both the above parameters.

The water flux at a given temperature is determined by the membrane properties and is defined by the equation:

$$J_v = L_p(\Delta P - \sigma\Delta\Pi)\ \mathrm{m^3/m^2s}. \quad (6)$$

Salt rejection is the ability of the membrane to reject the solution salts and leave only the solute, i.e., the water to pass the membrane mass. A perfect membrane would reject all salts contained in the feedwater and be highly permeable to the flux of water, or solute. Commercial membranes are not ideal and have certain amount of salts to move through the membrane. The salt rejection is defined as:

$$\%\ \text{Salt rejection} = \frac{\text{product concentration}}{\text{feedwater concentration}} \times 100. \quad (7)$$

A module characteristic is the recovery or yield which defines the fresh water product, m^3/d, to the feed water flow, m^3/d as well.

$$R = m_d/m_s \quad (8)$$

R is influenced by the required salinity in the product, fresh water.

The required mechanical energy to drive the RO pumps is determined by the required separation pressure, which in turn is proportional to the salt content of the feedwaters. It ranges between 8.0 to 12.0 kWh per m^3 freshwater produced, from seawater feed and 2 to 3.5 kWh/m^3 of brackish water feed. The corresponding pressure is 56 to 70 bars for seawater (812 to 1015 psi) and 20 to 28 bars (246 to 406 psi) for brackish water.

There is a large variety of membranes prepared from organic materials. For commercial use up to now the types of these composite membranes in general use are the ultrathin composite-spiral-wound membranes and the hollow fine fiber membranes. The best developed composite membranes are: Cellulose triacetate films deposited on a cellulose diacetate-cellulose nitrate support, furfuryl alcohol film on a polysulfone support and polyamide film on a polysulfone support. The polyamide-film membranes provide the best desalination performance. This development in membrane preparation brought the reverse-osmosis process next in importance to distillation during the last years so that distillation and reverse osmosis are today leading processes in seawater desalination.

The way by which the membranes are supported and the properties of the membranes define the reverse osmosis system.

A way to assemble membranes is the spiral wound module (SWM). Spiral membranes are cellulose acetate polymers or can be made of the thin film composite type. Spiral membranes have a diameter of 5.1 to 30 cm (2.0 to 11.8 inch) and a packing density of about 600 m^2/m^3.

Another module system is the tubular (TM) where the membrane surface is packed in a shell and tube arrangement. The membranes, usually cellulose acetate, are mounted inside the tubes made of metal or plastic. The active layer, i.e., the permeable layer, may be either on the inside or the outside of the tubes.

The hollow fine fiber module (FHFM) are very thin fibers, similar to human hair thickness. Their advantage is their high surface area. Inside the modules they present a packing area exceeding 30,000 m^2/m^3 of water produced. Millions of fibers are assembled inside a cylindrical bundle embedded in an epoxy resin tube sheet. Figures 18 to 20 present the reverse osmosis modules commercially available.

Freezing Processes

All variants of the freezing processes are based on the well-known phenomenon that, when a saline solution is cooled to its freezing temperature, ice crystals of pure water will form and the brine will be enclosed in the slurry.

The temperature of freezing is fixed by the concentration of the brine, while evaporation can operate over a wide temperature range. Freezing has basic advantages:

1. much lower latent heat of phase transition in the solid state than for evaporation (0.33 × 10^3 J/kg against 2.49 × 10^3 J/kg or 143.2 BTU/lb against 968 BTU/lb).
2. less heat losses (gains) because of working at temperature closer to the ambient;
3. no scale-formation from the usual impurities;
4. less corrosion of steel at the freezing point than at the boiling point of water; and
5. cheaper materials of construction may be used.

Against these there are basic disadvantages:

1. the time required for phase transition from liquid to solid is very much greater than that required from liquid to vapor;
2. handling the crystals of ice is very much more difficult than handling the fluids in evaporation processes;
3. separation of the pure water phase (ice versus steam) is extremely difficult;
4. the cost of removing heat energy is much more expensive than that of adding heat energy, and

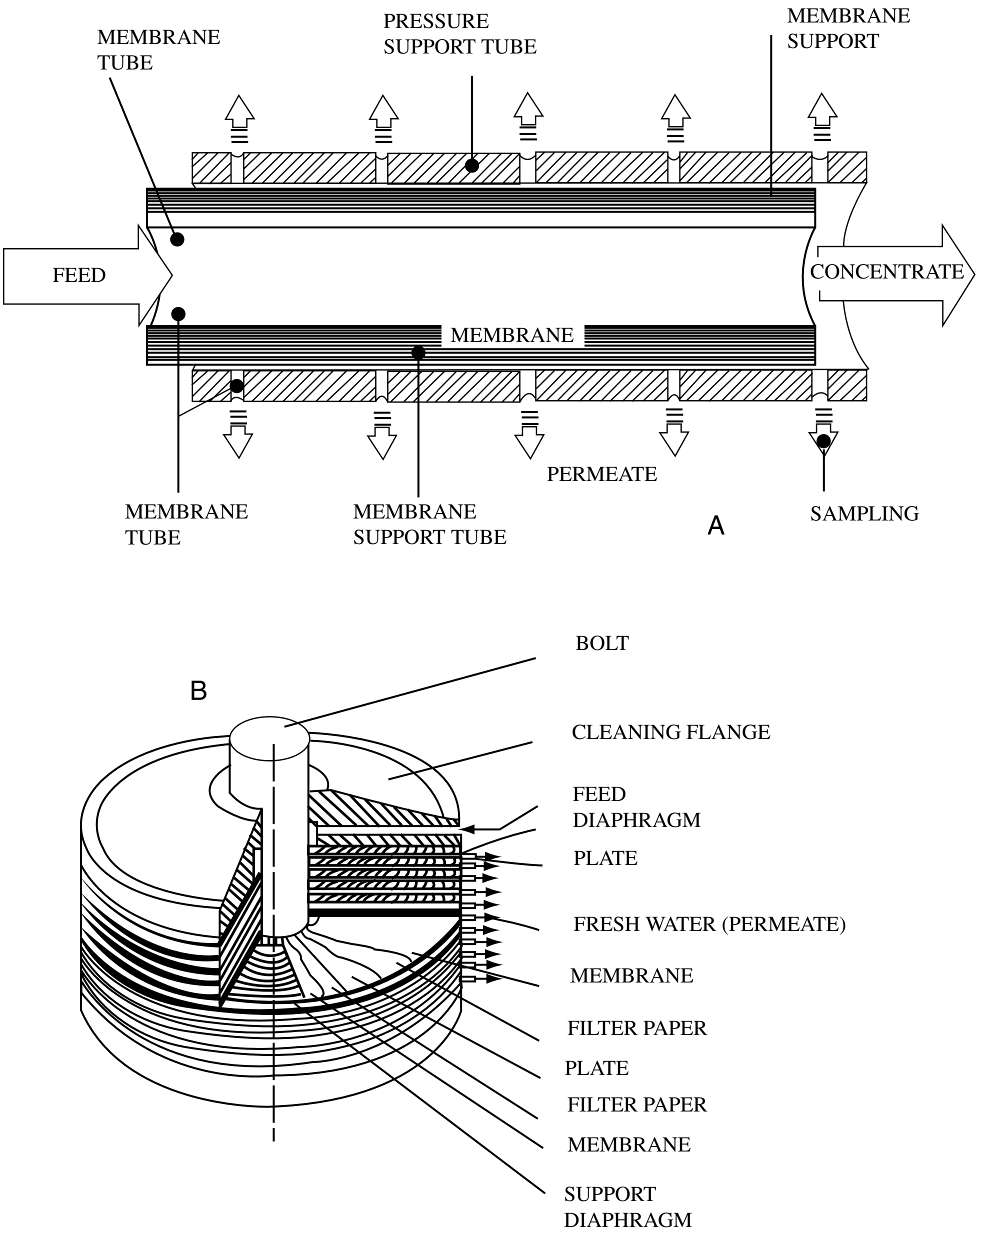

FIGURE 18 Schematic diagram of the reverse osmosis and ultrafiltration modules. A, the tube module arrangement. B, the plate and frame module arrangement. In the tube module membranes are formed as tubes with the active layer either inside the tube or the membrane support tube. In the plate and frame arrangement the membranes are flat sheets put onto the flat support diaphragms.

5. freezing operates, practically only at the freezing point of the final solution, and there can be no multistaging to reuse the latent heat of phase transition.

However, the major disadvantage of the freezing processes is the necessity of washing the ice crystals from adhering brine, an operation which inevitably consumes part of the product water.

As in all refrigeration, there are two types of processes for desalination of seawater:

1. mechanical compression of vapors, and
2. absorption of vapors by a hydrophylic liquid which then uses heat energy for desorption by evaporation. Both may use other refrigerants in either direct or indirect heat transfer relation.

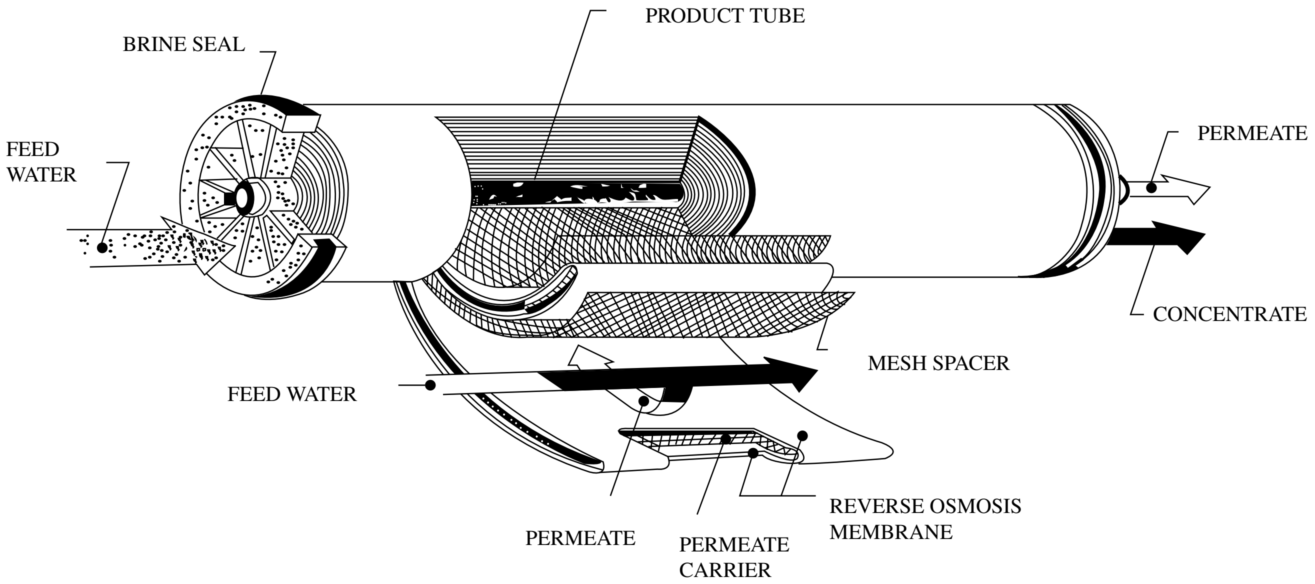

FIGURE 19 Reverse osmosis spiral wound arrangement, made from flat sheet, rectangular shaped membranes. A TORAY Industries, Inc. arrangement. Between the membranes is inserted a porous material, usually a dacron tricot, impregnated with a resin, and both are sealed together, forming the so called "sandwich" on three sides only, the fourth side joined to a slotted collection tube. More sealed membranes connected to the same tube compose the module. A spacer, mesh screen is inserted between the sandwiches and they are rolled to form the spiral wound module.

The vacuum flash vapor absorption system (VFVA) utilizes heat transfer by direct contact by means of an absorption refrigeration machine. For the above reasons, freezing processes found no commercial application. Worldwide there is only one unit producing 210 m^3/d.

Dual Purpose Plants

The economics of desalination plants can be considerably affected, and as a consequence the cost of product water, when electric-power generation is combined with a desalting plant in dual operation. This is especially true in locations where power demand and water requirements are in favorable relation, independent of the method applied in the desalting process. This system has been used for many years in various chemical plants, in which both electricity and low pressure steam are required for processing. This combination results in lower costs for both power and water than would be achieved by separate plants for the production of each.

The main part of the steam enthalpy used in distillation is the heat of condensation. On the other hand, turbines in a power plant use efficiently high temperature and pressure steam. The principle of a dual-purpose plant is to use high temperature steam for power production and low pressure steam leaving the turbine for the brine heater of the desalting plant. Thermodynamic considerations define dual-purpose plant profit when the ratio of water-to-power demand is between certain limits.

Electricity cannot be stored and its production has to meet the actual power demand. Water can be stored, up to the existing facilities, and this gives to the dual purpose plant a certain degree of flexibility in operation. The ratio of the water output to the power output is an important parameter in the economic analysis of dual-purpose plants, as the two products are not necessarily consumed by a single market.

To obtain this requirement the size and characteristics of each component of the dual-purpose plant must be selected in such a way, taking the power and water demand curves in consideration, as to arrive at the optimum cost. It should be noted that power and water demand may present daily and seasonal variations.

The ratio of the water output to the power output is an important parameter in the economic analysis of dual purpose plants. As the two products are not necessarily consumed by a single market, it is important to consider what product ratio can be marketed and how the costs of the two products are affected by varying the product ratio.

Many of the MSF desalination plants in the Arabian peninsula are dual-purpose plants producing electricity and desalinated water.

Water Reuse

The heavy pollution of river, lake or other natural land waters and the restricted sources of water in some places over the world led to the application of desalination methods to treat industrial or municipal effluents for reuse, either for drinking and household purposes or as process water.

The great variety of the raw water to be treated by a desalination process for reuse affects not only the selection of the

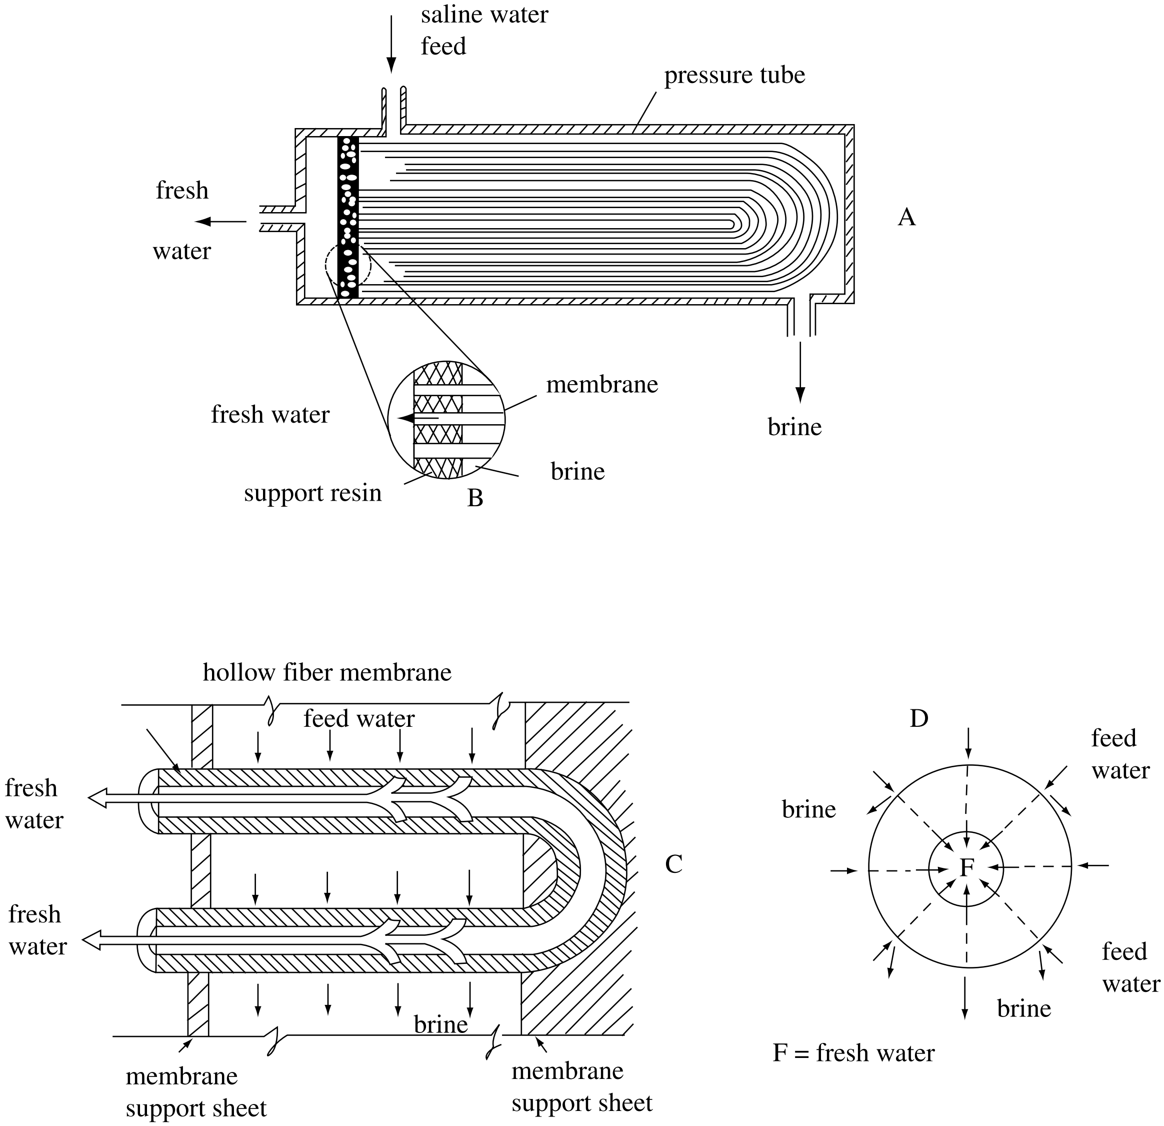

FIGURE 20 Reverse osmosis hollow fiber module, A. Millions of fiber loops, like hairpins, have both ends encapsuled in an epoxy tube sheet or short cylinder enclosed in the flanfed water end on right. Magnified section of the end of these threaded-fine fibers is indicated in B. C is a magnified hollow fiber and D its cross section. The saline water passes on the shell side from the feed at the left end to reject off the concentrated brine on the right. The permeate of fresh water discharges from the center of the hollow fiber, D, and from the center of the module A.

process but also the proper operation of the plant and the pretreatment needs of the desalination process. Reclamation of waste waters can be more efficient by combining desalination methods, i.e., electrodialysis and reverse osmosis, electrodialysis-distillation etc., depending on the raw water and the specifications.

Desalting processes are more expensive than conventional methods for purification of wastes but they provide the specific requirements for recycling. The recycling of the waste waters eliminates also the disposal of these waters, even partly purified, to already polluted streams, especially in land regions where the disposal can be limited by concentration and element content.

CONCLUSIONS

Fresh water, Man's greatest necessity, becomes more scarce every day, especially in certain places around the world, and this scarcity limits industry, agriculture and exploitation of various resources directly necessary for mankind and affects our lives in many ways.

Desalting processes, on the other hand, can provide freshwater in large quantities when and where it is needed. Nevertheless, desalinated water is an industrial product having higher cost than natural water resources, as all commercial products. Approximately 50% of fresh water costs are made up of variable charges, principally plant cost.

Large capacity plants usually produce, to some extent, cheaper water than small capacity plants.

Energy is usually an expensive item. The proposal to use cheap waste heat from nuclear plants failed, due to many reasons connected to the coupling of the two systems. Today the problem is reexamined and the trends are in favor of nuclear desalination. Nevertheless, no large plants have been erected.

The two leading processes of desalination are the MSF distillation and the reverse osmosis. In Table 3 the costs of the two processes are compared.

TABLE 3
MSF versus RO seawater desalting costs

	Plant capacity m^3/d (mgd)			
	3.8(1)	11.4(3)	18.9(5.0)	37.9(10.0)
Total capital cost $ × 10^3				
MSF	8.621	19.737	30.928	54.337
RO	5.887	15.581	24.082	43.01
Total operating $ × 10^3				
MSF	2.064	4.94	7.785	14.401
RO	1.758	4.675	7.404	13.806
Cost of product water				
MSF $/$m^3$ ($/kgallons)	1.65 (6.29)	1.32 (5.01)	1.25 (4.74)	1.15 (4.38)
RO $/$m^3$ ($/kgallons)	1.41 (5.35)	1.25 (4.74)	1.19 (4.51)	1.11 (4.20)

Viscosity, dynamic	η	N · s/m^2 or Pa s
Viscosity, kinimatic	v	m^2/s
Volume	V	m^3

Oil fired distillation plants require about 0.5 barrels of oil per m^3 produced fresh water with a performance ratio around 10. Solar distillation or solar-driven desalination have free energy but are still very expensive. To produce one m^3 of fresh water by conventional solar distillation the solar energy equivalent to oil is about 1.3 barrels of oil with a performance ratio of about 5. Solar energy is now used indirectly to drive conventional small size desalination plants and one day the sun's energy may be trapped 100%, not 2% as is the reality today.

In Figure 21 the increases in capacity of the desalination processes are presented by process, starting from the years of their commercial application.[5]

DISINFECTION

INTRODUCTION

Disinfection is a term which has for many years been used with different shades of meaning. It has frequently been confused with antisepsis which, although analogous to disinfection (see later), does not strictly have the same interpretation. This, particularly when considered in conjunction with other terminology, means that any article dealing with disinfection must clearly define the sense in which the term is being used. Davis (1968) rather vaguely defines a disinfectant as "a material having powerful germicidal activity and suitable for use as such."

Fortunately, at least some of the confusion relating to disinfection and to similar, but not identical, terms has now been resolved.

The terms defined in this report have been classified as shown in Table 1, but only those applicable to this chapter will be defined here, together with the term *chemosterilizer* (Borick, 1968).

Sterilization is the process of destroying or removing all microbial life.

A *sterilant* (sterilizer) is an agent used in sterilization which destroys microbial life, including bacterial spores, and is thus distinct from a disinfectant. The term "sterilant" may itself be somewhat confusing, however, for a "chemosterilant" is sometimes used in the Untied States to denote a "chemical substance used to sterilize insects and render them incapable of reproduction on mating with non-sterile partners" (Borick, 1968). Davis (1968) defines a sterilant as a disinfectant suitable for use in the food industry.

TABLE 1

Terminology[a] used in sterilization and disinfection

I. Definitive terms	II. Terms in common use
Sterile	Disinfectant
Sterilization	Disinfectant
Sterilizing agent	Antiseptic
-cide[b]	Antisepsis
-stat	Sanitizer
-statis	Sanitization

[a] British Standard Glossary of terms.

[b] Not germicide.

A *sporicide* is a chemical agent that kills bacterial spores.

A *chemosterilizer* (Borick, 1968) refers to a chemical compound which is used to destroy all forms of microbial life, and is thus the same as a sterilant defined above. The term has not been widely used.

Disinfection is the destruction of microorganisms but not usually bacterial spores. Commercially, the term applies solely to the treatment of inanimate objects, and does not necessarily imply that all microorganisms are killed, but rather that they are reduced to a level not normally harmful to health.

Antisepsis is the destruction of microorganisms, but not bacterial spores, on living tissues—not necessarily killing all microorganisms, but reducing them to a level not normally harmful to health. The term is thus analogous to disinfection.

A *sanitizer* is a disinfectant with the connotation also of cleansing; it is used mainly in the food and catering industries.

The suffices "-cide" and "-stat" may be added to various words to give a precise meaning, e.g., bactericide means a substance which kills bacteria but not spores, bacteriostat (bacteristat) a substance which inhibits the growth of bacteria, thereby producing the state of bacteriostasis. Other terms which are frequently used in this context include the following: sporicide (see earlier), fungicide, fungistat, virucide, microbiocide and biocide.

Not all authorities would agree with all of the definitions listed, and one term in particular which might be hotly disputed is "antiseptic." This is often used to denote a chemical agent usually applied to human skin and acting either by destroying microorganisms or inhibiting their growth (Olivant and Shapton, 1970).

Another term which is frequently employed is "detergent-sterilizers" or "detergent-sterilants"; these consist of two components, one of which has a cleansing action, and the other an antimicrobial activity. Unfortunately, "sterilizer" or "sterilant" has an absolute meaning (see above) and this would imply that a detergent sterilizer (sterilant) is sporicidal as well as being lethal to other microorganisms, whereas those compounds which comprise the "sterilizer" or "sterilant" component are usually not sporicidal. There is probably, however, need of a term which includes the word "detergent." Foster *et al.* (1953) use "sanitization" to denote the application of a bacterial process sufficient to render dairy equipment approximately sterile, this also implying that pathogens likely to be associated with such equipment and with eating and drinking vessels will be killed. Davis (1968) has employed the name "detergent-sterilant" throughout his review, although, as pointed out earlier, his definition of a sterilant differs from that above. Throughout the present chapter, "sanitizer," without quotes, will be employed rather than these other terms.

KINETICS

It is tempting to imagine that the application of an appropriate disinfection procedure will result in immediate elimination of all microorganisms from the site of interest. This temptation is often fostered by various advertising interests in pursuance of their sales campaigns. However, a cursory inspection of the literature soon dispels this cosy, over-simplified view. Disinfection has been shown repeatedly to be not only a gradual or even prolonged, process, but also a complex one.

Almost invariably, investigation into the course of disinfection processes have involved the study of purified cultures of microorganisms (usually bacteria) under specified conditions. This has led to certain criticisms that such systems are too far removed from reality to be of practical significance. While it is true that considerable caution must be exercised in applying the results of these studies to practical situations, the experimental systems are still far from simple, and have yielded much useful information.

Survivor Curves

The most common method of monitoring the progress of a disinfection process is by means of viable counting techniques. These suffer from certain inherent limitations. In particular, the absolute values obtained are dependent on the specific technique and the experimental conditions associated with it; and in addition, cells which have been exposed to the process, may respond quite differently from those examined prior to exposure. In order to obviate this difficulty, alternative methods of assessing "vital activity" have been suggested, usually biochemical in nature. Unfortunately, while the greater simplicity of these methods allows more precise measurements to be made, the killing of microorganisms usually involves a whole series of complex reactions, which makes correlation of the results rather difficult. Despite their faults, viable counting methods do reflect the complexity of the killing process.

The usual scheme of events is to expose the chosen culture of microorganisms to the disinfection process of interest, under controlled experimental conditions. Estimates of the viable population density of the system are made by performing viable counts on representative samples removed from the system: see, for example, Prince *et al.* (1975). For convenience, these estimates are usually plotted graphically against time of exposure or occasionally dosage of the disinfection agent employed. While the estimated numbers of organisms may be plotted directly, they are usually converted to a proportional basis such as "surviving fraction" or "percentage survivors," since this facilitates visual comparison of the results.

The simplest graph so obtained is the arithmetic plot which invariably exhibits a curve of similar general form to Figure 1. The main point of interest about this curve is that it indicates that the rate of disinfection varies inversely with the number of surviving organisms. This is interpreted as an indication that the individual cells of the culture exhibit differing sensitives to the process, i.e., there is a distribution of resistances. Unfortunately, curves of this type are difficult to analyze or to compare visually, and so the survivors are often plotted in a logarithmic fashion. This results in a whole "family" of possible results, as shown in Figure 2.

Figure 2(a) shows the simplest result, the familiar straight line which is often prized for its ease of characterization. It also possesses the sometimes dubious advantage of ease of extrapolation; a property which should be utilized only with extreme caution. This graph indicates that the rate of disinfection is inversely proportional to the logarithm of the number of surviving organisms. The similarity between this situation and the kinetics of a first-order chemical reaction has caused this type of response to be described as unimolecular or monomolecular. It is important to stress, however, that the description applies to the graphical response of the system; for it would be extremely naive to assume from this that the mode of death of the cells is attributable to a first-order chemical reaction. The straight line may be described mathematically by the equations:—

$$k = \frac{1}{t}\log\left(\frac{N_0}{N}\right)$$

where

k = rate constant or slope of line
t = time elapsed
N_0 = number of viable cells initially
N = number of viable cells at time t

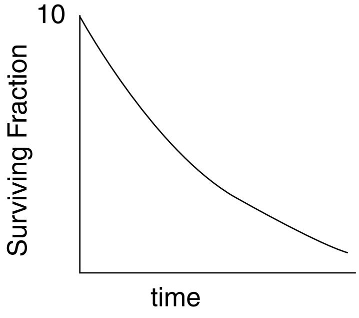

FIGURE 1

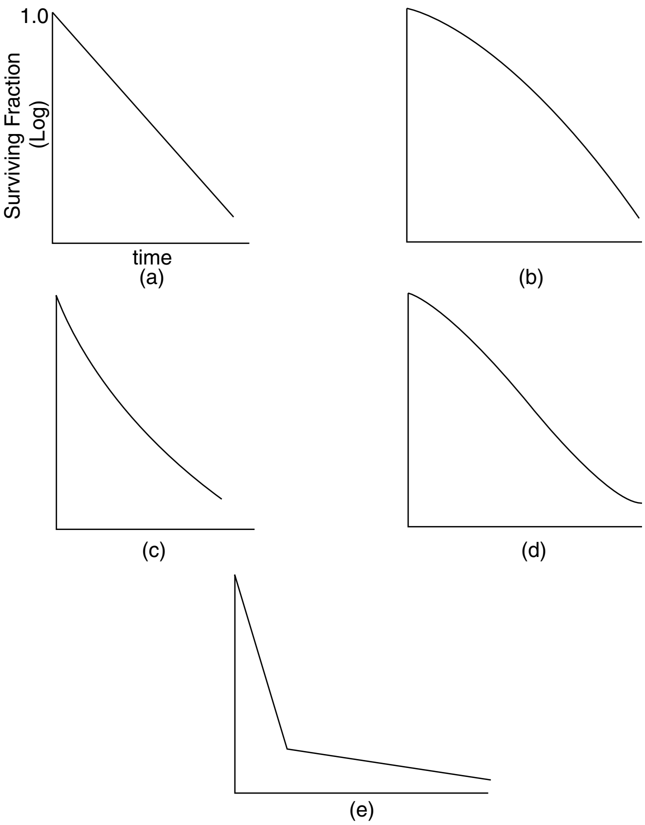

FIGURE 2

or, if natural logarithms are used:—

$$\frac{N_0}{N} = \exp(kt).$$

These equations have led to the alternative and preferred descriptions of the response as being exponential or logarithmic. Since the number of viable cells decreases throughout the process, then the rate constant, *k,* is always negative in character.

The two curves shown in Figures 2(b) and 2(c) illustrate similar, though opposite, deviations in response from the straight line case. These are described, according to their shape, as concave or convex, and qualified by the additional designation upward or downward, to indicate orientation. The graphs indicate that the rate of disinfection changes gradually in the early stages, but then assumes a more steady state of change similar to that in the straight case. In Figure 2(b), the rate of disinfection is relatively slow at first, but gradually increases to a steady, limiting value. Various interpretations have been suggested to account for this change; among them, that the distribution of resistances between the individual cells exhibits a relative deficiency of cells of low resistance; or alternatively, that the cells must pass through one or more intermediate stages before becoming sensitive to the disinfection process in question. The weakness of such interpretations is underlined by the fact that changes in the experimental conditions often result in a change in the shape of the graphical response. Figure 2(c) illustrates a relatively fast rate of disinfection initially, which gradually decreases to a steady, limiting value.

In Figure 2(d) is illustrated the most common deviation from the straight line response, the sigmoid curve. Responses of this type are more easily demonstrated in systems employing a moderate rate of disinfection. As the rate of disinfection is increased, the limitations of viable counting techniques make it more and more difficult to monitor the progress of the process with any precision. This results in the apparent response becoming indistinguishable from the straight line case. It is sometimes suggested that the sigmoid response is the most common situation encountered, but that it is often unrecognized due to the practical difficulties experienced. The sigmoid response is usually interpreted as an indication that the distribution of resistances between the individual cells is of the log normal type. Complete agreement with this model distribution is indicated when the sigmoid curve is symmetrical.

Figure 2(e) illustrates a response of particular interest. The graph consists of two parts, both of which are linear but of different slope, with a fairly sharp transition between the two. This would appear to indicate a fairly rapid rate of disinfection initially, followed by a fairly sharp transition to a lower, but steady, rate. Such a sudden transition naturally engenders interest, if not suspicion. It has been suggested that this type of response indicates the presence of two distinct groups of cells, each of which exhibits its own characteristic distribution of resistances. Experiments with a mixture of two bacterial cultures of different identity, whether obtained different species, or consisting of spores and vegetative cells of the same species, can be shown to yield this type of response. The first part of the graph corresponds to the usual response of the more sensitive component, and the second part to that of the more resistant component. However, at relatively low temperatures and humidities, exposure of nominally homogeneous cultures to ethylene oxide gas often yields this type of response. While it is sometimes suggested that this indicates the presence of two distinct groups of cells, as discussed above, it must also be considered that not only can this phenomenon be demonstrated with cultures apparently homogeneous to other sterilization methods, but also that this two part response reverts to the exponential type on increasing the temperature or humidity of the system.

As indicated in the foregoing discussion, consideration of the shapes of survivor curves may provide useful circumstantial evidence on which to base hypotheses relating to the response of cell populations to disinfection processes. However, as also indicated in the discussion, the operative word is "circumstantial."

Empirical Parameters

While a survivor curve illustrates the response of a cell population in terms of variation in number of survivors with time (or dose) of disinfection treatment, this is essentially a static situation since all other factors are held constant. Often, it is the variation in response of the system to changes in experimental conditions which is of particular interest. This variation in response may be monitored by constructing families of survivor curves, one curve for each level of the factor being varied. Comparison of curves within these families indicates the nature of the change in response.

The two factors most prominent in the regulation of disinfection processes are temperature and concentration of disinfectant. For both of these factors, it is found that their influence on the disinfection process varies in a regular manner over a fairly wide range of conditions. As a result, empirical parameters have been derived which enable the influence of these two factors to be characterized in a convenient form.

Temperature Coefficient

In general, it is found that the activity of a disinfectant varies directly with the temperature, i.e., the higher the temperature the greater the activity. This change in activity may be quantified by expressing the disinfection rates observed at two different temperatures as a ratio. The value of this ratio is found to remain reasonably constant over a wide range of temperature. This may be expressed mathematically:

$$\theta^{T_2 - T_1} = k_2/k_1$$

where k_1 and k_2 are the rate constants at temperatures T_1°C and T_2°C, respectively, with T_2 greater than T_1. The constant, θ, is termed the temperature coefficient, and assumes a numerical value which is characteristic of the agent and, to a certain extent, of the organism, employed. The superscript $(T_2 - T_1)$°C is necessary to indicate the temperature difference. Since the disinfection rate is inversely related to killing or extinction time, the latter may be used instead. The expression then becomes

$$\theta^{T_2 - T_1} = t_1/t_2$$

where t_1 and t_2 are the extinction times at temperatures T_1°C and T_2°C, respectively. At high value for θ indicates that the process is relatively sensitive to temperature changes.

It is usual to find two versions of the temperature coefficient in most common use: the coefficient for a 1°C temperature change, θ, when the superscript is usually omitted; and the coefficient for a 10°C temperature change, θ_{10}, which may be sometimes expressed as Q_{10}. The popularity of the 10°C coefficient follows from its use to characterize changes in reaction rates in chemical systems. This enables interesting comparisons to be made between disinfection processes and non-living chemical reactions. Attempts have been made to deduce modes of death of the organisms by such comparisons. However, subsequent biochemical investigations have tended to disagree with these deductions.

Dilution Coefficient

The activity of disinfectants under otherwise constant conditions is found to vary directly with the concentration of disinfectant employed over a considerable concentration range. As before, killing or extinction times are usually employed as a measure of disinfection rate. The effect of concentration may be expressed mathematically as:

$$c^{\eta}t = \text{a constant}$$

or:

$$\eta \log c + \log t = \text{a constant}$$

where

c = concentration of disinfectant
t = extinction time
η = dilution coefficient.

A high value for the dilution coefficient indicates that the process is relatively sensitive to changes in concentration of disinfectant. The dilution coefficient is sometimes referred to as the concentration exponent.

Other Factors Influencing Activity

The antimicrobial activity of several disinfectants is influenced to a considerable extent by changes in pH. For example, a rise in pH results in a decrease in the activity of phenols (Bennett, 1959), organic, acids, compounds liberating chlorine, benzoic acid and iodine, although iodine is less affected by acidity than is chlorine. An increase in pH increases the dissociation of phenols and benzoic acid (Wedderbern, 1964); chlorine in water forms HClO, which is dissociated with a rise in pH with a concomitant loss of activity. In contrast to the above, however, there is an increased microbicidal activity of the quaternary ammonium compounds (QACs) and of acridines (Foster and Russell, 1971); in the case of QACs, the effect of pH is considered by Salton (1957) to be on the cell rather than the disinfectant molecule, since the number of negatively-charged groups on the bacterial surface will be increased as the pH rises, thus influencing the number of positively charged molecules which can be attached.

Another factor which influences the activity of certain antimicrobial agents is organic matter, e.g., the presence of blood, serum, pus, etc. In general terms, the more chemically reactive a compound, the greater the effect of organic matter on its activity. This is particularly true with the hypochlorites. other examples are provided under individual compounds later.

Mathematical Models

A considerable number of mathematical models have been derived at various times, in attempts to reconstruct the disinfection process. These have utilized deterministic, probabilistic, and thermodynamic approaches to the problem, and have been reviewed in detail by Prokop and Humphrey (1970).

In general, these models are based on attempts to reconstruct the survivor curves obtained, even though, as already discussed, these are liable to be changed by changes in experimental conditions. In addition, they usually involve preliminary assumptions concerning the nature of the disinfection process. Consequently, attempts to deduce mechanisms of killing from these models tend to be rather disappointing. They are, however, useful in terms of concise descriptions of the results of the process; and as further biochemical information on modes of killing becomes available, their usefulness and reliability should increase further.

DISINFECTANT TESTING

The testing of disinfectants is a topic with a long history of controversy. Differing opinions on the merits and relevance of various methods are legion, and have been the cause of many heated exchanges between those holding them. The wide variety of methods may most conveniently be considered under the headings of screening, standardization and "in-use" tests, although there is a degree of overlap between the three categories. The interested reader should consult the papers by Forsyth (1975), Miner *et al.* (1975) and Reybrouck (1982) for further information.

Screening Tests

These are usually of the simplest type, since they are speculative by nature, and often involve the testing of large numbers of disinfection agents or formulations; both time and cost usually dictate this simplicity. The actual methods employed vary according to the physical characteristics of the disinfectant and the type of use envisaged. Ideally, any test should be as realistic as possible, although for screening purposes this will be subject to the requirements of simplicity discussed above.

Disinfectants which are soluble or miscible in water are often incorporated in microbiological culture media which are then inoculated with suitable microorganisms. After incubation under appropriate conditions, the inoculated media are examined for growth of the organisms, absence of growth indicating that the inoculum has been inhibited. Where the continuous presence of the disinfectant is inappropriate, then the method is modified to include a suitable means of removing or inactivating the disinfectant after a predetermined exposure time.

Other disinfectants may be tested in a similar manner, by arranging for inocula of suitable organisms to be subjected to standardized exposure to them. After exposure, the organisms are inoculated into suitable culture media, and incubated as before. Since the end-point in these tests is the death of all the organisms involved, this type of test is often referred to as an Extinction Test.

The phrase "suitable organisms" used above, represents one of the key factors in the testing of disinfectants. A disinfectant is expected to kill all undesirable organisms, which usually refers to organisms injurious to health (see previous section). Test organisms may be chosen, therefore, either for their resistance to disinfection or, like *Salmonella typhi,* for their medical significance. Although the designation "undesirable organisms" covers a wider range of life-forms, most disinfectant testing has employed various species of bacteria for reasons of convenience. In retrospect, this does not appear to have been a significant disadvantage, since activity against bacteria usually coincides with that against the other life-forms. However, although it is recognized that bacterial spores are much more resistant to disinfection than the vegetative forms, the latter have, with few exceptions, invariably been used in testing. This is partly due to convenience, but it should be noted that there are many disinfectants marketed which under normal conditions of use are incapable of killing bacterial spores. This has been countered, in certain quarters, by re-defining a disinfectant as a chemical agent capable of killing bacteria but not necessarily bacterial spores (see previous section).

Standardization Tests

This is the area which has given rise to the greatest amount of contention. In most cases, this has been due to misinterpretation and misapplication of the results of testing in situations where they have little, if any, relevance. The standardization of disinfectants usually requires the use of microbiological techniques rather than chemical assay. Even when chemical characterization of the active agent(s) involved is possible, the activity of a disinfectant will usually be significantly influenced by factors concerned with the formulation and method of use of the product. However, although the disinfectant may be standardized in terms of its intended biological effect, this is carried out under specific, controlled conditions. Depending on the similarity of their circumstances, the results from standardization tests may, or may not, be capable of extrapolation to practical situations. This is where the controversy tends to arise.

The most popular methods of testing for standardization purposes have been extinction tests. These are basically similar to the general method discussed in the previous section, except that the procedure and materials used are rigidly standardized in order to achieve best reproducibility of results. In addition, the most widely used tests employ the pure chemical, phenol, as a control of the resistance of the test organisms used. Since results are expressed by comparison of the activities of phenol and the disinfectant being tested, these tests are referred to as Phenol Coefficient methods. The most popular and official versions in use are the Rideal–Walker Method (as modified by B.S. 541), the Chick–Martin Method (as modified by B.S. 808), and the Association of Official Agricultural Chemists (AOAC) Phenol Coefficient Method (1970). Details of these tests may be found in the appropriate publications.

While the use of phenol as a control on the resistance of the test organisms is extremely valuable, it has led to widespread assumptions that the ratio of activities of disinfectant and phenol indicated by the phenol coefficient will hold true in all circumstances. This, of course, is far from true. The AOAC (1970) attempted to improve this situation by introducing a Use-Dilution Method. This test is based on the hypothesis that disinfectants in use shall be at least as efficient as 5% phenol, and that a dilution of twenty times the phenol coefficient should achieve this. Accordingly, this dilution is tested against standardized cultures in order to confirm this, or alternatively, in order to determine a correction factor.

Whereas the extinction methods discussed above evaluate the extinction concentration corresponding to predetermined exposure times, Berry and Bean (1954) devised a test for evaluating extinction times for chosen disinfectant concentrations. While the test is only applicable to phenolic and other easily inactivated disinfectants, it has been claimed to be at least as reproducible as other methods in common use (Cook and Wills, 1954). The method of assessing the end-point of the reaction has been further improved by Mathei (1949).

Methods other than extinction tests for standardizing disinfectants include various methods based on assessment of cessation of vital enzyme activities. The enzymes involved have generally been certain oxidases or dehydrogenases (Sykes, 1939; Knox *et al.*, 1949). In a less specific manner, inhibition of respiration has been used as a method of assessment (Roberts and Rahn, 1946). The controversy surrounding these methods centers around the problem of correlating enzyme activity with viability.

Other methods which have been proposed include measurement of post-incubation opacity corresponding to standard survivor levels (Needham, 1947), and also measurement of cell volume increase following post-exposure incubation (Mandels and Darby, 1953).

The range of tests discussed above is by no means exhaustive, and only covers general purpose tests applicable to water-misible disinfectants. Any number of alternative tests could be devised by appropriate selection and standardization of the various parameters. In addition, there are numerous tests which can be, and have been, devised in order to standardize disinfectants intended for specific uses such as sporicidal or tuberculocidal duties (AOAC 1970).

Methods of standardizing disinfectants other than those to which the above discussion applies are usually designed more closely around the particular use envisaged. Thus, a considerable element of actual, or simulated, in-use testing is usually involved. For convenience, they are best discussed in the following section.

A recent test is the Kelsey–Sykes test (Kelsey and Maurer, 1974), which is a form of capacity test. In this, incremental additions of test organisms are made to appropriate dilutions of test disinfectant and aliquots are removed for detecting survival immediately prior to the next addition of organisms. On the basis of this method, use-dilutions of the test disinfectant (which need not necessarily be a phenolic) under clean and dirty conditions can be recommended to hospitals, which should then check them during in-use tests (see also Coates, 1977; Cowen, 1978).

In-Use Tests

The previous two sections have dealt with testing methods applied in the laboratory, which yield information primarily of value to the disinfectant manufacturer. The "consumer," however, is almost solely concerned with the performance of disinfectant materials under the conditions of use which are associated with the application envisaged. To this end, he is more interested in testing methods which resemble, as closely as possible, these practical conditions. However, the foregoing remarks should not be taken to imply that laboratory standardization methods are completely arbitrary. In view of the greater difficulty experienced in killing organisms which are present as dried surface films, as opposed to those in fluid suspension, many standardization tests have employed films on various surfaces as their inocula. Surfaces used have included silk thread (Koch, 1881), garnets (Kronig and Paul, 1887), glass cover-slips (Jensen and Jensen, 1933), glass cylinders (Mallmann and Hanes, 1945), glass slides (Johns, 1946), stainless steel cylinders (AOAC Use-Dilution Confirmatory Test, 1960), and glass tablet tubes (Hare, Raik and Gash, 1963). It should be noted that while these surfaces represent a step toward the practical situation, they nevertheless comprise a collection of laboratory "artifacts" when compared with real situations. A nearer approach was achieved by use of surfaces such as rubber strips (Goetchins and Botwright, 1950) and glazed, waxed, and rubber tiles (Rogers, Mather and Kaplan, 1961).

Where the physical size of articles required to be disinfected is fairly small, it is quite feasible to carry out in-use testing in the laboratory. Hence metal trays were used by Neave and Hoy (1947), 10 gallon milk churns by Hoy and Clegg (1953), and small drinking glasses by Gilcreas and O'Brien (1941). Similarly, scalpels, syringes and similar small items may conveniently be subjected to in-use testing in the laboratory. Where the physical size of the system is somewhat greater, then the laboratory must be forsaken in order to carry out on-site testing. Typical examples of such situations include hospital walls and floors, and industrial or dairy processing machinery. The outstanding value of in-use testing arises from the fact that results obtained are directly applicable to the system without the need for interpretation and extrapolation, and that practical difficulties such as short contact times or inaccessibility of certain areas can be accounted for.

The choice of test organisms usually reflects either of two main approaches. The simplest approach is to inoculate the system artificially with organisms considered to be of practical significance in the particular application. This significance may be due to the resistance to disinfection of the organism, or alternatively, to its practical effect on the system should it survive the disinfection process. In order to simulate the practical system, the organisms may be suspended in appropriate materials before inoculation. An example would be the use of milk as a suspending fluid in tests on dairy disinfection. A slight variation on this approach is to inoculate with indeterminate mixtures of likely organisms obtained from natural sources, such as low quality, raw milk. The second approach involves the use of the normal, preexisting flora of the system which has arisen during normal use. Investigations of this flora before and after the disinfection process would provide direct evidence as to whether the process has achieved its object. One difficulty with this approach is that of providing suitable growth conditions for all of the possible species of organisms which may be present. Also, the normal flora is likely to vary with time, and so, ideally, this method is best applied in the form of a routine monitoring procedure. Both of these difficulties produce an increase in the financial cost of this type of approach, but the reliability of the results obtained is correspondingly high. The ideal method would involve a combination of these two approaches: an initial test with known resistant organisms in order to indicate the upper levels of activity which may be required; this to be followed by routine monitoring tests to guard against both unsuspected resistance amongst the normal flora, and unforeseen breakdowns in the method of application.

Any testing method which involves the use of surface films is subject to the problem of physical recovery of the organisms. In the case of small surfaces, the articles can often be placed in or on a suitable nutrient medium, and provided this allows contact between the medium and the organisms in the film, then growth takes place. Where larger or less accessible surfaces are concerned, then the simple direct method will have to be replaced by some kind of sampling technique. Sampling techniques vary widely and not all are applicable in all situations. In the case of accessible surfaces, simple methods such as wiping with sterile swabs may be used; or alternatively, flooding the surface with a sterile liquid, some or most of which is then removed by swab or pipette. An interesting alternative consisting of a sterile, agar medium, "sausage" was devised by Ten Cate (1965). The exposed transverse surface of this sausage is pressed against the surface to be sampled. After sampling a slice is cut from the sausage and incubated with the exposed side uppermost. A simple method which is used for sampling skin surfaces may also be used in other applications. This method employs adhesive cellophane tape. The adhesive surface is pressed onto the surface to be sampled, and then removed for transfer to a suitable medium. Where surfaces are inaccessible, as in pipes and processing machinery, then a rinsing technique is usually most convenient. The resulting liquid may be added directly to suitable nutrient media, or, if present in large bulk, may be filtered through membrane filters to remove the organisms. The resulting filter membrane is then transferred to a suitable medium.

One final problem which is of importance in all methods of testing which involve assessment of viability, is that of recovery and growth of the test organisms following exposure to the disinfectant. Organisms which have survived a disinfection process often show altered requirements for optimal growth. Response to physical conditions such as incubation temperature, as well as to biochemical conditions such as dependence on certain nutrients, may be completely altered from that of unexposed cells. While considerable effort has been made to derive efficient recovery methods (Flett *et al.*, 1945; Jacobs and Harris, 1960; Harris, 1963; Russell, 1964) the problem is so variable and so many combinations of factors must be considered, that it is far from being solved. There is general agreement that recovery methods should be selected which will allow maximum recovery of exposed organisms; but putting this into effect can be extremely difficult.

LIQUID DISINFECTANTS

Several chemical agents have long been employed for destroying microorganisms, although it is frequently asserted that such substances are without effect on bacterial spores. With many agents, however, this is untrue (Sykes, 1970; Russell, 1971, 1982). The most important substances are phenols and cresols, biguanides, chlorine-releasing compounds and other halogens, aldehydes, alcohols, quaternary ammonium compounds, mercury compounds, strong acids and alkalis and hydrogen peroxide. The majority of these are considered in detail below. Further information is provided by Hugo and Russell (1982).

Phenols and Cresols

Although Kronig and Paul (1897) and Chick (1908) showed that phenol was active against spores, the concentrations, 5%, employed, were considerably higher than those needed to kill vegetative bacteria. More recent studies have indicated that bacterial spores are not killed even after long exposure to phenols (Sykes, 1958, 1965; Loosemore and Russell, 1963, 1964; Russell and Loosemore, 1964; Russell, 1965, 1971; Rubbo and Gardner, 1965; Briggs, 1966). Of the bacterial spores. *Bacillus stearothermophilus* is the most resistant to phenol and *B. megaterium* the most sensitive (Briggs, 1966). However, in contrast to its lack of sporicidal activity, phenol is sporostatic at low concentrations.

Several factors influence the antimicrobial activity of phenols and cresols (Bennett, 1959; Cook, 1960; Bean, 1967):

1) Concentration. These compounds have high concentration exponents, η, which, as described above, indicates that they rapidly lose their antibacterial activity on dilution. This also means that dilution procedures can be used to prevent the carryover of inhibitory concentrations into recovery media when viable counts or sterility tests are being carried out (Russell, 1982; Russell *et al.*, 1979). Studies from Bean's laboratory (Bean and Walters, 1955; Bean and Das, 1966; Bean, 1967) are of interest, for they show that with dilute solutions of disinfectants with high intrinsic activity, e.g. benzylchlorphenol, the high proportion taken up by the cells means that the concentration remaining is only weakly bactericidal, so that the surviving cells do not meet lethal conditions.
2) Temperature. The bactericidal activity of the phenols and cresols increases rapidly with an increase in temperature. Examples of temperature coefficient (θ^{10}) against *E. coli* at 30–40° (Tilley, 1942) are: phenol 8.4, *o*-cresol 6.9, *p*-cresol 5.6.

Of importance, also, is the finding that these substances are sporicidal at elevated temperatures (Berry *et al.*, 1937; Russell and Loosemore, 1964). As a result of the findings of Berry *et al.* (1937), one method of sterilizing certain injections by heating them with 0.2% w/v chlorocresol is still an official method in Britain (British Pharmacopoeia, 1980).

3) pH. The phenols are more active at an acid pH than in alkaline solution, as phenates (phenoxides) are formed at high pH. Acid pH also results in a more effective, although still slow, sporicidal action (Sykes and Hooper, 1954).
4) Organic matter. The presence of organic matter may decrease the antimicrobial activity of these compounds; this was early recognized in the design of the Chick–Martin test for evaluating phenolic disinfectants (Chick and Martin, 1910; Garrod, 1934, 1935). The results do, however, depend on the actual phenol used and on the kind of organic matter, and the interference is less than with other disinfectants such as the quaternary ammonium compounds (Cook, 1960).
5) Oxygen tension. Anaerobic bacteria are generally more resistant than aerobes to phenols. Moreover, facultative organisms, e.g., *E. coli,* are more resistant when grown under anaerobic conditions.
6) Type of organism. As described above, these compounds are bactericidal and sporostatic at low concentrations, and sporostatic and not sporicidal even at high concentrations. As a group, however, they are also fungicidal to several moulds, and use is made of this in the inclusion of cresol and chlorocresol as preservatives in creams which are liable to fungal contamination (Wedderbern, 1964).

   Morris and Darlow (1971) have pointed out that phenolic compounds with high R-W coefficients are effective against some viruses, but that they are generally too variable in their activity to be suitable as general virucidal agents.
7) Chemical nature. Dihydric and trihydric phenols (Figure 3) are generally less active than phenols, and alkylation of monohydric phenols to give cresols potentiates the antimicrobial activity. Also halogenation of the phenols increases their activity (although to a lesser extent if the halogenation is in the ortho- than in the paraposition) and this is even more pronounced when accompanied by the introduction of aliphatic or aromatic groups into the nucleus, e.g., *p*-chloro-*m*-cresol (chlorocresol). This increase in antimicrobial activity is, however, paralleled by a decrease in water solubility.

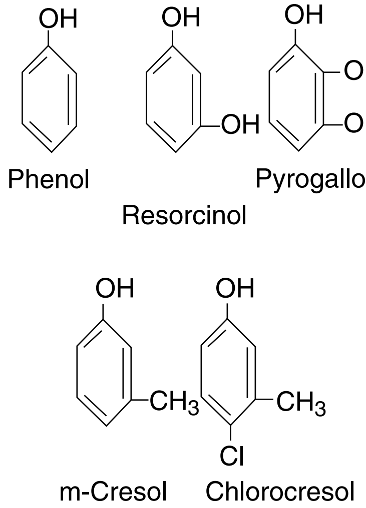

FIGURE 3

To overcome this decrease in aqueous solubility, various soaps have been used to render water-soluble (solubilize) these substances. However, the effect of soap on the biological efficacy of the phenols depends on two factors, firstly the nature of the soap, and second the proportion of soap to phenol. Solution of cresol with soap (Lysol, BP), for example, contains 50% of cresol in a saponaceous solvent and has a bactericidal activity which depends on the nature and amount of soap used. The ratio of cresols to soap may be critical, the optimal cresol–soap ratio being of the order of 2:1. In lysol, the soap content is *c.* 22%, and the ratio is thus 2.2:1. The soap solutions are able to solubilize insoluble phenols in the micelles; the critical micelle concentrations (cmcs) of different soaps vary, and this explains differences in bactericidal action noted above.

Lysol and the so-called "black-fluids," which consist of the lower coal tar phenols, are formulated in sufficient soap so that they are retained in solution when diluted with water. In contrast, the white fluids consist of concentrated emulsions of high boiling phenols stabilized with protective colloids; they can be diluted with hard or soft waters, whereas black fluids should be diluted with soft waters only.

Micelles have been considered as being reservoirs of phenols, so that when the concentrated solution is diluted before use, the phenols are released by dilution below the cmc to give a highly active solution. Two types of system have been investigated experimentally in attempts to assess the exact role of the micelles; these are (a) constant phenol concentration, and (b) a constant phenol/soap ratio (Berry, 1951; Berry and Briggs, 1956; Berry, Cook and Wills, 1956; Cook, 1960). With a constant phenol system, there is a rapid increase in bactericidal activity below the cmc of the soap which could be the result of an increased uptake of phenol together with an increased permeability of the bacterial surface (Mulley, 1964); however, above the cmc in this system, there is a decrease in bactericidal activity, as the increasing numbers of micelles being formed compete for the phenol with the cell surface. In systems where there is a constant phenol/soap ratio, there is likewise an increase in activity below the cmc, and a decrease in activity at the cmc. However, in this system the activity again increases at higher soap concentrations; thus, this increased bactericidal activity parallels a saturation of the soap micelles with the phenol. The reasons for this remain unclear, for although the soap itself could contribute to or be responsible for the increased activity, systems in which the soap has a low activity give similar results. The actual role of the micelles is thus difficult to assess. Of the two systems described, it is apparent that the system with the constant phenol/soap ratio is more important from the viewpoint of practical disinfection. It is necessary to use the lowest possible proportion of soap to phenol, thus giving a comparable situation to bactericides in two-phase systems, in which the bactericidal efficiency is related to the concentration in the aqueous phase (Bean and Heman-Ackah, 1965).

Phenol itself is an effective bactericide and anti-fungal agent, which is used as a preservative in some injections and creams; it is also the standard reference substance in some methods of testing phenolic bactericides (see earlier). Cresol, a mixture of *o*-, *m*- and *p*-cresol, in which the *meta*-isomer predominates, and of other phenols obtained from coal tar, is highly bactericidal and fungicidal. Apart from being the active constituent of Lysol, it is also used as a preservative in certain injections and creams. Chlorocresol is a powerful antimicrobial agent which, in conjunction with heat, is employed for the sterilization of certain injections. It is also used as a preservative in certain cosmetic creams and lotions, and is included in Sodium Benzoate and Chlorocresol Solution, which may be used for the storage of sterilized surgical instruments, the sodium benzoate delaying rusting. Chloroxylenol has low water solubility and is solubilized by means of soap, the solution being known as Roxenol. Its antimicrobial activity is markedly reduced in the presence of organic matter. Thymol is a potent bactericide and fungicide which, in the form of Glycerin of Thymol, is employed as an oral antiseptic. Hexachlorophane [2,2′-methylenebis(3,4,6-trichloro-phenol)] is most frequently used as a soap containing 2% of the substance; the effectiveness of this soap as a skin disinfectant may depend upon the accumulation of hexachlorophane on the skin. Pentachlorophenyl dodecanoate is extensively used as a fungicide and insecticide in the textile and packing industries. Unlike the parent molecule, pentachlorophenol, it is nontoxic to humans.

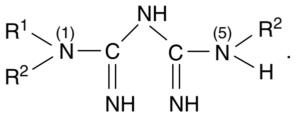
None of the above compounds can be relied upon to kill bacterial spores at ordinary temperatures.

Another group, related to the phenols, consists of the esters (parabens) of *p*-hydroxybenzoic acid (3-hydrobenzoic acid). Unlike benzoic acid, the dissociation of which increases with increasing pH with a corresponding decrease in activity, the parabens are active against bacteria and fungi over a fairly wide pH range. Their bactericidal and fungicidal properties increase within the homologous series, but this is paralleled by a decrease in aqueous solubility. The parabens are not sporicidal, and although on their discovery they were heralded as being the ideal preservatives, they are now used (often in combination of two or more) mainly as preservatives in various pharmaceutical and cosmetic products (Russell, Jenkins and Harrison, 1967; Parker, 1982).

The phenols and parabens have an effect on the cytoplasmic membranes of bacteria and fungi (Hugo, 1976a,b).

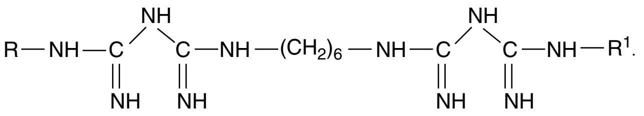
Biguanides and Bisbiguanides

Biguanides have the general formula



Three distinct antimicrobial actions of N^1, N^5-substituted biguanides have to date been recognized (Weinberg, 1968): germicidal, antiviral and antimalarial. Unfortunately, no one compound is generally active in more than one of these three categories. The requirements for each type of activity are fairly unique, e.g., for maximum broad-spectrum germicidal activity, both N^1 and N^5 should have a halogen-substituted aralkyl substituent.

Bisbiguanides have the general formula



For maximum broad spectrum germicidal activity R and R^1 should consist of a halogen-substituted aryl group. A number of bisbiguanides are known to be germicidal, and the most important member of this group is chlorhexidine (R and R^1 are both C_6H_5Cl).

Chlorhexidine was first described in 1954 (Davies *et al.*, 1954), and it is bacteriostatic in low concentrations; higher concentrations are bactericidal to several bacterial species, including strains of the genus *Proteus,* of which *Pr. mirabilis* is the most resistant, and *Pr. rettgeri* and *Pr. morganii* are the most sensitive to chlorhexidine, with *Pr. vulgaris* occupying an intermediate position. Some strains of *Ps. aeruginosa* may be highly resistant. Chlorhexidine also possesses antifungal activity. It is a membrane-active agent (Hugo, 1976a,b, 1982).

Chlorhexidine, the active constituent of "Hibitane," is used in surface disinfection, as an antimicrobial agent in eye-drops, and, in the presence of sodium nitrite to prevent corrosion, for the storage of surgical instruments.

Chlorine-Releasing Compounds

It was observed by Dakin (1915, 1916) that the commercial hypochlorites then in use were not of constant composition and contained free alkali and sometimes free chlorine. He thus developed a solution (Dakin's Solution or Chlorinated Soda Solution, Srugical) which is still in use today. The stability of free available chlorine in solution is dependent on a number of factors, in particular on the chlorine concentration, pH of the solution, the presence of catalysts, temperature, the presence of organic matter, and light (Dychdala, 1977).

The types of chlorine compounds which are frequently used are (1) Hypochlorites. These are cheap and convenient to use, and have a wide antibacterial spectrum (Davis, 1963). They possess potent sporicidal activity (Truman, 1971; Kelsey *et al.*, 1974; Waites, 1982) which may be potentiated by alcohols (Coates and Death, 1978; Death and Coates, 1979).

The hypochlorites are moderately effective against animal viruses.

The antibacterial activity of the hypochlorites decreases with increasing pH (Charlton and Levine, 1937; Weber, 1950; Ito *et al.*, 1967; Hays *et al.*, 1967), e.g., whereas 99% of spores of *B. cereus* are killed after 2.5 min at pH 6 by a solution containing 25 ppm available chlorine, nearly 8 hours are required for a comparable kill at a pH of *c.* 13 (Rudolph and Levine, 1941). At constant pH, the time to kill bacteria depends on the concentrations of available chlorine. The sporicidal activity of sodium hypochlorite may be potentiated by various compounds, e.g., by the addition of ammonia (Weber and Levine, 1944) or 1.5–4% sodium hydroxide (Cousins and Allan, 1967), notwithstanding the earlier comment about pH. In the presence of bromide, hypochlorite has an enhanced effect in bleaching cellulosic fibres as compared with hypochlorite alone, possibly because of a continuous generation of hypobromite when hypochlorite is in excess. A potentiation of the bactericidal effect of hypochlorite has been achieved by the addition of small amounts of bromide (Farkas–Himsley, 1964).

The antimicrobial activity of hypochlorites is considerably reduced by organic matter. However, the hypochlorites are used in the disinfection of water, dairy equipment and eating utensils. (2) Chloramine-T (sodium *p*-toluene sulphonchloramide). Dakin *et al.* (1916) considered that chloramine-T had a powerful germicidal action. It is bactericidal and sporicidal, although the rate of kill is slower than with the hypochlorites. Its activity is considerably higher at acid than at alkaline pH (Weber, 1950), and a drop of 10°C in the reaction temperature results in a 3–4 fold increase in the time necessary to kill microorganisms (Weber and Levine, 1944). Chloramine-T is employed as a wound "disinfectant," and as a general surgical disinfectant. It is nonirritant and nontoxic, in contrast to Dichloramine-T (toluene-*p*-sulphon-dichloramide) which although a powerful disinfectant is not used because of its toxicity and instability.

The mode of action of chlorine compounds is unknown, although several proposals have been made, e.g., the information of chloramines as a result of combination of chlorine with bacterial protoplasm, halogenation or oxidation reactions of chlorine with bacterial cells, changes in cellular permeability and an effect on enzyme systems. It has also been found, however (Bernarde *et al.*, 1967) that chlorine dioxide causes a marked and immediate cessation of protein synthesis in growing cells.

Iodine and Iodophors

Iodine in aqueous or alcoholic solution is considered by most authors (Gershenfeld and Witlin, 1950; Gershenfeld, 1956; Report, 1965; Sykes, 1970) to be a reliable and effective germicide which is lethal to vegetative bacteria, bacterial spores and acid-fast bacilli. Spaulding *et al.* (1977), however, consider that alcoholic iodine (0.5% iodine in 70% alcohol) possesses good activity against non-sporing bacterial and *M. tuberculoses* but none against bacterial spores, whereas Rubbo and Gardner (1965) state that bacterial spores are moderately resistant to iodine. Viruses are considered by Rubbo and Gardner (1965) to be moderately sensitive to iodine.

Iodine has a high fungicidal or fungistatic activity against yeasts and various moulds, but its antimicrobial properties are to a great extent inhibited in the presence of organic matter, since iodine is a highly reactive element.

Iodine is sparingly soluble in cold water, but more soluble in hot water. Stronger solutions can be made in potassium iodide solution or in aqueous alcohol. Iodine is more effective as a germicide at acid than at alkaline pH, but is less affected by pH than are chlorine compounds. The concentration of iodine to disinfect does not vary greatly with different types of microorganisms. Various types of iodine solution are used for the first-aid treatment of small wounds and abrasions, and in pre-operative skin "disinfection." Iodine has also been employed for the sterilization of surgical catgut (although this method is now little used) and is nowadays used for the disinfection of drinking and swimming pool water, the disinfection of instruments and of clinical thermometers, and the sanitization of eating and drinking utensils.

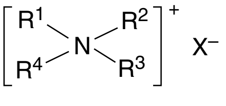
Unfortunately, iodine solutions stain fabrics and tissues and tend to be toxic. However, certain non-ionic surface-active agents can solubilize iodine to form compounds, the iodophors (Blatt and Maloney, 1961; Davis, 1962, 1963, 1968) which retain the germicidal activity of iodine, but not its undesirable properties; these iodophors are literally "iodine-carriers." They are active against bacterial spores, including pathogenic anaerobic spores (Lawrence *et al.*, 1957; Gershenfeld, 1962). It is the concentration of free iodine in an iodophor which is responsible for its microbial action; this has been well demonstrated by Allawala and Riegelman (1953) who made a log-log plot of killing time against amount of free iodine, and found that the 99% killing time of *B. cereus* spores was a function of the concentration of free-iodine in the presence or absence of added surface-active agent. The bactericidal properties of the iodophors are increased at low pH values, but their stability is unaffected (cf. hypochlorites). They may thus be employed with acids, e.g., phosphoric acid, to enhance their microbial action and also to assist in preventing the formation of film or milkstone (see later) in the dairy industry. The iodophors are considered (Davis, 1968) to be powerful detergents, although they do not dissociate protein as readily as do alkalis. The formulation of acidic solutions of iodophors is particularly useful when calcium or magnesium scale is encountered, but they can be corrosive, especially with galvanized iron.

Surface-Active Agents

Surface-active agents have 2 regions in their molecular structure, one a hydrocarbon, water-repellent (hydrophobic) group, and the other a water-attracting (hydrophilic or polar) group. Depending on the basis of the charge or absence of ionization of the hydrophilic group, surface-active agents are classified into (James, 1965):

1) Anionic agents, which usually have strong detergent, but weak antimicrobial properties, e.g., sodium lauryl sulphate.
2) Cationic agents, which have strong bactericidal, but weak detergent, properties. The term "cationic detergent" usually signifies a quarternary ammonium compound (QAC, onium compound), but this is not strictly accurate, as the concentration at which a QAC is germicidal is so low that its detergent activity is negligible.
3) Non-ionic agents, which consist of a hydrocarbon chain attached to a non-polar water-attracting group, which is usually a chain of ethylene oxide units, e.g., cetomacrogols. Non-ionic agents have no antimicrobial properties.
4) Ampholytic (amphoteric) agents, which are compounds of mixed anionic–cationic character, in which the charge can be similarly positive and negative. They are effective antimicrobial compounds, which are extensively used in the dairy industry.

The QACs are organically substituted ammonium compounds, in which the nitrogen atom has a valency of 5, four of the substituent radicals (R^1–R^4) are alkyl or heterocyclic radicals, and the fifth is a small anion. The sum of the carbon atoms in the 4R groups is more than 10. For a QAC to have a high activity, at least one of the four organic radicals must have a chain length in the range C_8 to C_{18}. The germicidal activities of the QACs were originally recognized in 1916, but they did not attain prominence until Domagk's work in 1935. They are primarily active against Gram-positive bacteria, with concentrations as low as about 1 in 200,000 being lethal; higher concentrations (*c.* 1 in 30,000) are lethal to Gram-negative bacteria, although *Pseudomonas aeruginosa* is highly resistant. The QACs possess antifungal properties, are sporostatic and not sporicidal (Russell, 1971) and are inactive against the tubercle bacillus. Their antimicrobial activity is markedly affected by organic matter, and they are incompatible with anionic surface-active agents, some of the non-ionic agents (such as Lubrols and Tweens) and the phospholipids, e.g., lecithin and other fat-containing substances (Russell, 1982; Russell *et al.*, 1979). The QACs exert their maximal bactericidal activity under alkaline conditions. Although the QACs are effective bactericidal and fungicidal agents, it has been found (Grossgebauer, 1970) that viruses are rather more resistant than bacteria or fungi.



Although several hundred QACs have been prepared and tested for antimicrobial activity, only a few are regularly used. These are:

1) Cetrimide (cetyltrimethylammonium bromide, CTAB), a mixture of dodecyl, tetradecyl- and hexadecyl-trimethylammonium bromide. In addition to it uses for pre-operative skin disinfection and treatment of seborrhoea of the scalp, cetrimide is also employed, in conjunction with sodium nitrite, which delays or prevents rusting, for the storage of sterilized surgical instruments, although this practice should be discontinued (Rubbo and Gardner, 1965).
2) Benzalkonium chloride (Zephirol, Zephiran) is the active constituent of a general purpose and skin sterilizing agent, "Roccal." It is also used to alleviate or prevent napkin rash caused by urea-splitting organisms, as a preservative in eye-drop preparations (Pharmaceutical Codex, 1979) and for the disinfection of blankets.

Other important QACs are domiphen bromide and cetylpyridinium chloride.

The value of QACs in the disinfection of woollen blankets has been observed by various authors (Frisby, 1957; International Wood Secretariat, 1961), although they cannot be incorporated in the wash with an anionic compound, because of incompatibility. In addition, it must be emphasized that residues of anionic agents on blankets from previous washings could interfere with the action of QACs. To overcome this, blankets may be washed in an appropriate non-ionic detergent, with a final prolonged rinse in a QAC, or they may be treated with a non-ionic detergent incorporating a QAC.

The QACs are also of considerable value as disinfectants in food and dairy plant. If an alkali detergent containing anionic surface-active wetting agents is used prior to sanitizing, then utensils and equipment must be thoroughly rinsed (Barrett, 1969). The QACs at their normally used concentrations are odourless and noncorrosive, but many are not free-rinsing, and undesirable traces may remain on equipment or even be present in dairy food (Clegg, 1967, 1970). However, a combination of a free-rinsing type of QAC and a suitable non-ionic agent may be usefully employed for washing instruments and cutlery, etc. (Barrett, 1969).

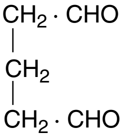
The cytoplasmic membrane of bacteria and fungi is the site of action of the QACs. The membrane is composed of lipoprotein, and it is considered (Russell, 1971) that the lipid moiety is involved in the lethal action of these compounds (for more recent information, see Hugo, 1976a,b).

There appears to be a clear relationship between the thermodynamic and antibacterial activities of QACs, with solutions having equal antimicrobial activity against an organism having surface concentration values of the same order of magnitude. Thermodynamic activities of QACs at two bacterial survivor levels (1% and 0.01%) have been shown to be sufficiently constant (Laycock and Mulley, 1970) to support the Ferguson (1939) principle that compounds with the same thermodynamic activity will have an equal bactericidal activity.

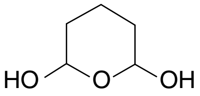
Amphoteric compounds, as already stated, are of mixed anionic-cationic character, and they combine the detergent properties of anionic compounds with the bacterial properties of the cationic substances; their bactericidal properties remain virtually constant over a wide pH range (Barrett, 1969) and they are less readily inactivated by proteins than are the QACs (Clegg, 1970). Examples of amphoteric surface-active agents are dodecyl-β-alanine, dodecyl-β-aminobutyric acid and dodecyldi(aminoethyl)-glycine (Davis, 1960a,b, 1968), the last named being a "Tego" compound. The Tego series of compounds have a high molecular weight, and in addition to being recommended for use in pre-operative hand cleansing and pre-operative skin preparation it has also been found that they are suitable for the cleansing of surgical operating theatre floors, walls and equipment and for ward cleansing (Frisby, 1959, 1961). It has, however, recently been shown that Tego 103S in 1% solution is less active than a 0.5% solution of chlorhexidine in 70% alcohol (Kuipers and Dankert, 1970). Amphoteric surface-active agents are inactivated by soaps and other anionic compounds (Frisby, 1959), but they are non-irritating and non-corrosive. Unfortunately, they tend to be expensive.

Aldehydes

The two most important aldehydes are glutaraldehyde (Pentanedial) and formaldehyde (methanal).



$$\begin{array}{l} CH_2 \cdot CHO \\ | \\ CH_2 \\ | \\ CH_2 \cdot CHO \end{array}$$



Hydrated Ring Structure

Glutaraldehyde is a dialdehyde which has been used for several years as a fixative in electron microscopy investigations and its antimicrobial activity has been comparatively recent (see Rubbo and Gardner, 1965; Rubbo *et al.*, 1967; Borick, 1968), but they do indicate that this substance has a valuable role to play. A 2% solution of glutaraldehyde buffered with sodium bicarbonate (0.3% w/v is considered to be the optimum bicarbonate concentration) is effective in killing nonsporing bacteria within 2 min, *M. tuberculosis,* fungi and viruses in 10 min, and spores of *Bacillus* and *Clostridium* spp. in 3 hours. Aqueous solutions of glutaraldehyde are acid, and are considerably less active against microorganisms than are alkaline ones (Pepper and Chandler, 1963; Stonehill *et al.*, 1963; Snyder and Cheatle, 1965; Lane *et al.*, 1966; Rubbo *et al.*, 1967; Munton and Russell, 1970a,b), but solutions become progressively less stable at pHs above 7. Concentrated solutions of glutaraldehyde (25%) can be purchased, diluted to the required concentration (2%) and "activated" by the addition of sodium bicarbonate. (Alternatively, 2% solutions ready for use when "activated" can also be purchased.) When made alkaline, glutaraldehyde solutions gradually undergo polymerization with a consequent loss of activity, this polymerization proceeding rapidly at pH values above 9. At pH 7.5–8.5, however, activity is maintained for at least 2 weeks.

Serum does not affect the antimicrobial activity of glutaraldehyde, but the dialdehyde is considerably less active in nutrient broth at pH 7.5 than it is at the same pH in buffer (Rubbo *et al.*, 1967; Munton and Russell, 1970a), the reason being that glutaraldehyde combines with the peptone present in broth (which is thereby discolored).

Glutaraldehyde is used as a fixative in the preparation of microbial cells for electron microscopy. It is a useful hospital disinfectant, particularly for articles which cannot be sterilized by physical means (Report, 1965). It has been employed in the sterilization of cytoscopes in urology (Lane, McKeever and Fallon, 1966) and of endoscopic instruments, such as bronchoscopes (Snyder and Cheatle, 1965), as it has no deleterious effect on the cement or lens coating. Glutaraldehyde is also employed as a tanning agent in preference in glyoxal and formaldehyde (Fein *et al.*, 1959), and has been shown to inactivate rapidly influenza virus and a coliphage in mouse tissue blocks (Sabel *et al.*, 1969).

Glutaraldehyde is non-corrosive, and does not affect rubber and plastic articles or the sharpness of cutting instruments; because it does not coagulate protein matter, such as blood and mucus, it does not render the cleaning of blood-covered instruments more difficult. It is obvious, therefore, that glutaraldehyde is most useful.

Rubbo *et al.* (1967) have proposed that the microbicidal activity of glutaraldehyde is due to the presence of two free aldehyde groups in the molecule. In solution, glutaraldehyde exists in an equilibrium between the open chain structure and the hydrated ring structure (see above), and there is a complete loss of activity if one or both of the aldehyde groups is altered, whereas a substitution elsewhere in the molecule reduces, but does not abolish, its activity. It is thus essential to have free aldehyde groups, which may react with cell sulphydryl or amino groups. Glutaraldehyde is about 10 times as active as glyoxal, with succinaldehyde occupying an intermediate position (Pepper and Chandler, 1963). Certain bacteria treated with glutaraldehyde become pink in color (Munton and Russell, 1970b) as a result of cell-aldehyde interaction.

Formaldehyde has long been employed as a disinfectant. Formaldehyde solution is rapidly sporicidal to *B. subtilis* (Ortenzio *et al.*, 1953; cf. Klarmann, 1956, 1959) but not to various *Clostridia* (Ortenzio *et al.*, 1953; Klarmann, 1956, 1959). Ethanol (Rubbo *et al.*, 1967) and methanol (Willard and Alexander, 1964) cannot be recommended as vehicles for formaldehyde, as there is a reduction in antibacterial activity.

Formaldehyde is an important virucidal agent which finds its greatest use in the preparation of certain sterile vaccines, e.g., Poliomyelitis Vaccine (Inactivated). As a result of the experimental evidence accumulated over several years, a considerable amount of information is now available on the kinetics of the virus inactivation by formaldehyde. This particular vaccine consists of poliovirus Types I, II and III, and each is inactivated separately and then blended to give the trivalent vaccine. It is thus essential that formaldehyde treatment be sufficient to destroy the viruses without affecting their antigenicity; prolonged exposure to the aldehyde will, in fact, destroy the antigenic potency also (Morris and Darlow, 1971). The inactivation of poliovirus by formaldehyde has been considered to be a first-order reaction so that extrapolation of the death curve would give a point at which the probability of any infective particles remaining would approach zero. However, first-order kinetics cannot be used with any degree of safety to extrapolate the inactivation curve. Similarly, although the inactivation of SV_{40} virus by formaldehyde has been shown by Sweet and Hilleman (1960) to be linear, it is now known that this linear inactivation is followed by a flattening of the curve indicating the persistence of a residual fraction which resists inactivation.

Formaldehyde is rapidly lethal to vegetative bacteria, and is sometimes used for this purpose in the preparation of inactivated bacterial vaccines.

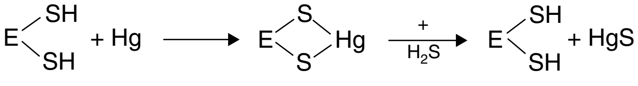
Metals

Because of their antibacterial and antifungal activity, compounds of mercury, silver, copper and tin are of importance from both medical and industrial points of view (Hugo and Russell, 1982).

Mercury Compounds These are of two types, the inorganic mercuric and mercurous salts and the organic substances. Mercuric salts are primarily bacteriostatic and fungistatic and contrary to earlier findings are not sporicidal (see Russell, 1971). Because of their toxicity, the mercuric salts do not find widespread use in modern medicine, but are extensively employed as industrial preservatives, e.g., in the preservation of wood, leather and paper, and in the control of fungal infections in seeds and bulbs. Mercurous salts have no application as preservatives.

The most important organic mercury compounds are the phenylmercuric salts (nitrate, acetate and borate) and thiomersal. Phenylmercuric nitrate (PMN) and acetate (PMA) are now mainly employed as preservatives in various pharmaceutical and cosmetic products. PMN is also used as a spermicide in certain contraceptive formulations, as a plant fungicide and for the disinfection of leather and timber. However, because of their lack of sporicidal activity at ordinary temperature, the organic mercury compounds cannot be recommended as sterilizing agents. Some plasmid-containing gram-negative bacteria are resistant to mercury compounds, which are vaporized (Chopra, 1982).

Various sulphydryl compounds, such as cysteine and thioglycollic acid, can reverse mercury-induced bacteriostasis, which led Fildes (1940) to propose that these compounds combined with, and displaced, mercury from its combination with the —SH group of an enzyme (E).



Silver Compounds Silver compounds have long been used in medicine for their antimicrobial activity, which extends to Gram-positive and Gram-negative bacteria and fungi. Of the silver compounds available, silver protein and silver nitrate are the most important. The latter, in the form of compresses, is highly effective in preventing the colonization of burns with *Ps. aeruginosa* and *Proteus* species.

Copper Compounds These are bactericidal and fungicidal. They have been used for the latter purpose for more than 200 years, and their sole use nowadays is as industrial preservatives against fungal spoilage. The most frequently used substances are copper naphthenate, oxinate, 1-phenylsalicylate and sulphate; the last-named, in combination with a lime mixture, is known as Bordeaux mixture.

Dialkyldithiocarbamates are considered (Albert, 1963) to be converted into active bactericides and fungicides in the presence of copper. Such salts are highly successful, widely used, agricultural fungicides (Owens, 1969).

Tin Compounds Stannous and stannic salts have little antimicrobial ctivity. However, when tin is coupled with organic radicals, forming what are known as the organotins, potent antimicrobial activity results. If R represents the organic radical linked directly to a tin atom, by C—Sn bond, and X an inorganic or organic radical not so linked, various types of compounds can be obtained, of which $R—SnN_3$ is most active. Gram-negative bacteria are less sensitive than Gram-positive bacteria to organotin compounds. Triphenyltin acetate and hydroxide are important agricultural fungicides.

Dyes

The acridines have held a valuable place in medicine for several years, although with the advent of the antibiotics and other chemotherapeutic agents, they are now less widely used than hitherto. The acridines are active against several Gram-positive and Gram-negative bacteria, and have been used mainly in treating infected wounds. Their uses and mode of action have been reviewed (Foster and Russell, 1971).

The most important members of the triphenylmethane group of dyes are crystal violet, brilliant green and malachite green. These have mainly been employed for local application to burns and wounds.

Some members of a third group of dyes, the quinones, are important agricultural fungicides. The quinones are natural dyes which impart color to many forms of plant and animal life. Chemically, the quinones are diketocyclohexadienes, the simplest of which is 1,4-benzoquinone (Figure 4). Naphtaquinones are the most toxic to bacteria, moulds and yeasts, followed (in this order) by phenanthrenequinones, benzoquinones and anthraquinones (Figure 4). Antimicrobial activity is increased by halogenation, and two powerful antimicrobial agents employed as fungicides are chloranil (tetrachloro-1, 4-benzoquinone) and dichlone (2,3-dichloro-1,4-naphthaquinone).

Alcohols

Ethyl alcohol, although active against Gram-positive and Gram-negative bacteria, is devoid of lethal activity against bacterial spores, and thus cannot be relied upon as a sterilizing agent (Russell, 1971). Methyl alcohol is likewise not

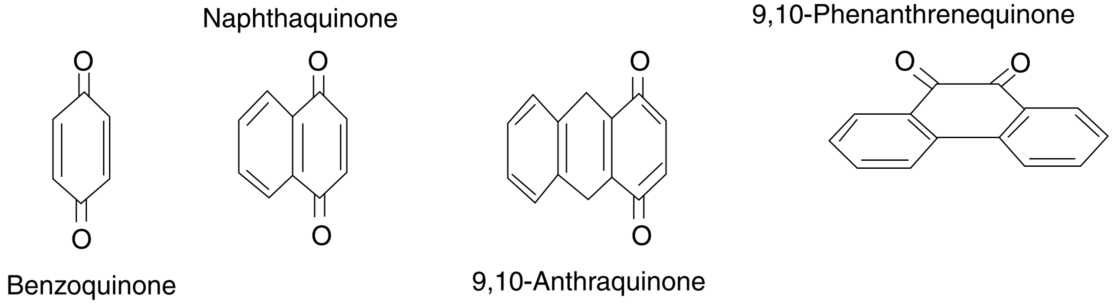


FIGURE 4

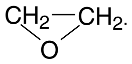
sporicidal. Moreover, alcohols may reduce the sporicidal activity of aldehydes.

GASEOUS ANTIMICROBIAL AGENTS

Gaseous agents may play an important role in sterilization of certain types of medical equipment and of components used in outer space research. However, only two gases (ethylene oxide and formaldehyde) are used extensively for the sterilization of medical products. Other gases (methyl bromide, β-propiolactone and propylene oxide) are not used as routine methods. Appropriate measures must be taken to counteract toxicity to humans (Christensen and Kristensen, 1982).

Ethylene Oxide

Ethylene oxide (EO) exists as a gas which is soluble in rubber, water, oils and several organic solvents. Chemically, it is



$$\underset{\diagdown\, O \,\diagup}{CH_2\!-\!CH_2}.$$

Its inflammability when in contact with air is overcome by using mixtures of EO with carbon dioxide or with fluorocarbon compounds (Phillips and Kaye, 1949; Barwell and Freeman, 1959; Freeman and Barwell, 1960). EO diffuses freely through paper, cellophane, cardboard and some plastics, but less rapidly through polythene; it cannot penetrate crystalline materials (Opfell and Miller, 1965). The antimicrobial activity of EO has been dealt with in many papers and reviews (Phillips, 1949, 1958, 1961, 1977; Phillips and Kaye, 1949; Kaye, 1949, 1950; Kaye and Phillips, 1949; Kaye *et al.,* 1952; Phillips and Warshowsky, 1958; Thomas, 1960; Bruch, 1961; Sutaria and Williams, 1961; Russell 1971; 1976; Kelsey, 1961, 1967; Sykes, 1970; Hoffman, 1971; Kereluk, 1971; Ernst, 1974, 1975; Hugo and Russell, 1982).

Several factors are known to influence the antimicrobial activity of EO (Christensen and Kristensen, 1982):

1) Concentration. As would be expected, the higher the concentration of EO (expressed as mg/l, which refers to the actual amount present in the sterilizer) the more rapid is the rate at which microorganisms are killed. However, even at high concentrations, EO is only slowly lethal, and long periods may, therefore, be needed for sterilization to be achieved.
2) Temperature. The lethal activity of EO increases with a rise in temperature. It has a temperature coefficient of 2.74 for each 10°C rise in temperature.
3) Type of organism. EO gas will kill bacteria and their spores, yeasts, moulds and their spores, and viruses (Griffith and Hall, 1938), and resistant strains have not been developed. In contrast to many other chemical substances which are considerably less effective against spores than against vegetative cells, bacterial spores are only about 2–10 times as resistant as the latter to EO (Toth, 1959; Phillips, 1958) and in some cases, e.g., *B. stearothermophilus* (Thomas *et al.,* 1969) even less resistant. These results imply that EO can freely penetrate the outer layer(s) of the bacterial spore, although experimental results in support of this contention are sadly lacking.

   In addition to its antibacterial and antifungal activity, ethylene oxide is also effective against rickettsiae and viruses (Hoffman, 1971).
4) Relative humidity (RH). Of all the factors which influence the activity of EO, RH is probably the most important. The optimum RH is considered to be *c.* 28–33% (Schley *et al.,* 1960), and EO is considerably less microbicidal at high RH and in relatively dry air. The correct RH may be achieved to prehumification of the sterilization chamber (Halowell *et al.* 1958; Ernst and Schull, 1962). However, the moisture content of microorganisms themselves, as well as the RH of the environment, is also important. Bacterial cells which have been desiccated and then equilibrated to successively high RH values contain less water and are more resistant to EO than cells which have not been desiccated but have instead been allowed to dry naturally until equilibrated to the same RH values. To overcome this resistance

to EO produced by dehydration, the cells have to be actually wetted (Perkins and Lloyd, 1961; Winge-Heden, 1963; Gilbert *et al.,* 1964).

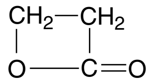
Alkylating agents act through alkylation of sulphydryl, amino, carboxyl, hydroxyl and phenolic groupings, with the loss of a hydrogen atom and the production of an alkyl hydroxyethyl group (Phillips, 1952, 1958; Kelsey, 1967), and it seems likely that EO kills microorganisms by an alkylation of protein molecules (Gilbert *et al.*, 1964). The influence of RH on the microbicidal activity of EO is related to this, since the presence of insufficient water prevents alkylation, whereas excess water causes hydrolysis of EO to ethylene glycol, CH_2OHCH_2OH (Wilson and Bruno, 1950).

5) Effect of drying medium on spore resistance. Organisms dried from salt solution always show some survivors after exposure to EO (Royce and Bowler, 1961; Beeby and Whitehouse, 1965). Moreover, organisms enclosed within crystals are protected from the action of EO (Abbott *et al.*, 1956; Royce and Bowler, 1961) as a result of the inability of the gas to penetrate crystalline materials.

EO has several uses in the pharmaceutical and medical fields. These include the sterilization of ophthalmic instruments, anaesthetic equipment, heart-lung machines, disposable syringes (Rubbo and Gardner, 1968) and hospital blankets (Kaye, 1950), and as a decontamination procedure for articles handled by tuberculous patients. There may, however, be a "crazing" of disposable syringes, and EO treatment is a slow, costly process, with a "quarantine" period necessary at the end of the process to ensure that complete dissipation of the gas has been achieved.

β-Propiolactone

β-Propiolactone (BPL) is a colorless liquid at room temperature. It has been employed as a chemosterilizer in both the liquid and gaseous states, and is microbicidal in both forms (Allen and Murphy, 1960). Its antimicrobial activity depends on its concentration and on the temperature and RH at which the vapor is used (Spiner and Hoffman, 1960), a temperature above 24°C being required for optimal activity. As with EO, RH is of considerable importance in determining the activity of BPL vapor, although with the latter a RH in excess of 70% is required for rapid microbicidal acivity (Hoffman and Warshowsky, 1958). Again, however, it is not necessarily the atmospheric RH which is of greatest importance but the location and content of water within the microbial cell. *B. globigii* spores equilibrated to 98% are rapidly killed by BPL at 45% RH, whereas they are more resistant if preconditioned at 75% RH before treatment with BPL at 45% RH, and a small proportion of spores equilibrated at 1% RH are subsequently highly resistant to BPL at 75% RH (Hoffman, 1968).



Bacterial spores are more resistant to BPL than vegetative cells, viruses or fungi (Lo Grippo *et al.*, 1955; Trafas *et al.*, 1954; Bruch and Koesterer, 1962; Toplin, 1962) although some strains of *Staph. aureas* may be almost as resistant as spores (Hoffman and Warshowsky, 1958).

BPL is also highly active against viruses and rickettsiae (Hoffman, 1971).

BPL has been used for the chemical sterilization of regenerated collagen sutures (Ball *et al.*, 1961), for the decontamination of enclosed spaces (Bruch, 1961b) and for the sterilization of a variety of instruments contaminated with various sporing and non-sporing bacteria (Allen and Murphy, 1960). However, its reported carcinogenic effects in rats and mice (Walpole *et al.*, 1954) mean that a considerable degree of caution is needed before BPL is employed as a chemosterilizer.

Formaldehyde

Formaldehyde vapor may be obtained by evaporating appropriate dilutions of standardized batches of commercial formalin (a 40% solution of formaldehyde in water) with 10% methanol added to prevent polymerization (Report, 1958). Temperature affects the activity of the gas, as does the RH, there being an increase in activity with increasing RH up to 50%, but little further increase in killing rate as the RH rises from 50 to 90% (Nordgren, 1939; Report, 1958). In contrast, gross wetting retards killing.

Bacteria protected by organic matter, such as blood and sputum are less rapidly killed by formaldehyde vapor (Nordgren, 1939; Bullock and Rawlins, 1954). Microorganisms may also be protected from it when they are included in a crystal mass, in contrast to surface-contaminated crystals (Abbot *et al.*, 1956).

Although bacterial spores are more resistant than vegetative cells to formaldehyde vapor, the degree of difference is not high (Phillips, 1952; Report, 1958; Sykes, 1965). The vapor only has weak penetration, and its application is thus normally limited to surface sterilization (Borick, 1968; Davis, 1968). However, the addition of formaldehyde vapor to steam under sub-atmospheric pressure at temperatures below 90°C results in deep penetration into fabrics with destruction of heat-resistant microorganisms (Alder *et al.*, 1966; Alder and Simpson, 1982).

Formaldehyde vapor has long been used for the disinfection of blankets, and is considered to be one of the best methods available for disinfecting woolen blankets that have not received a shrink-resist treatment (International Wool Secretariat, 1961). It is also used to decontaminate rooms, buildings and instruments (Hoffman, 1971).

PRACTICAL USES

This final section brings together some of the data presented in the preceding sections, and also provides information in certain specific instances. Disinfectants will be considered from two points of view, first their medical, and second their nonmedical uses. Some brief information on antiseptic and preservative use will also be supplied.

Medical Uses

The use and choice of disinfectants in hospitals have been extensively considered in the last decade in Britain by a special committee (Report, 1965) set up for this purpose. Our comments here are thus based on the recommendations of this report and on the findings presented by Kelsey and Maurer (1967). The Report (1965) recommended that two classes of disinfecting agents were needed, (a) for general disinfection and (b) for surface disinfection of clean objects. Agents for general disinfection should have a wide spectrum, and at appropriate dilutions should remain active in the presence of organic matter; the main purpose of such disinfectants, e.g., phenolic disinfectants based on coal-tar acids, is not necessarily to kill *all* bacteria but to ensure that an object is free of significant numbers of organisms. Chemicals for surface disinfection must be quick-acting, have a wide spectrum, be non-harmful to materials and leave no objectionable odours. Such disinfectants, e.g., hypochlorites, should be used for the rapid disinfection of clean surfaces such as trolley tops, kitchen tables and clinical thermometers.

Kelsey and Maurer (1967, 1972) have presented a list of the steps to be taken in drawing up a policy for the use of general purpose disinfectants in hospitals, and among the points they make is the non-usage of disinfectants in certain cases, especially where sterilization is the objective or where other more reliable means are available. For further information, see Lynn (1980), Ayliffe and Collins (1982) and Lowbury (1982). Preoperative disinfection of the skin (including surgeon's hands), disinfection of operation sites and topical prophylaxis, i.e., antisepsis in burns, are discussed by Lowbury (1982). Ayliffe and Collins (1982) provide a rational approach to hospital disinfection.

Nonmedical Uses

The main nonmedical uses of disinfectants occur in the food, dairy, brewing and fermentation industries (Foster *et al.*, 1958; Frazier, 1967). The maintenance of equipment for use in these industries in a proper sanitary condition cannot be overemphasized. This therefore means that the cleaning of such equipment is of considerable importance, since the presence of organic matter can reduce or virtually eliminate the effect of many disinfectants (page 164). In the dairy industry, milk stone—resulting from milk drying on equipment, and thus consisting of fat, protein and minerals—and milk film are a well-known problem in disinfection (Clegg, 1967). Chemicals which are of use against microorganisms in liquid suspension in laboratory tests may be of little use against such organisms on a soiled surface if they are poor detergents (Cousins, Hoy and Clegg, 1960).

To counteract the unwanted effects of organic matter, one of the following two methods may be employed (see also Davis, 1972a,b and BSI 1977):

1) detergent first, followed by a disinfectant;
2) combination of detergent and disinfectant (this corresponds to a sanitizer, or to the detergent-sterilant of Davis (1968), as described in the Introduction).

Harris (1969) stresses the need for using two operations, i.e., the use of cleaning before disinfection. Cleaning is the first essential in the sanitary care of food equipment, and approximate sterility the last (Foster *et al.*, 1958). Steam under pressure is an obvious method of sanitization, but this is limited only to closed systems which can withstand pressure (Frazier, 1967). Theoretically, separate procedures would be expected to give a better result (Clegg, 1970), because of the inactivating effect of organic matter on disinfectants; however, a finding made several years ago (Neave and Hoy, 1947) suggests that a detergent-disinfectant combination would be of greater use, because "the effect of the detergent on milk solids more than outweighs the effect of milk residues inactivating the disinfectant" (Clegg, 1970). An effective detergent should dissociate organic and inorganic solids, emulsify, saponify or suspend grease, fats and oils, have good wetting ability, be easily rinsed and be non-corrosive (Olivant and Shapton, 1970). Detergents are thus of considerable importance in this field, because they can also be responsible for the mechanical removal of bacteria (Gilbert, 1969). The most commonly used detergents are strong and mild alkalis, alkali salts, strong acids, anionic alkyl sulphates and aryl sulphonates and non-ionic condensates (Davis, 1968). An excellent descaling agent is nitric acid which can be used hot at concentrations of 0.25–0.5% or cold at 0.5–1%, and which is, in addition, a powerful disinfectant. It is, however, less effective than alkali in the removal of hardened protein films, and is normally employed with a corrosion inhibitor. In actual fact, many detergents are good disinfectants and vice versa, e.g., a detergent such as sodium hydroxide possesses considerable germicidal power (Whitehouse and Clegg, 1963), whereas hypochlorites have a useful detergent effect by disintegrating protein matter (Davis, 1968). Cleaning is an essential first part in high-speed food and beverage processing plant, and considerable economic benefit is achieved as a result of the production of stable liquid detergents and disinfectants which can be delivered by tanker and then distributed to the cleaning areas by pipeline (Hill, 1969). However, even with good precleaning, traces of inactivating protein material may remain on equipment, and it is thus important to choose a disinfectant which has a high protein tolerance (Harris, 1969). The design of equipment to facilitate cleaning must also be stressed, and stainless steel is an obvious example, with glass pipelines to give a high degree of visual cleanliness (Harris, 1969).

The disinfection of fermentation laboratories has been described by Darlow (1969). Gaseous disinfectants may be employed, and aerosols appear to have an important role to play. Local disinfection of bench tops, floors, etc. is also a standard practice. The importance of disinfectants in water conservation is emphasized by Fielden (1969), and in the pharmaceutical industry by Underwood (1980).

The control of airborne microorganisms is of particular importance in the fermentation industry, in laboratories where strict asepsis is essential (e.g., in the production of various sterile products in the pharmaceutical industry and in hospital pharmacy departments, as well as in the rearing of germ-free animals), in hospital wards to reduce the incidence of cross-infection, and in special wards set aside for patients with a rare disease (hypogammaglobulinaemia) who are particularly sensitive to infection.

This control is normally achieved by the use of special air filters, often in conjunction with ultraviolet lamps to irradiate the upper atmosphere. Disinfectants in the form of aerosols are also of importance in aerial disinfection. To be effective for air disinfection, a chemical should ideally possess the following properties:

1) be odorless, cheap and stable
2) be without toxic or irritant properties
3) be capable of being dispersed in the air, with consequent complete and rapid mixing of infected air and chemical
4) be capable of maintaining an effective concentration in the air
5) be highly and rapidly effective against airborne organisms
6) be unaffected by relative humidity (RH).

Aerosols consist of a very fine dispersed liquid phase in a gaseous (air) continuous phase. The germicide must be nebulized in sufficiently fine spray (aerosols droplets of <1 μm are the accepted standard) so that it will remain airborne and thus have ample opportunity to collide with any microorganisms present in the air. At low RH, particles are too dry for adequate condensation of the disinfectant that such organisms enclosed in particles, and thus bacteria occurring on dust or on surfaces are much less susceptible to the aerial disinfectant than such organisms enclosed in droplets (Sykes, 1965). The optimum RH is usually *c.* 40–60%.

Chemical aerosols are often generated in the following manner: if the chemical is liquid, it may be sprayed directly into the air from an atomizer; if the chemical exists as a solid, it may be dissolved in an appropriate solvent, e.g., propylene glycol, and atomized, or alternatively the solid may be vaporized by heat from a thermostatically-controlled hot-plate.

Chemicals which have been used as aerial disinfectants include hexylresorcinol, lactic acid, propylene glycol (this possesses antimicrobial activity in its own right), hypochlorous acid, formaldehyde gas and sulphur dioxide.

Other Uses of Antimicrobial Agents

Antimicrobial agents are widely employed as preservatives in pharmaceutical and cosmetic products. Factors influencing their activity, as well as those governing their choice in different classes of sterile or non-sterile products have been well considered by Bean (1972), Croshaw (1977), Parker (1978, 1982), Kazmi and Mitchell (1978a,b), Allwood (1980) and Beveridge (1980).

Preservation is also required in other specialized areas, e.g., in cutting oils (Hill, 1982a), fuels (Hill, 1982b), paper and pulp (Weir, 1982), wood (Richardson, 1982), paint (Springle and Briggs, 1982) and textiles (Hugo, 1982b) and in the construction industry (Bravery, 1982). A most important aspect concerns the use of chemical food preservatives and this has been comprehensively reviewed by Sofos and Busta (1982).

ECOLOGY OF PLANTS

Ecology is the study of the relationship between organisms and the environment and the interrleationships between organisms. The response of an organism to the environment is determined by the effects of the environment on the processes in the organism. Stated in another way, all environmental factors affect the growth and distribution of organisms only by affecting rates of processes in the organisms. The study of the effects of environmental factors on processes in organisms is *physiological ecology,* or in other words, it is the study of the physiological basis of ecological behavior. This field obviously represents a marriage between ecology and physiology, and is sometimes called *environmental physiology.* The field of physiological ecology is extremely broad: thus, this paper is restricted to certain aspects of physiological *plant* ecology.

ENVIRONMENTAL FACTORS

The environment is very complex, consisting of all influences external to an organisms. Many systems have been devised to classify the environment but space does not allow a discussion here. The following list of *specific* environmental factors is a satisfactory one although the list could obviously be subdivided in many ways:

1) water
2) temperature
3) radiant energy
4) essential elements
5) aeration
6) toxins
7) wind
8) topography
9) nature of geologic strata
10) altitude
11) organic matter content of soil
12) texture and structure of soil
13) base exchange capacity of soil
14) color of soil
15) plant growth regulators
16) soil organisms
17) parasites
18) plants and animals other than above.

Even cursory examination of this list makes it clear that the effects of all these factors on processes in plants could not be discussed in a brief survey. For example, thorough coverage of the effects of the various essential elements on plant processes would require a sizeable manuscript. I have decided, therefore, to discuss a few factors in sufficient depth to give the reader a feeling for the area.

INTERRELATIONSHIPS BETWEEN ENVIRONMENTAL FACTORS

In addition to having a direct effect on many plant functions, the water factor affects other factors through the amount and type of precipitation involved. It affects: (1) amounts of radiant energy, (2) temperature of air and soil, (3) amount of nitrogen brought down by rain, (4) amounts of minerals leached from the soil, (5) availability of various elements to plants, (6) topography of the region, (7) numbers and types of organisms in the soil, (8) toxins in the soil, (9) aeration of soil, and (10) numbers and types of parasites in a region.

All other environmental factors have many indirect effects also.

EFFECTS OF WATER FACTOR

Warming (1909) stated that "no other influence impresses its mark to such a degree upon the internal and external structures of the plant as does the amount of water present in the air and soil." This is due primarily, of course, to the following roles of water: (1) it is important as a solvent system in the soil and in cells of all living organisms on earth, (2) it serves as the dispersion medium for the colloidal systems present in cells, (3) there is a close interaction between the nature of the hydration shell surrounding protein molecules and the physicochemical properties of the proteins (Klotz, 1958), (4) it is important as a raw material in photosynthesis, (5) it is important as a raw material in all hydrolytic processes, and (6) it has some influence on leaf temperatures through transpirational cooling.

Klotz (1958) suggested that protein molecules in cells have hydration shells of lattice-ordered water which act like ice-shells around the molecules and that the maintenance of an active configuration is due to the shells. The effect of heat is thought to reduce the extent of the ice-shell, whereas lower temperatures increase the thickness of the shell. Urea is thought to be an effective denaturizer of proteins because its strong hydrogen bonding characteristics may break down the frozen structure of the water envelope. The observed effects of water stress on the viscosity of protoplasm suggests that reduced hydration has a definite effect on the ice-shell.

Jacobson (1953) offered considerable evidence for the presence of an ordered-water lattice around DNA molecules also. He suggested that such an ice-shell would make separation of the two chains of DNA during replication possible with low energies.

The models of Klotz and Jacobson have apparently been well received (Stocker, 1960; Slatyer, 1967). If these models are indeed correct, it is easy to see how water deficiency can have pronounced effects on all sorts of processes, because of the role of DNA in protein synthesis and the role of proteins in enzymes. It is probable that the integrity of specific water-protein structures is necessary for the continuance of organic processes at optimum rates. It is likely that the variations in reductions to different species to water stress are due chiefly to different degrees of sensitivity of essential metabolic systems.

Buckman and Brady (1960) state that a slight lowering of the available water content in the soil below field capacity stimulates growth of plants generally. Blair *et al.* (1950) found that the rate of stem elongation in sunflower (a dwarf type from an inbred line, apparently of *Helianthus annuus*) is markedly reduced before half the available water is used, and that zero growth results during the use of the last one-fourth of the available water. A reduction of 30–40% between field capacity and the wilting point probably slows growth in most plants.

Probably the most direct effect of water on plant growth is its effect on the turgor pressure of the individual cells. Turgor pressure affects cell enlargement and stomatal closure. Closing of the stomates due to reduced turgor pressure in the guard cells reduces both transpiration and photosynthesis and can ultimately reduce growth. Probably, many of the detrimental effects of moderate water deficits are due to stomatal closure. One important effect is that the temperature of leaves can rise to detrimental levels under some conditions when the transpiration rate is lowered markedly (Slatyer, 1967).

It appears that cell division is influenced less by water deficits than cell enlargement (Slatyer, 1967). Gates and Bonner (1959) found that the amount of DNA in water stressed tomato leaves remained constant during the period of their experiments whereas the amount increased steadily in control leaves. This indicated that chromosomal multiplication was continuing to occur in the control leaves but had ceased in the test leaves. Apparently, cell number is linearly related to DNA content (Slatyer, 1967) so it appears that there was a reduction in rate of cell division in the water stressed leaves. Gardner and Nieman (1964) found that water stress in cotyledonary leaves of *Raphanus sativus* (radish) reduced the rate of increase of DNA.

Gates and Bonner (1959) found that water stress prevented a net increase in RNA in *Lycopersicum esculentum* (tomato) leaves also. The water stressed leaves were able to incorporate P^{32}-labeled phosphate into RNA apparently at the same rate as in control leaves. They concluded, therefore, that the rate of destruction of RNA was greater in water stressed leaves than in controls. Kessler (1961) reported that drought stress causes a pronounced decrease in the RNA content of several plants. Despite this, the rate of incorporation of uracil-C^{14} was the same as in control leaves but had ceased in the test leaves—drought stressed plants. This was confirmed because the activity of RNase was found to increase markedly with water stress.

A reduction in the water content of leaves generally results in a decrease in the rate of photosynthesis (Meyer and Anderson, 1939). This may seem strange because less than one per cent of the water absorbed by a plant is used as a raw material in photosynthesis. According to Slatyer (1967) however, there are two main modes of action of water stresses on photosynthesis: (1) stomatal closure and reduced rates of CO_2 exchange can influence the supply of CO_2 and (2) there is probably a direct effect of the water deficit on the biochemical processes involved in photosynthesis. Gates (1964) maintained that the rate of photosynthesis is more closely related to the water content of leaves than to the diffusive capacity of the stomates. Certainly, if Klotz's model of protein hydration and behavior is correct, one would expect Gate's contention to be logical.

Gates (1964) reported that during water stress, the respiration rate is accelerated but later declines. There is an increase in starch hydrolysis and an increase in sucrose which later declines. The respiration rate appears to be correlated with the sucrose content. Protein synthesis is impaired and active proteolysis may occur with prolonged wilting, especially in older leaves. Finally, if the degree of protoplasmic desiccation reaches critical levels, individual cells, tissues and even the entire organism may die.

Flooding lowers the oxygen supply to the roots or roots and tops if the tops are covered with water also. Under these conditions, Crawford and Tyler (1969) found that plants intolerant of flooding have an increased rate of glycolysis including alcohol dehydrogenase induction and the greatest production of acetaldehyde. On the other hand, malic acid accumulates in flood tolerant species and falls in intolerant species. Organic acids can accumulate in cells in much greater quantities than ethanol without damaging the plant. In fact, malic acid helps preserve the electrical neutrality of the cell.

EFFECTS OF TEMPERATURE

The cardinal temperatures (i.e., minimum, optimum, maximum) often differ for the same function in different plants and different functions in the same plant. They often differ also for the same function at different stages of development, and often in different organs of the same plant at a given, stage. Moreover, they may differ with the general physiological condition of the plant, the duration of temperature regime, and changes in other environmental factors.

Daubenmire (1959) states that the minimum temperature for growth of melons (*Citrullus*) and sorghums (*Sorghum*) is in the range of 15 to 18°C; and for peas (*Pisum*), rye (*Secale*), and wheat (*Triticum*), −2 to 5°C. He further states that roots usually have a lower minimum for growth than shoots of the same plants. The optimum temperature for photosynthesis is below that for respiration in all known cases. This is probably the reason peaches, apples, white potatoes, and many other plants do not accumulate normal food reserves in low latitudes.

Seeds of many native plants of temperature or colder regions have a low temperature requirement for germination. The value of such a mechanism in seedling survival is obvious. Work in my laboratory at the University of Oklahoma has shown that seeds of *Ambrosia artemisiifolia* (common ragweed), *A. psilostachya* (western ragweed) and *Sporobolus pyramidatus* (drop seed) require exposure to temperatures in the range of 4–7°C for about 6–10 weeks in moist conditions to break dormancy. Lane (1965) reported that seeds of *Helianthus annuus* (annual sunflower) require 90 days at 4°C in moist sand to completely break dormancy. Donoho and Walker (1957) reported that Elberta peach (*Prunus persica*) seeds usually required stratification for 60–100 days at 7°C or below to break dormancy.

Overwintering buds of many, if not most, perennial plants of temperature or colder regions also have low temperature requirements for the breaking of dormancy. Weinberger (1956) found that Elberta peach buds require 950 hours at 7°C or below to break dormancy. Daubenmire (1959) stated that peaches in general require 400 or more hours of temperatures at or below 7°C, blueberries (*Vaccinium* spp.) require 800 hours at this level, and apples (*Pyrus malus*) require even more.

The chemical changes which are necessary for the breaking of dormancy in seeds and buds, and which are stimulated by exposure to low temperatures, are not definitely known. In fact, this is a fertile field for research. There is growing evidence, however, that the breaking of dormancy may be related to a change in balance between growth inhibitors and stimulators. Sondheimer, Tzou, and Galson (1968) reported that abscisic acid inhibits germination of excised nondormant embryos and this can be reversed with a combination of gibberellic acid and kinetin. Natural amounts of abscisic acid in seeds and pericarps of several species of *Fraximus* (ash) were determined, and it was found that the amount in *F. americana* decreased 37% in the pericarp and 68% in the seed with chilling treatment. They felt that it is unlikely that the amount in the pericarp influences dormancy but that the inhibitor in the seed does appear to play a regulatory role. Junttila (1970) found that dormancy of seeds of *Betula nana* (birch) was effectively broken by low temperatures or treatment with gibberellic acid. Haber, Foard, and Perdue (1969), reported 84% germination in dormant lettuce (*Lactuca sativa*) seeds treated with a 5×10^{-4} M gibberellic acid solution, 1.5% germination in seeds treated with a 5×10^{-4} M gibberellic acid solution plus 100 mg/l of abscisic acid, and 0% in water controls.

Donoho and Walker (1957) reported a 98% breaking of dormancy of Elberta peach buds after only 164 hours at 7°C when sprayed with a 4000 ppm gibberellic acid solution, despite the usual requirement of 950 hours at 7°C or below. Aung, Hertogh, and Staby (1969) found free gibberellic acid in *Tulipa gesneriana* (tulip) increased by 67% over the initial level in bulbs grown for 4 weeks at 18°C. Bound gibberellic acid showed a slight initial increase followed by a rapid decrease. In bulbs treated at 13°C, a marked decline, occurred in free gibberellic acid and a 2-fold increase occurred in the bound form. The rates of floral, shoot, and root development were accelerated at 18°C as compared with 13°C.

Cold hardening of plants (i.e., improving the ability of plants to withstand low temperatures without severe damage or death) is probably just as important to plant survival in regions with periods of relatively low temperatures as dormancy. Actually, some of the same internal changes may be responsible for both. Irving (1969) found a buildup during cold hardening in *Acer negundo* (box elder) of an inhibitor similar or identical to abscisic acid which has, of course, been associated with dormancy. He found that it or abscisic acid increased hardiness when applied to branches after a hardening period of 3 weeks at 5°C. There are several cellular chemical changes associated with cold hardening (Klages, 1947); (1) increase in bound water, (2) decrease in total water, (3) increase in osmotic pressure, (4) change of starch to sugars, (5) increase in pentosans, and (6) change of certain proteins to amino acids. Nothing new has been added to this list since Klages' publication in 1947.

Temperature obviously affects rates of all organic processes in plants, but a comprehensive discussion of such effects is outside the scope of this discussion. The relationship of temperature conditions at the geographic point of origin of plants to the optimum temperatures for photosynthesis and respiration in those plants is very important in explaining their distribution. Mooney and Billings (1961) studied relationships of temperature to photosynthesis and respiration in *Oxyria digyna* (alpine sorrel), a species with a circumboreal distribution of wide latiudinal range. The sources of the populations studied varied from an elevation of 12,300 feet at 39° 40′N latitude to a zero elevation at 68° 56′ N. They found that plants of northern populations had higher respiration rates at all temperatures than did plants of southern alpine populations. Moreover, they found that plants of northern populations had higher photosynthetic rates at lower temperatures and attained maximum rates at lower temperatures than did plants of the southern alpine populations. Obviously, there are definite temperature ecotypes in this species.

Mooney, Wright, and Strain (1964) investigated the gas exchange capacity of plants in relation to elevational zonation in the White Mts. of California. Field measurements over an elevational span of 4000 to 14,000 feet indicated that the ratio of photosynthesis to dark respiration decreased with altitude primarily due to increased respiration rates with increased elevation. When similar measurements were made on plants grown in uniform greenhouse conditions, from seeds collected at different elevations, no differences in respiration rates correlated with elevation were obtained indicating considerable environmentally conditioned plasticity in gas exchange capacity. However, the high elevation plants generally displayed peak photosynthetic activity at temperatures lower than the low elevation plants even though all were grown in the same conditions.

Mooney and West (1964) studied the photosynthetic and respiratory acclimation of five species in the White Mts. of California (Table 1). Seeds were collected at the indicated elevations, planted in pots in the greenhouse, and after establishment of the seedlings, they were taken to stations at various elevations in the mountains for acclimation (Table 2).

They were kept in the same pots and soil and subirrigated at each place. Water was thus not limiting and the soil type was constant. Gas exchange measurements were made after a minimum of 3 weeks acclimation. The dark respiration rates of plants of all species from all stations were similar. Plants of all species acclimated to the colder subalpine environment were more efficient in photosynthesis at colder temperatures than were plants grown at the warmer environment of the lowest elevation. Conversely, plants grown in the desert were more efficient in photosynthesis at high temperatures than were plants grown in the subalpine region. Plants of the two species with the widest natural distributional range in elevation in the White Mts. showed the greatest plasticity in their photosynthetic response as indicated by shifts in the optimum photosynthetic temperatures dependent on treatment.

TABLE 1

Natural distribution of experimental plants

Species	Elev. range (m)	Elev. origin of seeds used (m)
Artemisia tridentata	1829–3200	3078
Chamaebatiaria millefolium	1980–3200	3200
Haplopappus apargioides	3048–3962	3658
Artemisia arbuscula	3200–3719	3475
Encelia virginensis ssp. *actoni*	1372–1829	1402

TABLE 2

Acclimation stations

Natural vegetation	Elev. (m)	Mean air temp. °C[a] Max.	Mean air temp. °C[a] Min.
Desert scrub	1402	38.9	11.7
Pinyon woodland	2408	33.4	10.3
Subalpine forest	3094	19.5	–2.4

[a] Based on weekly maximum and minimum temperatures during period of June 17 to Aug. 12, 1963.

Miller (1960) compared the effects of temperature on the photosynthetic rate in *Agrostis palustris* (creeping bent) which is adapted to cooler regions of the US, and *Cynodon dactylon* (bermuda grass) which is adapted to the warmer regions. The relative rate of apparent photosynthesis in creeping bent increased from 64.6% at 15°C to a maximum of 100% at 25°C, then decreased to 62.2% at 40°C. On the other hand, the relative rate of apparent photosynthesis in bermuda grass increased form 54.9% at 15°C to a maximum of 100% at 35°C, and only dropped to 97.7% at 40°C.

In summary, it is evident that plants vary genetically in their photosynthetic and respiratory responses to temperature changes, and they vary also in such responses depending on the temperature conditions during acclimation.

EFFECTS OF LIGHT

According to Johnson (1954) solar radiation at the outer surface of the earth's atmosphere has a virtually constant intensity of 1400 watts m^{-2} or 2cal cm^{-2} min^{-1}. About 98% of the energy is in the wavelength interval of 0.2–4.5 μ, including about 40–45% in the visible range of 0.4–0.7 μ. About one-third of the energy is reflected back to space by the earth's atmosphere and smaller amounts are absorbed and scattered by various components of the atmosphere. As a result, only about 50% of the total radiation reaches the earth on the average. This figure may be greater than 70% in dry regions with little cloud cover and lower than 40% in tropical rainy areas (Slatyer, 1967). Obviously, on very cloudy days the energy reaching the surface of the earth may be very low. Of the solar energy reaching the earth, about 40–45% is still present in the visible range.

Radiation in the visible range is most important in affecting organic processes in plants, so the rest of this discussion will be concerned primarily with visible light. The chief processes in plants which are affected by light are: (1) chlorophyll synthesis, (2) photosynthesis, (3) phototropism, (4) photoperiodism, and (5) transpiration.

Light Intensity Effects. Many plants are able under most conditions to develop well in less than full sunlight. Red kidney beans (*Phaseolus vulgaris*) grow and fruit well in growth chambers in a light intensity of 700–1000 ft-c. Intensity of light has a definite effect on the distribution of plants. Many ferns grow well under trees because such ferns attain their maximum rate of photosynthesis at light intensities considerably below full sunlight. Species which characteristically grow in shaded locations are able to remain alive at very low light intensities. Redwood (*Sequoia sempervirens*) seedlings normally grow in the deep shade of the forest floor and they are able to grow at intensities of as little as 100 ft-c (Bonner and Galston, 1952). *Pinus taeda* (loblolly pine) and *Pinus echinata* (shortleaf pine) seedlings are found in great profusion along road cuts and other open areas in the southeastern United States, but they fail to survive under dense forest canopies. Many hardwood seedlings such as those of *Quercus alba* (white oak) and *Quercus rubra* (red oak) survive nicely under such canopies and thus replace the pines in succession. Kramer and Decker (1944) found that photosynthesis in loblolly pine increased with light intensity up to the highest intensity used which was almost that of full sunlight. On the other hand, photosynthesis in white oak and red oak reached a maximum at one-third or less of full sunlight and showed slight decreases at higher light intensities. These results indicate that lack of sufficient light for photosynthesis may be a significant factor in the failure of pine seedlings to become established under forest stands. Seedlings of many other climax forest dominants such as *Fagus grandifolia* (beech) and *Acer saccharum* (sugar maple) have very low light requirements for photosynthesis also (Daubenmire, 1959). After a long series of studies, Blackman (1950) concluded that the distribution of *Scilla nonscripta* (bluebell) in English forests is determined primarily by light intensity.

Björkman and Holmgren (1963) investigated the photosynthetic response to light intensity of sun and shade plants of *Solidago virgaurea* (golden-rod). They found that the shade plants had a higher chlorophyll content per unit leaf area in weak light (3×10^4 ergs cm^{-2} sec^{-1}) than in strong light (15×10^4 ergs cm^{-2} sec^{-1}) and more than did sun plants in weak light. On the other hand, the sun plants had lower concentrations of chlorophyll in weak light than strong light. The gross rate of photosynthesis (apparent rate plus respiration rate) in sun plants at light saturation was 25.5 ± 2.0 mg CO_2 dm^{-2} h^{-1} when the plants were grown in strong light (same as above) prior to testing whereas it was only 17.9 ± 0.6 mg CO_2 dm^{-2} h^{-1} in shade plants grown in strong light. The gross rate of photosynthesis at light saturation was higher in the shade plants than in the sun plants when the plants were grown in weak light prior to testing, 2.93 ± 0.08 in shade plants versus 2.31 ± 0.04 in sun plants. The difference of the means in the plants grown in low intensity was highly significant statistically. The authors concluded that the photosynthetic behavior was consistent with light intensities prevailing in the natural environment indicating that the behavior was a result of a genetic adaptation to the habitat. Hybridization experiments supported this conclusion.

Björkman (1966) reported on additional comparative studies of sun and shade plants of several species. Plants of shaded habitats consistently reached a higher percentage of the maximum photosynthetic rate at light saturation, when tested in a low light intensity of 10^4 ergs cm^{-2} sec^{-1} (Table 3). *Plantago lanceolata* (plantain) was found only in open meadows and *Lamium galeobdolon* (henbit) only in dense beech forests. Björkman found that the activity of Photosystem I (far red, 700 mμ) in *Solidago virgaurea* was about the same when grown in weak or strong light, regardless of the original habitat. On the other hand, the action of Photosystem II (>625 mμ used) was impaired in shade plants grown in high light intensity and in sun plants grown in low light intensity. The Emerson enhancement effect (increased photosynthesis from combination red–far red light over sum of photosynthesis in each light quality separately) was drastically reduced in shade plants grown in high light intensities.

Milner and Hiesey (1964) studied the photosynthetic responses to light intensity of several races of *Mimulus cardinalis* (monkey-flower) collected from an elevation of 45 m to 2220 m in California. They found that the saturating light intensity for the races increased with elevation of their original habitats. At 0°C, the saturating light intensity varied from 290 to 570 ft-c for different races, and at 40°C from 3500 to 5900 ft-c. Light intensity, of course, generally increases with elevation. Mooney and Billings (1961) in their study of ecotypes of *Oxyria digyna* found that the high elevation, low latitude plants attained photosynthetic light saturation at

TABLE 3

Photosynthesis at a low light intensity of 10^4 ergs cm^{-2} sec^{-1} in percent of the photosynthetic rate at light saturation[a]

Species	Sun plants	Shade plants
Plantago lanceolata	8	—
Solidago virgaurea	9	17
Rumex acetosa	11	16
Geum rivale	14	16
Lamium galeobdolon	—	25

[a] From Björkman (1966).

a higher light intensity than did low elevation, high latitude plants even when preconditioned under the same conditions.

Light Quality All visible light is effective in the synthesis of chlorophyll except wavelengths above 680 mμ (Sayre, 1928). Chlorophyll has a maximum absorption peak in the blue-violet (430 mμ) and a secondary maximum in the red (660 mμ), and chlorophyll b has a maximum absorption peak in the blue (455 mμ), and a secondary maximum in the orange-red (640 mμ) (Salisbury and Ross, 1969). Hoover (1937) reported that wheat (*Triticum* sp.) has a maximum rate of photosynthesis at 655 mμ in the red and a secondary maximum at 440 mμ in the blue. Warburg and Negelein (1923) gave a general curve for photosynthesis showing a maximum rate in the red and a secondary maximum in the blue. It is now known that photosynthesis actually consists of two photosystems which work together to complete the light reactions which result in the production of ATP and NADPH. Photosystem I has an absorption peak at 700 mμ and Photosystem II has an absorption peak around 672 mμ (Salisbury and Ross, 1969).

Phototrophic responses (movements in response to light) are chiefly due to wavelengths in the blue-violet, 400–490 mμ, but there may be some response to UV light (Johnston, 1934).

The most efficient light quality to interrupt the dark period to prevent a short-day photoperiodic response is in the wavelength range of 620–640 mμ.

Effects of Daylength The response of organisms to the relative lengths of the light and dark periods is termed photoperiodism. Garner and Allard (1920) discovered this phenomenon while working with Maryland Mammoth Tobacco (*Nicotiana tabacum*). They extended the work to many other species and found that flowering in many plants is regulated by the relative lengths of the light and dark periods. They classified plants into three categories on the basis of their photoperiodic flowering responses: (1) short-day plants—those plants which flower only when the day length is below a *certain critical maximum,* (2) long-day plants—those which flower only when the day length is above a *certain critical minimum,* and (3) day-neutral plants—those in which flowering is not determined by day length. Another category has been added, the intermediate-day plants—those which flower only between two critical day lengths. Larsen (1947) found that the strains of *Andropogon scoparius* (little bluestem) from the area south of 36°N latitude were intermediate-day plants because they failed to flower on a 13-hour photoperiod and also on a 15-hour photoperiod, but flowered well between those daylengths.

It is now known that numerous phenomena in plants are regulated by day length in many species, bulb formation, type of vegetative growth, dormancy, leaf abscission, seed germination, etc. The timing mechanism is still obscure, but it seems to involve a pigment called phytochrome which was discovered and isolated by Borthwick and his associates at the USDA laboratories in Beltsville, Maryland (Borthwick, Hendricks, and Parker, 1952). They found that phytochrome exists in two forms which can readily be converted from one form to another. One form has an absorption peak in the red at about 660 mμ and is designated as P_r. The other form has an absorption peak at a longer wavelength of red (730 mμ) and is designated as P_{fr}, for far-red. When P_{fr} absorbs light at 730 mμ it is converted to P_r, and when P_r absorbs light at 660 mμ it is converted to P_{fr}. In addition to these rapid changes brought about by light, there is a slow conversion of P_{fr} to P_r in darkness. In sunlight and broad spectrum artificial light the conversion of P_r to P_{fr} predominates. The P_{fr} form appears to be inhibitory to the flowering process, so darkness is important to eliminate all or part of this inhibitory form. Salisbury (1958) feels that the plant possibly synthesizes a postulated flowering hormone only during darkness also. Borthwick and Hendricks (1960) reported that the basic difference in long- and short-day plants may be in the ratio of P_r to P_{fr} required to initiate the flowering or other response.

The presence of photoperiodic ecotypes has been well documented in many geographically wide-ranging species of plants. Olmsted (1944) was the first to demonstrate such ecotypes in his work with *Bouteloua curtipendula* (sideoats grama). He found that plants of this species from southern Texas and southern Arizona were generally short-day or intermediate-day plants, with an upper critical photoperiod for flowering between 14 and 16 hours. These strains flowered more vigorously on a 13-hour than on a 9-hour photoperiod. The North Dakota strains consisted largely of long-day plants with a critical photoperiod of about 14 hours. The strains from Oklahoma, Kansas, and New Mexico included mostly long-day individuals although the length of the critical photoperiod decreased with decrease in latitude of origin.

Larsen (1947) found that only strains of *Andropogon scoparius* (little bluestem) originating south of 36°N latitude produced visible inflorescences on a 14-hour photoperiod. The northern strains flowered on a 15-hour photoperiod but not the southern strains. The northern strains were apparently long-day plants because they were able to initiate flowers on a long photoperiod but were inhibited from flowering on 13- and 14-hour photoperiods. As was previously indicated at the beginning of this section on effects of day-length, the strains originating south of 36°N latitude were apparently intermediate-day plants.

Vaartaja (1959) collected seeds from 19 genera of trees, 38 species and 82 origins of widely different latitudes in Europe and North America. Plants derived from these seeds were grown in uniform conditions except for photoperiod. Photoperiods of 12, 14, 16, and 18 hours were used with the total light energy being identical in all cases. He found that the farther north the origin of the strain, the longer was the critical daylength below which height growth of seedlings was retarded. Moreover, the more northerly the source, the shorter was the critical dark period which induced dormancy in several species. In some plants from the far north, photoperiods that inhibited elongation permitted great increases in weight of stems and roots, and in numbers of buds. Cambial growth thus would continue later in the growing season than elongation.

Irgens-Moller (1957) collected approximately 100 plants (2–6 year old) of *Pseudotsuga menziesii* (douglas-fir) from each of seven locations in Oregon at elevations of 60 feet to

4000 feet. The plants were potted and kept in a cold frame at Corvallis, Oregon, during two winters after collection so that all were exposed to the same winter conditions. On February 1 after the second winter, half of the plants from each locality were placed in a 9-hour photoperiod and half on an 18-hour photoperiod with all other conditions the same. There were no effects of photoperiod on time of bud bursting in the low altitude plants, but the long days hastened bud bursting strikingly in high altitude plants as compared with effects of short days. The selection probably results from the killing of seedlings by low night temperatures at high altitudes if they break dormancy in the short days of winter or early spring.

EFFECTS OF PLANT PRODUCED TOXINS

De Candolle first suggested the existence of naturally-occurring plant growth-inhibitors in 1832 (Bonner 1950). He noted from field observations that *Euphorbia* (spurge) was apparently inhibitory of flax (*Linum usitatissimum*), thistles (probably *Cirsium*) to oats (*Avena sativa*) and rye to wheat. Very little research was done on the subject for almost 100 years at which time Cook (1921) described the characteristic wilting of potato (*Solanum tuberosum*) and tomato plants grown near *Juglans nigra* (black walnut). Davis (1928) extracted juglone from mature hulls and roots of black walnut and found it to be very toxic to tomato and alfalfa (*Medicago sativa*) plants when injected into the stems. The juglone was identified as 5-hydroxynaphthaquinone.

Proebsting and Gilmore (1940) related the problem of re-establishing peach (*Prunus persica*) trees in old peach orchards to the presence of toxic substances in the soil. Bonner and Galston (1944) reported that the edge rows in guayule (*Parthenium argentatum*) plantings in California had much larger plants than the center rows and the differences could not be eliminated by heavy watering and mineral application. Experiments indicated that leachates from pots of year-old guayule plants were very inhibitory to guayule seedlings. The inhibitor was subsequently identified as transcinnamic acid.

Muller, Muller, and Haines (1964) observed areas free of vegetation around certain shrubs in California grasslands. They found that at least three shrubs, *Salvia leucophylla* (clearleaf sage), *S. apiana* (bee sage), and *Artemisia californica* (California sagebush) produced volatile materials which inhibited various test plants. Muller and Muller (1964) identified several terpenes which were produced by leaves of three species of *Salvia,* and two of these, camphor and cineole, were found to be very inhibitory to test plants. Muller, Hanawalt, and McPherson (1968) related the disappearance of herbaceous species in the open California chaparral during the fire cycle to the production of inhibitory chemicals by chaparral species.

My students and I have obtained good evidence that the rapid disappearance of the pioneer weed stage (2 to 3 years) in our revegetating old-fields in central Oklahoma is due to the inhibition of seedlings of species of that stage by several plants of the pioneer stage (Abdul-Wahab and Rice, 1967; Parenti and Rice, 1969; Wilson and Rice, 1968). Triple-awn grass (*Aristida oligantha*), the dominant of the second stage, is generally not inhibited by species of the pioneer weed stage and can grow well in the infertile soil, so it is able to invade the area.

There is some evidence that antibiotics (substances produced by microorganisms which inhibit other microorganisms) may be important in the growth and distribution of the higher plants as well as microorganisms. Certain soil bacteria inhibit the root-nodule bacteria which are important in adding nitrogen to the soil (Konishi, 1931). Iuzhina (1958) reported that many soil bacterial, fungi and actinomycetes are antagonistic to *Azotobacter,* a free living bacterium that adds nitrogen to the soil. Some soil microorganisms have been found to be inhibitory to certain microorganisms that cause diseases of higher plants (Cooper and Chilton, 1950).

Another level of inhibition is that of microorganisms against higher plants. There is no question that many, if not most, pathogenic microorganisms produce abnormal symptoms in the host plants through the production of toxins. Very few of these compounds have been identified and this remains an important and fruitful field for research. Microorganisms are sometimes responsible for changing certain non-inhibitory metabolites of higher plants into inhibitory compounds (Börner, 1960).

The remaining level of inhibition is that of higher plants against microorganisms. There is considerable evidence that resistance of many plants to fungal, viral, and bacterial diseases may be associated with the production by resistant varieties of inhibitors of the pathogens (Farkas and Kiraly, 1962; Hughes and Swain, 1960; Schaal and Johnson, 1955).

Ferenczy (1956) found that the seeds or fruits of 52 species and varieties from 19 plant families contained antibacterial compounds and that seeds of some species were attacked intensely by molds whereas others were attacked slightly or not at all. Lane (1965) found that fruits of the native sunflower, *Helianthus annuus,* rotted more frequently during germination tests if certain inhibitors were leached from them before the tests. Those species in which decay of the seeds during germination is less likely to occur would certainly stand a better chance of becoming established.

I have found that many of the low-nitrogen requiring early plant invaders of abandoned cultivated fields produce inhibitors of the nitrogen-fixing bacteria (Rice, 1964; 1965b; 1965c). Triple-awn grass, the dominant of the second stage, is one of the inhibitory species. This would give such plant species a selective advantage in competition over plants with higher nitrogen requirements. This probably slows succession in old-fields, because Rice, Penfound, and Rohrbaugh (1960) found that the order in which species invade revegetating fields in central Oklahoma, beginning with the second stage, is the same as the order based on increasing nitrogen requirements.

Muller (1965) found that the volatile terpenes from *Salvia leucophylla* reduce cell elongation and cell division in the radicles and hypocotyls of germinating *Cucumis sativus* (cucumber) seeds. Muller *et al.* (1969) reported that two volatile terpenes, cineole and dipentene, which emanate from

Salvia leucophylla leaves markedly reduce oxygen uptake by suspensions of mitochondria from *Avena fatua* (wild oats) or cucumber. The inhibition appears to be localized in that part of the Krebs cycle where succinate is converted to fumarate, or fumarate to malate. They also reported that the permeability of cell membranes appears to be decreased on exposure to terpenes.

Most of the inhibitors that my students and I have identified from our old-field species are phenolics (Abdul-Wahab and Rice, 1967; Parenti and Rice, 1969; Rice, 1965a, 1965b; Rice and Parenti, 1967; Wilson and Rice, 1968). Some of the inhibitors identified are: chlorogenic acid, p-coumaric acid, ferulic acid, gallic acid, p-hydroxybenzaldehyde, isochlorogenic acid complex, scopoletin, scopolin, sulfosaliyclic acid, and several tannins.

Sondheimer (1962) reported that chlorogenic acid is a strong inhibitor of several enzyme systems and it is possible that this may be its chief role in growth inhibition. Schwimmer (1958) found that a 10^{-3} M concentration of chlorogenic acid caused a 50% inhibition of potato phosphorylase activity. Mazelis (1962) reported that a peroxidase-catalyzed oxidative decarboxylation of methionine is strongly inhibited by a 5×10^{-6} M concentration of chlorogenic acid. Sondheimer and Griffin (1960) reported that indoleacetic acid oxidase is inhibited by chlorogenic acid and its isomers, and by isochlorogenic acid and dihydrochlorogenic acid.

Zenk and Müller (1963) reported that p-coumaric and ferulic acids increase decarboxylation of indoleacetic acid (IAA), resulting in reduced plant growth. Henderson and Nitsch (1962) found a pronounced inhibiting effect of p-coumaric acid on IAA induced growth also.

Bendall and Gregory (1963) found that phenol oxidases which are important in the formation of lignin-like polymers from coniferyl alcohol and oxidation products of tannins such as quinones react with each other to produce a complex that may make phenol oxidase catalytically inactive, or may produce an active protein of modified properties. Hulme and Jones (1963) and Jones and Hulme (1961) found that tannins caused considerable reduction of Krebs cycle succin oxidase and malic enzyme activity. Gallic and tannic acids were shown also to inhibit IAA induced growth (Zimsmeister and Hollmuller, 1964). Hall (1966) and Williams (1963) reported that relatively low concentrations of tannic acid were very inhibitory to pectolytic enzymes. Gallic and tannic acids are very inhibitory to the nodulation of heavily inoculated legumes and to hemoglobin formation in the nodules (Blum and Rice, 1969). The hydroxyl groups of tannins are known to have a strong affinity for the peptide linkages of proteins, so it is likely that reactions readily occur between the two compounds when they come in contact at a time when the ice-shell around the protein is appropriately modified. This would undoubtedly change the nature of the protein.

Einhellig *et al.* (1970) found that sunflower (*Helianthus annuus*) and tobacco plants treated with 10^{-4} and 5×10^{-4} scopoletin concentrations had significant increases in scopoletin and scopolin in their tissues. Net photosynthesis in tobacco plants treated with a 10^{-3} M concentration of scopoletin was depressed to as low as 34% of that of the controls. Reduced growth in leaf area over a 12 day experiment correlated well with the significant reduction in the rate of net photosynthesis.

The surface has just been scratched in identifying plant produced inhibitors of other plants. Moreover, the field is wide open for research on the mechanisms of action of the presently known inhibitors.

GENERAL CONCLUSIONS

I have discussed briefly the presently known physiological basis for some of the ecological responses of plants to the environmental factors of water, temperature, radiant energy, and toxins. It would obviously require most of the present volume to discuss the presently known effects of all environmental factors. Even so, our knowledge of the effects of most factors is superficial. Many of the known physiological effects may be indirect ones also.

In closing, I emphasize that the physiological ecologist is searching for the physiological basis for ecological behavior. It is essential that research in this area be vigorously pursued.

ECOLOGY OF PRIMARY TERRESTRIAL CONSUMERS

BASIC CONCEPTS

There are many approaches to the study and appreciation of the natural world. The ecologist looks at it with his interest focused on the relations between living things and their surroundings. For purposes of quantitative analysis, he finds it useful to think of nature as organized into ecological systems (*ecosystems*), in which the living units interact with their environments to bring about the *flow of energy* and the *cycling of matter* wherever life is found. In this conceptual framework, organisms can profitably be considered according to their major roles in the handling of matter and energy. Thus, living things have ecologically classified (Thienemann, 1926) as *producers* if they are *autotrophic,* i.e., able to manufacture their own food from simple inorganic substances with energy obtained from sunlight (photosynthetic green plants) or from the chemical oxidation of the inorganic compounds (chemosynthetic bacteria), or as *consumer* if they are *heterotrophic,* i.e., required to depend on already synthesized organic matter as the source of food energy. A special and very important group of consumers are the *decomposers,* which break up the complex organic substances of dead matter, incorporating some of the decomposition products in their own protoplasm and making available simple inorganic nutrients to the producers. Decomposers consist chiefly of fungi and bacteria, which absorb their food through cell membranes and thus differ significantly from the larger consumers, which ingest plant and animal tissue into an alimentary tract. There are, however, many different modes of nutrition, and it has recently been suggested (Wiegert and Owen, 1970) that energy flow and the cycling of matter may be better understood if heterotrophic consumer organisms are classified on the basis of their energy resources rather than in terms of their feeding habits. Thus we may recognize two major groups of consumers: *biophages* if they obtain their energy from living matter, and *saprophages* if they derive their energy from dead and decaying materials. These basic classifications do not accommodate such organisms as Euglena and the Venus fly-trap which are capable of both photosynthesis and heterotrophy, but they provide a reasonable framework for the majority of plant and animal species.

FOOD CHAINS AND FOOD WEBS

The concept of *food-chain* was developed by Elton (1927) to represent the series of interactions that occur between organisms in their efforts to obtain nourishment. Thus a hierarchy of relationships is formed as green plans or their products are eaten by animals and these are in turn eaten by other animals. Organisms, then, are functionally related to one another as links in a chain, i.e., as successive components in a system for the transfer of energy and matter. An organism can be characterized ecologically in terms of the position it occupies in its food-chain, and consumer organisms that are one, two and three links removed from the producer are referred to as *primary, secondary* and *tertiary consumers,* respectively. Thus primary consumers are those which subsist on green plants or their products, and are broadly termed *herbivores,* in contrast to secondary and higher-order consumers, which are termed *carnivores.* (Note again, as with the producer–consumer classification, that the herbivore–carnivore dichotomy is not perfect; it does not allow for *omnivores,* which eat both plant and animal tissue, or for those organisms which are herbivorous at one state in their life history and carnivorous at another.)

With each successive transfer, some of the energy that was incorporated by the producer organism (the initial link in the chain) is lost as heat, and for this reason food-chains generally do not involve more than four or five links from the beginning to the ultimate large consumer. A typical terrestrial food-chain consists of a green plant, e.g., grass, eaten by an insect, e.g., a grass-hopper, which is in turn eaten by a small bird, e.g., a sparrow, and this in turn by a larger bird, e.g., a hawk. However, food chains are generally linked to other chains at almost every point; the grass is likely to be eaten by numerous species of herbivore, each of which has its own set of predators, etc. The result is that the community ecosystem is made up, not of a set of isolated food-chains but of an interconnected *food-web* whose structure rapidly becomes very complex when more than a few species are considered. This complexity, however, is restricted in part by the limited length of food-chains and in part by the unidirectional flow of energy in these chains. Food-webs are made up of two principal types of food-chains: *grazing food-chains,* which involve the direct consumption and transformation of living tissue, as in the grazing of rangeland by cattle or sheep, and *detritus food-chains,* which involve the disintegration and conversion of dead matter, both plant and animal, by a sequence of decomposer organisms.

TROPHIC LEVELS AND ECOLOGIGAL PYRAMIDS

The concept of the food-chain permits us to equate, in terms of ecosystem function, all organisms which occupy the same feeding position, i.e., which are the same number of links removed from the producer organism. Organisms which are similar in this respect are said to occupy the same *trophic level.* Such levels form a natural hierarchy arranged from the producer level at the bottom, through the primary consumer (herbivore) level, to one or more successive levels of subsidiary consumers at the top. The trophic level concept was developed by Lindemann (1942) to compare the energy content of the different feeding groups in natural communities and to evaluate the efficiency with which energy is transferred from level to level.

If the number of individuals, the total *biomass* (weight of tissue), or the energy content of the organisms of successive trophic levels in a natural community is examined, the quantity is generally found to decrease as one goes upward from producer to ultimate consumer levels. Diagrammatic models of this trophic structure thus tend to be pyramidal and have given rise to the concept of *ecological pyramids.* Comparisons of trophic levels based on numbers of individuals can be misleading, however, especially when species of very different size and rate of growth are involved: herbivorous insects are likely to be much more numerous per unit of suitable habitat than are grazing or browsing mammals (Evans and Lanham, 1960). This difficulty is partly resolved by measuring total weight of organisms present, thus replacing a *pyramid of numbers* with a *pyramid of biomass.* If they are constructed for parasite food-chains (in which one host can support many parasites) or for communities whose producers (such as diatoms and other minute algae) have a more rapid rate of replacement, or *turnover,* than its consumers, such pyramids may appear inverted or may show a very narrow base. Furthermore, because the number of calories varies considerably from tissue to tissue because of differences in composition (fat averages about 9500, and carbohydrate and protein about 4000, calories per gram), biomass may prove a poor indicator of energy content. It is therefore desirable, whenever possible, to replace weights with calorific values and to convert the pyramid of biomass into a *pyramid of energy.* If the total amount of energy utilized at each trophic level over a set period of time is taken into account the quantity will always be less at each succeeding level and the upright pyramidal shape of the model will be maintained. Thus energy units provide the best basis for comparing the *productivity* (the rate at which energy and matter are stored in the form of organic substances) of different organisms, of different trophic levels, and of different ecosystems. They also offer the best means of evaluating the *efficiency* (the ratio of energy stored or put out in a process to that put in, usually expressed as a percentage) of organisms and ecosystems in carrying out their activities of transferring and transforming energy and matter.

STANDING CROPS, PRODUCTION, AND ENERGY FLOW

The quantity of living organisms present at a given time may be referred to as the *standing crop* or *stock.* For reasons already explained, this quantity is best expressed in terms of its energy content (in calories). The magnitude of the standing crop will vary from place to place, depending basically on the available quantities of energy and nutrients, and in almost all places from season to season, being influenced by all the factors affecting growth and reproduction. Relatively long-lived consumers like the large herbivorous mammals may accumulate and store considerable quantities of matter and energy in their bodies and thus achieve a large standing crop, but surprisingly high values can be reached by much smaller organisms, such as insects, which feed more efficiently and reproduce more rapidly. Unusually high standing crops are seen at times of population explosions, such as those of defoliating insects and of periodically fluctuating species like snowshoe hares and lemmings, but these levels cannot be sustained for more than a short time. Inverted pyramids of biomass illustrate the possibility of a relatively large standing crop of consumers supported by a small standing crop of producer plants, when the latter are smaller, grow more rapidly, and are replaced more frequently than the consumers.

Because organisms may be eaten or move away from an area, the standing crop often fails to be a good measure of the total quantity of tissue they have produced over a given period of time. This total quantity, or *production*, includes not only the new tissue added as *growth* to the bodies of individual organisms but also that resulting from the reproduction of new individuals. That part of the production that is removed by man (or some other species) is known as the *yield* or harvest. Because of the limited efficiency of the metabolic processes required in the formation of new tissue, more energy and matter are needed by the organism than are stored in production. Thus, to evaluate the complete functioning of an ecosystem, we need a measure of the total energy (or matter) involved in metabolism; for consumer organisms, this is referred to as *assimilation* or *energy flow.* (For producer organisms, the total energy or matter used in their metabolism is called *gross primary production*, while that incorporated as new tissue is called *net primary production.*)

ENERGY BUDGETS AND EFFICIENCIES

Full understanding of increases or decreases in standing crop or energy flow requires quantitative knowledge of the biological processes involved in the transfer of matter and energy. For consumer organisms, these consist of the processes of *ingestion* or intake, *respiration*—a measure of metabolic activity, and *egestion* (generally taken to include the elimination of both feces and urine). Use is made of the *energy budget* or balance described by the equations.

$$\text{Ingestion} = \text{Production} + \text{Respiration} + \text{Egestion}$$

$$\text{Assimilation} = \text{Production} + \text{Respiraton}$$

and other expressions to calculate the values for processes whose quantities are not known or to determine the net change of energy transfer. Such calculations enable the ecologist to estimate the efficiency with which these processes are carried out, as for example

$$\text{assimilation efficiency} = \frac{\text{calories assimilated}}{\text{calories ingested}}$$

$$\text{growth efficiency} = \frac{\text{calories in growth}}{\text{calories ingested}}$$

$$\text{yield efficiency} = \frac{\text{calories to man (or other exploiter)}}{\text{calories ingested}}$$

These and other efficiencies provide the means for comparing different trophic levels or other ecological units with respect to their functional roles in the ecosystem. For primary consumers, the ratio

$$\frac{\text{calories consumed by herbivore population}}{\text{calories of available plant food}}$$

measures their *food-chain efficiency,* while the ratio

$$\frac{\text{calories of herbivores consumed by carnivores}}{\text{calories of plant food consumed by herbivores}}$$

measures their *efficiency of energy transfer.*

DIVERSITY OF PRIMARY CONSUMERS

All parts of plants—leaves, buds, flowers and their products (seeds, pollen, nectar), stems, sap, roots, bark and wood—are eaten by primary consumers, who have evolved a great diversity of life form and habits in response to their food. Large grazers and browsers, such as elephants and deer, can ingest plant tissue in bulk, but others are specialized to particular products, e.g., the mylabrid weevils that feed on beans and peas, and the sap-sucking aphids and leaf-hoppers. The specialization may extend to particular kinds of plants; the Australian koala "bear," for example, is limited to leaves of *Eucalyptus*, and the larva of the swallowtail butterfly *Papilio marcellus* feeds exclusively on the foliage of the prickly ash (*Zanthoxylua*). Much less is known of the food habits of detritus-feeders, which never attain the large size of some grazers, but Petrusewicz and Macfadyen (1970) point out that "remarkably few species restrict their diets at all narrowly."

All of the principal phyla of land animals have developed forms which are partly or entirely herbivorous, and it is likely that the majority of terrestrial heterotrophic species are primary consumers. About half of the known kinds of insects are plant-eaters (Brues, 1946), and in some habitats the proportion may be considerably higher: Menhinick (1967) found that herbivores made up about 80% of the insect species of a bush clover (*Lespedeza*) stand in South Carolina, and Evans and Murdoch (1968) reported that 85% of approximately 1500 insect species encountered on a 30-year-old abandoned field in Michigan were herbivorous. With such *diversity,* it is unlikely that any species of plant has escaped exploitation by herbivores. Indeed, most plants are host to a wide range of consumers; for example, at least 227 species of herbivorous insects are known to be associated with the oaks (*Quercus robur* and *Q. petraea*) of British woodlands (Elton, 1966, 197).

The most important insect consumers of live vegetation belong to the orders Orthoptera (grasshoppers), Hemiptera (true bugs), Homoptera (leaf-hoppers, aphids, scales), Coleoptera (beetles), Lepidoptera (moths, butterflies), Diptera (flies), and Hymenoptera (bees, wasps, ants). Insects as a group share dominance as herbivores with the mammals, including such larger types as horses, pigs, deer, antelope, goats, sheep and cattle, and such smaller ones as hares, rabbits, squirrels, marmots, voles and lemmings. (In tropical regions, various monkeys and apes are also important herbivores, as are fruit-eating and nectarivorous bats.) There are significant herbivores among terrestrial birds, e.g., the Galliformes (grouse, quail, pheasants) and the "specialist" seed-eating finches and sparrows, the fruit-eating parrots, and the nectar-sucking hummingbirds, and among land mollusks, such as the "garden" snails and slugs.

Much less is known of the herbivores which feed on roots, underground stems, and other living plant parts in the soil. Studies by Bornebusch (1930), Van der Drift (1951), Cragg (1961) and Macfadyen (1961) indicate that the most important groups of herbivores in north temperate grassland and forest soils are the parasitic nematode worms, the molluscs, and the larvae of Diptera, Coleoptera, and Lepidoptera. They occur in close association with other primary consumers, the detritus feeders, which include the Oligochaeta (earthworms and enchytraeid worms), Isopoda (wood lice), Diplopoda (millipedes), free-living Nematoda, Collembola (spring tails), and Acari (mites). The mechanical comminution of dead matter by these organisms provides a substrate of small particles which can be more easily attacked by fungi, protozoa, bacteria and other microorganisms (Phillipson, 1966).

MEASUREMENT OF PRIMARY CONSUMPTION

The measurement of primary consumption involves the assessment, in terms of number of individuals, biomass, and energy equivalence, of the quantity of herbivorous animals present or produced over a period of time, the *energetic cost* of producing and maintaining that product, and the fate of the matter and energy that becomes incorporated in herbivore tissue. A detailed account of methods and techniques employed for these purposes is beyond the scope of this article, but a brief treatment is presented below.

The mobility, abundance, and small size of many primary consumers make it difficult to assess their numbers. Total counts or *censuses,* as of large mammals by aerial photography (Parker, 1971) or of small ones by intensive trapping (Gliwicz *et al.,* 1968), can only rarely be achieved, and it is general practice to rely on *sample collections* (e.g., Wiegert, 1964, 1965). The marking of individual organisms for subsequent recapture has been employed to estimate population size in such herbivores as grasshoppers (Nakamura *et al.,* 1971), and *indices of relative abundance* based on fecal pellet counts (Southwood, 1966, 229) or on damage to vegetation (Odum and Pigeon, 1970, 1–69) are sometimes used. Estimation of change in numbers with time involves a knowledge of birth, death and migration rates, the calculation of which requires considerable *lifetable information.*

Biomass values are commonly derived by multiplying the number of individuals by average weights obtained from sample specimens or calculated from formulas relating weight to body dimensions (Petrusewicz and Macfadyen, 1970, 51). More detailed studies require knowledge of the growth of individuals and the rate of weight gain. Ultimately, biomass should be converted to its energy equivalent by determining its calorific value; this requires the use of a *calorimeter,* such as that developed by Phillipson (1964), and because of the difficulty of obtaining complete combustion, it is generally carried out in the laboratory. Published tables of the caloric content of various plant and animal tissues (e.g., Golley, 1961) show a considerable range of values even for the same species, reflecting differences in life history stage, season, and environmental conditions.

It is also clear that the dimensions of primary consumption cannot be accurately gauged without knowledge of the processes (*ingestion, egestion, assimilation, respiration*) associated with it. It is important, therefore, to investigate the food habits and feeding rates of herbivores, as well as to determine the quality of the food consumed, the proportion rejected as feces, the digestive efficiency, and the rates of respiration (oxygen consumption can be measured by a *respirometer* such as that of Smith and Douglas, 1949; see also the book on manometric techniques by Umbreit *et al.,* 1957). Much of this work has had to be done on animals in confinement, and little is known as yet of activity levels and metabolic rates of herbivores in nature. Recent developments in the use of *radioactive isotope tracers* (Williams and Reichle, 1965) and the *telemetric measurement* of heart rate or other characteristics related to respiration (Adams, 1965) give promise that the study of metabolism under filed conditions will eventually be feasible.

EFFICIENCY OF PRIMARY CONSUMERS

With careful management and appropriate stocking large mammalian herbivores can consume a fairly high proportion of the available plant food. In Great Britain, sheep stocked at a density of 10 ewes per hectare on lowland pasture may ingest up to 70% of the annual production of grass (Eadie, 1970), and beef cattle on management rangeland in the United States, when stocked at the maximum recommended *exploitation rate,* will consume from 30% to 45% of the forage (Lewis *et al.,* 1956). The efficiency of feeding will of course vary with the situation: sheep on hill pastures, where a stocking rate cannot exceed 0.8 ewes per hectare, may utilize no more than 20% of the available food (Eadie, 1970), and Paulsen (1960) indicates that on alpine ranges in the Rocky Mountains the proportion of herbage production removed by sheep was only 7%. This latter figure is close to estimates of feeding efficiency obtained for large mammals in the wild: 10% for the Uganda kob (Buechner and Golley, 1967) and 9.6% for the African elephant (Wiegert and Evans, 1967). Where large, multispecies herds of ungulates occur, as on the savannas of Africa, their combined efficiency may be much higher: estimates of 60% for Uganda grassland and of 28% for Tanganyika grassland were obtained from observations by Petrides and Swank (1965) and Lamprey (1964), respectively.

At ordinary densities, small herbivores, both vertebrate and invertebrate, are much less efficient in their utilization of available food. Golley (1960) reports an efficiency of 1.6% for meadow voles (*Microtus*) in a Michigan grassland, and values of less than 0.5% are estimated for a variety of other small mammals and granivorous birds (Wiegert and Evans, 1967). Similar low efficiencies apparently characterize insect herbivores except when these are present in plague proportions. Wiegert (1965) found that grasshoppers (23 species of acridids and tettigoniids) consumed 1.3% of net plant production in a field of alfalfa, and Smalley (1960) obtained efficiency values of 1.6–2.0% for the meadow grasshopper *Orchelimum* in a *Spartina* salt marsh. Even if all invertebrate herbivores are considered together, their total consumption of net primary production seems rarely to exceed 10%; the following values appear to be representative:

Nature of ecosystem	% net plant production used by invertebrates	References
Bush-clover stand (S.C.)	0.4–1.4	Menhinick, 1967
Festuca grassland (Tenn.)	9.6	Van Hook, 1971
Spartina salt marsh (Ga.)	7.0–9.2	Teal, 1962
mesophytic woodland (Tenn.)	1.5	Reichle and Crossley, 1967
Mature deciduous forest (southern Canada)	1.5–2.5	Bray, 1964

These values do not necessarily indicate the total damage done to the plant crop. For example, Andrzejewska *et al.* (1967) report that grasshoppers may destroy 4.8 times the amount of plant material they ingest, by gnawing the grass blades so that part of the leaf falls off. Such material does not enter the grazing food-chain, however, but drops to the ground and is consumed by detritus feeders.

The nutritive value of most higher plants varies with age of the plant, season and environmental conditions, which also affect the *palatability* of the food. Few herbivores have the ability to digest cellulose without the assistance of *symbiotic bacteria* or *protozoa,* and much of the food that is eaten fails to be assimilated and is eliminated as feces. Assimilation therefore involves an important split in the flow of matter and energy through the ecosystem.

High assimilation/consumption ratios can be achieved by herbivores which are selective feeders on concentrated foods such as nuts, seeds and fungi; assimilation efficiencies of 85–95% have been recorded for such small mammals as *Clethrionomys, Apodemus* and *Microtus* (Drozdz, 1967; Davis and Golley, 1963, 81). Somewhat lower values are reported for large ruminants, ranging from 60–80% for sheep, cattle and deer down to 40% for moose and elephant (Graham, 1964; Dinesman, 1967; Davis and Golley, op. cit.). Interestingly, insect herbivores appear to be considerably less efficient feeders, reaching assimilation levels of 29% for the caterpillar *Hyphantria,* 27% for the grasshopper *Orchelimum,* 36% for the grasshopper *Melanoplus,* and 33% for the spittlebug *Philaenus* (Gere, 1956; Smalley, 1960; Wiegert, 1964, 1965). Detritus feeders seem to have even lower efficiencies, as witness values of 20% for oribatid mites and 10% for the millipede *Glomeris* (Engelmann, 1961; Bocock, 1963). Thus, grazing food-chains and detritus food-chains appear to be characterized by quite different assimilation rates.

Part of the energy assimilated by herbivores is stored as growth or production, while the rest is respired, dissipated as heat in the oxidation of organic matter. These respiratory losses may amount to as much as 98% of the energy assimilated (Petrusewicz and Macfadyen, 1970) but vary greatly, depending on such factors as environmental temperature, level of activity, and age of the individual. In mammals, there is a tendency for the *weight-specific respiration rate* to rise as body weight decreases, and this, in combination with the fact that growth and reproduction rates tend to be greater in small species than in large ones, apparently results in a rather constant low production/assimilation ratio of 1–2% for mammalian populations; values of this magnitude have been calculated for both elephants and mice (Wiegert and Evans, 1967). In contrast, herbivorous insect populations seem to show much higher assimilation efficiencies, on the order of 35–45% and, when only young life stages (larvae, nymphs) are involved, even of 50–60% (Macfadyen, 1967). Data are still too few to permit satisfactory generalizations, but the importance of further studies is evident when it is remembered that energy lost in respiration is irrevocably removed from the ecosystem and cannot be recycled.

Synthesis of these process ratios leads to an evaluation of the overall efficiency with which herbivores convert the energy of primary (plant) production into their own tissue. The value of the production/consumption ratio for a fairly broad spectrum of vertebrate and invertebrate herbivores seems to range from less than 1% to 15–20% as a maximum (Petrusewicz and Macfadyen, 1970), with some evidence that the insects are generally more efficient than the non-domesticated mammals; this difference may be due in large part to the necessity for the latter to maintain a steady, high body temperature. When these values are considered along with the proportions of available food ingested (see above), the efficiency of energy transfer of herbivores is rarely found to exceed 15%, and this has been suggested as a likely maximum level for natural ecosystems (Slobodkin, 1962).

REGULATORY MECHANISMS OF PRIMARY CONSUMERS

Although terrestrial herbivores are occasionally so abundant as to deplete the local supply of plant food, as sometimes happens when an introduced species like the Japanese beetle (*Popilia japonica*) or the Europena gypsy moth (*Porthetria dispar*) enters a new biotic community, such cases seem to be the exception rather than the rule, and, in contrast to many aquatic ecosystems, the bulk of net annual primary production on land is not eaten in the living state by primary consumers but dies and is acted on by decomposer organisms. Thus it appears that, on the whole, land herbivores usually occur at densities well below the level of their available plant food, and the reason or reasons for this are of great ecological interest.

Despite the fact that sound generalizations about abstract concepts such as "trophic levels" are not easily arrived at (Murdoch, 1966), several hypotheses about the *regulation of herbivore numbers* have been suggested. The apparent rarity of obvious depletion of vegetation by herbivores, or of its destruction by meteorological catastrophes, has led Hairston, Smith and Slobodkin (1960) to the belief that herbivores are seldom limited by their food supply; after rejecting weather as an effective control agent, they conclude that herbivores are most often controlled by their predators and/or parasites, interacting in the classical density-dependent manner. These views have been questioned on such grounds as (1) that much green material may often be inedible, unpalatable or even unreachable by the herbivores present, so that food limitation might occur without actual depletion (Murdoch, 1966) or (2) that native herbivores such as forest Lepidoptera and grasshoppers will often increase and cause serious defoliation even in the presence of their predators (Ehrlich and Birch, 1967). Despite these and other criticisms, Slobodkin, Smith and Hairston (1967) find it unnecessary to modify their views in any essential respect.

The possibility that herbivore (and other animal) populations have some capacity for *self-regulation* has not been overlooked. Pimentel (1961, 1968) has suggested the concept of "*genetic feedback*," according to which population density influences the intensity of selective pressure, selection influences the genetic composition of the surviving individuals, and genetic composition influences the subsequent population density. The models thus far proposed to explain how this system works appear to be untenable (Lomnicki, 1971), but the general validity of the concept seems to gain support from the numerous instances of the *co-evolution* of plants and herbivorous animals, e.g., the association between certain orchids and their insect pollinators (Van der Pijl and Dodson, 1966), or that between certain species of *Acacia* and ants (Janzen, 1966), which have been interpreted as involving reciprocal selective interaction.

Another suggested mechanism for self-regulation involves the elaboration of *social behavior patterns,* e.g., territoriality, social hierarchies, and warning displays, which tend to maintain animal populations at relatively low densities, thereby reducing the possibility of depletion of food supplies or other resources (Wynne Edwards, 1962, 1965). The evolution of such a mechanism seems to require that natural selection act on groups rather than on individual organisms, and for this reason Wynne Edwards' hypothesis has been heavily criticized (Williams, 1966; Maynard Smith, 1964).

The basic importance of self-regulatory mechanisms and other density-dependent interactions in limiting populations of animals has also been questioned. Ehrlich and Birch

(1967), for example, deny that "the numbers of all populations are primarily determined by density-regulating factors" and emphasize the significant limiting effects that weather conditions often have on natural populations of herbivores. This view maintains that limiting factors which act on populations without relation to their density commonly maintain such populations at levels where self-regulatory, *density-dependent mechanisms*, if they exist at all, are not called into play.

Wiegert and Owen (1971) suggest that the precise kinds of mechanisms limiting the population of a particular species of herbivore will depend firstly on (a) whether the population, in making use of its plant food resources, directly affects the rate of food supply (either by destroying or by stimulating its capacity to produce new plant tissue), and secondly on (b) the life history characteristics of both the herbivore and its plant food. Most stable terrestrial ecosystems are dominated by relatively large, structurally complex plants that are long-lived, slow-growing and have low rates of population increase, and by herbivores that are smaller, more numerous and faster-growing than their food plants. In contrast, open-water aquatic communities are often composed of small and structurally simple plants (phytoplankton) that are more abundant and multiply more rapidly than their consumers. In such aquatic communities, herbivores can attain high rates of consumption—approaching 100%—of net primary production without danger of completely exhausting their nutritional resources, and their populations are likely to be limited by direct *competition* to levels dictated by the rate at which food is supplied to them. As already noted above, in terrestrial ecosystems, such high rates of consumption by herbivores are rare, and when they occur their influence on the food plants is usually severe. In forest, and to a lesser extent in grassland, communities the herbivores are less likely to be limited by direct competition for food; they tend, rather, to be subject to the effects of predation and parasitism and to have evolved behavioral patterns such as migrations which result in reducing grazing pressure. At the same time, the plants of these systems have developed an array of toxic compounds, unpalatable tissues, thorns and other protective devices to resist grazing. Thus Wiegert and Owen's model of population control stresses the importance of trophic structure (grazing food-chains vs. detritus food-chains) and the biological properties of the interacting populations.

MANAGEMENT OF PRIMARY CONSUMERS

Although energy flow studies suggest that man should become predominantly herbivorous in order to make the most effective use of the solar radiation captured by plants, his need for protein, which he can obtain in more concentrated form from animal tissue, is likely to continue to motivate him toward increasing the production of primary consumers such as cattle, chickens, and fish. In fact, the majority of man's domesticated animals are herbivores.

It is clear that if the conversion of solar energy into animal protein for human use is to be maximized herbivores with high growth efficiencies should be cropped. The energy that man himself must spend in order to secure his food must also be assessed, and the time, effort and other costs of cropping have therefore to be taken into consideration. Over the several thousand years in which man has attempted to domesticate plants and animals, his selective efforts have been remarkably successful in developing efficient herbivores for his own use. Modern methods of *animal husbandry,* where animals are kept in specially constructed buildings and are fed specially processed foods, have greatly increased the amount of food energy reaching the animals (Phillipson, 1966). However, these methods require the expenditure of much energy that goes as hidden cost, in the activities involved in the construction and maintenance of facilities and in the production of the processed food. Are there ways of increasing the more direct conversion of plant tissue to animal protein useful to man?

Macfadyen (1964) has indicated that in Great Britain beef cattle raised on grassland commonly consume only one-seventh of the net annual primary production, the rest going to other herbivores and to decomposers. More care in stocking and better management of range are two of the principal ways in which possible improvement can be sought. Less obvious is the extension of husbandry to other herbivorous species, perhaps even to insects, that may be more efficient feeders than the large warmblooded mammals and that might, through selection, be developed as a productive source of high protein nourishment. The use of faster-growing herbivores, such as rabbits, would yield greater efficiency in terms of meat production per unit of time (Phillipson, 1966). In East Africa, increasing use for human food is being made of antelope, zebra and other native ungulates which are relatively immune to the parasites and diseases that afflict European cattle, and other unproductive areas are being managed for their propagation.

Increased production of plant food as a base for greater herbivore production is also possible. In this effort, man has tried particularly to exploit tropical regions with their higher average temperatures and longer growing seasons. Petrusewicz and Macfadyen (1970) point out, however, that primary productivity does not apparently increase proportionately to the increased light regime of tropical climates, largely due to higher respiration rates in tropical plants and to more rapid rates of decomposition; the tenfold increase in solar radiation experienced by some tropical forests seems not to result in any significant increase in energy available to primary consumers over that found in a temperate deciduous forest. It has long been apparent that agricultural practices developed in temperate regions are poorly adapted for use in the tropics. A great deal more needs to be learned about *tropical ecology* before marked improvement in environmental management can be expected (Owen, 1966).

CONCLUDING REMARKS

This article has attempted to outline the current view of nature as an interaction system in which organisms play a variety of roles in facilitating the circulation of matter and the flow of energy within that thin layer of the earth's surface known as the *biosphere.* Despite the relatively small quantities of material and energy that are channeled through primary consumers, as compared with autotrophic plants and decomposer organisms, the former play a vital role in the maintenance of such a system, in that they accumulate and concentrate inorganic nutrients such as nitrogen, phosphorus and potassium, as well as many trace elements, which are otherwise thinly dispersed in the environment. It has not been possible here to present more than a superficial account of the role of primary consumers, and indeed the study of these animals is still in its early stages. But further observation and experimentation in this aspect of ecology are clearly needed, if man is ever to understand and manage wisely the world he lives in.

ECOLOGY RADIATION: see RADIATION ECOLOGY

ECOSYSTEM THEORY

The concept of the ecosystem is not only the center of professional ecology today, but it is also the most relevant concept in terms of man's environmental problems. During the mid 70s, the public seized on the root meaning of ecology, namely "oikos" or "house," to broaden the subject beyond its previously rather narrow academic confines to include the "totality of man and environment," or the whole environmental house, as it were. We are witnessing what is called a historic "attitude revolution" (Odum, 1969, 1970c) in the way people look at their environment for the very simple reason that for the first time in his short history man is faced with ultimate rather than merely local limitations. It will be well for all of us to keep this overriding simplicity in mind as we face the controversies, false starts and backlashes that are bound to accompany man's attempts to put some negative feedback into the vicious spiral of uncontrolled growth and resource exploitation that has characterized the past several decades.

Man has been interested in ecology in a practical sort of way since early in his history. In primitive society every individual, to survive, needed to have definite knowledge of his environment, i.e., of the forces of nature and of the plants and animals around him. Civilization, in fact, began when man learned to use fire and other tools to modify his environment. It is even more necessary than ever for mankind, as a whole, to have an intelligent knowledge of the environment if our complex civilization is to survive, since the basic "laws of nature" have not been repealed; only their complexion and quantitative relations have changed, as the world's human population has increased and as man's power to alter the environment has expanded.

Like all phases of learning, the science of ecology has had a gradual, if spasmodic, development during recorded history. The writings of Hippocrates, Aristotle, and other philosophers of the Greek period contain material which is clearly ecological in nature. However, the Greeks literally did not have a word for it. The word "ecology" is of recent coinage, having been first proposed by the German biologist Ernst Haeckel in 1869. Before this, many of the great men of the biological renaissance of the eighteenth and nineteenth centuries had contributed to the subject even though the label "ecology" was not in use. For example, Anton von Leeuwenhoek, best known as a pioneer microscopist of the early 1700s, also pioneered the study of "food chains" and "population regulation" (see Egerton, 1968), two important areas of modern ecology. As a recognized distinct field of biology, the science of ecology dates from about 1900, and only in the past decade has the word become part of the general vocabulary. Today, everyone is acutely aware of the environmental sciences as indispensable tools for creating and maintaining the quality of human civilization. Consequently, ecology is rapidly becoming the branch of science that is most relevant to the everyday life of every man, woman, and child.

As recently as 1960 the theory of the ecosystem was rather well understood but not in any way applied. The applied ecology of the 1960s consisted of managing components as more or less independent units. Thus we had forest management, wildlife management, water management, soil conservation, pest control, etc., but no ecosystem management and no applied human ecology. Practice has now caught up with theory. Controlled management of the human population together with the resources and the life support system on which it depends as a single, integrated unit now becomes the greatest, and certainly the most difficult, challenge ever faced by human society.

As we have seen, an "anthropocentric" definition of the ecosystem might read something as follows: Man as a part of, not apart from, a life support system composed of the atmosphere, water, minerals, soil, plants, animals, and microorganisms that function together to keep the whole viable.

Any unit including all of the organisms (i.e., the "community") in a given area interacting with the physical environment so that a flow of energy leads to a clearly defined trophic structure, biotic diversity and material cycles (i.e. exchange of materials between living and nonliving parts) within the system is an *ecological system or ecosystem.*

The following formal definition is the one used in the third edition of *Fundamentals of Ecology* (E.P. Odum, 1971)

> The word ecology is derived from the Greek *oikos,* meaning "house" or "place to live." Literally, ecology is the study of organisms "at home." Usually ecology is defined as the study of the relation of organisms or groups of organisms to their environment, or the science of the interrelations between living organisms and their environment. Because ecology is concerned especially with the biology of *groups* of organisms and with *functional* processes on the lands, in the oceans, and in fresh waters, it is more in keeping with the modern emphasis to define ecology as the study of the structure and function of nature, it being understood that mankind is a part of nature.

One of the definitions in Webster's Unabridged Dictionary seems especially appropriate for the closing decades of the 20th century, namely, "*the totality or pattern of relations between organisms and their environment.*" In the long run the best definition for a broad subject field is probably the shortest and least technical one, as for example, "environmental biology."

To understand the scope and relevance of ecology, the subject must be considered in relation to other branches of biology and to "*ologies*" in general. In the present age of specialization in human endeavors, the inevitable connections between different fields are often obscured by the large masses of knowledge with the fields (and sometimes also, it must be admitted, by stereotyped college courses). At the other extreme, almost any field of learning may be so broadly defined as to take in an enormous range of subject material. Therefore, recognized "fields" need to have recognized bounds, even if these bounds are somewhat arbitrary and subject to shifting from time to time. A shift in scope has been especially noteworthy in the case of ecology as general public awareness of the subject has increased. To many, "ecology" now stands for "the totality of man and environment." But first let us examine the more traditional academic position of ecology in the family of sciences.

For the moment, let us look at the divisions of biology, "the science of life." Morphology, physiology, genetics, ecology, evolution, molecular biology, and developmental biology are examples of such divisions. We may also divide the subject into what may be called "taxonomic" divisions, which deal with the morphology, physiology, ecology, etc., of specific kinds of organisms. Zoology, botany, and bacteriology, are large divisions of this type, and phycology, protozo-ology, mycology, entomology, ornithology, etc., are divisions dealing with more limited groups of organisms. Thus ecology is a basic division of biology and, as such, as also an integral part of any and all of the taxonomic divisions. Both approaches are profitable. It is often very productive to restrict work to certain taxonomic groups, because different kinds of organisms require different methods of study (one cannot study eagles by the same methods used to study bacteria) and because some groups of organisms are economically or otherwise much more important or interesting to man than others. Ultimately, however, unifying principles must be delimited and tested if the subject field is to qualify as "basic."

Perhaps the best way to delimit modern ecology is to consider it in terms of the concept of *levels of organization* visualized as a sort of "biological spectrum." Community, population, organization, organ cell, and gene are widely used terms for several major biotic levels.

Interaction with the physical environment (energy and matter) at each level producing characteristic functional systems. By a *system* we mean just what Webster's College Dictionary defines as "regularly interacting and interdependent components forming a unified whole." Systems containing living components (biological systems or biosystems) may be conceived at any level in the hierarchy. For example, we might consider not only gene systems, organ systems, and so on, but also host-parasite systems as intermediate levels between population and community.

HISTORICAL REVIEW OF THE ECOSYSTEM CONCEPT

Although the term ecosystem was first proposed by the British ecologist, A.G. Tansley in 1935, the concept is by no means so recent. Allusions to the idea of the unity of organisms and environment (as well as the oneness of man and nature) can be found as far back in written history as one might care to look, and such an idea has been a basic part of many religions (less so in Christian religions as recently pointed out by historian Lynn White, 1967). Anthropologists and geographers have long been concerned with the impact of man on his environment and early debated the question: To what extent has man's continuing trouble with deteriorated environments stemmed from the fact that human culture tends to develop independently of the natural environment? The Vermont prophet George Perkins Marsh wrote a classic treatise on this theme in 1864. He analyzed the causes of the decline of ancient civilizations and forecast a similar doom for modern ones unless "man takes what we would call today an ecosystematic" view of man and nature. In the late 1800s biologists began to write essays on the unity of nature, interesting enough in a parallel manner in German, English, and Russian languages. Thus Karl Möbius in 1877 wrote about the community of organisms in an oyster reef as a "biocoenosis," while in 1887 the American S.A. Forbes wrote his classic essay on "The Lake as a Microcosm." The Russian pioneering ecologist V.V. Dokuchaev (1846–1903) and his disciple G.F. Morozov (who specialized in forest ecology) placed great emphasis on the concept of "biocoenosis," a term later expanded to geobiocoenosis (or biogeocoenosis) (see Sukachev, 1944), which can be considered a synonym of the word "ecosystem."

No one has expressed the relevance of the ecosystem concept to man better than Aldo Leopold in his essays on the land ethic. In 1933 he wrote: "Christianity tries to integrate the individual to society, Democracy to integrate social organization to the individuals. There is yet no ethic dealing with man's relation to the land" … which is "still strictly economic entailing privileges but not obligations." Thus, man is continually striving, with but partial success so far, to establish ethical relationships between man and man, man and government, and, now, man and environment. Without the latter what little progress has been made with the other two ethics will surely be lost. In the context of the 1970 scene Garrett Harden (1968) says it in another way when he points out that technology alone will not solve the population and pollution dilemmas; ethical and legal constraints are also necessary. Environmental science is now being called upon to help determine a realistic level of human population density and rate of use of resources and power that are optimum in terms of the quality of human life, in order that "societal feedback" can be applied before there are serious overshoots. This requires diligent study of ecosystems, and, ultimately, a judgment on the carrying capacity of the biosphere. If studies of natural populations have any bearing on the problem, we can be quite certain that the optimum density in terms of the individual's options for liberty and the pursuit of happiness is something less than the maximum number that can be sustained at a subsistence level, as so many domestic "animals" in a polluted feed lot!

My advanced ecology class recently attempted to determine what might be the optimum population for the State of Georgia on the assumption that someday the state would have to have a balanced resource input-output (i.e., live within its own resources). On the basis of a per capita approach to land use the tentative conclusion was that a density of one person per five acres (2 hectares) represented the upper limit for an optimum population size when the space requirements for quality (i.e., high protein) food production, domestic animals, outdoor recreation, waste treatment and pollution-free living space were all fully considered. Anything less than five acres of live support and resource space per capita, it was concluded, would result in a reduction in the individual person's options for freedom and the pursuit of happiness, and, accordingly, a rapid loss in environmental quality. Since the 1970 per capita density of Georgia is 1 in 8 acres and for the United States as a whole, 1 in 10 acres no more than double the present US population could be considered optimum according to this type of analysis. This would mean that we have about 30 years to level off population growth. The study also suggested that permanent zoning of at least one-third of land and freshwater areas (plus all estuarine and marine zones) as "open space" in urbanizing areas would go a long way toward preventing overpopulation, overdevelopment and social decay that is now so evident in many parts of the world today. The results of this preliminary study have been published (E.P. Odum, 1970b). See also the provocative symposium on *The Optimum Population for Britain* edited by Taylor (1970).

THE TWO APPROACHES TO ECOSYSTEM STUDY

G. Evelyn Hutchinson in his 1964 essay, "The Lacustrine Microcosm Reconsidered," contrasts the two long-standing ways ecologists attempt to study lakes or other large ecosystems of the real world. Hutchinson cites E.A. Birge's (1915) work on heat budgets of lakes as pioneering the *holological* (from holos = whole) or *holistic* approach in which the whole ecosystem is treated as a "black box" (i.e., a unit whose function may be evaluated without specifying the internal contents) with emphasis on inputs and outputs, and he contrasts this with the merological (from meros = part) approach of Forbes in which "we discourse on parts of the system and try to build up the whole from them." Each procedure has obvious advantages and disadvantages and each leads to different kinds of application in terms of solving problems. Unfortunately, there is something of a "credibility gap" between the two approaches. As would be expected, the merological approach has dominated the thinking of the biologist-ecologist who is species-oriented, while the physicist-ecologist and engineer prefer the "black box" approach. Most of all, man's environmental crisis has speeded up the application of systems analysis to ecology. The formalized, or mathematical model, approach to populations, communities, and ecosystems has come to be known as *systems ecology* which is rapidly becoming a major science in its own right for two reasons: (1) extremely powerful new formal tools are now available in terms of mathematical theory, cybernetics, electronic data processing, etc. (2) Formal simplication of complex ecosystems provides the best hope for solutions of man's environmental problems that can no longer be trusted to trial-and-error, or one-problem one-solution procedures that have been chiefly relied on in the past.

Again we see the contrast between merological and holological approaches in that there are systems ecologists who start at the population or other component level and "model up," and those who start with the whole and "model down." The same dichotomy is evident in the very rewarding studies of experimental laboratory ecosystems. One class of microecosystems can be called "derived" systems because they are established by multiple seeding from nature in contrast to "defined" microcosms which are built up from previously isolated pure cultures. Theoretically, at least, the approaches are applicable to efforts to devise life support systems for space travel. In fact, one of the best ways to visualize the ecosystems concept for students and laymen is to consider space travel, because when man leaves the biosphere he must take with him a sharply delimited enclosed environment that will supply all vital needs with sun energy as the only usable input from the surrounding very hostile space environment. For journeys of a few weeks (such as to the moon and back), man does not need a regenerative ecosystem, since sufficient oxygen and food can be stored while CO_2 and other waste products can be fixed or detoxified for short periods of time. For long journeys man must engineer himself into a complete ecosystem that includes the means of recycling materials and balancing production, consumption and decomposition by biotic components or their mechanical substitutes. In a very real sense the problems of man's survival in an artificial space craft are the same as the problems involved in his continued survival on the earth space ship. For example, detection and control of air, and water pollution, adequate quantity and nutritional quality of food, what to do with accumulated toxic wastes and garbage, and the social problems created by reduced living space are common concerns of cities and spacecrafts. For this reason the ecologist would urge that national and international space programs now turn their attention to the study and monitoring of our spaceship earth. As was the case with Apollo 13, survival becomes the mission when the limits of carrying capacity are approached.

THE COMPONENTS OF THE ECOSYSTEM

From the standpoint of trophic energy an ecosystem has two components which are usually partially separated in space and time, namely, an *autotrophic component* (autotrophic = self nourishing) in which fixation of light energy, use of simple inorganic substances, and the buildup of complex substances predominate; and secondly, a *heterotrophic component* (heterotrophic = other-nourshing) in which utilization, rearrangement and decomposition of complex materials predominate. As viewed from the side (cross section) ecosystems consist of an upper "green belt" which receives incoming solar energy and overlaps, or interdigitates, with a lower "brown belt" where organic matter accumulates and decomposes in soils and sediments.

It is convenient for the purposes of first order analysis and modelling to recognize six structural components and six processes as comprising the ecosystem as follows:

A. Components

1) *Inorganic substances* (C, N, CO_2, H_2O, etc.) involved in material cycles.
2) *Organic compounds* (proteins, carbohydrates, lipids, humic substances, etc.) that link biotic and abiotic.
3) *Climate regime* (temperature, rainfall, etc.).
4) *Autotrophs* or *producers,* largely green plants able to manufacture food from simple substances.
5) *Phagotrophs* (phago = to eat) or *macro-consumers,* heterotrophic organisms, largely animals which ingest other organisms or particulate organic matter.
6) *Saprotrophs* (sapro = to decompose) or *micro-consumers* (also called osmotrophs), heterotrophic organisms, chiefly bacterial, fungi, and some protozoa that break down complex compounds, absorb some of the decomposition products and release inorganic substances usable by the autotrophs together with organic residues which may provide energy sources or which may be inhibitory, stimulatory or regulatory to other biotic components of the ecosystem.

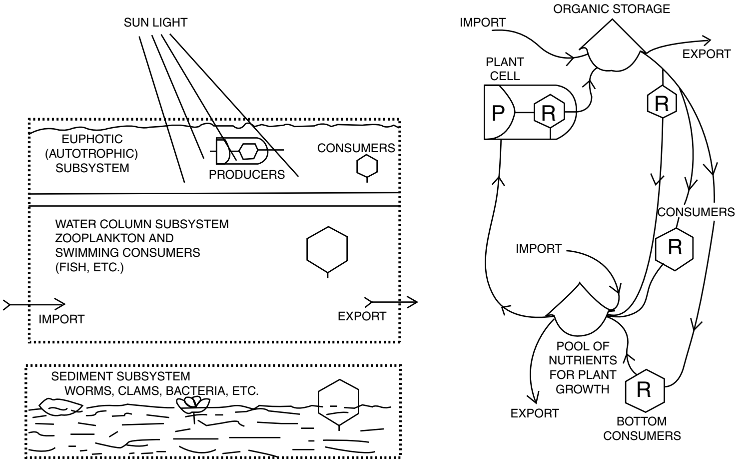
(Another useful division for heterotrophs: *biophages* = organisms that feed on other living organisms; *saprophages* = organisms that feed on dead organic matter.)

B. Processes

1) Energy flow circuits.
2) Foods chains (trophic relationships).
3) Diversity patterns in time and space.
4) Nutrient (biogeochemical) cycles.
5) Development and Evolution.
6) Control (cybernetics).

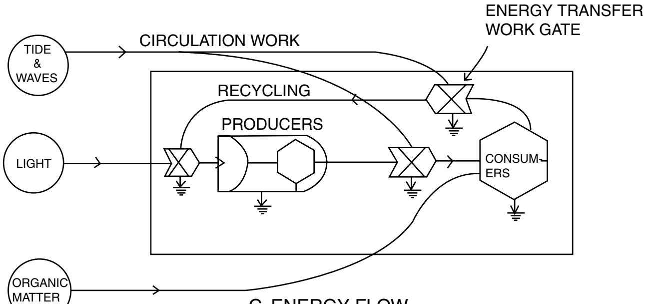
Subdivision of the ecosystem into these six "components" and six "processes," as with most classification, is arbitrary but convenient, since the former emphasize structure and the latter function. From the holistic viewpoint, of course, components are operationally inseparable. While different methods are often required to delineate structure on the one hand and to measure rates of function on the other, the ultimate goal of study at any level or organization is to understand the relationship between structure and function. It is not feasible to go into any detailed discussion of these component-processes in this brief introduction (one can refer to textbooks and review papers), but we can list a few key principles that are especially relevant to human ecology. Figure 1 is a schematic diagram that may be useful in picturing the basic arrangement and functional linkage of ecosystem components.

1) The living (items A4–6 above) and non-living (items A1–3) parts of ecosystems are so interwoven into the fabric of nature that it is difficult to separate them, hence operational classifications (B1–6) do not make a sharp distinction between biotic and abiotic. Elements and compounds are in a constant state of flux between living and non-living states. There are very few substances that are confined to one or the other state. Exceptions may be ATP which is found only inside living cells, and humic substances (resistant end-products of decomposition) which are not found inside cells yet are characteristic of all ecosystems.
2) The time-space separation of autotrophic and heterotrophic activity leads to a convenient classification of energy circuits into (1) a *grazing food chain* (where term grazing refers to direct consumption of living plants or plant parts) and (2) an *organic* detritus (from *deterere* = to wear away) food chain which involves the accumulation and decomposition of dead materials. To build up a stable biomass structure there must be negative feedback control of grazing—a need too often neglected in man's domesticated ecosystems.
3) As in well known available energy declines with each step in the food chain (so a system can support more herbivores than carnivores; if man wants to keep his meat-eating option open there will have to be fewer people supported by a given food base). On the other hand, materials often become concentrated with each step in the food chains. Failure to anticipate possible "biological magnification" of pollutants, such as DDT or long-lived radionuclides, is causing serious problems in man's environment.
4) It is becoming increasingly evident that high biological productivity (in terms of calories per unit area) in both natural and agricultural ecosystems is almost always achieved with the aid of *energy subsidies* from outside the system that reduces the cost of maintenance (thus diverting more energy to production). Energy subsidies take the form of wind and rain in a rain forest, tidal energy in an estuary (see Figure 1), or fuel, animal or human work energy used in the cultivation of a crop. In comparing productivity of different systems it is important to consider the *complete budget*—not just light input.
5) Likewise it is increasingly evident that *both harvest and pollution are stresses* which reduce the



A. VERTICAL ZONES

B. MINERAL CYCLE



C. ENERGY FLOW

FIGURE 1 Three aspects of the structure and function of ecosystems as illustrated by an estuarine system. A. Vertical zonation with photosynthetic production above (autotrophic stratum) and most of the respiration and decomposition below (heterotrophic stratum). B. Material cycle with circulation of plant nutrients upward and organic matter food downward. C. Energy flow circuit diagram showing three sources of energy input into the system. The bullet-shaped modules represent producers with their double metabolism, that is P (production) and R (respiration). The hexagons are populations of consumers which have storage, self maintenance and reproduction. The storage bins represent nutrient pools in and out of which move nitrogen, phosphorous and other vital substances. In diagrams B and C the lines represent the "invisible wires of nature" that link the components into a functional network. In diagram C the "ground" symbols (i.e., arrow into the heat sink) indicate where energy is dispersed and no longer available in the food chain. The circles represent energy inputs. The work gate symbols (large X) indicate where a flow of work energy along one pathway assists a second flow to pass over energy barriers. Note that some of the lines of flow loop back from "downstream" energy sources to "upstream" inflows serving various roles there including control functions (saprotrophs controlling photosynthesis by controlling the rate of mineral regeneration, for example). The diagram (C) also shows how auxilliary energy of the tide (energy subsidy) assists in (1) recycling of nutrients from consumer to producer and (2) speeding up the movement of plant food to the consumer. Reducing tidal flow by dyking the estuary will reduce the productivity just as surely as cutting out some of the light. Stress such as pollution or harvest can be shown in such circuit models by adding circles enclosing negative signs linked with appropriate heat sinks to show where energy is diverted away from the ecosystem. Both subsidies (+) and stress (−) can be quantitated in terms of Calories added or diverted per unit of time and space. (From E.P. Odum, 1971 after H.T. Odum, and B.J. Copeland, 1969.)

energy available for self-maintenance. Man must be aware that he will have to pay the costs of added anti-thermal maintenance, or "disorder pumpout," as H. T. Odum, 1971 (Chapter 5) calls it. It is dangerous strategy to try to force too much productivity, or yield, from the landscape (as is being attempted in the so-called "green revolution") because very serious "ecological back-lashes" can result from the following (1) pollution caused by heavy use of fertilizers and insecticides and the consumption of fossil fuels, (2) unstable or oscillating conditions created by one-crop systems, (3) vulnerability of plants to disease because their self-protection mechanisms have been "selected out," in favor of yield, and (4) social disorder created by rapid shift of rural people to cities that

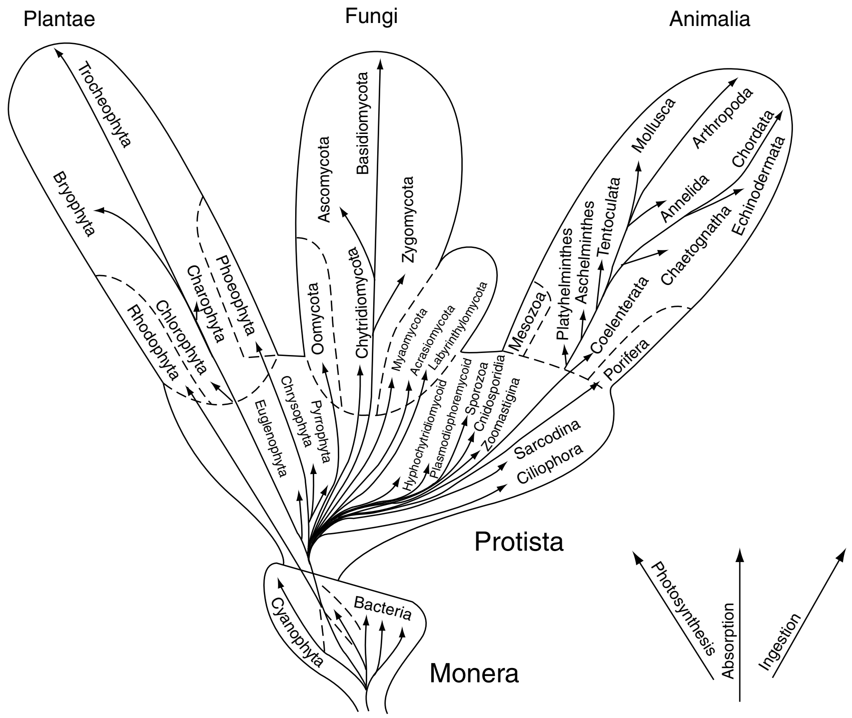


FIGURE 2 A five-kingdom system based on three levels of organization—the procaryotic (kingdom Monera), apearyotic unicelluar (kingdom Protista), and eucaryotic multicelluar and multinucleate. On each level there is divergence in relation to three principal modes of nutrition—the photosynthetic, absorptive, and ingestive. Many ecology and microbiology texts list four kingdoms by combining the "lower Protista" (i.e., Monera) with the higher "Protista" to form "Protista." Evolutionary relations are much simplified, particularly in the Protista. Only major animal phyla are entered, and phyla of the bacteria are omitted. The Coelenterata comprise the Cnidaria and Ctenophora; the Tentaculata comprise the Bryozoa, Brachiopoda, and Phoronida, and in some treatments the Batoprocta. (From Whittaker, 1969.)

are not prepared to house or employ them (the tragedy here is that industrialized agriculture *can* result in increased food per acre but it *can* also widen the gap between rich and poor so that there are increasing numbers of people unable to buy the food!).

6) While we generally think of production and decomposition as being balanced on the biosphere as a whole, the truth is that this balance has never been exact but has fluctuated from time to time in geological history. Through the long haul of evolutional history production has slightly exceeded decomposition so that a highly oxygenic atmosphere has replaced the original reducing atmosphere of the earth. Man, of course, is tending to reverse this trend by increasing, decomposition (burning of fuels, etc.) at the expense of production. The most immediate problem is created by the increase in atmospheric CO_2 since relatively small changes in concentration can have large effects on the heat budget of the earth.
7) Ecological studies indicate that diversity is directly correlated with stability and perhaps inversely correlated with productivity, at least in many situations. It could well be that the preservation of diversity in the ecosystem is important for man since variety may be a necessity, not just the spice of life!
8) At the population level it is now clear that the growth form of the human population will not conform to the simple sigmoid or logistic model since there will always be a long time lag in the effects of crowding, pollution and overexploitation of resources. Growth will not "automatically" level off as do populations of yeasts in a confined vessel where individuals are *immediately* affected by their waste products. Instead, the human population will clearly overshoot some vital resource, unless man can "anticipate" the effects of overpopulation and reduce growth rates *before* the deleterious effects of crowding are actually felt. Intelligent reasoning behavior seems now to be

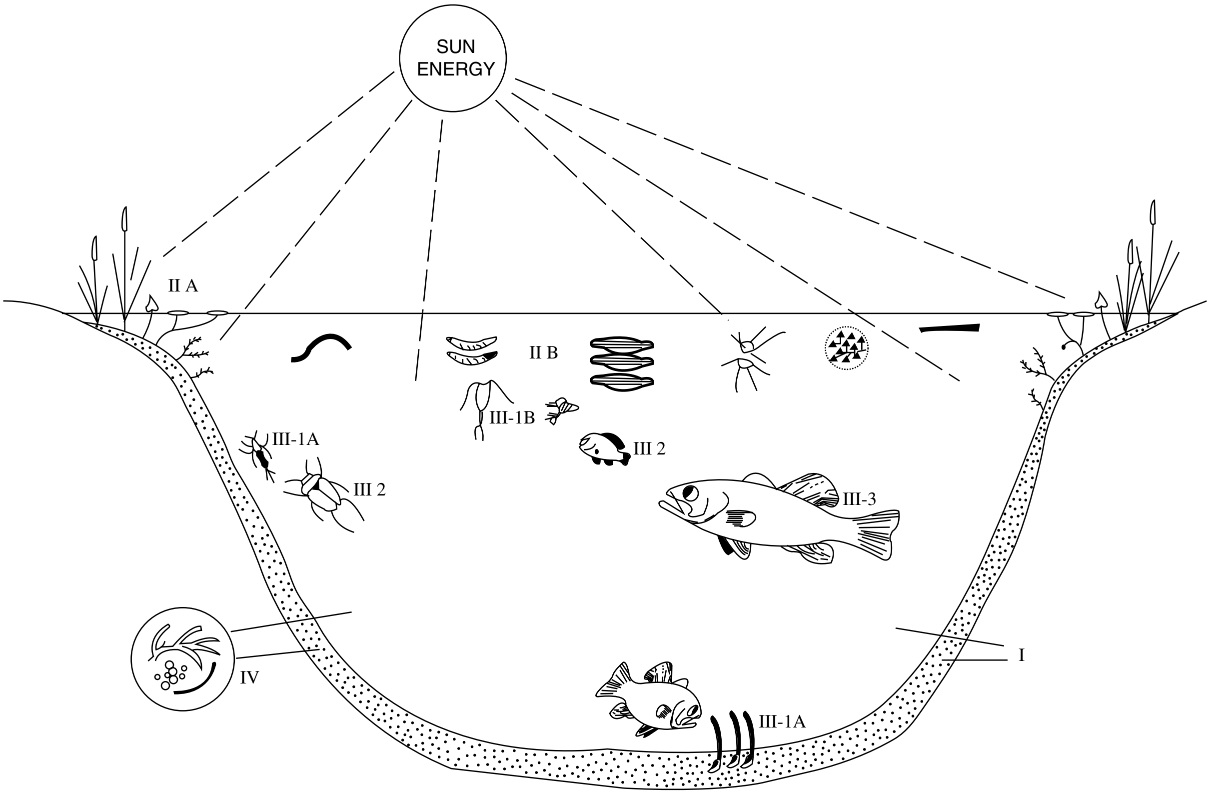

FIGURE 3 Diagram of the pond ecosystem. Basic units are as follows? I, abiotic substances—basic inorganic and organic compounds; IIA, producers—rooted vegetation; IIB, producers-phytoplankton; III-1A, primary consumers (herbivores)—bottom forms; III-1B, primary consumers (herbivores)—zooplankton; III-2, secondary consumers (carnivores); III-3, tertiary consumers (secondary carnivores); IV, saprotrophs—bacteria and fungi of decay. The metabolism of the system runs on sun energy, while the rate of metabolism and relative stability of the pond depend on the rate of inflow of materials from rain and from the drainage basin in which the pond is located. (From Odum, 1971.)

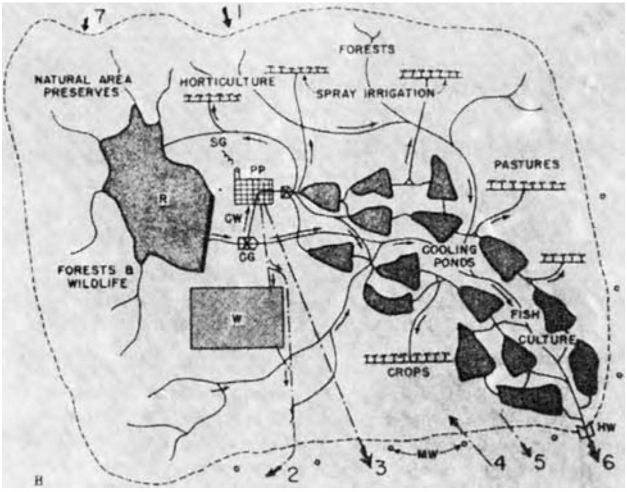

FIGURE 4 Schematic design for a waste management park for the atomic power plant (PP) of the future which is located in a natural watershed basic (outlined by the dashed lines). Waste heat (i.e., thermal pollution) in the reactor cooling water (CW) flowing from a large storage reservoir (R) is completely dissipated by evaporative cooling from the network of shallow ponds and spray irrigation systems. The warm ponds may be used for fish culture, sport fishing, or other recreation purposes. Irrigation of portions of the terrestrial watershed increases the yield of useful forest or agricultural products, while at the same time water recycles through the "living filter" of the land back into stream, ponds, and ground-water. Low-level nuclear wastes and solid wastes are contained within carefully managed land fill area (W); high-level nuclear wastes in spent fuel elements are exported to a special nuclear burial ground located outside of the management part. Stream flow, ground water, and stack gases are continuously monitored by hydrological weirs (HW), monitoring wells (MW), and stack gas control systems (SG) in order to make certain that no air or water pollution leaves the controlled area. The chief inputs and outputs for this environmental system include (see numbered marginal arrows): 1, input of sunlight and rainfall; 2, export of nuclear wastes to burial grounds; 3, electric power to cities, etc.; 4, input of nuclear and other fuels; 5, output of food, fibres, clean air, etc.; 6. downstream flow of clean water for agriculture, industry, and cities; 7, public and professional use for recreation, education, and environmental research. The size of such a complete waste management park will depend on regional climates and topography, and on the amount of electrical or other energy diverted to power cooling, but something on the order of 10,000 acres for a 2500 megawatt power plant would be the minimum needed to insure 100% pollution control and allow for accidents and mechanical malfunctions. However, such waste treatment capacity could also support a certain amount of light industry within the park. Heavy industry should be located within its own waste management park. (From Odum, 1971).

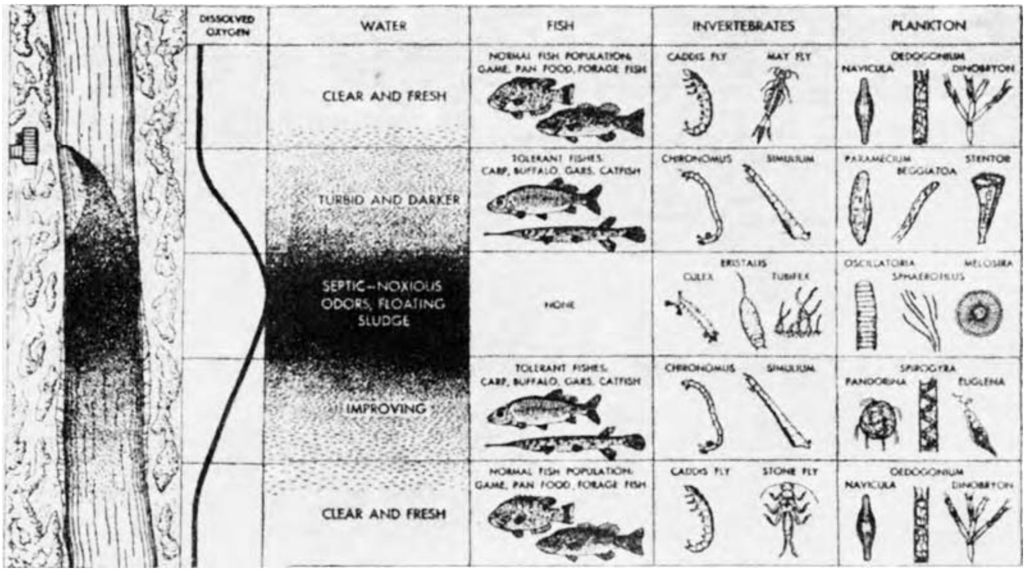

FIGURE 5 Pollution of a stream with untreated sewage and the subsequent recovery as reflected in changes in the biotic community. As the oxygen dissolved in the water decrease (curve to the left), fishes disappear and only organisms able to obtain oxygen from the surface (as in Culex mosquito larvae) or those which are tolerant of low oxygen concentration are found in zone of maximum organic decomposition. When bacteria have reduced all of the discharged material the stream returns to normal. (After Eliassen, *Scientific American,* Vol. 186, No. 3, March, 1952.)

the only means to accomplish this, as emphasized at the beginning of the article.

9) Some of the most important "breakthroughs" in ecology are in the area of biogeochemical cycling. Since "recycle" of water and minerals must become a major goal of human society the recycle pathways in nature are of great interest; there seem to be at least four major ones which vary in importance in different kinds of ecosystems: (1) recycle via microbial decomposition of detritus, (2) recycle via animal excretion, (3) direct recycle from plant back to plant via symbiotic microorganism such as mycorrhizae associated with roots, and (4) autolysis, on chemical recycle, with no organism involved. Pathway 3 seems to be especially important in the humid tropics which suggests tropical agriculture might be redesigned to include plant foods with mycorrhizae.
10) The principles inherent in limiting factor analysis and in human ecology can be combined to formulate the following tentative overview: In an industrialized society energy (power, food) is not likely to be limiting, *but the pollution consequences of the use of energy and exploitation of resources is limiting.* Thus, pollution can be considered the limiting factor for industrialized man—which may be fortunate since pollution is so "visible" that it can force us to use that reasoning power which is supposed to be a special attribute of man.

ECOSYSTEM DEVELOPMENT

Principles having to do with the development of ecosystems, that is ecological succession, are among the most relevant in view of man's present situation. I have recently reviewed this subject (Odum, 1970); accordingly a brief summary will suffice for this piece.

In broad view ecosystems develop through a rapid growth stage that leads to some kind of maturity or steady state (climax), usually an oscillating steady state. The early successional growth stage is characterized by a high Production/respiration (P/R) ratio, high yields (net production), short food chains, low diversity, small size of organism, open nutrient cycles and a lack of stability. In contrast, mature stages have a high biomass/respiration (B/R) ratio, food web, low net production, high diversity and stability. In other words, major energy flow shifts from production to maintenance (respiration).

The general relevance of the development sequence to land use planning can be emphasized by the following "mini-model" that contrasts in very general terms young and mature ecosystems:

Young	Mature
Production	Protection
Growth	Stability
Quantity	Quality

It is mathematically impossible to obtain a maximum for more than one thing at a time, so one can not have both extremes at the same time and place. Since all six characteristics are desirable in the aggregate, two possible solutions to the dilemma suggest themselves. We can compromise so as to provide moderate quality and moderate yield on all the landscape, or we can plan to compartmentalize the landscape so as to simultaneously maintain highly productive and predominantly protective types as separate units subjected to different management strategies. If ecosystem development theory is valid and applicable to land-use planning (total zoning), then the so-called multiple-use strategy, about which we hear so much will work only through one or both of these cases, because in most cases, projected multiple uses conflict with one another. Some examples and suggestions for implementing compartmental plans are considered in the above mentioned paper.

EFFECTS OF AIR POLLUTANTS: see AIR POLLUTANT EFFECTS

EFFECTS OF CHEMICALS

Almost daily one reads reports in the press about new dangers found or suspected in foods, medicines and other products. Public awareness of possible perils in everyday products has increased greatly. Smoking, asbestos, toxic and hazardous wastes (once called industrial wastes) are widely discussed.

Problems resulting from technological advances are being uncovered at an alarming rate. While it is possible to predict, with some accuracy, benefits to be expected from improvements and new approaches in applied science, seldom have serious efforts been made to determine adverse effects resulting from these. The general public is increasingly aware of potential hazards from new products and processes and the trend in industrialized countries is toward greater control and regulation of hazardous undertakings. The question as to the more effective approach, gentle persuasion to gain voluntary compliance or strong legislation for strict regulation, has not been satisfactorily answered. Probably there never will be agreement.

In the United States, the Office of Technology Assessment was dissolved. The stated reason was that this Office did long-term studies which were not immediately useful to a legislator. In remarks at the Conference on Technical Expertise and Public Decisions at Princeton University, the then Chairman of the House Science Committee said that it was more desirable to depend on the views of those most interested in the topic—the lobbyists.

The relationship among the air, water, and soil is not a static one. Effects of a pollutant may be demonstrated progressively in the various compartments into which the environment is divided. A substance may be initially present, without apparent ill effects, in one compartment. Later, the same substance, or a demonstrable derivative, may appear in a different part of the environment in a most undesirable way. An excellent example is the high mercury level found in fish. Initially, it was felt that disposal into the marine environment would conveniently remove a bothersome waste. However, by previously unsuspected paths the metal found its way into the systems of game and food fish. Food, thus, has become a secondary distributor of pollutant material.

Chemical pollutants may be divided into four categories:

1) Natural chemicals in excess.
2) Naturally occurring toxins.
3) Mixtures of air and water pollutants which produce adverse effects but with only partially defined or undefined components.
4) Synthetic chemicals.

The first group includes chemicals such as nitrates and nitrites. Nitrates, for example, can cause methemoglobinemia in infants by reduction of the capacity of the blood to carry oxygen. An intermediate reduction is involved. A famous case in New York involved accidental introduction of sodium nitrite into oatmeal and the resulting problems of "Eleven Blue Men." The victims, all heavy users of alcohol, apparently tried instinctively to compensate for low salt in the body. Through an accident, sodium nitrite instead of sodium chloride, was placed in salt shakers in a public eating place. The eleven victims all became cyanotic, with the characteristic blue color giving the name to the episode. Nitrites may also react with secondary amines to form nitrosamines, some of the which have been shown to be carcinogenic, teratogenic, and mutagenic, all in microgram doses. Oxides of nitrogen, thought to be significant in smog production, can also form nitrosamines.

The second group, natural fungal and plant toxins, usually are introduced into the human ecosystem through accident or carelessness. Conditions of harvesting, storage, and processing have been shown to be of possible importance.

An excellent example of the third group has already been mentioned. Mercury was discharged to the receiving water as an apparent ultimate solution to a waste disposal problem. The two components of the system, mercury and water, were assumed to be non-reactive. Unfortunately, the two-component system was, in fact, a multicomponent system and no endeavor was made to determine the complete mechanism. The problem was further complicated by the introduction of edible fish into the chain.

Minimata Disease is named for the city in which it occurred. Inorganic mercury was discharged in the effluent of a local industrial plant. Through action of marine organisms, the mercury was converted to lipid-soluble methyl mercury, which was taken up in the food chain to fish, the staple of the local diet. 43 deaths and about 700 serious illnesses were acknowledged by local authorities in the 1950s. Some unofficial estimates have put the death toll as high as 800. In 1989 two former company officials were given prison sentences for the 1950s pollution. Lawsuits resulting from the pollution were finally settled in 1996.

In Japan in 1968 about 1800 people developed a malady similar to chloracne after ingesting rice oil contaminated with a chlorinated biphenyl. Known as Yusho or Rice Oil Disease, the rice oil used in cooking had been contaminated by a PCB which had leaked from a faulty heat exchanger. In 1978 an outbreak similar to Yusho Disease occurred in Taiwan and is known as the Yu-Cheng Incident. The cause was the same, a faulty heat exchanger.

The last group, synthetic chemicals, includes pesticides and fertilizers used in agriculture, food additives, compounds containing heavy metals, plasticizers, fuel additives, household chemicals, industrial chemicals, therapeutic and prophylactic drugs, and drugs of abuse. Food additives may be intentional or accidental. Anti-oxidants and dyes are added routinely to many foods. However, almost any of the aforementioned may be accidentally introduced into food, often with most unpleasant results. There is much controversy concerning synthetic agriculture chemicals. Advantages and disadvantages are numerous and no definite decision has been reached concerning continued use of many substances. NTA (Nitrilotriacetic Acid) as a substitute for phosphates in detergents, is another excellent example of conflicting use. The problem is far from restricted to simple direct physiological effects.

Food additives may be classified as to function. They find use as coloring material, flavor enhancers, shelf life extenders, and in protection of food nutritional value. While valuable, color additives are not always essential. However, many of the foods now enjoyed by modern western society would not be possible, in their present form, without food additives.

It is estimated by the World Health Organization that about one fifth of the food produced in the world is lost by spoilage. Preservation, or retardation of spoilage, can be accomplished by addition of chemical preservatives, or by physical means such as freezing, drying, souring, fermenting, curing or ionizing radiation. There is some concern that irradiation of food may have adverse effects and leave unwanted residues. Little is known about possible chemical chain reactions.

Food additives have been classified by Kermode into five broad groups:

1) Flavors
2) Colors
3) Preservatives
4) Texture agents
5) Miscellaneous

In Table 1 are displayed food additives declared by the United States Food and Drug Administration to be "generally recognized as safe." Not included in Table 1 is a large group of natural flavors and oils. To be on the list an additive must have been in use before 1958 and meet specifications for safety. Materials introduced after 1958 must be tested individually in order to quality for inclusion of the FDA list. Examples of materials formerly listed but now removed are cyclamate sweetners and saccharin. A ban on cyclamates ordered by the US government after tests revealed development of bladder cancer in laboratory rats fed on a diet containing cyclamates. Further testing, after the ban, found cancer development in the same test species at dosage rates one sixth as large as those which brought about the ban.

Additives listed by the U.S. Food and Drug Administration as "generally recognized as safe." (Courtesy, *Scientific American*)

ANTICAKING AGENTS
Aluminum calcium silicate
Calcium silicate
Magnesium silicate
Sodium aluminosilicate
Sodium calcium aluminosilicate
Tricalcium silicate
CHEMICAL PRESERVATIVES
Ascorbic acid
Ascorbyl palmitate
Benzoic acid
Butylated hydroxyanisole
Butylated hydroxytoluene
Calcium ascorbate
Calcium propionate
Calcium sorbate
Caprylic acid
Dilauryl thiodipropionate
Erythorbic acid
Gum guaiac
Methylparaben
Potassium bisulfite
Potassium metabisulfite
Potassium sorbate
Propionic acid
Propyl gallate
Propylparaben
Sodium ascorbate
Sodium benzoate
Sodium bisulfite
Sodium metabisulfite
Sodium proponate
Sodium sorbate
Sodium sulfite
Sorbic acid
Stannous chloride
Sulfur dioxide

TABLE 1*(continued)*

Additives listed by the U.S. Food and Drug Administration as “generally recognized as safe.” (Courtesy, *Scientific American*)

Thiodipropionic acid
Tocopherols
EMULSIFYING AGENTS
Cholic acid
Desoxycholic acid
Diacetyl tartaric acid esters of mono- and diglycerides
Glycocholic acid
Mono- and diglycerides
Monosodium phosphate
derivatives of above
Propylene glycol
Ox bile extract
Taurocholic acid
NUTRIENTS AND DIETARY SUPPLEMENTS
Alanine
Arginine
Ascorbic acid
Aspartic acid
Biotin
Calcium carbonate
Calcium citrate
Calcium glycerophosphate
Calcium oxide
Calcium pantothenate
Calcium phosphate
Calcium pyrophosphate
Calcium sulfate
Carotene
Choline bitartrate
Choline chloride
Chopper gluconate
Cuprous iodide
Cysteine
Cystine
Ferric phosphate
Ferric pyrophosphate
Ferric sodium pyrophosphate
Ferrous gluconate
Ferrous lactate
Ferrous sulfate
Glycine
Histidine
Inositol
Iron, reduced
Isoleucine
Leucine
Linoleic acid
Lysine
Magnesium oxide
Magnesium phosphate
Magnesium sulfate
Manganese chloride
Manganese citrate
Manganese gluconate
Manganese glycerophosphate
Manganese hypophosphite
Manganese sulfate
Manganous oxide
Mannitol
Methionine
Methionine hydroxy analogue
Niacin
Niacinamide
D-pantothenyl alcohol
Phenylalanine
Potassium chloride
Potassium glycerophosphate
Potassium iodide
Proline
Pyridoxine hydrochloride
Riboflavin
Riboflavin-5-phosphate
Serine
Sodium pantothenate
Sodium phosphate
Sorbitol
Thiamine hydrochloride
Thiamine mononitrate
Threonine
Tocopherols
Tocopherol acetate
Tryptophane
Tyrosine
Valine

Additives listed by the U.S. Food and Drug Administration as “generally recognized as safe.” (Courtesy, *Scientific American*)

Vitamin A
Vitamin A acetate
Vitamin A palmitate
Vitamin B_{12}
Vitamin D_2
Vitamin D_3
Zinc sulfate
Zinc gluconate
Zinc chloride
Zinc oxide
Zinc stearate
SEQUESTRANTS
Calcium acetate
Calcium chloride
Calcium citrate
Calcium diacetate
Calcium gluconate
Calcium hexametaphosphate
Calcium phosphate monobasic
Calcium phytate
Citric acid
Dipotassium phosphate
Disodium phosphate
Isopropyl citrate
Monoisopropyl citrate
Potassium citrate
Sodium acid phosphate
Sodium citrate
Sodium diacetate
Sodium gluconate
Sodium hexametaphosphate
Sodium metaphosphate
Sodium phosphate
Sodium potassium tartrate
Sodium pyrophosphate
Sodium pyrophosphate, tetra
Sodium thiosulfate
Sodium tripolyphosphate
Stearyl citrate
Tartaric acid
STABILIZERS
Acacia (gum arabic)
Agar-agar
Ammonium alginate
Calcium alginate
Carob bean gum
Chrondrus extract
Ghatti gum
Guar gum
Potassium alginate
Sodium alginate
Sterculoia (or karaya) gum
Tragacanth
MISCELLANEOUS ADDITIVES
Acetic acid
Adipic acid
Aluminum ammonium sulfate
Aluminum potassium sulfate
Aluminum sodium sulfate
Aluminum sulfate
Ammonium bicarbonate
Ammonium carbonate
Ammonium hydroxide
Ammonium phosphate
Ammonium sulfate
Beeswax
Bentonite
Butane
Caffeine
Calcium carbonate
Calcium chloride
Calcium citrate
Calcium gluconate
Calcium hydroxide
Calcium lactate
Calcium oxide
Calcium phosphate
Caramel
Carbon dioxide
Carnauba wax
Citric acid
Dextrans
Ethyl formate
Glutamic acid

(continued)

TABLE 1*(continued)*

Additives listed by the U.S. Food and Drug Administration as “generally recognized as safe.” (Courtesy, *Scientific American*)

Glutamic acid hydrochloride
Glycerin
Glyceryl monostearate
Helium
Hydrochloric acid
Hydrogen peroxide
Lactic acid
Lecithin
Magnesium carbonate
Magnesium hydroxide
Magnesium oxide
Magnesium stearate
Malic acid
Methylcellulose
Monoammonium glutamate
Monopotassium glutamate
Nitrogen
Nitrous oxide
Papain
Phosphoric acid
Potassium acid tartrate
Potassium bicarbonate
Potassium carbonate
Potassium citrate
Potassium hydroxide
Potassium sulfate
Propane
Propylene glycol
Rennet
Silica aerogel
Sodium acetate
Sodium acid pyrophosphate
Sodium aluminum phosphate
Sodium bicarbonate
Sodium carbonate
Sodium citrate
Sodium carboxymethylcellulose
Sodium caseinate
Sodium citrate
Sodium hydroxide
Sodium pectinate
Sodium phosphate
Sodium potassium tartrate
Sodium sesquicarbonate
Sodium tripolyphosphate
Succinic acid
Sulfuric acid
Tartaric acid
Triacetin
Triethyl citrate
SYNTHETIC FLAVORING SUBSTANCES
Acetaldehyde
Acetoin
Aconitic acid
Anethole
Benzaldehyde
N-butyric acid
d- or *l*-carvone
Cinnamaldehyde
Citral
Decanal
Diacetyl
Ethyl acetate
Ethyl butyrate
Ethyl vanillin
Eugenol
Geraniol
Geranyl acetate
Glycerol tributyrate
Limonene
Linalool
Linalyl acetate
1-malic acid
Methyl anthranilate
3-Methyl-3-phenyl glycidic acid ethyl ester
Piperonal
Vanillin

The Delaney Amendment, dealing with food additives, has been in place since 1958. A substance which produced cancer in laboratory animals could not be used as a food additive. It was overhauled significantly in 1996. More foods are now covered. However, states cannot set standards which are more strict than the federal rules. The standard for pesticides in raw and processed food is based on the amount which may be expected to produce cancer in one person in a million.

It is estimated that there are as many as 1400 natural and synthetic flavors available today. Increased use of flavoring has paralleled the introduction of new food processing and distribution techniques.

Flavor enhancers are closely related to flavors. The best known of these is monosodium glutamate (MSG). There is evidence linking excessive intake of MSG to Kwok's disease, sometimes known as "Chinese restaurant syndrome." Symptoms include a tightening of the neck and face muscles, at times accompanied by nausea, headache, and giddiness. Some countries have placed limits on the amount of MSG in foods and require that the presence of this substance be prominently noted.

Color additives are utilized primarily for the purpose of giving an appetizing appearance to food. Synthetic dyestuffs are used much more often than natural materials. It can be expected that the synthetic dyes will be produced in a high state of purity. In general, small amounts of dye will suffice to give the desired food color. A material that gives a color that is durable is needed by the food processor. Regulations governing the colors that may be added to foods vary markedly from country to country and this causes some difficulties for food processors engaged in international operations.

Some commonly used preservatives are benzoic acid, sodium benzoate, sorbic acid, monosodium phosphate, sodium propionate, and sulfur dioxide. Of special interest is the use of sulfur dioxide for inhibition of mold and discoloration in wine. Sulfur dioxide is, of course, a prominent air pollutant. There is anxiety that the acceptable daily intake of sulfur dioxide will be exceeded in countries where wine intake is heavy. Experimental evidence indicates that sulfur dioxide inhibits the growth rate, probably due to destruction of Vitamin B_1 by sulfite.

Antioxidants, added to prevent rancidity in fatty foods, can be put in the classification of preservatives. A second use for antioxidants is developing with the growing practice of display of food in transparent containers and wrapping. Attendant exposure to light causes discoloration, not necessarily detrimental to nutritional value in itself, but detracting from attractiveness. The most commonly used antioxidants are butylated hydroxyanisole, butylated hydroxytoluene, propyl, octyl and dodecyl gallates, and tocopherols. Antioxidant effect of a substance can often be increased by addition of a second material, producing a synergistic reaction and allowing more effective product control.

Texture agents include emulsifiers, stabilizers, and thickeners. These are the largest single class in terms of total quantity consumed in food. Use of these agents has contributed greatly to the development of the new convenience foods.

The miscellaneous group includes acids, alkalies, buffers, neutralizing agents, anti-glazers, release agents, anticaking materials, clarifying agents, and foaming agents. All of these substances are primarily manufacturing and processing aids. Indeed, without many of these materials the range of modern foods would be much more limited.

Testing of food additives as with most other chemicals, is not usually done with human subjects. Exposure studies of both limited duration and long term are made on mice, rats, dogs, and other laboratory animals. When deviation from normal response is noted, the largest dosage that does not produce the change is used as the base for acceptable intake for humans. Normally, this dosage is reduced by a factor of about 100 in most countries. The allowable, or acceptable, dosage is expressed as milligrams of the substance per kilogram of receptor body weight. It must be emphasized that extrapolation from animals to humans is always a difficult undertaking.

International guidelines have been issued by the World Health Organization and the Joint Expert Committee on Food Additives of the Food and Agriculture Organization. The Codex Alimentarius Commission of the Food and Agriculture Organization has published six principles concerning the use of food additives.

1) The use of an additive is justified only when it has the purpose of maintaining a food's nutritional quality, enhancing keeping quality or stability, making the food attractive, providing aid in processing, packing, transporting or storing food or providing essential components for food in special diets. An additive is not justified if the proposed level of use constitutes a hazard to the consumer's health, if the additive causes a substantial reduction in the nutritive value of the food, if it disguises faulty quality or the use of processing and handling techniques which are not allowed, it deceives the customer or if the desired effect can be achieved by other manufacturing processes that are economically and technologically satisfactory.
2) The amount of additive should not exceed the level reasonably required to attain the desired effect under good manufacturing conditions.
3) Additives should conform to an approved standard of purity.
4) All additives in use, or proposed, should be subjected to adequate toxicological evaluation and permitted additives should be kept under observation for deleterious effects.
5) Approval of additives should be limited to specific foods or specific purposes and under specific conditions.
6) Use of additives in foods consumed mainly by special groups within the community should be determined by the food intake of that group.

Toxicity is the general term applied to adverse biological effects in man resulting from pollutants. Effects may range from lessened health levels to death. Chronic toxicity is of major interest here. Included under effects of chornic toxicity are carcinogenicity, teratogenicity, and mutagenicity. It has been suggested that some behavioral disorders are seated in the effect of toxic substances. This area has not been extensively investigated.

One or more of these types of toxicity may be induced by pollutants in the environment. Pollutants may cause adverse effects alone or may interact synergistically with ordinarily harmless substances to give unexpected results. The mechanism of smog formation is an excellent example, although Man is but indirectly affected.

It has been estimated that, over the expected life span of one malformed child, the total costs for care are in the neighborhood of a million dollars. This figure, which does not include loss of earnings, is a high price for society to pay.

Widespread, long-term genetic effects due to environmental pollution cannot be accurately predicted but the cost is certainly great. Such cost estimates have not, until recently, been applied in matching benefits to cost in evaluation of a potentially hazardous substance. Hazards from a particular substance need not be accepted when another substance of equal worth is available. Mandatory testing is usually looked upon as an unnecessarily bothersome expense by producers of synthetic substances. In fairness, however, it must be said that some chemicals, in use for years, have been unexpectedly indicated as potential hazards and the economic loss has been heavy. Cyclamates are a good example. It is of interest to speculate if such a situation could have been avoided. The basic question concerns the adequacy of existing legislation and difficulty of implementing regulations.

It has become increasingly clear that many diseases formerly regarded as spontaneous are caused by environmental pollutants. These diseases include cancer, birth defects, and mutations. The problem is compounded by greatly increased exposure of the population to new synthetic chemicals and their degradation products. Environmental effects of these substances are not usually adequately evaluated.

There is now overwhelming evidence that many human cancers are due to carcinogenic substances in the environment. These are, then, preventable. Studies of epidemiological factors have indicated strongly local environmental factors are of significance in cancer incidence.

There is a demonstrable link between cigarette smoking and lung cancer and other cancers have been shown to be related to smoking. Cigarette, pipe and cigar smoking have become socially unacceptable. Ayers has described the cigarette as a private air pollution source. There is strong evidence that effects of smoking are experienced by persons in the vicinity of the smoker. Environmental tobacco smoke can be defined as a mixture of sidestream smoke from the cigarette and mainstream smoke exhaled by the smoker. Smoking in schools, public buildings and businesses is now widely banned.

In 1604 James I described smoking as “A custom loathsome to the eye, hateful to the nose, harmful to the brain, dangerous to the lungs.” The first major paper suggesting a link between smoking and lung cancer was published in 1939. In 1950 Wynder and Graham reported that, in a group of 650 men with ling cancer, 95% had smoked for at least 25 years. Doll and Bradford, in a 1951 report of interviews with 1357 patients with lung cancer, found that 99.5% were smokers. There was a marked decrease of cigratte smoking after the 1963 Report of the Surgeon General of the US Public Health Service. In the same year, an internal document of a major tobacco company stated that the company was in the business of selling nicotine, an addictive drug effective in release of stress mechanisms. The British government banned television advertising of cigarettes in 1965. The first health warnings appeared on American cigarette packs in 1966 and on British packs in 1971. A 1984 review article in the *Journal of Epidemiology* confirmed the link between smoking and cervical cancer. A 1990 study related lung cancer in nonsmokers to passive childhood smoking. A former Prime Minister accepted a contract in 1992 with a tobacco company as an adviser on strategy for selling cigarettes in Eastern Europe and Developing Nations. In 1993 the US Environmental Protection Agency classified environmental tobacco smoke as a Class A carcinogen. The State of Texas, in a 1996 suit against a cigarette maker, quotes a company executive as saying “We don’t smoke the—, we just sell it. We reserve that for the young, the black, the poor and the stupid.” President Clinton, the first US President to engage in open conflict with the tobacco industry, declared tobacco to be an addictive drug.

While Legal Aid to fund claims against tobacco companies by former smokers was refused in the UK in 1996, lawsuits against tobacco companies in the United States have been filed by individuals and as class actions. 22 states have sued tobacco companies to regain vast sums of public money expended on care for smoking related maladies. Previously confidential documents from company files and information supplied by whisle-blowers have shown that the companies were aware of adverse health effects of smoking as early as the 1930s.

The tobacco industry, faced with decreasing usage at home, resorted to a creative marketing approach. It was decided that a new market must be developed. One large tobacco company targeted black people and young, blue-collar females. There was a strong public outcry when this was reported in the news media and the company withdrew the campaign. It was a public relations disaster.

There is increased effort to market American cigarettes in the Third World. American tobacco products enjoy a good reputation as to taste and are popular overseas. Officials in some developing countries have accused the US of following a double standard with regard to addictive drugs at home while promoting cigarette use abroad.

Cancer of the oral cavity in Asia is linked with chewing of tobacco leaves and betel nuts. High incidence of gastric cancer in Chile, Iceland, and Japan has been associated epidemiologically with a diet high in fish. It has been suggested that nitrosamines, formed by reaction between nitrites and secondary amines of the fish, may be a significant factor. Nitrites are employed as a preservative of fish. Dietary contamination with aflatoxin is thought to be a causitive effect of liver cancer in the Bantu. Aflatoxin is a fungal carcinogen.

Ingestion of azoglucoside carcinogens with Cycad plants is probably the chief cause of liver cancer in Guam. Cancer of the esophagus in Zambians may be related to high nitrosamine content of Kachasu spirits.

There is well documented evidence of occupationally related cancers. These include bladder cancer in the rubber and aniline dye industries, lung cancer in uranium workers, nasal sinus cancer in wood workers, skin cancer in shale oil workers, and lung cancer in asbestos workers.

The question of asbestos assumed great importance in the 1980s. Once widely used in building, it was found to be a serious health hazard. It is now felt that no exposure to airborne particles is safe.

The Environmental Protection Agency estimates that 30,000,000 tons were used between 1900 and 1980. Asbestos abatement has become big business. One estimate places the value as high as $200 billion per year. Asbestos has been used in more than 3000 products over the years. These include duct work, exterior shingles, floor and ceiling tiles, plaster, pipe lagging, cement, drywalls, theater curtains, brake linings, clutch facings and baby powder.

Asbestos occurs naturally as chrysotile, crocidolite, amosite, anthophyllite, actinolite tremolite. The thin, tiny fibers are not dangerous until disturbed. Then particles of a certain size can lodge in the lungs. When the substance can be crumbled under hand pressure—friable—it is considered extremely dangerous. Building renovation and demolition can release particles into the air. Water damage can loosen the binding matrix.

In the 1930s asbestos inhalation was linked to asbestosis and lung cancer. It was later shown that mesothelioma, cancer of the lining of the lung, is caused by asbestos. Gastrointestinal and larynx cancers have also been associated with asbestos. In the 1970s the Department of Health, Education and Welfare estimated that 8 1/2 to 11 million workers have been exposed occupationally in the last 40 years. Asbestos related illnesses can take 20 to 40 years to develop. World War II shipyard workers and prewar insulation workers comprise the majority of afflicted persons. In one study a premature death rate of 48% was found among insulation workers of the 1940s. Custodial personnel are also thought to be at high risk. Studies have found that wives of asbestos workers may well be in danger. It is thought that fibers on the husbands' clothes are the reason.

Asbestos fibers suspended in water are not thought to pose a hazard. However, steam pipe explosions have put fibers into the air, causing whole blocks to be evacuated and necessitating expensive cleanup operations.

Some claims that chrysotile, the asbestos form most commonly used in the US, may pose less danger than other varieties. This position has not yet been validated scientifically. The variety of asbestos versus fiber size as more important in causing disease is the current debate topic. Some European nations and Canada make distinctions among asbestos varieties but, in the US, the EPA and OSHA treat all forms the same for rule making purpose. The UK and Scandinavia follow closely the US approach.

Considerable uncertainty exists in risk assessment for nonoccupational and environmental settings.

Action on asbestos abatement began in the schools. Since the period for appearance of asbestos related diseases can be as long as 20 to 40 years, it was felt that school-age children were at particular risk. In 1982 the EPA Asbestos-in-Schools required all public and private schools to inspect for friable asbestos and report to parents and employees if any were found. The rule did not require abatement. In 1984 the Asbestos Hazard Abatement Act gave funds to assist in abatement. The Asbestos Hazard Emergency Response Act (AHERA) of 1986 established rules and regulations concerning identification, evaluation and control of asbestos containing materials in schools. It further required schools to identify friable and nonfriable asbestos found and submit management plans to state governors. Provisions were included for periodic reinspections, even though inspections were already made as a result of the notification rule of 1982. Of great importance was that portion of the Act dealing with removal situations and certification of workers. In the early days of removal, when guidelines were not yet available, there were too many "rip and skip" operators who performed such work without regard for proper procedures or air quality monitoring. In many cases there was probably more asbestos in the air after the operation than there was before.

It is felt that asbestos abatement in private homes will not be covered by formal regulations. However, it is estimated that about 75,000 commercial and industrial buildings contain friable asbestos.

There are four basic abatement approaches.

1) Removal
2) Encapsulation, in which friable asbestos is bound in a matrix.
3) Isolation of the asbestos containing area
4) Repair

All of these means have a place in dealing with the asbestos problem and it is necessary to seek advice of a qualified professional before undertaking any action. It should be noted that, in the early days of abatement efforts, some education departments allowed only removal. Encapsulation was forbidden. In retrospect, this inflexible position might be criticized.

The National Institute of Building Sciences (NIBS) has taken the position that there is no single correct answer for all situations.

Environmental carcinogens can be classed into two categories, potent and weak. Potent carcinogens, such as nitrosamines and aflatoxins, can induce cancers in animals in very low concentrations. Isolation of these substances in food has given rise to endeavors to relate food distribution patterns with local cancer incidence.

Weak carcinogens, such as atmospheric pollutants, some pesticides, and food additives, have effects much more difficult to evaluate and thus may pose as great a threat as the potent carcinogens because they are less likely to be recognized as a significant epidemiological factor. Often, evaluation must be by indirect means. A causal relationship has been demonstrated to exist between urban air pollution and lung cancer. Lung cancer mortality patterns differ in various sections of the United States and Great Britain. It has been clearly shown that increased mortality due to lung cancer is related to increased urbanization. A survey in the late 1950s found lung cancer rates in the United States to be 39 per one hundred thousand in rural areas and 52 per one hundred thousand in urban areas. Similar data were gathered in Great Britain and the added effect of smoking was evaluated. The conclusion of significance of urban air pollution is inescapable.

The first demonstration that environmental pollutants can cause genetic damage came with the discovery that high energy radiation induces mutations. Later, the development of the nuclear industry focused increased attention on the dangers of unwanted genetic change. Associated with possible genetic damage in this industry was the danger of radiation induced carcinoma. Accordingly, safeguards were developed and limits were set on radiation levels. These were functions of exposure time. Limits were changed periodically in the light of fresh evidence. It is of interest to note that changes were usually downward. Radiation from X-Ray machines and fluoroscopes was treated in the same way. A widely available hazard was the fluoroscope for fitting of shoes. It is impossible to determine possible genetic damage from this source but it was probably considerable. Such installations have all but disappeared. Medical and dental radiation sources are firmly regulated. There was suspicion that some chemicals might induce mutations but only about thirty years ago was the mutagenic effect of mustard gas on fruit flies shown. There is concern in some circles that strongly mutagenic chemicals, their effects not yet recognized, may already be in wide use.

A mutation can be a chemical transformation of a single gene or a rearrangement of a chromosome. The former, called a gene or point mutation, can cause an alteration in function. The latter may be microscopically visible and is known as chromosome aberration. In studies of human subjects the aforementioned changes are not always easily determined.

When genetic function of a cell is changed while reproductive capacity is unaltered the genetic change is transmitted to descendant cells. Mutations in germ cells are most serious in long-term effects because changes are transmitted to future generations.

Mutagenic effects are of many types. These range from lethal effects to changes so slight as to remain unnoticed. It is thought that many inherited diseases are based in mutagenic effects. At this time there is no known way to adequately evaluate long-term mutagenic effects. It is a cause for serious concern for future generations. Genetic effects over a long term are statistical rather than discrete. As natural selection has had its effect over a long period, so will externally induced mutations make their effect felt over a long period. Dominant mutations appear in the next generation while recessive mutations require contributions from both parents. This characteristic may not appear for many generations.

Most mutations are harmful or neutral. Many mutants which in the past would have produced death or lessened fertility now remain. This is due to higher standards of health care. The former equilibrium, in which old mutations disappeared about as rapidly as new mutants appeared, has been upset in favor of new mutants. Natural selection does not apply as strongly as before. It has been suggested that medical problems of the future will be more and more due to genetic origin. One estimate places our present health burden as being 25% of genetic nature.

If a mutation causes a gene to have a sterilizing or lethal effect, only one generation is involved. Less severe effects, however, may involve many generations. The less severe the effect, the more people will be exposed. Mild mutational effects, affecting many people, will have a greater public health impact than one severe, or fatal, case. Unfortunately, many of these milder effects may be difficult to detect.

Many chemical mutagens in the environment pose threats which have not yet been adequately evaluated. Mammalians test systems are available but extrapolation from smaller animals to man is indeed difficult and liable to error.

Trimethylphosphate, until recently, was added to gasoline for control of surface ignition and spark plug fouling. This substance has been implicated in chromosome damage in rats. The dosage in rats at which damage occurred was at subtoxic level. However, extrapolation of dosage levels to man is difficult and man's exposure to the substance in the environment is almost impossible to estimate.

Congenital malformations are those abnormalities which can be recognized at birth or shortly thereafter. The study of these abnormalities, which can cause serious disability or death, is known as teratology. A broader definition can include microscopial, biochemical, and functional abnormalities of prenatal origin. It is estimated that about 3% of live births involve congenital malformations, but this is only an estimate. Lack of adequate data at the national level makes such figures rather rough and probably inaccurate.

Three categories of human teratogens have been identified. These are: (1) viral infections, (2) ionizing radiation, and (3) chemicals. Thalidomide is the best known of the third category. Experimental evidence of teratogenicity of some compounds had been in existence for many years but requirements of three generation reproductive tests in animals were established only after the sensational thalidomide disaster of 1962. Some questions concerning the validity of such tests have been raised.

Pollutant materials to which humans are exposed must be examined for toxicity. These examinations must also include specific tests for carcinogenicity, mutagenicity, and teratogenicity. These effects have been studied in the past by separate disciplines and there has been inadequate interchange of results and ideas. It is to be hoped that the emerging profession of environmental scientist will aid in breaking down these historical and somewhat artifical barriers among disciplines.

There is need for more sensitive and reliable methods of testing effects of single chemicals, degradation products and mixtures. External environmental effects must also be included as system parameters in evaluation of pollutant effects. It is possible that human tests may become necessary, but moral and legal considerations pose serious questions.

Agents under test must be administered at subtoxic, toxic, and chronic levels. Effects of possibly significant but normally non-toxic agents on the system containing the toxic agent under investigation must also be evaluated.

Testing procedures must be realistic and reflect the pathways of human exposure. However, the exception to this rule is in sensitivity. Evaluation of carcinogenic effect may require administration to test animals by different means. Normal ingestion in humans might be by inhalation while adequate dosage in rats might require addition of the substance in question to daily food. This is particularly true when dealing with weak environmental carcinogens.

Metabolic compatibility between a test species and humans is important for extrapolations of test results. There is seldom a one to one correspondence and most authorities feel that at least two test species should be examined. There is much testing data on rodents, pigs, and subhuman primates. Thus, further utilization of these animals is indicated. In special cases, however, a less common species may be necessary in order to gain the desired data.

It is necessary to test levels much higher than human exposure for carcinogenic, teratogenic, and mutagenic substances. It must be noted that, even when large numbers of mice are tested, the number is still small compared to the millions of humans that might be exposed in the everyday environment. Not all humans exposed would respond, in any event, to the dangerous substance. As an example, meclizine, an antihistamine used for treatment of morning sickness, has been found to be teratogenic in the rat but not so in a relatively small number of women tested. The question as to effects on a larger population is unanswered. For thalidomide, humans are found to be 60 times more sensitive than mice, 100 times more sensitive than rats, 200 times more sensitive than dogs, and 700 times more sensitive than hamsters. It is obvious, therefore, that predictions as to teratogenic doses of thalidomide on the basis of animal testing would mean very high and dangerous exposure levels.

Complicating the testing picture is the increased effect of substances when a second, supposedly innocuous, substance greatly increases the undesirable end effect. Such reactions were the basis of the Delaney Amendment of 1968 to the Food, Drug, and Cosmetic Act (US). The Amendment required that no additive be considered safe if found, under appropriate testing conditions, to induce cancer in man or animal.

Recent advances in molecular biology have made it possible to give weight to a broad range of evidence, including details as how toxic agents affect human cells and on genetic material which controls cell reproduction. The relatively new concept of virtual risk may find application. It should be noted, however, that use of cost/benefit may not be desirable and should be treated with caution, if not suspicion. At times this concept has been used to evade existing environmental regulations. Elected officials are finding that efforts to weaken public health and pollution control legislation are unpopular.

Often, non-carcinogenic alternatives are available as replacements for questionable materials. There is considerable controversy about the pesticide DDT. Some authorities question the continued utility of DDT for control of cotton insects due to development of resistant strains. This controversy will not soon die down. Cyclamates, banned in recent years, were an intentional food additive and of no value nutritionally. Only after their widespread use for a number of years was there shown a carcinogenic danger.

The argument of economic loss to special interest groups is of no validity. In view of the uncertainty of long-term effects of carcinogenic materials, zero tolerance levels must be imposed for these substances.

It is important that chemicals, and their derivatives, suspected or implicated as toxic, carcinogenic, teratogenic, and mutagenic be detected and monitored in the environment. Epidemiological studies may show effects but it is necessary to quantitatively establish occurrence of these substances. It has been possible to demonstrate the relationship between cigarette smoking and lung cancer although some special interest groups seriously disputed this. However, in this case were two dissimilar populations, smokers and non-smokers. In the case of exposure of the general population to a suspect substance, evaluation and epidemiological treatment of data are more difficult. Apart from rubella virus, no known teratogens, such as ionizing radiation, mercury, etc. have been positively identified epidemiologically in the highly industrialized countries. This indicates the great need for better and more comprehensive gathering of data relating to birth defects. It is to be hoped that environmental effects should be segregated from natural and spontaneous mutation effects. It would be necessary to monitor special indicator traits. Such traits would have to be chosen with great care and followed for a considerable period.

Recently it has been suggested that mutation rates could be monitored by means of data on spontaneous abortions. Teratogens may cause chromasome aberrations but these act after fertilization and would be against a normal background.

The question of data on occupational hazards, long the major field of endeavor of the industrial hygienist, must be raised in connection with legislation thought to be inadequate and outdated. The correctness of much of the information on which maximum allowable concentrations are based is in doubt at this time. Probably a critical reexamination will soon come about as a result of increased environmental awareness.

Present toxicological techniques are not sufficiently sensitive to monitor adequately many weak carcinogens. Compounding the problem is the difficulty of recognizing effects of many substances in the general population. Special situations as to sample population at times help to simplify the problem, such as cigarette smoking. But there is certainly a great area in which problems are strongly suspected to exist but statistical validation is not possible at this time. Yet tolerance and allowable concentration limits must be set. There is a most fruitful area for research here.

Regulatory agencies are often understaffed and underfunded. Attention of existing resources is usually allocated on the "squeaky wheel" principle. They move from current crisis to current crisis and are frequently unable to devote enough time to prevention of new crises. This is contrary to good public health practice.

At times competition among various interest groups can lead to inconsistent positions by responsible officials. In the Report of the Surgeon General (1981) it was stressed that smoking, particularly cigarette smoking, can cause many types of cancers. However, the Surgeon General declined to take issue with the continued granting of subsidies to tobacco growers by noting that price supports are considered an economic and agricultural issue and not an issue concerning public health.

The most visible of Surgeon Generals, Dr. C. Everett Koop, was also the most outspoken about the dangers of tobacco use. He became something of a folk hero and was highly respected.

There have been some instances where persons not in sympathy with environmental control and public health have been appointed to high positions in environmental protection. The need for environmental protection does not change with political climate. Efforts to regress are a serious economic error. Damage from deferred action can cost many times the sums initially saved and the health effects can be cumulative. Public health practice is the basis of the great majority of environmental efforts.

ELECTROSTATIC PRECIPITATION

This article deals with high efficiency (99.5%) particulate removal techniques often required of modern central station power plants. The reader is also referred to the article "Particulate Removal" for a discussion of control methods including those used when more moderate conditions apply.

Electric power companies are required to analyze proposals for, and subsequently to purchase, electrostatic precipitators based on cost and performance.

The basic design factors which determine the collection efficiency are the collecting plate area, the velocity of the gas, the time that the gases are in contact with the discharge wires and collecting plates, and the electrical system supplying the useful power to the flue gas. It is the differences in these factors in the manufacturers' proposals that give the engineer the most trouble in choosing the precipitator that will continually produce the required efficiency. The amount of useful power, and therefore the collection efficiency, is primarily determined by the number of active high tension electrical bus sections into which the precipitator is divided (see Figure 1).

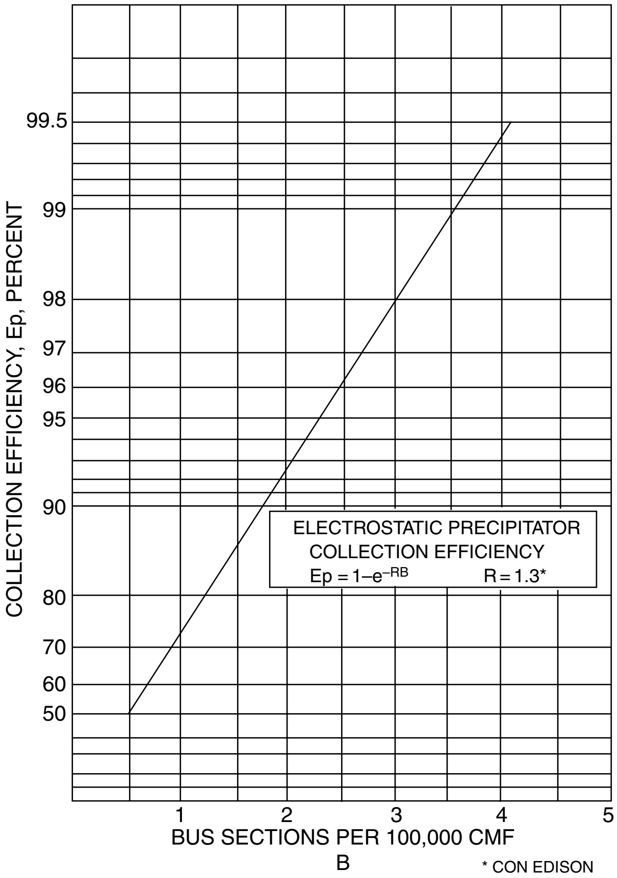
The collection efficiency of a precipitator is closely related to the useful amount of electrical power than can be supplied to the precipitator, the greater the useful power, the higher the efficiency. If we imagine a precipitator with all the discharge wires being supplied by one power source through a single cable, the highest voltage that could be maintained between the wires and the collecting plates would be limited by the first wire to spark excessively. The reason that one wire may spark excessively before another is due to many factors including uneven distribution of the gas and dust as they enter the precipitator, uneven build up of ash on the wires and plates, mechanical misalignment of the wires or plates and the fact that the collection process produces a different amount of ash in the gas at the entrance and discharge end of the precipitator. Even if all the wires spark, at the same voltage, there is an appreciable loss in efficiency due to lowered voltage in the wires operating in parallel because the excessive sparks from one wire affect all the others.

From this it is evident that the ideal precipitator would be one in which each wire has its own stabilization control and power source, but this, of course, would not be economically feasible. Somewhere between these extremes is the practical number of power sources or electrical bus sections that will continually produce the desired efficiency.

Figure 1 shows the efficiency curve which may be used in preparing specification and predicting actual operating efficiency. This relationship between efficiency and active bus sections has been referred to by White[2] as the "Ramsdell Equation."

An active bus section refers to a separately energized precipitator section where a transient electrical disturbance in a given section is not reflected in any other section. This condition exists when either one section is energized by a single rectifier or when two sections are energized by a double half wave rectifier.

A design criterion or an equation for the physical sizing of precipitation is required. A curve based on Con Edison's own experience and that of other utilities is presented in Figure 2.



* CON EDISON
1.0% SULPHUR
300°F

FIGURE 1

The fundamental efficiency formula for an electrostatic precipitator is

$$E = 1 - e^{-w/30.48\times AV}$$

where

E = Collection Efficiency
A = Collection Area
V = Rate of Gas Flow
w = migration velocity, factor which is related to useful electrical power

Low sulphur coal ash is not easy to collect with electrostatic precipitators because of its high resistivity. This was inferred from Figure 3 which shows by tests the effect of lowering the sulphur in the coal on collection efficiency.

The Ramsdell Equation based on bus sections is a variation of the fundamental formula and is expressed as

$$E = 1 - e^{-RB}$$

where

E = Collection Efficiency
B = Number of active bus sections which is related to useful electrical power
R = Performance Constant

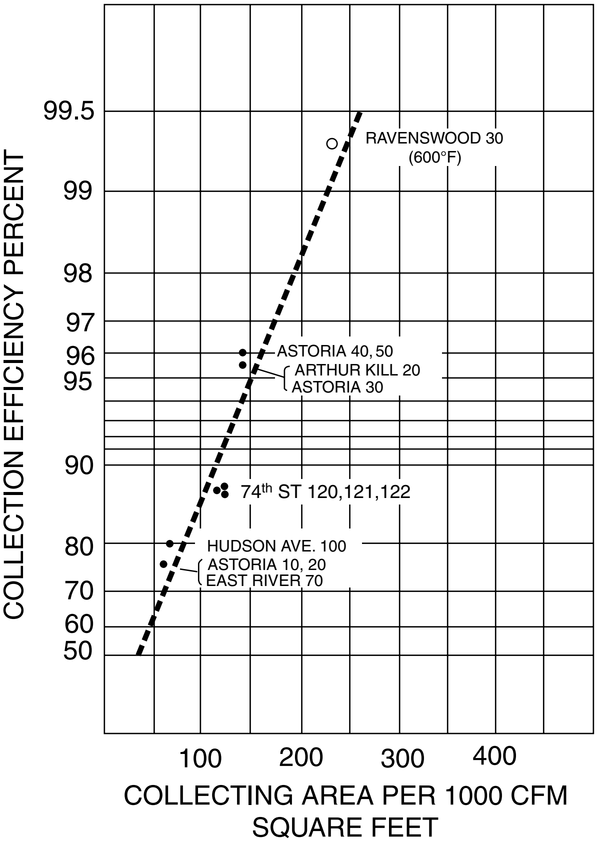


FIGURE 2 Collecting efficiency vs Collecting area per 1000 CFM. Using this efficiency test data and precipitator collecting area we were able to plot the equation or the dotted curve shown in Figure 2.

Using tests data with medium and low sulphur coals and information volunteered by other utilities for high sulphur coals, a family of curves may be drawn (see Figures 4 and 5).

FIGURE 5

There is another feature of precipitator design that is of vital importance to collection efficiency, namely the velocity of the ash laden gas flowing through the collector. The lower the velocity, the greater treatment time available to thoroughly charge the flue gas and the lower the velocity, the less chance there is for reentraining or sweeping off the fly ash accumulated on the collecting plates. The lower the sulphur content of the coal, the higher the resistivity of the ash. Since, under these conditions the collected ash has difficulty sticking to the collecting plates, lower sulphur coals require lower gas velocity. Figure 6 indicates the maximum gas velocities required to insure the required collection efficiencies when burning 1.0% sulphur coals.

It is known that the resistivity of the fly ash is related to sulfur content of the coal burned and also to the temperature of the flue gas.

We have already seen that the lower the sulphur content, the higher the resistivity of the fly ash but as the flue gas temperature drops below 300°F, the high resistivity effect of lower sulfur is substantially reduced. A 30°F decrease in gas temperature under certain conditions will offset the effect of a 1.0% decrease in the sulfur content of the coal.

All the data we have previously discussed in this paper was at a nominal operating temperature of 300°F.

In order to insure that adequate electric power is available for charging our precipitators we again reviewed the latest units on our system. Two sets of curves were developed from this study. Figure 7 shows the total rectifier capacity in milliamps and Figure 8 shows the total transformer capacity in kilovolt-amperes.

These curves are based on 2.0% sulfur coal. Having more electric capacity is of little value with the low sulfur coals with high resistivity ash because the determining factor is how much power the ash laden flue gas will absorb, not how much of a charge can be imposed on the gas. On the other

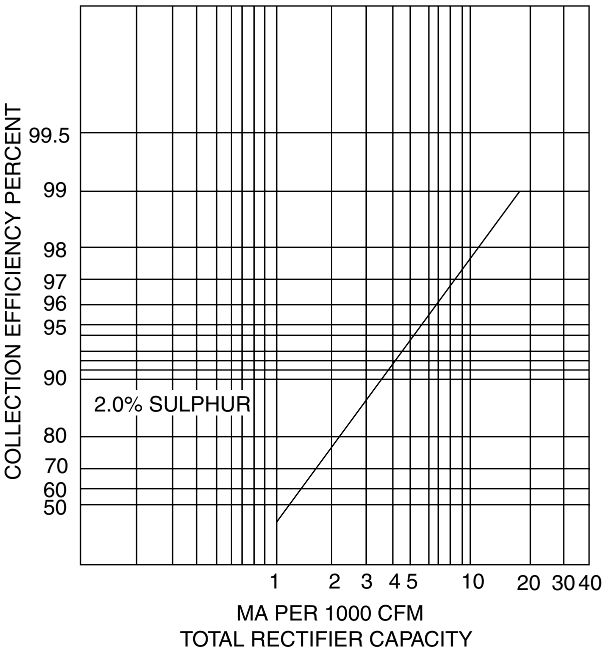

FIGURE 7 Precipitator design curve.

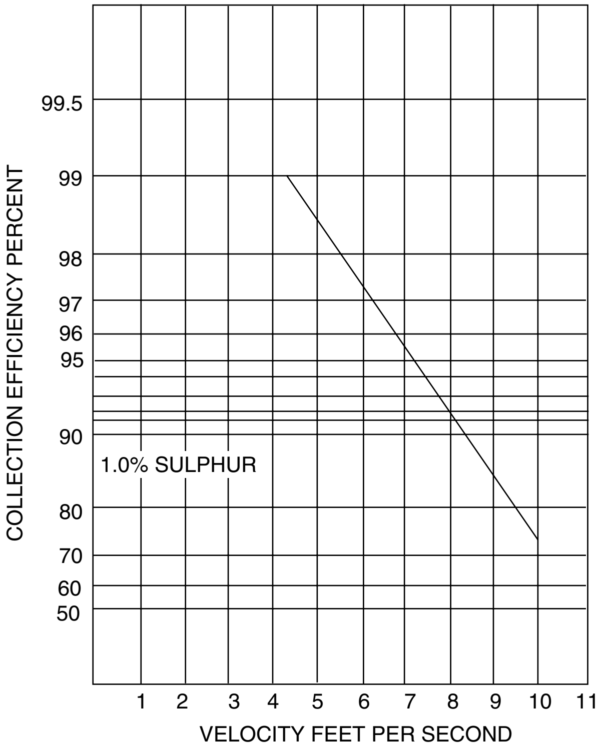

FIGURE 6 Precipitator design curve.

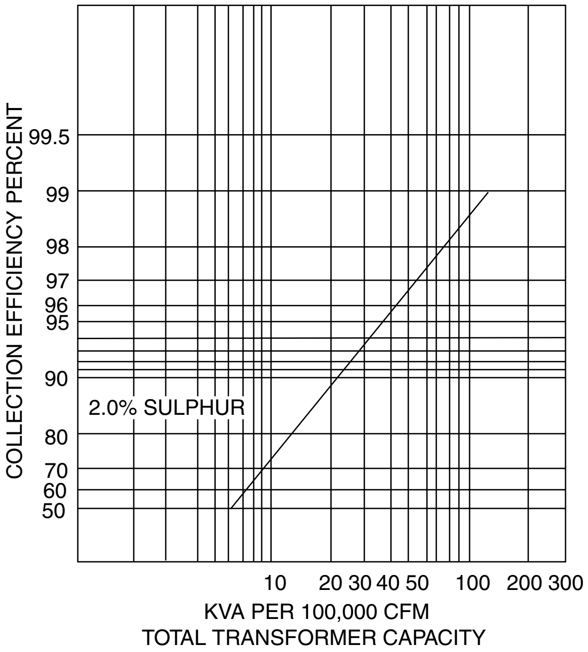

FIGURE 8 Precipitator design curve.

hand high sulfur coal ash does require much more electric capacity than shown on these curves. Precipitators operating under these conditions are sometimes referred to as power "Hogs."

Certain basic criteria should be met in order to attain high collection efficiency at a modern power plant installation. These include:

1) Low velocity of the gas passing through the collection zone.
2) High time of contact of the gas in the precipitator.
3) Reasonably large collecting surfaces.
4) High corona power.

The collection efficiency of a precipitator is closely related to the useful amount of high corona power that can be supplied to the precipitator: the greater the useful power, the higher the efficiency. For better efficiency this power should be distributed among many energized collecting sections, each having an individual control and power supply.

Burning low sulfur coals requires the upgrading of dust collection equipment. This leaves a company with the following alternatives if physical space exists:

1) Add collecting surface and electrical sets to existing 99.75% collectors for example to maintain the necessary efficiencies when burning low sulfur coals.
2) Add new precipitators in series with the existing precipitators to increase the efficiency for example from 99% to 99.8% when burning low sulfur coal.
3) SO_2 conditioning and pulsed energization.[7]

"HOT" PRECIPITATOR CASE STUDY

Hot gas temperature (>600°F) precipitation offers a feasible alternative for the low sulfur eastern coal situation.

This approach was used for the newest operating coal fired unit, at Con Edison's Ravenswood No. 30. The location of this precipitator, between the economizer outlet of the boiler and the air heater inlet, is shown in Figure 9.

The location of this "hot" precipitator was predicated on three considerations:

1) Anticipated reduced air heater fouling by locating the precipitator ahead of the air heater.
2) Ability to burn low sulfur coals without affecting the collection efficiency (see Figure 10).
3) The boiler was designed to burn oil as an alternate fuel and it was desired to be able to operate the precipitator when burning this oil. After extensive tests on a pilot installation at Ravenswood No. 10 while burning oil, it was determined that the precipitated oil ash caught in a "hot" condition could be handled. It has been demonstrated that such a precipitator is effective in collecting oil ash.

The collector is made up of four separate combination units, two double-decked for the north boiler and two double-decked for the south boiler. Extensive model study was required to attain the most efficient flue design that would result in proper gas and dust distribution entering each precipitator. The height of this precipitator for the 1000 MW unit is over 15 stories. The latest performance test on this Ravenswood No. 30 collector when burning coal has met the most optimistic expectations.

As previously mentioned, the design of the precipitator units for Boiler 30 at the Ravenswood Station featured the "hot gas" concept primarily because of its more efficient characteristics in collecting the particulate matter from flue gas while firing either fuel oil or low sulfur coal. Proposed air-pollution control legislation at the time confirmed the need for such characteristics in new precipitator equipment. An interesting structural problem arose in the design of the supporting steel for these precipitator units which we feel was resolved in a rather unique fashion.

Because the gas to be handled at the higher temperatures is much greater than would be required at the normal" cold precipitator" temperature levels, the equipment itself must be bigger and, therefore, heavier. The four precipitator units at Ravenswood—Blr 30 required a building volume approximately 90′ × 243′ × 167′ high which included space to install the large associated flue sections. The decision was made to enclose the building on all its exposed sides with uninsulated metal siding (and to provide a roof) for the following reasons:

1) To eliminate the need to weatherproof the flue and equipment insulaton.
2) To eliminate wind loading on the large exposed surfaces of the flues and precipitator units.
3) To improve the appearance of the installation which is only 150′ from a public street.
4) To reduce the external sound levels around the installation.
5) To reduce future maintenance costs.

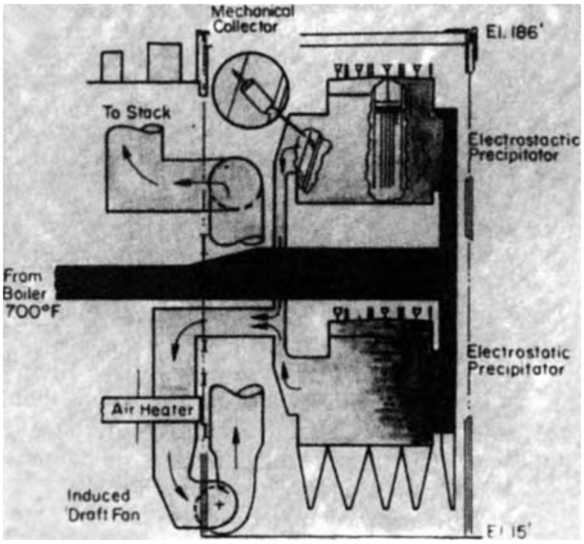

FIGURE 9

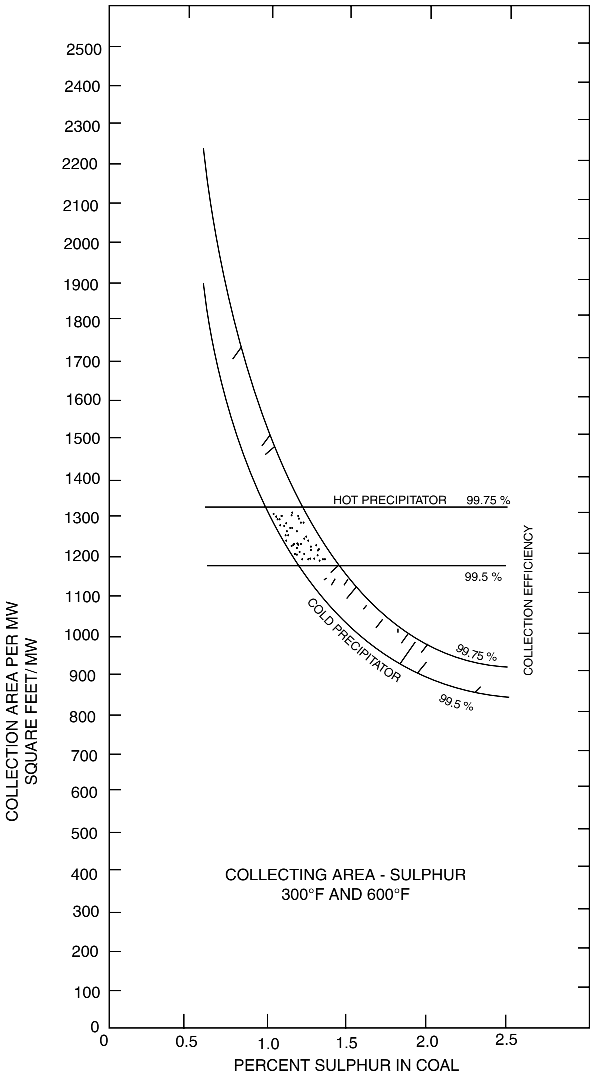

FIGURE 10

Initially, there was no reason to believe that these units would create an excessive expansion problem for the supporting steel, even with the high operating temperature expected. Calculations indicated that only a 20° temperature rise would result overall within the enclosed building with the possibility of a few local hot spots developing similar to what you would normally find in the boiler house.

Boiler 30 started out in construction as an oil fired unit with provisions included to convert to coal fired at some future date. It was decided during the initial construction to convert immediately even if it would not be ready to burn coal until two years after its initial operation burning oil.

Due to the close erection schedule which the coal conversion work on the unit was to follow, it was necessary to start the equipment foundations and supporting steel in the field as quickly as possible. Thus the steel was designed before the equipment design was completed.

The four units were designed to be installed on two elevations in a double deck fashion as shown in Figure 9. The lower units were supported from steel erected on the +42′−8″ elevation (Grade elevation is +15′ − 0″) which allowed for a convenient column arrangement below. The upper units, however, were to be supported from the +126′−2″ level and presented a more difficult column design. Since the interior columns that supported the lower units could not be carried up through the equipment to the upper supports, deep girders had to be utilized to span over the lower units to provide the required support. The maximum span required was 90′–0″ which resulted in a girder depth of 9′−1½″ for a total girder weight of approximately 110 tons. A high yield strength steel was utilized for these girders (ASTM A440 – f_y = 46 KSI). Bracing the building was also a challenge because of the equipment space requirements, and could only be provided around the periphery of the units except below the 42′−8″ elevation.

When the hopper detail drawings were received for the precipitator sections, it was noted that the upper hopper plate stiffeners were located very close to the steel support girders (see Section 1–1 in Figure 11). It was obvious that the hopper insulation above these upper stiffeners would be almost impossible to filed install with the stiffeners in place. But more important, the supporting steel member was now in a “heat pocket” which would not afford much air movement for cooling. Since the supporting members were designed for the same top elevations in both directions, this greatly reduced the possibility of air movement longitudinally along the interior members. This condition existed at all hopper locations at both levels. The possibility of over-heating the supporting steel resulting in an excessive outward movement of the support columns now had to be reckoned with for the safety of the structure.

Schemes were immediately proposed to provide some type of forced ventilation or cooling system which were dismissed because of lack of space as well as for economy reasons. Conditions in the field at the time were such that erection of the lower steel supports was nearing completion, and the lower precipitator shell plates were being delivered to the job site. A solution had to be found which would not delay the precipitator erection, and yet result in a stable structure under significant expansion movement.

The answer was to reduce the relative expansion of support framing in any one direction by providing expansion points at certain key connections. The centerlines for the north and south units were located on the 390 and 320 Column Lines respectively (see Figure 11). It was felt that the building should move north and south of these lines symmetrically as the building heated up during operation. This could be done by stiffening the support steel on these centerlines and by cutting loose the connections on the 36 Line and replace the fixed connections with movable ones. This meant that the maximum expansions would take place by moving the 29 and 430 Column Lines outward and at the same time allowing the center of the building (36 Line) to absorb the inward expansions on sliding connections. This approach had the advantages of having to cut loose only one column line instead of several, and also it reduced individual relative expansions to

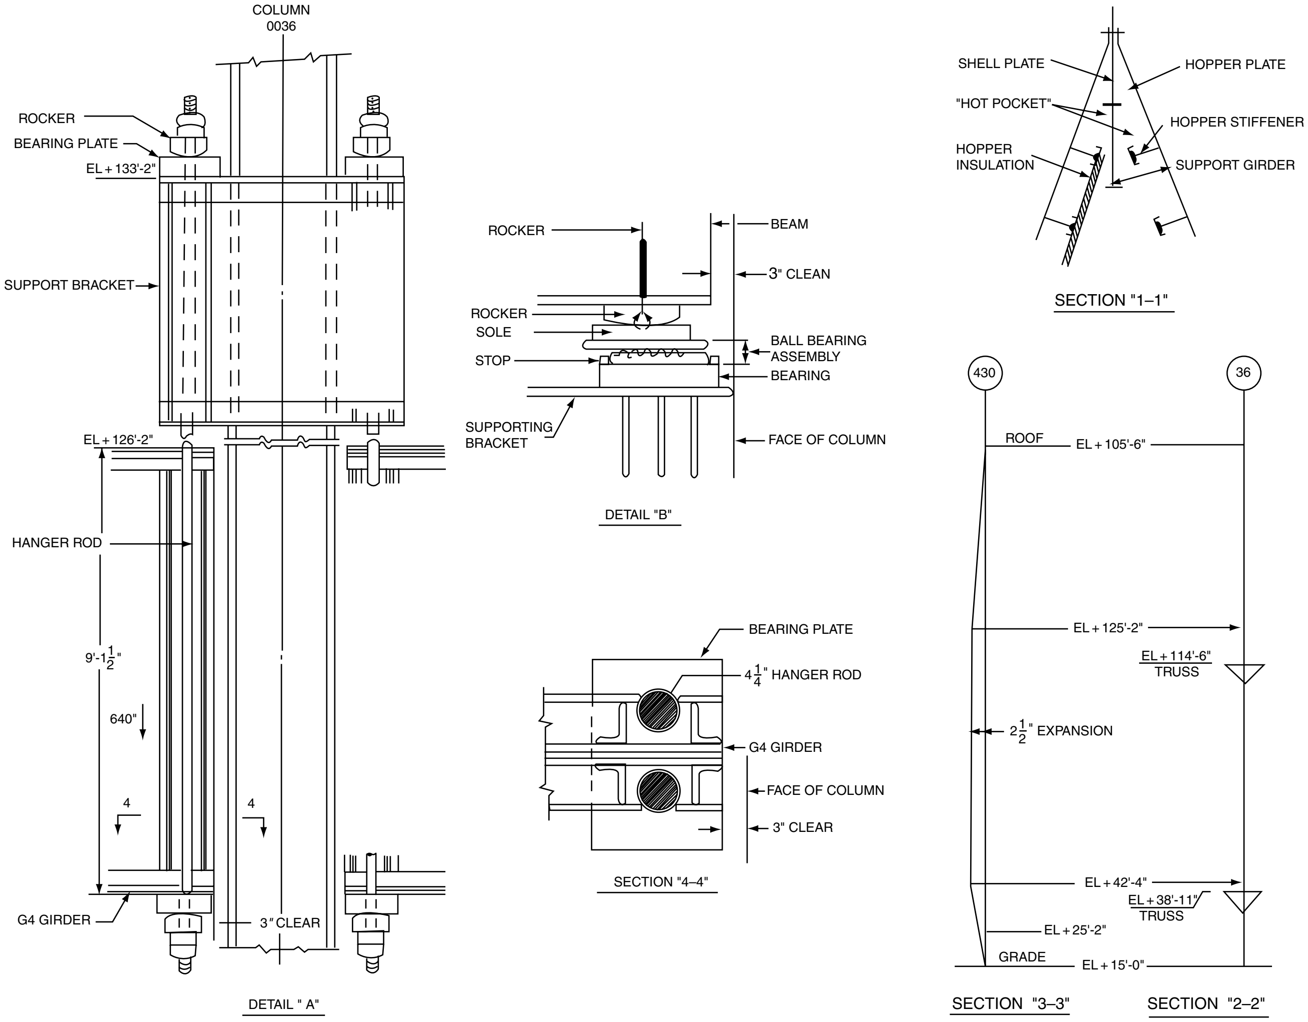

FIGURE 11

movement over one quarter of the building length rather than over one half, at least in the north–south direction.

Design Phase

To accomplish the above design changes, four major obstacles had to be overcome:

1) The centerline support girders for each precipitator unit had to be fixed, or at least stiffened, so that they could come as close to being a zero expansion line (N–S) as possible.
2) Expansion points had to be designed for the 36 Line girder connections.
3) Column Line 36 had to be braced in order to stabilize the building after the connections were cut free.
4) Provisions had to be made for the outward movement of the peripheral columns around the building.

For the normal operating temperature of the units (670°F), it was decided to assume the support steel temperature would rise to an average of 500°F during operation, and provide for the large movements involved. This temperature rise would be applied to all steel directly below the plan dimensions of each unit with the framing beyond these dimensions only assumed to rise to 200° F. Under this assumed combination of temperature rises, the maximum differential movement expected was approximately 2½″ in the north–south direction as well as in the easterly direction. The heavily braced LL Column Line in the boiler house would act as the zero movement line in the east–west direction.

The center support girders for the lower units were restrained by shifting adjacent vertical diagonal bracing to fix the PP320, PP390, M320, and MM390 columns at the + 42′−8″ elevation. The G5 girders on the upper units were stiffened with horizontal members and bracing as indicated in Figure 10.

The expansion joint design for the 36 Line connections utilized ball bearing assemblies except for the G4 connections at Column QQ36 at the +126′−2″ elevation. Detail B in Figure 11 shows the ball bearing type that was selected. The bearings (50 per assembly) were 7/8″ in diameter, and were made of M-50 steel as were the top and bottom assembly plates. The ball bearing retainer was made of stainless steel. The reaction of the G4 girder at Column QQ36 was 640 kips, which ruled out a ball bearing design as the size that would be required was too large for the space available. It was decided to hang the huge girders in a pendulum fashion from a bracket above, and allow them to expand by swinging. The connection finally used is shown in Detail A in Figure 11. For the hanger rod material, a high temperature service chrome-moly steel was selected (ASTM 193-Grade B7). The bar material was heat treated and stress relieved. Mill tests on the material used indicated yield points of 98 KSI and higher. The total required length of only 4¼″ diameter rod was 19′−10″

Horizontal bracing has to be added to the 36 Column Line to carry interior lateral loads out to the vertically braced RR and MM column lines. This was accomplished by adding two horizontal trusses, one at elevation 38′-11″ and the other at elevation 114′−11″ (see Section 2–2 in Figure 11). It was possible to place the lower truss just below the expansion connections for the precipitator support steel at elevation +42′−8″ so the "vertical" members of the horizontal truss could also act as supports for the ball bearing assemblies required for the lower units. This was not the case for the upper units as the existence of other steel (including the G4 girders) made it impossible to install the upper truss any closer to the +126′−2″ elevation. New support brackets were added to the 36 line columns to support the assemblies for the upper precipitator units.

The last major design obstacle to be overcome was the exterior column movement that would result from the 2½″ outward expansion of the framing at elevations +42′−8″ and +126′−2″. It was accomplished by reinforcing the column base billets (and in a few cases by extending the footings as well) to transfer the eccentric column loads which would be carried down predominantly by the exterior flanges. Section 3–3 in Figure 11 indicates the type movement expected. It was also necessary to cut free the support steel of some platforms at elevation +25′−2″ so as not to restrain the exterior columns close to their bases which would induce high moment forces in the columns. This platform steel was resupported on lubrite plate bearings before it was cut free to expand. The column splice plates were found to be flexible enough to carry the moments through the joints at the expanding levels.

Construction Stage

Once the necessary alterations were designed and approved, the difficult task of implementing the changes in the field still remained to be done. One major limitation in this phase of the job was that the precipitator erector was not anxious to have any building connections cut free until his erection work was essentially completed. He had placed a crawler crane on a runway structure atop the 126′−2″ support steel to erect the top units, and he felt that the vibrations already being experienced with crane movements were large enough with the original fixed connections in place, without increasing them by adding expansion joints. This meant that the expansion connections would have to be effected while they were carrying their full design dead loadings. This loading amounted to approximately half the total design load with the remaining half consisting primarily of fly ash loadings.

The erection work was done in three separate stages. First, the column base plates were reinforced as this material was easy to obtain and required little fabrication. Second, all the remaining work except for cutting free the expansion connections was erected. That is, the bracing changes required to fix the lower support columns, the stiffening of the upper centerline support girders, the two horizontal trusses along the 36 Column Line, and the brackets to support the ball bearing assemblies. During this stage also, the ball bearing assemblies were jacked up under the support girders, and the hanger rod connections at column QQ36 were installed. The assemblies were positioned by jacking up the support brackets. The G4 girder connections required the hanger rods to be lowered down through the upper bracket into position. After the top and bottom bearing and rocker plates were in place, the upper nuts were then turned until a snug fit was obtained. The third and final stage included the actual burning free of the original bolted connections in a very careful manner. Less than a sixteenth of an inch drop was observed in the G4 girder elevation after the rods were completely loaded at this point. The entire cutting operation at all elevations was done in less than four weeks.

Operating Experience

All precipitator units have been operating successfully. The tie-in to the boilers being done in two stages. The two southerly units being connected first and then the northerly ones directly after. This was accomplished by taking out the south and north boilers alternately, thus reducing the rate of the unit during this period to 500 MW. The complete tie-in period was just less than six months.

Position readings of several exterior columns were taken before any precipitator units were energized. Readings were taken at the +42′ and +126′ elevations of each column measured. These "cold" readings were taken to obtain base measurements from which to determine the outward movements of the columns once in operation. "Hot" readings were taken last summer with all the units energized and showed that the north columns had moved a maximum of 1½″ to the north, and the east columns had moved a maximum of 1 11/16″ to the east. Both north and east maximum movements were recorded at the +126′−2″ elevation. Comparing this to the design movement of 2½″ it appears that the assumed steel temperature rises were ample. The fact that the +126′−2″ framing is actually expanding more than the +42′−8″ framing is not surprising. It was expected that the upper reaches of the building would be hotter by convection, and because the elevation +126′−2″ framing has an operating unit both above and below it. The lower elevation steel is more readily cooled by outside air being pulled through louvers at grade and across the basement floor by the forced draft fans in the boiler house.

A visit to the precipitator building with all units energized indicated that the building temperature rises gradually as you ascend with the upper areas being as much as 50° warmer than in the basement. The "hot spots" that were originally expected were found to exist, especially where little clearance was left between the precipitator units and the entrance flues on the east side of the building above the +126′−2″ elevation. Air temperatures as high as 220°F were recorded in such areas. Support steel temperatures were taken where access was possible and found to be as high as 240°F. It is felt that the 500°F design temperature probably exists in the middle regions of the support steel at the +126′−2″ elevation but only thermo couples could confirm this. A temperature differential of 115°F was recorded between the top and bottom flanges of the north G4 girder at column QQ36.

In all, the precipitator building at Ravenswood Station—Boiler 30 houses some very unique equipment which created special temperature problems to support it and to enclose it. Operating experience indicates that the designs undertaken to satisfy these conditions are working well.

PARTICULATE CONTROL ANALYSIS OF DEIS

The precipitators proposed in 1981 will upgrade the controlled particulate emissions to below 0.033 lb/million Btu.[5] This rate assumes that coal with a heating value of 12,200 Btu/lb and 12.5% ash will be burned, that 80% of the ash if fly ash, and electrostatic precipitators have a design efficiency of 99.75% will be employed. This rate is equivalent to that from burning 0.3% sulfur oil.

Particulate emission control with the original precipitator was adequate to meet plume opacity standards. After the precipitator is upgraded, plume opacity is expected to be below 10%, or less than half of the opacity standard. This is comparable to the opacity when burning 0.3% sulfur oil and is well within the State and City limit.

Con Edison's plan was to commence coal burning using the existing hotside electrostatic precipitator at Ravenswood Unit 3 and to increase the design collection efficiency from 99.0% to 99.75%. This will control the total particulate emission rate to less than 0.033 lb/million Btu, which is equivalent to that from 0.3% sulfur oil. The existing Ravenswood Unit 3 precipitator was tested at 99.2% to 99.6% efficiency when burning 1% sulfur coal. The upgraded precipitator design includes the following to insure that the high collection efficiency is maintained:

> The mechanical dust collectors will be replaced with an additional 310,000 sq ft. of electrical collecting surface area. This will result in a specific collection area (SCA) of 329 (hot side). Figure 12 indicates that this will provide a design collection efficiency of 99.75% while burning coal with a sulfur content of 0.6–1%.
>
> Electrical sections will be isolated so that failure of one section will not affect performance of other sections. As many as 7% of the electrical sections could be out of service without degrading precipitator efficiency below 99.6%.

Electrostatic Precipitation

Existing electrostatic precipitator performance may be improved by the use of wide plate spacing (replacing weighted wire discharge electrodes with rigid type), by using intermittent energization (i.e., blocking selected half-cycles of power to the transformer–rectifier sets powering the ESP) and by applying flue gas conditioning.[7] The importance of modeling ESP performance via 3 different types of computer models enables utilities to optimize their upgrade taking into account hot-to-cold side conversion, fuel switching and sizing for bidding and licensing purposes.[8]

The effects of sulfur and sodium on fly ash resistivity and performance have been discussed in the literature.[9,10]

Daub[11] discusses the effects of computer controlled energization of the tranformer–rectifier sets of a precipitator. Typical results in various European situations are presented in Table 1. Greico and Wedig[12] discuss the performance and economics of ESP's for removal of heavy metals in coal, oil, and orimulsion fired units.

Good design provides for a mass flow 12% above that anticipated, and for a 5% variation in flow distribution between the precipitator boxes.

For particulate control application at Ravenswood Unit 3, the reasons for choosing to upgrade the hotside precipitator included.

1) Only minimal modification work is required for upgrading the existing precipitator.
2) Electrostatic precipitators will meet performance criteria on either coal or oil firing.
3) The low pressure drop across the system eliminate the need for additional booster fans or ID fan modifications.
4) Electrostatic precipitators are a comparatively low maintenance system.
5) Electrostatic precipitators performance is not adversely affected by a rapidly changing gas flow or boiler load.
6) Performance of the precipitator is not affected by changing ash characteristics or coal sulfur content since ash resistivity is low due to high gas temperatures (Figure 12b, 13).
7) Power requirements are comparable to a bag-house filter.
8) Ash removal is more reliable due to the higher temperatures.
9) Air heater performance and maintenance is improve because of the cleaner flue gas.

Fabric Filters: Alternative to Proposed Precipitator

Fabric filters (baghouses) can be installed at Ravenswood Unit 3 if the existing precipitators are removed. They offer no advantage in collection efficiency and opacity over the proposed precipitation upgrading (Figures 14 and 15), but will increase the reconversion costs by about $90 million more than the proposed precipitator upgrading.

Fabric filters, as applied in the utility industry, operate by drawing dust-laden flue gas through a porous fabric bag woven of multifilament glass yarn. During operation, a fly-ash cake is formed over the cloth pores (with the glass filaments forming a

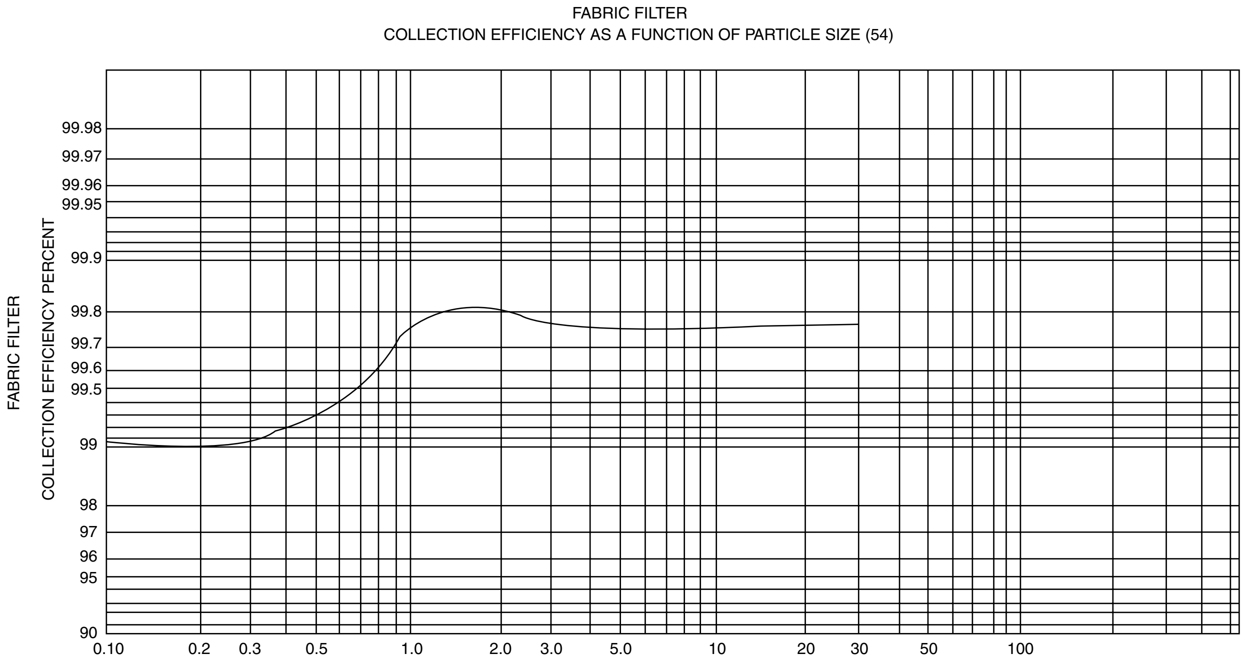

FIGURE 15 Fly ash particle size in microns, actual diameter.

substrate), with subsequent ash collection achieved by impaction of suspended particles on previously collected particles, as the gas flows through the cake. The collected dust cake is periodically dislodged into a bottom hopper by back flushing the fabric with clean flue gas or by shaking. This type of operation necessitates a multi-compartment approach with a typical installation consisting of 10 to 30 separately isolated compartments, each containing about 500 1 ft × 30 ft cylindrical bags.

The filtering medium (cloth) selected for use in a fabric filter must be compatible with the temperature and pH of the effluent. For coal-fired power plants, the present-day filtering medium for a fabric filter is glass fiber bags treated with either teflon or silicon-graphite for lubrication to avoid abrasion between the fabric fibers. The coated fiber fabric is resistant to the chemical attack of flue gas constituents and is capable of withstanding operating temperatures up to approximately 500°F. However, glass bags require precautions in handling and cleaning, due to their potential for self-abrasion. If a spray dryer is used for SO_2 removal, acrylic fiber bags are a less expensive alternative and are less vulnerable to self-abrasion. Their operating temperature limit is 280°F, which while above the typical operating temperature for gas leaving a spray dryer, is below the temperature of unscrubbed flue gas. Advances in filter media technology are continuing, with emphasis on increasing the thermal and chemical resistance of the bags and extending bag life.

As ash accumulates on the filtering media, the pressure loss across the fabric filter increases. In general bags are cleaned automatically upon reaching a specific pressure drop across the fabric filter or by a timing cycle. The compartmentalization of fabric filters on coal-fired boilers allows for one compartment to be isolated for cleaning while the remaining compartments treat the flue gas. To date, the cleaning of fabric filters on coal-fired boilers has generally been accomplished by reversing gas flow against the bag surface, by shaking the bags, or by a combination of the two approaches. The fly ash is then released from the bags and falls into a hopper for removal.

Prior to mid-1978, eight coal fired electric utility stations were equipped with fabric filters. The best documented of this group include Sunbury Units 1 & 2 for Pennsylvania Power and Light and Nucla Units 1, 2 and 3 for Colorado UTE. For the most part, these units were small (less than 50 MW) stoker-fired units with high air heater exit temperatures, (350°F), and fired with low sulfur coal.

EPA assessed the data from these units in mid-1978 and concluded that this technology was capable of reducing outlet emissions to less than 0.03 lb per million Btu (99.8% efficiency). This analysis formed the basis in a large part for the new NSPS for electric utilities of June, 1979.

An additional 1000–1500 MW of fabric filter capacity came on line during the 1978–1979 period and approximately 4000 MW of capacity has been installed in the 1980–1983 period, including numerous large units in the 350–750 MW size class. The fabric filter commitments are generally for use on western coals that have proven very difficult to control by standard electrostatic precipitator technology. This is because filter performance is not sensitive to fly ash composition. Another factor, which contributes to the rapid growth of fabric filter applications in the West, is that filters tend to achieve a lower stack opacity than comparable ESPs operating on western coal. Plume opacity and atmospheric visibility have historically been of much greater concern in the Western states.

The fabric filter has the following advantages for Ravenswood Unit 3:

1) Gas distribution is not as critical as in the precipitator.
2) The fabric filter can be compartmentalized to allow for maintenance while the fabric filter is onstream. This design allows for high availability to the power boiler.

The fabric filter has the following disadvantages for Ravenswood Unit 3:

1) Replacement of the existing precipitator with a baghouse will cost $120 million (1991) but will not improve the collection efficiency of the particular control system beyond that resulting from the proposed precipitator upgrading.
2) Fuel switching may cause permanent fabric blinding because of the sticky characteristics of oil ash.
3) New induced draft fans will be required because of a higher system pressure drop.
4) The furnaces were not designed for baghouses; therefore, the pressure drops that occur during a malfunction of the forced draft fans may exceed design limits.
5) Relatively limited field experience is available on fabric filter use on large units burning eastern coal.
6) Higher maintenance will be required than for electrostatic precipitators.
7) The maximum fabric filter operating temperature is approximately 500°F; therefore, complicated duct work would be required in order to install the baghouse downstream of the air preheater, which would require more plant site area.

ENERGY SOURCES—ALTERNATIVES

INTRODUCTION

Abundant and dependable sources of energy are vital to the social and economic welfare of an industrial nation. Energy resources, including fossil and nuclear fuels as well as solar, water, tidal, and geothermal energy, may be captured or recovered and converted into other energy forms for a variety of household, commercial, transportation, and industrial applications that enrich the human environment. The economic benefits of energy utilization are generally described by the relationship between the per capita GNP of a nation and its per capita energy use shown in Figure 1, which is based on United Nations data.[1] On the other hand, economic indicators such as GNP are not the sole measure of the quality-of-life and use of energy, particularly in the energy conversion step where resources are consumed to produce power, have been identified as major contributors to air and water pollution and to the despoilment of land; environmental factors that threaten the integrity of the biosphere and possibly endanger the life support system on earth.

Energy sources have effects on the environment that occur both naturally and as a result of man's efforts to exploit them. Natural effects range from the life sustaining action of solar radiation to the destructive manifestations of geothermal energy, volcanic eruption, which cause extensive damage and spew particulate matter and gases into the atmosphere at a rate rivaled by conventional man-made processes. These and other natural phenomena have not been controlled and should not be considered further because it can be presumed that these natural effects are now widely surpassed by human faults and advanced technologies which not yet consider in the due extent secondary environmental effects. These environmental effects encountered in the harnessing of various energy sources depend on the forms of energy in demand and on the resources and systems that are utilized to satisfy that demand. The impacts of this activity are controllable to varying degrees by the use of alternate fuels or resources, and by the proper design and application of the systems that are used to supply and utilize energy. Figure 2 is a simplified flowsheet indicating all of the activities required to deliver a useful form of energy to the consumer. In mining and drilling to recover energy resources, the environmental problems encountered include the despoilment of land, safety of the workers involved, and water pollution. The strip mining of coal and uranium is especially damaging to land areas, and underground coal mining is notoriously hazardous. Acid mine drainage is a significant source of pollution of streams and waterways, and oil drilling in offshore areas carries the possibility of uncontrolled discharges of crude oil that are damaging to the marine environment. Each fuel or resource has unique potential for environmental damage in its shipment and storage and in refining and treatment operations where waste materials are generated and must be disposed of. The major fraction of emissions and wastes, however, are generated in the energy conversion processes. A distinction is made in this step between centralized energy conversion, where fuels and other resources are consumed and converted to other energy forms, usually electrical, for distribution and utilization, and a decentralized operation, where fuels are distributed to the location of the ultimate utilization of energy. Although the centralized conversion system generally has economies of scale which may facilitate an increased investment in environmental protection systems, the concentrated nature of the activity aggravates emission and waste disposal problems. In certain cases, such as in the disposal of waste heat, dilution of emissions or discharges may be a valid control technique and is feasible with numerous distributed sources while it may not be as practical with large concentrated sources.

The release of wastes and pollutants from energy activities is at a level where significant external costs are being sustained in terms of hazards to health and damage to materials and property. From the economic viewpoint, these wastes and pollutants are residuals which have heretofore been disposed of to the environment by the producing activity with little or no economic penalty. The social and other external costs attributable to these residuals were external to the producing activity and did not affect decisions regarding the utilization and allocation of resources in that activity. Ayres and Kneese[2] have proposed a mathematical framework for tracing the flow of residuals and charging the external costs attributable to them to the producing activity. The materials flow diagram that they have developed is shown in Figure 3 and addresses the energy conversion operation in relation to industrial activity in the production of goods. The inputs are energy resources and other raw materials which are converted by this industrial activity into final goods and residuals. The residuals, or waste products, identified with the energy conversion operation include carbon dioxide, carbon monoxide, sulfur dioxide, oxides of nitrogen, fly ash, slag, radioactive materials, and waste energy in the form of thermal energy and noise. Control of these residuals may be

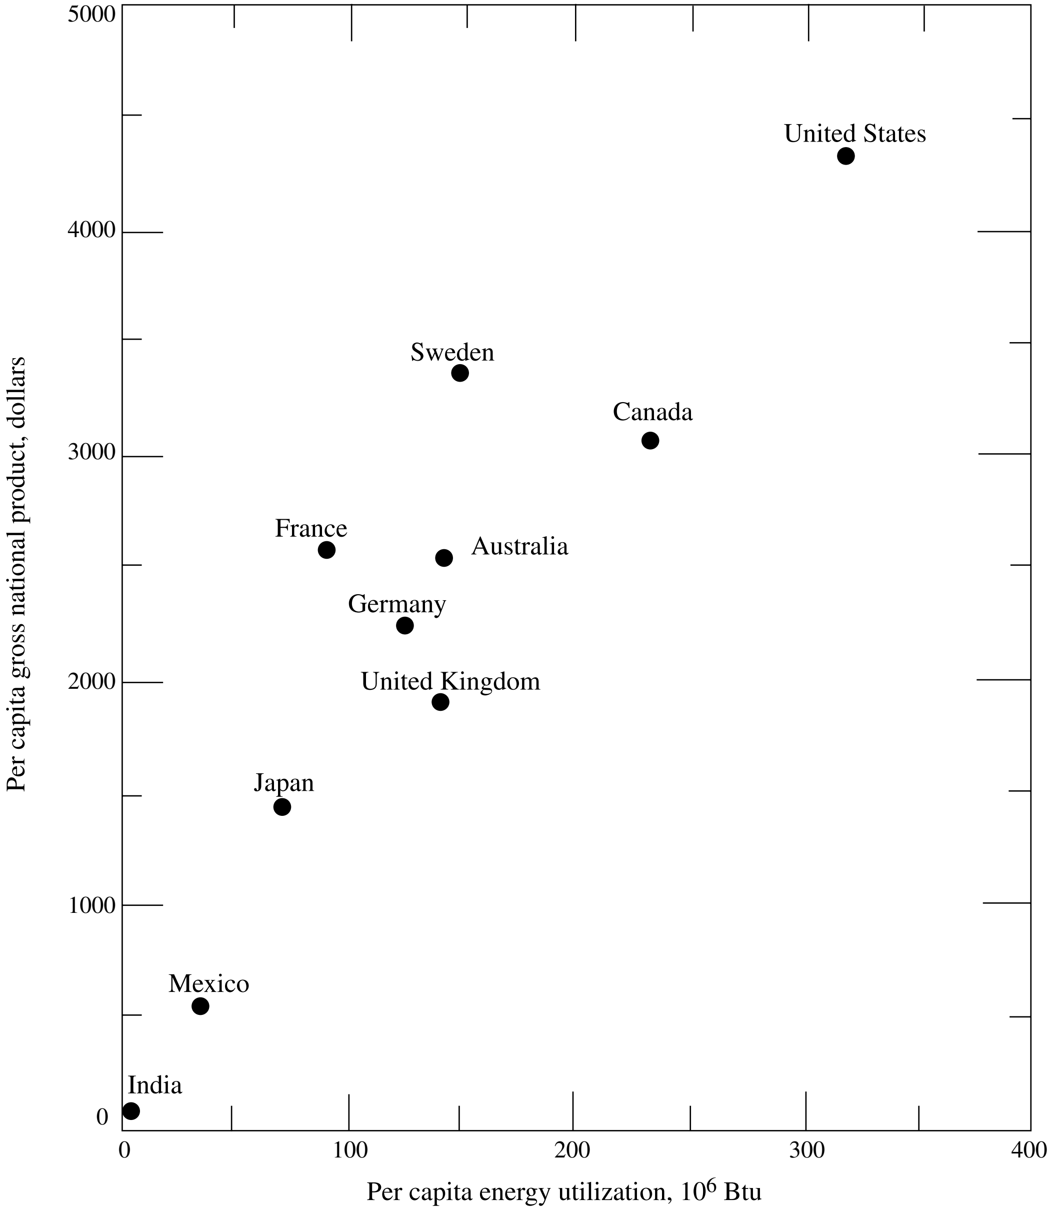

FIGURE 1 Relationship between per capita GNP and energy utilization for selected countries in 1968.[1,3]

stimulated by economic measures such as taxation, that lead to the internalization of all of the costs imposed on society by their discharge, or by regulatory action. Regardless of how controls are stimulated, however, the quality and form of residuals and the cost of their control will depend ultimately on the technological alternatives that are available. Because of the complexity of both the energy system and its impacts on the environment, it has been useful and will be of more and more importance for the humanity to view the subject from four reference points: *ENERGY DEMAND, ENVIRONMENTAL FACTORS, ENERGY RESOURCES,* and *ENERGY CONVERSION.* Consideration of the existing and projected patterns of *ENERGY DEMAND,* and a review of all of the *ENVIRONMENTAL FACTORS* involved in satisfying this demand, will serve to define the extent of the conflict between energy and the environment as well as to indicate trends that can aggravate or help to resolve the problem. Measures that can be taken to insure an adequate supply of energy with minimum environmental damage are centered on the availability of alternative *ENERGY RESOURCES* and on *ENERGY CONVERSION* systems which help to protect the environment or to harm it less by advanced or new conversion technologies. In the short term, fuels may be treated, modified, or substituted, and emission controls can be provided in fuel handling and in energy conversion operations, while in the longer term the development of new resources and an advanced conversion system may also be dictated. Both near- and long-term measures must be discussed to illustrate the range of selection available among alternatives. Considering the conventional energy sources, the increasing environmental problems and all energy sources alternatives, there can be predicted five essential developments:

1) the conventional energy sources will build also in the future the hard core of energy activities, substituting nevertheless as much as possible petroleum by other energies to strengthen the availability of petroleum into a longer future
2) the new energy sources—alternatives as weak energies will substitute partly the short-term demand on conventional energy sources and take over in the long-term future an increasing but not substantial portion of the total energy demand
3) the transportation and traffic systems of the world, which make a major contribution to environmental degradation, will be converted to new, or alternative energy sources, thus fundamentally changing their nature
4) the protection of environment necessitates for both, the conventional and the new energy technologies, high investment costs which will increase the cost of final energy for the consumer
5) to find out the best combination of conventional energies and energy sources—alternatives of old and new energy technologies and necessities as well as economic possibilities to protect the environment, the countries—and it can be only a national way of solution—must elaborate a long-term planning system like masterplan or energy strategies with computerized instrumentation, a typical task for the national energy commissions.

The energy strategies must not be understood as a kind of legislation, but they will give all industry connected with energy production, conversion and application the best path into the future.

ENERGY DEMAND

Energy is utilized in various forms by the demand sectors of the economy. Household and commercial consumers require thermal energy for comfort and for the preparation of food, and electrical energy for lighting and for the operation of electronic and motor-driven appliances that provide entertainment, communication, and labor-saving functions. Energy in mechanical form is needed for both public and private transportation. Industry has similar needs with added requirements involving thermal and chemical energy for materials processing, refining, and the manufacture of synthetic materials and consumer goods. The use of specific energy resources to satisfy these demands depends on their relative economics and convenience as well as on the systems that are available for conversion into the form of energy that is ultimately required.

In principle, especially in the northern countries, the heat demand is much higher than the demand on mechanical force. The demand on public and private light varies between one and fifteen percent. Highly industrialized and densely populated countries are the biggest consumer of light. The energies heat, mechanical force and light are called effective, final or util energies. While in the sixties still all of the energy demand in the United States was satisfied by consumption of the fossil fuel resources; coal, oil, and natural gas, the parts of the individual primary energy agents in the meantime have changed. Small amounts of power were supplied by hydroelectric and nuclear power plants and even less by solar, geothermal, tidal, and other energy resources. On the other hand the part of nuclear energy was increased.

Table 1 shows the direct consumption of energy resources by demand sector in the United States for the year 1968 with a projection to the year 2000. The consumption of energy resources in the production of electricity represents a centralized conversion, and the ultimate disposition of electrical energy to the various demand sectors is given in Table 2, again for the year 1968, with a projection to the year 2000. Since the data presented represent resource consumption, they imply an efficiency of energy conversion and utilization. Comparing the fuel consumption and electrical output of utilities in 1968, an average efficiency of about 32% is indicated. Fuels burned for thermal energy in decentralized household, commercial, and industrial applications

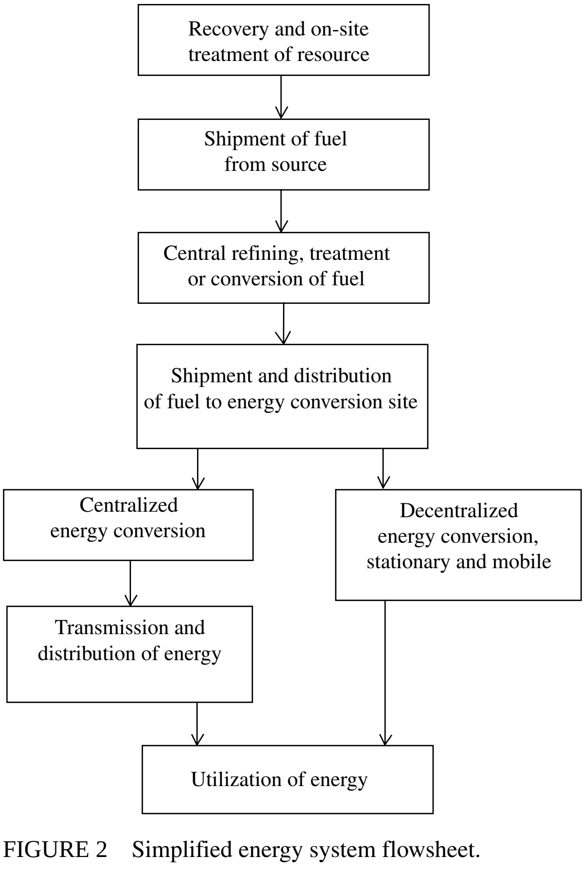

FIGURE 2 Simplified energy system flowsheet.

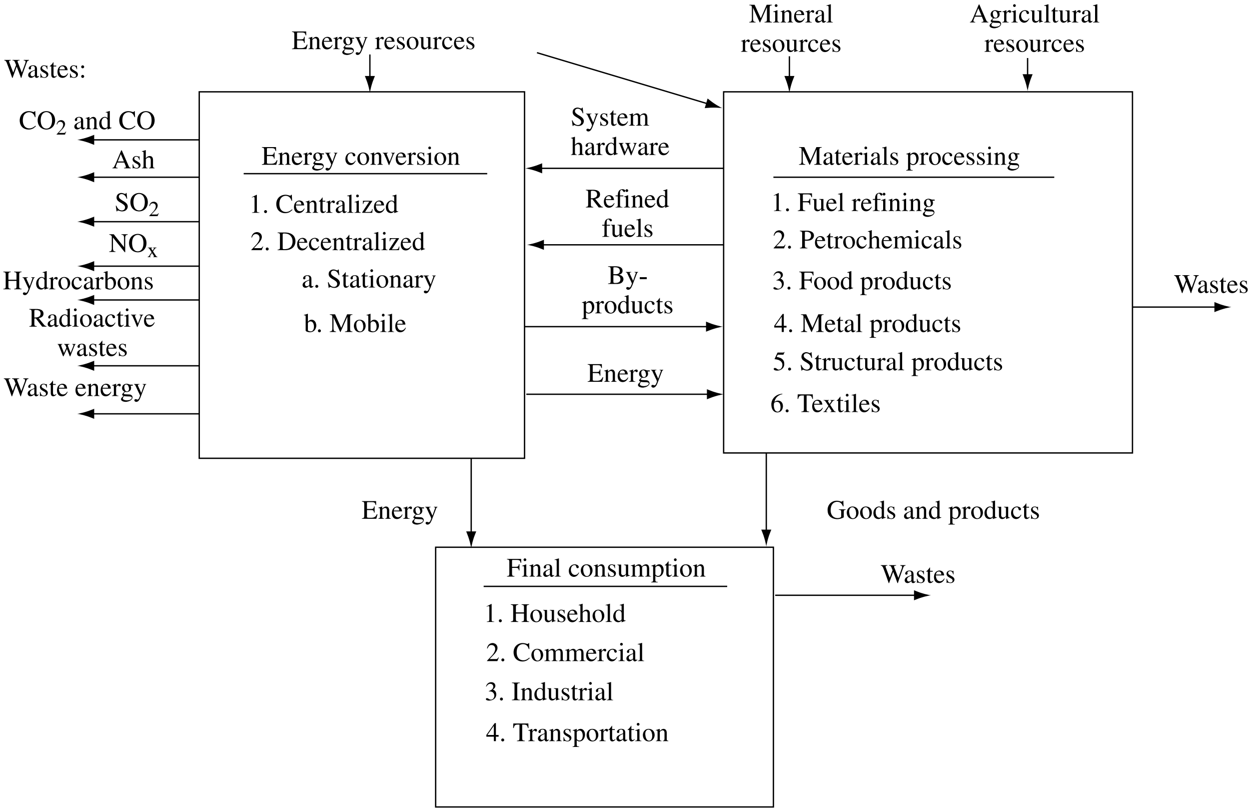

FIGURE 3 Materials flow diagram in economic activity.[2]

are used at efficiencies of 60% to 75%, while fuels used for transportation are converted first to thermal and then to mechanical energy at an average over-all efficiency of about 25%. The source of the 1968 data is the Minerals Yearbook[3] while the projections are those of Morrison and Readling,[4] who developed a loglinear relationship between the major subcomponents of energy demand and several independent variables that are assumed to influence demand, such as; population, economic indicators, and technological developments. Coefficients of the independent variables were to be obtained by regression analysis using data for the period 1947 to 1965.

The year 2000 projection of a total energy resource demand of 168.6×10^{15} Btu is a medium range case, and assumes a normal rate of improvement in energy conversion efficiency and the continuation of present trends of competition and substitution in energy markets. Other projections were made by Morrison and Readling on the basis of different assumptions, including high- and low-range cases that reflect changes in energy demand patterns and technological developments anticipated in energy conversion systems. The high-range case forecasts a demand of 209.4×10^{15} Btu in the year 2000 and assumes the establishment of an all-electric economy, where electricity is generated in fossil, hydroelectric, and nuclear power plants at an average efficiency of 43% and is consumed in household, commercial, and industrial sectors at 10% efficiency and in transportation, with battery-driven vehicles, at an efficiency of 42%. The low-range forecast is 106.5×10^{15} Btu and assumes that energy inputs to the household, commercial, and industrial sectors are satisfied with electricity from fuel cells operating at an efficiency of 75% with 50% recovery of waste heat, and energy requirements in the transportation sector are also provided by fuel cells but at an efficiency of 50%. This again, is an all-electric economy but no central station power generation is needed under these circumstances. Natural gas was the fuel considered for all sectors in the low-range case, however, alternative fuels suitable for fuel cells could also be provided by hydrogen or methane produced by the gasification of coal, or by hydrogen made by the electrolysis of water. Of course such forecasts are highly speculative since it is not certain that fuel cells will be economical in such application in the next 30 years. Numerous other forecasts of energy demand have been made and are summarized in a review[5] performed by Batelle-Northwest for the Energy Policy staff of the Office of Science and Technology (OST). All of these forecasts neglected supply restraints and thus do not reflect the effect of possible energy cost variations due to shortages of resources, increased requirements for environmental protection, and technological developments. None indicate any significant exploitation of solar, geothermal or tidal energy resources.

TABLE 1
Total US energy consumption by fuel and consuming sector
(trillions of Btu's in direct fuels used)

		1968[3] (actual)	2000[4] (projected)
Household and commercial:			
Gas		6,451	19,066
Petroleum		6,581	2,000
Coal		568	
	Total	13,600	21,066
Industrial:			
Gas		9,258	17,504
Petroleum		4,474	13,090
Coal		5,616	2,000
	Total	19,348	32,594
Transportation:			
Gas		610	1,000
Petroleum		14,513	41,649
Coal		12	—
	Total	15,135	42,649
Electric utilities:			
Gas		3,245	4,128
Petroleum		1,181	861
Coal		7,130	18,720
Hydro (coal equiv.)		2,359	5,056
Nuclear		130	43,526
	Total	14,045	72,291
Miscellaneous:			
Gas		—	—
Petroleum		295	—
Coal		1	—
	Total	296	—
Total Consumption		62,424	168,600

TABLE 2
Utility electricity distribution by consumer sector
(trillions of Btu's in electrical form)

		1968[3]	2000[4]
Household and commercial		2,469	20,045
Industrial		2,043	10,793
Transportation		18	100
	Total	4,530	30,938

The forecast methodology with its multiple "demand scenarios" has led to the development of computerized demand models with more or less comfort on the input side. Such models are useful for the analysis of different "scenarios" and consequences for the energy application. The uncertainty of some factors of the consumer market recommends to limit the comfort of full particulars of demand models.

The medium-range forecast for the year 2000, summarized in Table 1 indicates a shift in energy demand to electricity generated in centralized plants with its share of direct resource usage increasing from about 22% in 1968 to 43% in 2000. This shift is apparent in current trends with the demand for total energy growing at about 4% per year while the demand for electricity is growing at around 7% per year not considering the question of future acceptance. Nuclear power is projected to account for over half of the electrical generation in 2000. Such changes in energy demand patterns are seen to have profound effects on the amount of resources consumed and, consequently, on environmental effects. For example, in the case of space heating which constitutes a growing market for electrical energy, fossil resources may be used directly for their thermal effect at an average efficiency about twice that involved in the conversion to electricity in central station power plants. This results in a doubling of the amount of fossil fuel that must be burned to provide a given amount of space heat to the consumer. Although this substitution would be expected to result in the production of more wastes and emissions, it may be justifiable on the basis of the economies of scale that are at work in the centralized operation, which permit better control of emissions, and the opportunity it provides to utilize the more abundant nuclear fuels which cannot be applied economically in small decentralized conversion systems.

In a different example, for space heating and probably also some demand of process heating thermal power plants (coal, lignite, and nuclear) could be used by the double purpose electricity generating and district heating system, that would increase substantially the efficiency of such power plants, involving however the high investment costs for the take-out of heat in the power plants and the long distance tube circulating system to the main demand centers.

The demand indicated in Table 1 for petroleum in 1968 in the various sectors requires more detailed attention since this energy resource is consumed in a variety of product forms. The total demand for petroleum products was 4.9×10^9 barrels and Table 3 shows how this total breaks down among the various products. The end use of most of these is self-evident and it may be seen that less than 2% of the product was consumed as petrochemical feedstock. Diesel fuel for mobile and stationary power plants is included along with the lighter fuel oils in the distillate fuel oil category. Naphtha-type jet fuel is generally used in military aircraft while the kerosine-type fuel is used in civil aircraft.

The non-energy demand for natural gas as petrochemical feedstock and in the production of carbon black for the rubber industry accounted for about 2½% of the total demand for that resource. In the case of coal, about half of the resources used in the industrial sector were consumed as coke, carbonized from coal. About 1% of the total coal demand is consumed as industrial raw materials for the production of crude light oil and coal tars. There is much concern over the depletion of petroleum and natural gas for energy purposes when the demand for these materials, as organic molecular building blocks in the petrochemical industry, is growing rapidly and will expand further as natural mineral resources are depleted and must be replaced in their markets

TABLE 3
Domestic demand for crude oil products, 1968[3] (millions of barrels)

Gasoline—motor gasoline	1925
aviation gasoline	30

Liquefied gases for fuel and chemicals	386
Petrochemical feedstock	93
Miscellaneous	17
Total domestic product demand	4900

with synthetic materials. This dilemma suggests, for the long term, the implementation of an all-electric economy based on power plants consuming the more abundant nuclear fuels and thereby conserving fossil fuel reserves.

A more detailed breakdown of energy utilization for specific applications within the household, commercial, industrial, and transportation sectors is presented by Schurr.[6]

ENVIRONMENTAL FACTORS

All of the activities involved in supplying energy to the various demand sectors have some impact on the environment. The benefits to the human environment obtained in the utilization of energy have a social and economic basis. These benefits must be acknowledged and are also discussed in some detail by Schurr.[6] Other environmental factors involved in energy related activities may be measured in terms of land use, employment and working conditions in energy industries, air and water pollution, radiation hazards, solid wastes, and noise. These environmental factors are attributable to either the characteristics of the energy resource utilized, or to the technology used in the particular activity that is the causative agent.

Land Use

Physical space is required for all energy-related activities, with mining, electric power production, and electric power transmission being the largest users. The strip mining of coal is especially damaging to the landscape and represents an increasing method of recovery of coal, with about 34% of the coal produced in 1968 mined by this technique. In 1965 about 1.3×10^6 acres were involved in strip mining and the reclamation of this land was estimated to cost an average of \$230/acre for complete restoration and \$149/acre for partial restoration.[7] Strip mining areas are under study as possible solid waste disposal sites to serve urban areas that are nearby, where the cost of transporting the wastes is not excessive. Uranium mining poses potential problems similar to those of coal mining but on a reduced scale. The effects of oil and gas drilling, barring accidental discharges, are less severe.

Fuel shipments by rail and truck consume space with attendant noise, hazards, and general inconvenience. In 1968 there were 209,478 miles of petroleum pipeline and 861,000 miles of natural gas pipeline in service, including distribution lines.

The electric utilities require substantial areas of land for power generation and transmission. About 400 acres of land are required for a 3000 MW(t) nuclear power plant and 1200 acres are needed for a coal-fired plant of the same size, including space for on-site coal and ash storage. These sites are usually preferred near a source of cooling water, such as a river, lake, or other body of water. There are also over 300,000 miles of high-voltage overhead electric transmission lines in service with an average right-of-way width of 110 feet, for a total land requirement of over 4 million acres. This latter figure does not include local distribution lines although there is a growing tendency to put these, as well as high voltage transmission lines, underground. There is about 2400 miles of underground transmission line in use in the 69 to 345 kV range. Electrical energy cannot be conveniently stored in large quantities and some utilities use pumped storage facilities to satisfy peak electrical demands. Elevated water reservoirs are required at pumped storage sites and, like hydroelectric power plants, they are usually located in mountainous areas where there are natural sources of water. The electric utilities are facing severe problems in the siting of new facilities. Recognizing these difficulties and the growing demand for electric power, the Energy Policy staff of the OST has recommended[8] more long-range integrated planning by utilities, participation in this planning by environmental agencies, and notice to the public of new plant sites at least five years in advance of construction. In addition to calling for an expanded research and development program on pollution controls and improved generation techniques, the report asks for more attention to underground power transmission and advanced siting approaches such as offshore locations and underground nuclear installations. The availability of a transmission grid that could move very large blocks of power over some distance would relieve some siting constraints and could also improve service reliability.

In spite of numerous studies and analyses of locations and transmission systems, the above described experiments, tendencies, and intentions differ from the actual energy reality. The high tension up to 1100 kV (a.c.) serves less for the integration of long distance nuclear power plant capacities but formation of strong and dependable grids of interconnection which partly already pass over the border of neighborhood countries. Such transmission lines are planned mainly for the safety of supply of electricity in big areas of demand and for the compensation of peak loads respectively for the support of transmission systems when power plants and transmission lines drop out of operation. Regarding the field of production, the energy reality leads to realize the inclination to build the thermal power plants, that means in the future mainly the nuclear power plants, in case this technology

TABLE 4
Employment and safety record in selected energy industries

Industry	No. of employees, 1969 (thousands)	No. of injuries, 1968		Injury rate per 10^6 man-hours, 1968

remains or will be again accepted by political authorities and population, proceed nearer to the demand centers. This could be of double advantage, should the district heating technology be extended, what is recommendable. Whatever kind of energy source may be used, and in this connection the energy sources—alternatives are not excluded, the psychological distance to the energy in general will be shorter at the end of this century, and this fact may contribute to resolve some technical and economic problems, and regarding heat it could be advantageous to reduce urban air pollution.

Employment and Safety

The direct employment of labor in the various energy industries is a small fraction of the total labor force, however, such statistics do not reflect the vital need for energy in manufacturing and industrial processes and to provide comfort, light, and labor-saving functions in all working activities. The employment of labor in some energy industries is listed in Table 4 along with the injury rate in each industry. Additional data on the fatal injury rate and the number of injuries, both fatal and nonfatal, are given for mining activities. Statistics on injuries in federal government service, excluding military personnel, are also given for comparison purposes. It is apparent that the underground coal mining activity has the poorest safety record of the energy industries listed, the most significant problems involving collapse of mine tunnels and explosions due to the methane released from the coal bed during mining operations. Research and development is in progress in the coal mine safety area, including the study of methods of stabilizing mine tunnels as the coal is extracted and other methods of protecting the workers in the event of a fire or mine failure. An example of one novel scheme to guard against fire in high-methane mines is the provision of an oxygen-free atmosphere in the mine with the workers using portable breathing apparatus.[9]

Air Pollutants

A survey[10] performed by the National Air Pollution Control Administration (NAPCA) of the emission of air pollutants in the United States for the year 1968 identifies energy conversion operations in stationary and mobile power plants as the major source of carbon monoxide, particulates sulfur dioxide, hydrocarbons, and oxides of nitrogen. The total emissions of these pollutants are indicated by source in Table 5. The Office of Air Programs in the Environmental Protection Agency (EPA), formerly the NAPCA, has also published a compilation of air pollutant emission factors[11] which give the average quantity of pollutants released in the operation of various fuel-energy conversion system combinations. The emissions are given for uncontrolled sources unless otherwise noted. Control measures that may be used to reduce these emission factors involve treatment of fuels, modification of the energy conversion system, or treatment of effluents depending upon the particular case.

Carbon Monoxide

This poisonous gas is produced by the incomplete combustion of carbon in fuels. When combustion conditions are well controlled and excess air can be provided, combustion is generally complete and CO_2 is produced with only trace amounts of CO. In mobile power plants, such as internal-combustion engines which account for almost two-thirds of the total emissions of this pollutant, operating conditions are quite variable and CO may be in equilibrium in high concentrations with other combustion products at the high temperatures involved. These hot gases are cooled rapidly and there is not sufficient time to convert the CO to CO_2 before they are expelled from the cylinder.

Emission factors for CO from uncontrolled sources at average operating conditions are given in Table 6. Control of these emissions is accomplished, when possible, by proper

TABLE 5
Estimated nationwide emissions, 1968[10] (in millions of tons per year)

Source	Carbon monoxide	Particulates	Sulfur oxides	Hydrocarbons	Nitrogen oxides	Total

design of the combustion chamber to prevent regions of insufficient air and by providing residence time and temperature conditions that will allow conversion of all of the CO to CO_2. In cases where combustion conditions cannot be adequately controlled to permit complete conversion, the exhaust gases may be reacted with air either thermally or catalytically to complete the reaction to CO_2.

Particulates[12, 13]

This category of pollutants includes any matter, solid or liquid, in which individual particles are larger than molecular size but smaller than 500 microns. The burning of coal in central station power plants accounts for about 64% of all particulate emissions even with the widespread use of electrostatic precipitators with efficiencies of up to 99.5%. This particulate release is mostly in the form of fly ash, which is predominantly carbon, silica, alumina, and iron oxide, and when recovered from stack gases, poses a solid waste disposal problem. Markets for fly ash involve construction uses and are growing. Oil has a lower ash content than coal but is also a source of particulate emissions. The particulate emissions from mobile power plants include lead compounds, carbon, and metallic oxides. Lead alkyl additives used in gasoline to raise its octane number are present in concentrations of 2 to 4 g/gal and this lead content is ultimately discharged to the environment. The automotive and petroleum industries are moving toward reduction or elimination of these additives.

Emission factors for particulates from uncontrolled sources are given in Table 7. The emissions from the combustion of coal are given as a function of the per cent ash content, which depends on the grade of coal but averages about 10%. Wet bottom and cyclone-type burners capture more ash in the furnace in the form of bottom ash, which is a solid waste, and thereby reduce the fly ash particulate matter released with the flue gas. Control of particulate emissions from power plants is provided by cyclone separation, filtering of the flue gases, and electrostatic precipitation, and these techniques are used extensively.

Particulate matter in the atmosphere has adverse effects on materials and health and will have long-term effects on the thermal energy balance of the earth. It provides condensation nuclei which can increase cloud cover and thereby reflect more of the solar energy input to the earth back into space. It has been estimated[14] that a 1% increase in the earth's cloud cover can reduce the average temperature of the earth by 1.4°F and an increase of 5% could lead to the return of an ice age. Volcanic eruptions are believed to account for most of the particulate contamination of the upper atmosphere and in the past have been a source of meteorological changes. Jet aircraft exhausts add water vapor and particulates to the upper atmosphere and can also contribute to meteorological effects.

TABLE 6
Carbon monoxide emission factors[11]

	Average emissions per unit of fuel burned
Stationary Sources	
Coal:	
Household and commercial	10 lb/ton
Industry	2 lb/ton
Utility	1 lb/ton
Fuel oil:	
Household	5 lb/1000 gal
Commercial and industrial	0.2 lb/1000 gal
Utility	0.04 lb/1000 gal
Natural gas:	
Household and commercial	20 lb/million ft^3
Utility and industrial	0.4 lb/million ft^3
Mobile Sources	
Gasoline-powered vehicle urban 1970	2620 lb/1000 gal
Diesel-powered bus and truck	225 lb/1000 gal
Aircraft, long range turbofan	26 lb/engine-flight[a]
Jumbo jet	28 lb/engine-flight[a]

[a] Emissions during portion of flight at altitudes less than 3500 ft, including takeoff and landing.

Sulfur Dioxides[15,16]

SO_2 is produced in the combustion of sulfur-bearing fuels such as coal and residual oil and is released to the atmosphere in the flue gases from power plants using these fuels. Approximately 60% of the SO_2 released to the atmosphere in 1968 was produced in the burning of coal while the combustion of oil accounted for another 14%.

TABLE 7
Particulate emission factors[11]

	Average emissions per unit of fuel burned
General	16 A[a] lb/ton
Dry bottom	17 A lb/ton
Wet bottom	13 A lb/ton
Cyclone	2 A lb/ton
Spreader stoker	
Greater than 10×10^6 btu/hr	13 A lb/ton
Less than 10×10^6 btu/hr	2 A lb/ton
Hand-fired equipment	20 lb/ton

Diesel-powered bus and truck	27 lb/1000 gal
Aircraft, long range turbofan and jumbo jet	2 lb/engine-flight[c]

[a] S indicates % sulfur in fuel.

[b] This factor is for residual oil. For distillate oil use factor of 142 S.

[c] Emission during portion of flight at altitudes less than 3500 ft, including takeoff and landing.

This ratio may still change for the worse, since:

1) the combustion of oil will decrease, especially in power plants;
2) the burning of coal will increase until nuclear energy can substantially replace the coal in new power plants—supposed nuclear power plants will be accepted by population also in the larger future.

Therefore new coal burning power plants will be equipped with desulfurization equipment that may eliminate in increasing measure the emission of sulfur dioxide.

Emission factors are given for various uncontrolled sources in Table 8 as a function of the per cent sulfur content of the fuel. The average sulfur content of coal is about 2.5% by weight while that of crude oil is closer to 0.3%, but these levels can vary considerably depending on the source. In petroleum refining, the sulfur generally remains in the heavier fractions and reaches much higher concentrations in residual fuel oil, for example. Sulfur dioxide emissions may be controlled by fuel selection using either low sulfur fuels or by removing the sulfur from the fuel before burning it. At the beginning of the seventies other techniques have been proposed and developed to capture sulfur compounds during combustion or to remove them from the flue gas before it is discharged to the atmosphere. Flue gas scrubbing processes developed, under test and further improvement include the use of MgO, alkalyzed alumina, or limestone to neutralize oxides of sulfur, forming precipitates of sulfites and sulfates that can be collected as solids. A catalytic oxidation process, based on the technology of sulfuric acid production, that captures sulfur emissions as SO_3 in a weak acid solution is also quite promising.

Oxides of Nitrogen,[17] Hydrocarbons,[18] and Photochemical oxidants[19]

NO_x and reactive organic substances such as hydrocarbons (HC), when exposed in the atmosphere to solar ultraviolet radiation, form photochemical smog consisting of aldehydes and a group of oxidants including ozone and peroxyacyl nitrates.

Oxides of nitrogen are produced in all combustion processes that use air as the oxidant at a rate that is dependent on both the flame temperature and air supply. Nitric oxide (NO) is formed at high combustion temperatures and normally would convert to the more stable nitrogen dioxide (NO_2) as the gas temperature is reduced. The kinetics of that reaction are slow, however, and the gases cool to near ambient conditions before very much NO_2 can be formed. In the combustion of methane, the peak equilibrium NO_x emission concentration is developed with about 15% excess air while the peak flame temperature occurs at a slightly deficient air fuel ratio.

With different fuels the NO_x emissions will vary, depending on the theoretical flame temperatures and the combustion process used. Table 9 gives average uncontrolled emission factors for NO_x. These emissions may be reduced, but not eliminated, by the adjustment of the air supply to a fuel-rich condition and operation at as low a combustion temperature as possible by means of two stage combustion, exhaust gas recirculation, or water injection. Some of the flue gas scrubbing techniques proposed to control SO_2 emissions in power plants may also be effective for the removal of NO_x from the gas stream.

The main sources of hydrocarbon emissions are evaporation of fuel from vehicles and in fuel handling operations,

and unburnt fuel in vehicular exhausts. Emission factors for various sources of hydrocarbons are given in Table 10. Blowby of gasoline vapors from the cylinder into the crankcase was a large automotive emission source but has been largely brought under control by positive crankcase ventilation techniques that recycle these vapors back to the combustion chamber. Control of other sources may be provided by better fuel handling techniques, improved combustor design, treatment of exhaust gases and reduction of fuel volatility. The treatment of automotive exhaust gases involves control of both CO and hydrocarbon emissions using thermal oxidation in the 1600°F to 1800°F temperature range, or catalytic oxidation with transition metal oxide materials. These catalysts are generally poisoned by lead additives and offer extra incentive to eliminate lead additives in fuels.

Carbon Dioxide

This gas is inevitably produced in the complete combustion of carbon-bearing fuels. It is not normally thought of as a pollutant, however, there is some concern over its long-term effect on the thermal equilibrium of the earth because of the so-called "greenhouse effect." Carbon dioxide is a strong absorber in the long wavelength infrared region of the electromagnetic spectrum, a region where much of the energy that the earth loses by radiation to space is concentrated. The CO_2 absorbs this energy, reradiating it in turn to space at a lower source temperature. This mechanism effectively reduces the heat loss from the earth and causes its temperature to increase.

Bolin[20] has reviewed the carbon cycle mechanisms that are at work in the biosphere. The current annual release to the atmosphere of carbon, as CO_2, attributable to fossil fuel combustion is about 5×10^9 tons while a total of some 200×10^9 tons have been released to the atmosphere by combustion processes during the past century. During this same time period the average concentration of CO_2 in the atmosphere has increased from 290 to 320 ppm, a change that accounts for only about ⅓ of the total CO_2 emissions. Apparently, removal processes are effective and include photosynthesis, solution in ocean waters, and deposition in carbonate sediments. One analysis[14] indicates that an increase in atmospheric CO_2 concentration to 400 ppm, which will be attained in 1990 if fossil fuel consumption increases at an annual rate of 5% and if 60% of the CO_2 emissions remain in the atmosphere, would increase the temperature of the earth by 1.4°F. The growth of vegetation is stimulated by high CO_2 levels but, of course, carbon fixed in organic compounds by photosynthesis is ultimately released again either by combustion or natural decay processes. Also, to be considered are the increase of world population and the energy consumption per capita connected with a considerable decrease of surface available for natural vegetation.

Water Quality[14]

The energy activities have an impact on water quality in several ways. Severe damage is done to the marine environment in the accidental discharge of oil either from offshore drilling operations or from oil tankers and other vessels that carry petroleum products. In 1969 there were 1007 reported spills of oil in quantities over 100 bbl each. Vessels were identified as the source of 53 of the seaspills, 331 were from shore facilities, and 144 were unidentified. Individual discharges can be quite large however. In 1967 the tanker Torrey Canyon ran aground and discharged approximately 400,000 bbl of crude oil into the sea. It has been estimated[21] that the oil well blowout in the Santa Barbara channel in 1969 released about 75,000 bbl of oil by the 100th day of discharge. Smith[22] has outlined methods of dealing with spills after they have occurred that have been applied in the United Kingdom, including skimming, absorption, jelling, sinking, and emulsification.

Acid mine drainage, consisting of sulfuric acid and iron compounds formed by the reaction of water and air with sulfur-bearing minerals, contaminates local streams in coal mining areas. Martin,[23] in 1968, estimated that over 4 million tons of polluted water was released annually in the United States to about 11,000 miles of streams and other receiving waters from both abandoned and active mines. Control measures include eliminating the source of polluted water drainage by sealing off underground mines and restoring the surface of strip mines, and by collection and treatment of the drainage.

The petroleum- and coal-producing industries, in 1964, discharged about 7.3×10^{12} gal of industrial waste, or about 10% of the total discharge of industrial waste water. This waste involved 500×10^6 lb of biochemical oxygen demand (BOD), only about 2% of the total industrial waste water BOD. These industries also required 1.2×10^{12} gal of cooling water in the same year which was 2.4% of the total industrial cooling water demand. Electrical utilities accounted for 81.3% of the total demand by using 40.7×10^{12} gal of cooling water. This water is returned to the environment in a heated condition, which reduces the amount of dissolved oxygen that can be retained and thus has an effect similar to oxygen demanding wastes, but it is not otherwise contaminated. The need for cooling water is discussed in a more general context, along with alternate means of heat rejection, in the following section.

Thermal Effects

Heat must be rejected from all thermodynamic power cycles in quantities that depend on the efficiency of the energy conversion operation. The primary sources of waste heat are central station power plants, which can reject heat from their condensers to water or to the atmosphere through cooling towers, and automotive power plants, which discharge their waste energy to the atmosphere in exhaust gases. Atmospheric discharges of thermal energy can lead to local meteorological effects while discharges to water can have effects on the marine ecology.

In a 1000 MW (electrical output) fossil fuel power plant of 40% thermal efficiency, about 1275 MW of thermal energy must be rejected to the condenser coolant while about 225 MW is discharged directly to the atmosphere in the flue gas. A nuclear power plant of the same electrical capacity operating at 33% efficiency must reject all of its waste heat, 2000 MW, to the condenser coolant.

Discharges of waste heat can be controlled by improving the thermal efficiency of power plants, and the severity of local effects may be reduced by distributing the waste energy in large quantities of air or water. Many regulatory agencies have placed restrictions on the allowable temperature difference between inlet water and the water returned to the marine environment. Cooling ponds may be employed in such instances to hold up the effluent water until it has cooled to the allowable discharge temperature. Applications for this "waste" energy have been proposed,[24] including space heating and refrigeration in urban areas, thawing of ice-bound seaways, agricultural use to stimulate growth and to extend the growing season, and in aquaculture to stimulate the growth of algae, shellfish, and other potential marine food sources.

The use of waste heat for district heating systems may have a good chance to be applied on a large scale, although this technology needs a relatively high initial investment.

Radiation

There has been little addition to natural radiation levels in the environment as a result of energy related activities, excluding nuclear weapons testing as a source.

In the nuclear industry radiation problems begin with the mining of uranium-bearing ores. The alpha particle emitters, particularly radon gas, in the uranium-238 decay chain that ends with stable lead-206 pose the major health problem. Radon is chemically inert and diffuses from rock surfaces into the mine atmosphere where it and its daughter products can be inhaled by workers. Exposure standards and control measures have been published by the Bureau of Mines.[25] Mine tailings also contain these radiation sources which complicate the disposal of these solid wastes.

The largest source of radioactive materials are the products produced by the fissioning of uranium and plutonium fuel in nuclear reactors. These fission products are formed in the encapsulated fuel elements and must be handled in the reactor waste treatment system only in small amounts that may leak from the elements during reactor operation. Other radioactive materials found in the reactor system are isotopes produced by the irradiation of materials of construction, corrosion products, and coolant additives. The fission products must be handled in the fuel processing plant where uranium and plutonium that has not fissioned is recovered for use in new fuel elements. Table 11 indicates the activity of the long-lived radioactive materials that are generated in the fuel elements of a nuclear reactor and that pose a long-term disposal problem. Isotopes with a short half-life may be simply held-up until they decay to a harmless product that may be released to the environment, but the others must be chemically reacted and concentrated for disposal by some other technique. The long half-life materials must be sequestered in a manner such that they cannot be released to the environment for centuries. A most promising approach to long-term disposal under study by the Atomic Energy Commission (AEC) involves the concentration of radioactive wastes and their conversion into an inert solid form by calcination or fixation in glassy materials, which would be stored underground in isolated geological formations such as salt domes, shale, or rock.[26] Two long-lived radioactive isotopes that cannot be easily captured and concentrated for such disposal are krypton-85 and tritium. Krypton-85 is a chemically inert fission product with a 10.76-year half-life. Tritium, with a half-life of 12.26 years, is produced both by fission and by neutron irradiation of boron and lithium contained in the reactor coolant and ends up in aqueous form in waste treatment systems. Both of these isotopes are discharged to the environment in liquid and gaseous effluents but are first diluted to permissible concentration levels.

Fossil-fuelled power plants release small quantities of radioactive material that are attributable to trace amounts of uranium and thorium in coal and oil. A study performed by Department of Health, Education, and Welfare personnel[27] compared potential exposures to the population in the vicinity of coal fired and nuclear power plants. The only radiation sources attributable to either type of plant that could be detected above background levels were emissions to the atmosphere. A plant fired with a specific coal containing 9% ash and with 97.5% effective fly ash removal could lead to an exposure of 3.08×40^{-4} millirem of radiation annually per MW of electrical power produced. The exposure potential from a typical pressurized water reactor (PWR) plant was 1.05×10^{-5} millirem on the same basis. A boiling water reactor (BWR) included in the study had a higher exposure value but is not representative of plants of this type that are now being built. In any case, the maximum off-site exposure attributable to any nuclear plant was in the 5 to 15 millirem/yr range. The difference between the BWR and PWR in this study is attributed to the fact that the PWR had the ability to store gaseous wastes for about 60 days prior to release to the atmosphere, while the BWR had only a 30 minute hold-up. Larger volumes of waste gases must be handled in the BWR even though the total quantity of radioactive materials produced are comparable in the two reactor types.

TABLE 11

Long-lived radioactive materials generated in typical nuclear reactor fuel

Material	Half-life (in years)	Activity[a] (megacuries[b]/10^{15} Btu of thermal energy produced by fission)
Tritium	12.26	0.146
Krypton-85	10.76	3.4
Iodine-129	1.6×10^{7}	1.03×10^{-5}
Other fission products		
Cesium-137	30	40.2

Plutonium-240	6760	0.212
Plutonium-241	13	55

[a] After 90 days of cooling time following operation of a typical batch of 2.84% U-235, non-recycle, PWR fuel at a specific power of 40 kW/kg U to a burnup of 35,000 MW-days/long ton.

[b] A curie is the amount of a given radioactive substance which undergoes 3.7×10^{10} radioactive transformation/sec (equivalent to 1 g of radium).

Derived from data presented in: Safety Analysis Report, Barnwell Nuclear Fuel Plant, Allied Chemical Nuclear Products, Inc., Amendment 2, Docket No 50–332–4, March 21, 1969.

Solid Wastes[28]

In 1969 over 30 million tons of fly ash were recovered from power plants burning coal and lignite. About 20% of this is used commercially as a soil conditioner and as an additive to concrete and asphalt mixes. Bottom ash, which accounts for about one-fifth of the ash produced in coal-fired plants, is used in the manufacture of cinder blocks, as road ballast, and on highways in icy weather. Unused portions of these materials represent a solid waste disposal problem and are dumped in spoil areas which occupy land are unsightly.

Large amounts of solid wastes are generated in coal mining, uranium mining, and shale oil recovery. The residual wastes from the processing of coal are put in culm banks and coal waste piles. These contain a high content of carbonaceous material and besides their unsightly appearance and the landslide hazard that they represent, they can ignite spontaneously and emit air pollutants. A survey has located waste piles from 470 bituminous coal cleaning plants and 800 culm banks each containing 10,000 tons or more of waste material from the cleaning of anthracite coal. In 1964 about 495 refuse deposits located in 15 states and containing about 500×10^{6} yds^3 of material were found to be burning.

Overburden material from strip mines is piled in spoil banks which may be thousands of feet long and over 100 feet high. These are a source of acid water, will generally not support vegetation, and render the land unsuitable for recreation or industrial use. A thickness of overburden material averaging about eleven times the coal thickness was handled in US strip mining activities during 1970.

Control of the solid waste problem in these activities will require increase utilization of ash from coal burning power plants and of mill tailings from coal and uranium ore treatment. An obvious disposal method for the portions of these wastes that cannot be used and for spoil bank material is to replace them in depleted strip mining areas and thereby assist in restoration of the land whenever this is feasible.

Noise[14]

Energy conversion devices, particularly those used for mobile applications, are noisy in operation. Noise can impair hearing and has physiological and psychological effects on people.

The average level of sound at normal conversation amounts to 55 db (A) in a distance of 3 feet, the sound of elocution amounts to 70 db (A). For the noise in a living room a level of 35–40 db (A) is acceptable, the critical level of noise begins with 40 db (A), above 40 db the noise can reduce the attention and concentration of working people. For working places they are required by law to limit the noise level to:

1) mainly intellectual work 55 db (A).
2) simple or mainly mechanical office work 70 db (A).
3) all other work in office or workshop 85 db (A).

From 90 db (A) on it is required to wear ear protection.

Traffic noise, mainly from vehicular power plants, can reach 90 db (A) in urban areas and on heavily traveled highways, while a four-engine jet aircraft produces up to 120 db (A) on take-off at a distance of 200 feet. In internal combustion engines the sources of noise are the rapid combustion of fuels, high-velocity gas discharges through exhaust valves, and engine vibrations. The noise output is held down by muffling of the exhaust gases and by acoustic lining of the engine compartment. Turbine noises from both aircraft engines and stationary power plants arise from high-speed rotating components and high-velocity gas flows, and can be controlled by reducing the fan blade tip speed, the use of acoustic linings, and varying the geometry of the exhaust nozzle.

The necessity to build power plants also in the vicinity of towns and villages leads to expensive noise protection equipment.

ENERGY RESOURCES

Modification of fuel form and the substitution of alternate energy resources are useful procedures for controlling environmental effects. The selection among alternative resources depends on their relative abundance, ease of recovery, convenience in handling, and economics. Some resources, such as fossil and nuclear fuels, are present on earth in only finite amounts and are not renewed to any extent, although in the case of nuclear fuels the energy content of known reserves may be quite large. The other major category of energy resources involve energy that is supplied continually to the biosphere over a geological time span, including geothermal and tidal energy as well as solar energy and its derivatives, wind, waves, and hydropower.

In 1980 the average cost of coal, oil, and natural gas at their source was US $55–60 per ton, US $30–35 per bbl, and $1.6–1.8 per 1000 ft^3, respectively. Within the last years these costs have drastically escalated and further adjustments may be attributed to the cost of providing environmental protection systems and to governmental policy actions in specific areas such as mine safety, oil import quotas, and natural gas price regulation. Current prices for nuclear fuel supplied to fission reactors indicate a cost for this form of energy of about US $1.8–2 per 10^6 Btu.

The cost of treating, refining, and transporting fuels adds considerably to the price paid by the consumer for energy. Figure 4 shows the portion of the cost of electrical energy, produced in central station power plants, that is attributable to the transportation of coal, oil, and natural gas fuels and to high-voltage electric transmission as a function of distance and transport technique.[29] The spatial separation between the location of resources and the centers of energy demand poses the problem of optimal siting of fuel treatment, refining, and energy conversion activities and has been studied in a geographical format by Manners.[30] Consideration of environmental factors imposes additional constraints on such siting problems.

A number of estimates of the abundance of energy resources are available and have been assembled and refined by Hubbert[31] of the US Geological Survey. The exploitation of an exhaustible energy resource generally begins at a low level and increases to a period of maximum utilization, ultimately returning again to a low level as the resource is depleted or as recovery costs become prohibitive. Of interest with respect to an energy resource is the estimated time of peak annual consumption and the time at which 90% of the resource is expected to be consumed. The summation of annual recovery over the entire recovery time span is the ultimate recovery for that resource, Q_∞. The cost of obtaining a resource increases as that resource is depleted. In general, it is necessary to qualify any statement concerning resource abundance with a definition of the cost constraints that are assumed. In view of such difficulties, estimates of resource availability vary widely.

The estimated supply of coal and nuclear fuels can provide the projected US needs over several centuries, while Hubbert's analyses indicate that over 90% of the oil and natural gas resources may be consumed by the year 2015. Others are much more optimistic about new discoveries of oil and gas. Homan and Lovejoy[32] have reviewed the methods used in arriving at oil and gas supply estimates and compare the results arrived at by several investigators.

Any estimate of the abundance of a certain energy resource must however consider that the different process of substitution in the meantime under way may rapidly change the global picture of the quantity of energy resources. The process of substitution makes it necessary to analyze alternative energy strategies and to formulate a selected long-term strategy for each country or even multinational areas.[33]

Another pertinent characteristic of a specific fuel or energy resource is its versatility. Some fuels can be modified or treated with relative ease to provide a convenient form and can be utilized in a wide spectrum of energy conversion system while others may be limited in their periods of availability or in their adaptability. This characteristic accounts more than any other for the great demand for natural gas or oil and its derivative products. Coal, lignite, and their products coals are burnable products of decomposition of former vegetable substance in different phases of preservation. Coals consist of more than 50% (weight) and more than 70% (volume) of carbon and contain at maximum 30% unburnable parts (ash). Coals have brown up to black color. The vegetable substances produce first peat and then progressing through lignite, subbituminous, bituminous, and anthracite stages. It has been estimated that there is about

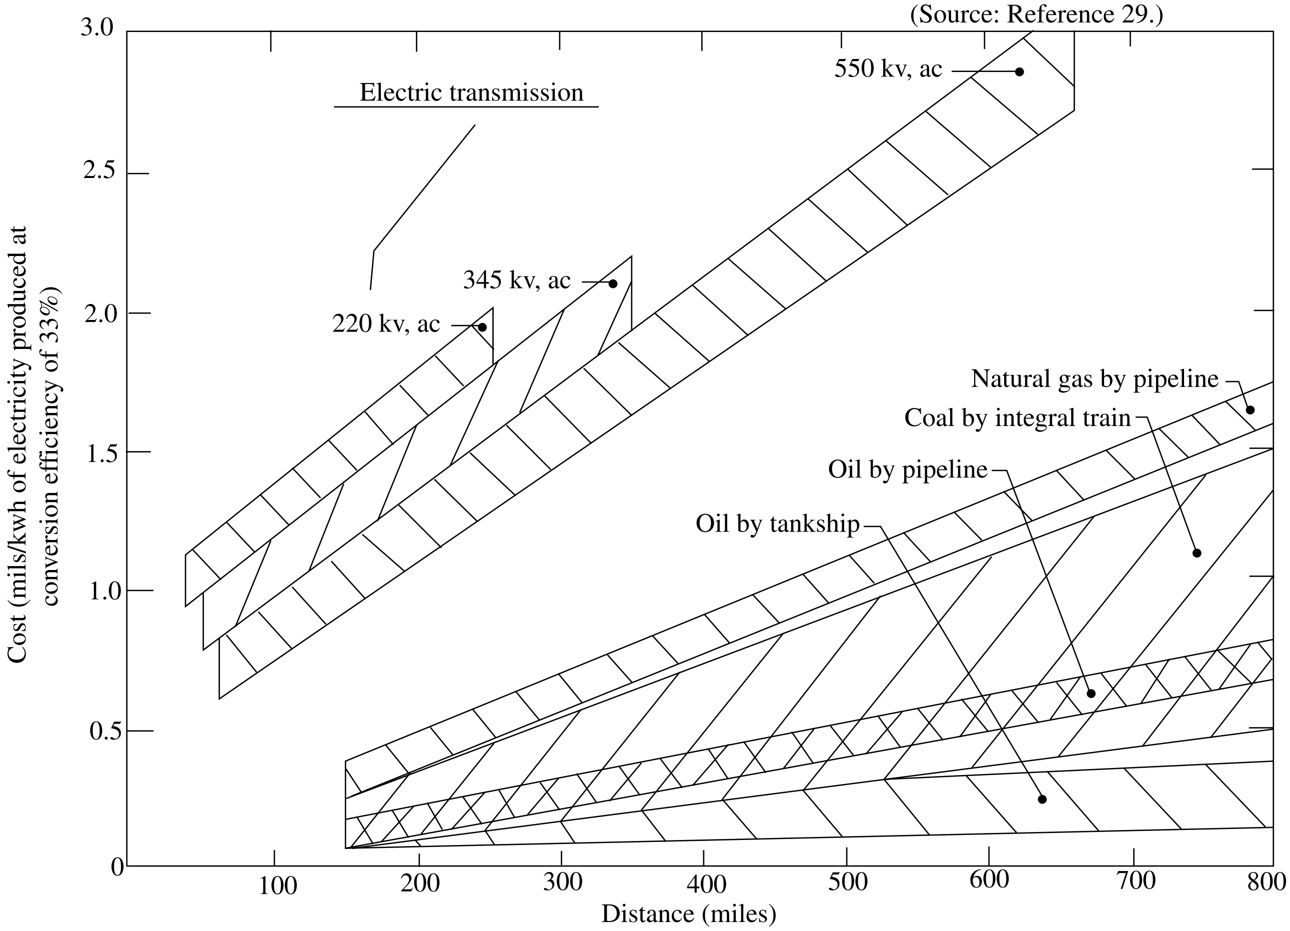

FIGURE 4 Portion of central station electric cost attributable to the transportation of energy.

1.58×10^{12} tons of coal in the US in seams at least 14 inches thick and at depths of less than 3000 feet, and about half of this is considered recoverable at a cost near current levels. These deposits are described by grade and sulfur content in Table 12. On the same basis, the world's coal resources are 8.3×10^{12} tons. The time of peak annual recovery and the time at which about 90% of this resource will be consumed are projected to be the year 2150 and 2440, respectively, for the US and 2150 and 2380 for the world. The annual extraction of bituminous coal in the world was in 1974 2245 M of tons, the extraction of lignite 847 M of tons (Data source: Friedensburg/Dorstewitz, Enzyklopaedie Naturwissenschaft und Technik, Muenchen, 1980).

Sulfur is present in coal as pyrite (FeS_2) and organic sulfur in roughly equal amounts. The organic sulfur is difficult to remove, while only 30% of the sulfur present as pyrite is removed by the standard coal-cleaning technique of crushing and flotation. Processes are available for the liquefaction and gasification of coal and lignite, the process for the liquefaction and gasification of coal had worked before the petroleum era and is working with improved technologies in semi-industrial installations, the process for the liquefaction and gasification of lignite may go in the near future into the phase of pilot plants. These processes will provide a sulfur-free fuel in more convenient form. Hydrogenation plants are foreseen that will produce 100,000 bbl/day of synthetic crude oil from 3.24×10^5 tons of coal[34] at a cost after sufficient development of about the double of the world marked price of natural crude oil, that means, all gasification and liquefaction plants are not yet competitive with the conventional process of refining natural crude oil. But the engagement of several industrial countries demonstrates that the technical processes of substitution exist and are available for a certain period to overcome the problems of modification of the world energy economy until alternative energy sources of long-term significance and necessary quantities are available for the then modified applications in the human life.

The liquid of synthetic crude oil has a high gasoline content and the process yields a high-sulfur char residue. In the gasification of coal, the sulfur is recovered as H_2S. Carbonization, or pyrolysis, yields a gas, mostly hydrogen,

TABLE 12
Estimated remaining coal reserves of the United States by rank and sulfur content, 1965 (in billions of tons[a])

			Coal rank

[a] Coal in seams at least 14 in thick and less than 3000 ft deep in explored areas. Approximately one-half of these reserves are considered recoverable.

Data source: Decarlo, J.A., E.T.T. Sheridan, and Z.E. Murphy, Sulfur Content of US Coals, Dept of Interior. Bureau of Mines, Information Circular 8312, 1966, Washington, DC.

with 15 to 30% of the original energy content of the coal with the balance in the coke that is produced. Hydrogasification processes can produce methane, a pipeline quality gas. The waste products produced in a coal conversion include particulates, CO_2 and sulfur compounds but they are generally easier to handle in this step which may also be carried out at a site more remote from population centers than where the fuel is consumed in an energy conversion operation.

Hydropower

Hydropower is the most important of the regeneratable energy sources because of its highest efficiency at the energy conversion. But its share on the total energy production lies worldwide at only 3%. The possibilities of extension are limited and it is expected that in the year 2000 hydropower will bring only 5% of the worldwide needed energy. That means in absolute figures: throughout the world installed electrical capacity of hydropower was in 1962 2.857 GW, while in 1978 it amounted to 3.960 GW. Some countries have almost used their potential on available and usable hydropowers:

Switzerland	near 100%
Germany	about 75%
Austria	about 60%
Europe	more than 50%
USA	about 22%
Brazil	about 20%

There are two types of hydroelectric power plants:

1) Run-of-river power plants for the use of affluent water;
2) Storage power plants (power stations with reservoir) where the influx can be regulated with the help of a reservoir.

Mostly greater differences in altitudes are being used, like mountain creeks. Power stations with reservoirs are generally marked by barrages with earth fill dam or concrete dams. A special kind of storage power stations is the pump storage power station which makes it possible to use surplus energy of the grid to pump the water to the reservoir and to provide kinetic energy.

Though hydropower generally can be called environmentally acceptable, there exist also some problems:

1) Change of ground water level and fill up of the river bed with rubble.
2) Risk of dam breaks.
3) Great demand for land space for the reservoir (the Kariba Dam in Central Africa produced a reservoir surface of 1930 square miles and made necessary the resettling of 50,000 people).
4) Diminution, but partly also increase of value of recreation areas.

As the hydropowers of the world are limited, the world energy demand however is rising, finally the share of hydropower will decrease.

Crude Oil

Hubbert estimates that the ultimate recovery, *QF* of crude oil in the US, including Alaska, will be about 200×10^9 bbl.

Other estimates are higher than this by a factor of 2 or 3. The world resources are felt to be between 1350 and 2100 × 10^9 bbl. Peak annual recovery and the 90% depletion point are projected to be attained by the years 1995 and 2000, respectively, for the US and 2000 and 2050 for the world, considering that the processes of saving and substitution have begun. Petroleum resources may be extended considerably by the recovery of this fuel from shale oil. About 80 × 10^9 bbl of oil can be recovered in the US under present conditions, using shale with a content of oil of more than 10 gallons per ton. The total US resources of shale oil in place with more than 10 gallons of oil per ton is figured at 1430 × 10^9 bbl. Before a substantial production could be achieved, however, high investments must be affected—and prototype plants of semi-industrial and industrial size would have to be constructed.

A wide range of control of product yield is available in the oil refining process. Separation of light and heavy fractions are generally performed by distillation into liquefied petroleum gas (mostly propane and butane), gasoline, kerosine, fuel oil, and residual crude. The normal yield of gasoline from a typical crude is about 15% but this can be increased substantially by thermal and catalytic cracking techniques. In 1968 the average gasoline yield from US refineries was 45% of the crude oil consumption. Petroleum can also be used to produce methane, hydrogen, ammonia, methanol, and other clean fuels that are being studied for various applications including mobile power plants.

The sulfur content of crude oil is generally concentrated by refining operations in the heavier fractions, such as the residual oil used to fuel central station power plants. Table 13 gives the 1966 crude oil production in the US by area and sulfur content of the original crude. Since much crude oil and petroleum product is imported, similar information on foreign production is given in Table 14. Sulfur may be removed from oil by several techniques including delayed coking, solvent deasphalting, and hydrogen treatment.

Natural Gas and Natural Gas Liquids

The principal component of natural gas delivered to the consumer is methane. As recovered in the field the gas contains hydrocarbons of the composition C_nH_{2n+2} (methane, ethane, propane, butane, and pentane), natural gas liquids, and other gases such as hydrogen sulfide (H_2S) and, in some cases, helium. The H_2S content varies from field to field and is removed to recover and sell the sulfur. Natural gas resources are classified into nonassociated, associated, and dissolved categrories depending on whether the gas exists alone, in a gas cap with oil beneath it, or dissolved in oil. About 75% of the gas reserves are in the nonassociated category. Gas associated with oil generally provides pressurization of the oil pool and stimulates its recovery, so the gas is usually left in place until the oil is depleted. Natural gas liquids (NGL) are recoverable from the gas and supplement other liquid fuel resources.

The ultimate recovery, Q_∞, of natural gas in the US is estimated by Hubbert at about 1200 × 10^{12} ft^3 and for the world at 8000 to 12,000 ×10^{12} ft^3. Cumulative production through 1969 was about 400 × 10^{12} ft^3 in the US. On the basis of these figures, the year of peak annual recovery will be about 2000 and 90% of the resources will be consumed by the year 2025.

Uranium and Thorium

Natural uranium has an isotopic makeup of 0.711% uranium-235, 0.006% uranium-234, and the balance is uranium-238. Only uranium-235 among the naturally occurring isotopes is fissionable to any extent and natural uranium must be enriched in this isotope to between 2 and 3% to provide fuel for current nuclear reactors. If only the naturally occurring uranium-235 were utilized in fission reactors, the nuclear industry could be limited, for economic reasons, to those US resources of U_3O_8 that are recoverable at a suitable cost. These are estimated at 660,000 tons and would furnish only about 232 × 10^{15} Btu of energy. Fortunately, it is possible to extend the degree of utilization of our uranium resources by converting the abundant uranium-238 isotope into fissionable plutonium-239. Thorium, which is available in large quantities, can also be converted into a fissionable isotope, in this case uranium-233. These conversion processes, involving the capture of neutrons by the fertile isotopes, may be carried out in power producing reactors, which are called breeders if the amount of new fissionable generated is greater than that consumed, or converted if the amount generated is less than that consumed. Breeding is required in order to fully utilize uranium-238 and thorium-232 resources and makes the economics of nuclear power less dependent on the cost of fuel resources. There are estimated to be about 25 × 10^6 tons of U_3O_8 in the US recoverable at reasonable costs and eventual utilization of all of this natural uranium, including the uranium-238 isotope after conversion into plutonium-239, would develop some 1.25 × 10^{21} Btu of energy.

Fusion Resources

There are several fusion processes that are currently under study or in development as a source of energy but none have been attained in a controlled reactor. These reactions depend on the hydrogen isotope deuterium, D, in seawater as a primary fuel. One process, the D–D reaction involves the feeding of deuterium into a magnetically confined high temperature plasma and has the net result of converting five deuterium atoms into one atom each of helium-4, helium-3, and hydrogen, in addition to two neutrons, releasing 24.9 MeV of energy in the process. An alternate and, in theory, easier reaction to obtain is the D–T reaction which involves the fusion of one atom of deuterium and one atom of tritium to produce an atom of helium-4, one neutron, and 17.6 MeV of energy. The neutrons generated in the D–T reactor must be captured in a lithium-6 blanket

$$\begin{aligned} D + T &\rightarrow {}^4He + n + 17.58\ \text{MeV} \\ D + T &\rightarrow {}^3He + n + 3.27\ \text{MeV} \\ D + D &\rightarrow T + p + 4.04\ \text{MeV} \end{aligned}$$

producing another atom of helium-4, an additional 4.8 MeV of energy, and most importantly, an atom of tritium which is recovered and fed to the fusion device, along with fresh deuterium to fuel the reactor. Thus, the D–T concept produces a net 22.4 MeV for each deuterium atom supplied, but also requires a continuous supply of lithium-6 and seems to be limited by the availability of this material rather than deuterium.

There are 1.028×10^{25} atoms of deuterium per cubic meter of seawater or about 1.5×10^{43} atoms in all of the oceans. Recovery and utilization of 1% of these in a D–D Reaction would provide 1.14×10^{26} Btu of energy.

The measured and probable resources of lithium in the US amount to about 21×10^6 tons containing 6.54×10^{34} atoms of lithium-6. Since the number of lithium-6 atoms recoverable appear to be less than the deuterium resources, the energy available through the D–T reaction is limited by the availability of lithium-6 to about 2.2×10^2 Btu, an amount comparable to the energy content of the world's coal resources.

In spite of all research and development work for fusion reactors no reliable statement can be given whether it will be possible to reach the aim to develop an economically working fusion reactor. On the other hand the successful development of such a fusion reactor would be an enormous gain and worth all efforts.[36]

Geothermal Sources

The temperature of earth increases with depth at the rate of about 2°F every 100 feet in rock and at about 3 times the rate near natural steam sources. The thermal energy in deep underground zones can be recovered either by tapping natural steam or hot water sources, or by fracturing dry hot rock formations and flooding them with water to generate steam for use in a conventional steam-electric power plant. As this energy is withdrawn it is replaced by the normal conduction of heat from below. The installed electrical capacity in 1980 of such power plants was about 1350 MW in the world, the capacity of heat plants about 5500 MW. Recent surveys indicate a potential electrical output of 20,000 MW from natural steam sources in California's Imperial Valley, with a like amount available in Oregon. The use of nuclear explosives to fracture hot rock formations can extend the availability of this resource considerably and is under study by the AEC.

In comparison with other energy sources the presently used geothermal energy is extremely low, even if it may locally be of great importance. There is no hope that in the near future its contribution to the total energy consumption will be more than 1–2%.

Tidal and Wave Power

The energy resource of tidal power results from gravitational interaction between the earth and the moon. It may be harnessed by constructing dams in tidal areas to create a difference in elevation between two bodies of water. The potential energy in the higher body of water can then be recovered to produce electrical power by the same techniques used in hydroelectric plants. The maximum energy recoverable is proportional to the area of the basin and to the square of the tidal range. In North

America various sites on the Bay of Fundy have a total potential for the production of about 29,000 MW of electrical power, although little of this can be developed economically.

The use of wave power of the oceans was proposed repeatedly and in different systems, firmly installed at the beach or near the beach swimming. Theoretically it is possible to use the wave power and this can be demonstrated on models. But in great quantities it will not be economical, and as the aim is the production of electrical energy, it would be necessary to install enormous conventional stand-by plants because of its irregular turn.

Biomass

In the ecology the entire living components of ecological systems are called biomass. Biomass is subject to dynamic changes because phases of production follow phases of consumption and decomposition. As this runs by law of nature but principally is controllable by suitable production terms, there arose already before the productional ecological research out of practice the agricultural production oriented economy which is, under several aspects, only a synonym for productional ecology. The productional ecology integrates the biological energy flow. As with each productional process a portion of the absorbed energy at living organisms is used to maintain metabolism, there remains from the gross production only a fraction as usable net production. We must consider the turnover which makes the production, and this turnover is not comparably high competed with the hard energy.

Another problem is that the use of biomass as industrial initial position for energy production at equal conditions for the protection of the environment can easily become uneconomical. The conclusion is that biomass will reach only a small percentage of the total energy volume, should be used in small plants of conversion only, brings principally advantages only for decentralized small consumers, and has no economic basis should the regulations for the protection of the environment be valid also for big biomass systems.

Sun[37,38,39,40,41]

The rate at which solar energy intercepts the diametral plane of the earth is about 17.7×10^{10} MW. At the surface of the earth the average solar power is about 1820 Btu/ft^2-day but this figure can vary widely depending upon the location and, of course, is only available during sunny periods.

The principle difficulty in utilizing solar thermal energy for endothermic reactions is thus not so much matching the technology of the power plant to the solar-specific conditions, but to tie in the processes for which the power demand is usually constant to the fluctuating conditions of insolation. The problem of intermittent energy supply originating in the day/night cycle has therefore to be countered by the development of storage devices, hybrid strategies or by selecting interruptable processes, before large-scale utilization of solar energy can be considered.

Possibilities which show promise for the future are the development of technically efficient devices suitable for commercial exploitation, and a similarly attractive proposition appears to be a method of storing the fluctuating solar energy in processes which are interruptable, or at least can be modified over time. Conversion of such processes to solar power appears conceivable, and likewise simultaneous utilization of thermal and photochemical energies could result in advantages that up to now have not been fully exploited. Possibly hydrogen produced by solar power will play a part in the storage and transportation of energy from solar plants. In all solar thermal power plants, the low radiation flux density of the incoming solar radiation is collected and concentrated by a field of mirrors, referred to as collectors or heliostats. As much as possible of the radiation energy is absorbed and converted to energy. The balance of plant elements correspond to the conventional components of a normal power plant, but they have to be matched to the solar-specific mode of operation.

Figure 5 shows the general arrangement of a central receiver system power plant, which shall be briefly

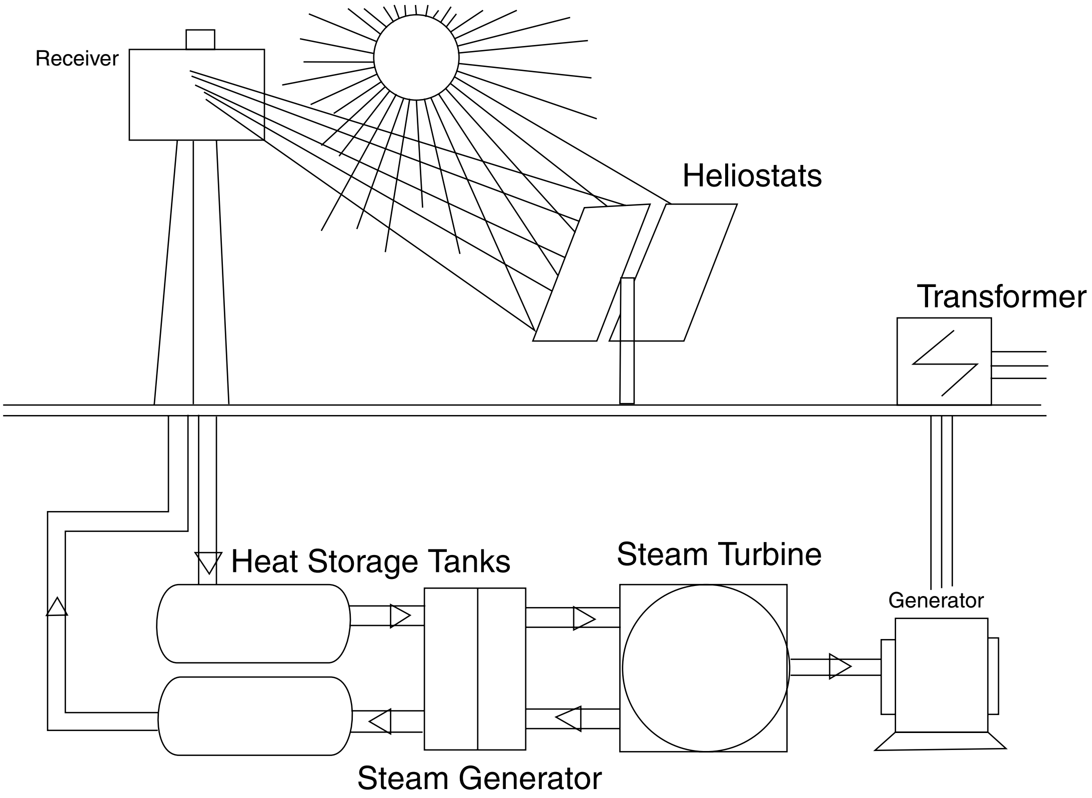

FIGURE 5 General arrangement of Central Receiver Systems (CRS).

described in the following as a example of a solar power plant. In this CRS (Central Receiver System) tower concept, heliostats reflect all incident radiation to a central receiver at the top of a tower. Within this receiver, temperatures ranging from 500 to 1000°C can be obtained. Table 15 lists the tower plants constructed up to now, of which solar 1 in Barstow in California, USA, Table 16, is the largest at 10 MW. For some 10 years, such prototype power plants have been designed, constructed and tested in different parts of the world. In their key characteristics, such as technology, conceptual design, size, heat carrying medium and power may differ from each other. For the tower power may differ from each other. For the tower power plants Solar 1 (Barstow, USA), CESA 1 (Almeria, Spain), Sunshine (Nio, Japan) and Eurelios (Adrano, Italy), steam was employed as the heat-carrying medium. The SSPS plant in Almeria, Spain, was operated with liquid sodium; the French power plant Themis used a molten salt for this purpose.

Since the beginning of 1987, the plants have been brought together under one organization under the leadership of Spain to make up the "Platform Solar de Almeria" (PSA) and now represent the European centre for solar thermal energy research.

Research work in the future will result from consultations between West Germany and Spain, as well as the participation of other nations in the SSPS project (participants: Switzerland, West Germany, United Kingdom, Italy, Sweden, USA). The activities are directed to the three following areas:

- maintenance and upgrading of the plants
- high-temperature technology of the components (in particular concentrator, receiver, storage device)
- utilization of the radiation and thermal energy during endothermic reactions in chemical processes for the production of transportable fuels and chemicals

In the farm concept, which is under investigation not only in Almeria but also in the USA and Australia, solar radiation is focused by parabolic troughs onto pipelines under glass functioning as receivers. The maximum temperatures attainable with such systems are in the range 300 to 400°C depending on the oils used as heat-transfer media.

Direct conversion of solar energy into electrical energy is, environmentally, the most acceptable way of electrical power generation. Solar cells are already supplying spaceships with electrical energy. For the construction of solar power plants, concept and feasibility studies are in hand. Even if electricity generation in this type of plant does not fulfill conventional ideas of "profitability" great importance must be attached to attempts to introduce environmentally-neutral systems of power generation into the world. These endeavours are

worthy of generous support by governments. In any case, the studies will be continued, and progress is considerable.

Refuse

Solid waste products including paper, rags, cardboard, and plastics may be considered as an energy resource. Combustible wastes may be used as a fuel for electric power production and process heat and have a heating value of about 5000 Btu/lb. If fully utilized, these wastes could furnish about 10% of the fuel needs of central station power plants. Environmental problems are encountered in burning this material just as in the incineration of waste, and emissions depend upon the chemical characteristics of the refuse.

An alternate use of refuse, studied by the Bureau of Mines,[42] involves its conversion by pyrolysis into fuels such as combustible gases and light oils as well as other useful by-products. A ton of urban refuse containing mainly plastics can be converted, by pyrolysis at 900°C, into 328 lb of solid residue, 1.5 gal of tar, 0.5 gal of light oil (mostly benzine), 97.4 gal of aqueous liquor, 31.5 lb of ammonium sulfate, and 18,058 ft^3 of gas consisting of hydrogen, methane, CO, and ethylene. Other processes may be used to produce predominantly liquid fuels rather than a gaseous product.

Agricultural wastes, from animals and vegetation, are more abundant than urban wastes and constitute a large, though difficult to exploit, energy resource.

ENERGY CONVERSION

Most of the air pollutant and waste heat discharges attributable to energy-related activities are released in the energy conversion step. Here, energy resources are consumed to provide other energy forms either for direct utilization or for transmission to centers of energy demand.

The range of technological alternatives available in energy conversion is illustrated in Figure 6. The columns and rows represent input and output energy forms, respectively, with specific devices or power plants capable of making the transformation indicated in the appropriate block. The most widely used systems involve chemical (fossil fuel) and nuclear energy inputs and the following conversions or series of conversions:

1) For space heat (non-electric);
   chemical → thermal.
2) For the generation of electricity;
   Chemical or nuclear → thermal → kinetic → electrical.
3) For the propulsion of a vehicle (non-electric);
   chemical → thermal → kinetic.

In the conversion from thermal to kinetic energy a power cycle is used and its efficiency is limited by the second law of thermodynamics to a value less than that of the theoretical Carnot cycle. The Carnot cycle efficiency is equal to the difference between the temperatures at which heat is supplied to and rejected from the cycle working fluid, divided by the absolute temperature at which the heat is added. This theoretical limit on conversion efficiency increases for a given heat rejection temperature as the temperature at which heat is supplied to the cycle working fluid is raised.

A 1968 inventory of prime movers that are involved in the kinetic energy portion of various conversion systems is given in Table 17. Although automotive engines make up over 90% of the total installed horsepower, this figure is deceptive because of differences in the annual usage of the various power plants. A better indication of their relative use can be obtained from fuel consumption data.

The state-of-the-art in energy conversion systems and associated operations has been reviewed in a study performed for the OST[43] and by the FPC in both its 1964 and most recent 1970 National Power Survey.[29] It is convenient in reviewing alternative power devices that might be used to reduce harmful environmental effects, to maintain the distinction between centralized and decentralized power plants, where the latter may be either stationary or mobile.

FIGURE 6 Energy conversion matrix.

Centralized Power Plants

To take advantage of economies of scale, electrical energy is generated in large centralized facilities for distribution to consuming activities. The demand for electrical energy varies on a daily, weekly, and seasonal cycle. Since this form of energy cannot be conveniently stored, the installed generating capacity must match the peak demand and some of this capacity must be idle during periods of low demand. The more economic plants in the system, which may be fossil or nuclear facilities operating on a steam power cycle or hydroelectric plants, are usually operated as much as possible in a so-called baseloaded condition, while the older and less efficient plants and special gas-turbine installations are utilized only during periods of peak demand. The use of pumped storage can serve to flatten out the demand curve by using excess power produced during periods of low demand to pump water uphill where it can be used during later periods of high demand by recovering its potential energy. Transmission ties between electric utility systems in different regions of the country can be used to take advantage of load diversity since the timing of seasonal and daily peak demands varies depending on location.

Electric generating plants with an output of over 1000 MW are not uncommon and stations of up to 10,000 MW capacity are anticipated by the year 2000, perhaps involving an energy center concept where the power source is integrated on the same site with industrial, agricultural, and/or desalination operations. The concentrated environmental effects of large central station power plants are receiving increased attention and have been the subject of congressional hearings.[40] Natural gas and low-sulfur residual oil may be used in steam-electric plants with minimal air pollution but these fuels are limited in their availability. The provision

of control systems for SO_2 and NO_x emissions from steam plants fired with coal or high sulfur oil will increase the cost of power generation. Baron[41] estimates that flue gas scrubbing would add about 7% to the cost of power generation in a 1000 MW output plant using oil with a 1% sulfur content. The provision of dry cooling towers that reject waste heat to the atmosphere with no waste usage would increase the cost in the same plant by another 30%. The EPA has recently proposed[46] emission standards for coal-fired steam generators that would limit particulate releases to 0.2 lb per 10^6 Btu, SO_2 releases to 1.2 lb per 10^6 Btu, and NO_x to 0.7 lb per 10^6 Btu heat input.

The necessity to substitute oil by other energy agents as well as the little acceptance of nuclear power plants by the population of industrialized countries may lead for a certain time to a renaissance of conventional coal and lignite fired power plants but with a more sophisticated equipment for protection of environment. This protection will not include dry cooling towers, but washing equipment of flue gas to wash out partly SO_2 and NO_x as well as precipitators for dust. This environment protecting equipment increased the cost of the last built 750 MW coal fired power plant in Germany up to 27%. With full desulfurization and wet cooling tower the provision of environment protection will cost about 35%. It seems that there are two tendencies:

1) Big power plants of coal and lignite fired units with full SO_2 protection, and wet cooling tower (350 and 750 MW).
2) In the second place nuclear power plants with two and more units of 1000 and 1300 MW considering the difficulty to find new locations accepted by the population.

Improvements in the efficiency of energy conversion reduce the fuel consumption and attendant environmental effects directly for a given electrical output. Steam-cycle power plants operating with fossil fuels attain a thermal efficiency of about 40% with a maximum steam temperature in the power cycle of 1000° to 1050°F, which is well below the combustion temperature of these fuels. Current nuclear power plants operate with a maximum steam temperature of about 550°F and have a lower thermal efficiency. The cycle efficiency increases as the steam temperature is raised but the more severe temperature and pressure conditions would lead, in both fossil and nuclear systems to materials problems and higher plant capital costs that would more than offset the economic gains of increased efficiency. Topping cycles, which are added to the steam cycle and use other thermodynamic working fluids such as mercury or potassium in higher temperature ranges, therefore providing higher efficiency, have been studied for fossil-fueled systems and actually operated in the case of mercury but the gains appear to be marginal. Thermionic topping devices[47] that convert thermal energy directly to electrical energy have also been proposed and promise to increase the over-all efficiency of conventional plants to about 50% performance must be improved before they can be used to advantage. A combined cycle, involving a gas turbine topping unit that would operate at high temperature on gas produced from coal and would reject its heat to a conventional steam cycle, is another promising system and could have an overall efficiency in the 42 to 43% range.

Some promising alternatives for centralized power production that can utilize fossil resources are fuel cells and magnetohydrodynamic (MHD) generators. The number of nuclear reactor plants being installed by utilities is expanding and further developments in breeder reactors and fusion systems are also anticipated. Solar power plants are of great interest in the longer term as a clean energy source.

Fuel Cells

This direct conversion device is not limited in efficiency by thermodynamic considerations and can convert chemical energy directly into electrical energy without the intermediate conversion to thermal and kinetic energy. Over-all efficiencies as high as 75% have been attained in special purpose applications. With hydrogen and oxygen fuel fed to electrodes submerged in a suitable electrolyte, this device produces 0.7 to 0.85 volts (dc)/cell and many cells must be connected in series to produce useful voltages for transmission. Development work is in progress on cells that could operate on gasified coal or other gaseous fuels with air as the oxidizer and a conceptual design has been completed for such a plant.[48]

Air pollution and waste heat discharges would be reduced in a fuel cell power plant because of the improved efficiency of fuel utilization. If coal were used as the source of a gaseous fuel, the impurities in the coal and particulates would have to be controlled in the gasification plant, but such control would be easier to provide in this operation than in a conventional power plant. In the course of the development of fuel cells, it is more likely that they will be applied first to smaller decentralized power systems.

Magnetohydrodynamics

MHD generators can utilize either a fossil or nuclear thermal energy source. In a fossilfueled system, hot combustion gases, seeded with potassium or cesium to make the gas conductive, are expanded at high velocity through a magnetic field. The dc current produced in the moving conductive gas is picked up at electrodes embedded in the walls of the gas channel in various geometries depending upon the particular type of generator. The advantage of this system is its high thermal efficiency of 50 to 60% when operated at a gas temperature in the 4000° to 5000°F range. A panel[49] has conducted a study of MHD for the OST and concluded that additional research and development should be performed before an MHD plant is constructed. Much of this development effort must be directed toward materials research to permit extended operation at high temperatures.

The environmental effects of MHD generation would be similar to those in any fossil-fueled combustion system but would be mitigated because of the improved efficiency of conversion. The seed material in the gases could not be released in any case, for economic as well as environmental reasons, and must be recovered. It is anticipated that recovery of the other pollutants can be accomplished in the same operation.

Fission Reactors

Current light-water cooled nuclear reactor systems used for electric power production operate with fuel slightly enriched in the uranium-235 isotope and have a conversion ratio of about 0.6, i.e., they generate about 60% as much new fuel as they consume by converting fertile uranium-238 into fissionable plutonium-239. These plants have a thermal efficiency of about 33% because of limitations on the temperatures at which they can operate. Alternate reactor systems that are under study, including the molten salt reactor (MSR) and the high temperature gas-cooled reactor (HTGCR), can generate steam at conditions comparable to those of fossil-fueled plants and the molten salt system, when fueled with uranium-233 fuel that is produced from thorium by neutron capture in a reactor, can breed about 5% more fuel than it consumes. All of these systems operate with a thermal (or slow) neutron spectrum in the reactor. By operating with a higher energy neutron spectrum in a fast reactor, better neutron economy can be achieved and more neutrons are available for the conversion of fertile material. Such reactors may be cooled with helium, steam, or liquid sodium. These fast breeder reactors, when developed and integrated into the centralized power system, will greatly extend the nuclear energy resources by fully utilizing the more abundant uranium-238 isotope to produce additional fissionable fuel. An analysis of the various reactor concepts and their potential roles in a nuclear power economy has been performed by the AEC[50] and led to the selection of the liquid metal cooled fast breeder reactor (LMFBR) as the high priority development task.

The various topping and MHD systems discussed previously are also applicable to nuclear power plants and may be useful additions if higher reactor operating temperatures can be reached.

All reactor systems generate similar quantities of radioactive materials for a given thermal energy output and the handling of these materials is closely controlled during all fuel cycle and reactor operations. The amount of such materials produced, and waste heat discharged, for a given electrical output depends, of course, on the plant efficiency. It is important to recognize that in all reactor systems the cooling water that carries away the waste heat is physically separated from the reactor primary coolant whether it be gas, water, or liquid sodium. Because of the large quantities of radioactive materials present in the fuel region of a reactor during operation, there is concern over incidents that might accidentally discharge this material to the environment and no nuclear plants have been constructed in regions of high population density. Protection against such discharge is provided by safety systems that minimize the possibility of an accident and by incorporating several physical barriers within the plant to contain the radioactive products in the unlikely event that they are released from the fuel region.

Fusion Reactors

The successful development of a controlled and economic fusion device would make available the tremendously large energy reserves of deuterium in sea water. Current research is directed toward devices in which the combination of plasma temperature, density, and confinement time required for a sustained reaction may be attained. The status of this research and the outlook for fusion power has been summarized by Rose.[51] The deuterium-tritium (D−T) reaction, wherein these materials are confined as a plasma at a temperature of about 40×10^{6}°C in a high strength magnetic field while they react, releases most of its energy in the form of neutrons that must be captured in a lithium blanket to generate new tritium fuel. The blanket fluid may then be circulated to generate steam for a conventional steam-cycle system. Topping cycles may also be used depending on the operating temperatures and the over-all efficiencies will be competitive with fossil-fired power plants.

The deuterium-deuterium (D−D) reaction appears to be more difficult to attain, requiring confinement at a temperature of some 350×10^{6}°C, but releases much of its energy in the form of charged particles which might be used to generate electricity directly without using a power cycle. Higher operating efficiencies may be achieved in such a system. There are still other fusion reactions that are of interest because of their special characteristics.

It now seems that fusion power will be more economical in very large plants of greater than 5000 MW capacity and such plants will pose substantial waste heat disposal problems unless very high efficiencies are attained. In the D−T concept, tritium must be recovered from the blanket and handled during the fuel cycle. Another source of radioactive products the structural material that is activated by the neutrons produced in either reaction. In any case, the problems of disposing of radioactive materials appear to be less severe than those in fission reactors and, because of the small amounts of fuel material present in the device at any given time, the accident hazard is apparently minimal.

Solar Power Plants In-Orbit and Terrestrial-Based Systems

Several concepts for utilizing solar energy in a centralized power plant have been proposed. Glaser[52] outlined a conceptual system that uses a satellite with a large array of solar cells placed in a synchronous orbit. The solar cells would convert the solar energy to electricity and this energy would be beamed by microwave to a receiving station on earth. To supply the annual electrical energy demand of the northeast region of the US in 1980, estimated at 1.7×10^{15} Btu, a 105 square mile array of silicon cells would be required on the satellite and the receiving antenna on earth would be of the order of 20 square miles. Another scheme proposed by Meinel[53] involves a terrestrial-based plant that would capture thermal energy from the sun by means of specially coated surfaces to provide a "greenhouse" effect. A working fluid would be heated to a temperature of about 1000°F for use in a power cycle to produce electricity. A terrestrial-based system of 1000 MW electric capacity would require a land area of about 5.5 square miles. The satellite concept, like the utilization of fossil and nuclear resources, does add to the thermal burden that must be dissipated to the environment, while the terrestrial-based solar plant merely implies a redistribution of energy that impinges on the earth in any event.

Single and Dual Purpose Power Plants: Advantages and Problems

The more simple service of electricity generating units is the operation of single purpose power plants, on the other hand a second purpose can help to increase the efficiency of the plant, using for instance, the waste heat for district heating systems or desalination of sea water. Naturally the structure of the regional or national energy economy must allow the technical and economical interconnection of two aims. The increasing cost of fuel oil and natural gas may promote the use of fossil-fueled and nuclear power plants for the district heating in high populated towns and regions. When fully used for the two purposes the efficiency of a coal-fired power plant can increase up to 75 to 80%. But the high investment costs of big district heating systems and the take out of heat in the power plant brings the advantage of higher efficiency only during the winter period, in the summer time there will be needed in parallel the normal wet cooling tower. This is only one argument, the other is, that the coal, fired in the plant boiler, substitutes fuel oil unburdening the national balance of payment from the import cost for petroleum. If suitable a dual purpose power plant may be taken into consideration in the prefeasibility study period of new projects and here, in particular, also under the aspect that district heating systems could result in a dramatic reduction of air pollution in towns.

Decentralized Stationary Power Plants

Energy conversion systems currently utilized in this category involve mainly combustion devices for space heat and industrial process heat applications. For economic reasons they are generally not as amenable to as high a level of emission control as larger centralized systems, save for conversion to cleaner fuels such as natural gas and perhaps methane or hydrogen produced from coal. These applications are also candidates for conversion to electrical energy thereby shifting the emission problem from decentralized plants to centralized power generating facility.

Decentralized electric power generating facilities of up to 5 MW output are sometimes installed in shopping centers and housing complexes. These now use diesel generators or gas turbines but could also use fuel cells when these are developed. Waste heat from these power plants is used for space heating and air-conditioning, and it is claimed[54] that up to 85% of the energy in the fuel may be effectively utilized in these systems as compared with only about 40% in central station power plants.

The use of solar energy for individual home space conditioning and water heating will further on increase but involves a substantial capital investment in these applications. The payback time for the investment costs, however, will become shorter, because the natural gas, fuel oil, and electric costs will rise in future overportional to the cost of primary energy.

Nuclear reactors are not competitive in small decentralized applications for economic and technical reasons partially attributable to the requirement for shielding and other auxiliary systems. They are used, like other new devices such as fuel cells, in special military and space applications and may have potential in very large aircraft. Certain isotopes, produced by neutron irradiation in a nuclear reactor, have also been used as energy sources for small power systems in space and remote terrestrial applications.

Mobile Power Plants

Energy conversion devices used in motor vehicle, rail, and aircraft applications must provide acceptable performance characteristics in terms of horsepower–weight ratio and specific fuel consumption. The gasoline-fueled, internal-combustion (I-C) engine has dominated the motor vehicle field and the gas turbine has achieved the same level of preeminence in aircraft. An appraisal of automotive transportation in relation to the problem of air pollutant was performed by a Department of Commerce panel.[55] Alternate systems were reviewed and a five-year development program was recommended to support innovative developments on energy sources, propulsion systems, and emission control devices. Alternative energy sources were considered further in system studies performed on electric vehicles by A.D. Little[56] and on the whole spectrum of unconventional low pollution-potential power sources by Battelle Memorial Institute.[57] It also is possible to use alternate fuels such as propane, methanol, natural gas, and hydrogen in I-C engines to reduce the level of emissions. Propulsion devices that may have some future potential include gas turbines, external combustion systems operating with a steam of organic Rankine cycle or with a Stirling cycle, fuel cells, and battery driven electric motors. The characteristics of some

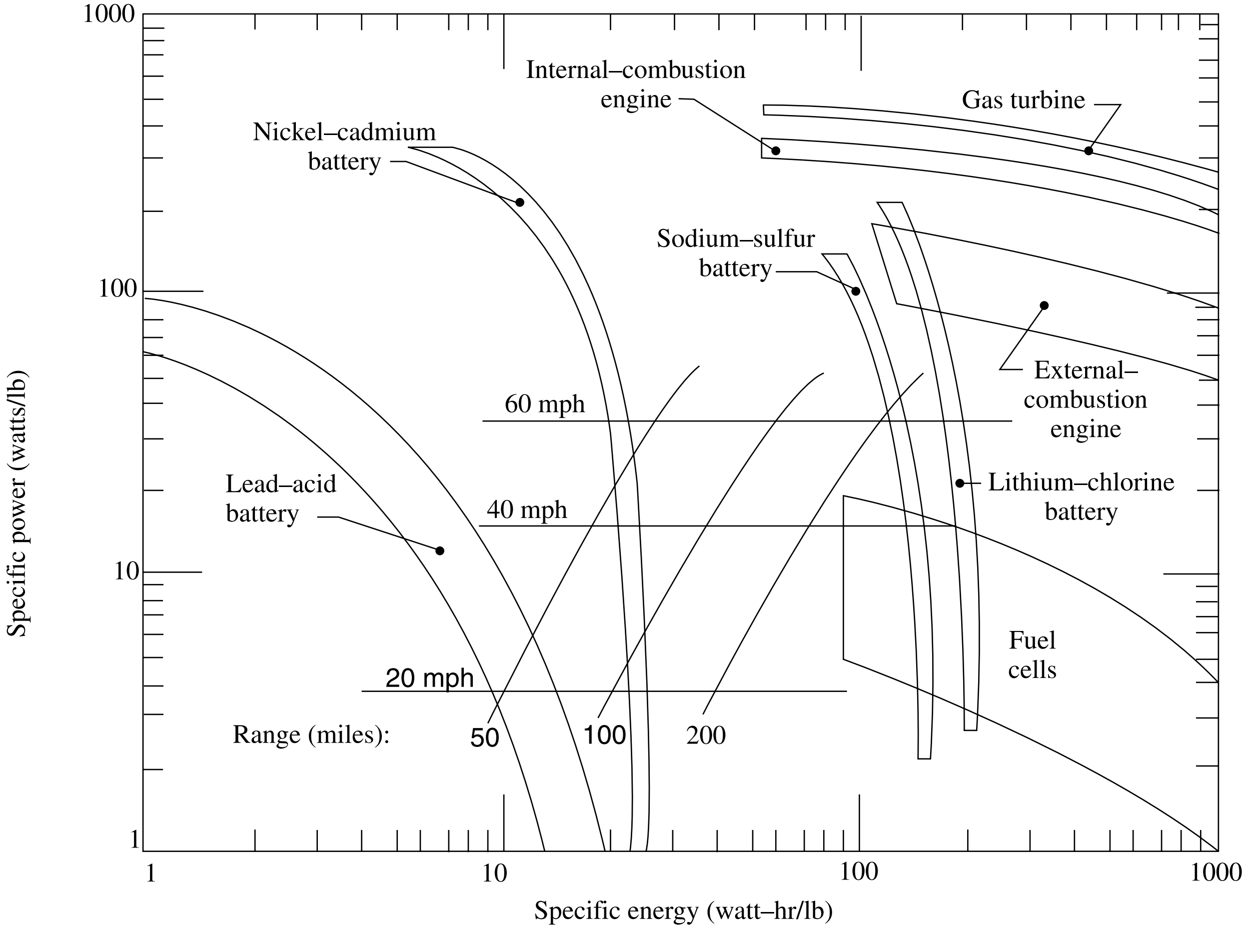

FIGURE 7 Vehicle requirements, and characteristics of mobile power plants for a 200 lb vehicle with a 500 lb power source.

alternative power plants are illustrated in Figure 7 which indicates the range of specific power in watts/lb and specific energy in watt-hr/lb available with these devices. The propulsion system requirements for a 2000 lb vehicle propelled with a 500 lb power source at speeds of 20, 40, and 60 mph, and for vehicle ranges of 50, 100, and 200 miles are also indicated. From these characteristics it may be seen that the gas turbine and external-combustion engine are the systems most competitive with the current I-C engine. Various types of battery systems are shown and these as well as fuel cell systems may be applicable to limited-purpose vehicles. The sodium–sulfur and lithium–chlorine systems may approach the performance of combustion engines but are still in the development stages. Introduction of a battery driven vehicle will shift the emission problem from the automobile to a central station power plant where the electrical energy required to recharge the battery would be generated (see section: The Problem of Transport).

Emissions from automotive power plants are variable and depend upon engine, load, level of maintenance, and individual driving habits. To allow for variable engine loads, emission standards are often related to a given driving cycle involving specified warm-up, acceleration, deceleration, cruise, and idel periods. The hydrocarbon, CO, and NO_x emission standards now in effect in California and those established by the EPA for 1974 concurrent are shown in Table 18 along with emissions from a representative uncontrolled gasoline fueled I-C engine as well as alternative power plants. The pollutants from current I-C engines have been reduced from uncontrolled levels by control of gasoline evaporation sources and by crankcase ventilation systems that recirculate cyclinder blow-by gases back to the combustion chamber. Further reductions of CO and hydrocarbon releases, especially NO_x, will involve high temperature or catalytic reaction of exhaust gases in unregulated or regulated catalysts, which are more and more applied in Gasoline I-C engines. The advantages of the gas turbine and external combustion engines, which can operate on distillate fuels such as kerosine, over the I-C engine lie in the better control of combustion conditions that can be achieved by separating the fuel combustion chamber from the working parts of the engine. The emission figures for a battery driven electric vehicle indicated in Table 18 were developed by Agarwal[58] on the basis that the electrical energy is provided from a central station

TABLE 18
Emissions from alternate vehicular power plants

	Emissions (g/mile)		
	HC	CO	NO_x
California standard, 1971[a]	2.2	23	4
EPA standard for 1975[b]	0.41	3.4	3
EPA standard for 1976[b]	0.41	3.4	0.4
Gasoline I-C engine, no controls	11.6	64	5.6
Natural gas I-C engine[a]	1.5	6	1.5
Diesel engine[c]	3.5	5	4
Regenerative gas turbine[c]	0.32	3.5	1.9
Stirling engine[c]	0.1	1.0	2.6
Steam engine[a]	0.2	1.0	0.4
Electric battery vehicle[d]	0.04	—	4.3

[a] Congressional Record H 903, February 17, 1970.

[b] Federal Register, July 2, 1971, pp. 12658.

[c] Personal communication, R. Tom Sawyner.

[d] Reference 58; emissions in this case are from a coal-fired central power plant and also include about 16.25 g of SO_2/mile and 2.1 g particulates/mile.

power plant. It was assumed that 0.95 lb of coal was burned at the power plant for each mile of vehicle travel. In this case the emissions would also include an SO_2 release of 16.25 g/mile if the coal contained 2% sulfur and no control were provided. This actual situation however will change when coal fired centralized power plants are equipped with desulfurization installations or when in the future the percentage of electricity produced in nuclear power plants will be much higher.

Diesel engines used in trucks, buses, and trains are accountable for a small fraction of transportation vehicle emissions but have local objectionable effects such as smoke and odor. Aircraft engines have similar effects but in the long run may be able to effectively utilize alternate fuels such as methane and hydrogen that will reduce emissions.

The expansion of mass transportation facilities to reduce automobile usage, especially in urban areas, is an effective way to utilize energy more efficiently in moving people from place to place. A bus carrying 50 people and traveling at a speed of 60 mph may consume about 0.003 gallons of fuel/passenger mile, while an automobile carrying three people will consume about 0.023 gallons of fuel/passenger mile traveling at the same speed with a corresponding increase in emissions and traffic congestion.

Disintegrated Methods

Analyzing alternative energy sources and alternative energy economies the centralized social order ruling presently was compared with disassociated way of life. For this alternative social order disintegrated methods of energy supply were suggested. These suggestions start from the point of view that the effective (final) energies heat, mechanical work and light can also be produced in small closed systems. As they must not be available steadily, the temporal not-necessity of these models get a favorable valuation in the ranking list. Investment for connection, transmission and interconnection become inapplicable as well as measures for environment. Such considerations lead to self-operating island stations on the basis of a suitable primary energy, for example, crude oil or diesel fuel which through conversion may produce mechanical work, heat, and light. Also biomass or bioenergies are part of such computer models. These disintegrated methods are possibly suitable for peripheral agricultural structures and may relieve the world energy supply unessentially. In industrialized countries they cannot be applied.

The Problem of Transport

The demand on kinds of effective energies, especially in industrial countries with cool climate are generally divided as follows:

	percentage of total supply	possibilities of improvement of efficiency of conversion
heat	60–69%	10–15%
mechanical work	25–35%	3–4%
light	1–15%	less than 1%

whereby chemical energy as effective energy, which is hard to inquire statistically and without important share, shall be neglected here.

In Germany the effective energies were supplied to 43.6% to private households, 36.8% to the industry and 19.6% to the field of transport and traffic (all figures valid for 1976).[59] If in the sector transport and traffic the above mentioned 19.6% (48.6 Mio tons SKE) would be again 100%, the following figures refer to

road	85.8%
railroad	5.1%
airlines	6.4%
inland navigation	2.7%

The main part of energy (and that mainly converted from crude oil) flew into the road traffic—8% of the total primary energy of the FRG. Railroad traffic, i.e., “Deutsche Bundesbahn” and private railroad companies, consumed only 5.1% or 0.8% of the total primary energy consumption. Though road traffic consumed tenfold of primary energies, the output of transport amounted only to 2.3-fold of the output of railroad (1976). Hence it follows that:

1) Railroad is with regard to energy consumption more economical than road.
2) The electrification of the railroad has reduced within 10 years the primary energy consumption to round about 50%.
3) Road traffic offers the greatest possibilities for saving energy and for the substitution of crude oil products by electricity.

A favourable combination for the energy economies of industrial countries would be:

1) A far-going electrification of railroad.
2) An increased portion of transport and traffic on electrified railroad.
3) Electrification of road traffic by electric-driven cars (battery cars).

As an electric-driven car with battery at present can drive about 200 miles, it can be suggested that for long-distance traffic the railroad should be used and for city traffic the electric car. For trips which by all means cannot be made by electrified railroad nor by electric cars, the conventional motor car should be available (as far as possible by rented cars). This combination would extend the world stock of crude oil, but for the transport sector it would mean a great change. Also the vehicle industry should help to carry this energy alternative. To bring "The Problem of Transport" into a favorable relationship to the above-mentioned 3-cornered problem energy/economy/ecology, it is unavoidable that, to a great extent, overland air traffic must be replaced by electrically-driven high speed trains travelling at 250 to 300 miles per hour. Environmental problems will make this development unavoidable.

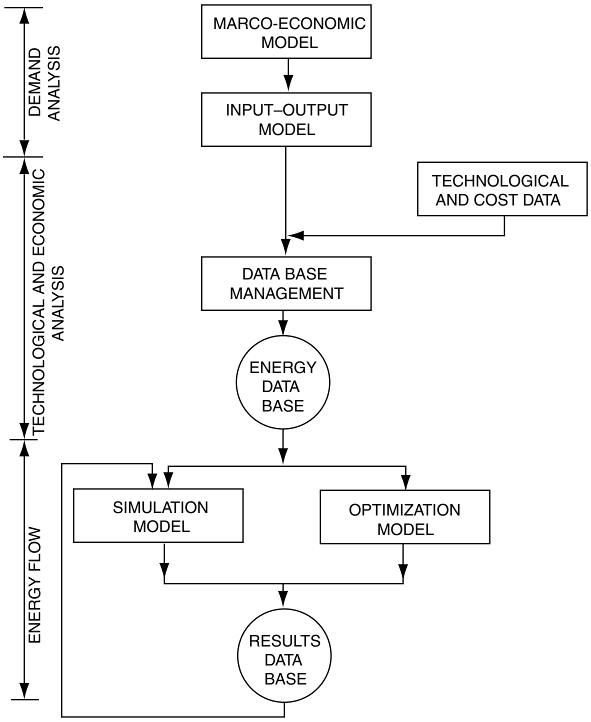

FIGURE 8 General flow-chart of the energy model.

Energy Strategies[33]

State and regional energy authorities in many countries bear the responsibility to bring about fundamental alterations of the energy economy, the ultimate object of which is to assure an adequate supply of clean, low cost, safe, and dependable energy. In general it can be assumed that population and national economies will continue to expand but that the extent and nature of this growth is as difficult to forecast as it is to accurately determine energy demands over a long period.

There are, as explained before, numerous alternative technical, and ecological economic solutions to these problems, comprising different priorities in the research and development of new energy systems, the choice of various primary energy sources, and the application of particular energy conservation and transport technologies. Further, non-technical elements of planning and shaping the energy economy lie in the enactment of tax, subsidy policy, and pricing.

The three main aspects of energy planning are as follows:

1) The problems presented by energy economies should not be considered in isolation. Rather, because of their central importance to the whole of a country's economy, these problems must be treated as sub-systems, interacting with other components in the economic nexus, such as technological concepts and environmental factors.
2) The energy system is mapped in a model. Depending upon the particular questions the model is to answer, three broad methods may be correspondingly applied: optimization models (linear programming, dynamic programming); simulation models; input/output analysis.
3) The model is mathematically designed for computer analysis. Interdisciplinary working groups, representing several scientific fields, are required to develop the model because of the complexity of the systems to be mapped and the many different areas to which the model's elements and subsystems belong.

This modelling method serves to furnish the basis for rational choices about energy supply as an integral part of a national (or regional) economy. After thorough investigation of the interrelation between the energy economy, the national economy and the environment, the knowledge of all technical and economic facts and influences as well as alternative possibilities will be given into formulated computer programs and become the foundation for long-term energy planning. The programs can simulate alternative strategies, check the effects of measures adopted, and make quantitative statements and forecasts about the energy economy. Figure 8 shows a simplified flow-chart of an energy model used for national energy studies.

In Figure 9 are shown the different steps from the inventory of energy resources with own sources, trade, and sources provided by trans-border energy transfer.

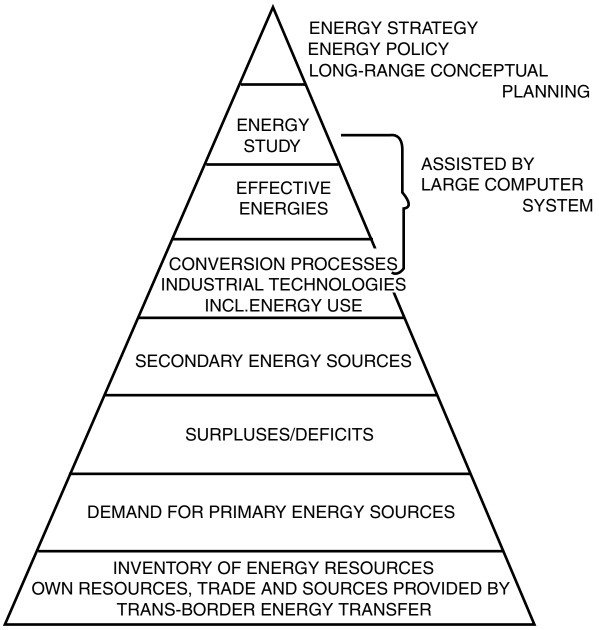

FIGURE 9 Energy pyramid analysis and strategy.

The implementation of a national or regional energy study yields the following results:

1) A long-range development plan for the energy system in terms of exploitation and extraction capacities, energy conversion and production capacities, total demand in relation to capital investment and population growth.
2) Annual consumption of primary energy and its structure.
3) An energy flow diagram.
4) Annual costs for each operation in the energy system.
5) Equipment requirements for each process and the additional capacity investment.
6) Ratio of indigenous to imported energy.
7) Sites for new plants.
8) Effects of new technologies on the energy system.

CONCLUSION

The role of energy in the well being and progress of a nation is obviously quite complex, involving many conflicting social, economic, and environmental factors. It is generally recognized that a national energy policy in many countries is urgently needed. The governments of especially the industrial countries have understood the dependence of their economy from a healthy energy economy and initiated steps to secure the basis for a reorganization of governmental and semi-governmental institutions engaged with energy and to be able to give reliable recommendations to the industry. The endeavours of governments and industries become more difficult because of the lack of healthy bases and the uncertainty how the numerous energy technologies will be developed and which availabilities and costs in the long-term future can be expected for the different primary energy agents. The energy program of the USA includes a broad program to accelerate the development of fast breeder reactors, SO_2 control techniques, coal gasification and liquefaction, and several other energy conversion techniques up to the bio-energy. Furthermore the program includes the development of leasing provisions for geothermal fields and shale oil resources and the acceleration of gas lease sales on the Outer Continental Shelf, steps that are intended to increase the availability of fuels which are or will be in short supply. The balance for the program outlined in the energy messages of the Government includes programs to utilize energy more wisely and specifies increased insulation requirements in Federal Housing Administration standards for federally insured homes. Increasing attention is being directed toward individual energy utilizing activities, such as space heating and cooling, to determine how more efficient systems and practices can serve to reduce per capita energy demands. However, the crucial revelation of the past decades is that, put simply, there is a relationship between energy and the environment fundamental to the survival of mankind—energy demand cannot be met by employing technological and economic means if over the long term the finite resources of the environment are consumed in the process. The solution of this problem in which energy, ecology and economy are, as it were, represented as being at the apexes of a triangle requires that human and artificial intelligence be deployed which are available but needs governments to channel their endeavours before it is too late, and to hinder vested interest from deflecting them from their course. In this respect, the USA has assumed a leading role. Subsequent efforts are being undertaken by other governments in industrialized or semi-industrialized countries and it may be of advantage to interchange any experience and know-how in the problematical fields of energy and environment.

A tremendous increase has been seen in renewable energy sources such as wind and solar power throughout the world.[61] The reduction in air pollution by these renewables results directly from the reduction in fossil fuel combustion (see www.refocus.net). Renewables are approaching 2% of the utility mix in some states of the United States. Wind parks, both on- and offshore can generate many megawatts with large wind turbines producing power on the order of one MW each.[62]

ENVIRONMENTAL ASSESSMENTS AND RELATED IMPACTS

BACKGROUND

This author has previously written on the subject of environmental assessment by outlining its typical content requirements, as well as the types of expertise that are required in the preparation of an Environmental Impact Statement(EIS). The author has also discussed some of the problems associated with the EIS process and has provided some suggestions in improving the quality of EIS documents. This paper examines the role of the EIS at the project level, where ultimately, most decisions of project approvals or denials are made in the 1990s by municipal reviewers rather than by state or federal agencies.

INTRODUCTION

With the advent of the National Environmental Policy Act (i.e., NEPA) in 1969, the requirements for environmental impact reporting was originally restricted by the Act to Federal projects, or projects subsidized in whole or in part by Federal funding. Since NEPA, many states and municipalities have developed their own environmental impact requirements to aid in the review of projects under their jurisdiction. As a result of the above evaluation, which has coincided with a general decentralization of power under the Reagan administration, the approval or denial of proposals often rest with local review of the environmental impacts of the specific project regardless of its funding source (i.e., public or private). The evolution of ultimate decision-making at the local level is inevitable when one considers that the most potentially noxious sitings (e.g., nuclear power plants, resource recovery facilities, airports, etc.) would be accepted more critically by municipalities serving as potential host communities than by state or federal entities. Since environmental standards promulgated at the federal and state levels can be adopted or be made more restrictive at the municipal level, the opportunity presents itself for municipalities to utilize local environmental impact ordinances to tightly regulate land-use development within their boundaries. Even in cases where states have the power to "force" sitings in municipalities in order to insure the health and well being of all its constituents, most have tried, for political reasons, to justify their positions through an environmental review process, which, in many cases, has caused extensive delays and/or total abandonment of such sitings. As such, the preparation and presentation of environmental impact statements at the municipal level have often become the most critical element in the consideration and fate of many development projects.

VARIATION IN EIS REPORTING AT THE MUNICIPAL LEVEL

The quality of EIS reporting at the municipal level often exhibits tremendous variations for one or more of the following reasons:

1) The expectations of municipalities relating to EIS documentation varies from it merely being a formality with the application process to the document being a pivotal component in the approval or denial of the project. In municipalities where growth is encouraged and variances to the zone plane are given consideration with regularity, the environmental impact statement requirements may be minimal. In contrast, in municipalities which practice "no-growth" policies and/or rigidly protect their zone plan, the review and critique of the EIS often is used as a weapon for denial or delay of applications.
2) The assessment ordinances, as promulgated, often allow too much subjective interpretation insofar as EIS preparation is concerned. Examples are as follows:

   a. Normally there are no regulations specified for the preparers of component portions of the EIS to be identified or to provide their credentials pertinent to the sections they have prepared.
   b. There generally are no guidelines to provide the applicant with information as to the extent of documentation required to deem an EIS "complete" for submission purposes.
   c. Specific environmental quality standards to be maintained are often either not specified in the ordinances, or are written in qualitative rather than quantitative terms. This encourages assessors to respond to environmental issues in qualitative terms rather than to conduct proper monitoring programs to establish baseline data, project thereon the added impact of the

proposal, and assess resultant values versus existing quantitative standards. The latter approach is clearly a meaningful measure of determining environmental conditions.

d. Most municipalities do not have detailed baseline data available in such environmental categories as ambient noise, air and water quality levels. This condition makes it difficult and expensive for the applicant to obtain a reliable data base, and helps create the huge variation in real data presentation found in impact statements.

e. Often distinction is not provided in the assessment requirements for projects of vastly varying magnitudes of scale and sensitivity. This generally results in unnecessary detail provided in small projects, and insufficient detail provided in more complex proposals.

Because of the subjectivity noted above in attempting to "adequately" respond to many municipal environmental ordinances, many applicants are reluctant to commit sufficient funds to insure the preparation of a comprehensive assessment. As such, impact statement preparers may indirectly be encouraged to prepare statements hastily in order to accelerate the application process. Unfortunately, and perhaps unfairly, this can appear to be a reflection on the assessment preparer rather than on the process itself, which may help to foster inadequate responses.

SUGGESTED METHODOLOGIES FOR PROVIDING APPROPRIATE EIS DOCUMENTATION AT THE MUNICIPAL HEARINGS

In order to resolve some of the aforementioned difficulties encountered when attempting to prepare an appropriate EIS, the following suggestions are offered:

1) The statement preparer should confer early in the process with the client and all the other professionals involved to develop a scope of services needed to prepare an adequate assessment *independent* of the ordinance requirements. The scope should include the professionals needed, the developed and generated data required, the respective environmental quality standards which exist, and the general adversities that will have to be mitigated if the proposal is to be approved.
2) The scope of effort should clearly reflect the magnitude of the project, and should concentrate on critical environmental issues associated with the project.
3) The assessment specialist should meet early in the application process with the individuals, e.g., Township Engineer, Environmental Consultant, and Environmental Commission members who will be directly involved with the review of the assessment. These individuals should be questioned as to their specific areas of concern, which, in turn, will generate more comprehensive analyses in the EIS. The reviewers may also be helpful in citing other documents, reports, etc., known to the Township, which may be useful reference materials for the EIS preparer.
4) After the EIS is completed, the reviewers should be provided copies well in advance of the formal hearing on the application. Hopefully, any questions, differences, etc., can be resolved prior to the hearing. Although this approach won't always be agreed to by the reviewers, it will establish a good faith effort by the applicant to communicate and resolve differences with the assessment reviewers.

It should be appreciated that not all applications are approved, and further, that assessments can be used (properly or improperly) as the main reason to reject an application. Because of this fact, it is most important that the EIS be well written and well documented such that it can prevail, if needed, in an appeal situation where more objective review may be involved. In essence, a good report should ultimately stand the test of objective critical review even if that situation never occurs.

GENERAL GUIDELINES FOR PREPARING AND PRESENTING ENVIRONMENTAL IMPACT STATEMENTS AT THE PROJECT (MUNICIPAL) LEVEL

Practice in the preparation of EISs at the project level has generally focused on addressing the inventory, impacts, mitigations provided, and potential alternatives to the project including the so-called "no build" alternative. In addition, most EISs do not include a traffic or planning analysis as these documents are normally prepared separately by traffic and planning consultants. Generally, the concept of "no build" in an EIS prepared for a project is not a realistic consideration when one is hired specifically to defend a particular application. Furthermore, applicants desirous of receiving approvals for a specific development plan on a particular site normally are not seriously interested in any other permitted or conditional use alternatives allowed in the zoning regulations of the affected jurisdiction. As such, EISs are usually prepared and reviewed basically as a go or no-go situation for a specified development plan.

Regarding the levels of sophistication required in the preparation of an EIS, it generally is a function of two factors, namely, the scale (i.e., magnitude) and sensitivity of the project and the anticipated formal opposition to the project. While theoretically, the level of effort required in an EIS should be independent of the extent and nature of the opposition, one must recognize that additional care in the preparation is crucial when the statement can be expected to stand the test of extreme scrutiny by individuals dedicated to defeating the project by attacking and/or discrediting portions of the EIS.

Lastly, it should be appreciated that even if no expected opposition to a project may arise, one should prepare a document to the extent that the preparer can feel professionally comfortable with the report findings and could testify with confidence on same under the potential of cross-examination.

PACKAGING AND DELIVERY OF THE EIS

The packaging of the EIS generally resides with one individual who may have written the entire EIS or may have prepared it in concert with other professionals. The packager must be well versed in all discipline areas involved in the EIS to be able to edit the entire report and blend it into a cohesive document for presentation purposes. The document should contain an executive summary at the beginning of the report to provide an overview of the scope of work and the pertinent findings in the EIS.

PERSONNEL INVOLVED IN EIS PRESENTATION

Project level EIS preparation and presentation will require at the minimum a site engineer, a traffic engineer, an architect, a planner, an attorney, and an environmental engineer well versed in the management and development of EISs. Depending upon the specific project and its relative complexities, it may be wise to call upon other professionals with varied backgrounds in such disciplines as zoology, botany, archeology, hydrology, noise and air quality assessment, fiscal impact analysis, socioeconomics, etc., who may have to prepare sections of the EIS and defend and/or support the project in the above environmental areas.

Since these experts and their findings may well determine the viability of the project, it is important that the credentials of these experts be recognized and respected at least in the regions in which the development is proposed.

PRESENTATION OF THE EIS TO THE PUBLIC

The EIS should be viewed as a mechanism for "selling" the proposal in question, and the capability of the presentors involved in the public hearing process can greatly affect the acceptance or rejection of the project.

The presentation should include the purpose of the EIS, the nature of the study undertaken, basic findings from the study including any unavoidable adverse impacts found, and methods to be employed to mitigate the impacts. Often, the overall findings of the EIS can be communicated to the municipal reviewers by the person responsible in charge of managing and packaging the EIS.

In an adversarial situation where opposing expert witnesses are anticipated as well as cross-examination by an attorney(s), it may be prudent for the applicant to have the individual experts describe their specific contributions in the EIS document to establish a proper record. In such instances, it is wise for the attorney of the applicant to review the testimony of the respective witnesses well before the public hearing so that the presentation can be cohesive and effective. Each witness should describe the inventory study conducted, the projections of changes resulting from the project, comparisons of same (where applicable) to related environmental standards, resultant beneficial and/or adverse impacts generated if the proposal is constructed and operated, and mitigations suggested and/or incorporated to alleviate or minimize adverse impacts to acceptable levels.

Because EIS documents normally must be defended at public hearings, it is important that the witnesses have good written and oral skills, and are well versed in expert testimony proceedings.

The use of visual or summary materials is effective for public presentations in that audiences generally can follow visual material more closely than solely listening to speakers. At times, hand-outs may be useful to highlight findings. The visual material often aids speakers in the "flow" of information they will be presenting through the presentation of key headings and/or issues. It is helpful to have another individual objectively critique the visual material prior to presentation at the formal hearings for purposes of interpreting the effectiveness of the material.

THE NOMINAL GROUP TECHNIQUE

The Nominal Group Technique is a methodology used for site selections which incorporates a quantitative means for differentiating between alternative sites considered based upon a weighting and scoring system of environmental factors associated with each alternative. Although quantitative decision-making models have been utilized in environmental assessment reporting since the advent of NEPA, the Nominal Group Technique is unique in that it places the decision-making in site selection on a nominal group of citizens, usually appointed by municipal officials, who reside in the areas that may be ultimately impacted by the site selection process. After the consultants have removed potential sites from consideration based upon generally recognized exclusionary criteria (such as wetlands, floodplains, archeologically significant sites, conservation areas, farmland preservation districts, etc.), the nominal group, with guidance from the environmental consulting firm preparing the environmental impact report will generally perform the following functions in the process:

1. Develop a list of environmental factors that they collectively deem pertinent in the site selection process.
2. Develop a relative weighting of importance of each of the environmental factors noted above. The weighting is normally based upon some arbitrary scale (e.g., 0 to 100 with 100 being of greatest significance and zero indicating no significance). Each member provides a weighting figure for each environmental factor considered, and a weighted average value is determined for

each of the factors involved. Typical environmental impact studies may include of the order of 25 to 35 different environmental factors for consideration.

3. Once the environmental factors are determined by the nominal group, the consulting group generally develops criteria for the nominal group to aid them in weighting the impact of each environmental factor involved for the sites in question so that the nominal group can "score" each of the sites involved.

For example, assume that the nominal group considered noise as a factor in the siting of an airport, and further, they judged that noise impacts should have an importance weighting of 87 (out of 100).

In order to assess the impacts of sound generation from a proposed airport on the potential sites to be considered, the consulting group would review the demographics and housing characteristics of the sites under consideration and develop scoring criteria which is applied to all sites such as in the following example:

SCORING LEVEL:	SOUND LEVEL CONDITIONS
0 points	—no dwelling unit within 2 miles of the proposed airport boundaries.
1 point	—less than 5 dwelling units within 2 miles of the proposed airport boundaries.
2 points	—between 6 and 25 dwelling units within 2 miles of the proposed airport boundaries.
3 points	—between 26 and 75 dwelling units within 2 miles of the proposed airport boundaries.
4 points	—greater than 75 dwelling units within 2 miles of the proposed airport boundaries.

As such, if the area surrounding a particular site in question had between 6 and 25 dwelling units within 2 miles of the airport boundaries, it would achieve a score of 87 × 2, or 174 points for the factor of noise, whereas, if it had no dwelling units within 2 miles, it would obtain a score of 87 × 0, or zero points for the factor of noise. For this system scoring approach, the higher the point value accrued for the sites would indicate the sites most environmentally sensitive to impacts resulting from a proposed airport.

Each environmental factor would be scored by the nominal group in a fashion as noted above, and the cumulative score for each site would be tallied and the sites ranked accordingly in terms of the least to the greatest sensitivity to the proposal.

In order to insure the integrity of the nominal group (i.e., to avoid potential conflicts of interest in their voting behavior), the sites they would be scoring would be "masked" so that they would not be able to identify the sites in question from the data provided to them by the consulting groups.

Normally, professionals from the consulting group are available to the nominal group to respond to any technical questions the group might have in formulating their numerical evaluations in the process. Also, in general, a series of rounds of voting would be utilized until the nominal group felt that they had reached a consensus.

Use of the Nominal Group Technique methodology for site selection purposes has the following recognized benefits:

- It provides a resultant site or sites for ultimate selection purposes which is determined on a quantitative basis.
- The nominal group members are unbiased in that they do not know the sites they are evaluating during the site selection process.
- The process is democratic, and interactive sessions between members allows for interchange and stability of the process.
- The group members are the decision makers rather than the consultants and, as such, they (i.e., the public) govern their own destiny in the site selection process.

The Nominal Group process is an excellent tool for consultants and/or County or State Agencies, in applications which face strong opposition, to provide the burden of decision-making on the Nominal Group Committee.

The effectiveness of the Nominal Group Technique Method in the site selection process is related to the following factors:

- The size of the nominal group.
- The credentials of the nominal group to conduct assessments.
- The method of selection of the nominal group members.
- The charge given to the group before and during the site selection processes.
- The role of the group and their involvement (if any) in selecting exclusionary criteria.
- The basis utilized for weighting the environmental issues considered by the group members.
- The basis utilized for scoring each of the issues considered by the group members.
- The analysis and interpretation of the data received from the process and its related statistical significance.

Depending upon how the above issues are handled in a particular study, the results can range from excellent to ridiculous, and the Nominal Group Members can play roles ranging from enlightened decision-makers to manipulated individuals who serve solely to justify a site selection at the conclusion of the process.

POTENTIAL FLAWS IN IMPLEMENTATION OF THE NOMINAL GROUP TECHNIQUE APPROACH

One must be careful in the implementation of the Nominal Group Technique not to allow for flaws in the process which can ultimately be utilized by astute objectors to defeat the proposal. Once the validity of the process can be critically questioned, the Nominal Group Technique, in itself, can prove to be the death knell of the study.

Some of the flaws noted in studies previously reviewed and critiqued by this author which utilized the Nominal Group Technique are as follows:

- The nominal group members may not be asked to participate in developing exclusionary criteria to initially exclude some sites.
- The nominal group size varied from five (5) members to twelve (12) members for three major studies reviewed by this author. One can seriously question the statistical significance of the findings of such a sample of respondents.
- Environmental criteria and nominal group members were changed in one study as it proceeded to reduce the number of feasible sites in the staged process. The problem which occurs is that with inconsistent evaluation criteria and evaluators, different final conclusions regarding site selection may be drawn depending upon when the various criteria and evaluators entered into the process.
- As nominal group members vote through a series of rounds in order to arrive at a "consensus" in the process, a reasonable consistency in the voting pattern through each round for each individual group member should be fairly evident. Major shifting in the voting posture of group members suggests a lack of understanding and knowledge of the issues in evaluating the sites, which places resultant findings into serious question.
- When weighing each site for each environmental factor considered, the point system used to differentiate between sites must be sensitive enough for evaluators to recognize distinct differences between the sites. If such sensitivity cannot be established, the quality of the resultant scores can be questioned. Generally, sensitivity can be achieved if and only if the consultants have thoroughly reviewed each site in question to establish meaningful criteria for nominal group members to vote upon.

Because of common flaws as noted above, it would be relatively easy for people well versed in the impact assessment process to either stop or seriously delay a project.

POSSIBLE STEPS TO ENHANCE THE SUCCESS OF UTILIZING THE NOMINAL GROUP TECHNIQUE IN ASSESSMENT REPORTING

Steps which may be taken to increase the probability of successful outcomes (i.e., sitings) utilizing the Nominal Group Technique approach are as follows:

1. Utilize a statistically significant sample of nominal group members to insure that potential errors in site selection can't be attributed solely to sample size.
2. Use a consistent nominal group with consistent criteria throughout the entire evaluation process.
3. Screen candidates to ensure that they have sufficient knowledge of the proposal and related impacts associated therewith to make credible value judgments.
4. Nominal group members should participate in the selection of exclusionary criteria which will be used to eliminate sites at the beginning of the process.
5. Provide the environmental consultants with responsibility for the project with sufficient time and budget to reasonably develop criteria for each environmental factor considered by the nominal group for the group to differentiate between the subject sites.

Although the above steps will not insure the acceptance of the proposals in question, it will enhance the probability of success and it will not detract from the potential benefits of utilizing the Nominal Group Technique approach in environmental impact analyses.

Since the early 1970s, the concept of the wetlands and the resultant need for wetlands delineation in the United States has become a paramount issue in site development and related assessment reporting. Parcels which are characterized as wetlands are normally deemed so on the basis of their soil strata, their relatively shallow depth to seasonal high groundwater table and by the nature of the vegetation that they will be able to sustain. If a parcel is deemed a wetland (which is a somewhat subjective approach usually negotiated in the field by engineers and botanists representing the applicants and the review agencies), buffers must also be established beyond the delineated wetlands based on the "quality" of the wetlands.

In densely populated areas, where prime developable land is often scarce, the potential for encountering wetlands on a site is a distinct possibility. From a site development standpoint, it is incumbent that a wetlands delineation survey be conducted initially by competent professionals to assess the potential loss of site acreage. This approach should also be considered by potential developers prior to purchasing or taking an option to purchase a site. Too often, this author has witnessed applications well into the review process which are either withdrawn or are no longer economically feasible to construct because of subsequent findings of wetlands on the site. This often leads to time consuming and costly litigation between applicants and their design professionals.

The analysis of traffic-induced noise and air quality impacts in environmental assessment reporting has been conducted in most reports since the passage of NEPA. Normally, many attendees at public hearings are confused about the logarithmic nature of decibel levels (the standard noise descriptor) and how multiple sources of sound are added in terms of decibels. In addition, they generally do not have the technical background to assess results generated from noise and air pollution mathematical models often employed by professionals preparing assessments. However, the public, over the last thirty years, have demonstrated an increasing tendency to voice more concerns at hearings related to noise and air quality issues, and quality of life issues as a whole.

In addition, because traffic noise generation by vehicles on public highways, and rail and aviation noise generation are not normally regulated by municipalities, and further, because the agencies which regulate rail and aircraft noise have less stringent or no standards of compliance at residential property lines (or properties in the case of aircraft) compared to typical municipal noise ordinances, noise generation from these sources is being challenged more often by the public.

In populated and well developed communities, the remaining parcels to be developed are often situated in close proximity to rail lines, airports and heavily traveled highways. Lastly, society is trending toward greater longevity, and noise and air pollution more adversely affect senior citizens than the rest of the general population. As such, credible assessment reporting in the disciplines of noise and air quality, as well as providing meaningful mitigation techniques in site design and orientation for residential applications proposed in proximity to major potential noise and air quality generators are critical for one to be successful in convincing an often cynical public.

Lastly, the air quality standards promulgated for mobile source (i.e., traffic) pollutants in the Clean Air Act of 1970, with the exception of ozone (which is generated about equally by mobile and stationary air pollution sources) have remained unchanged, yet most urban areas, where air pollution generation is normally at the highest levels, have remained in compliance over the period in question. This has occurred despite a major increase in driver registration and vehicular miles traveled on US highways since 1970, due in major parts to technological advances (e.g., catalytic mufflers since the mid 70s, which have reduced vehicular emissions to offset population growth. However, in the United States in the near future, we will be challenged with the need to find alternative fuel sources for vehicles which generate less air pollutants if we are to remain in compliance with the Ambient Air Quality Standards promulgated in 1970 for mobile source pollutants.

In summary, issues such as wetlands delineation, air pollution and traffic-induced noise must be given serious attention in assessment reporting for applications to be approved by reviewing bodies. Increased public awareness on how effectively to critique decision-making methodologies and basic assumptions associated with mathematical models employed in conjunction with assessment preparation is placing an increased burden to defend properly their application in the reporting process.

RISK ASSESSMENT REPORTING AND ASSOCIATED STRATEGIES

If an application involves a project which can (or may) be deemed as a potential threat to life, limb or property resulting from its construction and/or operation, reviewing agencies will normally require a risk assessment to be prepared in addition to an environmental assessment. The function of a risk assessment is to quantify (where possible) the risk of death, injury and potential loss of personal property associated with the worst-case scenarios that can be perceived occurring on the subject site. Typically, risk assessors are to prepare their assessment utilizing the principle of Murphy's Law that "all that can go wrong, will!" All aspects of the operation on the site, including transportation, handling, storing, processing of the product involved and related by-product generation and disposal must be considered, and probabilities of risk quantified (based upon industry practice and history) for each phase of the operation on an annual basis.

For all aspects of risk considered, one assesses the so-called "safe separation distance" (SSD) from the site should a particular failure mode occur either on the site or by transmission from the site (e.g., vapor dispersion of a product or by-product). If potential sensitive receptors are located within the SSD, then those cumulative risks from all potential modes associated with the site in question must be quantified. For parcels located beyond the SSD, the risks are considered negligible.

Once a potential risk is quantified for a particular site, mitigations to the risk can be investigated, based on the proposed implementation of mitigating factors for the subject site and the historical value based on industrial experience related to their effectiveness in reducing risk. Examples of mitigating factors may include the following: availability of fire-fighting capability on the site or within a short distance of the site, accident history of the particular company involved, training of personnel on site, etc. Generally, a value between 0 and 1 is assessed for each mitigating factor, which is then multiplied by the cumulative risk probability for the proposal. This, in essence, produces a reduced probability of risk.

The risks associated with the proposal are typically compared to the "normal risk" to which individuals are subjected in conducting their daily lives. To develop such a perspective, published annual fatality statistics due to accidents (vehicular, aircraft, drowning, lightning, electrocution, falls, etc.) are available from all industrialized nations which, based on total population statistics, can be normalized to a probability of fatality per year basis for the general population. Utilizing the above information, a risk assessment can then compare the risks associated with functioning daily as opposed to the risk associated with living in proximity to a proposed development with a perceived and quantified risk.

The purpose of the above comparisons is to provide decision-makers with a quantitative means to evaluate the risks associated with a proposal with its potential for impact on the quality of life of individuals who would be living in close proximity to the site. Although any application will provide some increased risk to the general public (which will normally create a negative response), the *relative* risk compared to the daily risk to which one is normally subjected provides reviewers with an added tool upon which to render an informed decision. Lastly, it is not the role of a risk assessment preparer to try to convince the public to accept a particular project! Rather, the burden is to provide sufficient quantitative information for decision makers to render an informed decision on a difficult application which will generally be viewed with anxiety by neighboring residents.

FORENSIC ENGINEERING REPORTING AND ASSOCIATED STRATEGIES

In certain situations, environmental engineers normally engaged in environmental and/or risk assessment reporting may be approached to conduct forensic engineering studies.

Forensic engineers are generally involved in providing technical support and, perhaps, expert testimony for attorneys representing plaintiffs or defendants in civil claims wherein a plaintiff has been killed or injured allegedly due, in part, to one or more defendants. Attorneys representing plaintiffs or their estate in cases of the death of the plaintiff generally accept cases on the basis of contingency (i.e., they collect a fee for service only either through a settlement out of court or by winning the court case), whereas defendants are represented by attorneys they retained directly or attorneys representing insurance companies who insure the defendant (which is typical for small businesses and/or corporations).

Environmental engineers operating in the forensics area for a plaintiff will generally be asked to prepare a report which supports the claims of an attorney representing a plaintiff versus one or more defendants. Engineers representing a defendant will be asked to review the plaintiff's expert(s) reports and to prepare a report which can either totally or partially discount claims by the opposing expert(s) against the defendant.

Forensic engineering studies are unique compared to environmental or risk assessments in that claims are often introduced after the occurrence of the incident which precipitated the case. As such, forensic engineers normally must digest a volume of paperwork regarding the incident itself, as well as reports and interrogatories that may have been responded to by parties with knowledge of the incident, or other professionals (i.e., physicians, psychologists, etc.) who have been asked to present their expert opinions on the case. Forensic engineers additionally will normally perform site visits, speak to parties of interest, and perform technical analyses (where appropriate) in support of preparation of their expert report.

Environmental and risk impact report preparers will invariably be required to also provide expert testimony before municipal, state or federal hearing Officers to defend their document and related findings as a part of a process to secure approvals to construct and operate a structure(s). In forensic engineering investigations, at least in the United States, it has been the author's experience (as well as others in the discipline with whom he has consulted) that only about 10% of the cases ever go to trial. The remaining 90% of the cases are settled out of court. The reasons for this may be explained by some or all of the following.

The plaintiff's attorney is paid only on contingency and will often try to avoid the risk of a lengthy trial by accepting a settlement out of court. In major cases, defendants are usually defended by insurers who would prefer to make a settlement payout as a "nuisance" value rather than pay attorneys to prepare and be involved in a lengthy court case.

Because technical experts are generally required to "reconstruct" events which occurred years before they were retained and because many of the parties of interest in the case cannot be contacted due to death, illness, change of address, etc., the resultant expert reports are more subject to scrutiny and question than when one is reporting on current situations. As such, attorneys for both plaintiffs and defendants may be more concerned about the abilities of their experts to defend their positions under intense cross examinations by opposing lawyers. Civil cases are generally heard and decisions rendered by a jury, and both sides consider this to be a difficult body "to read" and select on the jury, particularly, when cases involve issues and arguments which are highly technical in nature. As a result, the technical reports prepared by the respective forensic engineers representing the plaintiff and defendant are often the key determinant in the amount of settlement award that will ultimately be agreed upon by both sides.

Environmental engineers who wish to pursue employment in the field of forensic engineering can best accomplish this by informing injury litigators and/or insurance companies of their interest.

ENVIRONMENTAL EDUCATION

The broad field of environmental science and engineering is truly interdisciplinary in nature and any discussion of environmental education must address the many facets and levels of this topic. Is the effort to increase understanding and respect for one's surroundings? This might well begin in the primary school and extend to the post secondary level. Is the intent to produce a practicing professional in one or more of the fields which comprise environmental science and engineering? This involves undergraduate and, possibly, graduate work. The discussion presented here will deal with practicioners. Practicioners will mean scientists, engineers, managers, planners, policy makers, environmental lawyers, etc. 'Etc.' is used because almost every human action will affect the environment and it is not possible to restrict the disciplines. The fundamental breakdown of environmental effort might be public health, conservation and resource management but even this classification is too simplistic.

The education must be quite broad. It has been said that a technician knows everything about the job except its place in the universe. One cannot be certain that the first position after graduation will last until retirement. A broad background gives greater flexibility. Although a topic may be 'hot' (newsworthy) at the moment, one may be certain that equally serious and sensational problems will arise during the working life of the student. While concentration can be in one or more of many areas, an environmental scientist or engineer must have more than superficial knowledge of physics, chemistry, biology and microbiology. (Odum defines ecology as 'environmental biology'). Meteorology, oceanography, geology, geography and hydraulics will be important as will be fundamentals of non-ideological economics. Mathematics should be carried to a fairly high level, particularly statistics. Knowledge of local, national and international statutes and regulations will be applied constantly. An awareness of politics will be *very* important. Public health practice and the fundamentals of conservation should be studied. Computer literacy will be necessary. It is very important that written and oral communications skills be developed. The world is becoming ever smaller and competence in one or more foreign languages will be valuable. In addition to the scientific and cultural subjects just mentioned, an engineering student will study the specialized parts of that particular field of applied science. One is, in essence, becoming a well-rounded person in a broad discipline. It will be concluded that there is simply too much material to compress into a four-year course of study. This is correct and graduate study will be necessary in the majority of cases.

The preceding brief discussion is meant as an introduction to the reader of the many disciplines which might well be involved in education leading to careers in environmental science or environmental engineering. One final observation should be offered. When entering upon one's post secondary education there will be pressure pushing the student toward currently fashionable fields. Such a course should be resisted. One can expect to work on the order of forty years after the terminal degree and it is wise to follow a field in which one has developed an interest and can expect to be satisfied.

ENVIRONMENTAL HEALTH

INTRODUCTION[†]

Definitions

"Environmental Health" encompasses what is also known as environmental engineering and sanitation, public health engineering, and sanitary engineering. It is concerned with "the control of all those factors in man's physical environment which exericise or may exercise a deleterious effect on his physical development, health and survival,"[1] with consideration of the physical, economic and social[‡] impact of the control measures applied. Included is the application of engineering principles to the control, modification or adaptation of the physical, chemical, and biological factors of the environment in the interest of man's health, comfort, and social well-being. The concern is not merely with simple survival and prevention of disease and poisoning, although even these are not entirely under control. In addition, environmental health involves the maintenance of an environment that is suited to man's efficient performance, and to the preservation of comfort and enjoyment of living today and in the future.[2,3]

The environment is defined as the sum of all external influences and conditions affecting life and the development of an organism. The Committee on Environment of the American Public Health Association goes a step further and says that "The Environment is considered the surroundings in which man lives, works and plays. It encompasses the air he breathes, the water he drinks, the food he consumes and the shelter he provides for his protection against the elements. It also includes the pollutants, waste materials, and other deterimental environmental factors which adversely affect his life and health."[4]

Scope

It is apparent from the above that the field of environmental health covers an extremely broad area of man's universe. The World Health Organization, the American Public Health Association, and others have suggested what the scope should be and how the programs should be administered. In all instances, a totality is envisioned with consideration of the impact of man on the environment and the impact of the environment on man, with a balanced appraisal and allocation of available resources to both.

A report of a WHO expert Committee[5] considers the scope of environmental health to include or relate to the following:

1) Water supplies, with special reference to the provision of adequate quantities of safe water that are readily accessible to the user, and to the planning, design, management, and sanitary surveillance of community water supplies, giving due consideration to other essential uses of water resources.
2) Wastewater treatment and water-pollution control, including the collection, treatment, and disposal of domestic sewage and other waterborne wastes, and the control of the quality of surface water (including the sea) and ground water.
3) Solid-waste management, including sanitary handling and disposal.
4) Vector control, including the control of arthropods, molluscs, rodents, and other alternative hosts of disease.
5) Prevention or control of soil pollution by human excreta and by substances detrimental to human, animal, or plant life.
6) Food hygiene, including milk hygiene.
7) Control of air pollution.
8) Radiation control.
9) Occupational health, in particular the control of physical, chemical, and biological hazards.
10) Noise control.
11) Housing and its immediate environment, in particular the public health aspects of residential, public, and institutional buildings.
12) Urban and regional planning.
13) Environmental health aspects of air, sea, or land transport.
14) Accident prevention.
15) Public recreation and tourism, in particular the environmental health aspects of public beaches, swimming pools, camping sites, etc.
16) Sanitation measures associated with epidemics, emergencies, disasters, and migrations of populations.
17) Preventive measures required to ensure that the general environment is free from risk to health.

[†] This chapter is based on material which appears in a book by the author entitled *Environmental Engineering and Sanitation*, John Wiley & Sons, Inc., New York, NY, 1972.

[‡] Includes political, cultural, educational, biological, medical, and public health.

The APHA Committee on Environment[4] proposed the following program areas and also the planning considerations, and methods to implement programs.

Environmental Program Area

Wastes

1) Air
2) Sewage and liquid
3) Solid

Water Supply
Housing and Residential Environment
Food and Drugs
Radiation
Noise
Accidents
Occupational and Institutional Hazards
Vectors
Recreation

Planning Considerations

Health
Economic
Demographic and Land Use
Social
Esthetic
Resource Conservation
(Also manpower, facilities, and services.)

Methods and Technics

Research
Demonstration
Education
Standards
Legislation
Inspection
Enforcement
Planning
Evaluation
Incentives
Systems Analysis

The discussions that follow will briefly review and introduce some of the major program areas listed above. Detailed treatment of some of the subject matter can be found in other chapters of this Encyclopedia.

ENVIRONMENTAL HEALTH AND ENGINEERING PLANNING

The Principle of the Total Environment

The central community or city is dependent upon the surrounding areas for its human resources and its economic survival. The surrounding areas are dependent in whole or in part on the central community or city for employment, cultural and other needs. Increasing urbanization is erasing the boundary between the two except for the governmental jurisdictions involved and even these are being blended. The health, welfare, library, police, transportation, recreation, drainage, water, sewerage, and superimposed school systems are examples of combined services now provided in some areas. It is self-evident that regional problems require regional solutions even though operationally individual control may be temporarily required as a political expedient until mutual confidence is established between adjoining governmental units. This emphasizes however the necessity of interim comprehensive planning so that adjoining governmental units may capitalize on improvements and services provided to the long term mutual benefit of their residents. For no one lives in a vacuum and the interdependency of governmental units must be recognized as a fact of life.

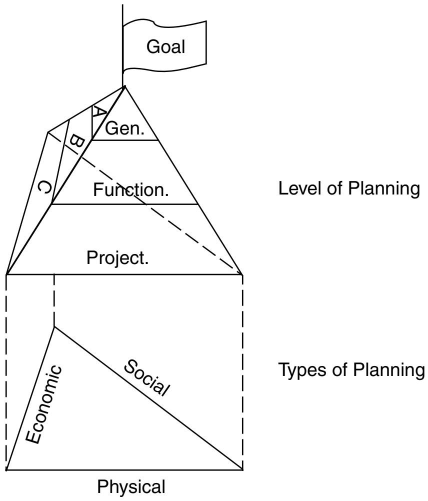

FIGURE 1 Types and levels of planning. (Applicable to National, State, Regional and Local planning.) From Joseph A. Salvato, Jr., *Environmental Engineering and Sanitation,* John Wiley & Sons, Inc., New York, NY, 1972.

Planning and the Planning Process

It is important that environmental health and engineering planning take place within the context of comprehensive regional or area wide planning. It is equally important however that comprehensive community planning fully recognize the environmental health and engineering functions and needs of the area. As used here, the term planning means the systematic process by which goals (policies) are established, facts are gathered and analyzed, alternative proposals and programs are considered and compared, resources are measured, priorities are established, and recommendations are made for the deployment of resources designed to achieve the established goals.[6]

There are many types and levels of planning for the future ranging from family planning to national planning for survival. Figure 1 shows three different types of planning and three different levels of planning. These are all interdependent.

A. *General, Overall Policy Planning*—Identification of goals, aspirations and realistic objectives. Establishment of functional priorities.
B. *Functional Planning*—Such as for transportation, water supply, wastewater, recreation, air pollution, solid wastes, or medical care facilities in which *alternative functional solutions are presented,* including consideration of the economic, social and ecological factors, advantages and disadvantages.
C. *Project Planning*—Detailed engineering and architectural specific project plans, specifications, drawing and contracts for bidding. Plan of action.

Construction, Operation and Maintenance—Plan adjustment as constructed; updating and planning for alterations and new construction.

Figure 2 gives an example of the *general, overall policy planning process.* It recognizes in the process the environmental health and engineering goals and objectives, considerations, plans, and the implementation programs and devices needed. The next level of planning, depending on the functional priorities established, would be specific functional planning such as for recreation, transportation, sewerage, solid wastes, or environmental health.

Environmental Health and Engineering Planning

Since this chapter deals with environmental health, a report outline for that purpose follows.

1) Letter of transmittal to the contracting agency.
2) Acknowledgments.
3) Table of contents.
    a) List of tables.
    b) List of figures.
4) Findings, conclusions, and recommendations.
5) Purpose and scope.
6) Background data and analysis, as applicable, including base maps, reports, and special studies.
    a) Geography, hydrology, meteorology, geology, and ground water levels.
    b) Population and characteristics, past, present, future, and density.
    c) Soils characteristics; flora and fauna.
    d) Transportation and mobility. Adequacy and effects produced, present and future.
    e) Residential, industrial, commercial, recreational, agricultural, and institutional development and redevelopment.
    f) Land use, present and future; spread of blight and obsolescence; inefficient and desirable land uses.
    g) Drainage, water pollution control, and flood control management.
    h) Water resources, multi-use planning and development with priority to water supply, environmental impact.
    i) Air and water pollution, sewerage, and solid wastes management.
    j) Public utilities and their adequacy—electricity, gas, oil, heat.
    k) Educational and cultural facilities, size, location, effects.
    l) Economic studies—present sources of income, future economic base and balance, labor force, markets, industrial opportunities, retail facilities, stability.
    m) Sociological factors, characteristics, knowledge, attitudes; behavior of the people and their expectations.
    n) Local government and laws, codes ordinances.
    o) Special problems, previous studies and findings, background data.
7) Supplementary background environmental health and engineering information.
    a) Epidemiological survey including mortality, morbidity, births and deaths, and specific incidence of diseases; social, economic, and environmental relationships; also water-, insect-, and food-borne diseases; animal- and animal- related diseases, airborne and air-related diseases, pesticide and chemical poisonings; adequacy of data and programs.
    b) Public water supply, treatment, and distribution including population served, adequacy, operation, quality control, cross-connection control, storage and distribution protection, operator qualifications. For individual systems—population served, special problems, treatment and costs, adequacy, control of well construction.
    c) Waste-water collection, treatment and disposal, adequacy of treatment and collection system, population served, operator qualifications; sewer connection control. For individual systems—population served, special problems, control of installations. Water pollution control.
    d) Solid wastes management—storage, collection, transportation, processing, and disposal; adequacy.
    e) Air resources management and air pollution control including sources, air quality, emission standards, problems and effects, regulation, and control program.
    f) Housing and the residential environment—control of new construction, house conservation

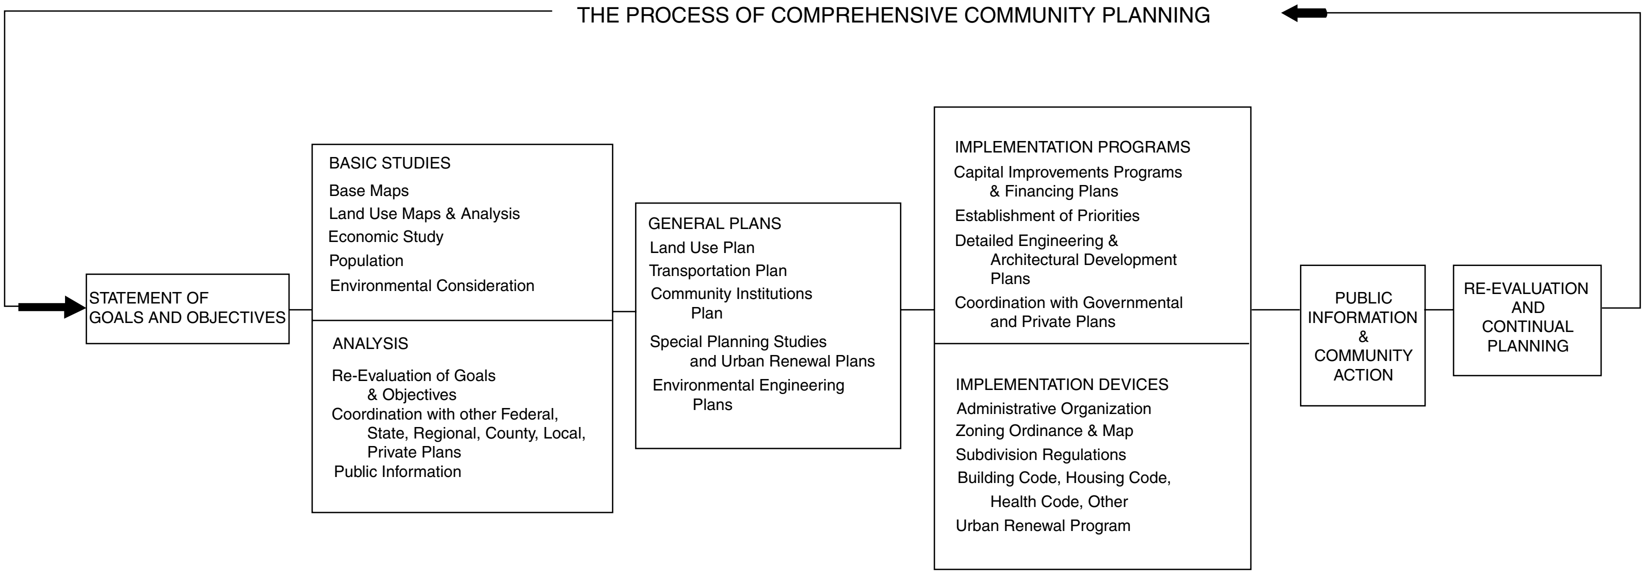

FIGURE 2 An example of the planning process. From Joseph A. Salvato, Jr., “Environmental Health and Community Planning,” *Journal of the Urban Planning and Development Division,* ASCE, Vol. 94, No. UPI, Proc. Paper 6084, August 1968, pp. 22–30.

and rehabilitation, enforcement of housing occupancy and maintenance code, effectiveness of zoning controls, and urban renewal. Realty subdivision and mobile home park development and control, also effect of development on the regional surroundings and effect of the region on the subdivision, including the environmental impact of the subdivision.
   - g) Recreation facilities and open space planning, including suitability of water quality and adequacy of sewerage, solid waste disposal, water supply, food service, rest rooms, safety, and other facilities.
   - h) Food protection program—adequacy from source to point of consumption.
   - i) Nuclear energy development, radioisotope and radiation environmental control including fallout, air, water, food, and land contamination; thermal energy utilization or dissipation, and waste disposal; naturally occurring radioactive materials; air, water, plant, and animal surveillance; federal and state control programs, standards; site selection and environmental impact, plant design and operation control; emergency plans.
   - j) Planning for drainage, flood control, and land use management.
   - k) Public health institutions and adequacy of medical care facilities such as hospitals, nursing homes, public health centers, clinics, mental health centers, rehabilitation centers, service agencies.
   - l) Noise and vibration abatement and control.
   - m) Noxious weed, insect, rodent, and other vermin control, including disease vectors and nuisance arthropods; regulation, control, and surveillance including pesticide use for control of, aquatic and terrestrial plants, and vectors; federal, state, and local programs; and effects of water, recreation, housing, and other land resource development.
   - n) Natural and manmade hazards including safety, slides, earthquakes, brush and forest fires, reservoirs, tides, sand storms, hurricanes, tornadoes, high rainfall, fog and dampness, high winds, gas and high tension transmission lines, storage and disposal of explosive and flammable substances and other hazardous materials.
   - o) Aesthetic considerations, also wooded and scenic areas, prevailing winds, and sunshine.
   - p) Laws, codes, ordinances, rules, and regulations.
   - q) Environmental health and quality protection; adequacy of organization and administration.

8) The comprehensive regional plan.
   - a) Alternative solutions and plans.
   - b) Economic, social, and ecologic evaluation of alternatives.
   - c) The recommended regional plan.
   - d) Site development and reuse plans.

9) Administration and financing.
   - a) Public information.
   - b) Administrative arrangements, management, and costs.
   - c) Financing methods—general obligation bonds, revenue bonds, special assessment bonds; taxes, grants, incentives, federal, and state acid.
   - d) Cost distribution, service charges, and rates. Capital costs—property, equipment, structures, engineering, and legal services; annual costs to repay capital costs, principal and interest, taxes. Regular and special charges and rates.
   - e) Legislation, standards, inspection, and enforcement.
   - f) Evaluation, research, and re-planning.

10) Appendices
   - a) Applicable laws.
   - b) Special data.
   - c) Charts, tables, illustrations.

11) Glossary.
12) References.

HEALTH ASPECTS

Life Expectancy

The life expectancy at birth has varied with time, geography, and with the extent to which available knowledge concerning disease prevention and control could be applied. Table 1 shows the trend in life expectancy with time. The gains in life expectancy between 1900 and 1968 shown in Table 1a have occurred mostly in the early years, 21 years at birth and 15.5 years at age 5, reducing to 4.8 years at age 45 and 2.4 years at age 70. The life expectancy gains are due to better sanitation and nutrition and to the conquest of the major epidemic and infectious diseases including immunization and chemotherapy.

The vital statistics in Table 2 are of interest in that they show the changes in major causes of death in 1900 related to 1960 and the net reduction in total death rate. Table 2a shows the leading causes of death as of 1967. The leveling off that is apparent in the United States is due to our inability thus far to identify the causes and to control the chronic, non-infectious diseases such as heart disease and cancer.

Communicable Disease Control

Although the communicable diseases as causes of death have been largely brought under control in the more advanced countries, this is not the case in the undeveloped areas of the world. Even in the so-called advanced countries, illnesses associated with contaminated drinking water and food are not uncommon.

TABLE 1
Life expectancy at birth

Period or year	Life expectancy
Neanderthal man (50,000 BC–35,000 BC)	29.4[a]
Upper paleolithic (600,000 BC–15,000 BC)	32.4[a]
Mesolithic	31.5[a]
Neolithic anatolia (12,000 BC–10,000 BC)	38.2[a]
Bronze age—Austria	38[a]
Greece classical (700 BC–460 BC)	35[a]
Classical Roman (700 BC–200 AD)	32[a]
Roman empire (27 BC–395 AD)	24
1000	32
England (1276)	48[a]
England (1376–1400)	38[a]
1690	33.5
1800	35
1850	40
1870	40
1880	45
1900	48
1910	50
1920	54
1930	59
1940	63
1950	66
1960	68
1970	71

Note: The 1970 life expectancy reported by the United Nations for Sweden was 71.9 for males and 76.5 for females and for the United States 67.0 for males and 74.2 for females.

[a] E.S. Deevy, Jr., "The Human Population," *Scientific American,* Vol. 203, No. 3, September 1960, p. 200.

Life expectancy figures from 1690 to 1970 are for the United States.

TABLE 1a
Increase in life expectancy between 1900 and 1968 at selected ages[a]

Age	Years added	Age	Years added
0	21	45	4.8
1	15.5	55	3.6
5	12.0	60	3.1
15	10.4	65	2.7
25	8.8	70	2.4
35	6.7	75	2.0

TABLE 2
Selected vital statistics—deaths per 100,000 in the United States

	Death rate for year	
Cause	1900	1950–60
Pneumonia and influenza	202	32
Tuberculosis	195	7
Diphtheria	40	0+
Measles	14	0.2
Diarrhea	110	—
Typhoid	31	0+
Malignant neoplasms	64	150
Cardiovascular and renal diseases	345	520
All causes	1719	934

TABLE 2b
Leading causes of death—deaths per 100,000 population in the United States

Cause	Death rate
Diseases of the heart	364.5
Cancer	157.2
Cerebral hemorrhage (stroke)	102.2
Accidents	57.2
Motor vehicle	26.8
All others	30.4
Pneumonia and influenza	28.8
Certain diseases of early infancy	24.4
Arteriosclerosis	19.0
Diabetes mellitus	17.7
Other diseases of the circulatory system	15.1
Other bronchopulmonic diseases	14.8
Cirrhosis of liver	14.1
Suicide	10.8
Congenital malformations	8.8
Homicide	6.8
Other hypertensive disease	5.6
Other and ill-defined	88.7
Total of all causes	9.537

From U.S. Public Health Service, 1967.

Between 1946 and 1960 a total of 228 waterborne outbreaks with 25,984 cases were reported in the United States.[7] An outbreak in California involving *Salmonella typhimurium* affected an estimated 18,000 persons in a population of 130,000.[8] An explosive epidemic of infectious hepatitis in India with about 29,300 cases of jaundice was attributed to inadequate chlorination and poor operation control.[9]

Sewage normally contains organisms causing various types of diarrhea, dysentery, infectious hepatitis, salmonella infections, and many other illnesses. It becomes obvious that all sewage should be considered presumptively contaminated, beyond any reasonable doubt, with disease producing organisms. The mere exposure of sewage on the surface of the ground, such as from an overflowing cesspool or septic tank system, or its improper treatment and disposal into a stream or lake, immediately sets the stage for possible disease transmission. The means may be a child's ball, the house fly, or ingestion of contaminated water or food. Sanitary safeguards, including adequate water treatment, must therefore be always maintained if the water- and filthborne diseases are to be held in check.

It may appear inconceivable, but there are still many urban areas, as well as suburban areas, in the United States and abroad where the discharge of raw or inadequately treated sewage to roadside ditches and streams is commonplace. Although the disease hazard is ever present, the public pressure for sewage treatment and water pollution abatement stems more from aesthetic, recreational, and related economic considerations rather than from actual disease hazard and transmission. As a matter of fact, a critical reappraisal may be in order to review current expenditures and perhaps achieve a better balance in the allocation of public funds for the public good.

Whereas a safe and adequate water supply is taken for granted by most people in the United States, for about 2 billion people, about two thirds of the world's population, this is still a dream. The availability of any reasonably clean water in less developed areas of the world just to wash and bathe would go a long way toward the reduction of such scourges as scabies and other skin diseases, yaws and trachoma, and the high infant mortality. The lack of a safe water makes commonplace high incidences of shigellosis, amebiasis, schistosomiasis, leptospirosis, infectious hepatitis, typhoid, and paratyphoid.[10]

Between 1923 and 1937 there were an average of 43 milkborne outbreaks with 1724 cases and 47 deaths reported each year in the United States. Between 1938 and 1956 an average of 24 milkborne outbreaks per year with 980 cases and 5 deaths were reported to the U.S. Public Health Service. Between 1957 and 1960 the outbreaks averaged 9 and the cases 151 per year. There were no deaths reported since 1949. The success achieved in the control of milkborne illnesses can be attributed to the practical elimination of the sale of raw milk, greatly improved equipment and to effective control over the pasteurization of milk and milk products.

Whereas milkborne diseases have been brought under control, foodborne illnesses remain unnecessarily high. Between 1938 and 1956 there were reported 4647 outbreaks, 179,773 cases and 439 deaths. In 1967, there were still 273 outbreaks reported with 22,171 cases and 15 deaths. The major bacteria related to foodborne illnesses in recent years (1967–68) are Salmonella, *C. perfringens,* and Staphylococcus. Banquets accounted for over half of the illnesses reported with schools and restaurants making up most of the rest. The largest number of outbreaks occurred in the home.[11]

In addition to waterborne and foodborne diseases, consideration should be given to the environmental related respiratory diseases, the insectborne diseases and zoonoses, and the many miscellaneous diseases. These too must be controlled to the extent possible where indicated. The common cold, encephalitides, malaria, rabies, and disabilities related to air pollution are examples.

More effect must be directed to the total environmental pressures and insults to which the body is subjected. The cumulative body burden of all deleterious substances gaining access to the body through the air, food, drink, and skin must be examined both individually and in combination. The synergistic effects and neutralizing effects must be learned in order that proper preventive measures may be applied. It has been difficult to determine the effects of the presence or absence of certain trace elements in air, water, and food on human health. Some elements such as fluorine for the control of tooth decay, iodine to control goiter, and iron to control iron-deficiency anemia have been recognized as being beneficial in proper amounts. But the action of trace amounts ingested individually and in combination of lead, cadmium zinc, hexavalent chromium, nickel, mercury, manganese, and other chemicals are often insidious. The effects are extended in time to the point where direct relationship with morbidity and mortality is difficult to prove in view of the many possible intervening and confusing factors. Some may even prove to be beneficial.

Mercury

A brief discussion of one of these metals, namely mercury, is of interest. The poisoning associated with (a) the consumption of mercury contaminated fish in Japan between 1953 and 1964; (b) bread made from mercury-contaminated wheat seed in West Pakistan in 1961, in Central Iraq in 1960 and 1965, and in Panorama, Guatemala in 1963 and 1964; (c) pork from hogs fed methylmercury treated seed in Alamogordo, New Mexico; and (d) methylmercury treated seed eaten by birds in Sweden, directed worldwide attention to this problem. The discovery of moderate amounts of mercury in tuna and most fresh water fish, and relatively large amounts in swordfish, by many investigators in 1969 and 1970 tended to further dramatize the problem.[12,13,14]

The organic methylmercury forms of mercury are highly toxic. Depending on the concentration and intake, it can cause unusual weakness, fatigue and apathy followed by neurological disorders. Numbness around the mouth, loss of side vision, poor coordination in speech and gait, tremors of hands, irritability and depression are additional symptoms leading possibly to blindness, paralysis, and death. The mercury also attacks vital organs such as the liver and kidney. It concentrates in the fetus and can cause birth defects.

Mercury has an estimated biological half-life of 70 to 74 days in man, depending on such factors as age, size, and metabolism, and is excreted mostly in the feces at the rate of about one percent per day. Mercury persists in large fish such as pike one to two years.

Mercury is ubiquitous in the environment. The sources are both natural and manmade. Natural sources are leachings and volatilization from mercury containing geological formations. Manmade sources are waste discharges from chloralkali and pulp manufacturing plants, mining, chemical manufacture and formulation, the manufacture of mercury seals and controls, treated seeds, combustion of fossil fuels, fallout, and surface runoff. The mercury ends up in lakes, streams and tidal waters, and in the bottom mud and sludge deposits.

Microorganisms and macroorganisms in water and bottom deposits can transform metallic mercury, inorganic divalent mercury, phenylmercury, and alkoxialkylmercury into methylmercury. The methylmercury thus formed, and perhaps other types, in addition to that discharged in wastewaters, are assimilated and accumulated by aquatic and marine life such as plankton, small fish, and large fish. Alkaline waters tend to favor production of the more volatile dimethylmercury, but acid waters are believed to favor retention of the dimethyl form in the bottom deposits. Under anaerobic conditions, the inorganic mercury ions are precipitated to insoluble mercury sulfide in the presence of hydrogen sulfide. The process of methylation will continue as long as organisms are present and they have access to mercury. The form of mercury in fish has been found to be practically all methylmercury and there is indication that a significant part of the mercury found in eggs and meat is in the form of methylmercury.

The amount of mercury in canned tuna fish has averaged 0.32 ppm, in fresh swordfish 0.93 ppm, in freshwater fish 0.42 ppm (up to 1.4 and 2.0 ppm in a few large fish such as Walleyed Pike), and as high as 8 to 23 ppm in fish taken from heavily contaminated waters. The mercury in urban air has been in the range of 0.02 to 0.2 μg per cu m, in drinking water less than 0.001 ppm, and in rain water about 0.2 to 0.5 ppb (μg/1). Reports from Sweden and Denmark (1967–69) indicate a mercury concentration of 3 to 8 ppb (ng/gm) in pork chops, 9 to 21 ppb in pig's liver, 2 to 5 ppb in beef fillet, 9 to 14 ppb in hen's eggs, and 0.40 to 8.4 ppm in pike.

In view of the potential hazards involved, steps have been taken to provide standards or guidelines for mercury. The maximum allowable concentration for 8 hour occupational exposure has been set at 0.1 mg metallic vapor and inorganic compounds of mercury per cubic meter of air. For organic mercury the threshold limit is 0.01 mg per cu m of air. A maximum allowable steady intake (ADI) of 0.03 mg for a 70 kg man is proposed, which would provide a safety factor of ten. If fish containing 0.5 ppm mercury (the actionable level) were eaten daily, the limit of 0.03 mg would be reached by the daily consumption of 60 gm (about 2 ounces) of fish.[13] The proposed standard for drinking water is 0.002 ppm. A standard for food has not yet been established; 0.05 ppm has been mentioned.

There is no evidence to show that the mercury in the current daily dietary intake has caused any harm, although apparent health does not indicate possible non-detectable effects on brain cells or other tissues. Nevertheless, from a conservative health standpoint, it has been recommended that pregnant women not eat any canned tuna or swordfish. Also implied is caution against the steady eating of large fresh water fish or other large saltwater fish. The general population should probably not eat more than one fish meal per week.

The identification of mercury as coming from manmade and natural sources requires that every effort be made to eliminate mercury discharges to the environment. At the same time the air, drinking water, food, fish, and other wildlife, aquatic plants and animals, surface runoff and leachates, precipitation, surface waters, and man himself should be monitored. This should be done not only for mercury, but also for other potentially toxic and deleterious chemicals. Further research and studies are needed to determine the subtle and actual effects of mercury and other metals, as normally found, on man and his environment.

WATER SUPPLY

A primary requisite for good health is an adequate supply of water that is of satisfactory sanitary quality. It is also important that the water be attractive and palatable to induce its use; for otherwise, water of doubtful quality from some nearby unprotected stream, well or spring may be used. Where a municipal water supply as available, it should be used as such supplies are usually under competent supervision, ample in quantity and also provide fire protection. However, this is not always the case. Because of the excellent water service generally available in the United States, the people and public officials have tended to become complacent and take for granted their water supply. As a result, in some instances, funds have been diverted to other more popular causes rather than to maintenance, opeation, and upgrading of the water supply system.

Status of Water Supply

A survey[15] made by the Public Health Service in 1962 is of interest in pointing out the number and type of public water supplies in the United States and populations served. It was reported that there were 19,236 public water supplies serving approximately 150,000,000 people; 75% were ground water supplies, 18% were surface water supplies, and 7% were a combination. Of significance is the finding that 75,000,000 people in communities under 100,000 population were served by 18,873 public water supplies, and 77,000,000 people in communities over 100,000 were served by 399 public water supplies. Also, of the 19,236 supplies, 85% served communities of 5,000 or less. The information emphasizes the need for giving at least equal attention to small public water supplies as is given to large supplies. In addition, millions of people on vacation in relatively uncontrolled rural environments depend on small water supplies which often are not under close surveillance.

The Public Health Service completed a study in 1970 covering 969 small to large public surface and ground water supply systems serving 18,200,000 persons (12% of the total United States population served by public water supplies) and 84 special systems serving trailer and mobile home parks, institutions, and tourist accommodations.[16] Although the drinking water supplies in the United States rank among the best in the world, the study showed the need for improvements. Based on the 1962 USPHS Drinking Water Standards it was found that in 16% of the 1969 communities surveyed the water quality exceeded one or more of the *mandatory* limits established for coliform organisms (120), fluoride (24), lead (14). It is of interest to note that of the 120 systems that exceeded the coliform standard, 108 served populations of 5,000 or less and that 63 of these were located in a state where disinfection was not frequently practiced or was inadequate. An additional 25% of the systems exceeded the *recommended* limits for iron (96), total dissolved solids (95),

[a] The defined treatment process has little effect on this constituent. (Coagulation, sedimentation, paid rapid filtration and chlorination.)

[+] No concensus on a single numerical value which is applicable throughout the country. See reference.

[b] Microbiological limits are monthly arithmetic averages based upon an adequate number of samples. Total coliform limit may be relaxed if fecal coliform concentration does not exceed the specified limit.

[c] As parathion in cholinesterase inhibition. It may be necessary to resort to even lower concentrations for some compounds or mixtures. (Permissible levels are based upon the recommendations of the Public Health Service Advisory Committee on Use of the PHS Drinking Water Standards.)

From *Water Quality Criteria,* Report of the National Advisory Committee to the Secretary of the Interior, April 1, 1968, Washington, DC, p. 20.

manganese (90), fluoride (52), sulfate (25), nitrate (19). The study also showed that 56% of the systems were deficient in one or more of the following: source protection; disinfection or control of disinfection; clarification (removal of suspended matter) or control of clarification; and pressure in the distribution system. It was also reported that 90% of the systems did not have sufficient samples collected for bacteriological surveillance; 56% of the systems had not been surveyed by the state or local health department within the last three years; in 54%, cross-connection prevention ordinances were lacking; in 89%, reinspection of existing construction was lacking; in 61%, the operators had not received any water treatment training; in 77%, the operators were deficient in training for microbiological work and 46% of those who needed chemistry training did not have any. Finally, the smaller communities had more water quality problems and deficiencies than the larger ones, showing the advisability of consolidation and regionalization where this is feasible.

Water Cycle

The movement of water from the atmosphere to the earth and back again to the atmosphere can be best illustrated by the

TABLE 4
Guides for water use

Type of establishment	Gallons per day[a]
Residential:	
Dwellings and apartments (per bedroom)	150
Temporary quarters:	
Boarding houses	65
Additional (or non-resident boarders)	10
Camp sites (per site)	100
Cottages, seasonal	50
Day camps	15–20
Hotels	65–75

From *Rural Water Supply,* New York State Department of Health, Albany, NY, 1966.

hydrologic or water cycle shown in Figure 3. The average annual precipitation in the United States is about 30 inches of which 72% evaporates from water and land surfaces and transpires from plants, and 28% contributes to the ground water recharge and stream flow.[17]

Water Quality

Water quality is usually determined by the water source, the treatment it receives and its method of distribution. Standards of water quality take into consideration the physical, chemical, and microbiological characteristics, the radioactivity, and compliance with the *Public Health Service Drinking Water Standards* 1962.[18] Interpretation of water quality analyses should be based on a sanitary survey. This is defined as "(1) An investigation of any condition that may affect public health. (2) A study of conditions related to the collection, treatment, and disposal of liquid, solid, or airborne wastes to determine the potential hazard contributed from these sources to the environment. (3) A study of wastewater discharges on sources of water supply, on bathing or other recreational waters, on shellfish culture, and other related environments."[19]

Surface waters by their very nature are subject to natural and manmade pollution which in many instances is not readily controllable. Hence the selection of a surface water supply source must take into consideration the treatment that may be needed now and in the future to ensure that the finished water will at all times meet the *Drinking Water Standards.* It is obvious that this objective can be met with greater certainty if the source of water is from a protected watershed and reservoir rather than from a stream passing through urban areas which may also be used for wastewater disposal and navigation.

Raw water quality criteria for public water supplies have been developed which recognize the great variability in surface water quality. The criteria are shown in Table 3. The *permissible criteria* are for raw waters which can by conventional rapid sand filtration treatment or less meet the *Drinking Water Standards.* The *desirable criteria* are for raw waters which can meet the *Drinking Water Standards* at less cost and with greater factors of safety than is possible with waters meeting the desirable criteria. It is important to point out that the constituents marked with an asterisk in Table 3 are not removed by conventional rapid sand filtration treatment. In some instances additional treatment with coagulant aids or activated carbon may suffice, and in others elimination of the source of the contaminant may be the only practical answers.

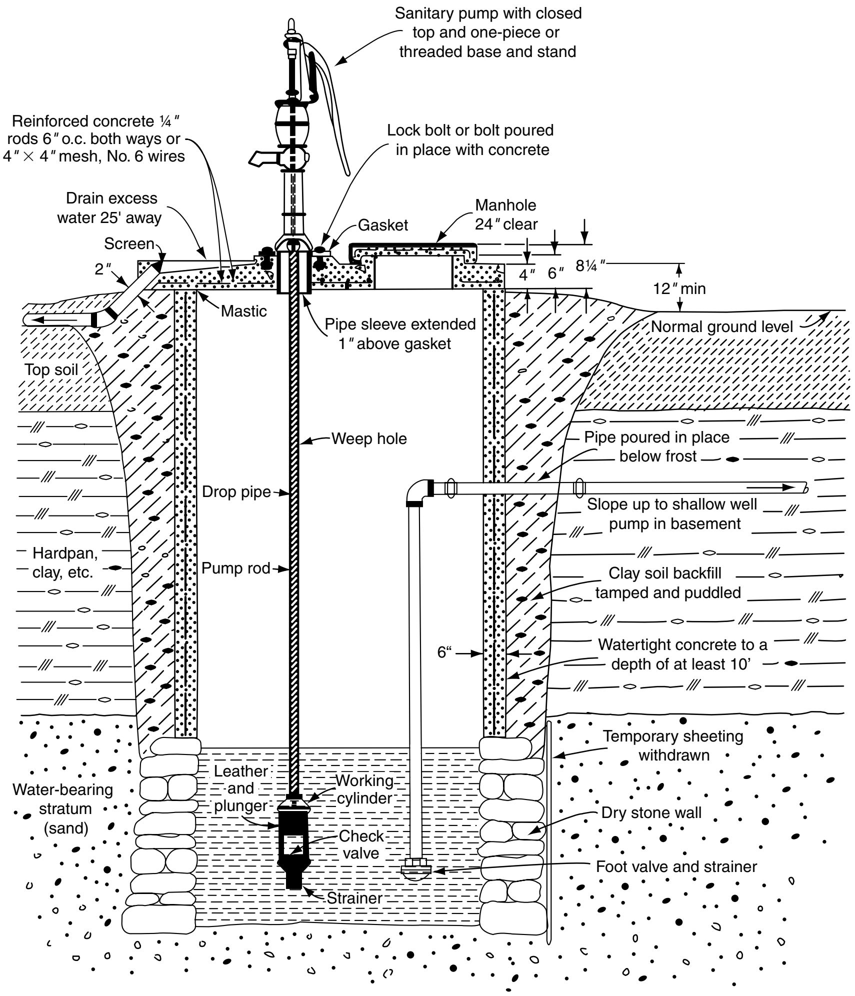

FIGURE 4 A properly developed dug well. Reprinted, with permission, from *Environmental Sanitation,* Joseph A. Salvato, Jr., John Wiley & Sons, Inc., copyright, 1958.

Water Use

The quantity of water used for domestic purposes will, in general, vary directly with the availability of the water, the habits of the people, the number and type of plumbing fixtures provided, the water pressure, the air temperature, the newness of a community, the type of establishments, and other factors. Wherever possible, the actual water consumption under existing or similar circumstances and the number of persons served should be the basis for the design of a water and sewerage system. Special adjustment must be made for industrial use. Municipal water consumption varies widely dependent on location, industrial usage, metering, size, economic, social and other factors. An average is 155 gpcd.

Table 4 gives estimates of water consumption at different types of places. Additions should be made for car washing, lawn sprinkling, and miscellaneous uses. If provision is made for firefighting requirements, then the quantity of water provided for this purpose to meet fire underwriters' standards will be in addition to that required for normal domestic needs in small communities.

Sources of Water

The sources of water supply are divided into two major classifications; namely, ground water and surface water. To these should be added for completeness rain water and demineralized water. Ground water supply sources include dug, bored, driven, and drilled wells; rock and sand or earth springs, and infiltration galleries. Figure 4 shows details of well and spring construction and sanitary protection. Standards for well construction are given in *AWWA Standard for Deep Wells,* AWWA A 100–66 published by the American Water Works Association and in *Recommended State Legislation and Regulations,* Department of Health, Education, and Welfare, Public Health Service, Washington, D.C., July 1965. Surface water supply sources include lakes, reservoirs, streams, ponds, rivers, and creeks. The development of surface water supplies is covered in standard sanitary engineering texts and state publications.

Note: 1. Springs should be located at least 100 ft and preferably 200 ft from privies, cesspools, barnyards, leaching pits, tile fields, etc. Springs should not be located downgrade

TABLE 5

A classification of waters by concentration of coliform bacteria and treatment required to render the water of safe sanitary quality

Group No.	Maximum permissible average MPN coliform bacteria per month[b]	Treatment required[a]
1	Not more than 10% of all 10-ml or 60% of 100 ml portions positive; not more than 1.0 coliform bacteria per 100 ml.	No treatment required of underground water, but a minimum of chlorination required to surface water, advised for ground water.
2	Not more than 50 per 100 ml.	Simple chlorination or equivalent.
3	Not more than 5000 per 100 ml and this MPN exceeding in not more than 20% of samples.	Rapid sand filtration (including coagulation) or its equivalent plus continuous chlorination.
4	MPN greater than 5,000 per 100 ml in more than 20% or samples and not exceeding 20,000 per 100 ml in more than 5% of the samples.	Auxiliary treatment such as 30–90 days storage, pre settling, pre-chlorination, or equivalent plus complete filtration and chlorination.
5	MPN exceeds group 4.	Prolonged storage or equivalent to bring within groups 1–4.

[a] Physical, inorganic and organic chemicals, and radioactivity concentrations in the raw water and ease of removal by the proposed treatment must also be taken into consideration. See Table 3, *Water Quality Criteria,* Report of the National Technical Advisory Commitee, to the Secretary of the Interior. April 1, 1968, Washington, DC. And *Manual for Evaluating Public Drinking Supplies* U.S. Department of Health, Education, and Welfare, Public Health Service, Environmental Control Administration, Cincinnati, OH 1969.

[b] Fecal coliforms not to exceed 20% or total coliform organisms. The monthly geometric mean of the MPN for group 2 may be less than 100 and for group 3 and 4 less than 20,000 per 100 ml with the indicated treatment.

Adapted from *Environmental Sanitation,* Joseph A. Salvato, Jr., John Wiley & Sons, Inc., New York, 1958.

so as to be in the direct line of drainage from sources or pollution. 2. If a handpump is provided it should be of sanitary design, installed with a watertight connection.

Note: 1. *Locations.* Wells should be located at least 100 ft and preferably 200 ft from privies, barnyards, leaching pits, cesspools, tile fields, and other sources of pollution. Wells should not be located downgrade so as to be in the direct line of drainage from sources of pollution. *Concrete.* Mix one bag of cement, 2 cu ft of sand, and 3 cu ft of gravel. Then add 5 gal of water, for moist sand, and mix again.

Water Treatment

As an aid in determining the treatment that should be given water to make it safe to drink, the United States Public Health Service has classified waters into several groups.[20] The treatment required by this classification is based upon the most probable number (MPN) of coliform bacteria per 100 milliliters (ml) ot sample. The classification is summarized in Table 5. It needs to be supplemented by chemical, physical, and microscopic examinations. For water to be generally acceptable, other treatment may be required in addition to that necessary for the elimination of disease-producing organisms. People expect the water to be safe to drink, attractive to the senses, sort, nonstaining, and neither scale-forming nor corrosive to the water system. The various treatment processes employed to accomplish these results are shown in the flow diagram in Figure 8. The untrained individual should not attempt to design a water treatment plant for life and health will be jeopardized. This is a job for a competent sanitary engineer.

Plant capacity—50 to 100% greater than average daily demand, with clear well. Possible chemical combinations: A—Chlorine. B—Coagulant; aluminum sulfate (pH 5.5–8.0), ferrous sulfate (pH 8.5–11.0), ferric chloride (pH 5.0–11.0), sodium aluminate and or other (activated silica) (polyelectrolytes). C—Alkalinity adjustment; lime, soda ash, or polyphosphate. D—Activated carbon. E—Dechlorination; sulfur dioxide, sodium sulfite, sodium thiosulfate. F—Fluoridation treatment. X—Chlorine dioxide.

Note: The chlorinator should be selected to pre-chlorinate surface water at 20 mg/l and post-chlorinate at 3 mg/l. Provide for a dose of 3 mg/l plus chlorine demand for ground water.

WASTEWATER

Definitions

Excreta is the waste matter eliminated from the body, including feces, urine, and sweat. *Domestic sewage* is the used water from a home or community and includes toilet, bath, laundry, lavatory, and kitchen-sink wastes. Sewage from a community may include some industrial wastes, ground water and surface water, hence the more inclusive term *wastewater* is coming into general usage. Normal sewage from a private sewage disposal system contains about 99.8% water and 0.2% total mineral and organic solids. Domestic sewage contains less than 0.1% total solids. The strength of wastewater is commonly expressed in terms of 5-day biochemical oxygen demand (BOD), suspended solids and chemical oxygen demand (COD).

The biochemical oxygen demand of sewage, sewage effluents, polluted waters, industrial wastes or other wastewaters is the oxygen in parts per million (ppm) or milligrams per liter (mg/l) required during stabilization of the decomposable organic matter by aerobic bacterial action. Complete stabilization requires more than 100 days at 20°C. Incubation for 5 or 20 days is not unusual but as used in this chapter BOD refers to the 5-day test unless otherwise specified.

Suspended solids are those which are visible and in suspension in water. They are the solids which are retained on the asbestos mat in a Gooch crucible.

The *chemical oxygen demand* (COD) is also used, particularly in relation to certain industrial wastes. The COD is the amount of oxygen expressed in parts per million (ppm) or milligrams per liter (mg/l) consumed under specific conditions in the oxidation of organic and oxidizable inorganic material. The test is relatively rapid. It does not oxidize some biodegradable organic pollutants (pyridine, benzene,

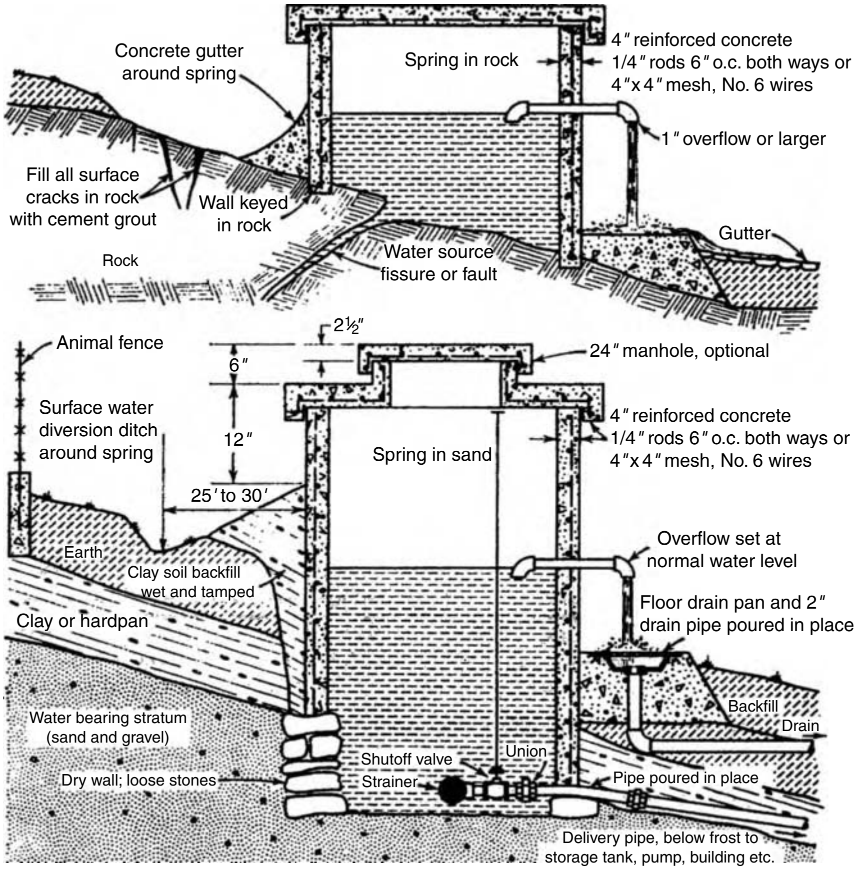

FIGURE 5 Properly constructed springs. Reprinted, with permission, from *Environmental Sanitation,* Joseph A. Salvato, Jr., John Wiley & Sons, Inc., copyright, 1958.

toluene) but does oxidize some inorganic compounds which are not measured, that is, affected by the BOD analysis.

When storm water and domestic sewage enter a sewer it is called a *combined sewer.* If domestic sewage and storm water are collected separately, in a *sanitary sewer* and in a *storm sewer,* then the result is a *separate sewer system.* A *sewage works* or *sewage system* is a combination of sewers and appurtenances for the collection, pumping and transportation of sewage, sometimes, also called *sewerage,* plus facilities for treatment and disposal of sewage, known as the *sewage treatment plant.*

The *privy,* or one of its modifications, is the common device used when excreta is disposed of without the aid of water. When excreta is disposed of with water, a *water-carriage* sewage disposal system is used; generally all other domestic liquid wastes are included.

Stream Pollution and Recovery

Although the 5-day BOD is the best single measure of wastewater or polluted water organic loading, aquatic organisms when measured with the biochemical oxygen demand, the chemical oxygen demand where indicated, the dissolved oxygen, and the sanitary survey taken all together are the best indicators of water pollution. Other chemical and bacterial analyses provide additional information.

In a freshly polluted water, during the first stage (5 to 20 days at 20°C), mostly carbonaceous matter is oxidized. This is demonstrated by an immediate increase in the stream BOD and oxygen utilization in the area of pollution discharge, followed by the second or nitrification stage where a lesser but uniform rate of oxygen utilization takes place for an extended period of time. This is accompanied by a related characteristic change in the stream biota. The amount of dissolved oxygen in a receiving water is the single most important factor determining the waste assimilation capacity of a body of water.

Stream pollution (organic) is apparent along its length by a zone of degradation just below the source, a zone of active decomposition and, if additional pollution is not added, a zone of recovery. In the zone of degradation the oxygen in the water is decreased, suspended solids may be increased and the stream bottom accumulates sludge. The fish life changes from game and food species to coarse. Worms, snails, and other biota associated with pollution increase. In the zone of active decomposition, the dissolved oxygen is further reduced and may approach zero. The water becomes turbid and gives off foul odors. Fish disappear, anaerobes predominate in the bottom mud and sludge worms become very numerous. In the zone of recovery the process is gradually reversed and the stream returns to normal. The zones mentioned may not be discernible or experienced where sewage has been given adequate treatment before discharge.

Small Waterborne Sewage Disposal Systems

The provision of running water in a dwelling or structure immediately introduces the requirement for sanitary removal of the used water. Where public sewage works are available, connection to the sewer will solve a major sanitation problem. Where public or central sewage works are not provided or anticipated, such as in predominately rural areas, then consideration must be given to the proposed method of collection, removal, treatment, and disposal of sewage on each lot as shown in Figure 9. With a suitable soil, the disposal of sewage can be simple, economical, and inoffensive; but careful maintenance is essential for continued satisfactory operation. Where rock or ground water is close to the surface or the soil is a tight clay, it would be well to investigate some other property.

The common system for sewage treatment and disposal at a private home in a rural area consists of a proper septic tank for the settling and treatment of the sewage, and a subsurface leaching system for the disposal of the septic tank overflow, provided the soil is satisfactory. The soil percolation test and soil characteristics are used as means for determining soil permeability or the capacity of a soil to absorb settled sewage. This and the quantity of sewage from a dwelling are the bases upon

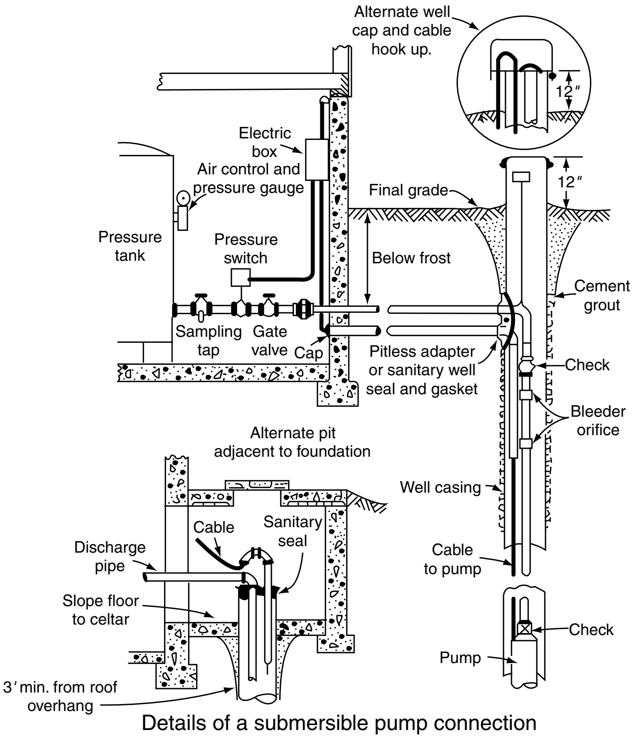

FIGURE 6 Sanitary well caps and seals. Reprinted with permission, from *Environmental Sanitation,* Joseph A. Salvato, Jr., John Wiley & Sons, Inc., copyright, 1958.

which a subsurface sewage disposal system is designed. Sand filters, evapotranspiration beds, aeration systems, stabilization ponds or lagoons, recirculating toilets and various types of privies are used under certain conditions.

Large Sewage Works

The design of sewers and treatment plants should take into consideration the broad principles of comprehensive community planning discussed at the beginning of this chapter. Regional and area-wide sewerage planning (preliminary) should take place within the context of the general overall comprehensive community plan. It recognizes the extent of present and future service areas, the established water quality and effluent standards, and the alternative solutions with their first costs and total annual costs. This information is needed to assist local officials in making a decision to proceed with the design and construction of a specific sewerage system and treatment plant.

These are essential first steps to ensure that the proposed construction will meet the community, state and national goals and objectives.

Water Quality Standards The purpose of stream and other surface water quality standards is to protect, improve where needed, and maintain the highest practicable water quality for certain specified best uses. Such uses are usually grouped under "public water supply," "bathing and recreational," "fishing, aquatic life and wildlife," and "natural drainage, agricultural and industrial water supply." In general, sludge deposits, solid refuse, floating solids, oils, grease, and scum are not allowed under any uses. Waters are also required to be free from organic and inorganic chemical or radiologic constituents in concentrations or combinations which would be harmful to human, animal, or aquatic life for the specified water use. For sources of drinking water supplies, the sewage and industrial waste treatment before discharge to a stream is such that with conventional (coagulation, sedimentation, rapid sand filtration) water treatment the Public Health Service Drinking Water Standards are not exceeded.

For sources of drinking water with chlorination treatment alone, the maximum permissible average most probable number (MPN) of coliform bacteria per month should not exceed 50 per 100 ml with not more than 20% of the samples exceeding 240. With coagulation, rapid sand filtration, and chlorination the average MPN should not exceed 5000 with not more than 20% of the samples exceeding 5000. Fecal coliforms should not exceed 20% of the total coliform counts. For sources of water for bathing and other contact recreation uses the average MPN should not exceed 2400 (or 1000) per 100 ml with not more than 20% (or 10%) of the samples exceeding 5000 (or 2000). The fecal coliform count (log mean) should not exceed 200 with not more than 10% of the samples collected during any 30-day period exceeding 400. In all cases the coliform counts should be interpreted in the light of a sanitary survey and related factors.

Water quality standards also specify a minimum dissolved oxygen content of 5.0 mg/l for trout waters, 5.0 or 4.0 mg/l for non-trout waters and a minimum 2.0 or 3.0 mg/l for any other waters. Similar standards as above are used for marine waters. If waters are used for shellfish harvesting for direct human consumption, the coliform bacteria shall not exceed a median MPN of 70 per 100 ml and not more than 10% of the samples shall ordinarily exceed 230.

Effluent Standards It should be obvious that the realistic compliance with water classification standards requires control over all sewage and industrial wastewater discharges to the classified waters. In Britain, the Ministry of Housing and local government reaffirmed in 1966 the Royal Commission "General Standard" as a "norm" for sewage effluents, i.e., 5-day BOD 20 mg/l and suspended solids 30 mg/l with a dilution factor of 9 to 150 volumes in the receiving watercourse having not more than 4.0 mg/l BOD. A higher effluent standard of 10 mg/l BOD and suspended solids may be required if indicated.[21] In any case, sewage and industrial waste effluents should not contain any matter likely to render the receiving stream poisonous or injurious to fish, or if used for drinking water supply injurious to man.

TABLE 6

Sewage-treatment plant unit combinations and efficiencies

Treatment plant	Total % reduction—approximate: Suspended solids	Total % reduction—approximate: Biochemical oxygen demand
Sedimentation plus sand filter	90–98	85–95
Sedimentation plus standard trickling filter, 600 lb BOD per acre-foot maximum loading	75–90	80–95
Sedimentation plus single stage high rate trickling filter	50–80	35–65[a]
Sedimentation plus two stage high rate trickling filter	70–90	80–95[a]
Activated sludge	85–95	85–95
Chemical treatment	65–90	45–80
Pre-aeration (1 hr) plus sedimentation	60–80	40–60
Plain sedimentation	40–70	25–40
Fine screening	2–20	5–10
Stabilization, pond aerobic		70–90
Anaerobic laboon	60–70	40–70

[a] No recirculation. Efficiencies can be increased within limits by controlling organic loading, efficiencies of settling tanks, volume of recirculation, and the number of stages: however, effluent will be less nutrified than from standard rate filter, but will usually contain dissolved oxygen. Filter flies and odors are reduced. Study first cost plus operation and maintenance. From *Environmental Sanitation,* Joseph A. Salvato, Jr., John Wiley & Sons, Inc., New York, 1958.

Wastewater Treatment The need for wastewater treatment can be better justified for aesthetic, economic, recreation, and fish reasons rather than for reasons of reduction of health hazards. Treatment of sewage and industrial wastes does not usually remove the need for nor reduction in required treatment for drinking water. On the contrary, greater emphasis needs to be placed on the improvement and maintenance of drinking water quality. The increasing urbanization and industrialization has and will continue to result in the discharge of viruses, organic, and inorganic chemicals, which are not readily removed by conventional water treatment, and whose long-term health effects are not yet known. Many people may be misled into thinking that money and effort spent in stream pollution abatement justifies relaxation of effort, money to be spent and support for drinking water treatment. Nothing could be further from the truth!

Wastewater treatment usually involves screening and sedimentation for primary treatment. When followed by oxidation and disinfection it is given secondary treatment. If secondary treatment plant effluent is passed through a sand filter, oxidation pond, or some combination of chemical treatment and filters plus chlorination, in which additional organic and inorganic materials are removed, together with bacteria, protozoa and viruses, then it would be receiving tertiary treatment. Some possible combinations of sewage

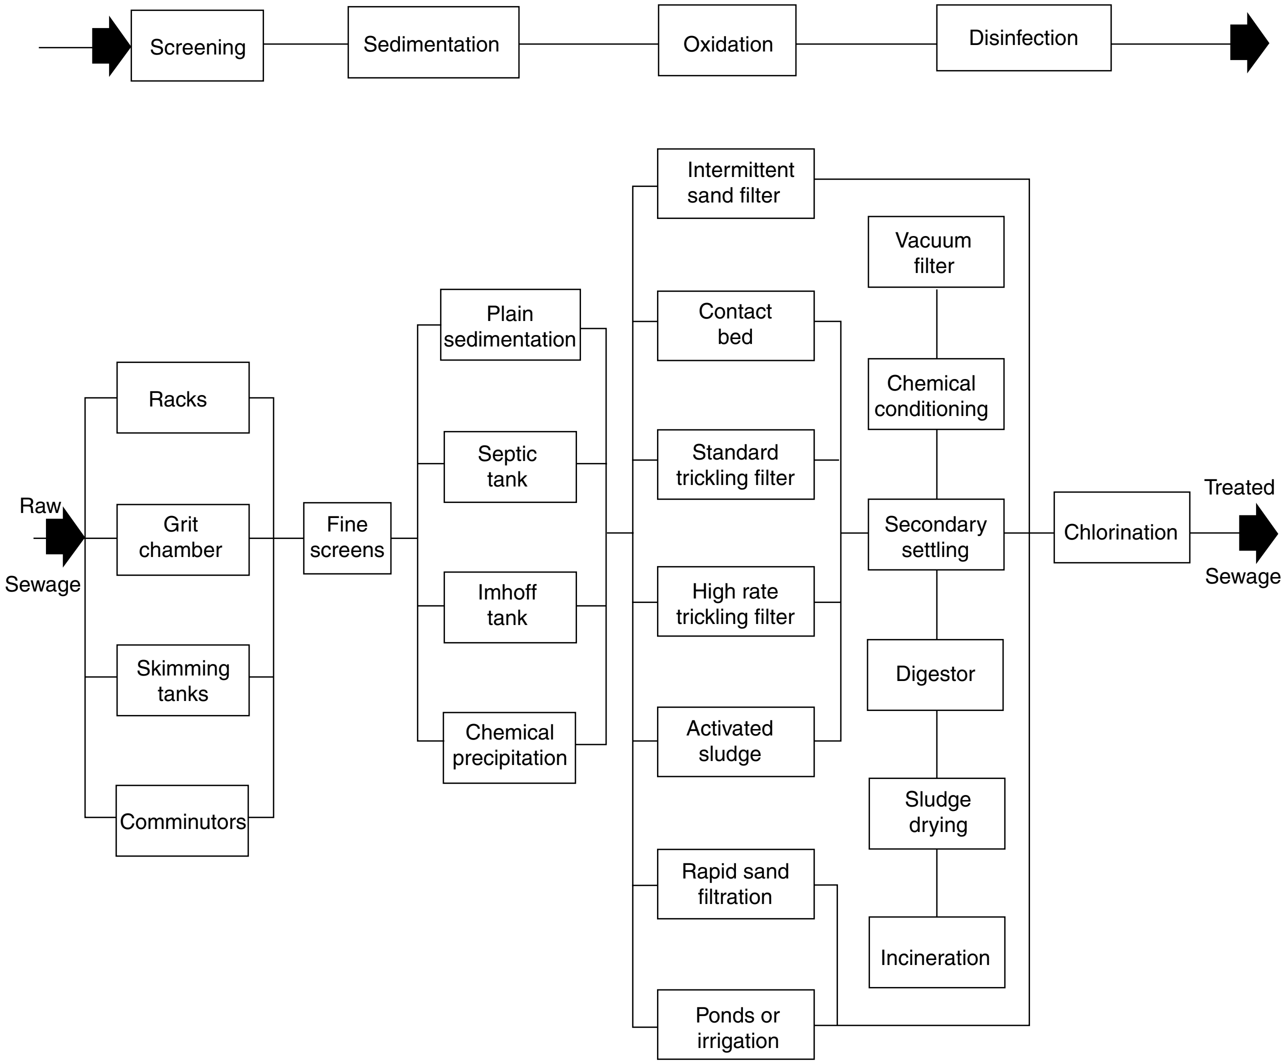

FIGURE 10 Sewage-treatment processes. From *Environmental Sanitation,* Joseph A. Salvato, Jr., John Wiley & Sons, Inc., New York, 1958.

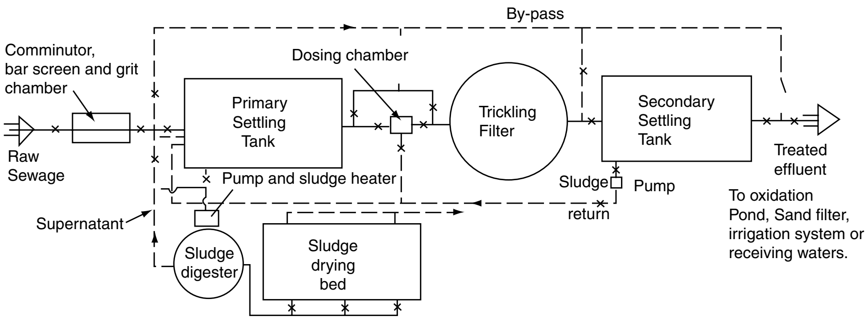

FIGURE 11 A secondary sewage treatment plant.

treatment unit processes are shown in Figures 10 and 11; their efficiencies are shown in Table 6.

There are two major factors which can determine the success or failure of a sewer and treatment plant construction program once completed. First is the positive exclusion of surface water, ground water, roof leaders, and rooting drains by ordinance and inspection. Many a sewage treatment plant constructed has been so hydraulically overloaded as to render it almost useless as a stream pollution abatement facility. Next is proper operation of the treatment plant by competent adequately paid personnel. Here the consulting engineers and the regulatory agencies share a joint responsibility to ensure that public officials are properly informed and that the huge investments in water pollution control accomplish the intended objectives.

SOLID WASTES

General

Aesthetic, land use, health, water pollution, air pollution, and economic considerations make proper solid waste storage, collection, and disposal municipal, corporate, and individual functions which must be taken seriously. Indiscriminate dumping of solid waste and failure of the collection system in a populated community for two or three weeks would soon cause many problems. Odors, flies, rats, roaches, crickets, wandering dogs and cats, and fires would dispel any remaining doubts of the importance of proper solid waste storage, collection, and disposal.

The complexities of proper solid waste management are not readily appreciated. There are numerous sources and types of solid wastes ranging from the home to the farm and from garbage to radioactive wastes, junked cars, and industrial wastes. Handling involves storage, collection transfer, and transport. Processing includes incineration, densification, composting, separation, treatment, and energy conversion. Disposal shows the environmental inter-relation of air, land, and water, and the place of salvage and recyling. All these steps introduce constraints—social, political, economic, technological, ecological, legal, information, and communications which must be considered in the analysis of the problem and in coming up with acceptable solutions.

All these factors show the need for comprehensive planning. It is necessary to come up with alternative solutions together with the environmental and social impact of each. In this way one is more likely to come up with a practical and acceptable plan that will have a good chance of being implemented.

Composition, Weight, and Volume

The solid waste of a municipality may consist of garbage, rubbish, ashes, bulky wastes, street refuse, dead animals, abandoned vehicles, construction and demolition wastes, industrial solid wastes, special hazardous wastes, animal and agricultural wastes, sewage treatment plant residues, and septic tank cleanings. Garbage is the putrescible organic material discarded or remaining as a result of the storage, processing, preparation, and consumption of food. Rubbish includes paper, wood, glass, metal, leaves, plastics, tin cans, stones, and dirt. Bulky wastes include stoves, refrigerators, auto parts, furniture, large creates, trees, and tree branches.

Various estimates have been made of the quantity of solid waste generated and collected per person per day. The amount of municipal solid waste *generated* in 1968 was estimated to be 7 pounds per capita per day and expected to increase at about 4% per year. The amount collected was found to average 5.32 pounds. The figures given in Tables 7a and 7b are averages, subject to adjustment dependent upon many local factors, including time of the year, habits and economic status of the people, whether urban or rural, education, and location. The estimates should not be used for design purpose. Each community should be studied by itself and actual weighings made to obtain representative information.

TABLE 7a
Average solid waste collected, 1968 (pounds per person per day)

Solid waste type	Urban	Rural	National
Household	1.26	0.72	1.14
Commercial	0.46	0.11	0.38
Combined	2.63	2.60	2.63
Industrial	0.65	0.37	0.59
Demolition, construction	0.23	0.02	0.18
Street and alley	0.11	0.03	0.09
Miscellaneous	0.38	0.08	0.31
Totals	5.72	3.93	5.32

TABLE 7b
Approximate composition of domestic solid wastes[a]

Component	% by weight
Food waste	15
Paper products	50
Plastics, rubber, leather	3
Rags	2
Metals	8
Glass and ceramics	8
Wood	2
Garden wastes	5
Rock, dirt, miscellaneous	7

[a] Moisture content approximately 30%.

Collection

Collection cost has been estimated to represent about 80% of the total cost of collection and disposal by sanitary landfill and 60% when incineration is used. In 1968 collection cost alone was found to average 10 to 13 dollars per ton.

The frequency of collection will depend upon the quantity of solid waste, time of the year, socio-economic status of area served, and municipal or contractor responsibility. In business districts refuse, including garbage from hotel and restaurants, should be collected daily except Sundays. In residential areas, twice a week refuse collection during warm months of the year and once a week at other times should be the maximum permissible interval. Slum and ghetto areas usually require at least twice a week collection. The receptacle should be either emptied directly into the garbage truck or carted away and replaced with a clean container. Refuse transferred from can to can will invariably cause spilling, with resultant pollution of the ground and attraction of rats and flies. If other than curb pick-up is provided, the cost of collection will be high. Some property owners are willing to pay for this extra service.

Transfer Station

The urban areas around cities have been spreading leaving fewer nearby acceptable solid waste disposal sites. This has generally made necessary the construction of incinerators in cities or on the outskirts, or the transportation of wastes longer distances to new sites. However, as the distance from the centers of solid waste generation increases, the cost of direct haul to a site increases. A distance is reached (in terms of time) when it becomes less expensive to construct an incinerator, or a transfer station near the center of solid waste generation where wastes from collection vehicles can be transferred to large tractor-trailers for haul to more distant disposal sites.

Rail haul and barging to sea also involve the use of transfer stations. They may include one or a combination of grinding, compaction to various densities, and baling.

Treatment and Disposal of Solid Wastes

Solid waste treatment and disposal methods include the open dump, hog feeding, incineration, grinding, and discharge to a sewer, milling, compaction, sanitary landfill, dumping, and burial at sea, reduction, composting, pyrolization, wet oxidation, and anaerobic digestion. The common acceptable methods are incineration, sanitary landfill and in some part of the world composting.

Open Dump The open dump is all too common and needs no explanation. It is never satisfactory as usually maintained. Refuse is generally spread over a large area providing a source of food and harborage for rats, flies, and other vermin. It is unsightly, an odor and smoke nuisance, a fire hazard, and often a cause of water pollution. It should be eliminated or its operation changed to a sanitary landfill.

Hog Feeding Where garbage is fed to hogs, careful suspervision is necessary. The spread of trichinosis in man, hog cholera, the virus of foot-and-mouth disease, and vesicular exanthema in swine is encouraged when uncooked garbage is fed to hogs. In some instances, tuberculosis, swine erysipelas, and stomatitis may also be spread by raw garbage. The boiling for thirty minutes of all garbage fed to hogs will prevent transmission of trichinosis and economic loss of the swine industry due to hog illness and death.

Grinding The grinding of garbage is fast becoming a common method of garbage disposal. It is highly recommended from a convenience and public health standpoint, but the disposal of other refuse remains to be handled. The putrescible matter is promptly removed thereby eliminating this as a source of odors and food for rats, flies, and other vermin. In one system, the home grinder is connected to the kitchen sink drain. Garbage is shredded into small particles while being mixed with water and is discharged to the house sewer. In another system, garbage is collected as before but dumped into large, centrally located garbage grinding stations that discharge garbage to the municipal sewerage system. In small communities, the garbage grinding station may be located at the sewage-treatment plant. The strength of the sewage is increased and additional sludge digestion and drying facilities will be required when a large amount of garbage is handled.

Disposal at Sea Where dumping at sea is practiced, all garbage and other refuse is dumped into large garbage scows or barges. The scows are towed by tugs and the garbage is taken out to sea and dumped a sufficient distance out to prevent the refuse being carried back to shore and causing a nuisance. Bad weather conditions hamper this operation and unless this method is kept under very careful surveillance, abuses and failures will result. Because of the cost of maintaining a small navy and difficulties in satisfactorily carrying out this operation, coastal cities have reverted to sanitary landfill and incineration. In recent years, consideration has been given to the compaction of refuse to a density greater than 66.5 pounds per cubic foot prior to transport and then disposal by burial in the ocean at depths greater than 100 feet, based upon oceanographic conditions, to ensure there will be no mixing with surface water. More research is needed to determine stability of the compacted refuse and effect on marine life. See *High density compaction.*

Garbage Reduction In the reduction method of garbage disposal, the garbage is cooked under pressure. Fats melt out and are separated from the remaining material. The fat is used in the manufacture of soaps or glycerines and the residue is dried, ground, and sold for fertilizer or cattle feed. Odor complaints are associated with this process and, where a solvent such as naphtha is used to increase the extraction of fat, a greater fire hazard exists. The use of synthetic detergents and chemical fertilizers and high operating costs have led to the abandonment of this process.

Composting Composting is the controlled decay of organic matter in a warm, moist environment by the action of bacteria, fungi, molds, and other organisms. This may be an aerobic and/or anaerobic operation. Moisture is maintained at 40–65%, 50–60% is best. Composition of the refuse, disposal of refuse not composted, demand for compost and salvaged material, odor production and control, public acceptance and total cost are factors to be carefully weighed. Compost is a good soil conditioner but a poor fertilizer. The process is very attractive, but because of the factors mentioned has not met with success in the United States.

The composting operation involves a combination of steps. These may include: (a) weighing, (b) separation of non-compostables and salvage by hand and by a magnetic separator, (c) size reduction to 2 inches or less by means of a shredder, grinder, chipper, rasp mill, hammermill, (d) ballistic and magnetic separation, (e) biological digestion by any one of a number of composting methods, (f) screening and possible standardization of fertilizer value, and (g) disposal by bagging for sale, or to a sanitary landfill.

Pyrolization Pyrolization as applied to solid wastes (metal and glass removed) is an experimental thermochemical process for conversion of complex organic solids, in the absence of added oxygen, to water, combustible gases, tarry liquids, and a stable residue. Intermediate products may be collected or may be used to contribute heat to support the process. The end products would be carbon, water and carbon dioxide if carried to completion. If the raw material contains sulfur and nitrogen, these oxides will be formed with resultant air pollution unless provision is made for their removal. Temperatures of 900–1700°F have been used. In a variation, some oxygen and a temperature up to 2100°F is used. It is a process of destructive distillation similar to that used for making charcoal and for the recovery of organic by-products such as turpentine, acetic acid, and methanol from wood.[22] The Lantz converter and the Urban Research and Development Corporation unit are variations of the pyrolytic process. The Lantz system uses a temperature of 1200–1400°F with ground refuse.

High temperature incineration High temperature incineration is carried out at 3400°F (Melt-zit), 2500–2600°F (FLK Slagging Incinerator, Germany), 2600–3000°F (Torrax system), 3000°F (American Design and Development Corporation). These units are in the developmental and pilot stage. Combustibles are destroyed and non-combustibles are reduced to slag or sand-like grit. A 97% volume reduction is reported.

Wet oxidation Wet oxidation and anaerobic digestion of refuse are in the experimental stage. In wet oxidation, the refuse can be processed under high pressures and temperatures, or the refuse can be ground and aerated while in suspension in a liquid medium. In anaerobic digestion, decomposable material is separated from refuse, ground and then digested at controlled temperature in the absence of air. The resultant gases are mostly methane and carbon dioxide and the residue can serve as a soil conditioner.

Size reduction Shredders, hoggers, and chippers are devices which reduce refuse, bulky items, and other solid wastes to a manageable size for disposal by landfill or for processing through an incinerator.

High density compaction High density compaction of solid wastes is accomplished by compression to a density of more than 66.5 pounds per cubic foot. The resulting bales may be enclosed in chicken wire, hot asphalt, vinyl plastic, plain or reinforced cement, or welded sheet steel depending on the method of disposal or intended use of the bales or blocks. Rogus reports on the Tezuka-Kosan process in Tokyo that liquid release during compression ranged from 2–5% by weight and that it will require treatment. The bales had a density of 70–109 pounds per cubic foot; they sank in sea water; had good structural cohesiveness; resisted corrosion; were reasonably free of odors, and insect, rodent hazard; and showed no evidence of aerobic or anaerobic decomposition.[23] This system has not yet been adopted in the United States but offers attractive possibilities for solid waste reuse, economic hauling, and more acceptable disposal.

Other methods of achieving high density are subjecting refuse to pressure in a hydraulic pressure chamber and forcing baled refuse through a tube extending 30–50 feet below the water surface. Plastic toys and containers do not remain compressed or submerged. The effect of time on decomposition with possible gas formation, disintegration and floating of the refuse is not known. The long-term effect of the submerged material on the marine ecology is also an unknown.[24]

Incineration

Incineration is a controlled combustion process for burning solid, liquid, or gaseous combustible waste to gases and a residue containing little or no combustible material *when properly carried out.* It is a volume reduction process suitable for about 70% of the municipal solid wastes.

Incineration, if properly designed and controlled, is satisfactory for burning combustible refuse provided air pollution standards can be met. Continuous operation six days a week and a controlled temperature are needed for efficiency, prevention of excessive air pollution and odor control.

An operating design temperature range of 1500–1800°F is generally recommended. Excessively high temperatures and extreme variations cause cracking and spalling with rapid deterioration of fire tile and brick linings (refractories). Batch feed or one-shift operation promote spalling and loosening of tile linings. Other types of lining and design may permit higher operating temperatures. Actually, the temperature in the furnace will range from 2100–2500°F. When the gases leave the combustion chamber the temperature should be between 1400 and 1800°F and the gas entering the stack 1000°F or less. The temperature will have to be lowered to 450–500°F before the gas is filtered or to 600°F or less if electrical precipitators are used.

Sanitary Landfill

A sanitary landfill is an engineering method of disposing of solid waste on land by spreading the waste in thin layers, compacting it to the smallest practical volume and covering it with a layer of earth at the end of each day or more frequently in a manner which prevents environmental pollution.[25] The cost of sanitary landfill versus incineration for various populations is shown in Figure 12.

Social and political factors An important aspect of refuse disposal site selection, in addition to engineering factors, is the evaluation of public reaction and education of the public so that understanding and acceptance is developed. A program of

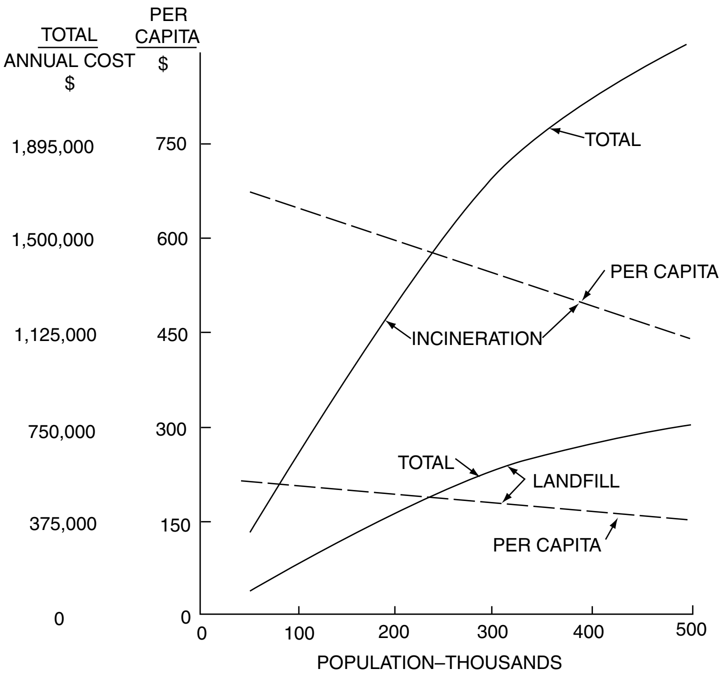

FIGURE 12 General cost comparison of sanitary landfill and incineration. From *Municipal Refuse Collection and Disposal.* Office for Local Government, Albany, NY, 1964. Adjusted to 1970 costs.

public information is also needed. Equally important are the climate for political cooperation, cost comparison of alternative solutions, available revenue, aesthetic expectations of the people, organized community support, and similar factors.

Experience shows that where open dumps have been operated, there will be opposition to almost any site proposed for sanitary landfill or an incinerator for that matter. However, local officials will have to study all of the facts and make a decision to fulfill their responsibility and exercise their authority for the public good in spite of any expressed opposition. Usually the critical factor is convincing the public that a nuisance-free operation can and will in fact be conducted. A private contract may make possible regional disposal, whereas an intergovernmental operation may be politically impractical.

Planning Local officials can make their task easier by planning ahead together on a county or regional basis for 20–40 years in the future, and by acquisition of adequate sites at least 5 years prior to anticipated needs and use. The availability of federal and state funds for planning for collection, treatment, and disposal of refuse on an area-wide basis such as a county should be explored. The planning will require an engineering analysis of alternative sites including population projections, volume, and characteristics of all types of solid wastes to be handled, cost of land and site preparation, expected life of the site, haul distances from the sources of refuse to the site, cost of operation, and possible value of the finished sites. Consideration would be given to the climate of the region, prevailing winds, zoning ordinances, geology, and topography. Location and drainage to prevent surface water or ground water pollution, access roads to major highways, and availability of suitable cover material are other considerations.

Special attention must be given to the diversion of surface water, to the highest ground water level so as to keep the bottom of the fill well above it, and to the soils available. The type of soil used for cover and its placement should minimize infiltration. The intervening soil between the bottom of the landfill and maximum ground water level should prevent or control leachate travel, or if this cannot be reasonably assured, an artificial membrane or clay soil barrier with an underdrain collection system may be needed.

Once a decision is made it should be made common knowledge and plans developed to show how it is proposed to reclaim or improve and reuse the site upon completion. This should include talks, slides, news releases, question and answer presentations, and inspection of good operations. Artist's renderings are very helpful in explaining construction methods and final use of the land. Figures 13 and 14 show the area and trench sanitary landfill methods.

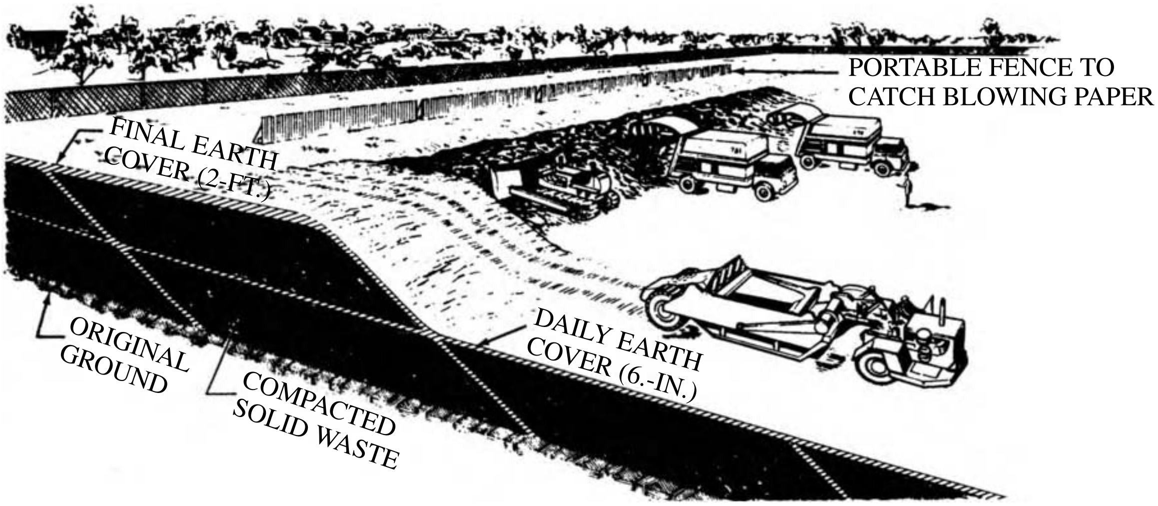

FIGURE 13 Area method. The bulldozer spreads and compacts solid wastes. The scraper (foreground) is used to haul the cover material at the end of the day's operations. Note the portable fence that catches any blowing debris. This is used with any landfill method.

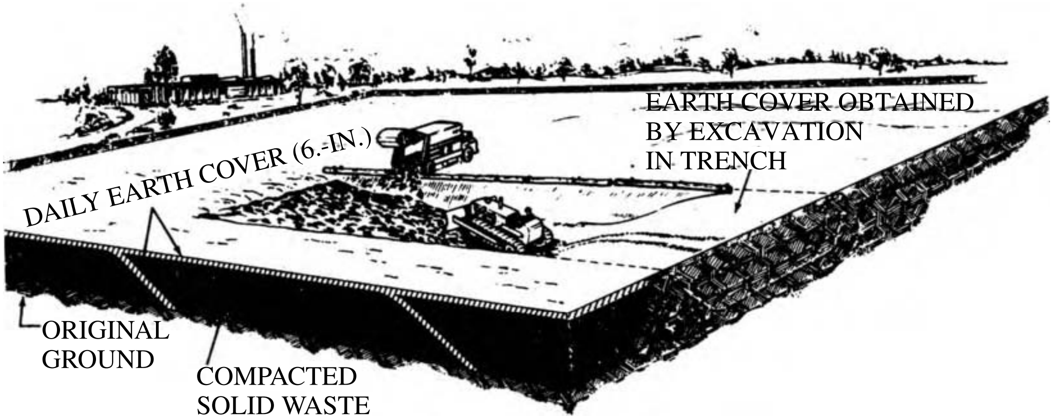

FIGURE 14 Trench method. The waste collection truck deposits its load into the trench where the bulldozer spreads and compacts it. At the end of the day the dragline excavates soil from the future trench; this soil is used as the daily cover material. Trenches can also be excavated with a front-end loader, bulldozer, or scraper. From *Sanitary Landfill Factors,* Thomas J. Sorg and H. Lanier Hickman, U.S. Department of Health, Education and Welfare, Public Health Service Publication N. 1792, Superintendent of Documents, Washington, DC, 1970.

RECREATION AREAS AND TEMPORARY RESIDENCES

Bathing Beaches and Swimming Pools

The sanitation of bathing places is dictated by health and aesthetic reasons. Few people would knowingly swim or water ski in polluted water; and insanitary surroundings are not conductive to the enjoyment of "a day at the beach." People are demanding more and cleaner beaches and pools, and a camp, hotel, club, or resort without a pool or beach is not nearly as popular as one that has this facility.

Health Hazards

From our knowledge of disease transmission, it is known that certain illnesses can be transmitted by improperly operated or located swimming pools and beaches through contact and ingestion of polluted water. Among these are typhoid fever, dysentery, and other gastrointestinal illnesses; conjunctivitis, trachoma, leptospirosis, ringworm infections, schistosomiasis, or swimmer's itch; upper respiratory tract diseases such as sinus infection, septic sore throat, and middle ear infection. The repeated flushing of the mucous coatings of the eyes, ears, and throat, and the excessive use of alum or lack of pH control, expose the unprotected surfaces to possible inflammation, irritation, and infection. Contraction of the skin on immersion in water may make possible the direct entrance of contaminated water into the nose and eyes.

Stevenson[26] reported that "an appreciably higher overall illness incidence may be expected in the swimming group over that in the nonswimming group regardless of the bathing water quality." It was further stated that "eye, ear, nose, and throat ailments may be expected to represent more than half of the over-all illness incidence, gastrointestinal disturbances up to one-fifth, and skins irritations and other illnesses the balance." Although based on limited data, swimming in a lake water with an average coliform content of 2300 per 100 ml caused "a significant increase in illness incidence . . ." and swimming in a river "water having a median coliform density of 2700 per 100 ml appears to have caused a significant increase in such (gastro-intestinal) illness." The study also showed the greatest amount of swimming was done by persons 5 to 19 years of age.

Diesch and McCulloch[27] summarized incidences of leptospirosis in persons swimming in waters contaminated by discharges of domestic and wild animals including cattle, swine, foxes, racoons, muskrats, and mice. Pathogenic leptospires were isolated from natural waters, confirming the inadvisability of swimming in streams and farm ponds receiving drainage from cattle or swine pastures.

Joyce and Weiser report that enteroviruses which are found in human or animal excreta, if introduced into a farm pond by drainage or direct flow, can constitute a serious public health hazard if used for recreation, drinking or other domestic purposes.[28]

Many other studies[29–30] have been made to relate bathing water bacterial quality to disease transmission with inconclusive or negative results.

British investigators[29] have drawn the following general conclusions:

1) That bathing in sewage-polluted sea water carries only a negligible risk to health, even on beaches that are aesthetically very unsatisfactory.
2) That the minimal risk attending such bathing is probably associated with chance contact with intact aggregates of faecal material that happen to have come from infected persons.
3) That the isolation of pathogenic organisms from sewage-contaminated sea water is more important as evidence of an existing hazard in the populations from which the sewage is derived than as evidence of a further risk of infection in bathers.
4) That, since a serious risk of contracting disease through bathing in sewage-polluted sea water is probably not incurred unless the water is so fouled as to be aesthetically revolting, public health requirements would seem to be reasonably met by a general policy of improving grossly insanitary bathing waters and of preventing so far as possible the pollution of bathing beaches with undisintegrated fecal matter during the bathing season.

The findings of the Public Health Activities Committee of the ASCE Sanitary Engineering Division[31] are summarized in the following abstract:

"Coliform standards are a major public health factor in judging the sanitary quality of recreational waters. There is little, if any, conclusive proof that disease hazards are directly associated with large numbers of coliform organisms. Comprehensive research is recommended to provide data for establishing sanitary standards for recreational waters on a more rational or sound public health basis. British investigations show that even finding typhoid organisms and other pathogens in recreational waters is not indicative of a health hazard to bathers but is only indicative of the presence of these diseases in the population producing the sewage. The Committee recommends that beaches not be closed and other decisive action not be taken because current microbiological standards are not met except when evidence of fresh sewage or epidemiological data would support such action."

In view of the available information, emphasis should be placed on elimination of sources of pollution (sewage, storm water, land drainage), effective disinfection of treated wastewaters, and on the proper interpretation of bacterial examinations of samples collected from representative locations.

In swimming pools there is a possibility of direct transmission of infection from one bather to another if the water does not have an active disinfectant such as free available chlorine. Proper operation and treatment therefore are of prime importance.

FOOD PROTECTION

Site Location and Planning

It is extremely important that a preliminary investigation be made of a site proposed for a new plant to determine the suitability of a site for a given purpose. This should include restrictions related to zoning, sewage, and wastewater disposal, solid wastes disposal, air pollution control, and noise.

Time and money spent in study, before a property is purchased, is a good investment and sound planning. For example, a factory that requires millions of gallons of cooling or processing water would not be located too distant from a lake or clear stream, unless it was demonstrated that an unlimited supply of satisfactory well water or public water was available at a reasonable cost. An industry having as an integral part of its process a liquid, solid, or gaseous waste would not locate where adequate dilution or disposal area was not available, unless an economical waste treatment process could be devised.

Such factors as topography, drainage, highways, railroads, watercourses, exposure, swamps, prevailing winds, dust, odors, insect and rodent prevalence, type of rock and soil, availability and adequacy of public utilities, the need for a separate power plant, and water-, sewage-, or waste-treatment works and special air pollution control equipment should all be considered and evaluated before selecting a site for a particular use.

Engineering and Architectural Considerations

The design of structures and facilities are properly engineering and architectural functions that should be delegated to individuals or firms who have become expert in such matters. The design and construction material used is dependent upon the type of structure, its geographical location and operation. Some materials can be used to greater advantage because of location, availability of raw materials, labor costs, type of skilled labor available, local building codes, estimate, and other factors.

In many instances plan approval and permits are required from federal, state or local regulatory agencies. Check with the agency having jurisdiction before any decisions are made or any plans are prepared.

Basic Sanitation Requirements for Food Processing and Food Service Establishments

Regulation The regulation and supervision of food establishments such as restaurants, caterers, commissaries, pasteurizing plants, frozen dessert plants, frozen prepared food plants, vending machine centers, slaughter houses, poultry processing, bakeries, shellfish shucking and packing plants, and similar places is in the public interest. This responsibility is usually vested in the state and local health and agriculture departments, and also in the Food and Drug Administration, the U.S. Department of Agriculture and in the U.S. Public Health Service when interstate traffic of the food is involved. The industry affected as a rule also recognizes its fundamental responsibility.

Industry and regulatory control emphasis needs to be placed at the foci of food collection, processing and distribution and on self-inspection. See page 355. Proper design, equipment and layout, and construction must build out environmental sanitation problems and simplify sanitary operations. Quality control procedures must also be applied to convenience type food such as prepared frozen dinners. The food catering industries which now serve banquets, hospitals and nursing homes, airlines, and other mass feeding facilities are particularly vulnerable. Food preparation is leaving the home and small restaurant and is becoming a centralized production process leaving only final conditioning or heating at the point of service. Such operations make possible more centralized control and certain efficiencies, but also increase the potential of foodborne outbreaks affecting large numbers of people.

General requirements It is to be noted that certain basic sanitation requirements are common to all places where food is processed. McGlasson[32] has proposed a set of standards under the following headings:

1) *Location, construction, facilities, and maintenance* (a) Grounds and premises, (b) Construction and maintenance, (c) Lighting, (d) Ventilation, (e) Dressing rooms and lockers.
2) *Sanitary facilities and controls* (a) Water supply, (b) Sewage disposal, (c) Plumbing, (d) Rest-room facilities, (e) Handwashing facilities, (f) Food wastes and rubbish disposal, (g) Vermin control.
3) *Food-product equipment and utensils* (a) Sanitary design, construction, and installation of equipment and utensils, (b) Cleanliness of equipment and utensils.
4) *Food, food products, and ingredients* (a) Source of supply, (b) Protection of food, food products, and ingredients.
5) *Personal* (a) Health and disease control, (b) Cleanliness.

A similar set of basic standards were published in the Federal Register in April 1969.[33]

Specific requirements The general sanitation requirements should be supplemented by specific regulations applicable to a particular establishment or operation. Excellent codes, compliance guides, and inspection report forms are available from regulatory and training organizations.

Food preparation Temperature control and clean practices should be the rule in kitchens and food-processing plants if contamination is to be kept to a minimum. All food contact surfaces and equipment used in food preparation must be kept clean and in good repair.

Frozen meat, poultry, and other bulk frozen foods should be thawed slowly under controlled refrigeration (36–38°F is ideal) and *not left to stand at room temperature overnight to thaw.* Frozen vegetables and chops need not be thawed but can be cooked directly. Prepared foods, especially protein types, should be served immediately, kept temporarily at a temperature of 45°F or less, or on a warming table maintained at a temperature above 140°F until served. If not to be served, the food should be refrigerated in shallow pans to a depth of 2 to 3 inches within 30 minutes at a temperature of 45°F. Bulk foods such as roasts should be refrigerated within 30 minutes of preparation and cooled so that the internal temperature is 40°F or less within two hours, unless immediately served. Note that souring of hot foods is prevented by prompt refrigeration.

Food handlers are expected to have hygienic habits. A conveniently located wash basin in the kitchen or work room, and in the toilet room, supplied with warm running water, soap, and individual paper towels are essential.

Microbiological standards Natural microbial variations in different foods, and the statistical aspects of sampling present considerable difficulties in the establishment of firm standards. In addition, because of normal errors inherent in laboratory techniques, it is practical to allow some leeway in the standards proposed and hence refer to them as guidelines. One might use the geometric mean of say 10 samples or allow one substandard sample out of four. Parameters used include total aerobic count, toxigenic molds, number of coliforms, number of *E. coli,* coagulase-positive staphylococci, salmonellae, shigella, *Clostridium perfringens, Clostridium botulinum,* and betahemolytic streptococci as indicated.

Milk Control

The milk industry and the regulatory agencies have a joint responsibility in ensuring that all milk and milk products consistently meet the standards established for protection of the public health. Inspection duplication should be avoided; instead there should be a deliberate synergism of effort. With proper planning and cooperation the industry, local, state, and federal systems can actually strengthen the protection afforded the consumer. The role of industry and official agencies to accomplish the objectives stated is described below.

Certified industry inspection Industry quality control inspectors are qualified by the official agency (usually health or agriculture) based upon education, experience, and examination to make dairy farm inspection pursuant to the milk code or ordinance. Certificates issued are issued for a stated period of time, one to three years, may be revoked for cause, are renewed based on a satisfactory work record, and may require participation in an annual refresher course. Copies of all inspections, field tests, veterinary examinations, and laboratory reports are promptly forwarded to the official agency or to an agreed upon place and kept on field at least one year.

Cooperative State—Public Health Service program for certification of Interstate Milk Shippers The federal-state program is commonly referred to as the IMS Program. A State milk sanitation rating officer certified by the U.S. Public Health Service makes a rating of a milk supply. The name of the supply and rating is published quarterly by the Public Health Service. If the milk and milk products are produced and pasteurized under regulations which are substantially equivalent to the PHS Milk Ordinance, and is given an acceptable milk sanitation compliance and enforcement rating, the milk and milk products may be shipped to another area of jurisdiction which is participating in the IMS Program.

The procedures for rating a milk supply are carefully designed with detailed instructions to be followed by the industry and the rating officer. Independent evaluations are made by Public Health Service rating officers to confirm ratings given, or changes since the last rating, and ensure reproducibility of results.

Official local program supervision and inspection The official agency makes regular review of the industry inspection files mentioned above, takes whatever action is indicated, and at least annually makes joint inspections with the industry inspector of a randomly selected significant number of dairy farms, including receiving stations. The quality of work done is reviewed, the need for special training is determined, and recommendation concerning certificate renewal is made to the permit issuing official. A similar review is also made of the sample collection, transportation and the procedures, equipment, and personnel in the laboratory making the routine milk and water examinations.

In addition, the local regulatory agency collects official samples as required by the state milk code, advises the industry having jurisdiction of the results and corrective action required, participates in training sessions, and serves as the state agent in securing compliance with the state milk code. The authorized local, city, or county agency usually has responsibility for the routine inspection of processing plants, sample collection, and overall program supervision for compliance with the code. The agency sanitarian serves as a consultant to the industry in the resolution of the more difficult technical, operational, and laboratory problems. This whole procedure makes possible better use of the qualified industry inspector, and the professionally trained sanitarian, with better direct supervision over dairy farms and pasteurization plants, and more effective surveillance of milk quality. In some states the local activities are carried out in whole or in part by the state regulatory agency.

Official state surveillance and program evaluation The state department of health, and in some instances the state department of agriculture, share responsibility for milk sanitation, wholesomeness and adulteration. The responsibility is usually given in state law, sanitary code or milk code, and in rules and regulations promulgated pursuant to authority in the law. Most states have adopted the *Grade "A" Pasteurized Milk Ordinance,* 1965 Recommendations of the United States Public Health Service, or a code which is substantially the same. This makes possible a reasonable basis for uniformity in regulations and interpretation both interstate and intrastate. However short-term and alleged economic factors frequently limit reciprocity and interstate movement of milk. Both industry and regulatory agencies need to cooperate in the elimination of milk codes as trade barriers. Health agencies usually have no objection to reciprocity where milk quality compliance and enforcements is certified under the Public Health Service IMS Program. However not all states or farms participate in the program.

The IMS Program also gives the state regulatory agency a valuable tool to objectively evaluate the effectiveness of the local routine inspection and enforcement activities. The types of additional training needed by the qualified industry inspector, the assistance the dairy farmer should have, and the supervisory training needed by the regulatory agency sanitarian become apparent. Changes in technology and in practices are noted and need for clarification of regulations, laws, and policies are make known to the state agency.

A common function of a state regulatory agency is periodic in-depth evaluation of local milk programs. This includes the effectiveness with which the local unit is carrying out its delegated responsibilities as described above, the quality of work done, the staff competency and adequacy, the reliability of the official laboratory work, the record keeping, the equipment and facilities available, the number of inspections and reinspections made of dairy farms and processing plants and their adequacy of excessive frequency. The state agency usually has responsibility for approving all equipment used in milk production and service from the cow to the consumer. The standards recommended by national organizations are generally used as a basis for the acceptance of equipment.

Pasteurization Pasteurization is the process of heating every particle of milk or milk product to at least 145°F and holding at or above such temperature continuously for at least 30 minutes, or to at least 161°F and holding at such temperature continuously for at least 15 seconds, in approved and properly operated equipment. A temperature of at least 150°F for 30 continuous minutes (155°F for 30 minutes in practice) or at least 166°F for 15 seconds (175°F for 25 seconds in practice) is needed for milk products which have a higher milkfat content than milk or contain added sweeteners. Higher temperatures and shorter times are also being used. The heat treatment should be followed by Prompt cooling to 45°F.

The effectiveness of pasteurization in the prevention of illnesses that may be transmitted through milk-borne disease organisms has been demonstrated beyond any doubt. The continued sale and consumption of raw milk must therefore be attributed to ignorance of these facts. Pasteurization does not eliminate pesticide residues, anthrax spores, or toxins given off by certain staphylococci; but the production of toxins is nil when milk is properly refrigerated. The equipment used to pasteurize milk is of three general types. These are the holder, high-temperature short-time, and in-the-bottle pasteurizers. High-temperature pasteurizers include the vacuum type (temperature 162–200°F) and the ultra-high temperature type (190–270°F).

Quality control Quality control involves herd health, milk handling, transportation, processing, and distribution. Field and laboratory testing coupled with inspection, supervision, education surveillance, enforcement, and evaluation are the major methods used.

The tests used to control the quality of milk are explained in detail in *Standard Methods for the Examination of Dairy Products* Twelfth Edition. The major tests are mentioned here. Raw milk quality is determined by temperature, sediment, odor and flavor, appearance, antibiotics test, direct microscopic counts including clumps of bacteria, leucocytes, and streptococci; standard plate counts, abnormal milk tests, and thermoduric determination. Tests for brucellosis and animal health are also made. Pasteurized milk quality is indicated by the standard plate count, direct microscopic count, phosphatase test, coliform test, taste, and odor tests. Other common tests are for butterfat, total solids, and specific gravity.

ENVIRONMENTAL LAW

1

Environmental Law can be defined as those statutes, administrative regulations, executive orders, court decisions and international agreements that pertain to protection of Nature and human beings from the consequences of unwise resource extraction, production or development and the procedural means by which these 'laws' can be invoked by citizens and government.

Constitutionally, the United States exhibits a federal system: Law making and enforcement power is divided among the Federal government, the fifty State governments, regional units and local governments according to formulas contained in Federal and State constitutions and statutes. Environmental Law is a complex and delicate set of relationship among various levels of government. For example the *Clean Water Act* on the federal level establishes the general framework of water pollution control laws, empowering the Federal Environment Protection Agency (EPA) to set federal minimum performance standards for discharges to waterways, distribute grant monies for publicly owned treatment works and perform backup permitting, surveillance, and enforcement functions. But, in most cases it is the States that grant discharge permits (which can be stricter than the federal minimum standards), determine the recipients of federal grant funds, monitor discharger compliance and enforce against violators. Water quality management is frequently a function of substate regional planning agencies. Moreover, in some areas interstate regional organizations, such as the Delaware River Basin Commission, have regulatory authority over dischargers. Finally, most municipalities possess storm-water and other "public nuisance" ordinances.

Because of the multi-level nature of Environmental Law and its administration, there are numerous state, regional and local variations on the generally uniform federal environmental legal regimes. Consequently, this article will focus on Federal Environmental Law. Most federal environmental protection statutes are lengthy and complicated documents. When augmented by federal executive orders, administrative regulations and judicial interpretations, each federal statutory system would merit an article unto itself. Rather than that, the function of this article is to identify and briefly describe the major federal environmental protection statutes and to provide the reader with references so that he or she can seek out relevant regulations, orders, and decisions if more information is desired in a particular area. (For each statute mentioned the *United States Code* citation is given.)

2

The term "Environmental Law" did not come into general usage until the enactment of *The National Environmental Policy Act* (42 USC 4321 *et seq.*) in early 1970. However, long before NEPA Congress was occupied with conserving the Nation's natural resources from reckless despoilation. For example, Yellowstone National Park was created in 1872 and the US Forest Service, in the United States Department of Agriculture, was entrusted with the care of forested public domain lands in 1897. In addition, after World War II Congress began to legislate in the area of pollution control, culminating in the major federal pollution control statutes of the 1970's. The contemporary body of Federal Environmental Law consists of laws in the conservation and pollution control areas, along with key planning and coordination statutes, such as NEPA. But even more than most fields of law, Environmental Law is constantly changing and evolving as the Nation responds to shifting priorities and pressures on resources. Thus, current information is particularly important when it comes to Environmental Law.

3

In this section major federal environmental protection statues will be discussed under the following headings: Right-to-Know Statutes, Right-to-Sue Statutes, Product-Licensing Statutes; Standard-Setting Statutes; Cleanup-Response Statutes; and Conservation Statutes.

RIGHT-TO-KNOW STATUTES

NEPA

NEPA requires each federal agency that proposes a major federal action which may have a significant effect on the human environment to prepare and circulate—in draft and final form—an Environmental Impact Statement (EIS) discussing the environmental impact of the proposed action, reasonable alternatives, irretrievable commitments of resources, and the agency's balance among environmental protection and economic development, national security and other factors. Federal actions covered by NEPA are not only federal projects (roads, dams, etc.), but also federal licenses, permits, leases, contracts, and research projects that may have significant effects on the environment. NEPA does not mandate particular results: it does not require a federal agency to adopt the least environmentally damaging alternative. Courts frequently refer to NEPA as an "environmental full disclosure law," obliging an agency to take a "hard look" at the environmental consequences of its action. Once the EIS is complete (i.e., the agency makes full disclosure), the political process, not the courts, determines whether the agency will complete the proposed action. In most instances NEPA does guarantee that other federal agencies having expertise in the field, State officials and the general public will have an opportunity to formally comment on a proposed federal action before it is undertaken. When federal agencies have taken their responsibilities seriously, they have integrated environmental planning into the early stages of project planning, giving good faith consideration to alternatives and mitigation measures. However, all too often the EIS becomes a massive, unreadably technical rationalization of a project chosen for traditional reasons—economics, politics or bureaucratic inertia.

Energy Planning and Community Right-to-Know Act of 1986

Title III of the 1986 amendments to the Comprehensive Environmental Response, Compensation, and Liability Act (42 USC 9601 *et seq.*) established a regulatory program that will require disclosure of information to workers and the general public about the dangers of hazardous chemicals as well as development of emergency response plans for chemical emergencies.

Emergency response plans will be prepared by local emergency planning committees under the supervision of state emergency response commissions. Local committees are appointed by state commissions; and each committee must include representation from a wide range of community groups, including owners and operators of facilities in the planning area. Plans for responding to chemical emergencies were to have been completed by 1988. Facilities that release extremely hazardous chemicals in amounts over threshold limits must immediately notify the community emergency coordinator and the state commission.

Facilities that are required by the Federal Occupational Safety and Health Act to have "material safety data sheets" (MSDSs) for hazardous chemicals must submit a copy to the local committee, the local fire department, and the state commission. All MSDSs must be made available to the public. In addition, these facilities must prepare and submit detailed "emergency and hazardous chemical inventory forms" which describe amounts of hazardous chemicals present at the facility and their approximate locations.

Section 313 of CERCLA requires certain facilities to submit to EPA and the host state annual "Toxic Chemical Release Forms" reporting on the total quantity of listed chemicals used on-site and released to the environment—either accidentally or intentionally—through discharges to air, water, and land.

RIGHT-TO-SUE STATUTES

Citizen Suits

Almost every federal environmental protection statute contains a provision granting citizens, no matter where they are located, standing to bring suit in federal district court against violators of the statute or against EPA for failure to perform a mandatory duty. No specific injury need be alleged by a plaintiff in a statutory citizen suit, but plaintiff must allege that no government agency is effectively enforcing against the defendant. In a citizen suit, a judge may fine the defendant and award reasonable counsel and expert witness fees to a citizen plaintiff.

Judicial Review

Under the Federal Administrative Procedure Act (5 USC 701 *et seq.*), any "aggrieved person" may sue to obtain judicial review of a final decision made by a federal administrative agency. Potential damage to a person's interest in a clean and natural environment will confer standing on a plaintiff under this statute. Agency decisions are accorded a strong presumption of correctness by our legal system. Thus, in order to overturn an agency decision, a plaintiff must prove that it conflicts with the agency's statutory authority, is "arbitrary and capricious", or violates constitutional safeguards.

PRODUCT LICENSING STATUTES

Toxic Substances Control Act (TSCA)

Under TSCA (15 USC 2601 *eq seq.*), EPA is empowered to require the testing of new and existing chemicals that are potentially toxic, and to prohibit or place conditions on the manufacture, distribution, and usage of a chemical if it poses an unreasonable risk to human health or the environment.

The heart of TSCA is its requirement of a "premanufacture notice" (PMN) to EPA by any person who proposes to import, manufacture, or process a new chemical or to introduce a significant new use of an existing chemical. Once a PMN is received, EPA must act within one hundred eighty days to regulate or prohibit the manufacture of the chemical. If EPA does not act within one hundred eighty days, the manufacturing process may begin. However, if on the basis of the PMN EPA finds that production, use, or disposal of the chemical "may present an unreasonable risk" to human health or the environment, EPA may promulgate "test rules" requiring further testing of health effects, environmental effects, and chemical fate. If these tests confirm the existence of an unreasonable risk, EPA may act to limit or prohibit production, use, or disposal. "Reasonableness" in TSCA consists of a "risk-benefit" analysis in which the health and environmental risk is weighed against the social and economic benefits of the chemical.

As for existing chemicals, TSCA established an "Interagency Testing Committee" (ITC) that screens chemicals and recommends to EPA existing chemicals that are so potentially dangerous as to deserve further study. The ITC has developed several lists of potentially dangerous chemicals, including a "priority list" and a "suspicious list". Chemicals on these lists are subject to extensive monitoring and reporting requirements with regard to production, release, and exposure data. When a report by a manufacturer, processor, or distributor indicates that the substance or mixture might present an unreasonable risk to human health or the environment, EPA may require further tests or act to limit manufacture, use, or disposal of the chemical.

Finally, TSCA establishes a framework for regulating certain extraordinarily dangerous chemicals, for example asbestos, TRIS and PCBs. TSCA is one of the federal statues that could be relied upon to regulate products of genetic engineering.

Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA)

Under FIFRA (7 USC 136 *et seq.*), all new pesticides must be registered with EPA and all pesticides registered in the past must be reviewed with regard to potential adverse impacts on public health and the environment. A registration must be approved or renewed unless the pesticide will have "unreasonable adverse effects on the environment." EPA is authorized to restrict the use of certain pesticides to particular uses or to certified applicators, order specific packaging or labeling requirements, cancel a registration, or suspend the production and distribution of a pesticide.

If information disclosed in a pesticide application indicates toxicity exceeding EPA "risk criteria," a presumption against registration arises and the burden of proof shifts to the applicant. States are also authorized to regulate pesticides and pesticide applicators.

Food, Drug, and Cosmetic Act (21 USC 301 et seq.)

No "food additive", "color additive", drug or cosmetic may be sold unless it has been approved by the Food and Drug Administration (FDA). No FDA approval may be issued if the substance is found to cause cancer in humans or laboratory animals. EPA also sets tolerance levels for pesticide residues on raw agricultural products.

Atomic Energy Act (42 USC 2011 et seq.)

A Nuclear Regulatory Commission license must be obtained for the production or distribution of nuclear materials. Separate licenses must be obtained in order to construct or operate a nuclear power plant. The Food and Drug Administration's Bureau of Radiological Health regulates the uses of nuclear materials in the medical arts, and also regulates radioactivity levels in milk. The Environmental Protection Agency has responsibility for advising on environmental standards for radioactive materials, and for setting such standards for drinking water (under the Safe Drinking Water Act) and for ambient air and air emission sources (under and Clear Air Act).

STANDARD-SETTING STATUTES

Clean Air Act (42 USC 7401 et seq.)

This Act establishes federal nationwide ambient air quality standards for conventional air pollutants and provides for their attainment by reducing pollution from stationary and mobile sources. Stationary sources must meet emissions limitations set in State Implementation Plans (SIPs) administered by the States. Mobile sources pollution control is achieved by federal emissions limitations on new motor vehicles and state inspection and maintenance programs plus warranty provisions for vehicles in actual use. The Act also regulates new sources of air pollution, emissions of hazardous air pollutants, emissions limitations and transportation control plans in "Nonattainment Areas" (areas where the federal standards are being exceeded) and allowable pollution in "Prevention of Significant Deterioration" (PSD) areas where standards are presently being met.

Clean Water Act (33 USC 1251 et seq.)

Enacted in 1972 and amended several times since then, this statute sets out a goal of "fishable/swimmable" waters wherever attainable, and attempts to achieve it through (1) a construction loan program authorizing federal grants to State revolving loan funds for the construction and rehabilitation of publicly owned treatment works; (2) permit system for point sources of pollution incorporating progressively stricter technology-based effluent limitations set by industrial subcategory; (3) a requirement that publicly owned treatment works achieve the equivalent of secondary treatment; (4) areawide water quality management for the diminution of nonpoint sources of pollution and (5) setting of Total Maximum Daily Loads (TMDLs) where water quality standards are not achieved.

The Act makes it illegal to discharge a pollutant without a permit. Most States have assumed administration of the point source permit program from EPA. Also included in the *Clean Water Act* are provisions dealing with wetlands protection, sludge disposal, estuarine protection and ocean discharge. (Permits for ocean dumping are provided for in the *MarineProtection Research and Sanctuaries Act,* 33 USC 1401 *et seq.*) Concentrated Animal Feeding Operations (CAFOs) are regulated as point sources under the Act.

Safe Drinking Water Act (42 USC 300f et seq.)

Whereas the Clean Water Act regulates ambient water quality, the Safe Drinking Water Act controls the quality of tap water. The Act specifies procedures for setting maximum contaminant levels for drinking water provided by public water systems. It also governs underground injection of wastewater and limits federal development programs in areas designated as "sole source aquifers." Special programs are included for the protection of aquifer recharge areas and areas contiguous to wellheads.

Resource Conservation and Recovery Act (RCRA)

RCRA (40 USC 6901 *et seq.*) is the statute that governs the management of hazardous waste in the United States. RCRA's approach to hazardous waste management consists of 4 major elements:

- federal identification of hazardous wastes:
- a manifest system of tracing hazardous wastes from generator, to transporter, to treatment, storage, or disposal facility;
- federal minimum standards for hazardous waste treatment, storage, and disposal, enforced through a permit system; and
- state implementation of hazardous waste management programs at least equivalent to the federal program.

First enacted in 1976, RCRA was significantly amended in 1984. Under the 1984 amendments the land disposal of hazardous waste, including deep well injection, must be banned unless EPA determines that a particular method of land disposal will be consistent with protecting human health and the environment. A method of land disposal cannot be acceptable unless a petitioner demonstrates that there will be no migration from the land disposal unit for as long as the waste remains hazardous. If a disposability determination is not made within sixty-six months, land disposal of the hazardous waste is automatically banned.

The 1984 RCRA amendments also prohibited the landfilling of noncontainerized liquids, tightened performance standards for existing landfills, and established a regulatory program for underground storage tanks.

Occupational Safety and Health Act (29 USC 651 et seq.)

This statute imposes a duty on employers to furnish each employee with a place of employment that is free of recognized hazards that are causing or likely to cause illness, injury or death. The Department of Labor can promulgate safety and health standards, conduct inspections, issue citations, impose penalties, and require employers to maintain records. Health standards may be expressed as "permissible exposure limits" (PELs) which must be imposed where there is a significant risk to worker health and safety. PELs must be technologically and economically feasible.

Consumer Product Safety Act (15 USC 2051 et seq.)

Congress, through this Act, created the Consumer Product Safety Commission and authorized it to impose performance standards or packaging and labeling requirements on consumer products in order to prevent an "unreasonable risk of injury." This entails a benefit-cost analysis before the Commission can impose a restriction on a consumer product. In an extreme case, a hazardous product may be banned from commerce.

CLEANUP-RESPONSE STATUTES

Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA)

CERCLA (42 USC 1901 *et seq.*), also known as "Superfund," established an 8.5 billion dollar fund to finance cleanup activities at currently operational and abandoned facilities. The Act also contains spill notification provisions covering listed hazardous substances.

When a release has occurred, EPA can use fund monies to clean up the site and then proceed against responsible parties for reimbursement, or move against responsible parties in the first instance. CERCLA imposes strict "joint and several" (recovery may be obtained from one or all) liability against (1) current owners or operators of facilities, (2) owners or operators at the time the hazardous substances were released, and (3) generators and transporters of the hazardous substances that were ultimately released by the facility. Only innocent purchasers who have made reasonable investigations are insulated from cleanup liability. CERCLA amendments enacted in 1986 have significant bearing on how quickly, and to what extent, superfund sites will be cleaned up. Remedial investigation/feasibility studies for facilities on the National Priority List must be commenced at the following rate: 275 with in three years; and additional 175 within four years; and an additional 200 within five years; for a total of 650 by 1991.

The amendments require EPA to select, to the maximum extent practicable, remedial actions that utilize permanent solutions and alternative treatment technologies or resource recovery technologies. A preference is established for remedial actions that utilize treatment to permanently and significantly reduce the volume, toxicity, or mobility of hazardous substances. Offsite transport and disposal without treatment is the least preferred option where practicable treatment technologies are available. If the selected remedy does not achieve the preference for treatment, EPA must publish explanation. For on-site remedial actions, the amendments require attainment of "legally applicable or relevant and appropriate Federal and state standards, requirements, criteria, or limitations" (ARARs), unless such requirements are waived. Maximum contaminant level goals under the Safe Drinking Water Act and water quality standards under the Clean Water Act must be met where relevant and appropriate.

Congress' failure to reauthorize CERCLA has caused a depletion of Superfund so that State cleanup funds are now of primary importance for site remediation. However, since 1990 CERCLA has been amended to provide various incentives for remediation of urban ("Brownfields") contaminated sites.

Oil Pollution Act of 1990 (OPA '90)

Galvanized into action by the Exxon Valdez oil spill in 1989, Congress enacted the Oil Pollution Act of 1990 (OPA '90), which integrated and strengthened prior federal law covering liability for and cleanup of oil spills. Modelled on CERCLA, OPA '90 establishes a billion dollar Oil Spill Liability Trust Fund financed by the imposition of a five cents per barrel tax on oil delivered at the refinery. Owners and operators of vessels and onshore and offshore facilities are strictly liable for cleanup and natural resource damages, subject to the defenses of (1) act of God, (2) act of war, or (3) negligence of a third party not associated with the owner or operator. Facilities must develop spill prevention, control, and countermeasure (SPCC) plans, have them approved by EPA or the Coast Guard, and implement them, or face heavy civil and criminal penalties. Single hull tankers are to be phased out, and licensing and supervision of officers and seamen are strengthened. The OPA '90 explicitly does not preempt state oil spill laws.

CONSERVATION STATUTES

The *Surface Mining Control and Reclamation Act* (30 USC 1201 *et seq.*) provides extensive federal regulation of private coal surface mining on private lands and also regulates excavation of coal by strip-mining on public lands. The basic regulatory mechanism of this act is a permit system, to be implemented by the States according to federal standards, with provision for federal enforcement if a state program does not meet federal standards. There are also flat prohibitions on surface mining in environmentally sensitive areas. The Act is administered by the Office of Surface Mining in the Department of Interior.

The *Fish and Wildlife Coordination Act* (16 USC 661 *et seq.*), originally passed in 1934, requires federal agencies proposing water resource development projects, either directly or by permit, to consult with the United States Fish and Wildlife Service, United States Department of the Interior, with a view towards conserving fish and wildlife resources. The reports of the Secretary of the Interior under the Act must include proposed measures for mitigating or compensating damage to wildlife resources resulting from the project. The proposing agency is only required to fully consider the Secretary's report.

The *Endangered Species Act* (16 USC IS31 *et seq.*) requires federal agencies to ensure that any action authorized, funded, or carried out by them are not likely to jeopardize the continued existence of any listed endangered or threatened species, or result in the destruction or adverse modification of its critical habitat. The key to the Act's implementation is mandatory consultation by the proposing agency with the Fish and Wildlife Service. When FWS makes a formal finding that the proposed action will violate the Act, and after a good faith effort to find alternatives has failed, an Endangered Species Committee, composed of Federal officials and a representative of the affected States, must balance preservation against development and decide the issue: but the Act weighs the balance in favor of preservation.

The *National Historic Preservation Act* (16 USC 470 *et seq.*) established the National Register of Historic Places. It requires federal agencies to consult with the Advisory Council on Historic Preservation whenever proposed federal projects might have adverse impacts on historic or archaeological sites listed or eligible for listing on the National Register. By regulation, the proposing federal agency must consult a State Historic Preservation Officer when determining how its activities will affect historic or archeological sites. The procedures also require that the SHPO, along with the Advisory Council and the proposing agency, reach written agreement in certain cases on how to mitigate any adverse effects expected from a federal project.

The *Wild and Scenic Rivers Act* (16 USC 1271 *et seq.*) was originally enacted in 1968 and has been subsequently amended several times. The statute is jointly administered by the Secretary of the Interior, through the National Park Service and, when national forests are involved, by the Secretary of Agriculture through the National Forest Service. The Act established "a national wild and scenic rivers system" and defines criteria for eligibility under each of the following three classifications: wild, scenic, and recreational rivers. The Act provides that "no department or agency of the United States shall assist by loan, grant, license or otherwise in the construction of any water resources project that requires a direct adverse effect on the values for which such river was established, as determined by the Secretary charged with its administration." Adjacent federal lands must be managed consistent with the river's conservation values.

The *Coastal Zone Management Act* (16 USC 1451 *et seq.*) provides for federal financial assistance to coastal state governments for the development of Coastal Zone Management Plans. Coastal Zone Management Plans have as their primary function land-use management for the Coastal Zone to assure the orderly and environmentally sound development of these ecologically sensitive areas. Under the Act, federal or federally assisted or licensed projects are required to be approved by the coastal state as consistent with an approved Coastal Zone Management Plan. At the federal level the Coastal Zone Management Program is administered by the Office of Coastal Zone Management of the National Oceanic and Atmospheric Administration of the Department of Commerce.

Sixty-one percent of all federal lands, some 470 million acres, is administered by the Department of Interior's Bureau of Land Management. The statute under which BLM administers the national resource lands is the *Federal Land Policy and Management Act* (43 USC 1701 *et seq.*). Among the Act's declared policies is that public lands should be retained in federal ownership unless disposal will serve the national interest. In pursuit of this policy, all public lands and resources are to be inventories periodically: all previous land classifications are to be reviewed; and all land use decisions are to be the result of a land-use planning process. When resources or land are to be disposed of or utilized, effort must be made to assure a fair market value return to the United States. Guidelines for land-use planning and management must assure attainment of multiple-use and sustained yield. Like most federal conservation statutes, the Act incorporates the *Multiple-Use and Sustained Yield Act* (16 USC 528 et seq.). Most important for our purposes, planning and management activities are to be undertaken so as to protect the environmental, ecological, scientific, scenic, historical, air, atmospheric and water resource values of the public domain. Areas of critical environmental concern are to be identified and protected through regulation and planning as soon as possible. Land-use plans must be consistent with all state and federal pollution control statutes.

The second largest administrator of public lands is the US Forest Service, which controls the use of over 187 million acres dispersed throughout the United States. Consolidation and clarification of the FS mission were accomplished by enactment of the *Forest and Rangeland Renewable Resources Planning Act* and its subsequent amendment by the *National Forest Management Act* (16 USC 16 *et seq.*). These Acts, like the *Federal Land Policy and Management Act,* established a comprehensive planning structure for the management of the national forest system in general as well as particular forests. Unit plans must integrate both economic and environmental considerations. The Act declares that each unit plan should protect the environment, provide for restocking, and perpetuate multiple-use and sustained yield. Clearcutting is prohibited unless it is determined to be the best means of meeting the objectives of the unit plan. If clearcutting is chosen, efforts must be made to mitigate its effects. Other standards in the Act prevent premature harvesting of trees unless such harvesting is compatible with other multiple uses of the forest. While developing unit plans, lands unsuitable for timber production are to be identified and timber production from such lands is to be prohibited for a period of ten years.

National Forest Lands and other federal lands can be withdrawn from logging if Congress designates them as Wilderness Areas under the *Wilderness Act* (16 USC 1131 *et seq.*). These lands must be administered to preserve wilderness character and must be devoted to scenic, historic, recreational, and similar uses.

As for mining on federal lands, the antiquated *General Mining Act of 1872* (30 USC 21) governing the location and patenting of claims to hardrock minerals, has not provided an adequate basis for mitigating the environmental abuses of hardrock mining. However, where energy resources are concerned, environmental protection is one factor to be considered in awarding mineral leases under the following statutes: *Mineral Leasing Act* (30 USC 181 *et seq.*); *The Outer Continental Shelf Lands Act* (43 USC 1331 *et seq.*); *Multiple Mineral Development Act* (30 USC 521 *et seq.*); *The Geothermal Steam Act* (30 USC 1001 *et seq.*); and *The Federal Coal Leasing Amendments* (30 USC 201 *et seq.*).

A number of federal transportation statutes deal with conservation of natural resources. Under both the *Federal-Aid Highway Act* (23 USC 101 *et seq.*) and the *Urban Mass Transit Act* (49 USC 1601 *et seq.*) the Secretary of Transportation cannot approve a transportation project which encroaches upon park land, wildlife refuges or historic sites unless there is “no feasible and prudent alternative” and the “program includes all possible planning to minimize harm to such areas.” Highway planning must include environmental factors and be consistent with State transportation plans prepared under the *Clean Air Act.*

The conservation of Alaska’s vast natural resources has been a high priority of conservationists for many years. In 1978 President Carter, under the authority of the *Antiquities Act* (16 USC 431 *et seq.*), designated 17 National Monuments encompassing 56 million acres of Alaskan land. The *Antiquities Act* empowers the Secretary of the Interior to designate certain federally owned lands as National Monuments, including “historic landmarks, historic and prehistoric structures and other objects of historic or scientific interest.” Once a designations has been made, the Secretary can prohibit any activity that would adversely affect the site. An additional 50 million acres of land in Alaska were withdrawn for wildlife refuges under the *Federal Land Policy and Management Act.* Finally, in late 1980, Congress passed the *Alaska National Interest Lands Conservation Act,* ratifying most of the previous executive withdrawals.

America’s National parks have been referred to as its “Crown Jewels.” The National Park Service was created in 1916 (16 USC 1 *et seq.*) to “promote and regulate the use of National Parks, monuments and reservations and to conserve the scenery and natural and historic objects and the wildlife therein and by such means as will leave them unimpaired for the enjoyment of future generations.” Parks are created by individual Congressional enactments, so that one must look to the individual organic acts in order to understand the legal restrictions applicable to each park. However, mining in National Parks was severely restricted by the *National Park Service Mining Activity Act* (16 USC 1901 *et seq.*). NPS also administers the Wild and Scenic Rivers Systems and the National Trails System (16 USC 1241 *et seq.*). Financing for purchases of National Park Lands has frequently been provided by the *Land and Water Conservation Fund Act* (16 USC 460 *et seq.*).

National Wildlife Refuges are administered under the *National Wildlife Refuges System Administration Act* (16 USC 668dd *et seq.*). Hunting, fishing, and other public recreation may be permitted in National Wildlife Refuges if they are compatible with the conservation purpose of the refuge.

Finally, there is extensive federal legislation relating to the protection of particular wildlife species, including habitat acquisition programs. Some of these statutes are the *Marine Mammal Protection Act* (16 USC 1361 *et seq.*); the *Wild Free-Roaming Horses and Burros Act* (16 USC 1331 *et seq.*); the *Bald Eagle Protection Act* (16 USC 668 *et seq.*); the *Migratory Bird Hunting Stamp Act* (16 USC 718 *et seq.*); and the *Water Bank Act* (16 USC 1301 *et seq.*).

4

In recent years, international environmental law has burgeoned to the degree that it is now one of the most active areas in the field. The international community has recognized that environmental threats are frequently transnational, multinational, regional or even global in scope. As a result, international agreements (treaties, conventions and protocols) have entered into effect governing activities involving diverse environmental issues, such as biodiversity (e.g., The Convention on Biological Diversity), climate change, ozone depletion (e.g., the "Montreal Protocol"), the protection of Antarctica, transboundary disposal of hazardous wastes, vessel-based water pollution and ocean dumping, transboundary air and water pollution, conservation of whales and other marine resources, trade in endangered species and nuclear weapons testing.

International agreements, unlike most national environmental laws, are essentially voluntary in nature: that is, they cannot be enforced by an international legislature, court system or police force. Such agreements can only be enforced by the nations that consent to be bound by a particular international compact. However, political methods, for example, international exposure of violating nations and potential trade boycotts, are often successful in achieving compliance by nations that either do not adopt international agreements or else adopt them and systematically violate their provisions.

EPIDEMIOLOGY

ORIGINS AND DEFINITIONS

Epidemiology (Waterhouse, 1998) is a science that basically borrows from the other sciences to form its own area of expertise. The actual word *epidemiology* can be broken down into three parts: first *epi,* which means "upon"; then *demo,* which is population; and finally *ology,* which refers to studying. So we can in a simple form say epidemiology is the study of events that occur upon or on populations or groups. Overall, epidemiology is not interested in the individual, but rather the population; however, these data are often used to relate and infer risks to an individual. The field of epidemiology interacts with other science areas and rarely functions on its own. For example, in the study of occupational diseases, there may be an interaction of occupational exposure and health effects in determining the risk of a specific disease (Stern, 2003). Biostatistics, the study of statistical relationships for biological systems, is an area often in close association with epidemiologists. It could even be argued that epidemiologists cannot easily function without using basic biostatistics. Thus, epidemiologists are routinely trained in the basics of biostatistics as well. In addition, it is not uncommon for some epidemiologists to have been originally trained or cotrained in other disciplines (e.g., environmental health).

The field of epidemiology can be broken down into different subject areas. In the simplest form it can be grouped as acute (e.g., accidents), chronic (e.g., type II diabetes), and infectious (e.g., malaria). However, it can also be grouped by subject name, such as occupational epidemiology, environmental epidemiology, cardiovascular epidemiology, and so forth. The other way of classifying epidemiology is by disease name, such as malaria epidemiology, epidemiology of heavy metals, and so forth. Thus, like most scientific fields of study, this area can be categorized in many different ways depending on one's prospective. In this chapter, we are concerned with the area of epidemiology that is most closely associated with environmental science and engineering. Traditionally environmental and occupational epidemiology were related to those in environmental science and engineering, but as the world changes and the concept of global epidemiology emerges, most if not all subfields or subjects of epidemiology are becoming interspersed among previously distinct and separate scientific and other fields of study (e.g., sociology). However, due to the necessity of brevity in this chapter, the focus will stay on the traditional subject areas of environmental and occupational epidemiology.

One of the biggest problems with environmental epidemiology is that studies rarely find a strong association for cause and effect. This is commonly thought to be a result of confounders and problems in conducting studies of this nature. These problems include the lack of a clear study population, low-level exposures, inaccurate exposure doses, and related confounding factors. Some of these concerns can be overcome in occupational studies where the population is better defined and exposures have been better documented, although the same issues can also occur in this area of epidemiology as well. However, these problems should not discourage us from conducting or evaluating epidemiological investigations. Readers should be aware of general texts on this subject, and a few are mentioned here as potential references (Lilienfeld and Stolley, 1994; Timmreck, 1998; Friis and Sellers, 1998), although this list is not complete.

Epidemiology begins with the application of numbers to a disease, set of cases, or event (like accidents), primarily in the sense of counting rather than measurement. Some can even say that counting is at the heart of epidemiology, because it provides us with how many of the cases or events exist or occurred (Lange *et al.,* 2003a). Disease, which is used here to include all events or occurrences that may be identified in an epidemiological study, are identified as either *incidence* or *prevalence.* These two terms are rates of occurrence or existence for the disease. The term *disease,* in this chapter, will also mean and include any event or case that is measured, such as cancer, injury, disorder, or a similar occurrence. Incidence is the number of cases that arose during a specific time period, usually a year; prevalence is the number of cases that exist at some point in time or within a time period of interest, again, usually a year. In most cases, prevalence will be a larger numerical value than incidence. This is true when people with the disease survive for a long period of time, which would be a time period longer than the time period established for the incidence rate. However, if the disease event is very short or can occur multiple times over a short period of time, incidence and prevalence can be similar. If the same disease event can occur more than once in the same person, it is possible that the incidence can be greater than prevalence. An example of this would be influenza (the flu, which is a viral disease) in a small population, say 15 people in an isolated location (e.g., a research station in the Arctic). If prevalence is counted as anyone having the disease during the time period and incidence of the occurrence of the disease, if all 15 had the flu and someone contracted the disease twice, incidence would be 16 times in a population of 15, with prevalence being 15 out of 15. As noted, very seldom will the incidence be larger than prevalence; this would only occur in rare or unusual events and would likely involve small populations. It is important to understand the difference between each of these terms, in that they represent different "values" for a disease or event in the population being studied. Table 1 provides an example of incidence and prevalence for data collected from a computer database of different diseases (Centers for Disease Control and Prevention [CDC], 2004).

In Table 1, the incidence and prevalence (I/P) are the same, since both involve the occurrence of death. For Parkinson's disease there was an increase in I/P for both the United States and Pennsylvania, while for cancer there was a decrease (1970–2000) for the United States and a steady state for Pennsylvania. Adjustment involves standardizing the population for such variables as age, race, and sex. These variables can also be considered confounders.

Epidemiology was recognized at first implicitly by a general appreciation of probabilities, rather than explicitly by recording each incident. This is noted by some of the first attempts to conduct epidemiological investigations where the number of events was noted but no rate of the event was determined. Just knowing the number of cases alone, without a rate of occurrence, does not allow comparison with other events. However, lack of a rate does not necessary minimize an epidemiological study, although in the modern day, rates are often essential. But, in parallel cases with the base population among whom the cases have occurred, in order to obtain in ratio from the rate incidence or occurrence of the disease, suitably refined, according to the circumstances of the situation and in ways we shall discuss later, such a rate can be used as a measure for purposes of comparison in the same place between different time periods, or between different places at the same time, or in a variety of other ways. Rates are represented in units of a population, like per 100,000 people. By an appropriate extension we can measure the impact of disease, whether in general or of a particular type, on the population. But we also find that the characteristics of the population itself can alter the manifestation of the disease, so that the science of epidemiology can be symmetrically defined as measuring the impact of disease on a population, or of a population on a disease—perhaps better expressed by saying that the concern of epidemiology is with the measurement of the interaction of disease and population. Thus, at the heart of epidemiology is counting (Lange *et al.*, 2003a), which is then concerted to a rate as expressed as either incidence of prevalence.

TABLE 1

All races and all gender death rates for Parkinson's disease and cancer of bronchus and lung unspecified for 1979–1998 using 1970 and 2000 standardized populations

Standard Population	Region	Crude*	Age-adjusted*
Parkinson's Disease			
2000	US	4.8	4.9
1970	US	2.9	2.2
2000	Pennsylvania	3.5	3.3
1970	Pennsylvania	3.5	2.2
Cancer of Bronchus and Lung Unspecified			
Standard Population	Region	Crude*	Age-adjusted*
2000	US	52.5	55.2
1970	US	46.0	60.7
2000	Pennsylvania	54.4	60.7
1970	Pennsylvania	46.0	60.7

* Rates are per 100,000.

The issues of rates can be illustrated through two historical studies. The first did not employ rates in determining a cause of scurvy, while the other employed rates to locate the source of the infectious agent in causing cholera. These studies illustrate how rates can be used in evaluating disease, although the importance of basic observation cannot be forgotten or lost in a study.

In the study by James Lind on scurvy (Timmreck, 1998), in 1753, he noted that some sailors developed this disease while others did not. Lind examined the diet of those with and without the disease as part of the investigation into the cause of scurvy. Although he did identify a crude rate in a population of sailors initially studied (80 out of 350 had the disease), this rate or its comparison was not employed in his study design. To evaluate the differences in reported diets, he provided oranges and lemons to two sailors and followed their progress. After a few days he noted that their scurvy subsided and concluded that these dietary supplements were most effective at treating and preventing the disease. In modern epidemiology we would most likely look at the rates of disease occurrence and cure rather than using observational numbers, as had been used by Dr. Lind. However, Dr. Lind did make observations of cause and effect and time and place, as well as sources of causation in the disease process (Timmreck, 1998). It is worth noting that today the size of this study would likely be considered too small for publication in a scientific journal. However, this demonstrates the importance of observation even for small study populations.

What most consider the first true epidemiology study that employed rates was conducted by John Snow in the 1850s and concerned an outbreak of cholera. Dr. Snow actually conducted two studies on the epidemiology of cholera: the first was a descriptive study in the SoHo district of London (this is in the Broad Street area), and the second was a classical investigation in determining rates of disease.

In the first study he observed that two different populations were affected by cholera, one with a low number of deaths and the other with a high number. By mapping locations of deaths, commonly used today in geographic and ecological epidemiology studies, he concluded that there were different sources of exposure (Paneth, 2004). The population with a low number of deaths was obtaining water from a brewery source that had its own well, which as we now know was not contaminated, and those in the second population, having a high number of deaths, were obtaining it from the Broad Street pump. From these data, he plotted the occurrences and extent of the outbreak, which we now look at as the duration of the epidemic. Near the end of the epidemic, Snow had the Broad Street pump handle removed for to prevent the reoccurrence of the disease. From his investigation, a foundation of causative agents (which was not known at the time), population characteristics, environment, and time were connected in evaluating the disease process with an applicability of prevention.

During an epidemic in 1853, Snow examined the sources of water. At the time, there were three water companies serving the area, Southwark, Vanxhall, and Lambeth. Southwark and Vanxhall collected water from a polluted section of the Thames river, while Lambeth collected water upstream of the pollution. By using deaths published by the registrer general in London, Snow was able to deduce that those obtaining their water from Southwark and Vanxhall had a much higher death rate that those getting water from Lambeth. Snow obtained the addresses of those that died, and by knowing the water source and the population in the area, he was able to calculate death rates for the various water sources. He determined that those having Southwark and Vanxhall water experienced a death rate of 315 per 10,000 and those with Lambeth had a rate of 37 per 10,000 (Lilienfeld and Stolley, 1994). This provided evidence that obtaining water from the polluted area of the river resulted in a high rate of death from cholera and that cholera was a waterborne disease. Snow's discovery, through epidemiology, occurred approximately 40 years before Robert Koch, in 1884, identified *Vibrio cholera* as the causative agent of cholera. This certainly established a relationship of disease with the environment, but also showed the importance of representing epidemiological data in the form of a rate. Today, rates are commonly reported as a number per 100,000 or million. However, any rate expression is acceptable. Even when cause of a disease is not known, as shown by Snow, a great deal can be learned about the agent through epidemiology.

Today, the pump handle from the Broad Street well is in possession of the John Snow Society. One survey reported that Snow was the most influential person in medicine, with Hippocrates being second (Royal Institute of Public Health, 2004). Certainly this report does suggest that there may be bias in the survey, with a larger number of votes coming from the John Snow Society, but it illustrates the importance of his contribution and the influence that epidemiology has had on medicine. It should be mentioned that Snow was one of the originators of the field of anesthesiology as well. Thus, his contribution is not limited to pure epidemiology.

From these examples, it becomes clear that the methods of epidemiology are in essence those of statistics and probability. It is also clear that much of medicine is based on observation within the field of epidemiology; diagnosis depends upon a recognizable cluster of signs and symptoms characteristic of a disease, but this is only so because of their statistical similarity extended over many cases. And in a like manner, the appropriateness and efficiency of treatment methods summarize the result of practice and observation. Many of the developments of modern medicine, both in methods of diagnosis and treatment, depend upon epidemiological procedures for their assessment and evaluation, such as in clinical trials (see below) and many experimental studies, as was illustrated by Dr. Snow's study of water sources.

Generally, epidemiological studies can be divided into four groups: ecological, cross-sectional, case-control, and cohort. Ecological and cross-sectional studies are hypothesis-generating investigations, while case-control and cohort studies can establish a causal effect. Case-control and cohort studies can provide odds ratios (ORs) and relative risks (RRs). In most cases, the OR and RR will be equal to each other, and represent the risk associated with exposure and occurrence of disease.

MORTALITY AND THE FIRST LIFE TABLES

It is in the description and measurements of mortality that we first meet quantitative epidemiology. The *London Weekly Bills of Mortality* begun early in the sixteenth century continued irregularly during that century and were resumed in 1603, largely to give information about the plague. John Graunt published an analysis and comparison of them in the middle of the seventeenth century (*Natural and Political Observations upon the Bills of Mortality*), and later Sir William Petty published *Five Essays in Political Arithmetic*, a book that was devoted rather less to numerical data that was Graunt's. Graunt had examined deaths by causes and age, which led to the interest at this time in the construction of life tables. A life table aims to show the impact of mortality by age through a lifetime. Starting with an arbitrary number of people (e.g., 1,000—known as the "radix") who are regarded as having been born at the same time, the life table thus opens with 1,000 persons at exactly age zero. A year later this number will be diminished by the number of infant deaths that have occurred among them, leaving as survivors to their first birthday a number usually designated $\int_1$. Similarly, the deaths occurring in the second year of life reduces the number still further, to $\int_2$. By the same process the diminution of numbers still alive continues until the age at which none survive. The first actual life table was constructed in 1693 by Edmund Halley, the mathematician (best known perhaps for the comet named after him), and it was based on 5 years' experience of deaths in the German city of Breslau. Since it recorded deaths by age, without reference to birth, the radix was obtained from a summation that the population was in dynamic equilibrium. Although there were other life tables constructed around this time, when life-insurance companies began to be founded, it was not possible to construct an accurate life table without using rates of mortality rather than numbers of deaths. Rates required denominators to be both appropriate and accurate, and the obvious source was a census.

CENSUSES

Apart from censuses of Roman and biblical times, the first modern census was taken in Sweden in 1751. The first in the United States was in 1790, and the first in England was in 1801. Censuses traditionally were taken for two main purposes, military and fiscal. Their epidemiological value in supplying denominators for the construction of rates of mortality was very much an incidental usage. Just as the concern about the plague gave a new impetus to the regular production of the London *Bills of Mortality,* so the anxiety about attacks by cholera was an important factor in setting up national registration of deaths in England and Wales in 1837. But from that time onward, mortality rates were published annually in England and Wales, and their implications, medical, social, geographical, and occupational, were very effectively analyzed and discussed by William Farr, the first medical statistician appointed to advise the register general, which collected information on Mortality.

CAUSES OF DEATH AND THE ICD

With the advent of routine death registrations and censuses throughout Europe and North America, the publication of mortality rates in successively increasing detail stimulated comparison, and demanded at the same time an agreed basis for terminology. This led to the setting up in the middle of the nineteenth century of international Statistical Congresses to produce a classification of causes of death. Gradually these lists of causes became generally adopted by individual countries, and in order to keep up with medical advances, the list was required to be revised every 10 years. From a list of causes of death it was extended to include diseases and injuries not necessarily resulting in death, so that it could be used for incidence by hospitals as a diagnostic index. The ninth revision of the International Statistical Classification of Diseases, Injuries, and Causes of Death (ICD) came into force in 1979 and has recently been replaced by the ICD-10, on January 1, 1999. The ICD was originally formalized in 1893 as the Bertillon Classification of International Causes of Death. The ICD-10 is copyrighted by the World Health Organization (WHO). The WHO publishes the classification and makes it available to countries of the world. In the United States, the U.S. government developed a clinical modification for purposes of recording data from death certificates.

The degree of detail it is now possible to convey through the use of the latest ICD code is very great, but of course it is entirely dependent upon the subtlety of the information available to the coder. However, the hierarchical design of the code does permit expression of a rather less specific diagnosis when the data are inadequate or vague. One of the biggest problems with this type of system is that the data are extracted from death certificates, which may not accurately reflect the true cause of death.

The WHO collects mortality data from its member states and publishes mortality rates by cause, sex, and age group, in the *World Heath Statistics Annual.* Individual countries also publish their own mortality data, often including more detailed subdivisions, for instance of geographical areas. The same offices in nearly all countries are responsible for collecting and publishing statistics of births and marriages, and probably also for the censuses, which recur at intervals of 5, 7, or 10 years, according to the practice of the country.

THE SEER PROGRAM

Another evaluator of specific mortality is the Surveillance, Epidemiology, and End Results (SEER) Program of the U.S. National Cancer Institute (NCI). This report provides information on cancer incidence and survival using various geographic locations of the United States. The concept of these areas is to represent occurrence for the overall population. SEER registries now include in its collection about 26 percent of the U.S. population. Information collected by the SEER registries includes patient demographics, primary tumor site, morphology, stage at diagnosis, first course of treatment, and follow-up status. Currently this is the only source of population-based data on cancer that includes its stage and diagnosis and survival rates for the stages of cancer. This is also a Web-based source and is provided by the National Center for Health Statistics. Analyses of SEER data are commonly published in the literature, including for determining trends of disease (Price and Ware, 2004).

OTHER DATA SYSTEMS

There are other Internet-based data systems that provide information on rates on deaths in the United States. This includes the CDC Wonder system (CDC, 2004). This system provides both crude and age-adjusted death rates as categorized by the ICD-9 and ICD-10 (specific causes or diseases). Thus, by using this system, rates can be determined by county and state and for the United States as a whole for any year or group of years. Such systems allow evaluation of varying rates over time and determination of trends. These data can also be used in ecological epidemiological studies to evaluate trends.

COMPARISON OF MORTALITY RATES AND STANDARDIZATION

When comparing the experience of two different countries with respect to mortality from a specific disease, the rates for each age group can be contrasted perhaps most easily in graphical form. But comparing their crude rates of mortality from the disease, in an endeavor to simplify the comparison, is only legitimate in the unlikely event of their age structures being identical. Thus, in most studies there is an age adjustment (Baris *et al*., 1996). This adjustment is based on a large population, which is usually based on the national or state population. Use of crude rates alone, without age adjustment, may lead to inaccurate interpretation of the rate of disease and does not allow these rates to be compared to other studies (Lange, 1991).

The overall mortality rates increase sharply with age after puberty (Figure 1): the increase is in fact close to exponential in its shape, as is clear from its linear form when plotted on a logarithmic vertical scale (Figure 2). Consequently, if one of the two populations to be compared has a greater proportion of the elderly than the other, its crude rate will exceed the other, even if their age-specific rates are identical throughout the age range. The crude rate is the ratio of the total deaths to the total population (this may be for both sexes together or separately by sex), and more deaths will result from the larger population of the elderly groups. However, it is possible to obtain a legitimate comparison using a single figure for each population by the simple method of applying the separate age-specific rates observed in the first population to the numbers of the population in the corresponding age groups of the second. In this way we find the numbers of deaths that would have occurred in the second population if it had experienced the mortality rates by age of the first. These "expected" deaths can be totaled and expressed similarly to a crude rate by dividing by the total of the second population. This comparison is legitimate because the population base is now identical in its age structure and cannot distort the results. The process has been called by some "standardization," and the rates of the first population are described as having been standardized to the second. Clearly it would be equally possible to reverse the procedure by standardizing the second to the first population. A different pair of rates would of course be obtained, but it would in general be found that their ratio was similar to the ratio of the first pair.

An example of the differences of crude and age-adjusted rates can be observed by using the CDC Wonder system (CDC, 2004). Table 1 (see previous discussion) shows the crude and age-adjusted death rates for Parkinson's disease (ICD code 332) and cancer of bronchus and lung unspecified (ICD code 162.9). These rates are standardized for 2000 and 1997 for the United States and Pennsylvania. As can be seen from the table, there is a difference in rates between crude and age-adjusted as well as for different standardized populations for the United States and Pennsylvania. This also illustrates that there are different rates for disease in specific populations, like Pennsylvania versus the United States. Such rates can be used to evaluate trends for disease by time and geography. When evaluating and reading epidemiological studies, it is important to note that the title of tables and figures should first be carefully read so as to understand the information presented.

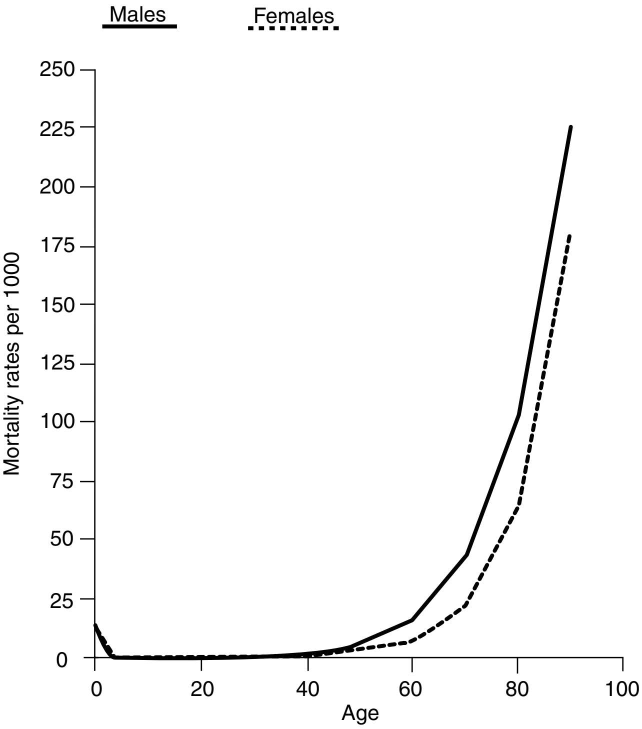

FIGURE 1 Mortality rates by age and sex (arithmetical vertical scale).

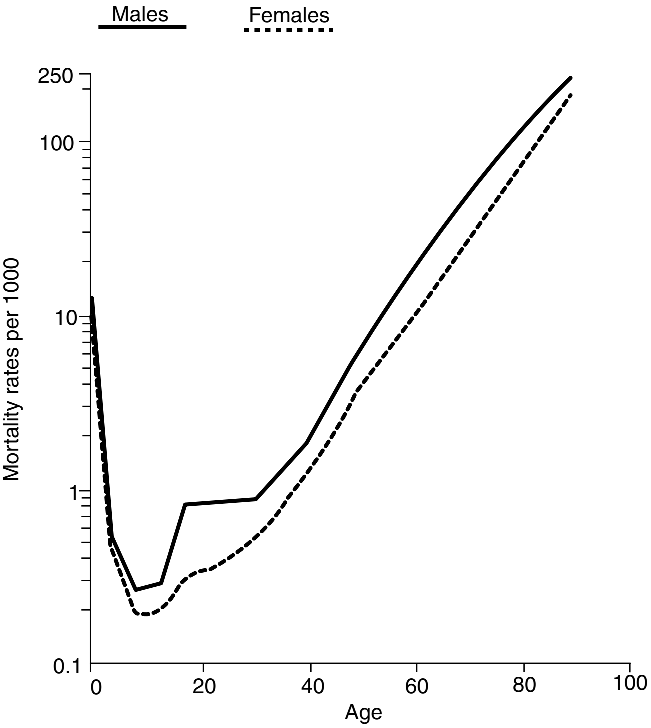

FIGURE 2 Mortality rates by age and sex (logarithmic vertical scale).

WORLD STANDARDIZED RATES

Another method of standardization, essentially similar to that described above, makes use of standard population, defined in terms of the numbers in each age group. The rates of each population are applied to this standard population to obtain a set of expected mortality deaths and thus a rate standardized to the standard population. It is becoming increasingly common today to use a constructed "world standard population" for this purpose, so that rates so obtained are described as "world standardized rates" (WSRs). This concept was created originally by the late Professor Mitsui Sigi, a Japanese epidemiologist, when attempting to compare cancer mortality rates between different countries throughout the world. The age structure of a developing country (often typified as Africa) has a triangular form when depicted as a pyramid, at least before the onset of AIDS (see Figure 3), with a small proportion of the elderly, but its proportion increasing regularly toward the lowest age groups. A typical pyramid for a developed country (typified as European) is that in Figure 4, which shows a rather more stable pattern until the ultimate triangle at the upper end.

These forms of standardization have been disrupted by HIV, which is the causative agent of AIDS. In Botswana for the year 2020 it has been predicted that there will be a larger population around the age group 60–70s than for 40–50s as a result of AIDS (Figure 5). The dramatic effect on the population structure of this virus will change how age adjustment must be performed for many of the affected countries. Thus, in the future, age adjustment will not be as straightforward as described in many standard epidemiology textbooks.

INDIRECT STANDARDIZATION

When the objective is to compare the mortality rates of various subpopulations, such as geographical, occupational, or other subdivisions of a single country, a different method is commonly used. What has already been described is known as the "direct method" of standardization, using a standard population to which the rates for various countries are applied. The "indirect method" of standardization makes use of a standardized set of mortality rates by age group, and these rates are applied, age by age, to each of the subpopulations, providing thereby a total of expected deaths; the actual total of deaths observed in each subpopulation is then divided by the expected total to provide what is known as the "standardized mortality ratio" (SMR). The standard set of mortality rates used is that of the overall population's experience, and almost invariably that population is the sum of all the subpopulations. Clearly if some SMRs are greater than 100 (it is conventional to multiply the SMR by 100, which has the convenience of making apparent the percentage difference from expectation), then some will be below, since the weighted mean of the SMRs must be 100.

For the purposes of comparisons of this type, the indirect method has a number of advantages over the direct method. Several of the subpopulations may be quite small in size, especially in some age groups where the numbers observed may be very small, so that age-specific mortality rates can fluctuate widely. The mortality rates of the parent population, on the other hand, are inherently more stable than those of any fractional subpopulation. The structure by age of each subpopulation will in general be easily obtainable, often from the census, with reasonable accuracy, and so will the total number of deaths. The ratio of observed to expected deaths—the SMR—is then easily interpreted as a percentage above or below expectation. An assessment of the statistical significance of its difference from 100 can be obtained by assuming a distribution similar to the Poisson, so that the standard error would be $100E$, where E is the expected number of deaths: deviations from 100 of more than twice this quantity would be regarded as statistically significant at

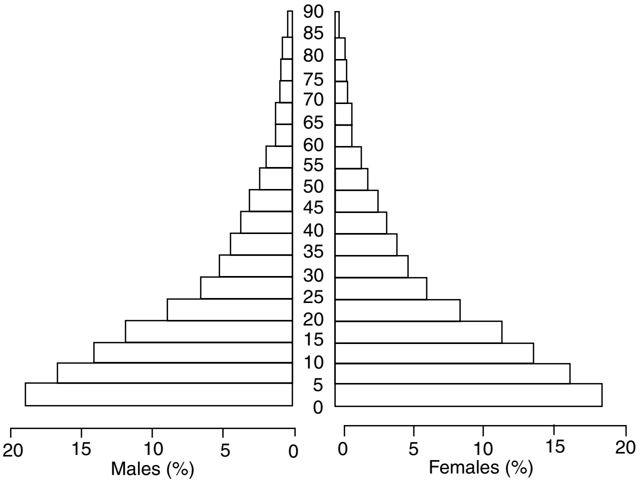

FIGURE 3 Population pyramid: a developing country.

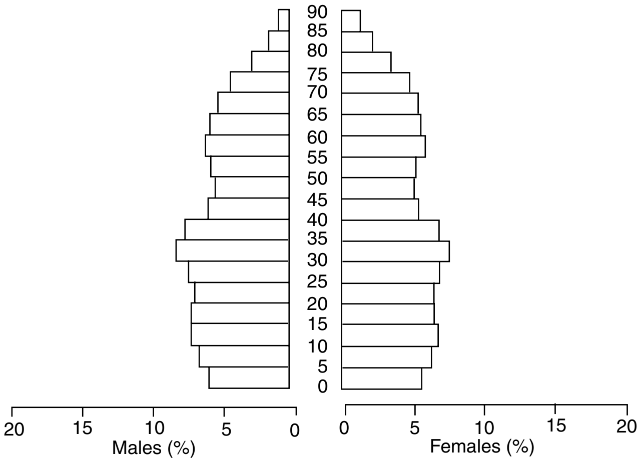

FIGURE 4 Population pyramid: a developed country.

the 5% level. In many studies a confidence interval (CI) at 95% is presented. Even if an SMR is above or below 100, a CI that has an overlap with 100 is often considered to be in the range of nonsignificant. In most cases, statistical significance exists when the summary value and its CI do not overlap 100.

OCCUPATIONAL MORTALITY COMPARISONS

It will be obvious that precisely the same methods can be applied to mortality rates from any single disease—or group of diseases, such as cancer—as to total mortality from all causes. By appropriate choice of cause groups it is possible to examine the pattern of mortality in a particular industry or occupation—for example, to highlight any excesses or deficits, when compared to the overall experience of the total population. But such a comparison often needs to be made with caution and circumspection; the total population includes the handicapped, the chronically sick, and the unemployable, none of whom will be found in the industrial population. This leads to the healthy-workers effect (HWE) whereby the overall mortality experience of the industry is often better than that in the total population, partly for the reasons just given and partly because there may well have been a medical examination to select only healthy new recruits to the industry. Another effect, known as the survivor-population effect (SPE) or survivor effect, arises because those workers in an industry who find the work too strenuous or beyond their capacity will leave to find more suitable work; those who remain in the industry—the survivors—will again be a group selected to be of better health, stronger, and more competent at the work. A thorough ongoing epidemiological review of the industry or of a sufficiently large factory within it will generally allow these effects to be separately measured and assessed, together with the specific hazards, if any, that may be characteristic of the industry.

Many occupational epidemiology studies (McMichael, 1976) now carefully evaluate the influence of the HWE and SPE. Both the HWE and SPE are considered a form of bias. In many ways both the HWE and SPE are similar or the same occurrence. However, it can be inferred that the SPE involves, at least initially, those that are best able to tolerate the work conditions or are best able to cope with exposure to occupational stress, most notably at the beginning of an occupational activity. The SPE will likely include the HWE for those that remain at an occupation for a longer period of time and would include an adaptive response as would be related to injuries. Many of the factors associated with these effects are commonly called confounders. Some of these would include personal confounders like smoking. Not all events are equally affected by the HWE. For example, the HWE has been suggested to have a weak-to-nonextant influence on cancer mortality, while having a stronger impact on mortality from cardiovascular disease (McMichael, 1976). However, by employing appropriate methodology, confounders and the HWE can be controlled for (Mastrangelo *et al.*, 2004). It should be noted that the most important confounders in epidemiology are age, sex, social and economic status, and smoking, although many others may be important as well depending on the study. The importance of a confounder is best illustrated by cigarette consumption (smoking) and lung cancer (Lee *et al.*, 2001).

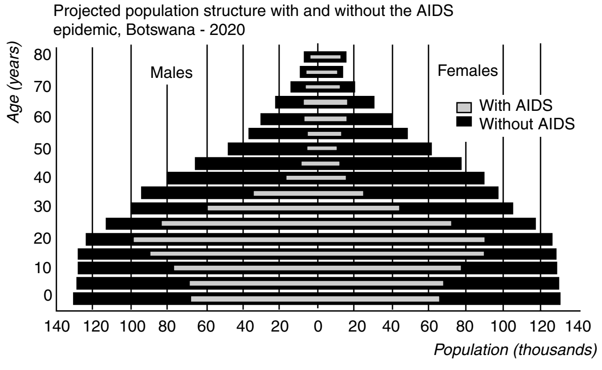

FIGURE 5 Botswana is predicted to have more adults in their 60s and 70s in 20 years' time than adults in their 40s and 50s.

LIFE TABLES

We have already referred to some of the early essays on the production of a life table, and to the difficulties of having to use various records, because the appropriate mortality rates were not yet available. When death registration was reasonably complete and census sufficiently accurate, it was possible to construct a much better life table. William Farr, for his first life table, used the census of 1841 and the deaths of the same year. In his second table he broadened his basis, using both the 1841 and 1851 censuses, and the deaths of a period of 7 years (1838–1844). Modern practice usually combines the deaths of 3 years, to reduce the effects of minor epidemic or climatic variations, and uses the census of the middle year for the denominators. Mortality rates by sex and single years of age then enable the construction of a full life table, advancing in single years from 0 to about 110 years of age. The successive l_x figures denote the numbers of living to the exact age x from the radix at l_0 of 100,000. The larger radix is justified by the greater degree of accuracy now available. Essentially the mode of calculation is the same:

$$l_{x+1} = l_x - d_x$$

where d_x = number of deaths between ages x and the day before attaining age $x + 1$, and

$$d_x = l_x \cdot q_x$$

where q_x = mortality rate at exact age x.

Single-year mortality rates are generally obtained as the ratio of the number in a calendar year of deaths whose age was given as x to the mid-year population aged x: for each of these quantities the age given as x would range from exact age x (the xth birthday) to the day before the $(x + 1)$th birthday, and would thus average $x + 1/2$. This mortality rate is designated m_x, such that $m_x = d_x/p_x$, where p_x = midyear population aged x.

If we go back 6 months to the beginning of the calendar year, the average age of those encumbered in the middle of the year at $x + 1/2$ would become x, but they should also be augmented by half of the deaths (also of average age), on the plausible assumption that they were divided approximately equally between the two halves of the year. This is of course because none would have died by the beginning of the year, and furthermore their average age would then be x rather than $x + 1/2$. Now we can obtain the mortality rate at exact age x since

$$q_x = d_x/(p_x + 1/2d_x)$$

Dividing through by p_x, this becomes

$$q_x = m_x/(1 + 1/2m_x)$$

thus relating the two mortality rates.

SURVIVAL RATES ADJUSTED FOR AGE

Strictly speaking, the life table is a fiction, in the sense that it represents an instantaneous picture or snapshot of the numbers of living at each single year of age, on the assumption that the mortality rates at the time of its construction remain unchanged at each period of life. Mortality rates have generally tended to fall, though they are rather more stable, on a worldwide basis, than they have been earlier in the century. However, there are modern-day exceptions, as is seen in the old Soviet Union countries where life expectancy is declining (Men *et al.*, 2003). Even though life expectancy was lower than that for Western Europe, a dramatic decline has been observed after the fall of the Soviet Union around 1991. This decline in life expectancy, an increase in premature deaths, has been attributed to social factors and alcohol use, resulting in increased incidence of ischemic heart disease, infectious diseases (e.g., tuberculosis), and accidental deaths (Men *et al.*, 2003). Changes in mortality in the old Soviet Union show the dynamics of epidemiology. However, for the world overall, especially Westernized nations, this means that as time goes on the life table is more pessimistic in its predictions than is the reality of life experience. Nevertheless the life table can be put to a number of uses within the field of epidemiology, quite apart from its commercial use in the calculation of life-insurance premiums for annuities. One of these uses is in the computation of age-adjusted survival rates. Frequently in comparing the experience of different centuries, whether geographically separated or over periods of time, with respect to survival from cancer, a 5-year period is taken as a convenient measure. Cancer patients are not of course immune to other causes of death, and naturally their risk of them will increase progressively with age. In consequence, a comparison using 5-year survival rates of two groups of cancer patients, one of which included a greater proportion of elderly patients than the other, would be biased in favor of the younger group. By using the life table it is possible to obtain 5-year survival rates for each group separately, taking full account of their makeup by sex and age, but considering only their exposure to the general experience of all causes of death. The ratio of the observed (crude) 5-year survival rate of the cancer patients to their life-table 5-year survival rate is known as the "age-adjusted" or "relative" survival rate. Changes in survival, by age adjustment, resulting from a dramatic health effect, as seen in Africa from AIDS (Figure 5), can greatly impact the regional or national survival table. When this procedure is done for each group, they are properly comparable since allowance has been made for the bias due to age structure. Clearly the same mode of adjustment should be used for periods other than 5 years, in order to obtain survival rates free of bias of specific age structures. If the adjusted rate becomes 100% it implies that there is no excess risk of death over the "natural" risk for age; a rate above 100% seldom occurs, but may imply a slightly lower risk than that natural for age.

OTHER USES OF THE LIFE TABLE

The ratio of l_{70} to l_{50} from the life table for females will give the likelihood that a women of 50 will live to be 70. If a man marries a woman of 20, the likelihood that they will both survive to celebrate their golden wedding (50 years) can be obtained by multiplying the ratio l_{75}/l_{25} (from the male life table) by l_{70}/l_{20} (from the female life table). These are not precise probabilities, and furthermore they include a number of implicit assumptions, some of which have already been discussed. Similar computations are in fact used, however, sometimes in legal cases to assess damages or compensation, where their degree of precision has a better quantitative basis than any other.

INFANT MORTALITY RATES

In the construction of life tables, as has been noted, it is necessary to use a mortality rate centered on an exact age rather than the conventional rate, centered half a year later. Only one of the mortality rates in common use is defined in the life-table way, and that is the infant mortality rate (IMR), which measures the number of children born alive who do not survive to their first birthday. The numerator is thus the number of deaths under the age of 1 year, and the denominator is the total number of live births; usually both refer to the same calendar year, although some of its deaths will have been born in the previous year, and likewise some deaths in the following year will have been among its births. The rate is expressed as the number of infant deaths per thousand live births, and it has changed from an average of 150 in much of the last century (but attaining much higher figures in some years) down to below 10 in many countries today. It has been very dependent on general social conditions: low wages, poor housing, and bad nutrition, all having shown close correlation with high IMRs. When infections were rife, and brought into the home by older children, the rate was higher. But with the improvement of infection prevention and treatment, much related to sanitation, vaccination, and antibiotics, infant mortality has occurred close to the time of birth. For this reason, the national neonatal mortality rate (NMR) has been used, a neonate being defined as up to the age of 28 days. The same denominator is used as for the IMR, and the difference between them is known as the postneonatal mortality rate. Defined in this way, as it is, it contravenes the proper definition of a rate, which should refer to the ratio of the number to whom some event has happened (e.g., death) to all those who were at risk for that event. The denominator of the postneonatal mortality rate is the number of live births, just as it is for the IMR and the NMR. But all those who succumbed as neonates are no longer at risk in the postneonatal period, and thus should be excluded from the denominator. The difference, however, is usually small, and it is more convenient to use two rates, which add to the overall IMR.

Further reductions in the deaths at this period of life have focused attention nearer to the time of birth. Deaths in the first week of life (up to the age of 7 days) have been recorded for many years now, as well as separately for each of those 7 days, and even for the first half hour of life. Clearly many of the causes of those very early deaths will have originated in the antenatal and intrauterine period. They will share causes with those born dead (stillbirths), and indeed they are combined together in the prenatal mortality rate. This includes both stillbirths taken together. The stillbirth rate (SBR) alone must of course use the same denominator, since all births were at risk of death in the process of birth, to which the stillbirths fall victim. All of these rates have been devised to highlight specific areas of importance, especially in pediatrics. Closely related is the measurement of the material morbidity rate (MMR). Here the numerator is the deaths of women from maternal or puerperal causes, and the denominator, interestingly, is the total number of births, live and still. A moment's reflection will show that it is the occasion of birth (whether live or still) that puts a woman at risk of this cause of death, and that if she has twins—or higher orders of multiple births—she is at risk at the birth of each, so that the correct denominator must include all births.

FERTILITY RATES

The information collected on the birth certificate usually permits the tabulation of fertility rates by age and number of previous children. Age-specific fertility rates are defined as the number of live births (in a calendar year) to a thousand women of a given age. If they are expressed for single years of age, and they are separated into male and female births, then we add together all the rates for female births to give what is known as the gross reproduction rates (GRRs). If this quantity is close to unity, then it implies that the number of girl children is the same as the number of women of reproductive age, and the population should thus remain stable in number. But no allowance has been made for the number of women who die before the end of their reproductive life, and thus will fail to contribute fully to the next generation. When this allowance is made (using the female mortality rates for the appropriate ages) we obtain the net reproductive rates (NNRs). Note, however, that there remains an assumption that may not be fulfilled—that the age-specific rates remain unchanged throughout the reproductive age range (usually taken as 15 to 45), that is, for a period of 30 calendar years. Indices such as the NRR were devised as attempts to predict or forecast the likely future trends of populations. The crude birth rates (CBRs), defined as the ratio of the number of births to the total of the population, is like the crude death rate in being very sensitive to the age structure of the population. Nonetheless, their difference is called the rates of natural increase (RNI) and provides the simplest measure of population change:

$$\text{CBR} - \text{CDR} = \text{RNI}$$

The measure excludes the net effect of migration in changing the population numbers: in some countries it is very rigidly controlled, and in others it may be estimated by a sampling process at airports, seaports, and frontier towns.

POPULATION TRENDS

Previously it has been noted that both the GRR and NRR make the assumption of projecting the rates observed in 1 calendar year to cover a 30-year period (15 to 45). It would of course be possible to follow a group of women, all of the same age, from when they were 15 up to the age of 45 in the latest year for which figures are available. Such a group would be called a "cohort"—the term used in epidemiology for a group defined in a special way. To cover this cohort would necessitate obtaining fertility rates for up to 30 years back, and in any case that cohort would of course have completed its reproductive life. The highest fertility rates are commonly found at younger ages: it is possible to show graphically a set of "cohort fertility rates" by age labeled by their year of birth (often a central year of birth, since the cohort may be more usefully defined as a quinquennial group). If they are expressed in cumulative form (i.e., added together) and refer only to female birth, it will become clear how nearly they approach unity, from below or above, if the population is increasing. No adjustment for female mortality in the period is required, since the rates are, for each year (or quinquennium), calculated for those women of that cohort alive at that time. The method therefore represents the most useful prediction of future population trends, which can be projected further forward by assumptions that can be made explicit in their graphical depiction.

COHORT ANALYSIS OF MORTALITY

A similar breakdown of age-specific mortality rates can be made, in order to reveal different patterns of relationship to the passage of time. Figure 1, for instance, shows mortality rates by sex and age in a single calendar year—the age in which death took place. Mortality rates are given for 5-year age groups, which is the usual practice, so that if a similar curve were to be drawn on the same graph for the calendar year 5 years earlier, you could join together the point representing, say, the age group 60–64 on the original curve to the point for 55–59 5 years earlier. This line would then represent a short segment of the cohort age-specific mortality curve born in the period 60–64 years before the date of the first curve. By repeating the process, it is clearly possible to extend the cohort curves spaced 5 years apart in their birth years. Figure 6 shows how the cohort mortality makes clear the rising impact of cigarette smoking in the causation of lung cancer, since successive later-born cohorts show increases in the rates, until those of 1916 and 1926, which begin to show diminishing rates. The cohort method is thus of particular relevance where there have been secular changes similar to that of cigarette smoking.

MEASUREMENT OF SICKNESS (MORBIDITY)

If, instead of death, you look for ways of measuring sickness in the population, once again you are confronted by several major differences in both interpretation and presentation. In the first place, illness has a duration in a sense that is absent from death. Secondly, the same illness can repeat in the same individual, either in a chronic form or by recurrence after complete remission or cure. And thirdly, there are grades of illness or of its severity, which at one extremity may make its recognition by sign or symptom almost impossible without the occurrence of the individual. The tolerance of pain or disability, or their threshold, differ widely between people, and therefore complicate its measurement. In the case of absence from work, where a certificate specifying a cause may (or may not) be required, various measures have been used. A single period of absence is known as a "spell," and thus the number of spells per employee in a year, for instance, can be quoted, as well as the mean length of spell, again per employee, or perhaps more usefully, by diagnosis. Inception rate, being the proportion of new absences in a given period (1 year, or perhaps less) is another measure, which again would be broken down into diagnostic groups. Prevalence is yet another measure, intended to quantify the proportion of work by sickness (perhaps by separate diagnostic groups) at a particular time. This may be, for instance, on one particular day, when it is known as "point prevalence," or in a certain length of time (e.g., 1 month), which is known as "period prevalence." Most prevalence rates are given for a year, and the definition often referred to is the number of cases that exist within that time frame. On the other hand, incidence is the number of cases that arose in the time period of interest, again usually a year. When sickness-absence certificates are collected for the purpose of paying sickness benefits, they have been analyzed to present rates and measures such as those discussed here, often against a time base, which can show the effect of epidemics or extremes of weather—or may indicate the occurrence of popular sports events! But such tabulations are either prepared for restricted circulation only, or if published are accompanied by a number of caveats concerning their too-literal interpretation.

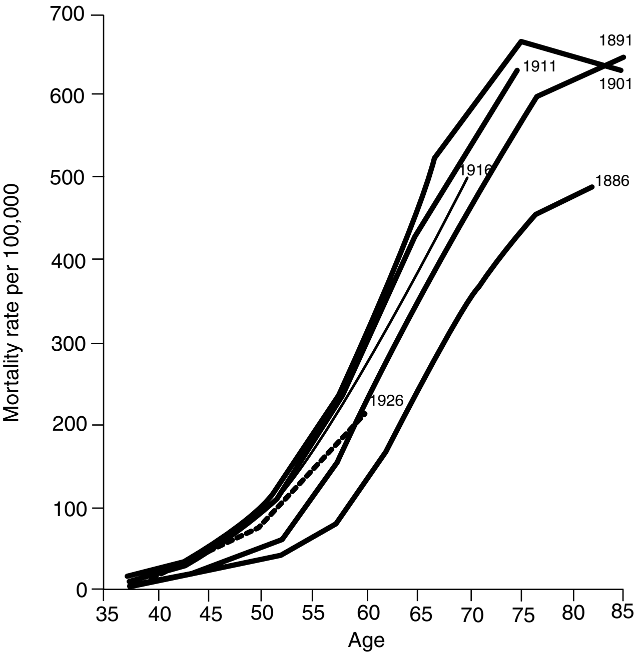

FIGURE 6 Lung-cancer incidence in birth cohorts.

Incidence and prevalence rates are related to each other, and it is not unusual to have both reported in a single study (Mayeux et al., 1995). An example of prevalence and incidence for Parkinson's disease for the total population and different ethnic groups is shown in Tables 2 and 3. For prevalence, the study identified 228 cases of the diseases (Parkinson's) for the time period 1988–1989, with the final date of inclusion being December 31, 1989. Not included in the table is the mean age of cases (prevalence) (73.7 years, standard deviation 9.8) for patients having ages 40 to 96 years. Mayeux also reported that the mean age of occurrence (symptoms) was 65.7 (standard deviation 11.3), with differing ages for men (64.6, standard deviation 12.7) and women (67.4, standard deviation 10.6), with these differences having a p value of 0.06, or 6%. It should be noted that if a statistical significance of 5% is used for establishing a difference, the age difference in years between men and women when symptoms of Parkinson's disease were first observed (occurrence or onset of diseases), thus, is not different. However, this raises an important issue that using a cutoff value, say 5%, does not provide a definitive determination for evaluating data, in this case the importance of disease occurrence between the two sexes. Most when examining these data would suggest that even though the difference is not significant, an important difference between men and women appears to exist for the onset of disease, with men's being much earlier. This would indicate, for example, that screening for this disease be initiated at an earlier time period for men.

Table 2, by Mayeux *et al*. (1995), also indicates a difference of disease onset by age. There is a dramatic prevalence rate (total) for populations under 45 (1.3 per 100,000) as compared to those over (e.g., 99.3 per 100,000 for the age group 45–64 years). The prevalence also overall increases with age. There are also differences in prevalence among ethnic groups and sex within these groups. This demonstrates the importance of studies examining race and sex as important factors in disease (Ness *et al*., 2004; Lange *et al*., 2003b). This study (Mayeux *et al*., 1995) examined the age-adjusted prevalence rate for combined men and women by ethnic group (race), and a significant difference (p value < 0.01) was observed among blacks (57 per 100,000), whites (116 per 100,000), and Hispanics (130 per 100,000). This indicates that there is not only a difference in the onset of Parkinson's

Source: From Mayeux et al. (1995), The frequency of idiopathic Parkinson's disease by age, ethnic group and sex in northern Manhattan, 1988–1993, American Journal of Epidemiology, 142:820–27; with permission from Oxford Press.

disease by age and sex, but by ethnic group as well. These differences in Table 2 illustrate the importance of controlling for various confounders such as sex, age, and race in epidemiological studies.

When examining the incidence rate of Parkinson’s disease (Table 3), this study reports 83 new cases during the 3-year period. For the incident cases, the mean age was 76.3 years, with a standard deviation of 9.5 and a time period of symptoms (duration of 1.4 years). There was reported no difference in the mean age (75.2 years) for men and women for the onset of symptoms. From Table 3, the annual incidence of Parkinson’s disease in New York City is 13 per 100,000. Unlike that reported for prevalence, there were no incidences of Parkinson’s diseases below the age of 45 years during this study period. However, as noted for prevalence, the incidence rate of disease increases with age. There is also a difference in the rates for men and women and among ethnic groups evaluated.

The data in Tables 2 and 3 can be used to evaluate the numbers of cases and the occurrence of disease in a

Source: From Mayeux et al. (1995), The frequency of idiopathic Parkinson’s disease by age, ethnic group and sex in northern Manhattan, 1988–1993, American Journal of Epidemiology, 142:820–27; with permission from Oxford Press.

population. This provides information on the distribution of the disease and possibly allocation of resources in its prevention and treatment. Although the use of prevalence and incidence was demonstrated for a chronic disease, Parkinson's disease, it can also be used for occupational and environmental diseases and events. Application of preralence incidence are illustrated in Table 2 and 3.

SICKNESS SURVEYS

In some cases an estimate of the amount of sickness in the population has been made by market-research techniques, whereby people in the street are interrogated about their health in the last week (or month, but the shorter period is preferred for purposes of better accuracy). This method was used by the British government during World War II and was described as the "Survey of Sickness." There are several obvious omissions that are likely to distort the findings, such as the chronically ill who cannot get out into the street, or those who return straight to work after short illness and are not available to be questioned in the street. Nevertheless it is a cheap method that may have sufficient consistency to validate time trends of indices based on it. For more severe illnesses, statistics of admissions to hospitals, diagnoses, treatment methods, length of stays, etc. may serve to supplement the measurement sickness in the population. Not all hospitals may be able to provide useful figures, however, nor may their catchment areas be sufficiently clearly defined. However, with the advent of computers and development of databases for diseases, these issues of disease are better defined, especially in Westernized countries. Because of the wide range of sickness itself, the means of dealing with it, and variation in reporting, some form of sampling from the various sources is likely to yield the most useful results. However, even with attempts at standardization, ICD codes, there is often a wide variation in the incidence and prevalence of disease, even in the same community. One solution to this problem, in providing an accurate estimate of disease, is to employ the capture-recapture method (CRM). Since the problem in determining the occurrence of sickness and disease is at the heart of counting, the CRM has been suggested as the most accurate method for counting (Lange *et al.*, 2003c). However, since this method was originally derived for counting wildlife, it is best known as an ecological- and population-biology method, and has not been widely adopted by epidemiologists. Its recent use in counting hazardous-waste sites (Lange *et al.*, 2003a) demonstrates this method's versatility for counting, including in the area of epidemiology.

DISEASE REGISTERS

For a number of diseases, attempts have been made to make and maintain lists or registers of those affected. Infectious diseases are among the most obvious to fall into this category, since isolation of those affected was for so long the only effective deterrent to their spread. The advent of specific treatment methods, or more usefully of vaccines and immunization, has greatly reduced their impact, except perhaps for rarities such as Lhasa fever, or, in another category, AIDS. The pulmonary-tuberculosis register was an important one until treatment became readily available. Notification of the local health authority of any of the range of diseases has often been a requirement of general practitioners, in order to obtain early warning of an impending epidemic, and to monitor the occurrence of those diseases. Some heart conditions have formed the subjects of registers, though limited usually by time or space. Furthermore, a number of diseases, usually rare and often genetic, have registers or societies of affected patients, which can be useful not only for the discussion and possible alleviation of common problems, but also for the purposes of research. Most recently, disease registries, or what could be included as registries, have emerged for specific cohorts such as migrant agricultural workers (Zahm and Blair, 2001) as well as for specific occurrences of disease (Lange *et al.*, 2003d).

CANCER REGISTERS

Cancer registers, or more commonly registries, form a very distinct and important group of disease lists. They fall into three categories: (1) special registries concerned only with certain sites of the disease (e.g., bone cancer or gastrointestinal cancers); (2) hospital-based registries, which record all those cases seen at a particular hospital or groups of hospitals; and (3) population-based registries, which endeavor to collect records of every case of cancer within a specific population. The last group is the most important as a source of morbidity data about cancer. Cancers form a special group of diseases of exceptional importance, at least historically, which attract a great deal of interest and research, and for which epidemiological methods are of outstanding relevance. The date of diagnosis of cancer can be used as the basis of morbidity rates analogously to the mortality rates, so that from a population-based registry, rates of morbidity by sex, age, and site can be constructed, using the sex and age structure of the population for appropriate denominators. Cancer registries exist now in many parts of the world, though more in developed than in the underdeveloped countries, and their incidence rates by sex, age, and site have been collectively published in the successive volumes of *Cancer Incidence in Five Continents*, beginning in 1966 and subsequently at intervals of approximately 5 years. They have formed a valuable source of comparative data about the different patterns of cancer found geographically, and in combination with other data sources can lead to the generalization hypotheses of etiology. To their use in a variety of other ways, such as in the evaluation of occupational and environmental carcinogenic hazards, in the conduct of comparative clinical trails (especially in those patients not included), and among the sequelae of certain types of chronic disease, we shall refer later.

The pattern of cancer displayed in relation to sex, age, and site, whether in terms of mortality or morbidity, can provide important information on carcinogenic hazards in the area to which it refers. The different proportions by site throughout the world, where data are available, affect climatic, geographical, and lifestyle variations but are not always simple to analyze. Furthermore, some sources of data may consist of numerator information only (e.g., deaths or diagnosed cases of disease) without the corresponding population figures by sex and age, which enable the construction of rates of mortality and morbidity. Rather than have to ignore such partial information, it is possible to present it in the form of proportionate mortality or morbidity rates. In its simplest form this method expresses the omitting age, since it may not be available; then it may facilitate comparison with another source of data that may have affinities, perhaps in the likely age structure or in climate, to one under study.

PROPORTIONATE MORTALITY RATE

A situation somewhat similar to what has just been described can occur when a factory may be able to provide details (of cause, sex, and age) of the deaths of former employees over a period of time, but without adequate additional information to permit further analysis (see below). The pattern of their mortality, by cause and sex, can then be compared with the general patterns of the area where the factory is situated. Usually the deaths will be categorized into broad groups (e.g., cardiovascular, neoplasms, respiratory) (Lange *et al.*, 2003b), but if there is a reason to examine certain sites of cancer individually, they can be included. Each observed death is allotted an age group in the general population; the proportions of deaths (as fractions of 1) occurring in each of the chosen cause categories are entered and summed after all the observed deaths have been included. The accumulated fractions in each group will then constitute the expected number of deaths to compare with the number observed. Accumulated by age into numbers of expected and observed deaths by sex and cause, the comparison can be evaluated statistically for its significance (see below). If the observed deaths are spread over a number of years, the expected deaths should be strictly obtained from the corresponding calendar years, though they can usually be taken in quinquennial groups without serious loss of accuracy. It will be evident that an assumption implicit in the method is that the factory population has been sufficiently similar to the general population to justify the comparison. Thus, proportionate mortality rates (PMRs) are commonly used for occupational cohorts.

ANALYTICAL EPIDEMIOLOGY

It is conventional to divide epidemiology into two distinct branches: descriptive and analytical. Up to this point we have been concerned mainly with the description of the health status of a population by means of rates of mortality and morbidity, by sex, age, and cause; for geographical and other subgroups; and in calendar time. Some of the methods of comparison we have discussed, necessitating standardization of the calculation of expected figures, have touched on the analytic division, though the definitions are not always clear-cut. Other methods that will be discussed are experimental in their design, such as clinical trials where the treatments of a disease by two different regimes forms the basis of a comparison of their relative efficiency, the numbers of patients being decided by consideration of the statistical power required or attainable.

SCATTERGRAMS

A method that has been frequently used in searching for factors related, possibly in an etiological way, to the incidence of disease is to display in graphical form a correlation diagram—a scatter diagram or "scattergram" where the incidence (or mortality rate) of the disease is measured on one scale and the factor of interest on the other. Figure 7 gives an example of the method, whereby each point represents a country whose (standardized) rate of colon cancer is set against the per-capita consumption of fat in that country. It is clear that there is a relationship between these two measures, such that as one increases so does the other. This apparent movement together may suggest a possible causative relationship, such that the higher the average consumption of fats, the greater the risk of colon cancer. But note first that it is the average per-capita factor, which is obtained from the total fat consumed in a country divided by population. Clearly, individuals in the population will vary in their mean levels of consumption; some average more while others less than the average. If there is a causative relationship, we would expect

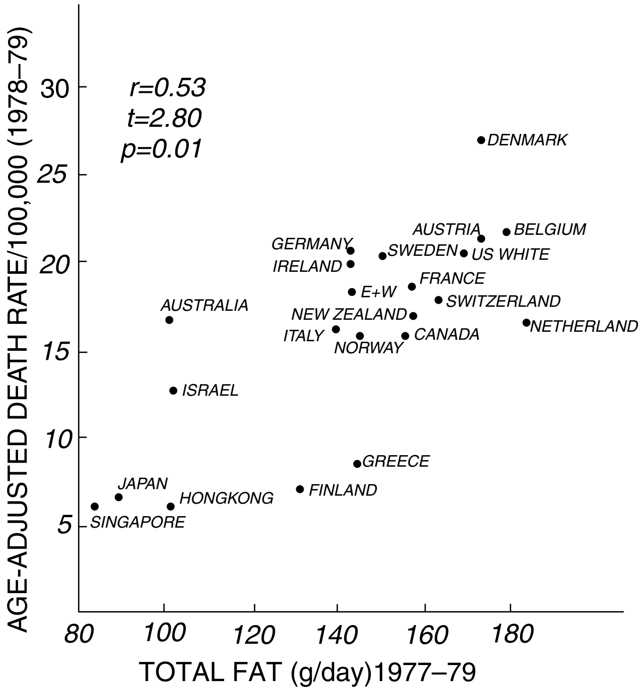

FIGURE 7 Cancer of the colon and fat consumption (scattergram).

to find higher rates of colon cancer among those consuming more than the average. But this information we do not posses, though it is precisely what is required to demonstrate the relationship conclusively.

LATENCY PERIOD

Another consideration, which is of particular relevance in the field of cancer and other areas of epidemiology, is that there is a latency period, often of at least 20 years, between exposure to a substance (like a carcinogen) and the development of a clinically observable disease (again, like cancer). Thus the per-capita fat consumption should refer to figures of 20 or more years ago. If the cancer incidence is not showing rapid secular change, this consideration may not be important. It has also been shown that there is a similar relationship between the consumption of protein and colon cancer. It may well be that both fat consumption and a diet high in protein are among the causative factors of colon cancer, but it may also be that some other factor or group of factors, correlated with these two in particular, is more directly relevant. Lifestyle factors or social status may each be included, and both subsume at the same time a wide variety of other measures, some of which may be more legitimately described as directly etiological. In sum, therefore, a correlation diagram can lead to the generation of hypotheses of causation but cannot of itself prove the relationship. The gross correlation between national averages and disease incidence needs to be investigated on individual cases of the disease, for each of which measures of consumption of putatively carcinogenic items of diet can be obtained, preferably over a large period of time in retrospect. Data of this kind, if sufficient in quantity and reliability in substance, can form the basis of an informative etiological study, probably using multivariate analytical techniques.

REGRESSION AND CORRELATION ANALYSIS

The relationship between the incidence of lung cancer and the number of cigarettes smoked is now well known, and has been verified many times in a variety of situations. For most of these studies it is possible to obtain a graph of the mortality (or morbidity) rate against the number of cigarettes smoked per day, yielding a straight-line relation of the form $y = a + bx$ between them, where y is the morbidity rate and x the cigarettes smoked per day, a and b being appropriate constants. The values of a and b can of course be readily obtained from the data, being the parameter of the simple linear regression between the two quantities. Many books on statistics prescribe the technique of fitting regression lines.

INTERACTION

A relationship of a similar kind has been shown between the incidence of esophageal cancer and the number of cigarettes smoked. The same disease is also related in the same way to quantity of alcohol consumed. We could combine these two findings to obtain a regression equation using two quantities as influencing a third (the morbidity rate), of the form

$$z = a + bx + cy$$

where z is the morbidity rate,

x is the number of cigarettes smoked,
y is the quantity of alcohol consumed,
and a, b, and c are appropriate constants.

The form of this equation assumes independence between the actions of each quantity on the morbidity rate. It has been found in actual study that the combined effect of both quantities in the same individuals results in an enhanced rate of morbidity, above the additive effect of the two separately. This enhancement, amounting to a multiplicative rather than an additive effect, is known as "synergism" (Figure 8). A similar example of a synergistic effect is found in the occupational field by the combination of the effects of exposure to asbestos and cigarette smoking on the development of lung cancer. Figure 9 shows the separate effects of each agent in terms of a rate set at 1 for those exposed to neither and also the rate for both together, which corresponds to multiplying rather than adding the separate rates. The establishment of a genuinely synergistic effect requires both extensive and reliable data.

ANALYSIS OF OCCUPATIONAL DISEASE

In studies of occupational disease, the basic question to be answered is whether there is an excess of cases of the disease

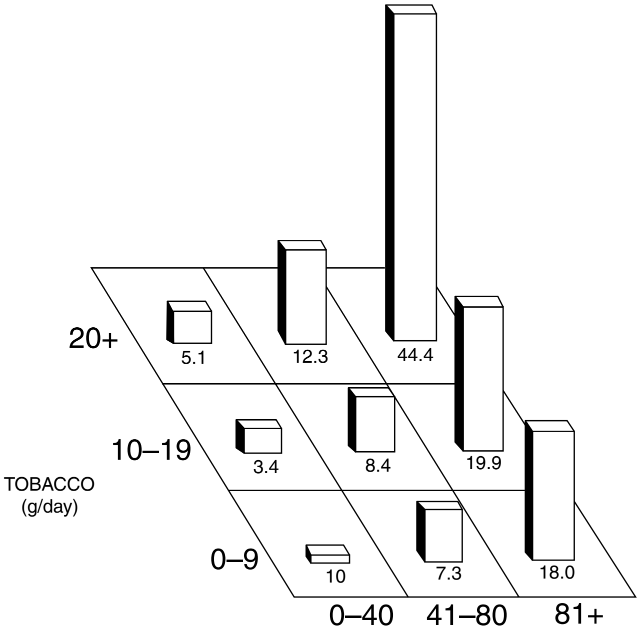

FIGURE 8 Cancer of the esophagus in relation to alcohol and smoking.

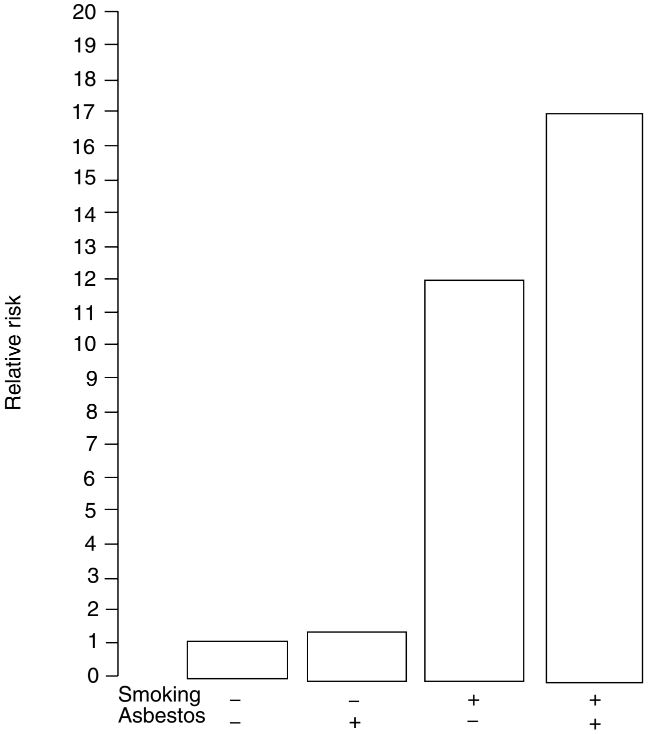

FIGURE 9 Cancer of the lung in relation to asbestos and smoking.

among the workers exposed to the putative causative factor, whether that is a substance or a process that is used in certain parts of a factory. In its most elementary form, the results of an investigation can be put in the form of a 2 × 2 table, as in Figure 10.

The first two cells of this table, horizontally, include the numbers of those who were exposed (+) to the presumed hazard, the first cell containing the number of those who developed the disease in question (a), the second those who did not (b). In the lower line are those who were not exposed (−), the first cell again including all those for this group who developed the disease (c) and the second those who did not (d). Clearly if the ratio of the left to the right is the same in both rows, there is no evidence of an effect. This is an example of the 2 × 2 or fourfold table to which the X^2 test can easily be applied, with one degree of freedom, to assess whether any difference in the proportion, horizontally or vertically, attains statistical significance, at whatever level may be chosen. The conventional levels of significance are 0.05 (5%), 0.01 (1%), and 0.001 (0.1%), each referring to the probabilities that the observed result could have occurred by chance alone (the levels are sometimes quoted in the form of percentages, multiplying their probabilities by 100). For each cell of the table of Figure 10 an "expected" figure can be calculated from the marginal and grand totals, by dividing, for instance, each row total in the proportions of the column totals: thus the expectation for the top left cell is the product of the first row's total divided by the grand total. The difference between the observed number in each cell is squared and divided by the expectation for that cell, and the sum of these four quantities constitute X^2. Tables provided in almost all books on statistics will enable the level of significance to be obtained for the value of X^2 and for one degree of freedom. Two caveats should be noted: first, that no expectation should be less than 5—if it is, a larger size of sample is required—and second, that when numbers are small (yet satisfy the proceeding conditions), Yates's correction should be made, which reduces the absolute size of the difference between observed and expected by the quantity 1/2. It will have been noted that this difference is the same magnitude in each of the four cells, though it changes sign, but that is irrelevant since it is squared. It is the absolute magnitude of this common difference that should be reduced by 1/2.

		Disease	
		+	−
Exposure	+	a	b
	−	c	d

FIGURE 10

ODDS RATIO AND RELATIVE RISK

In the circumstances set out above and in Figure 10, the ratio $c/(c + d)$ is the risk of disease in the unexposed group, which we can call P_0, and P_1/P_0 is known as the "relative risk," RR or r. In many cases the disease in question will be rare, even among the exposed, so that a and c will be small relative to b and d. If $Q_0 + 1 - P_0$ and $Q_1 + 1 - P_1$ express the risk of not contracting the disease, then they will both be close to 1, since P_0 and P_1 are supposed to be small. The quantity $(P_1/Q_1)/(P_0/Q_0)$ is known as the "odds ratio," since it is the ratio of the odds of occurrence of the disease in the exposed to the unexposed groups. Since we are presuming the Q's to be close to 1, the odds ratio can be put as P_1/P_0, which is the same as the relative risk, r. We shall see later that this fact permits the estimation of the ratio of the incidence of disease in the exposed and unexposed groups from a case-control type of investigation, though their absolute incidences are not obtainable.

ETIOLOGICAL STUDIES

A situation that is formally very similar to what we have just been considering arises if we suspect a certain factor may be one that is involved in the etiology of the disease. We shall again be comparing persons with and without the disease and those affected in the form of a 2 × 2 table like Figure 10, where we replace "Factor" for "Exposure." If the factor is indeed an etiological one, it will be found more frequently

		Lung Cancer		
		+	−

	−	21	59	80
		709	709	1418

FIGURE 11

in association with the presence of the disease, and less so with its absence.

A case-control investigation led naturally to this end point, though it may take a variety of different forms. Take one of the earliest studies of smoking and lung cancer, Doll and Hill (1950), which was followed by a cohort of English physicians using a questionnaire (Doll and Hill, 1954) and then continued as a prospective study up to the present day (Doll *et al.*, 2004). For this study 709 patients with lung cancer, in 20 hospitals, were matched with the same number of patients from the same hospital, but not having cancer or a respiratory disease. The matching was for the same hospital, of the same sex, and within the same 5-year age group. All the patients were interviewed according to a standard questionnaire. The simplest form of the results is shown in Figure 11.

The expectations in the two lower cells of the square are each 40, and in the upper cells each 699. The difference therefore in each cell is 19, with the result that the X^2 value, whether or not Yates's correction is used (it is not necessary here), is very large, and the probability that the association between smoking and lung cancer might be a chance one is extremely unlikely. In the study itself the result of smoking (in numbers of cigarettes smoked per day) was quantified, and the results given separately by sex. For the purpose of this illustration the study is summarized in Figure 11, but clearly the additional evidence afforded by the quantification data, which for each sex showed a steadily increasing risk of lung cancer at each successive level of smoking, reinforces the basic etiological relationship of smoking to lung cancer.

CASE-CONTROL STUDIES

In any case-control study ("case-referent study" is a synonymous term) the choice of appropriate controls is of special importance. In the study discussed above, the controls were matched for sex and age group—the two most commonly used characteristics for matching—and also for hospital, lest there should be some factor associated with that. There were two exclusions: cancer and a respiratory condition, which could confuse the contrast between cases and controls. When there are few cases available, and in some other circumstances, it may be advisable to use more than one control per case. Beyond four controls per case little further advantage can be gained, but two, three, or four controls for every case may be useful, though expensive. In general the more closely the controls resemble the cases in terms of characteristics, the more efficient the contrast, except that one or more of those characteristics may be of genuine etiological significance, but because it is possessed by both case and control, it is impossible to distinguish.

CLINICAL TRIALS

The underlying philosophy is that of the experimentalists of the scientific renaissance, who began in physics or in chemistry to look at the effects of a single factor alone, varying its contribution to the ultimate effect while endeavoring to keep other factors constant. The method could then be repeated for other factors, and thus the independent effects assessed, as well as those where separation proved impossible because of close correlations. The aim of the clinical therapeutic trial, for instance, is to obtain two groups of patients so similar in all known relevant respects that any difference in their responses can be reasonably attributed to their different treatments. Not only sex and age but the type and severity of the disease and its history, together possibly with socioeconomic or lifestyle factors, if relevant, need to be taken into account in ensuring the parallelism of the two treatment groups. It is important that the full treatment regimen in both groups (experiment and control) be decided in advance and adhered to precisely. There must be of course a provision for emergencies, and therefore escape clauses or alternative regimens should form part of the design of the trial. A pilot trial, perhaps amounting to around 5% of the full trial, can greatly help to reveal aspects previously overlooked, and if the modifications it suggests are not too great, it may be possible to include it as the start of the main trial. For the reason that those directly concerned with the conduct of the trial, or with its assessment, may form premature opinions about its outcome and hence introduce a bias if they know the actual treatment that patients receive, it is customary to run many clinical trials "blind"—that is, in such a way that the clinicians are unaware of the treatment given. If the active treatment consists of tablets, the control could be a placebo presented in the same form; if it is an injection, the control can receive an injection of normal saline; etc. The trial may also be "double-blind," when neither clinician nor patient knows the identify of the "apparent" treatments. Of course, a singly blind trial may imply that the patient is unaware of his treatment but the clinician does know. There are also occasions when the two treatments have differences that cannot be distinguished, such as surgery for one and radiotherapy for another.

STRATIFICATION

We have stressed already the importance of the close similarity—almost identity—of the two groups of patients, referring to obvious characteristics such as sex and age. Other relevant features should also, if feasible, be similarly balanced between the groups, and each of them may be described as a stratum, so that the trial is described as stratified. An example may be the stage of disease (if distinct stages are discernible), while another might be for an ethnic group. Finally, when the numbers of strata have been decided, the patients within each ultimate subgroup should be randomly allocated to the treatment groups. The more strata that are used, the more patients will be required to enable a proper balance between treatments.

FOLLOW-UP

When a clinical trial of treatments for a cancer is conducted within the territory of a cancer registry, and, as almost invariably happens, not all eligible patients have been included in the trial, the data from the registry concerning those patients excluded (for whatever reason) can help to indicate whether the trial represents a reasonably unbiased selection of the totality of patients with the specific tumor in the period covered. If the registry also usually undertakes follow-up of its cases, it can also provide this service for the clinical trial, although the time intervals may be different, and there may also be certain monitoring requirements for trial patients to be added.

ETHICAL CONSIDERATIONS

Some clinical trials have been set up for a fixed period of time, or with a certain number of patients, sufficient to evaluate a difference of a previously determined size between the treated and control groups. For these, therefore, there is an endpoint at which the outcome is assessed. Often, the desired magnitude of the difference was not attained, and so the trial was in that respect inclusive. Sometimes the reverse was the case, and those on the new treatment fared so much better that it could be considered unethical to proceed with the trial, but instead, the control group should be given the new treatment also. The ethical question raised is a difficult one, since it has sometimes happened that the favorable difference has not continued into a longer follow-up period. There are many other aspects to questions of ethics in the field of clinical trials, which are not appropriately considered here other than to note that they exist.

SURVIVAL: LIFE-TABLE FORM

Often the results of a clinical trial will be displayed in what is described as life-table form. This can be constructed at specific intervals of time (e.g., 3 months, 6 months, then annually) or can be related directly to the times of events, such as the death of a patient or his withdrawal from the trial. This latter event could be because that period represents his whole experience of the trial from entry to the current date: this situation is sometimes described as a "censored" survival time, since it will be true that his survival is, at its least, that time, and is likely to be greater if follow-up can continue. If withdrawal is made on grounds related to the conditions on the trial itself, such as a side effect of treatment, it will clearly have an effect on the ultimate interpretation of the trial as a whole. These patients may be removed from the trial, but their number and the cause of removal must be reported.

When the life table is constructed in relation to the occurrence of events, the patients in a specific group (e.g., treatment, or control) are arranged in order of their survival time (including censored times). If there are n patients in one such group, they will of course start at time zero ($t_0 = 0$), as 100% alive. When the first event occurs, at time t_1, suppose it is that one patient has died. Then the probability of dying at that time can be regarded as $1/n$ ($= q_1$), and the probability (p_1) of surviving as its complement ($p_1 = 1 - q_1$). Suppose the next event is the death of two patients at time t_2; the number of patients at risk at the time of the event is $(n - 1)$, and so q_2. The survival probability to time t_2 is therefore the product of p_1 and $p_2 = s_2$. Now, at time t_3, one patient arrives at his censored survival period. The probability of dying then is $q_3 = 0$ (since he is still alive) and thus $p_3 = 1$, and $s_3 = s_2$, the same proportion. At the time q_4 is $5(n - 4)$, since four had been removed from the numbers continuing up to the maximum follow-up time. The resultant curve is in the form of a series of steps, at varying intervals (the t's), and represents the survival curve for that group.

RETROSPECTIVE AND PROSPECTIVE METHODS

The case-control study discussed earlier can be regarded as a clinical trial, but in the field of etiology rather than in therapy. There is the same call for close similarity between case and control as between the parallel cases of the therapeutic trial. The etiological study, however, is essentially retrospective, beginning with cases of a disease, and appropriate controls, and comparing their past experiences in an attempt to discover relevant differences that could be etiological factors. The therapeutic trial, on the contrary, is prospective, in the sense that, having set up the two-treatment group, the outcome of the trial is awaited and assessed. Another type of etiological study is known as a "cohort" study because its basis is a group or cohort of people defined in a certain way and exposed to some putative hazard (an etiological factor of a resultant disease or disability). In the realm of occupational health, for instance, we may need to investigate whether the work of a particular factor or substance thereof might include some carcinogenic aspects.

We have already referred to the phenomenon of latency as one of the difficulties encountered when investigating carcinogenic hazards. This is the term used for describing the long period elapsing between the first exposure to the hazard and the development of a recognizable tumor. In other words, this is the time from the first exposure to the time of diagnosis of the disease and can be applied to any disease. The duration of the latency period varies from a few years (short period of time), possibly even less, up to decades, like 20, 30, and over 40 years. Some of the shortest latency periods are found with the leukemias and lymphomas, and the longer with solid tumors. Often this long period of latency has led to the failure to recognize an occupational cancer because its manifestation has been relatively late in a man's working life and has been regarded therefore as a spontaneous incidence with age; this has also been true of postretirement cases.

COHORT ETIOLOGICAL STUDIES

In its basic design, the cohort etiological study is prospective, since it notes the essential details of all those exposed to the suspected hazard and awaits the possible development of cancers. It is possible to estimate the number of cancers of various sites that would be expected to occur in a group (cohort) constituted in the same way by sex and age and observed for the same period of time, from rates of incidence obtained from a cancer registry in the same area. This would of course compare morbidity, though it would be equally possible to use mortality: in general, rather more information becomes available from the morbidity study, largely because of differential survival rates. The same design of study (i.e., a cohort etiological study) can be conducted in a retrospective way by the use of records, if well maintained by the factory. If, for instance, a full list is available of those employed, say, 30 years ago, when a new process or chemical (substance) was first used, and all the personnel changes since then to present time are also available, then the situation is almost precisely equivalent to that postulated above. We set ourselves 30 years back in time, collect all the original personnel data, and continue to do so until we are back to the present day. For this reason the method is often called the "historic cohort method." The only other information required is the present health status of each worker employed over that period, whether still employed, retired, or dead. From this information, which is seldom entirely complete, a comparison is made with the expectations of deaths and cases of disease, obtained by applying morbidity and mortality rates to the exposure data.

CALCULATION OF EXPECTED DEATHS

Since both mortality and morbidity rates change rapidly with age, and also to a lesser extent with calendar years, the calculation of expectations requires a systematization of the exposure data by sex, race, age, and calendar years. Usually it is sufficient to use 5-year age groups and also groups of 5 calendar years, classifying the data into "person-years" within the groups. Thus, if in the age group 55–59 in the early 1970s, the incidence rate of stomach cancer in white males was 75 per 100,000 (note that this is a rate), and there were 1,000 person-years (that is, men who were within that age group and in the early 1970s, for up to a maximum of 5 years each), the total contribution to the expectation of stomach cancer from this group would be 0.75. The overall expectation for white-male stomach-cancer cases could be a result from the summation of similar figures to cover the full range of ages and calendar years required for the known workforce. In all these computations it is usual to include only their observed lifetimes, so that a man who dies during the period of observation contributes to person-years only until the time of his death. An alternative method ignores the actual durations of life, substituting the life-table expectations from their sex and age at the time of entry, including only of course up to the endpoint of the study. If one of the effects of exposure at the factory were to cause a shortening of the normal lifespan, this method would serve to reveal it. In general, however, it is best to use either method with circumspection, since other features may also contribute to distortion of the expectations, such as the HWE or SPE, both described earlier in this chapter. The appropriate rates, whether of mortality or morbidity, need to also be carefully chosen. There may be no choice, if only the rates for the country as a whole are available: this is often true for mortality rates, though there may be some regional variants. Cancer registry data may be more regionalized and therefore more appropriate to the location of the factory or study population.

COMPARISON: THE SMR

The comparison of the observed numbers of deaths (or cases of disease) with the number expected is usually expressed in the form of an SMR, since the aim of the method of calculation of expectations is to obtain figures that have allowed for all the pertinent factors that distinguish those at risk, such as sex, age, race, calendar-year period, and region, amounting to a similar process to that of standardization described earlier. In general the comparisons will be made separately for different hazards, and also for different disease groups. Frequently they are evaluated for their statistical significance by use of the Poisson test, where the difference between the observed and expected numbers is set against the square root of the expected to provide a ratio that, if the expected is sufficiently large (12 or more), can be regarded approximately as a *t*-test, but otherwise needs specific calculation or recourse to tables of the function. In interpreting the contrast between observed and expected, it is important to keep in mind the source of the expectations, and its relevance to the comparison: if it based on mortality rates for a whole country, it will include those physically handicapped or otherwise unable to work, which favors the factory population and leads to the HWE, and also will include other groups of the population (e.g., social classes, other industries and occupations) that may serve to distort the comparison. SMR values are commonly used to evaluate risks associated with occupational and industrial situations.

THE PROPORTIONAL-HAZARDS MODEL

A different approach to the evaluation of specific hazards has been devised that makes use in effect of a series of internal comparisons. It is known as the method of regression models in life tables (RMLT), the name given to it by the originator, D.R. Cox, or as the proportional-hazards model. Essentially it is a form of multiple regression analysis, into which it is incorporated as many as possible of the variants that distinguish the workers in the factory: sex, age, race, duration of employment, type of job, area of work, exposure levels, etc. The comparisons are then made within the factory itself, so that the workers in an area of potential hazard are evaluated against the experience of the rest of the factory, taking into account all those factors included in the regression and likely to influence the behavior of each individual. Because of its independence of any external standard as a basis for the control, this method has a clear advantage over other kinds of comparisons. Its disadvantages stem from mainly information required, and an adequate varied range of areas of work. Given the requisite data, it provides probably the most powerful form of epidemiological analysis in this field.

SOME OTHER APPLICATIONS OF EPIDEMIOLOGY

The methods of epidemiology are increasingly being used in the investigation of a wide variety of health deficiencies or of areas of group ill health. The study of the relationship between Legionnaires' disease and defective maintenance of air-conditioning plants owes much to such methods. Another example, not fully worked out, is that of the sick-building syndrome, where a number of symptoms of malaise, together with respiratory and eye afflictions, have been related to ventilation problems and lighting conditions in some kinds of modern buildings. Incidents of food poisoning have been among the "classical" applications of methods perhaps more akin to those of crime detection than a strictly epidemiological type. More recently studies of outbreaks of food-borne disease—some due to inadequate cooking, some to the increased demand for precooked convenience foods, some to more intensive animal husbandry and processing of the meat—have made extensive use of methods of epidemiological analysis. Other obvious areas of application include inquiries into sudden outbreaks of other forms of disease, especially when localized in time or space, and the study of road accidents, whether in general or of specific "hot spots."

CONFIDENTIALITY

The usefulness of epidemiology, whether in its descriptive or analytical manifestation, depends essentially on the extent and consistency of the data on which it is based. A current trend in a number of countries has been that of "data protection," ostensibly to protect the privacy of the individual, and resulting in the "anonymization" of many data items. For a great many, if not all, items of information concerning an individual, the name is the most useful identification to link them together. Consequently the movement toward data protection has been against the interests of epidemiology, and has hampered much of its development. In many of the countries of Europe a residue of the Code of Napoleon has made the link between the cause of death and the name of the deceased an item of strict confidentiality, so that the death certificate is in two parts: a statement of the fact of death of a named individual, for legal purposes, and a separate statement of the cause(s) of death of an anonymous person, of stated sex, age, and race, for purposes of preparation of the country's mortality statistics. Consequently, epidemiological study has been considerably hindered by this dissociation. It is ironic, therefore, that whereas in those countries there have been attempts to liberalize this restriction in the interest of useful epidemiological studies, the reverse has been the trend in some countries where access to such data has previously been unrestricted. It should be possible to devise a compromise that permits suitably motivated and qualified investigators to obtain free access to all data necessary to their study without jeopardizing the general right of the individual to the confidentiality of the data concerning himself.

EUTROPHICATION

INTRODUCTION

For a considerable time, scientists have been aware of the natural aging of lakes, a process so slow that it was considered immeasurable within the lifetime of human beings. In recent years, however, that portion of the nutrient enrichment or eutrophication of these and other natural bodies of water contributed by man-made sources have become a matter of concern. Many bodies of water of late have exhibited biological nuisances such as dense algal and aquatic weed growths whereas in the past they supported only incidental populations of these plants.

Excessive nutrients are most often blamed in the scientific literature for the creation of the plant nuisances. Among the nutrients, dominant roles have been assigned by most researchers to nitrogen and phosphorus. These elements can be found in natural waters, in soils, in plants and animals, and in precipitation. Man-made sources for these nutrients are in domestic wastes and often in industrial wastes.

This chapter concerns itself with the nature of algae, the environmental factors affecting their growth, the nature of the entrophication problem (sources, relative quantities of nutrients contributed by these sources, threshold limits for the growth of aquatic plants), and various techniques for the removal of those nutrients usually associated with the eutrophication problem.

THE PHYSICAL NATURE OF ALGAE

Most bodies of water which can be considered eutrophic exhibit various predominant forms of algae at different times of the year. Algae that are important to investigators concerned with the eutrophication problem may be classified into four groups which exclude all but a few miscellaneous forms. The four groups are:

1) Blue-green algae (Myxophyceae)
2) Green algae (Chlorophyceae)
3) Diatoms (Bacillariophyceae)
4) Pigmented flagellates (Chrysophyceae, Euglenophyceae)

The basis for this classification is the color of the organism. Blue-green and green algae are self descriptive, whereas diatoms are brown or greenish-brown. Pigmented flagellates can be brown or green. They possess whip-like appendages called flagella, which permit them to move about in the water. It is not inferred by the above list that all algae are restricted to these colors. Rhodophyceae, for example, which are primarily marine algae, are brilliant red.

Aquatic biologists and phytologists do not agree on the number of divisions that should be established to identify algae. Some authorities use as many as nine divisions while others use seven, five and four. Nevertheless, the four divisions as suggested by Palmer will be used as they are adequate for the ensuing discussions.

BLUE-GREEN ALGAE

Blue-green algae as a group are most abundant in the early fall at a temperature range of 70 to 80°F. Data obtained from water sources in the southwestern and southcentral United States indicate that for this section of the country maximum growth occurs at the end of February and throughout much of April, May and June. When blue-green algae becomes predominant, it frequently indicates that the water has been enriched with organic matter, or that previously there had been a superabundance of diatoms. Blue-green algae are quite buoyant due to the oil globules and gas bubbles which they may contain. For this and other reasons they live near the surface of the water often producing offensive mats or blankets. Since these algae are never flagellated, they are not considered swimmers although a few, such as oscillatoria and spirulina, are able to creep or crawl by body movements. Some of the common blue-green algae are anabaena, aphanizomenon, rivularia, gomphosphaeria and desmonema.

GREEN ALGAE

Green algae are most abundant in mid-summer at a temperature range of 60 to 80°F. For water bodies in the southwestern and southcentral United States, maximum growth occurs during the first half of September with little variation throughout the remainder of the year. Like the blue-green algae, green algae usually contain oil globules and gas bubbles which contribute to the reasons why they are found near the surface of the water. Green algae are distinguished by their green color which comes from the presence of chlorophyll in their cells. Many of the green algae are flagellates and due to their swimming ability they are frequently found in rapidly moving streams. Some of the common green algae are chlorella, spirogyra, chlosterium, hydrodictyon, nitella, staurastrum and tribonema.

DIATOMS

Diatoms are usually most prevalent during the cooler months but thrive over the wide temperature range of from 35 to 75°F. For water bodies in the southwestern and southcentral United States, diatoms thrive best in May, September and October with the maximum growth observed in mid-October. It is generally recognized that many diatoms will continue to flourish during the winter months, often under the ice. The reason for the increase in growth twice a year is due to the spring and fall overturn, in which food in the form of carbon, nitrates, ammonia, silica and mineral matter, is brought to the surface where there is more oxygen and a greater intensity of light.

Diatoms live most abundantly near the surface, but unlike the buoyant green and blue-green algae, they may be found at almost any depth and even in the bottom mud. Diatoms may grow as a brownish coating on the stems and leaves of aquatic plants, and in some cases they grow along with or in direct association with other algae. In rapidly moving streams they may coat the bottom rocks and debris with a slimy brownish matrix which is extremely slippery. Lastly, diatoms are always single-celled and nonflagellated.

PIGMENTED FLAGELLATES

No classification of algae has caused more disagreement than that of the pigmented flagellates. The difficulty arises from the fact that hey possess the protozoan characteristics of being able to swim by means of flagella, and the algae characteristic of utilizing green chlorophyll in association with photosynthesis. Thus they could be listed either as swimming or flagellated algae in the plant kingdom, or as pigmented or photosynthetic protozoa in the animal kingdom. One of many attempts to resolve this problem has been the proposal to lump together all one-celled algae and all protozoa under the name "Protista." This method, however, has not met with general acceptance. For the sanitary engineer the motility of the organism is of lesser importance than its ability to produce oxygen. The pigmentation characteristic associated with green chlorophyll and oxygen production is sufficient criteria for separating these organisms into a class by themselves. Thus a distinction is made between pigmented flagellates (algae) and nonpigmented flagellates (protozoa).

Pigmented flagellates are more abundant in the spring than at any time of the year although there is generally considerable variation among the individual species. Apparently flagellates are dependent on more than temperature. They are found at all depths, but usually are more prevalent below the surface of the water than at the surface.

For present purposes pigmented flagellates can be divided into two groups: euglenophyceae which are grass-green in color and chrysophyceae which are golden-brown.

Euglenophyceae are usually found in small pools rich in organic matter, whereas chrysophyceae are usually found in waters that are reasonably pure.

Some of the more common pigmented flagellates are euglena, ceratium, mallomonas, chlamydomonas, cryptomonas, glenodinium, peridinium, synura and volvox.

MOTILITY

Of additional value in the classification of algae are their means of motility. Three categories have been established, namely:

Nekton—algae that move by means of flagella.
Plankton—algae that have no means of motility.
Benthic algae—algae that attach themselves to a fixed object.

NEKTON

Nekton are the most active algae and are often referred to as "swimmers." Due to their activity they use more energy and in turn release more oxygen during the daylight hours. Their cells are supplied with one, two, or more flagella which extend outward from the front, side or back of the cell. These flagella enable the organisms to move about freely in the aquatic environment and to seek food which, in the case of turbulent water, is constantly changing in location.

In general nekton have the most complex structure of the three categories and come nearest to being simple animals. Nekton are the predominant algae found in swiftly moving rivers and streams.

According to Lackey, results of tests performed on waters of the Ohio River show that certain nekton are the only algae that provide reliable clear-cut responses to the presence of pollution and thus are true indicator organisms. Five flagellates have been singled out on the genus level as being common and easily recognized. They are (1) cryptomonas, (2) mallomonas, (3) synura, (4) uroglenopsis, and (5) dinobryon. Dinobryon is perhaps the most easily recognized due to its unique shape which resembles a shaft of wheat. Samples taken from several rivers indicate that these algae react adversely to the presence of sewage and are found in abundance only in clean water. Unfortunately not all experts agree on what constitutes clean water and what algae serve as indicator organisms. Patrick states that the "healthy" portion of a stream contains primarily diatoms and green algae. Rafter states that the absence of large amounts of blue-green algae is an indicator of clean water. Palmer lists 46 species which have been selected as being representative of "clean-water algae," and these consist of diatoms, flagellates, green algae, blue-green algae and red algae. In addition Palmer lists

47 species of algae condensed from a list of 500 prepared from reports of more than 50 workers, as being representative of "polluted-water algae." These consist of blue-green algae, green algae, diatoms and flagellates.

PLANKTON

Plankton are free-floating algae which are most commonly found in lakes and ponds, although they are by no means limited to these waters. Most species are unicellular; however, they tend to become colonial when their numbers increase, as in the formation of a heavy concentrated growth known as a "bloom." An arbitrary definition of a bloom is that concentration of plankton that equals or exceeds 500 individual organisms per ml. of raw water. Blooms usually show a predominance of blue-green algae although algae from other classes can also form blooms.

An algae bloom often becomes sufficiently dense as to be readily visible on or near the water surface, and its presence usually indicates that a rich supply of nutrients is available. Other environmental factors may stimulate the formation of blooms, and a bloom of the same organism in two bodies of water may or may not result from identical favorable environmental conditions. These growths are extremely undesirable in bodies of water, in general, and in potential water supply sources in particular for the following reasons:

1) They are very unsightly.
2) They interfere with recreational pursuits.
3) When the water becomes, turbulent, fragments of the mat become detached and may enter a water treatment system clogging screens and filters.
4) When the algae die (as a result of seasonal changes or the use of algicides), decomposition occurs, resulting in foul tastes and odors.
5) They may act as a barrier to the penetration of oxygen into the water which may result in fish kills.
6) They may reduce the dissolved oxygen in the water through decay or respiration within the bloom.
7) Some blooms release toxic substances that are capable of killing fish and wild life.
8) They may cause discoloration of the water.
9) They attract waterfowl which contribute to the pollution of the water.

Some of the common blue-green algae that form blooms are anabaena, aphanizomenon, oscillatoria, chlorella and hydrodictyon. Synedra and cyclotella are common diatoms that form blooms and synura, euglena and chlamydomonas are common flagellates that form blooms. Filamentous green plankton, such as spirogyra, cladophora and zygnema form a dense floating mat or "blanket" on the surface when the density of the bloom becomes sufficient to reduce the intensity of solar light below the surface. Like blooms, these blankets are undesirable, and for the same reasons cited earlier. However, in addition, blankets also serve as a breeding place for gnats and midge flies, and after storms they may wash up on the shores where they become offensive. In many cases hydrogen sulfide and other gases which are able to spread disagreeable odors considerable distances through the air are liberated. In large amounts, hydrogen sulfide has been known to seriously discolor the paint on lakeside dwellings.

BENTHIC ALGAE

Benthic algae are those algae which grow in close association with a supply of food. That is, they seek out an aquatic environment where nutrients are adequate, then attach themselves to a convenient stationary object such as a submerged twig or rock. They may be found in quiet ponds and lakes or in fast-moving rivers and streams. In some cases they break away from their attachments and form unsightly surface mats, or they may re-attach themselves somewhere else. Chlamydomonas is such an organism, where in one growth phase it may be found attached to a fixed object, and in another phase it may be dispersed throughout the water.

Benthic algae include diatoms, blue-green algae, green algae and a few species of red fresh-water algae. None of the pigmented flagellates are benthic. Most attached algae grow as a cluster of branched or unbranched filaments or tubes and are fastened at one end to some object by means of an anchoring device. Others take the shape of a green felt-like mat (gomphonema), a thin green film or layer (phytoconis), or a soft fragile tube (tetraspora). Some of the most common benthic algae are cladophora, chara, nitella, ulothrix, cymbella, vaucheria and gomphonema.

ENVIRONMENTAL FACTORS AFFECTING GROWTH OF ALGAE

The effects of certain environmental factors on the growth of the aforementioned forms of algae have been fairly well defined. The most important parameters to be considered in the growth pattern are light intensity, temperature, pH and nutritional requirements.

LIGHT INTENSITY

Light is essential to all organisms which carry on photosynthesis; however, requirements or tolerance levels differ greatly with the organism. For example, terrestrial species of vaucheria grow equally well in fully-illuminated soil and densely-shaded soil, while a number of blue-green algae grow only in shaded habitats. In addition, some algae are unable to endure in the absence of sunlight caused by several consecutive cloudy days, whereas certain submerged algae are unable to withstand exposure to full sunlight. Thus, an algae kill may be noted during a drought where shallow water prevents depth-dwelling algae from escaping the intensity of the sunlight penetration. Often muddy rivers are virtually algae-free due to the lack of penetration of the sunlight, the Missouri and the Mississippi being two such rivers.

The distribution of algae at the various depths in a body of water is directly correlated with the intensity of illumination at the respective depths. This distribution would be difficult to express in general terms when dealing with algae on their species level. In addition, the depths at which these species would be found would change with such variables as growth phase of the organism, temperature and the absorptive and reflective characteristics of the water. It can be stated, however, that certain fresh-water red algae and blue-green algae are found only at considerable depths and that some diatoms exist in the bottom mud. In the most general terms it can also be stated that algae are found at all levels, but most commonly near the surface.

The vertical distribution may also be related to the division of light rays into various spectral colors. This division varies with the concentration of dissolved color material, plankton and particulate matter, with the seasons, and with the depth. In colored water the violet-blue end of the spectrum is absorbed more readily. As depth increases light rays divide differently with greater absorption occurring at the red end of the spectrum.

The depth to which light penetrates has a direct influence on photosynthetic activity. The seasonal variation in this light and the resulting availability of certain dominant wave lengths may be the reason for fluctuations in the composition of the algal population from spring to fall. Much more work is needed in this area.

TEMPERATURE

In general, temperature is not the key factor in determining the nature of the algal flora. Most species are able to grow and reproduce if other environmental conditions are favorable. According to Patrick, however, the above statement is not true in the case of diatoms, where temperature changes are more important than any other environmental factor in influencing their rate of growth. Additional work in this area by Cairns indicates that certain diatoms grow best only at a specific temperature, and that at some temperatures they will not grow at all.

Most algae are not affected by minor changes in pH brought about by the seasonal variations, growths of carbon-dioxide producing organisms, etc. Large changes such as would be caused by the introduction of industrial wastes or acid mine waters, will greatly affect algae, usually causing a decrease in population.

The majority of algae thrive when the pH is near 7.0. Some blue-green algae prefer high pHs. Anacystis and coccochloric are found at about pH 10.0 with little or no growth below pH 8.0. Other algae such as eugleny mutabilis, cryptomonas erosa and ulothrix zonata prefer low pHs.

NUTRITIONAL REQUIREMENTS AND TOXIC ELEMENTS FOR ALGAE

Calcium

Calcium is not an essential element for most algae, although some cannot develop without it.

Calcium and Magnesium

As bicarbonates they are a supplemental supply of carbon dioxide for photosynthesis. This accounts for the greater abundance of algae in hard-water lakes than in soft-water lakes.

Iron

Most algae grow best when the ferric oxide content of the water is between 0.2 to 2.0 mg per liter. Above 5 mg per liter there is a toxic effect unless it is overcome by the buffering action of organic compounds or calcium salts. Certain diatoms (eunotia and pinnularia) are found in iron-rich water. Effluent from steel mills may be toxic to most algae if the resulting iron concentration exceeds the toxic limitation.

Copper

Copper is extremely toxic to algae in the range of 0.1 to 3.0 ppm as copper sulfate; the sulfate form being used as an algicide. Some algae are able to tolerate large amounts of copper ion and are considered copper-sulfate resistant. Protococcus, for example, is not destroyed by 10 ppm of copper sulfate.

Phenol

At a concentration of up to 1.9 mg per liter, phenol apparently has no toxic effect on diatoms.

Nitrates, Phosphates and Ammonia

These are essential food elements necessary for growth. Nitrogen may be obtained from nitrates, nitrites or simple ammonia compounds. The primary source of these nutrients is from sewage treatment plant effluents, although nitrogen may be derived from the atmosphere, land runoff, etc. (See section on EUTROPHICATION.) In general as little as 0.3 to 0.015 ppm of nitrates and phosphates will produce blooms of certain species of algae, other conditions being favorable.

Oil

Streams polluted with oil are usually low in algae. One variety of diatoms may be dominant in such waters.

Salinity

Increases in salinity up to about one percent do not affect the algae population. Significant increases, such as caused by salt-brine wastes, may destroy most of the algae present, however. Certain fresh-water algae may become adapted to water with slowly increasing salinity.

Hydrogen Sulfide

At a concentration of 3.9 ppm, hydrogen sulfide is toxic to most diatoms. Some resistant species are achnanthese affinis, cymbella ventricosa, hantzschia amphioxys and nitzschia palea.

Silica

Silica is necessary for the growth of diatoms whose cell wall is composed of silica. Presently no limits have been determined (to the author's knowledge).

Vitamins

Several vitamins in small quantities are a requisite to growth in certain species of algae. Chief among these vitamins are vitamin B-12, thiamine and biotin. These vitamins are supplied by bottom deposits, soil runoff and by the metabolites produced by other organisms.

Micronutrients

Substances such as manganese, zinc, molybdenum, vanadium, boron, chlorine, cobalt, etc. are generally present in water in the small concentrations sufficient for plant growth.

Carbon Dioxide

Carbon dioxide is necessary for respiration. If it is deficient, algae may remove carbon dioxide from the atmosphere.

Chlorine

Chlorine is toxic to most algae and is used as an algicide in the range of 0.3 to 3.0 ppm. It is used as an algicide in the treatment plant and distribution system. Some algae, cosmarium for example, are resistant to chlorine. Protococcus, which is resistant to copper sulfate, is killed by 1 ppm of chlorine. Therefore, algae resistant to the copper ion may not be resistant to the chlorine ion and vice versa.

Calcium Hydroxide (lime)

An excess of lime in the water, as may be introduced during pH adjustment for coagulation, results in the death of certain algae. Five ppm of lime with an exposure of 48 hours has been lethal to melosira, nitzschia and certain protozoa and crustacea.

THE EUTROPHICATION PROBLEM

Of the factors previously discussed which promote the growth of algae, that factor which man has altered is the nutrient concentration in may of the natural waterways.

In simplest terms, eutrophication is the enrichment of waters by nutrients from natural or man-made sources. Of the many nutrients which are added to the waters by man-made sources, nitrogen and phosphorous are most often cited by researchers as being the key nutrients responsible for the promotion of algae growth. In nearly all cases when the nitrogen and phosphorus level of a body of water increases, there will be a corresponding increase in the growth of algae and aquatic plants. Such growth greatly speeds up the aging process whereby organic matter invades and gradually displaces the water until eventually a swamp or marsh is formed. Unfortunately, the process of eutrophication is often difficult to reverse in bodies of water such as large lakes where the flushing or replacement time for the waters can be in the order of years.

The following sections provide the relative magnitude of natural and man-made sources of nutrient material associated with plant growth.

SOURCES OF NUTRIENTS

While it is recognized that certain algae require a number of chemical elements for growth, it is also known that algae can absorb essential as well as superfluous or even toxic elements. Although every essential element must be present in algae, this does not mean that every element is essential. On the other hand, the absence of certain nutrient elements will prevent growth. Nutrients may be classified as (1) "absolute nutrients," which are those which cannot be replaced by other nutrients, (2) "normal nutrients," which are the nutrients contained in the cell during active growth, and (3) "optimum maximum growth." It may also be well to assign a broad meaning to the word "nutrient" and define it as anything that can be used as a source of energy for the promotion of growth or for the repair of tissue.

In evaluating the effects of nutrients on algae, care must be exercised to consider the interaction between nutrients and other physical, chemical or biological conditions. Rapid growth of algae may be stimulated more by factors of sunlight, temperature, pH, etc., than by an abundance of nutrient material. Tests performed with nitzschia chlosterium, in order to study the interaction of environmental factors showed that two identical cultures of the organism, when supplied with a reduced nutrient level, had a lower optimum light intensity and optimum temperature for maximum growth. Thus light intensity and temperature data should accompany data on nutrient concentration and growth rate.

Of all the possible nutrients, only nitrogen and phosphorus have been studied in depth both in the field and in the laboratory. This is because of the relative difficulties associated with the study, analysis and measurement of trace elements, compounded by the minute impurities present in the regents and distilled water. In addition, nitrates and phosphates have a long history of use in agricultural fertilizers where determination of their properties have been essential to their economical use.

The following are the most common sources of nitrogen and phosphorus in bodies of water:

1) Rainfall—Based on experimental data, it has been found that rainwater contains between 0.16 and 1.06 ppm of nitrate nitrogen and between 0.04 and 1.70 ppm of ammonia nitrogen. Computations based on the nitrogen content of rainwater show that for Lake Mendota, Wisconsin, approximately 90,000 pounds of nitrogen are available each year as a result of rainfall. Thus it can be seen that rainfall plays a significant role in building up the nitrogen content of a lake or reservoir especially if the surface area is large.

An examination of the phosphorus content of rainwater of different countries shows that a number of concentrations may exist ranging from 0.10 ppm to as little as an unmeasurable trace, the latter reported in the Lake Superior region of the United States. In view of the wide variation in the determinations, little can be stated at present regarding the degree of phosphorus build-up in impoundments resulting from rainwater.

2) Groundwater—Studies conducted on sub-surface inflows to Green Lake, Washington, show that this water contains approximately 0.3 ppm of phosphorus. Other reports, however, claim that the amount of phosphorus in groundwater is negligible.

Investigations into the nitrate content of groundwater produced variable results; however, it can be stated that 1.0 ppm is a reasonable figure. The results of the above studies on both nitrogen and phosphorus can be summarized by stating that groundwater should not be discounted as a possible source of nutrients and that quantitative values should be obtained for the specific locality in question.

3) Urban Runoff—Urban runoff contains storm water drainage, overflow from private disposal systems, organic and inorganic debris from paved and grassed areas, fertilizers from lawns, leaves, etc. In view of the variable concentration of the above material, precise figures cannot be obtained on the phosphorus or nitrate content that would be meaningful for all areas.

Studies conducted in 1959 and 1960 by Sylvester on storm water from Seattle street gutters shows the following nutrients:

Organic nitrogen—up to 9.0 ppm

Nitrate nitrogen—up to 2.8 ppm

Phosphorus—up to 0.78 ppm soluble and up to 1.4 ppm total.

4) Rural Runoff—Rural runoff for the purposes of definition may be considered as runoff from sparsely-populated, wooded areas with little or no land devoted to agriculture. Investigations by Sylvester showed that the phosphorus content of drainage from three such areas in the state of Washington contained 0.74, 0.77 and 0.32 lb./acre/year, or a total concentration of 0.069 ppm. The corresponding nitrate nitrogen concentration and organic nitrogen concentration amounted to 0.130 and 0.074 ppm, respectively.

5) Agricultural Runoff—Agricultural runoff is one of the largest sources of enrichment material and may be derived from two sources—wastes from farm animals and the use of nitrogen and phosphorus-containing fertilizers.

Farm-animal wastes add both large quantities and high concentrations of nutrients to adjacent streams and rivers. The large concentrations are due primarily to the practice of herding animals in relatively confined areas. A comparison on the nutrient value of animal wastes and human wastes has been made in a study by the President's Science Advisory Committee. According to the findings, a cow generates the waste equivalent of 16.4 humans, a hog produces as much as 1.9 humans and a chicken produces as much as 0.14 humans.

The use of chemical fertilizers in the United States has grown almost 250% in the decade from 1953 to 1963. In 1964 the use of phosphorus-containing fertilizers and the use of nitrogen-containing fertilizers reached approximately 1.5 and 4.4 million tons, respectively, per year. Most all of this fertilizer is distributed to soil already high in natural-occurring nitrogen. When nitrogen fertilizer and natural soil nitrogen combine, there is a great increase in crop production, but also a greater opportunity for loss of this nitrogen in runoff. This loss will increase if the fertilizer is not properly applied, if it is not completely utilized by the crops, if the crops have a short growing season (the land being non-productive for a time), if the land is irrigated, and if the land is sloped.

The addition of nitrogen-bearing fertilizers also increase the quantity of mineral elements in the soil runoff which are necessary for the growth of aquatic plants and algae. When applied, the nitrogen in the fertilizer is converted into nitric acid which combined with the minerals in the soil, such as calcium and potassium, rendering them soluble and subject to leaching.

6) Industrial Wastes—The nutrient content of industrial waste effluents is variable and depends entirely upon the nature, location and size of the industry. In some cases the effluents are totally free of nitrogen and phosphorus.

The meat packing industry is one of the chief producers of nitrogen-bearing wastes. The greatest producer of phosphate-bearing wastes is most likely the phosphate-manufacturing industry itself. Most phosphate production in the United States is concentrated in Florida and as a result many severe localized problems of eutrophication have resulted in that state.

Fuel processing industries and petroleum refineries discharge vast quantities of nitrogen into the atmosphere both in the gaseous state and solid state as particulate matter. This nitrogen is then washed from the atmosphere by the rain and carried back to earth. In 1964, the 500 billion tons of coal used in the United States released about 7.5 million tons of nitrogen into the atmosphere, most of which has returned to be combined with the soil. This greatly exceeds the use of nitrogen in the form of fertilizers which, as previously stated, amounted to 4.4 million tons for that year. Thus, through the atmosphere we are bringing more nitrogen into the soil than we are taking out, and much of this excess ultimately gets washed out into our waterways.

7) Municipal Water Treatment—The water treatment plants themselves are to a degree responsible for adding to the eutrophication problem as approximately 33% of the municipal water in the United States is treated with compounds containing phosphorus or nitrogen. Some of the commonly used nutrient-bearing chemicals or compounds are ammonia (in the use of chloramines) organic polyelectrolytes, inorganic coagulant aids, sodium hexametaphosphate, sodium tripolyphosphate, and sodium pyrophosphate.
8) Waterfowl—It has been estimated that wild ducks contribute 12.8 pounds of total nitrogen/acre/year and 5.6 pounds of total phosphorus/acre/year to reservoirs or lakes. A number of studies have been conducted on waterfowl, but it may be concluded that, although there may be some bearing on localized eutrophication, in general the overall effect is negligible.
9) Domestic Sewage Effluent—Undoubtedly the greatest contributor toward the eutrophication of rivers and lakes is the discharge from sewage treatment plants. Conventionally treated domestic sewage usually contains from 15 to 35 ppm total nitrogen and from 6 to 12 ppm total phosphorus. In addition there are a large number of minerals present in sewage which serve as micro-nutrients for algae and aquatic plants.

Phosphorus in domestic sewage may be derived from human wastes, waste food (primarily from household garbage-disposal units), and synthetic detergents. Human wastes have been reported in domestic sewage at the rate of 1.4 pounds of phosphorus/capita/year. The largest source of phosphorus, however, is from synthetic detergents which amounts to approximately 2.1 pounds/capita/year. Sawyer indicates that detergent-based phosphorus represents between 50 and 75% of the total phosphorus in domestic sewage. It should be noted that both the use of household garbage-disposal units and detergents is fairly recent, and accordingly they may be considered as contributing strongly to the development of the recently magnified eutrophication problem.

Not all the phosphorus entering a sewage treatment plant will leave the plant since chemical removal does occur during the treatment process. Calcium and metallic salts in large concentrations form insoluble phosphates which are readily removed. Very often phosphate-precipitating agents are present in waters containing industrial wastes, and when these agents are received at the plant, removals in the neighborhood of 60% may be realized.

Nitrogen in domestic sewage is derived from human wastes and from waste food primarily from household garbage-disposal units. Human wastes, the major source of nitrogen, contributes an average of about 11 pounds of nitrogen/capita/year. Some reduction in the nitrogen also takes place during the treatment of the sewage. Many plants treat the sludge anerobically which permits significant release of the nitrogen. In general the removal amounts to between 20 and 50%. The higher percentage of removal occurs when fresh wastes are given complete treatment with no return of sludge nutrients to the effluent.

EUTROPHICATION STUDIES

In recent years a considerable number of studies have been made on eutrophication and related factors. Most of the studies can be grouped into the following categories:

1) nutrient content of runoff, rainwater, sewage effluent, bottom mud, etc.
2) nutrient analysis and physical distribution of nutrients in bodies of water before and/or after enrichment.
3) methemoglobinemia (illness in infants due to drinking high nitrate-content water)
4) toxicological and other effects on fish of high nitrate/high phosphate-content water
5) the chemical composition of plants in both eutrophied and non-eutrophied waters
6) the nutrient values of various fertilizers, manures and other fertilizing elements
7) the nutrient value of various soils
8) the effects of eutrophication on aquatic plants, animals and fish
9) studies on specific algae under either controlled laboratory conditions or in a particular body of water, using artificial or natural environmental conditions
10) methods for the removal or reduction of nitrogen and phosphorus
11) nutrient thresholds for growth of algae and aquatic weeds
12) the effects of eutrophication on the oxygen balance.

Of the above list, only studies conducted in the areas of (11) and (12) will be presented below. Work done in regard to (1) has already been presented. The removal or reduction of nitrogen and phosphorus (10) will be discussed separately as part of the subject matter in “CONTROL METHODS.”

NUTRITIONAL THRESHOLDS FOR THE GROWTH OF ALGAE

Studies conducted by Chu indicate that for growth on artificial media most planktonic algae flourish if the total nitrogen content ranges from 1.0 to 7.0 ppm and the total phosphorus content ranges from 0.1 to 2.0 ppm. If the nitrogen is reduced below 0.2 ppm and the phosphorus below 0.05 ppm, the growth of algae appears to be inhibited. The same inhibiting effect is created when the nitrogen or phosphorus content is raised above 20.0 ppm. The lower limit of the optimum range of nitrogen varies with the organism and with the type of nitrogen. For ammonia nitrogen the optimum range varies from 0.3 to 5.3 ppm and for nitrate nitrogen the optimum range falls between 0.3 and 0.9 ppm. Below these values the growth rate decreases as the concentration of nitrogen decreases.

Apparently the use of the various forms of nitrogen by algae is not constant throughout the year. Tests conducted at Sanctuary Lake in Pennsylvania (1965) indicate that the order of preference for the three forms of nitrogen—ammonia-nitrogen, nitrate-nitrogen, and nitrite-nitrogen—are defined by three seasonal periods, which are:

Spring	(1) Ammonia nitrogen
	(2) Nitrate nitrogen
	(3) Nitrite nitrogen
Midsummer	(1) Ammonia nitrogen
	(2) Nitrite nitrogen
	(3) Nitrate nitrogen
Fall	(1) Ammonia nitrogen
	(2) Nitrate nitrogen
	(3) Nitrite nitrogen

The amount of nitrogen in the aquatic environment is important to algae because it determines the amount of chlorophyll that may be formed. Too much nitrogen, however, inhibits the formation of chlorophyll and limits growth.

Laboratory studies on algae conducted by Gerloff indicate that of all the nutrients required by algae, only nitrogen, phosphorus and iron may be considered as limiting elements, and of these three, nitrogen exerts the maximum limiting influence. Approximately 5 mg of nitrogen and 0.08 mg of phosphorus were necessary for each 100 mg of algae produced. The corresponding nitrogen/phosphorus ratio is 60 to 1.

Hutchinson cites phosphorus as being the more important element since it is more likely to be deficient. When phosphorus enters a body of water, only about 10% is in the soluble form readily available for algal consumption. During midsummer total phosphate may increase greatly during the formation of algal blooms, while soluble phosphate is undetectable due to rapid absorption by the growing algae. Very often during warm weather these blooms are stimulated by the decomposition and release of soluble phosphates from the bottom sediments, deposited by the expired blooms of previous seasons. Thus when phosphates are added to a lake, only a portion of the phosphates are used in producing blooms. The blooms thrive and consume phosphates for only a short time, and a significant amount finds its way to the bottom sediments where it will be unavailable to further growth of aquatic vegetation.

Prescott examined a number of algae and concluded that most blue-green algae are highly proteinaceous. Aphanizomenon flos-aquae, for example, was shown to contain 62.8% protein. Green algae were found to be less proteinaceous. Spirogyra and cladophora, for example, contain 23.8 and 23.6% respectively. Thus it can be concluded that the nitrogen requirement (for the elaboration of proteins) depends on the class of algae, and that blue-green algae would require more nitrogen than green algae.

Provasoli examined 154 algal species to determine the requirements for organic micronutrients. He found that although 56 species required no vitamins, 90 species were unable to live without vitamins such as B_{12}, thiamin and biotin, either alone or in various combinations. He concluded that these vitamins are derived from soil runoff, bottom muds, fungi and bacterial production (B_{12}), and from a natural residual in the water.

Ketchum and Pirson conducted a series of examinations on the inorganic micronutrient requirements of algae and concluded that a number of elements are necessary for growth. No numerical values were assigned to the requirement levels. Those elements shown to be essential were C, H, O, P, H, S, Mg, Ca, Co, Fe, K and Mo. Those elements which may be essential (subject to further study) were Cu, An, B, Si, Va, Na, Sr, and Rb.

In summation, absolute values and nutrient thresholds cannot be set at this time because too little is known regarding the requirements of individual species. It might be stated in general terms, however, that nitrogen and phosphorus are two essential nutrient elements related to the production of blooms, and that if they are present in the neighborhood of 0.2 ppm and 0.05 ppm, respectively, algal growths will increase significantly.

NUTRITIONAL THRESHOLDS FOR THE GROWTH OF AQUATIC PLANTS

Studies conducted by Harper and Daniel indicate that submerged aquative plants contain 12% dry matter of which 1.8% are nitrogen compounds and 0.18% are phosphorus compounds. Hoagland indicates that when the nitrate content of water is high, nitrates may be stored in aquatic plants to be reduced to the usable ammonia nitrogen form as required. Subsequent investigations show that ammonia nitrogen can be substituted for nitrate nitrogen and used directly. Light apparently is not a necessary factor in the reduction of the nitrogen.

Muller conducted a number of experiments on both algae and submerged aquatic plants, and concludes that excessive growths of plants and algae can be avoided in enriched waters if the concentration of nitrate nitrogen is kept below 0.3 ppm, and if the concentration of total nitrogen remains below 0.6 ppm.

OXYGEN BALANCE

Recently, attention has been given to the effect of the intense growths of algae on the oxygen balance of natural waterways. It has been established that the dissolved oxygen concentrations may exhibit wide variation throughout the course of the day. This variation is attributed to the ability of algae to produce oxygen during the daylight hours, whereas they require oxygen for their metabolic processes during the hours of darkness.

In addition, since algae are organic in nature, they exert a biochemical oxygen demand (BOD) on the stream oxygen resources as does other materials which are organic.

Extensive tests were run on the Fox River in Wisconsin by Wisniewski in 1955 and 1956 to examine the influence of algae on the purification capacity on rivers. In the most general terms, the studies indicate that algae increase the B.O.D. by adding organic matter capable of aerobic bacterial decomposition and by the respiration of the live cells which utilize oxygen during the absence of light. In the presence of light, algae produce oxygen and as a result may cause a "negative" B.O.D. for a production of oxygen in excess of that required for the normal B.O.D. requirements or aerobic bacterial stabilization. In addition to the above, the following specific conclusions were drawn from the tests:

1) The oxidation rate resulting from the respiration of live algae was much lower than that obtained by the biological oxidation of the dead algae.
2) The ultimate B.O.D. of live algae was practically the same as for dead algae.
3) A linear relationship was found to exist between the five-day B.O.D. of suspended matter and volatile suspended solids concentration.
4) The B.O.D. increases with increases in suspended solids, the latter consisting largely of algae.

Additional work was done in this area and reported in 1965 by O'Connell and Thomas. They note that the oxygen produced by photosynthetic plants is affected greatly by changes in the availability of light due to cloud cover, turbidity in the water, etc., and therefore it may be too variable to be used as a reliable factor in evaluating the oxygen resources of a river. Another variable may be the loss of oxygen to the atmosphere during the daylight hours, caused by excess oxygen production and localized supersaturation.

An important consideration is the type of photosynthetic plants which are prevalent in a river. According to the above authors, if benthic algae and/or rooted aquatic plants are predominant (in lieu of phytoplankton), there will be little beneficial effect on the oxygen balance. In addition nighttime absorption of oxygen through respiration can seriously reduce daily minimum concentrations of dissolved oxygen. Determination of the effects of the benthic algae oscillatoria along a fivemile stretch of the Truckee River in Nevada indicated that on the average of the organism produced 72.5 pounds/acre/day of oxygen through photosynthesis. Oxygen uptake for these same organisms amounted to an average of 65.4 pounds/acre/day.

An examination of the oxygen profiles indicated that the oxygen variation throughout the day ranged from 2 (at night) to 13 (during daylight) parts per million.

It is dissolved oxygen variations such as the above which has been responsible for the disappearance of high quality game fish in many of our natural waterways.

CONTROL METHODS TO PREVENT EUTROPHICATION

There are a number of methods which attempt to limit the amounts of nutrients in bodies of water once the point of eutrophy has been reached. Some of these include dredging and removing bottom sediments with an inert liner, harvesting the algae, fish, aquatic weeds, etc., and diluting the standing water with a water of lower nutrient concentration. Although these methods may have their proper application, if eutrophication is to be decelerated, nutrient removal must start before wastes are permitted to enter the receiving waters.

Regarding the specific nutrients necessary to be removed, most researchers have placed the blame of eutrophication in waters to the inorganic forms of phosphorus and nitrogen. A smaller number of researchers are claiming that the algae–bacteria symbiosis relationship might be responsible for the rapid growth of blooms and that the amount of algae present in natural waters is in direct balance with the amount of carbon dioxide and/or bicarbonate ions in the waters. They further argue that an external supply of the above elements is necessary for the growth of algae populations. Since neither theory has been proved conclusively to date, the control methods given will be for the removal of nitrogen and phosphorus since it is these nutrients which most researchers lay to the blame of eutrophication and which have been therefore subsequently studied in detail.

NITROGEN REMOVAL

Land Application

It has been found that nitrogen-bearing waters, when percolated through soil are subjected to physical adsorption and biological action which removes the nitrogen in the ammonium form. It appears, however, that the nitrate form of nitrogen remains unaffected. At present this process is only at the theoretical stage, and to the author's knowledge no full-scale application has been attempted. Considerable land area would be involved which may prove a deterrent.

Anaerobic Denitrification

In this process, the nitrate present in sewage is reduced by denitrifying bacteria to nitrogen and nitrous oxide gases which are allowed to escape into the atmosphere. In order to satisfy the growth and energy requirements of the bacteria, methanol in excess of 25 to 35% must be added as a source of carbon.

The removal efficiency ranges from 60 to 95%. The major advantage to anaerobic denitrification is that there are no waste products requiring disposal. This process is still primarily in the experimental stage at this date.

Ammonia Stripping

Ammonia stripping is an aeration process modified by first raising the pH of the wastewater above 10.0. At this pH the ammonia nitrogen present is readily liberated as a gas and is absorbed into the atmosphere. Aeration is usually accomplished in a packed tray tower through which air is blown.

This process is suited to raw sewage where most of the nitrogen is either in the ammonia form or may be readily converted to that form. In secondary treatment processes the conversion of ammonia nitrogen to nitrate nitrogen can be retarded by maintaining a high organic loading rate on the secondary process.

Efficiency of nitrogen removal by ammonia stripping is excellent with 80 to 98% reported. There is also the advantage that there are no waste materials which must be disposed of.

PHOSPHORUS REMOVAL

Chemical Precipitation

Precipitation of phosphorus in wastewater may be accomplished by the addition of such coagulants as lime, alum, ferric salts and polyelectrolytes either in the primary or secondary state of treatment, or as a separate operation in tertiary treatment. In general, large doses in the order of 200 to 400 ppm of coagulant are required. However, subsequent coagulation and sedimentation may reduce total phosphates to as low as 0.5 ppm, as in the case of lime. Doses of alum of about 100 to 200 ppm have reportedly reduced orthophosphates to less than 1.0 ppm.

Phosphorus removal by chemical coagulation generally is efficient with removals in the order of 90 to 95% reported. Additional benefits are gained in the process by a reduction in B.O.D. to a value of less than 1.0 ppm. Both installation and chemical costs are high, however, and the sludges produced are both voluminous and difficult to dewater.

Sorption

Sorption is the process of passing wastewater downward through a column of activated alumina whereby the common form of phosphate are removed by ionic attraction. Regeneration of the media is accomplished by backwashing with sodium hydroxide followed by acidification with nitric acid.

Contrary to alum treatment, this process has the advantage in that sulfate ions are removed and thus the sulfate concentration is not increased. Since no salts are added, the pH and the calcium ion concentration remain unchanged. The process is efficient with more than 99% removal reported. The process should be limited to wastewater with a moderate amount of solids so as not to clog the media.

REMOVAL OF NITROGEN AND PHOSPHORUS

Biological (secondary) Treatment

In the secondary method of sewage treatment, bacteria utilize soluble organic materials and transform them into more stable and products. In the process nitrogen and phosphorus are removed from the wastes, utilized to build new cellular materials, and the excess is stored within the cell for future use. For each pound of new cellular material produced, assuming the material to be in the form of $C_5H_7NO_2$, about 0.13 pounds of nitrogen and about 0.026 pounds of phosphorus would be removed from the sewage. In the actual operation of this process not all of this nitrogen is removed unless additional energy material in the form of carbohydrates is added. Although it may be possible to eliminate all the nitrogen, a considerable amount of soluble phosphorus may remain, possibly because of the high ratio of phosphorus to nitrogen in sewage, attributable to synthetic detergents. Much of this phosphorus can be removed by absorption on activated sludge floc when it is later separated and removed.

This process offers a 30 to 50% removal of nitrogen and about a 20 to 40% removal of phosphorus without the special addition of carbohydrates.

Reverse Osmosis

The process of reverse osmosis consists of passing wastewater, under pressures as high as 750 psi, through a cellulose acetate membrane. The result is the separation of water and all ions dissolved therein. In actual practice the process has been plagued with difficulties primarily due to membrane fouling or premature failure of the membrane. In addition some nitrate and phosphate ions escape through the membrane.

Removal efficiency ranges from between 65 to 95% (for nitrogen).

Electrodialysis

Like reverse osmosis, electrodialysis is a non-selective demineralization process which removes all ions which would include the nitrate and phosphate ions. Essentially an electric current is used in conjunction with a membrane inserted in the line of current flow to separate the cations and anions.

The problems that have developed in the operation of this process include membrane clogging and precipitation of low-solubility salts of the membrane. Acidification of the water and removal of some of the solids prior to treatment has been effective in minimizing these problems, although it adds to the cost.

Removal efficiency ranges from between 30 to 50% (for nitrogen).

Ion Exchange

In the ion exchange process wastewater is passed through a media bed which removes both anionic phosphorus and anionic nitrogen ions and replaces them with another ion from the media. Regeneration of ion exchangers is commonly accomplished with inexpensive sodium chloride, and frequently the salt is salvaged by recycling the backwash water.

Difficulties in the process may be caused by fouling of the exchange resin due to organic material and reduction in the exchange capacity due to sulfates and other ions. The former may be reduced by removing the organic matter from the resin with sodium hydroxide, hydrochloric acid, methanol and bentonite.

The efficiency and cost of nitrogen and phosphorus removal by ion exchange depends largely on the degree of pretreatment and/or the quality of the water to be treated. Removal of nitrogen ranges from between 80 to 92%.

A number of ions exchange resins are available for nitrogen removal alone. These include zeolites, strong base anion resins (Amberlite IRA-410) and nuclear sulfonic cation resins (Nalcite HCR and Amberlite IR-120).

Algae Harvesting

A two-phase process which involves (1) growing algae in special shallow wastewater ponds where they feed on the absorb nutrients, and (2) removing the algae which then contain the nutrients within their systems. Algal predominance will depend upon the type of nutrients available and the concentrations. Frequently the flagellates euglena and chlorella will predominate where the nutrient concentration is high, and filamentous green algae such as spirogyra, vaucheria and ulothrix will predominate where the nutrient concentration is more moderate. The most desirable algae would be those that are large, those that would grow rapidly and those that would require vast quantities of food for energy, such as the swimming algae. In addition to removing nutrients, algae produce oxygen which reduces the B.O.D., and certain flagellates which ingest inorganic solids, are able to stabilize some of the organic material.

One of the major difficulties experienced with this process involves the harvesting procedure. A number of methods have been tried which include screening, settling, centrifuging and chemical screening. All have been found to present some form of difficulty, although it appears from the standpoint of performance and economy, the screening method may be the least unsatisfactory. Another problem is that complete nitrogen removal is seldom achieved unless a carbon source, such as carbon dioxide or methanol, is supplied. Still another problem is the need for disposing of a huge, sloppy mass of slimy and odoriferous dead algae.

Pilot studies show that a high-rate continuous-flow process is feasible when light is not limiting, and that orthophosphate concentrations can be reduced 90% to less than 1.0 ppm within 6 to 12 hours. Nitrogen removal is variable with estimates ranging from 40 to 90% efficiency depending upon the feed rate, pond design, and climatic conditions. The major drawbacks to this process aside from those mentioned, are the large land requirements needed and the necessity to rely on climatic conditions. In the latter case, artificial illumination may prove of value depending on power rates in the area.

CONCLUSIONS AND OBSERVATIONS

It might be concluded after examining a vast array of material that the bio-physical and bio-chemical factors which affect algae are extremely complex, and it is difficult to predict, with exacting certainty, future events relating to algal growth. The complexity is greatly magnified by the interaction which apparently exists between the numerous factors themselves. When these factors are examined and evaluated, the conclusions reached by one observer are not always in complete agreement, or may disagree entirely, with the conclusions reached by another observer. Commonly, specific organisms may produce different reactions because of their phase of life, seasonal changes, or because of other complex and little understood metabolic functions.

In few areas is there less accord than in the literature written about algae. (See references—The Physical Nature of Algae, #1 to 33, at the end of this article.) Authorities vary sharply in their opinions as to classification, physical descriptions, toxicity thresholds, etc. When this disagreement is added to the previously expressed uncertainties, it can be seen that our current knowledge is subject to various interpretations. Thus it is evident that there is a need for more work; work to develop new and useful information which will receive universal acceptance and which will clarify and expand our present knowledge. Conferences dealing with unique and local problems involving algae and eutrophication are ongoing. (See References—Eutrophication, #53, 55, 56 and 57, at the end of this article.)

ACKNOWLEDGMENTS

My sincere appreciation is extended to Mr. Robert G. Wieland who helped in the preparation of the manuscript and to the Research Foundation of the Newark College of Engineering for their aid in the typing of the manuscript.

F

FLUIDIZED BED COMBUSTION

INTRODUCTION

The technology for reacting suspended coal particles with a gas flowing through them dates back to the 1920s when the Winkler gas generator was developed in Germany. The petroleum industry was responsible for the commercial expansion of fluidization techniques in the U.S. (1940s), particularly in the use of solids which catalytically crack vaporized heavy oils to produce gasoline and other petroleum fuels. The application of fluidized bed combustion (FBC) technology (to various solid fuels) is widespread in the U.S. and in other countries for all types of industrial processes. More than 350 atmospheric fluidized bed units are operating in North America, Europe and Asia. FBC is part of the answer to the question—how do we control our major emissions from coal sources? Briefly an FBC boiler is a finely divided bed of solid fuel particles in admixture with limestone particles which are suspended or conveyed by primary combustion air moving in the vertical upward direction. The limestone reacts with sulfur dioxide to remove it from the flue gas. The low uniform temperature (ca 1550°F) has a beneficial effect on nitrogen oxide suppression. The emission from coal combustion schemes of nitrogen oxides (NO_x) and sulfur dioxide (SO_2), together with carbon oxides (CO and CO_2), particulate matter and solid wastes must always be compared when evaluating various alternative schemes. The potential consequences of gaseous emissions, include the greenhouse effect and acid rain, which have received much publicity in recent years. The practical FBC limit of SO_2 removal is currently about 95%. Nitrogen oxide formation is lower than with conventional pulverized coal (PC) boiler NO_x control.

TYPES OF FLUIDIZED BED COMBUSTORS (FBCs)

FBCs are generally referred to as either circulating (CFB) or bubbling beds. However, the bubbling type may be classified according to whether reaction takes place at atmospheric (AFB) or under pressurized conditions (PFB).

A. Circulating Fluidized Bed Combustors

In the basic CFB combustor, coal or some other type of fossil fuel, e.g., natural gas or petroleum, is injected into the combustor together with a calcium based material such as limestone or dolomite to be used as a sorbent for SO_2. The bed material is entrained by fluidizing air usually in the velocity range of 12–30 ft/sec. The entrained material is forced into a refractory-lined cyclone located between the combustor and the convective pass. The separated larger particles are reintroduced at the bottom of the combustion chamber or, as in some designs, to an external heat exchanger. The mean bed particle size is usually between 50 and 300 microns. Combustion temperature will vary but generally is kept between 1550°F and 1650°F.[1] In this temperature range SO_2 sorption is optimized and the formation of nitrogen oxides is minimized.

The heavier solids fall to the bottom of the cyclone and are recirculated at a ratio of between 15:1 and 100:1 (solids to feed). The carbon content of the bed is usually about 3–4%. Calcium sulfate, ash, and calcined limestone make up the bulk of the recirculated material. The flue gas exits the top of the cyclone, travels through the convective pass and typically goes into an economizer (heat exchanger—superheated steam produced) and into a tubular air preheater. From there the gas may enter an electrostatic precipitator or a bag house dust collector (for removal of fine particulate matter from the gas). An induced draft fan is finally employed to force the gas up a stack and into the atmosphere.

Combustion air is provided at two levels of the combustor. Primary air enters through the bottom of the combustor and is evenly distributed by a gas distributor plate. Secondary air enters through a number of ports in the sidewalls of the combustor. Hence, there are two staged areas of combustion within the combustor. In the lower combustor, combustion takes place under reducing conditions. In the upper combustor nitrogen oxides are further reduced as is particulate matter. The admission of secondary air is also beneficial in controlling the temperature of the combustor as well as in maintaining the transport (entrainment) of the bed material throughout the length of the combustor. The density of the bed naturally varies with the combustor height, with density increasing towards the bottom.

Steam may be produced at several locations. Water-walls fixed to the upper portion of the combustor extract heat generated by the combustor. The convective pass also emits heat associated with the hot flue gas and solids which pass through it. External heat exchangers are also employed for the steam production. These heat exchangers (EHE's) are unfired, dense fluidized beds, which extract heat from the solids which fall to the bottom of the cyclone(s). More than one cyclone may be employed. The heat exchange is accomplished before the material is returned to the combustor. The external heat exchanger is a device which can, thus, be used as an effective additional method for controlling combustor temperature. The heat transfer coefficients to the water-walls usually lie between 20 and 50 Btu/hr. ft.^{2}°F.

B. Bubbling Fluidized Bed Combustors

Bubbling fluidized bed combustors are characterized by distinct dense beds. The bed material may be recirculated as in the case of CFB's, but at substantially lower recycle ratios (between 2:1 and 10:1). Particle velocities are usually between 2–15 ft/sec and a small amount of bed material is separated out (elutriated) as compared with CFB's. The mean bed particle size generally lies between 1000 and 1200 microns.

As with CFB's, the fuel used is usually coal or some other type of fossil fuel. Limestone or some other sorbent material is also used to decrease SO_2 emissions. The feed material may be fed either over the bed or under the bed. The manner of the feeding is an important design criterion in that it effects boiler control, emissions control (especially for SO_2) and combustion efficiency. Many bubbling bed designs incorporate overbed feeding in which the feed is "thrown" into the combustor by pressurized air. This overbed method can often be a disadvantage because throwing distance is limited. Hence, a long, narrow boiler is often required.

The underbed method of feeding is often associated with plugging and erosion problems. However, these problems can be avoided with proper design considerations. The Tennessee Valley Authority (TVA) has designed a 160 MW bubbling bed unit at its Shawnee station in Kentucky. The facility was constructed at a cost of $232,000,000 (1989). EPRI believes that most retrofits would fall into the $500–1000/kW range (1989 dollars) and that the levelized generation cost would be 5–10% less than a conventional unit with downstream flue gas treatment.[1a] The coal used for this unit is crushed to less than ¼ inch and dried with flue gas to less than 6% moisture. The fuel then passes through a fluidized bottle splitter with a central inlet and fuel lines arranged concentrically around the inlet. The feed material is forced into the combustor from the bottles, which are pressurized, by blowers. Each bottle acts as an individual burner and can be used to control load in the same way as cutting a burner in and out.[2] When overbed feeding is used, the fine material in the fuel has a tendency to elutriate too swiftly. If the fuel is fed underbed, the fines will have a longer residence time. Excess CO generation can result with the excessive burning of fines. This in turn can lead to overheating which could cause superheater controls to trip-off. Ash-slagging is another potential problem associated with overheating. Sometimes it may be necessary to recycle the fly-ash in order that carbon is more thoroughly burned and sorbent more completely utilized.

In-bed combustor tubes are generally used to extract heat (create steam). The heat transfer coefficient range is higher than that of CFB's, i.e., 40–70 Btu/hr.ft^2°F. Erosion of the tubes is a problem which is ever present in the bubbling bed combustor. The problem worsens as bed particle velocity increases. Horizontally arranged tubes are more susceptible to erosion than are vertical tubes. Various methods of erosion protection include metal spray coatings, studding of the tube surfaces with small metal balls, and wear fins. Occasionally recycled cold flue gas is used in lieu of tubes.

Waterwalls located in the upper portion of the combustor are also used (as with CFB's) to extract heat. The lower portion is refractory lined. Combustor free-board is usually between 15 and 30 ft. The typical convective pass, cyclone, air heater, particle separator scenario closely resembles that of the CFB.

C. Pressurized Fluidized Bed Combustors (PFBCs)

The pressurized fluidized bed combustor is essentially analogous to the bubbling bed combustor with one exception—the process is pressurized (10 to 16 atmospheres) thereby allowing the flue gas to drive a gas turbine/electric generator. This gas turbine along with a stream-driven turbine creates a very efficient "combined cycle" arrangement.

PFBCs may also be "turbocharged," i.e., before the flue gas enters the gas turbine, heat is extracted via a heat exchanger. Steam created by the energy transfer is used to drive the compressor which pressurizes the system. There is no energy excess to drive an electric generator in this case.

Deeper beds (typically 4 m.) may be used in PFBCs because they are pressurized. The residence time of a particle in the bed is longer than that of a particle in the shallower bed of a bubbling bed combustor. The fluidizing velocity (typically 1 m/s) is also lowered because of pressurization. As mentioned before, lower velocities minimize the amount of in-bed tube erosion.

Two other benefits of pressurization are a reduced bed cross-sectional area and reduced boiler height.

Since combustor efficiency and sorbent utilization are excellent, recycle is rarely needed. However, when very unreactive fuels are burned, recycling of fines may be necessary.

Since PFBCs are pressurized, certain design characteristics must be taken into consideration, especially in regard to the gas turbine. This turbine supplies the combustion and fluidizing air for the bed. Unlike conventional AFBC's the turbine inlet air is dependent upon certain temperature and pressure conditions since this inlet air is actually the exhaust gas from the combustor. To compensate for variations in load and subsequent changes in the exhaust gas conditions the gas turbine must be flexible. An effective turbine should be able to accept low gas temperatures, be minimally affected by unremoved fines in the gas, compensate for low load conditions, and allow the gas velocity through the hot gas clean up (HGCU) system and excess air to remain near constant over much of the load range. Most FBC systems incorporate a free-wheeling low pressure and constant velocity high pressure shaft design to accomplish the aforementioned requirements. The HGCU system generally consists of one or several cyclones. Sometimes a back-end filter at conventional pressuers and temperatures is used in addition.

The gas turbine accounts for approximately 20% of a FBC's total power output while the steam turbine creates the remainder.[5] The steam turbine is powered from steam created via combustor tubes and is totally independent of the exhaust gas and gas turbine. Steam turbine performance is therefore only affected by fuel/feed conditions. Two types of fuel feeding are generally used for FBC's—dry and wet. For fuels with high heating values the fuel is mixed with water to create a paste (20–25% water). With this method there is naturally no need for coal drying, and evaporated water creates additional mass flow through the gas turbine. Dry fuel feeding is more beneficial with low heating value fuels.

FEDERAL AIR EMISSIONS STANDARDS

The standards of performance for fossil-fuel-fired steam generators (constructed after August 17, 1971) were last revised by the federal government as of July 1, 1988.

Regulated facilities include fossil-fuel-fired steam generating units of more than 73 megawatts (heat input rate 250,000,000 Btu/hr.) and fossil-fuel and wood-residue-fired steam generating units capable of firing fossil fuel at a heat input rate of more than 73 megawatts. Existing fossil-fuel-fired units which have been modified to accommodate the use of combustible materials other than fossil fuels are regulated in a different manner.

Within 60 days after the maximum production rate is attained by a regulated facility, the facility must conduct performance tests and provide the E.P.A. with the results of the tests. The tests must also take place before 180 days after the initial start-up of a facility. Each test is specific and used for the determination of such things as nitrogen oxide emission. These test methods and procedures may be found in 40 C.F.R. (Code of Federation Regulations) Part 60.46.[6] After a performance text is completed, a facility must not discharge pollutants into the atmosphere at levels greater than those established and listed in the federal regulations.

Gases may not contain more than 43 nanograms of particulate matter per joule heat input (0.10 lb. per million Btu) where particulate matter is defined as a finely divided solid or liquid material, other than uncombined water as measured by the reference methods specified in 40 C.F.R. Part 60.46. These gases must also not exhibit greater than 20% opacity except for one six-minute period per hour of not more than 27% opacity. Opacity is defined as "the degree to which emissions reduce the transmission of light and obscure the view of an object in the background."

Less stringent standards have been developed for the three following facilities.[6]

The Southwestern Public Service Company's Harrington Station No. 1 in Amarillo, Texas must meet an opacity of not greater than 35%, except that a maximum of 42% opacity is permitted for not more than six minutes in any hour. The Interstate Power Company's Lansing Station Unit No. 4 in Lansing, Iowa must meet an opacity of not greater than 32%, except than a maximum of 39% opacity is permitted for not more than six minutes in any hour. The Omaha Public Power District's Power Station in Nebraska City, Nebraska must meet an opacity of not greater than 30%, except that a maximum of 37% opacity is permitted for not more than six minutes in any hour.

Gases may not contain more than 30 nanograms per joule heat input (0.80 lb. per million Btu) of sulfur dioxide (SO_2) derived from liquid fossil fuel or liquid fossil fuel and wood residue. 520 ng/joule heat input (1.2 lb. per million Btu) is the maximum allowable SO_2 discharge from gases derived from solid fossil fuel or solid fossil fuel and wood residue.

When different fossil fuels are burned simultaneously in any combination, the SO_2 emission standard is calculated by the following formula:

$$\mathrm{PS}_{\mathrm{so}_2} = (y(340) + z(520)) / (y + z)$$

where $\mathrm{PS}_{\mathrm{so}_2}$ is the prorated standard in ng/joule heat input derived from all fossil fuels or fossil fuels and wood residue fired, y is the percentage of total heat input derived from liquid fossil fuel, and z is the percentage of total heat input derived from solid fossil fuel.

The SO_2 emission standard for Units 1 and 2 at the Central Illinois Public Service Company's Newton Power Station must comply with the 520 ng/joule requirement if the units individually comply with the 520 ng/joule requirement or if the combined emission rate from both unites does not exceed 470 ng/joule (1.1 lb/million Btu) combined heat input to both units.

It is interesting to note that the federal SO_2 emission limit for West German coal fired boilers is 2.5 lB./Mbtu (avg.) for boilers of between 18 and 110 MW and 0.51b./MBtu (avg.) for boilers of over 110 MW.[7]

Gases may not contain more than 86 ng/joule heat input (0.20 lb/million Btu) of nitrogen dioxide (NO_2) derived from gaseous fossil fuel. 129 ng/joule heat input (0.30 lb/million Btu) is the maximum allowable NO_2 discharge from gases derived from liquid fossil fuel, liquid fossil fuel and wood residue, or gaseous fossil fuel and wood residue. 300 ng/joule (0.70 lb/million Btu) is the maximum allowable NO_2 from solid fossil fuel or solid fossil fuel and wood residue (except lignite or a solid fossil fuel containing 25%, by weight, or more of coal refuse). 260 ng/joule (0.60 lb/million Btu) is the maximum allowable NO_2 from lignite or lignite and wood residue with the exception that 340 ng/

joule is the limit for lignite which is mined in North Dakota, South Dakota, or Montana and which is burned in a cyclone fired unit.

When different fossil fuels are burned simultaneously in any combination, the nitrogen oxide emission standard is calculated by the following formula:

$$PS_{NO_x} = \frac{w(260)+x(86)+y(130)+z(300)}{w+x+y+z}.$$

Where PS_{NO_x} is the prorated standard in ng/joule heat input for nitrogen oxides (except nitrous oxide) derived from all fossil fuels or fossil fuels and wood residue fired, w is the percentage of total heat input derived from lignite, x is the percentage of total heat input derived from gaseous fossil fuel, y is the percentage of total heat input derived from liquid fossil fuel and z is the percentage of total heat input derived from solid fossil fuel (except lignite).

There is no standard for nitrogen oxides when burning gaseous, liquid, or solid fossil fuel or wood residue in combination with a fossil fuel that contains 25%, by weight, coal refuse. Coal refuse is defined as "the waste products of coal mining, cleaning and coal preparation operations (e.g., culm, gob, etc.) containing coal, matrix material, clay, and other organic and inorganic material."[6]

The NO_x emission standards for West Germany and Japan are even more stringent than those of the U.S.[7] For new and existing West Germany boilers of over 110 MW, the limit is 0.16 lb./MBtu (6% O_2). For Japanese boilers built after 1987, the limit is 0.33 lb./MBtu.

PROMINENT FBC INSTALLATIONS IN THE U.S.

Recently, in order to reduce SO_2 emissions, Northern States Power Company (NSP) converted its Black Dog pulverized coal-fired boiler to that of a bubbling bed combustor. This unit is the largest of its kind in the world; its capacity is 130 megawatts.

NSP received a new Emissions Permit from the Minnesota Pollution Control Agency (MPCA) for the upgraded unit. The emissions standards set forth in this permit are less stringent than those of the federal standards for particulate matter and SO_2. In the event that utilities should become regulated, the operating parameters of the system or the system itself would have to be modified.[10]

The most recent literature available to the author (April 1988) stated that limestone was being added to the bed in order to lower SO_2 emissions sufficiently to help NSPS standard. The control of particulate matter was difficult at the onset. However, this problem was resolved by changing the bed material to an inert fired-clay material. NO_x emissions requirements have easily been met.

The Tennessee Valley Authority (TVA) has built a 160 MW bubbling bed combustor for the utility's Shawnee steam plant in Paducah, Kentucky. It has been operating sporadically since autumn of 1988.

A pilot plant (20 MW) was completed in 1982 and had brought forth some very promising results. With a Ca : S ratio of 2 to 2.5 (typical range) and a recycle ratio of 2 to 2.5 the SO_2 retention was approximately 90%.[11] This result has been matched by the scaled-up plant. The pilot plant has both an underbed and overbed feed system. Overbed feed does not produce as great a combustion efficiency as that achieved by the underbed method. This would be expected due to the lack of control over fines in the feed. NO_x emissions were less than 0.25 lb/million Btu.[11] The NSPS for NO_x is 0.7 lb/million Btu for solid fuel.

The original underbed feed system was determined to be inadequate because of plugging and erosion problems. The system was redesigned and proved to be successful. The feed system is one of pressurized bottles mentioned earlier in this report under "Bubbling Bed Combustors."

As stated in the "Introduction," fluidized bed combustion can be used for many different types of industrial processes. An example of this is the installation of the direct alkali recovery system at Associated Pulp and Paper Mills' Burnie, Tasmania mill.

In this process, sodium carbonate (residual) found in soda-quinone black liquor (a waste product) reacts with ferric oxide to produce sodium ferrite in the combustor (bubbling bed). The sodium ferrite is then contacted with water to yield sodium hydroxide (desired) and ferric oxide. The ferric oxide is returned to the combustor to be reused. It is interesting to note that most of the steam produced in this process is created from the extraction of heat from the exhaust gas and not from bed tubes. The exhaust gas is cleaned via a fabric filter and the dust collected is palletized. The pellets are later used in the process. The fluidizing air is heated from the heat extracted from the hot sodium ferrite after it has been removed from the combustor.

Since there is no sulfur involved in this process the exhaust gas is easily cooled, thereby allowing greater production of high-pressure steam.[13]

The title for the world's largest CFB probably belongs to the nuclear generating station owned by Colorado-Ute Electric Association. The original 25-year-old plant was replaced because it was uneconomical to operate. The capacity of the new plant is 110 MW.

In May of 1988 on EPRI (Electric Power Research Institute) assessment began and is scheduled to continue until May of 1990. As of April 1988, the unit was reported to be easy to operate, responsive to load variations, and easily restarted following a trip. However in 1989 operational difficulties were reported. SO_2 emissions standards were expected to be easily met and NO_x emissions were well under the limit. Final determination of the optimum Ca : S ratio still needed to be determined. Particulate matter emissions are expected to be less than 0.03 lbs/million. Btu because of the addition a new baghouse to the existing three baghouses.

Some valuable information has been learned from the unit thus far, e.g., control of coal feed size has been important in maintaining the bed quality and agglomerations can be avoided if the feed is started in short bursts prior to being continuous; this is to allow the temperature rise to be more uniform.[14]

One of the larger *commercial* units in the U.S. is located in Colton, California and was installed for Cal-Mat Co. The 25 MW CFB was constructed because electric utility rates were rising and the availability of power was uncertain. The company manufactures cement—a process requiring much electricity. Since the company had easy access to coal and limestone as well as a large quantity of heat from its kilns, CFB technology became an effective solution to their energy needs. Bottom ash waste and flyash could also be used in the cement-making process.

As could be expected, the air pollution controls instituted by the state of California are very strict. However, a permit was granted to CalMat in a relatively short period of time because of the fine performance demonstrated by this unit. The exhaust gases were found to contain SO_2 at 30 lb/hr., NO_x at 57 lb/hr. and CO at 24 lb/hr.[15] There were initial problems with equipment and systems, however, these were eventually eliminated. Bed retention and temperature control problems have also been resolved through modifications of the air flows and nozzles.

PFBC's have been installed in Sweden, the U.S. and Spain.

Two PFBC modules of 200 MW each have been installed in Vartan, Stockholm. The first unit is due for start-up in late 1989. The Swedish emission standards are very strict and include special restrictions on noise and dust since the units are located very close to a residential area.

A 200 MW combined cycle PFBC will be installed by American Electric Power (AEP) at its Tidd Power Plant at Brilliant, Ohio. Test results from joint studies proved PFBC technology to have environmental benefits surpassing those of traditional boilers with flue gas desulfurization systems (FGD), selective catalytic reduction, etc.

A 200 MW PFBC will be installed by Empresa Nacional de Electricidad S.A. (ENDESA) at its Escatron Power Plant as a retrofit for an existing unit. 90% sulfur removal and a NO_x decrease of 30% are expected. Many different technologies were considered but PFBC was chosen because of the high sulfur/ash/moisture black lignite coal that they burn.[16]

NO_X/SO_2 FORMATION AND CONTROL

Fossil fuels naturally contain sulfur in varying percentages. As fuel is burned the sulfur combines with oxygen to form SO_x, and primarily, SO_2. When emitted into the atmosphere this SO_2 can combined with water vapor to form sulfuric acid (and sulfurous acid to a lesser extent). This is a part of the basic mechanism by which acid rain is created.

In order to control sulfur dioxide emissions, the oldest and still most common method used is to react the gas with limestone or a similar calcium based material. Crushed limestone ($CaCO_3$) can be fed continuously to a conventional coal boiler or fluidized bed where it calcines to lime (CaO) and then reacts with SO_2 in the presence of oxygen to form calcium sulphate ($CaSO_4$). This material precipitates to the bottom of the combustor and is removed.

Coal particle size has a definite impact on desulfurization. Bed composition also has an effect on sulfur removal. A typical bed might be composed of coarse partially sulfated limestone and ash (produced by combustion). The particle size of the coal and limestone would probably be equal however combustor operation conditions such as fluidizing velocity will dictate the particle size.

An alternate scenario might be to pulverize the limestone and introduce it to a bed composed of ash or some other type of refractory material. Fines naturally have shorter residence times than do coarse materials and, hence, would probably have to be recycled to increase efficiency.

A series of experiments were carried out by Argonne National Laboratory[17] using three different types of limestones to test their effects on sulfur capture during combustion. The average particle size of the limestone was 500–600 micrometers. The Ca : S ratio was 2.3–2.6 and the combustion temperature was 1600°F. SO_2 removal was 74 to 86%. The test proved that the amount of SO_2 removal was relatively independent of the type of limestone used. The test also proved that particle size did not have much of an effect on SO_2 removal. The explanation offered for this observation was that although larger particles are less reactive than smaller particles, the increased residence time in the combustor of larger particles compensates for the lower reactivity.

Dolomite was also evaluated for SO_2 capture. In two experiments, Tymochtee dolomite was added to a bed composed of alumina at Ca : S ratios of 1.5 and 1.6. The average particle size was 650 micrometers. The SO_2 removals were 78% and 87% respectively. MgO is contained within the dolomite matrix and is believed to keep the particles more porous such that sulfation is greater, especially in larger particles.

Combustion temperature had a marked effect on SO_2 removal in these experiments. Dolomite No. 1337 was most effective in reducing SO_2 at 1480°F. Limestone No. 1359 was most effective in the range of 1500–1550°F. Both sorbents achieved approximately 91% SO_2 removal. The average particle size was approximately 500 micrometers. Pulverized limestone No. 1359 with an average particle size of 25 micrometers was most effective in the range of 1550–1600°F. The extent of calcination is more dependent upon bed temperature for finely pulverized limestone. The greater the calcination, the greater the reactivity with SO_2.

An unusual finding occurred in that Tymochtee dolomite was observed to be most effective in SO_2 removal at 1800°F. For all of the other sorbents the SO_2 removal was very poor at this temperature. Explanations for this phenomenon have been proposed. One explanation suggests that above a certain temperature the sorbent's pores close thereby ending sulfonation. Depending upon the sorbent's structure and composition, this temperature would be different for each sorbent. Another explanation involves the effect of fluidized bed gas circulation on bed chemistry. An emulsion phase and a gas bubble phase exist in any gas-solid fluidized bed. Excess gas which is not needed for fluidization circulates back and forth between the two phases. This gas does not react with the sorbent until it reaches the emulsion phase. All of the oxygen in the lower portion of the emulsion phase reacts with the fuel to from CO. As the bubbles rise through the bed, air exchanges between the bubbles and the emulsion phase. The upper portion of the emulsion phase contains excess oxygen. The following reaction was thus proposed as one which takes place in the lower portion of the combustor:

$$CaSO_4 + 4CO \rightleftharpoons CaS + 4CO_2. \qquad (1)$$

One or more of the following reactions were proposed to occur in the upper portion of the combustor:

$$CaS + 1\frac{1}{2}O_2 \rightleftharpoons CaO + SO_2 \qquad (2)$$

$$CaS + 3CaSO_4 \rightleftharpoons 4CaO + 4SO_2 \qquad (3)$$

$$CaS + 2O_2 \rightleftharpoons CaSO_4. \qquad (4)$$

Reactions 2 and 3 would limit the unit's ability to remove sulfur because of the regeneration of SO_2. This regeneration of SO_2 is so dependent upon temperature that it could very possibly be an explanation as to why SO_2 removal generally suffers at high temperatures.

Nitrogen also occurs naturally in fossil fuels. This nitrogen reacts with oxygen during combustion and later forms acid rain in very much the same manner as with sulfur. Oxides of nitrogen (NO_x) are also responsible for the creation of "smog." As nitrogen dioxide (NO_2) absorbs light of certain wavelengths it dissociates photochemically to form nitric oxide (NO) and atomic oxygen. This atomic oxygen is very reactive and readily combines with O_2 to from ozone (O_3). Ozone in turn oxidizes hydrocarbons in the air to form aldehydes. Ozone and the aldehydes are components of smog. NO_2 is the reddish-brown gas which can often be seen on the horizons of cities such as Los Angeles.

The principal oxide of nitrogen formed during combustion is nitric oxide. Nitrogen in the fuel combines with oxygen in the fluidizing air as follows:

$$\frac{1}{2}N_2 + \frac{1}{2}O_2 \rightleftharpoons NO.$$

The kinetics of NO decomposition are slow enough so that equilibrium levels are not achieved. Various experiments conducted by Argonne National Laboratory as well as by other researchers have proven that most of the nitrogen forming NO_x is from the fuel and not from the air. This has been easily demonstrated by substituting an inert gas (such as argon) for nitrogen in the fluidizing air and then comparing the results to those of combustion with standard fluidizing air.

As previously mentioned in this report two-stage combustion is an effective method of decreasing NO_x emissions. As with SO_2 reduction bed composition has an important effect on NO_x. It has been determined through experimentation and experience that limestone also decreases NO_x emissions. Skopp and Hammons[18] observed that when using a limestone bed two factors were changing with time which could have been responsible for decreasing NO emissions: the $CaSO_4$ concentration in the bed was increasing and so was the SO_2 concentration. The increase in $CaSO_4$ suggested that it could be a selective catalyst for reduction of NO. The increasing SO_2 concentration suggested that there might be a reaction occurring between it and the NO which was lowering the NO. This was investigated by conducting experiments using synthetic $NO—SO_2—N_2$ gas mixtures. The results showed that no reaction in the gas phase occurred. There was also no reaction between the NO and SO_2 over $CaSO_4$. However, there was a reaction occurring over a bed of 20% sulfated lime. This reaction was found to have a negative temperature dependence. The following mechanism was proposed by Skopp and Hammons[18] as an explanation for their results:

$$CaO + SO_2 \rightleftharpoons CaSO_3$$

$$CaSO_3 + 2NO \rightleftharpoons CaSO_3(NO)_2$$

$$CaSO_3(NO)_2 \rightleftharpoons CaSO_4 + N_2O$$

$$N_2O \rightleftharpoons N_2 + \frac{1}{2}O_2.$$

Esso researchers investigated the possibility of NO being produced by CO catalyzed by $CaSO_4$. The rate of this reaction was found to increase with increasing temperature.

Argonne researchers[17] investigated the use of metal oxides, among them, aluminum oxide (Al_2O_3), zirconium oxide (ZrO_2) and cobalt oxide (Co_3O_4). At the time these experiments were conducted, the literature had indicated that these metal oxides were effective in reducing or catalytically decomposing NO. The results showed that the addition of Al_2O_3 and ZrO_2 did nothing to reduce NO formation during combustion in a fluidized bed. The addition of Co_3O_4 actually increased rather than decreased the formation of NO.

A study was conducted by McCandless and Hodgson[20] for the U.S.E.P.A. on the use of metal sulfides as a way to reduce NO emissions. The following is well known as the "Thiogen" process and has been used in the recovery of sulfur from SO_2

$$CaS + 2SO_2 \rightleftharpoons CaSO_4 + S_2$$

$$4CaS + 6SO_2 \rightleftharpoons 4CaSO_3 + 3S_2.$$

Based on this process it was determined that the following reaction might also be possible

$$CaS + 4NO \rightleftharpoons CaSO_4 + 2N_2.$$

Preliminary studies indicated that the reaction did proceed and could be an effective method for NO_x control. Nineteen metal sulfides were used. All but one reduced NO to N_2 at temperatures between 194°F and 1202°F. However, a weight loss did occur indicating that an undesirable side reaction was taking place—probably the formation of SO_2. Some metal SO_4 was formed in most of the tests. However, the alkaline earth sulfides were determined to be the most stable.

It was also found that the temperature at which the reduction reaction occurs can be lowered if certain catalysts such as NaF and $FeCl_2$ are mixed with the sulfides. Reaction temperature was again reduced when the sulfide/catalyst combination was impregnated on alumina pellets. Tests were also conducted involving synthetic flue gas containing 1000 ppm NO, 1% O_2, 18% CO_2 and the remainder N_2. Using this gas in combination with the CaS showed that NO was significantly reduced above temperatures of 1112°F, by using the sulfide/catalyst combination. The results of the experiments showed that between 0.372 and 0.134 grams of NO were reduced per gram of metal sulfide. Between 0.76 and 0.91 grams was achieved when using the impregnated alumina pellets. The authors recommended that more research be done to evaluate the economical implications of using these materials.

Several other interesting facts known about NO_x control and found in the literature are that increasing fluidizing velocity decreases NO_x, NO_x is not significantly affected by excess air, and NO_x production increases at lower temperature, especially below approximately 1500°F.

For conventional coal-fired boilers the most common approach to control NO_x and SO_x simultaneously is the combination of selective catalytic reduction (SCR) and wet-limestone or spray dryer flue gas desulfurization (FGD). The SCR process converts NO_x to N_2 and H_2O by using ammonia as a reducing agent in the presence of a catalyst. The catalytic reactor is located upstream from the air heater and speeds up the reaction between the NO_x and the ammonia, which is injected into the flue gas in vapor form immediately prior to entering the reactor. The reduction reactions are as follows:[21]

$$4NH_3 + 4NO + O_2 \rightleftharpoons 4N_2 + 6H_2O$$
$$4NH_3 + 2NO_2 + O_2 \rightleftharpoons 3N_2 + 6H_2O.$$

It can be seen that the amount of NO_2 removed primarily depends on the amount of NH_3 used. Although SCR technology has proved to be an effective means to reduce NO_x with removal results as high as 90% in some European facilities, the U.S. does not consider the technology economically feasible. In addition to the high cost there are the undesirable effects of unreacted NH_3, by-product SO_3 and increased CO production to consider. There are also catalyst deactivation problems caused by contamination by trace metals in the fly ash and by sulfur poisoning. The Japanese have improved on the design of catalysts and their arrangement within the reactor. However, these modifications are still too new to evaluate their merit.[22] U.S. industry also feels that more data has to be generated for the medium to high sulfur coals most commonly used in this country. Since characteristics such as high sulfur, low flyash alkalinity and high iron content are common in U.S. coal, and these qualities do influence SO_3 production, SCR would not appear to be one of the likely options for U.S. industry at least in the near future.

Exxon has developed a process called "Thermal deNO_x" which makes use of ammonia injection into the flue gas at temperatures of between 1600 and 2200°F. This process is claimed to remove NO_x by up to 90%. years, CFB's have become the dominant FBC choice in industry. The most common problems that have been associated with bubbling beds include erosion of the inbed tubes. This can be reduced through the use of studding, fins, etc. as previously mentioned in this report. However, CFB's are also prone to erosion, i.e., the waterwalls, as well as the refractory lining. Agglomeration is another common problem associated with bubbling beds. Sand can fuse in localized hot spots to form clinkers or "sand babies" especially when the fuel has a high concentration of alkali compounds.[9] In severe cases, agglomerations can cause the bed to defluidize, block air ports, and make bed material removal more difficult. Sulfur removal is more difficult with bubbling beds. In general, large quantities of double-screen stoker coal must be used to attain the high sulfur removal rate displayed by CFB's. Most overbed feed bubbling beds in existence must use coals which contain less than 10% fines. This can often be quite costly. As previously mentioned, underbed feed also has problems associated with it. Since low fluidizing velocities are required with underbed feed, the bed plan area must be larger and, subsequently, contain a higher density of feed ports. This serves to complicate the already unreliable feed system. In order to utilize the sorbent better, the recycle ratio has to be increased. However, above a certain recycle ratio, and in-bed tubes might have to be removed in order to maintain combustor temperature, compromising the CFB design.

NO_x control is better with CFB's than with bubbling beds. This is because of the aforementioned stage combustion which is physically unachievable in bubbling beds due to the large bed plan area and low fluidizing velocity. On average, 0.1 lb/million Btu less NO_x is produced by CFB's than by bubbling beds.

As of the present, there are no federal regulations governing CO emissions. However, some states have promulgated regulations. As would be expected with overbed feed bubbling bed combustors, the CO emissions are high. While emissions of over 40 ppmv are common with bubbling beds, CFB's are usually under 100 ppmv.[3] This is due to better circulation and recycle. There is not much data on CO emissions for underbed feed bubbling beds. However, it evidently reduces CO more than does overbed. Unfortunately, with CFB's there is a trade-off between SO_2/NO_x and CO. Staged combustion will increase CO emissions as the primary to secondary air ratio becomes smaller. SCR/SNR specific to CO also may cause an increase in NO_x.

TABLE 1

Major chemical components of composite residues: pilot and full-scale CFBC units

Component	Concentration (wt percent)				
	Test no.1[a]	Text no. 2[a]	Test no. 3[a]	Baghouse[b]	Full-scale residues

[a] As determined by standard Proctor test.

[b] Samples were cured at 100 percent relative humidity at 23 ± 2°C for periods shown.

Other problems associated with bubbling beds are scale-up and turn-down. Scale-up is limited because of the feed distribution problem and turn-down is usually more frequent because of the erosion problem. Incidentally, it should have been mentioned before, that, in general, FBC's take longer to start up and turn down than conventional boilers because of the large amounts of bed material which must be heated or cooled.

The major advantage which PFBC's hold over AFBC's is that NO_x, SO_2, and CO are weakly linked. Thus, 60 mg/MHJ NO_x can be attained while at the same time only 50 mg/MJ SO_2 (or less) and 10 mg/MJ (or less) CO are produced. Another advantage of PFBC's is that the waste contains negligible lime, sulfides, and sulfites. The decreased lime concentration makes the waste less reactive and probably renders it nonhazardous. The decreased sulfites makes the material a good candidate for use in cement kilns and concrete. The maximum sulfur content per ASTM standards is 1.2% by weight or 3.1% by weight as sulfites. The material has been found useful for building roads, manufacturing gravel and formed bricks or tiles, and for roofing and flooring material.[3]

Other advantages of PFBC's include compactness because of smaller bed requirements, plant cycle efficiencies of 40–42% and subsequent reduced fuel costs, and unit modularity for ease in increasing future capacity.[8]

Disadvantages include in-bed tube erosion and potential damage to the gas turbine if the hot gas clean-up is ineffective. It should be noted that the technology is too new to accurately assess its advantages versus its disadvantages.

CHARACTERIZATION OF SOLID WASTES FROM FLUIDIZED BEDS

The characterization and use of fluidized-bed-combustion coal/limestone ash is discussed in the articles of Behr-Andres and Hutzler[23] and Anthony *et al.*[24] The former dealt with the use of the mixture in concrete and asphalt. The latter presented chemical and physical properties for the waste (see Tables 1 and 2 above).

Hot-gas cleanup (HGCU) technologies have emerged as key components of advanced power generation technologies such as pressurized fluidized-bed combustion (PFBC), and integrated gasification combined cycle (IGCC). The main difference between HGCUs and conventional particulate removal technologies (ESP and baghouses) is that HGCUs operate at higher temperatures (500 to 1,000°C) and pressures (1 to 2 MPa), which eliminates the need for cooling of the gas. See Website (2005): http://www.worldbank.org/html/fpd/em/power/EA/mitigatn/aqpchgas.stm

FISH ECOLOGY: see POLLUTION EFFECTS ON FISH; THERMAL EFFECTS ON FISH ECOLOGY

FOSSIL FUEL CLEANING PROCESSES

The amount of pollutants, especially sulfur oxides and particulates emitted to the atmosphere may be reduced by treating fuels prior to combustion. This approach may be more energy efficient than treatment of flue gases as per *Vapor and Gaseous Pollutant Fundamentals.* More than thirty million tons of sulfur dioxide are discharged annually in the United States, 75% of which is the result of fuel burning.

FOSSIL FUEL PRODUCTION, RESERVES AND CONSUMPTION

The world's production of oil in 1980 was 66 million barrels per day with a projected value of 77 MBPD for the year 2000. The relatively small anticipated increase reflects increased conservation and alternate fuel source application. The overall oil output of the USSR was about 14 MBPD[1] as compared to about 12 MBPD for combined US and Canadian production (1980).

About 2500 trillion cubic feet of natural gas reserves are estimated to exist worldwide. The US reserves are 200 TCF with an annual consumption of about 20 TCF. Soviet bloc production was about 15 TCF in 1980. Most oil and natural gas reserves fall in a crescent shaped area extending from Northern Algeria Northward to West Siberia. Lynch[2] felt that the level of surplus capacity would remain stable for the early '90s with the then world stock level of about 100 gigaliters (1.3 giga barrels).

Coal is consumed at a rate of 600 million tons annually in the US utility industry. Only a small portion of Eastern US coals fall in the low (less than 1% sulfur) category—see Table 1. The US, USSR and China own about two thirds of the world's 780 billion tons of presently recoverable coal reserves. The US has about one quarter of the total. Coal accounts for 90% of the US's proven reserves.[3]

Consumption of fuel might be measured in "quads" or quadrillion Btu's. It has been estimated that US electric consumption was 13 quads and nonelectric industrial about 16 quads for the year 1980.[3] Total US fossil fuel consumption is about 76 quads, most in the non-industrial sector. Worldwide energy consumption is predicted to double over the next 25 years according to the World Energy Council.[3a] The predicted fossil fuel usage in terms of billions kwh electric generation in the year 2015 is for coal-2000, natural gas-1000, nuclear-400, and petroleum-less than 100. Renewables are estimated at 400 billion kwhs. Divide these numbers by 100 to estimate the number of quads; assuming a plant efficiency of current Rankine cycle plants (about 34%) or by 170 if a combined cycle (Brayton = Rankine) is assumed.

SULFUR REMOVAL

Typical legislative actions have been the setting of limits on the allowable sulfur content of the fossil fuel being burned or on the SO_2 emission rates of new sources. In California, regulations have limited the use of fuel oil to those of 0.5% or less sulfur. Since 1968, a limit of a 0.3% sulfur oil has been in effect in New York City. In 1980, Massachusetts set a 1% sulfur limit on the coal to be burned. This limit is being considered for other Atlantic seaboard states as coal conversion is increasingly encouraged. Chemical and physical desulfurization of fossil fuels can be used to produce levels of sulfur which comply with government standards. To reduce a 3% sulfur coal to a 1% sulfur coal may add about 10% to the cost of coal F.O.B., but may save on transportation and flue gas desulfurization costs.

The amount of sulfur dioxide emitted worldwide might double in the next decade due to increased energy demands (approximately 3.5% annually) and the use of more remote crudes having higher sulfur concentration.

The chemical and power industries must strike a delicate balance between the public's dual requirement of increased quantities and preparation of fossil fuel. More fuel must now be desulfurized more completely and/or more sulfur dioxide must be removed from stack gases. The techniques for cleaning fossil fuels used throughout the petroleum, natural gas and coal production industries are covered in this article. Treatment of stack gases to effect particulate and sulfur removal are discussed separately in other articles.

PROCESSES INVOLVING THE BASIC FUELS

The two most commonly combusted energy sources are coal and fuel oil having typical sulfur ranges of 1–4% and 3–4%, respectively; a 3% sulfur oil produces about the same SO_2 emission as a 2% sulfur coal when based on a comparable energy release. Fuel oil desulfurization is used by most major oil producers. Hydrogenation, solvent extraction, absorption and chemical reaction are used to varying extents at petroleum refiners. Finfer[4] claims a possible sulfur reduction from 2.5 to 0.5% by a hydrodesulfurization process. Coal contains sulfur which may be combined with either the organic or

inorganic (pyritic and sulfate) matter. The organics may be removed by various cleaning processes, but little reduction in organic sulfur has been found to occur by physical cleaning methods. Currently an extraction process, followed by hydrogenation, is being tried. Some coals have been reduced to S contents below 2%, and typical sulfur reduction estimates are in the range of 20–40% reduction.[5,6,7] Even if these reduced levels are achieved, a need for further removal of sulfur from the flue gases might exist. Cleaning, when combined with flue gas desulfurization as a method of SO_2 control, could eliminate the need for reheat and considerably reduce the sludge handling requirements of the plant.

Fuel Oil Desulfurization (General)

Before the ecological need for fuel oil desulfurization was recognized, oil stocks were desulfurized for a number of other reasons:

1) To avoid poisoning and deactivation of platinum catalysts used in most catalytic reforming processes.
2) To reduce sulfurous acid corrosion of home burner heating equipment.
3) To demetalize crude stocks (sulfur removal from crude is generally accompanied by a concomitant removal of such trace metals as sodium, vanadium and nickel).
4) To recover pure sulfur.
5) To reduce or eliminate final product odor.

By definition, hydrodesulfurization is the removal of sulfur by a catalytic reaction with hydrogen to form hydrogen sulfide. As carried out in the petroleum industry, the hydrodesulfurization process is not a specific chemical reaction. Various types of sulfur compounds (mercaptans, sulfides, polysulfides, thiophenes) with varying structures and molecular weights are treated. Obviously, they react at various rates.

In addition, during the course of desulfurization, non-sulfur containing molecules may be hydrogenated and in some cases cracked.

The flow design of hydrosulfurization process systems is relatively simple. Preheated oil and hydrogen under pressure are contacted with catalyst. The effluent from the reactor is passed to one or more separators to remove most of the effluent hydrogen and light hydrocarbon gases produced in the operation. These gases are generally recycles with or without prior removal of light hydrocarbons by absorption. The separator liquids may be stripped, rerun or otherwise treated to obtain hydrogen sulfide free products of the desired boiling range.

Except in the case of residuum processing, plant design options are few in number and relatively simple. For example, in the processing of distillates, correlation systems have been developed which relate degree of desulfurization to about three parameters which define the charge stock, reactor temperature, temperature, pressure, feed space velocity, hydrogen rate and a catalyst activity parameter.

When residuum stocks are considered, however, generalizations are not so easily made. The wide variance in residuum properties (i.e., atmospheric or vacuum type, viscosity, Conradson carbon content, metal content and the paraffinic or aromatic nature of residuum) makes each case a special one as far as process design. Catalyst poisoning due to metals deposition on the catalyst surface can reduce overall desulfurization yields. Catalyst must then be regenerated or replaced, thus adding to overall cost of the particular system employed.

An alternative to desulfurization exists, that being the use of natural low sulfur fuel oils. They may be used alone or in blends with higher sulfur content material. The major source of low sulfur fuel oil is North African crudes, principally from Libya and Nigeria, and some Far Eastern crude from Sumatra. Fuels made from these crudes will meet even very low sulfur regulations calling for 0.5% sulfur or less. However, the highly waxy nature of these paraffinic materials makes handling difficult and costly. Therefore, the blend becomes a more palatable course of action.

Blends of natural low-sulfur fuels oils with other high sulfur fuel oils will be adequate in some cases to meet more moderate sulfur regulations. The fuel oil fractions of North African crudes contain about 0.3% S. Thus significant amounts of higher sulfur fuel oils can be added to make blends calling for 1–2% sulfur. These blends have physical properties which obviate the need for specialized handling (a must for existing industrial installations).

Before delving into specific desulfurization technology and applications, pertinent terms will be defined. Figure 1

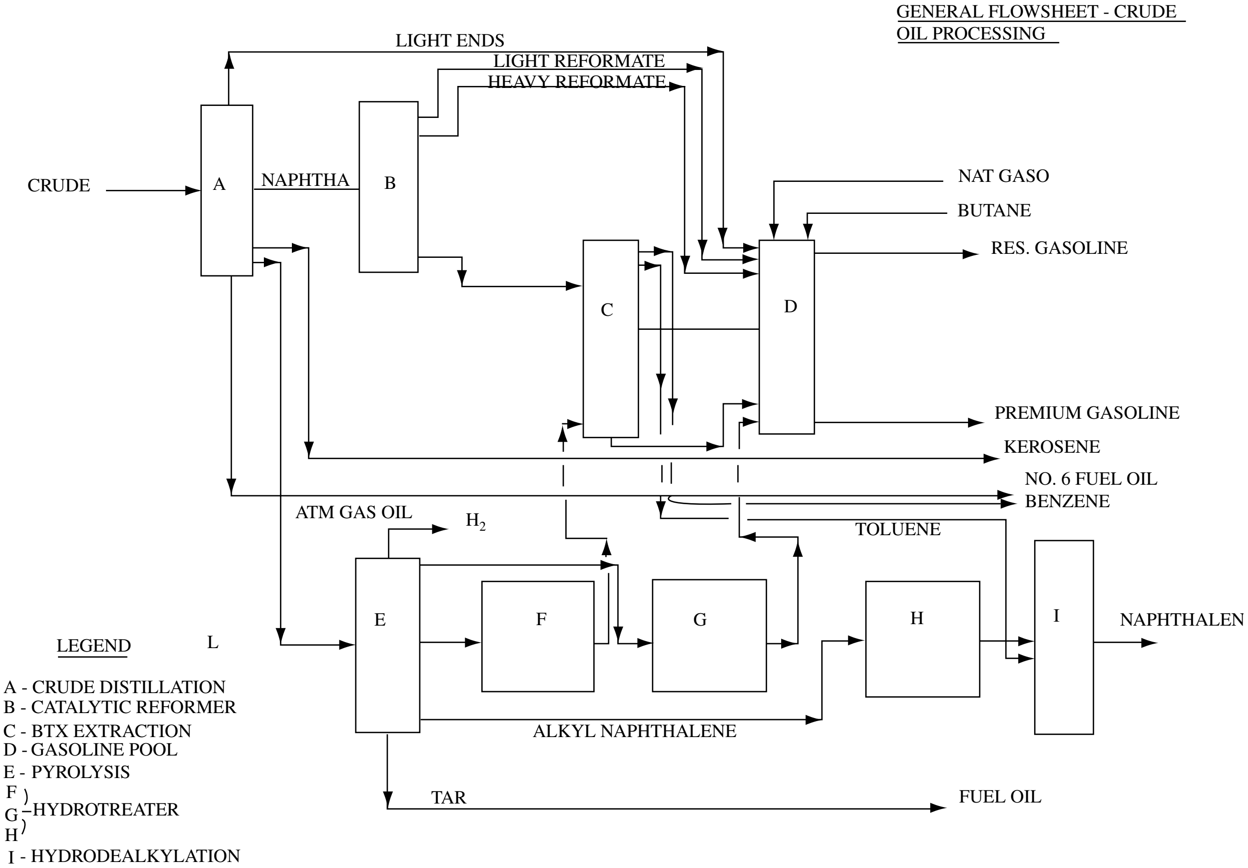

FIGURE 1

schematically represents a general flowsheet for crude oil processing. Crude oil, as received from the source is first atmospherically distilled. Light ends and mid-distillates from this operation are further processed to yield gasolines and kerosene. Atmospheric residuum can be directly used for No. 6 fuel oil, or further fractionated (*in vacuo*) to produce vacuum gas oil (vacuum distillate) and vacuum residuum. After atmospheric distillation, the average crude contains about 50% of atmospheric tower bottoms, which is nominally a 650°F$^+$ oil. The vacuum distillation yields roughly equal parts of vacuum gas oil and vacuum residuum. The bottoms from this unit is nominally a 975°F$^+$ oil, although the exact cut point will vary for each vacuum unit.

Desulfurization of vacuum residuum would be applicable where a refinery has use for the virgin vacuum gas oil other than fuel oil, and sulfur restrictions or increased prices make desulfurization of vacuum bottoms attractive. Another situation is where desulfurizing the vacuum gas oil and blending back with vacuum bottoms no longer produces a final fuel oil meeting the current sulfur specification.

Present in the residuum (vacuum) is a fraction known as asphaltenes. This portion is characterized by a molecular weight of several thousand. The majority of the organometallic compounds are concentrated in the asphaltene fraction. Although many of the metals in the periodic table are found in trace quantities, vanadium and nickel are usually present in by far the highest amounts. Residual oils from various crudes differ from each other considerably in regard to hydrodesulfurization. These differences reside to a great extent in the asphaltene fraction.

Light Oil Desulfurization

The G O-Fining Process The G O-Fining process is designed for relatively complete desulfurization of vacuum gas oils, thermal and catalytic cycle oils, and coker gas oil. It represents an extremely attractive alternative where a lesser degree of sulfur removal from the fuel oil pool and/or a very low sulfur blending stock is required. The feed to the G O-Finer System is atmospheric residuum. This stream is vacuum fractionated and the resulting vacuum gas oil (VGO) is desulfurized using a fixed bed reactor system. Resultant VGO is then reblended with vacuum bottoms to yield a desulfurized fuel oil or used directly for other applications. Figure 2 shows quantitative breakdown of various process streams for a 50,000 barrel per stream day (BPSD) operation utilizing a 3% sulfur Middle East atmospheric residuum feed. The process has the capability of producing 49,700 BPSD of 1.72% S fuel oil.

There are currently a number of G O-Fining units in commercial operation.

Investment and operating costs will vary depending on plant location and crude stock characteristics, but for many typical feedstocks (basis 50,000 BPSD) total investment is about 16.3 million dollars and operating costs average out at 60¢/barrel fuel oil (1989).

UOP's gas desulfurization process Another light oil desulfurization process is UOP's gas oil desulfurization scheme. Unlike the previously discussed G O-Fining process, UOP's scheme (already commercial) is designed for almost complete (∼90%) desulfurization of a 630 to 1050; F blend of light and vacuum gas oils (approximate sulfur content of feed—1.5%). Vacuum residuum is neither directly nor indirectly involved anywhere in the process.

In almost all other respects, however, UOP's process parallels G O-Fining. The current plant facility is of 30,000 BPSD capacity with above mentioned feed.

Comparison of UOP and G O-Finer costs show that both are of the same order of magnitude and differ markedly only in initial capital investment. This is in part attributable to the fact that a G O-Fining facility requires atmospheric residuum fractionation whereas UOP's does not.

Stocks of high-sulfur content are difficult to crack catalytically because all or most of the catalysts now in commercial use are poisoned by sulfur compounds. In recent years the trend has been toward processes that remove these sulfur compounds more or less completely. The high sulfur

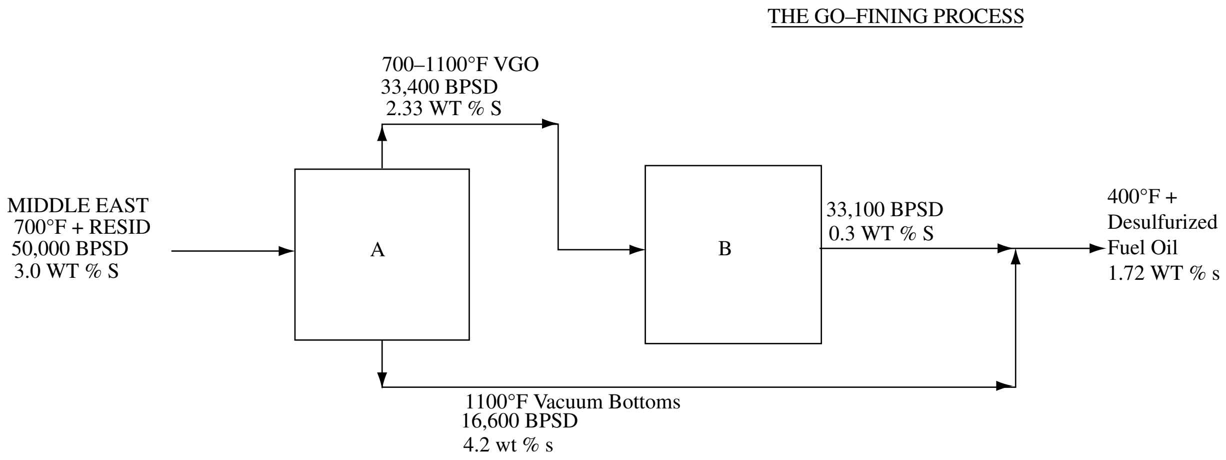

FIGURE 2

contents of petroleum stocks are mainly in the form of thiophenes and thiophanes and these can be removed only by catalytic decomposition in the presence of hydrogen. The Union Oil Company has developed a cobalt molybdate desulfurization catalyst capable of handling the full range of petroleum stocks encountered in refining operations. Even the more refractory sulfur compounds associated with these stocks are removed. This catalyst exhibited excellent abrasion resistance and heat stability, retaining its activity and strength after calcination in air at temperature as high as 1470°F.[8] Cobalt molybdate may be considered a chemical union of cobalt oxide and molybdic oxide, $CoO \cdot MoO_3$. The high activity of this compound is due to an actual chemical combination of these oxides with a resultant alteration of the spacing of the various atoms in the crystal lattice.[8] Catalyst life is two to five years. Catalyst poisons consisted of carbon, sulfur nitrogen and polymers. Regeneration is accomplished at 700 to 1200°F using air with steam or flue gases.

The fundamental reactions in desulfurization are as follows:

General Reaction

$$C_nH_mS_p + xH_2 \rightarrow C_nH_{m+2x-2p} + pH_2S$$

Desulfurization of ethyl mercaptan

$$C_2H_5SH + H_2 \rightarrow C_2H_6 + H_2S \ \Delta H = -19.56 \text{ kg cal/mole}$$

Desulfurization of diethyl sulfide

$$(C_2H_5)_2S + 2H_2 \rightarrow 2C_2H_6 + H_2S \ \Delta H = -36.54 \text{ kg cal/mole}$$

Desulfurization of thiophene

$$C_4H_4S + 4H_2 \rightarrow C_4H_{10} + H_2S \ \Delta H = -73.26 \text{ kg cal/mole}$$

Desulfurization of amylene

$$C_5H_{10} + H_2 \rightarrow C_5H_{12} \ \Delta H = -33.48 \text{ kg cal/mole.}$$

The change in heat content for all these reactions is negative, indicating that they take place with evolution of heat. The sulfur content in Middle East Gas Oil, a typical feed, is 1.25% by weight. The pilot plant data shows that the heat effect is not serious and whole process can be treated as isothermal.

The chemical reaction process on the catalyst is postulated to proceed on the surface of the catalyst by interaction of the sulfur-bearing molecules and hydrogen atoms formed through activated absorption of hydrogen molecules.[9] Oil molecules are more strongly absorbed than hydrogen molecules, and therefore may preferentially cover part of the surface, leaving less surface available for dissociation of hydrogen molecules. In the presence of diluent, namely, N_2, it can also compete for free sites on the surface, and accordingly may cause a reduction in the concentration of hydrogen on the surface, thus giving the lower rate constant when working with H_2–N_2 mixture.

Conversion of the sulfur compounds to hydrogen sulfide and saturated hydrocarbons occurs by cleavage of the sulfur to carbon bonds; essentially no C—C bonds are broken.

Residuum Desulfurization

The H-Oil-process (*Cities Service*) In order to meet the need for an efficient method of desulfurizing residual oils without the complexities encountered in the myriad of existing fixed bed catalytic systems, Cities Service developed what is known as the H-Oil system.

Although fixed bed catalytic reactors had been extensively used for desulfurizing distillate oils, desulfurization of residual oil in a fixed bed reactor presented several difficulties:

1) the high temperature rise through the bed tended to cause hot spots and coking,
2) the presence of solids in the feed and the formation of tar-like coke deposits on the catalyst tended to cause a gradual build-up of pressure drop over they catalyst bed and
3) because of the relatively rapid deactivation of the catalysts, system shut down for catalyst replacement occurred often, on the order of six times yearly.

To overcome these problems an ebbulated bed reactor was designed. Figure 3 is a simplified drawing of reactor workings.

The feed oil is mixed with the recycle and makeup hydrogen gas and enters the bottom of the reactor. It passes up through the distributor plate which distributes the oil and gas evenly across the reactor.

The reaction zone consists of a liquid phase with gas bubbling through and with the catalyst particles suspended in the liquid, and in random motion. It is a back-mixed, isothermal reactor, with a temperature gradient between any two points in the reactor no greater than 5°F.

Due to the catalyst suspension in liquid phase, catalyst particles do not tend to adhere to one another, causing blockage of flow. Any solids present in the feed pass directly through the reactor. Reactor pressure drop is constant.

One of the more important aspects of the ebbulated bed reactor system is that periodic shutdowns for catalyst replacement is not necessary. Daily catalyst replacement results in a steady state activity.

Table 2 shows examples of H-Oil desulfurization performance with atmospheric and vacuum residuals. In addition, investment and operating cost data are shown to illustrate the important effect of feed stock characteristics on overall economics.

Cases 1–3 describe processing of three atmospheric residual feeds. The Kuwait Residuum treated in case 1 is a high sulfur oil containing relatively low metals content (60 PPM). Therefore, the rate of catalyst deactivation is low and operating conditions are set to minimize hydrocracking and maximize desulfurization. In fact, only 2–3% naphtha and 9–10% middle distillate are produced. The actual chemical hydrogen consumption is fairly close to the estimated needed to remove the sulfur. For many atmospheric residuals which are not too high in metals, this case is typical to give maximum production of low sulfur fuel oil at minimum conversion and hydrogen consumption.

OP cost, (20,000 BPSD UNIT)	33	40	39	44	46	65

In case 2, although metals content is also low (~40 PPM), hydrogen consumption is exceptionally high. This is due to the fact that conversion was not minimized and 7% naphtha and 13% middle-distillate was produced by hydrocracking.

Case 3 is characteristic of high metals content (~320 PPM) oils from that area. As noted previously, catalyst deactivation increases with metals content. Therefore, catalyst addition rates are higher, resulting in increased operating costs. To compensate for the reduced catalyst activity, higher operating temperatures and/or residence times are used.

Cases 4–6 summarize vacuum residua operations. Desulfurization rates for vacuum residua are lower than for atmospheric. The asphaltenes and metallic compounds reside in the vacuum residuum, consequently increasing catalyst deactivation rates and therefore catalyst costs per barrel. In all the cases depicted (4–6) hydrogen consumption, relative

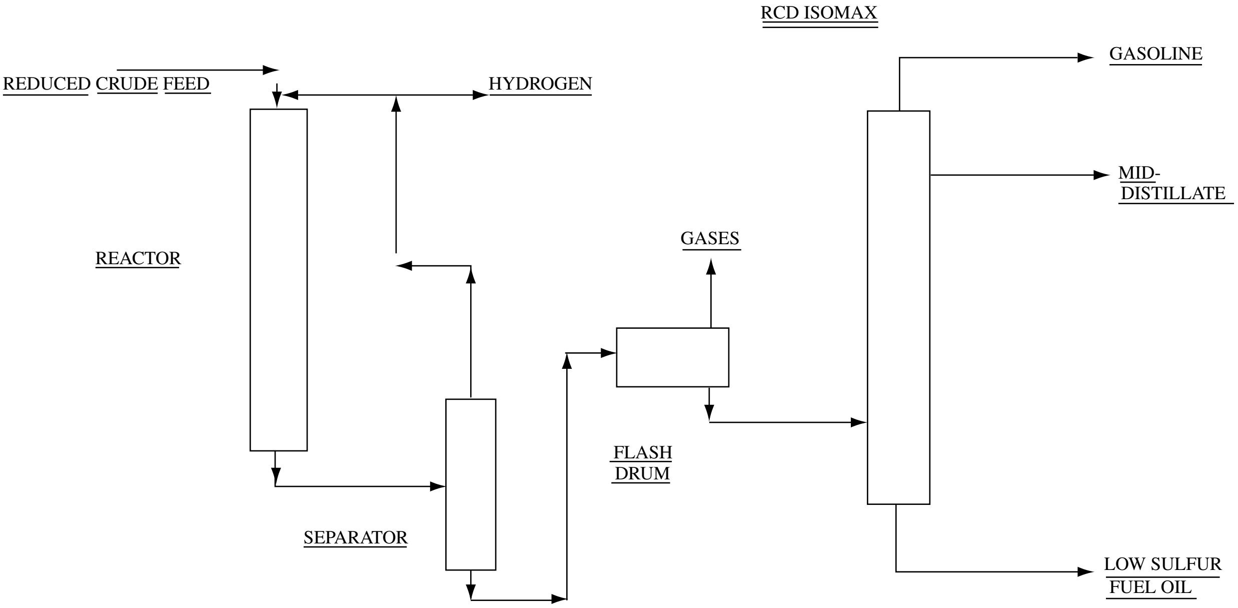

FIGURE 4

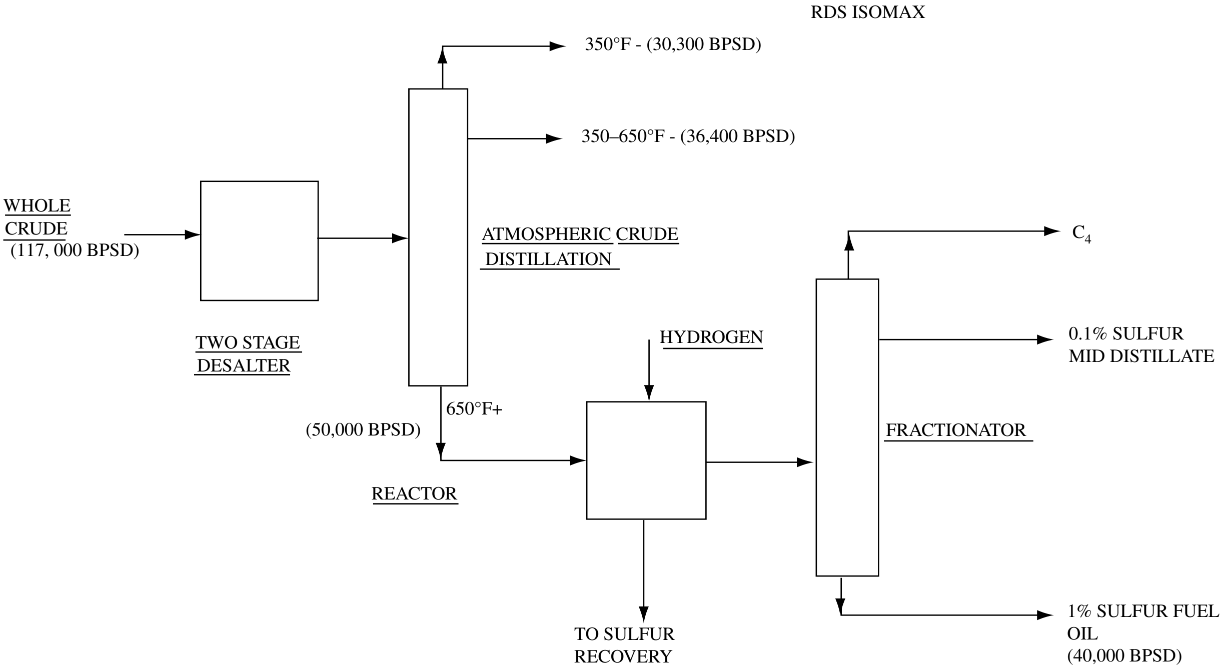

FIGURE 5

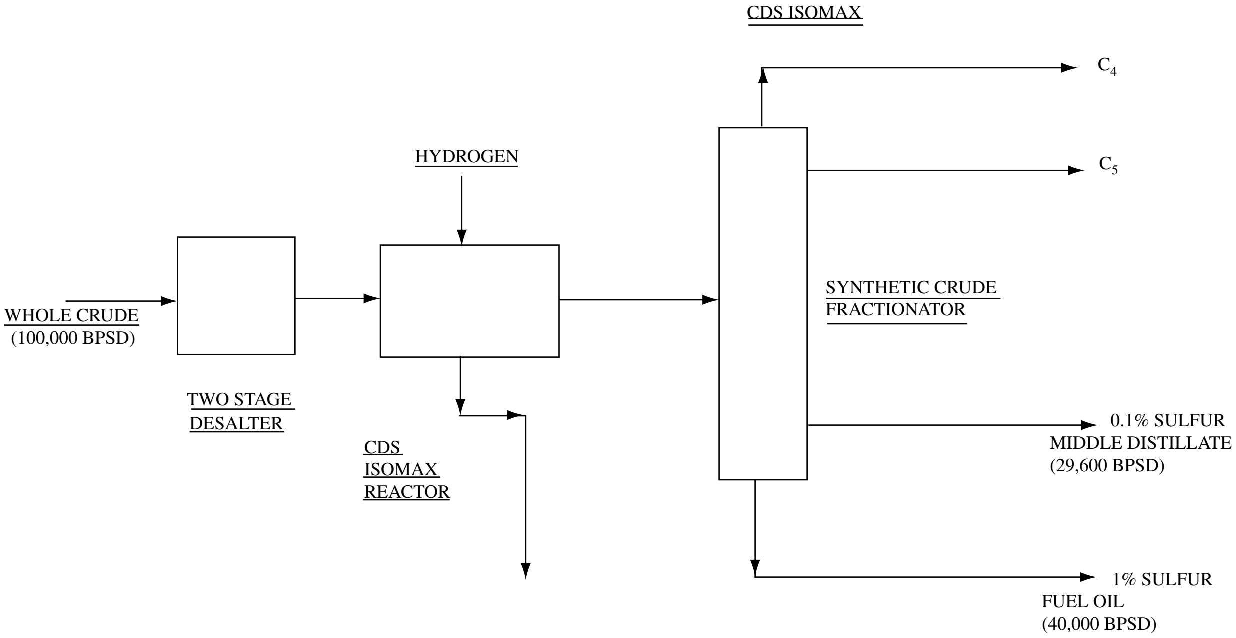

FIGURE 6

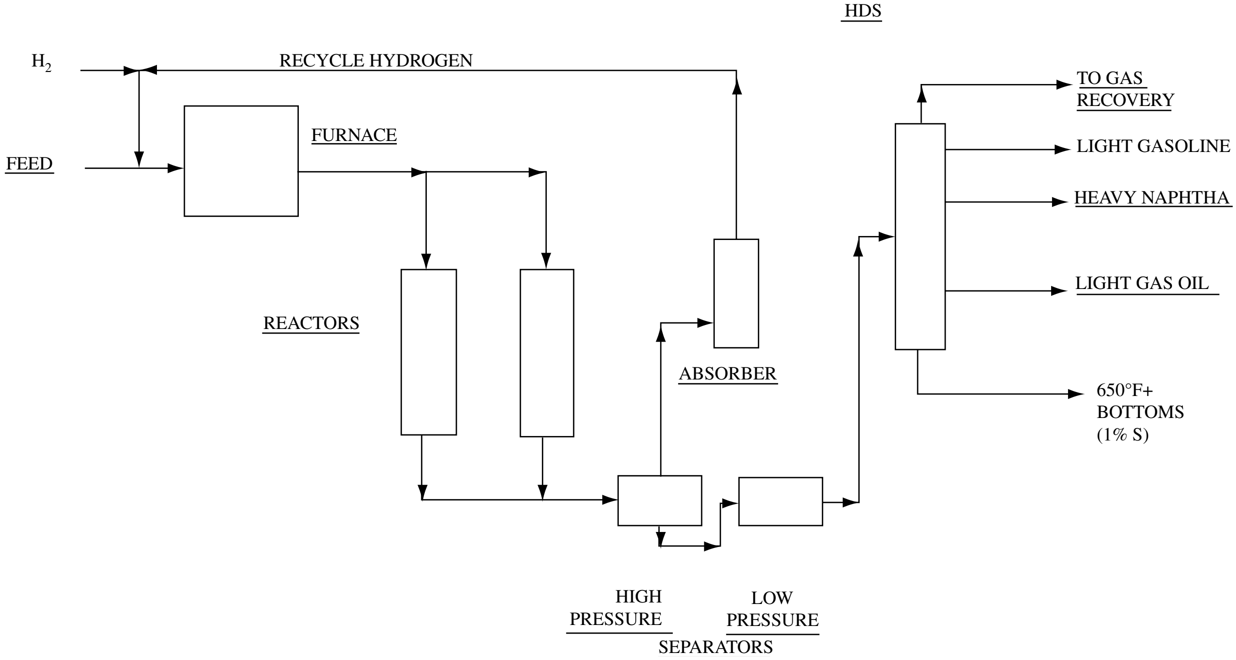

FIGURE 7

to that needed for desulfurization, is high indicating that high sulfur content of feed precludes setting of operating conditions to minimize conversion. In fact, naphtha production ranges from 7–15%, mid-distillates from 15–23%.

The Isomax processes A broad spectrum of fixed bed desulfurization and hydrocracking processes are now in operation throughout the world. They are characterized by their ability to effectively handle a wide range of crude feedstocks. In addition, some of the processes are capable of directly desulfurizing crude oil while others treat only residual stocks.

Rather than discuss each process individually, a comparative summary of the major ones is presented in Table 3.

There are many other processes which in one way or another effect a reduction in the amount of sulfur burned in our homes and businesses. All of them use some type of proprietary catalytic system, each with its own peculiar optimum operating ranges with regard to feed composition and/or reactor conditions.

The hydrodesulfurization process is still relatively expensive (in 1989 more than 75¢/BBL) by petroleum processing standards. The capital investment for large reactors which operate at high pressures and high temperatures, the consumption of hydrogen during the processing and the use of large volumes of catalyst with a relatively short life all contribute to the costs. In addition, processing costs also depend on the feedstock characteristics.

But when one considers the awesome annual alternative of 30 million tons of sulfur dioxide being pumped into the atmosphere, the cost seems trifling indeed.

Desulfurization of Natural Gas

Approximately 33% of the natural gas in the United States and over 90% of that processed in Canada is treated to remove normally occurring hydrogen sulfide. The recovered sulfur, which now accounts for about 25% of the free world's production is expected to increase in the future.

Current processes may be classified into four major categories:

1) Dry Bed—Catalytic Conversion,
2) Dry Bed—Absorption—Catalytic Conversion,
3) Liquid Media Absorption—Air Oxidation,
4) Liquid Media Absorption—Air Conversion.

Dry bed catalytic conversion (*the Modified Claus Process*) The Modified Claus Process is used to remove sulfur from acid gases which have been extracted from a main sour gas stream. The extraction is done with one of the conventional gas treating processes such as amine or hot potassium carbonate.

The process may be used to remove sulfur from acid gas streams containing from 15 to 100 mole % H_2S. The basic schemes use either the once through process or the split stream process. Figure 8 shows flow characteristics of the once-through scheme, which in general gives the highest overall recovery and permits maximum heat recovery at a high temperature level.

Split stream processes are generally employed where H_2S content of the acid gas is relatively low (20–25 mole %) or when it contains relatively large amounts of hydrocarbons (2–5%).

Pertinent design criteria for dry bed catalytic conversion plants include the following:

1) Composition of Acid Gas Feed,
2) Combustion of Acid Gas,
3) For a Once-Through Process, Retention Time, of Combustion Gases at Elevated Temperatures,
4) Catalytic Converter Feed Gas Temperature,
5) Optimum Reheat Schemes,
6) Space Velocity in the Converters,
7) Sulfur condensing Temperatures.

FIGURE 9

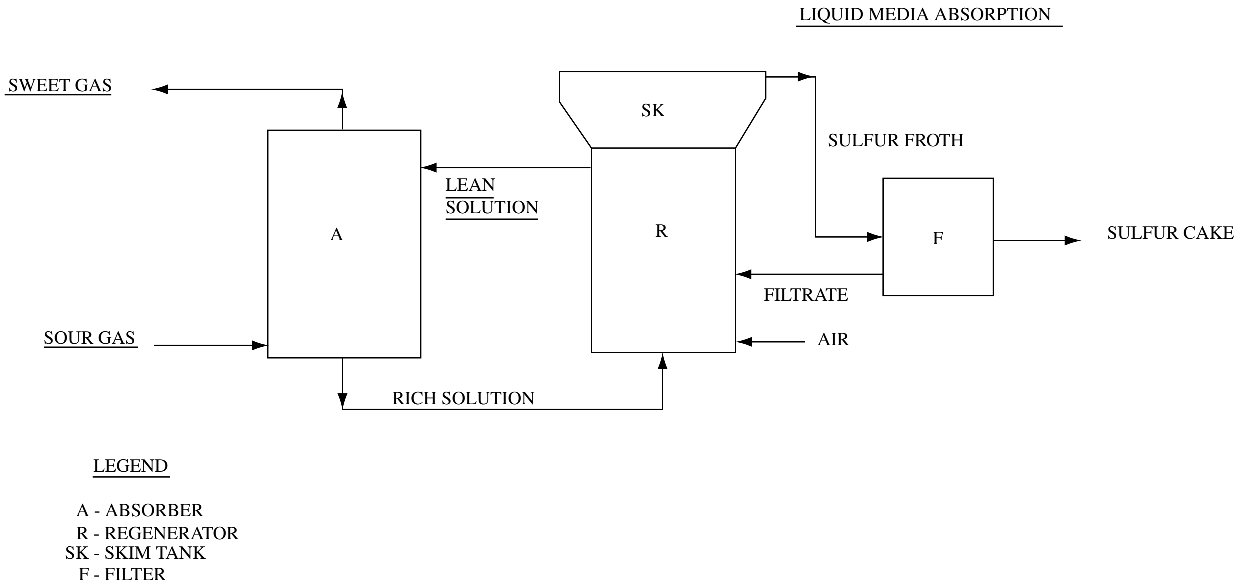

FIGURE 10

The sulfur from a claus plant may be produced in various forms, such as liquid, flaked or prilled. Form of choice is determined by transportation mode and end usage.

Dry bed absorption—catalytic conversion (*Haines Process*) In the Haines Process (see Figure 9), sulfur is removed from sour natural gas using zeolites or molecular seives.

Hydrogen sulfide is absorbed from the gas on a bed of zeolites until the bed becomes saturated with H_2S. The bed is then regenerated with hot SO_2 bearing gases, generated from burning a part of the liquid sulfur production.

The zeolite catalyzes the reaction of H_2S form sulfur vapor. The regeneration effluent gases are cooled and sulfur is condensed.

Liquid media absorption—air oxidation Most commonly in use in Europe for removal and recovery of sulfur from manufactured gases such as coal gas or coke oven gas, several processes in this category are available today.

Typically, the process scheme involves absorption of H_2S in a slightly alkaline solution containing oxygen carriers. Regeneration of the solution is by air oxidation. The H_2S is oxidized to elemental sulfur. Figure 10 shows the typical processing scheme.

The air also acts as a flotation agent for the sulfur which is collected at the regenerated solution surface as a froth. The sulfur sludge is either filtered or centrifuged to yield a sulfur cake which may be recovered as a wet paste or dry powder.

Liquid media absorption—direct conversion (*Townsend Process*) The Townsend Process is perhaps one of the newest sulfur removal processes on the scene today. Still in formative stages of development, its potential advantages point to it directly challenging the other conventional system containing an amine plant, a dehydration plant and a claus sulfur plant. The Townsend plant offers the added advantage of recovering a higher percentage of the sulfur.

The Townsend Process uses an aqueous solution of an organic solvent such as triethylene glycol to contact the sour gas and simultaneously sweeten the gas, dehydrate the gas and convert the gas to elemental sulfur.

ENVIRONMENTAL CONCERNS

Trowbridge[10] states that reductions in lead content of fuel oil are occurring world wide. Unleaded mo gas originally introduced in California in 1975 is now available throughout the U.S., where permissible maximum lead levels were established at 0.1 grams/gal after 1986. Trowbridge describes additional environmental concerns and fuel treatment procedures which are summarized below:

- ozone formation—reduction of gasoline vapor pressure
- carbon monoxide emissions—add oxygenates to blend
- benzene emissions—reduce fraction in reformate by extraction for example.

DESULFURIZATION OF COAL

Although coal buring accounts for only about 1/4 of the nation's energy, approximately 2/3 of all the sulfur dioxide emitted in the United States is traceable to its usage. And since coal supplies far outstrip gas and oil reserves, interest in coal desulfurization is great.

Presently, however, there are no processes sufficiently developed, either technically or commercially, which have any significant impact on the industry. The following is, therefore, a brief summary of the more pertinent processes currently under evaluation.

A typical high-sulfur, bituminous coal (4.9%) sulfur may be characterized by the composition shown in Table 4.

The solvent refine process Solvent refined coal (SRC) is one name among others given to a reconstituted coal which has been dissolved, filtered, and separated from its solvent. It is free of water, low in sulfur, very low in ash, and sufficiently low in melting point that it can be handled as a fluid.

In the process (see Figure 11), coal is ground to 80% through a 200 mesh screen and slurried in an initial solvent oil. The slurry is pumped to a pressure of 1,000 lb/sq.in. and passed upwards through a heater to bring the slurry to a temperature of 45°C.

The flow rate is between a half and one space velocity. As the material leaves the heater, more than 90% of the carbon in the coal is in solution. (Anthracite coal is an exception.)

A small amount of hydrogen is introduced into the slurry prior to preheating. The hydrogen prevents repolymerization of the dissolved coal. A portion of the organic sulfur in the coal unites with hydrogen to form hydrogen sulphide, which is later separated as a gas. The unutilized hydrogen is recycled back to the preheater. After the coal has been dissolved, the ash is filtered at a pressure of about 50 lb/sq.in. The pyritic sulfur leaves the process mixed with the other separated mineral matter.

The filtrate or coal solution, now greatly reduced in ash and sulfur is flash evaporated to obtain the necessary recycle solvent. It has been demonstrated that no make up solvent is required. In fact, an excess of solvent oil, released from the coal structure itself during solvation is recoverable, if desired. The remaining hot liquid residue is discharged and cooled to form a hard, brittle solid of solvent refined coal.

Table 5 shows a comparative analysis of a raw coal (% S—3.27%) and the solvent refined process, along with rough economies.

Obviously, solvent refined coal represents a marked improvement over the raw starting material. Sulfur content is reduced by about 30%, Ash content by 93% and heating value (in BTU/LB) is significantly increased. However, the cost of these improvements produces a fuel whose cost is higher than low sulfur oil.

Devolatilization I carbonization to a low sulfur char United Engineers and Company have investigated the use of a fluidized bed desulfurization process. Figure 12 shows general flow scheme for the label scale process.

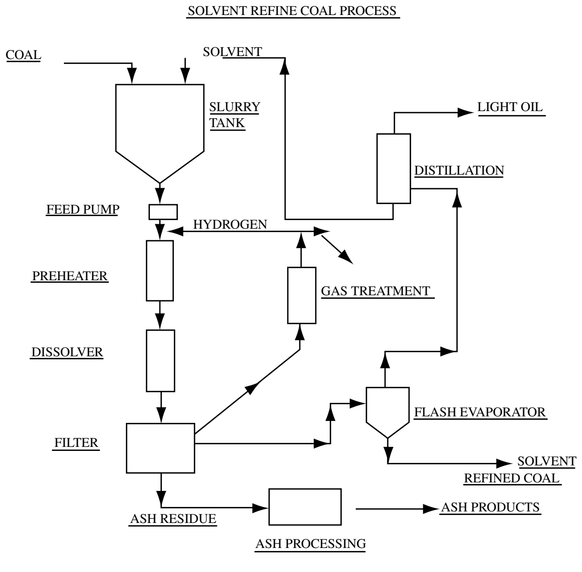

FIGURE 11

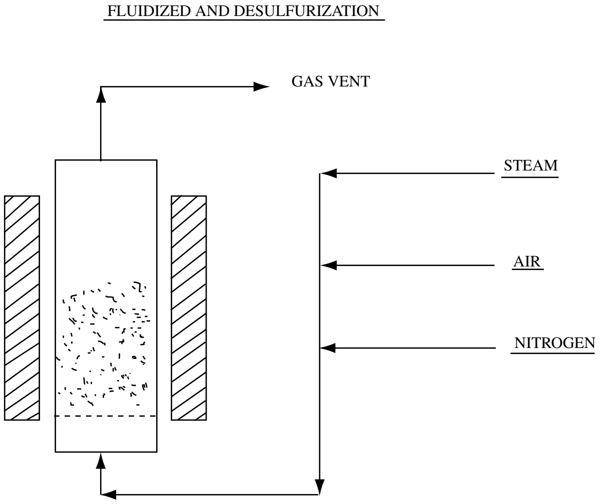

FIGURE 12

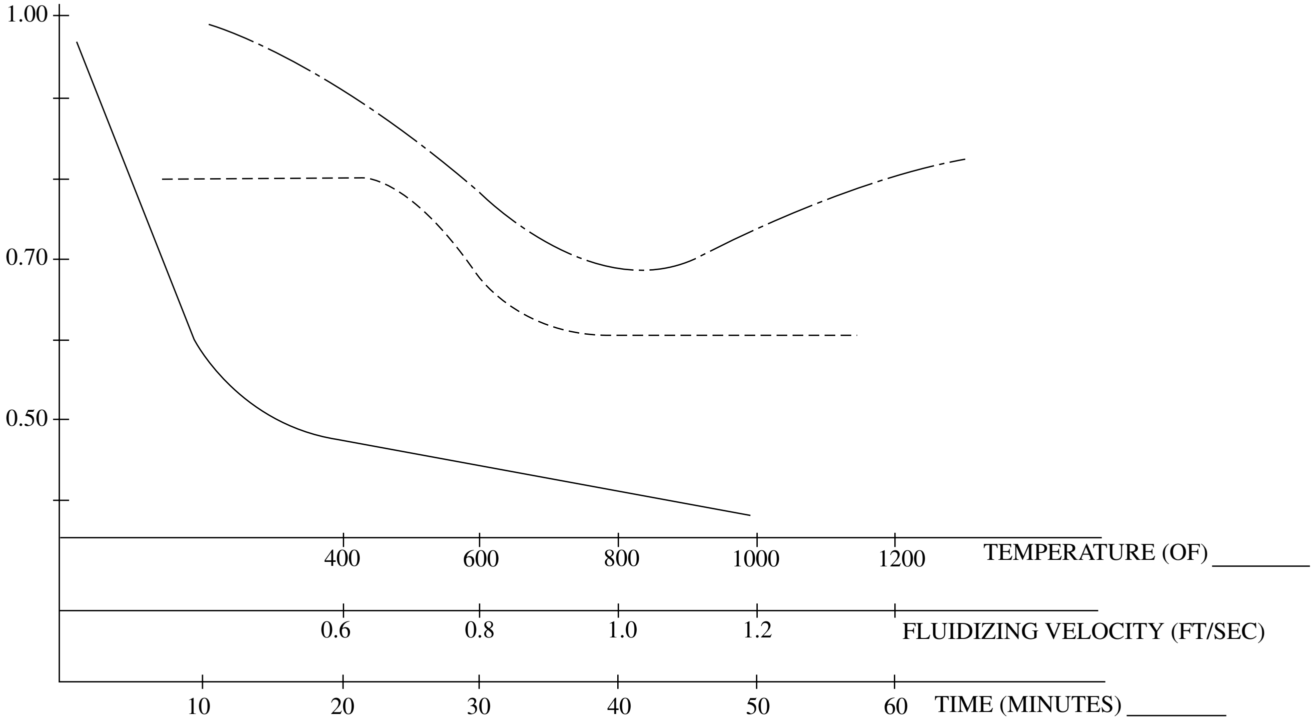

FIGURE 13

Ground coal (1/16″) is introduced into the heated, tubular reactor. Gas flow is then adjusted to maintain bed fluidity. Reactor temperatures approach 950°F.

The char is then removed through the bottom of the reactor.

The factors most directly affecting desulfurization are particle size, reactor residence time, reaction temperature and fluidizing velocity. Figure 13 summarizes relationships between extent of desulfurization (expressed as the ratio of sulfur in char to that in feed-ΔS) and above mentioned parameters.

Other processes, in various stages of development include causticized fluidized bed desulfurization, gasification to high and low BTU Gases and extr action of pyritic sulfur from raw coal. The Bureau of Mines, bituminous coal research and others have sought to remove sulfur (pyritic) by washing, using various techniques including centrifugation, flotation and magnetic separation methods. None of these has the potential to remove more than half the sulfur and each leads to significant product losses.

Bartok *et al.*[11] point out the advantages of systems which combine advanced processing techniques with advanced combustion recovery cycles. Gasification combined cycle, for example, couples the precombustion clean-up of coal (via gasification) with gas and steam turbines for power generation. As the efficiency of such plants improves their economics will improve relative to conventional coal fired plants while having a superior environmental impact (much lower nitrogen oxides, for example).

COAL ASH REMOVAL

Detroit Edison Company demonstrated the benefits of operating with low ash coals. In addition to the lower ash removal requirements, they lead to reduced transportation costs, higher heating values and improved boiler performance. One possible disadvantage of water cleaning method is additional drying which might be required prior to combustion.

Ash removal is considered primarily for coal production. Ash contents of oils are relatively small and of natural gas are negligible. The popular separation techniques usually depend on specific gravity differences (physical) or froth flotation (chemical) methods. The dispersing medium for specific gravity separation may be water, air or suspended matter in water. Coal specific gravities may range from 1.1 to 1.8, whereas impurities typically have specific gravities above 2.0 for carbonates and silicates and as high as about 5.0 for pyrites.

Bowling *et al.*[12] state that the levels of ash-forming mineral matter in most coals can be reduced by a combination of physical and chemical methods, to yield ultraclean coals with ash yields of 0.1–1%.

nations in Asia and Latin America, nations are reviewing their fuel alternatives. One such fuel is petroleum coke (PC), being produced at a worldwide rate of over 50 tons per year in 2000. PC is a byproduct of oil refining that can be burned along with other fossil fuels. The cement industry is currently one of the widest consumers of blended PC. When co-firing liquid or gaseous fuel, PC will usually require additional control equipment for particulate and sulfur oxides reduction. In boilers cofiring coal particulate controls may be adequate since PC ash contents are low, however, the flue gas may require scrubbers to reduce sulfur oxides, since PC sulfur contents are high. See table for typical PC properties. The low ash content and low grindability reduce solids handling costs. The high vanadium content may, however, contribute to secondary plumes problems in the absence of sulfur removal equipment.

GEOGRAPHIC INFORMATION SYSTEMS

The term "Geographic Information System" (GIS) varies as a matter of perspective, and ranges in scope from specific computer software packages to software, hardware and data, to software, hardware, data, and support personnel. The most exhaustive definition is given by Dueker and Kjern as:

> Geographic Information System—A system of hardware, software, data, people, organizations, and institutional arrangements for collecting, storing, analyzing, and disseminating information about areas of the earth.

While this is an all-inclusive definition, the software packages at the heart of a GIS have their roots in the work of two researchers at Ohio State University, Marble and Tomlinson, in the mid to late 1960s. These men coined the phrase "Geographic Information System," and defined a GIS as having the following four components:

1. Data Input and the ability to process data.
2. Data Storage and Retrieval with the ability to edit.
3. Data Manipulation and Analysis.
4. Data Reporting Systems for the display of tabular and graphic information.

Data input, storage/retrieval, and reporting were (and still are) common to two other computer software packages—Computer Assisted Mapping (CAM) and Database Management Systems (DBMS) which separately managed graphical and tabular information. The development of GIS combined these packages to provide what many refer to as "intelligent maps," which are maps with extended information. Extended information can include information from areas such as census, tax assessment, natural resources availability/quality, which may be linked to a map, but are managed as part of a separate database. However, the true distinction of a GIS is Marble and Tomlinson's third component—the ability to analyze spatial information. The analysis capability enables a GIS to automatically evaluate information from several sources as a function of their spatial context. CAM systems may provide some of the same information as a GIS through a series of separate maps, but they require manual interpretation.

There are six basic analytical questions which many GIS software packages are able to address, partially or in full. These are:

1. Location—"What is it?"—What types of features exist at a certain place, such as "What is the population of a given census tract?"
2. Condition—"Where is it?"—Finding a site with certain characteristics, such as "Which agricultural fields are within 100 meters of a stream?"
3. Trend—"What has changed?"—Evaluation of spatial data as a function of time.
4. Routing—"Which is the best way?"—A variety of problems to determine paths through a network, such as finding the shortest path or optimum flow rates.
5. Pattern—"What is the pattern?"—A function which allows environmental and social planners to account for spatial distribution. Examples include the spread of diseases, population distribution versus urban development, or targeting specific consumer trends.
6. Modeling—"What if?"—Allow model development and evaluation, including "Monte Carlo" evaluation, where a variety of factors influence a situation, and their relationship is determined by varying one factor while holding the others constant.

A GIS is able to perform the above operations because they maintain the topology, or spatial associations, of the elements of their database. For example, an individual looking for 617 East Central Avenue on a map is able to see that this address is between 6th and 7th streets, on the south side of the street. Furthermore, if the individual wants to drive to this address and the map indicates that these streets are one-way in given directions, they are able to plan their route accordingly. A GIS may perform the same operation because it has the same information—that 6th and 7th intersect Central Avenue, the directed flow of traffic on these streets, and the distinction of areas on the left and right side of a line. This case is an example of what is called a "vector format" GIS, where space is represented by a two dimensional manifold of polygons (city blocks) which are bounded by a set of directed line segments (streets).

The other format by which a GIS may represent spatial data is referred to as "raster format." In this format, an area or volume is represented by a two or three dimensional matrix of uniform data elements, called "grid cells." Grid cells are the smallest areas that this type of GIS may resolve and are artificial constructs uniform in size and shape and are considered to have homogeneous data properties. An example would be a Soil map represented as a series of 30 meter by 30 meter plots of ground, where each plot is considered to be one particular type of soil, or a uniform blend of multiple soil types. An advantage of the raster format is the ability to show gradual changes and trends over a spatial area, because the matrix indices of the grid cell coordinates inherently imply the topology of the GIS data set. One of the disadvantages of the raster format is that data in the "real world" may not conveniently break down into uniform grid cells. Consequently, using this format involves an optimization problem to select a grid cell resolution that adequately represent the given data set, while minimizing the database size. Decreasing the size of gird cells in a raster exponentially increases the database size.

With the growing usage of Geographic Information Systems, there is a corresponding need for standardization. Standardization does not mean that all GIS databases contain the same format and quality of information; instead it provides a common terminology and format for maintaining appropriate metadata, or data about data. Currently in the United States, the official federal standard regarding GIS is the Spatial Data Transfer Standard, which provides a specific terminology for GIS through a set of definitions and format for maintaining an appropriate spatial data quality report for metadata. The importance of providing a standard, such as the SDTS, is that it provides the end user with and ability to assess whether or not the output from a GIS has the quality necessary to carry out further operations or analysis.

Dueker and Kjern's definition of a GIS is the most appropriate to consider, because the successful adoption of a GIS does not rely only on purchasing a software package. A GIS relies on people gathering the appropriate data, which is then input and manipulated in the GIS software environment, and which has knowledgeable individuals interpreting and analyzing results for their acceptability. Therefore, these elements must be considered as part of a Geographic Information System.

GREENHOUSE GASES EFFECTS

INTRODUCTION

The possibility that man-made emissions of carbon dioxide and other infra-red absorbing gases may enhance the natural greenhouse effect and lead to a warming of the atmosphere and attendant changes in other climate parameters such as precipitation, snow and ice cover, soil moisture and sea-level rise, constitutes perhaps the most complex and controversial of all environmental issues and one that is likely to remain high on both the scientific and political agenda for a decade or more. The issues have been obscured by a good deal of exaggeration and distortion by the media, and by some scientists, so that governments, the public, and scientists in other disciplines are confused and sceptical about the evidence for global warming and the credibility of the predictions for the future.

Until very recently the atmospheric concentrations of carbon dioxide had been increasing and accelerating since regular measurements began in 1958. Only during the last few years has there been a levelling off, probably because of the world-wide recession, the run-down of industry in the former Soviet bloc, and the substitution of gas for coal. This pause is likely to be only temporary, and if the concentrations resume their upward trend, they will eventually lead to significant climate changes. The important questions concern the likely magnitude and timing of these events. Are they likely to be so large and imminent as to warrant immediate remedial action, or are they likely to be sufficiently small and delayed that we can live with them or adapt to them?

Careful reconstruction of historical records of near-surface air temperatures and sea-surface temperatures has revealed that globally-averaged annual mean temperatures have risen about 0.6°C, since 1860 (see Figure 1). There is general consensus among climatolologists that this can now confidently be ascribed to enhanced greenhouse warming rather than to natural fluctuations. The last decade has been the warmest of this century and 9 of the 10 warmest years have occurred since 1990. Moreover, as described later, any temperature rise due to accumulated concentrations of greenhouse gases may have been masked by a concomitant increase in concentrations of aerosols and by delay in the oceans.

ROLE OF CARBON DIOXIDE IN CLIMATE

Carbon dioxide, together with water vapor, are the two main greenhouse gases which regulate the temperature of the Earth of its atmosphere. In the absence of these gases, the average surface temperature would be −19°C instead of the present value of +15°C, and the Earth would be a frozen, lifeless planet. The greenhouse gases act by absorbing much of the infrared radiation emitted by the Earth that would otherwise escape to outer space, and re-radiate it back to the Earth to keep it warm. This total net absorption over the whole globe is about 75 PW an average of 150 Wm^{-2}, roughly one-third by carbon dioxide and two-thirds by water vapour.

There is now concern that atmospheric and surface temperatures will rise further, owing to the steadily increasing concentration of carbon dioxide resulting largely from the burning of fossil fuels. The concentration is now 367 ppmv, 31% higher than the 280 ppm which prevailed before the industrial revolution and, until very recently was increasing at 0.5% p.a. If this were to continue, it would double its pre-industrial value by 2085 AD and double its present value by 2135. However, if the world's population continues to increase at the present rate, the concentration of carbon dioxide may well reach double the present value in the second half of this century.

Future concentrations of atmospheric carbon dioxide will be determined not only by future rates of emissions, which can only be guessed at, but also by how the added CO_2 is partitioned between the atmosphere, ocean and biosphere. During the decade 1940–9, the rate of emission from the burning of fossil fuels and wood is estimated at 63 ± 0.5 GtC/yr (gigatonnes of carbon per year). The atmosphere retained 3.2 GtC (about half of that emitted), leaving 3.4 GtC/yr to be taken up by the oceans and terrestrial biosphere. Models of the ocean carbon balance suggest that it can take up only 1.7 ± 0.5 GtC/yr so that there is an apparent imbalance of 1.4 ± 0.7 GtC/yr. Some scientists believe that this difference can be accounted for by additional uptake by newly growing forests and by the soil, but this is doubtful, and the gap is a measure of the uncertainty in current understanding of the complete carbon cycle. Reliable quantitative estimates of the combined effects of the physical, chemical and biological processes involved, and hence of the magnitude and timing of enhanced greenhouse warming await further research.

Nevertheless, very large and complex computer models of the climate system have been developed to simulate the present climate and to predict the likely effects of, say, doubling to atmospheric concentration of CO_2, or of increasing it at an arbitrary rate. This approach bypasses the uncertainties

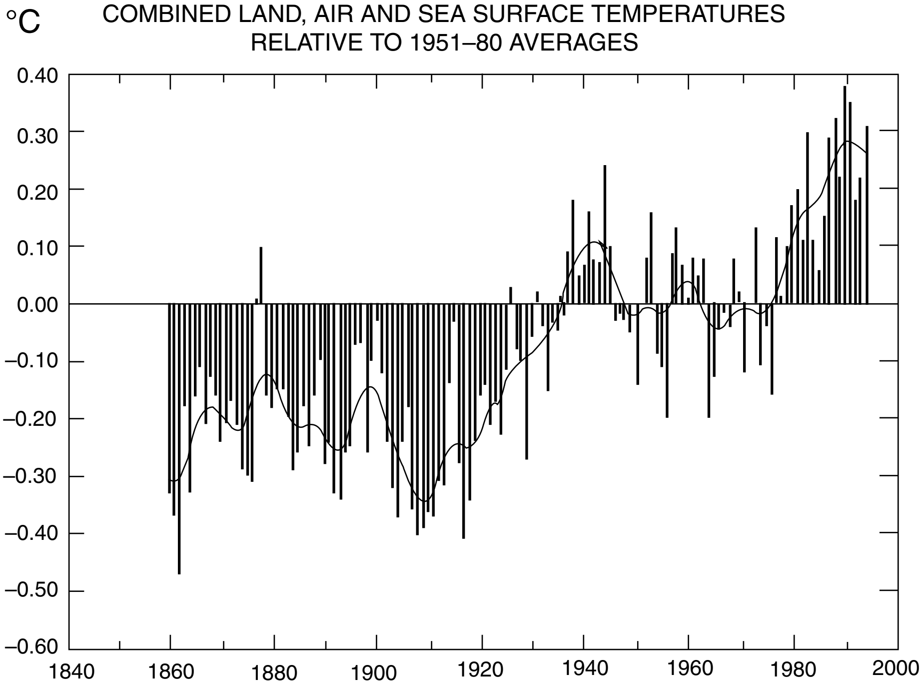

FIGURE 1 Observed changes in the globally-averaged surface temperatures from 1860–1991 relative to the 30-year mean for 1951–1980.

in future emissions and the natural regulation of atmospheric concentrations and is therefore unable to predict *when* the climate changes are likely to happen.

MODEL SIMULATIONS AND PREDICTIONS OF CLIMATE CHANGE

Introduction

Since changes in global and regional climates due to anthropogenic emissions of greenhouse gases will be small, slow and difficult to detect above natural fluctuations during the next 10 to 20 years, we have to rely heavily on model predictions of changes in temperature, rainfall, soil moisture, ice cover, sea level, etc. Indeed, in the absence of convincing direct evidence, concern over an enhanced greenhouse effect is based almost entirely on model predictions, the credibility of which must be largely judged on the ability of the models to simulate the present observed climate and its variability on seasonal, inter-annual, decadal and longer time scales.

Climate models, ranging from simple one-dimensional energy-balance models to enormously complex three-dimensional global models requiring years of scientific development and vast computing power, have been developed during the last 25 years, the most advanced at three centres in the USA and at the UK Meterological Office and, recently, at centers in Canada, France and Germany.

Until very recently, effort was concentrated on developing models (that evolved from weather prediction models) of the global atmosphere coupled to the oceans and cryosphere (sea and land ice) only through prescribing and up-dating surface parameters such as temperature and albedo, from observations. However, realistic predictions of long-term changes in climate, natural or man-made, must involve the atmosphere, ocean play, cryosphere and, eventually, the biosphere, treated as a single, strongly coupled and highly interactive system. The oceans play a major stabilizing role in global climate because of their inertia and heat storage capacity. Moreover, they transport nearly as much heat between the equator and the poles as does the atmosphere. The oceans absorb about half of the carbon dioxide emitted by fossil fuels and also absorb and transport a good deal of the associated additional heat flux and hence will delay warming of the atmosphere.

During the 1980s the UK Meterological Office (UKMO) developed one of the most advanced models of the global atmosphere coupled to a shallow mixed-layer ocean and used this to simulate the present climate and to study the effects of nearly doubling the present level of carbon dioxide to 600 ppmv. A general description of the physical basis, structure and operation of the model, of its simulations and predictions may be found in Mason (1989).

Simulation of the Present Climate

Models of the type just mentioned, the most important computed variables of which are:

E–W and N–S components of the wind
Vertical motion
Air temperatures and humidity

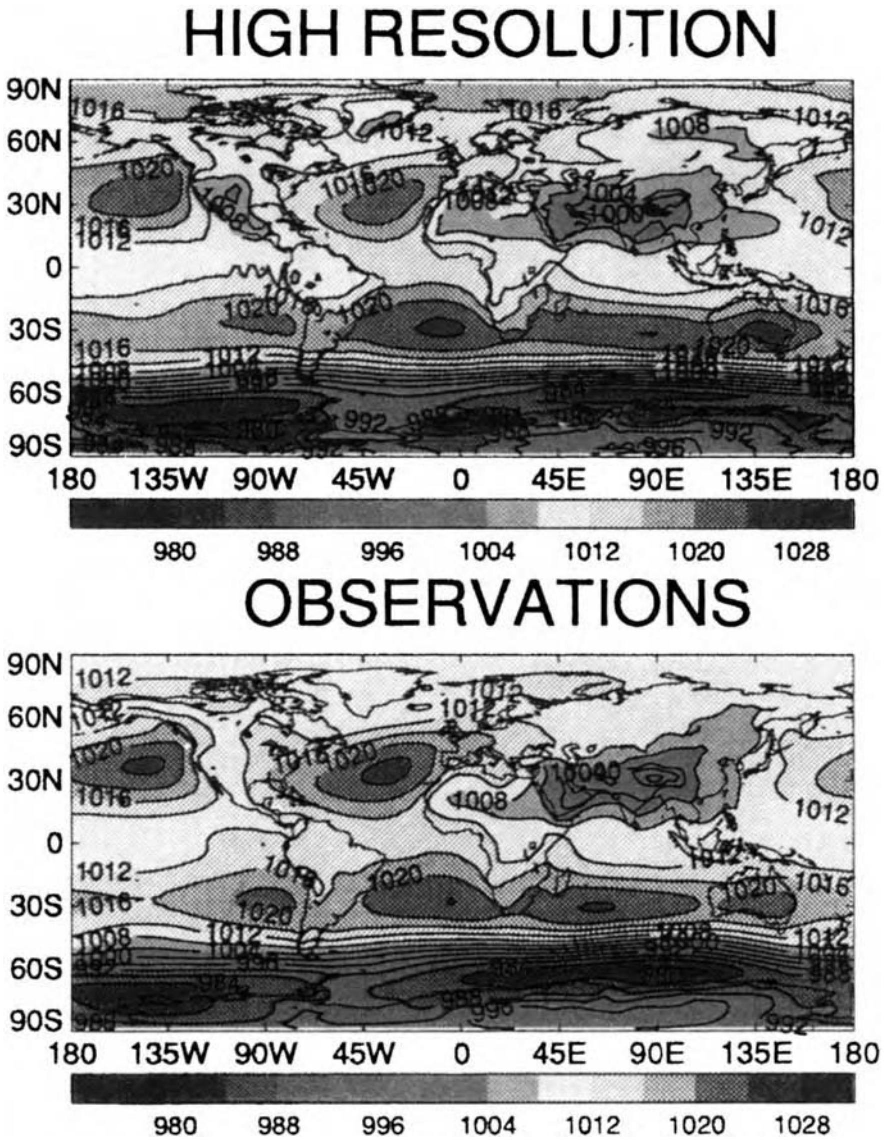

FIGURE 2 Simulation of the global mean surface pressure field for June, July and August by the UKMO climate model compared with observation.

Heights of the 11 specified pressure surfaces
Short- and long-wave radiation fluxes
Cloud amount, height and liquid-water content
Precipitation/rain/snow
Atmospheric pressure at Earth's surface
Land surface temperature
Soil moisture content
Snow cover and depth
Sea-ice cover and depth
Ice-surface temperature
Sea-surface temperature

are remarkably successful in simulating the main features of the present global climate—the distribution of temperature rainfall, winds, etc. and their seasonal and regional variations. They do, however, contain systematic errors, some different in different models, and some common to most. Identification of these errors and biases by comparison with the observed climate is important since these must be taken into account when evaluating predictions. These may not appear to be too serious in making predictions of the effects of a prescribed (e.g., man-made) perturbation since these involve computation of the *differences* between a perturbed and a control (unperturbed) simulation in which the systematic errors may largely cancel. However this linear reasoning may not necessarily be valid for such complex non-linear systems even if the perturbations are small, and the predictions will carry greater credibility if the control runs realistically simulate the observed climate and its variability.

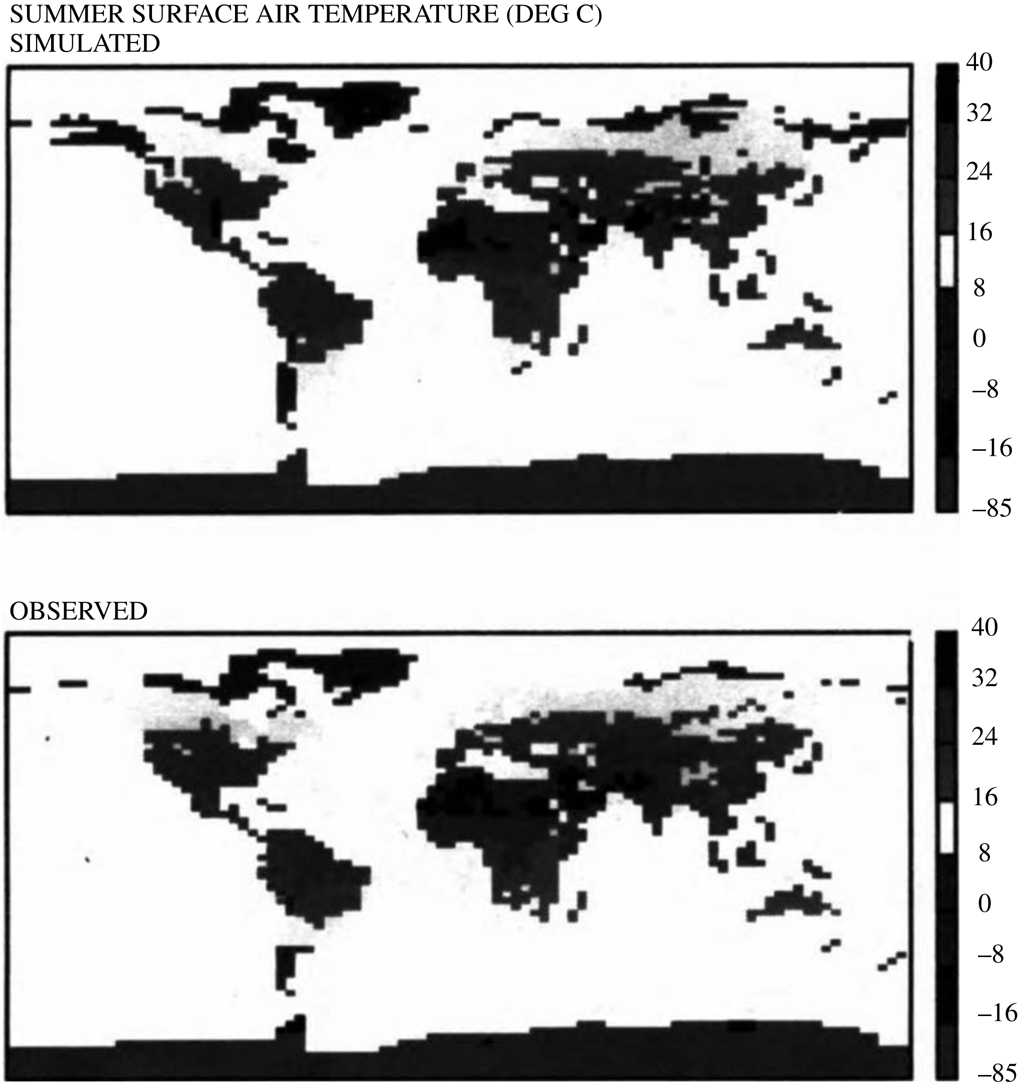

FIGURE 3 Model simulation of the mean near-surface temperatures over land for June, July and August compared with observation.

The main errors in model simulations of the present climate are discussed in IPCC (1992, 1996) and by Mason (2004). Simulations with the best models are close to reality despite the rather low model spatial resolution as illustrated by Figures 2 and 3.

Model Simulations of Ocean Climate

The role of the oceans in influencing climate and climate change is discussed in some detail in Mason (1993). Only the salient facts will be summarised here.

The oceans influence climate change on seasonal, decadal and longer time scales in several important ways. The large-scale transports of heat and fresh water by ocean currents are important climate parameters and affect the overall magnitude, timing and the regional pattern of response of the climate system to external forcing. The circulation and thermal structure of the upper ocean control the penetration of heat into the deeper ocean and hence the time delay which the ocean imposes on the atmospheric response to increases of CO_2 and other greenhouse gases. The vertical and horizontal motions also control the uptake of CO_2 through the sea surface and thus influence the radiative forcing of the atmosphere.

If *ocean models* are to play an effective role in the prediction of climate change, they must simulate realistically the present circulation and water mass distribution and temperature fields and their seasonal variability. Ocean modelling and validation are less advanced than atmospheric modelling, reflecting the greater difficulty of observing the interior of the ocean and of inadequate computer power. They suffer from inadequate spatial resolution, problems in parameterizing sub-grid-scale motions, and in estimating the fluxes of heat, moisture and momentum across the air/sea interface.

When forced with observed surface temperatures, salinities and wind stresses, ocean models have been moderately successful in simulating the observed large-scale circulation and mass distribution, but most models underestimate the meridional heat flux and make the thermocline too deep, diffuse and too warm.

The deeper ocean is also driven, in part, by fluxes of radiant heat, momentum, and of fresh water derived from precipitation, river run-off and melting ice, but measurements of all these are difficult and very sparse at the present time. Different models show considerable differences in their simulations of the deep ocean circulation, but identification of systematic errors is hardly possible because of the paucity of observations. The distribution of temperature and salinity are the primary sources of information for checking model simulations, but it is very difficult to simulate the salinity field because the distribution of sources and sinks of fresh water at the surface is so complex.

Perhaps the most effective way of checking ocean models on decadal time scales is to see how well they simulate the horizontal spread and vertical diffusion of transient tracers such as tritium/He^3 and C^{14} produced in nuclear bomb tests. Current models simulate quite well their shallow penetration in the equatorial ocean and deep penetration in high latitudes but fail to reproduce the deep penetration at 30–50°N, probably because of inadequate resolution of the Gulf Stream and its interaction with the North Atlantic current. The computed poleward transport of heat and the transport across other designated vertical sections can be checked against hydrographic measurements being made from research ships as part of the World Ocean Circulation Experiment, as described in Mason (1993). Some detailed measurements are also being made on the seasonal variation in the depth of the mixed ocean layer and the thermocline that can be compared with the model simulations.

Coupled Atmosphere—Deep Ocean Models

The UKMO has developed a deep global ocean model coupled to its global atmospheric model to carry out long-period climate simulations and to make realistic predictions of climate changes produced by *gradual* increases of atmospheric CO_2 until it reaches double the present value. The results of the first of these enhanced CO_2 experiments, and of similar ones conducted elsewhere, are described in the following section.

Here we summarise the structure and operation of the coupled model, its problems and deficiencies, and the research in progress to overcome them. A more detailed analysis of the first version is given by Murphy (1995). In the latest version, the model atmosphere is divided into 19 layers (20 pressure levels) between the surface and 50 km with 5 levels in the surface boundary layer (lowest 1 km) to allow calculation of the surface fluxes of heat, moisture and momentum. There are also four levels in the soil to calculate the heat flux and hence the surface temperature. The variables listed in the previous section Simulation of the Present Climate are calculated on a spherical grid with mesh 2.5° lat × 3.75° long, about 7,000 points at each level.

The incoming solar radiation is calculated as a function of latitude and season, and diurnal variations are included. Calculations of radiative fluxes at each model level use four wavebands in the solar radiation and six bands in the long-wave infra-red, allowing for absorbtion and emission by water vapour, carbon dioxide, ozone and clouds. Sub-grid-scale convection is represented by a simple cloud model that treats the compensating subsidence and detrainment of air and the evaporation of precipitation. Precipitation is calculated in terms of the water and ice content of the cloud; cooling of the atmosphere by evaporation of precipitation is allowed for. Reduction in wind speed caused by the aerodynamic drag of mountains, oceans waves, and by the breaking of orographically-induced gravity waves are computed. In calculating changes in the extent and thickness of sea ice, drifting of the ice by wind-driven ocean currents is taken into account.

In the land surface model the different soil types and their differing albedos are specified, as are the different types of vegetation, their seasonal changes and their effects on evaporation, albedo, aerodynamic drag.

The ocean model computes the current, potential temperature, salinity, density and the transports of heat and salt at 20 unequally-spaced levels (depths) in the ocean, eight of these being in the top 120 m in order to simulate better the physics and dynamics in the active, well-mixed layer, its seasonal variation, and the surface exchanges of heat, moisture and momentum with the atmosphere. The vertical velocity at the sea floor is computed assuming flow parallel to the slope of the bottom topography specified on a 1° × 1° data set. The horizontal grid, 2.5° × 3.75°, the same as that of the atmospheric model, is too coarse to resolve oceanic meso-scale eddies of scale ~100 km which contain much of the total kinetic energy, but are crudely represented by sub-grid-scale turbulent diffusion and viscosity. The latter has to be kept artificially high to preserve computational stability with the penalty that the simulated currents, such as the Gulf Stream, are too weak. Lateral diffusion of heat and salt take place along ispycnal (constant density) surfaces using diffusion coefficients that decrease exponentially with increasing depth. The coefficients of vertical diffusion are specified as functions of the local Richardson number, which allows for increased mixing when the local current shear is large.

Coupling with the atmosphere is accomplished in three stages. The atmospheric model, starting from an initial state based on observations, is run on its own until it reaches an equilibrium climate. The ocean model, starting from rest and uniform temperature and salinity is also run separately, driven by the wind stresses, heat and fresh-water fluxes provided by the atmospheric model. This spin-up phase of the ocean takes place over 150 years (restricted by available computer time) during which a steady state is achieved in the upper layers of the ocean as they come into equilibrium with the atmospheric forcing. Finally, the ocean is coupled to the atmosphere, sea-ice and land-surface components

and run in tandem with two-way feedbacks between ocean and atmosphere transmitted at five-day intervals. Thus the atmospheric model is run separately for five days with unchanged sea-surface temperatures and sea-ice extents, accumulating relevant time-averaged surface fluxes, which are then used to drive the corresponding time step of the ocean model, following which the updated sea-surface temperatures and sea-ice cover are fed back to the atmosphere for the next iteration. When an internally consistent balance is obtained between all four main components of the climate system, the final state may be taken as the starting point for perturbation experiments such as the doubling of carbon dioxide.

MODEL PREDICTIONS OF CLIMATE CHANGES CAUSED BY DOUBLING PRESENT CONCENTRATIONS OF CARBON DIOXIDE

Introduction

We recall that atmospheric concentrations of carbon dioxide are likely to double by the second half of this century and that simple radiative calculations, allowing only for feedback from the accompanying increases in water vapour, indicate that this might cause the globally and annually averaged surface air temperature to rise by about 1.5°C. Because, as discussed by Mason (1995), many other feedback processes, both positive and negative, operate within the complex climate system, and because their effects are likely to vary with season, latitude and geographical location, firmer estimates can come only from model experiments in which the climate simulated by a model perturbed by the doubling of CO_2 is compared with that from an unperturbed (control) model, the differences being attributed to the enhanced CO_2.

We now compare and discuss the results of two types of experiments, produced by different models. In one set, involving a global atmosphere coupled to only a shallow ocean, the CO_2 concentration is doubled in one step and the climatic effects are assessed after the system has reached a new equilibrium. In the second set, in which the atmosphere is coupled to a multi-layered deep ocean, the CO_2 is allowed to increase at 1% p.a. compound and so doubles after 70 years.

Prediction of Global Mean Changes in the 'Equilibrium' Experiments

All six models cited in Table 1 comprise a global atmosphere with 9–12 levels in the vertical, coupled to a shallow (50 m deep) ocean with prescribed heat transport. The input solar radiation to all models follows a seasonal cycle, but only those marked with an asterisk include a diurnal cycle. All the models have a rather low horizontal resolution and all the experiments were run for <50 years. Furthermore, all of them *prescribe* the cloud amount and height by empirical formulae that relate cloud to relative humidity and are based on satellite observations of cloud. The radiative properties of the clouds (classified into low, medium and high-level categories) are also prescribed and remain fixed during the model simulation.

The predicted globally and annually-averaged increases in surface air temperature due to doubling of CO_2 are remarkably similar, ranging from 4.2°C to 5.2°C with an average of 4.6°C. This is probably because the sea-surface temperatures and sea-ice cover are constrained to be near observed values by adjusting the advective heat fluxes in the shallow ocean. The predicted increase in precipitation,

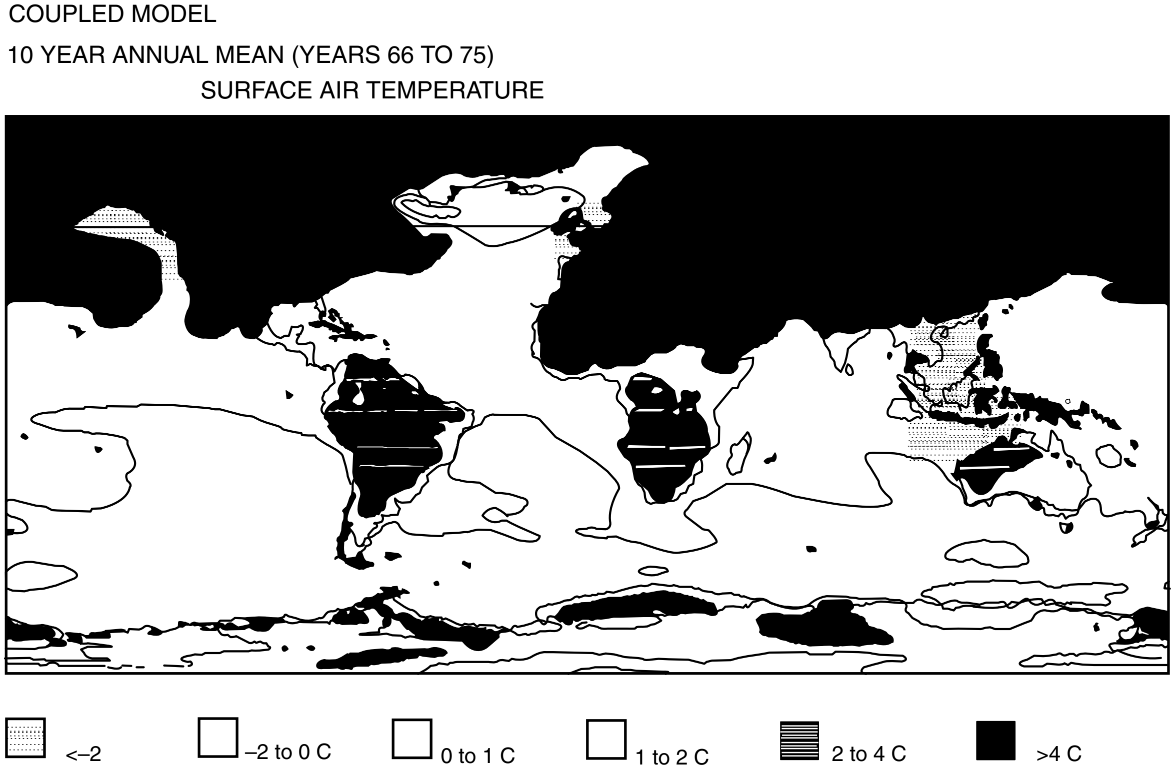

FIGURE 4 Prediction of the UKMO coupled atmosphere—deep ocean model of global warming caused by increasing the concentration of atmospheric carbon dioxide by 1% p.a. compound after 75 years.

not surprisingly, show a greater spread, from 5 to 15% with an average of 10%.

These predictions were not much affected by doubling the horizontal resolution (having the grid spacing). However, they were much more sensitive to the formulation of physical processes, in particular the representation of clouds and their interactions with solar and terrestrial radiation. Model simulations in which the cloud water was *computed* from the model variables and their radiative properties (emissivity, absorptivity and reflectivity) were allowed to vary with the liquid water and ice content produced significantly different results as summarized in Table 1.

The UKMO model, using three progressively more sophisticated and realistic cloud/radiation schemes, has progressively reduced the predicted global warming from 5.2°K to 1.9°K and the corresponding precipitation increases from 15% to 3%. It is important to identify and understand the underlying physical reasons for these results which, if confirmed, are likely to have an important influence on the whole GHW debate.

In the first version of the model, in which cloud cover was related empirically only to relative humidity and the radiative properties were fixed during the whole simulation, enhanced CO_2 produced unrealistic *decreases* in high-, medium- and low-level clouds, except at very high latitudes and, consequently, an exaggerated warming of the atmosphere. Decrease in cloud amount seems inconsistent with the predicted increase in precipitation and suggests that the empirically derived cloud cover was incompatible with the internal dynamics of the model. In the most sophisticated treatment, the cloud water is computed from the dynamical and physical equations; it is transformed progressively from liquid water to ice as the temperature falls below −15°C; rapidly growing ice crystals are allowed to fall out of the cloud; and the radiative properties are varied as a function of the cloud water path and the solar angle for the incoming solar radiation and as a function of the water/ice path for terrestrial long-wave radiation. In this case, enhanced CO_2 leads to a marked *increase* in the extent and optical depth of call clouds, and especially of low clouds in middle and high latitudes, which reflect more of the solar radiation to space and therefore reduce the GHW of the atmosphere to only 1.9°K. The small 3% increase in precipitation is consistent with a 2–3% increase in low cloud cover and a 2% increase in medium-level cloud in the Northern Hemisphere. A more detailed account is given by Senior and Mitchell (1993).

Transient Experiments in Which CO_2 Increases at 1% p.a.

The fact that we now have fully three-dimensional models of the global oceans coupled interactively to the atmosphere, land-surface and sea-ice components of the climate model, enabling

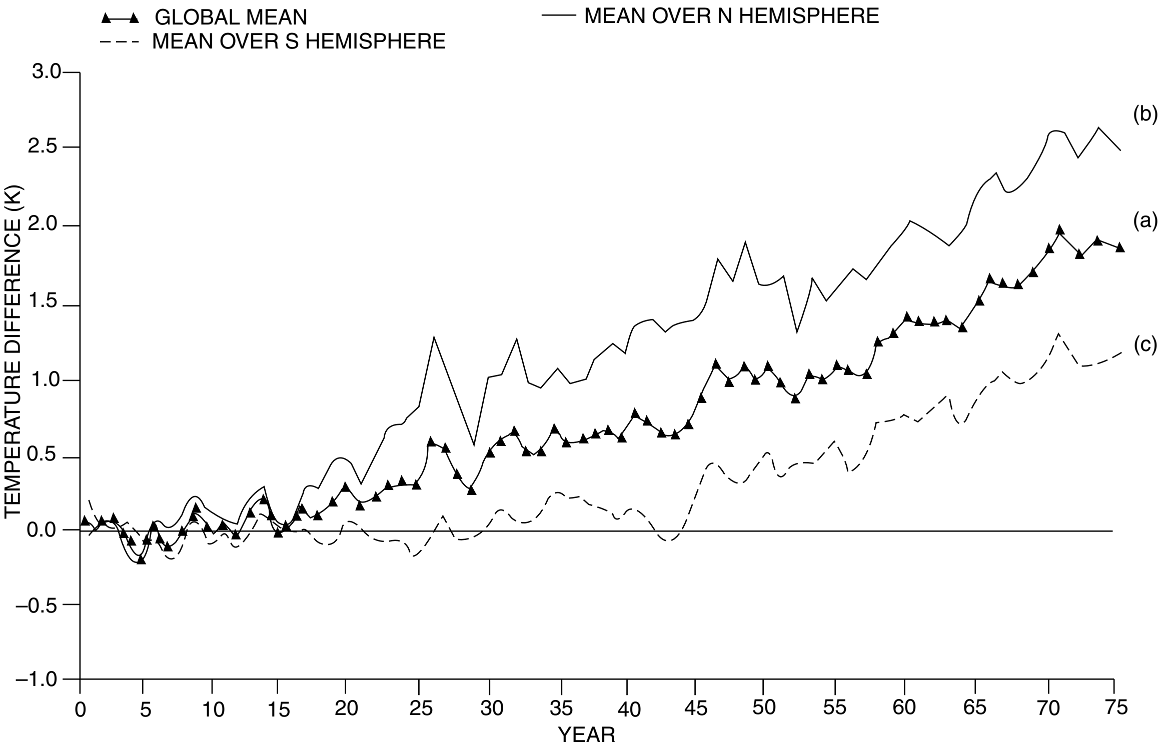

FIGURE 5 Predictions of globally—averaged warming caused by increasing the concentration of carbon dioxide by 1% p.a. compound over 75 years showing the year-to-year changes. The changes for the northern and southern hemispheres are shown separately.

more realistic simulations in which the carbon-dioxide, instead of being doubled in one step, is increased gradually at 1% p.a. compound to double after 70 years. On this time-scale, the atmospheric response will be influenced by changes occurring at depth in the oceans, and especially in the top 1 km.

The first results of such an experiment were published by Manabe *et al.* (1990) from GDFL. The globally and annually averaged increase in surface air temperature was 2.3 K, lower than in earlier models with a shallow ocean. The reduced warming was especially marked in the Southern Hemisphere, which showed little amplification in the Antarctic compared with the Arctic. This is explained by the ocean circulation in the southern oceans having a downward branch at about 65°S, which carries much of the additional 'greenhouse' flux of heat from the surface to depth of >3 km, where it remains for many decades.

Very similar results were produced with the earlier version of the UKMO model by Murphy (1990), Murphy and Mitchell (1995). The annually averaged response in global mean surface temperature to CO_2 increasing 1% p.a. over 75 years is shown in Figure 4, and also in Figure 5, which also shows the results for the hemispheres separately. Averaged over the years '66 –'77, the global mean warming was 1.7°K. The corresponding increase for the Northern Hemisphere was 2.6°K, with warming of >4°K over large areas of the Arctic. The UKMO model, like the GDFL model, shows that the much smaller response of the Southern Hemisphere is due to the transport of heat from the surface to depth in a strong down-welling circulation near 60°S. A similar vertical circulation, caused by melting ice, and penetrating to about 1.5 km depth, occurs at about 60°N in the North Atlantic (see Figure 6). After a slow start, the enhanced global warming settles down at about 0.3 K/decade. Moreover, the model exhibits variability on inter-annual and decadal time-scales; the peak-to-peak variation on the decadal scale being about 0.3°K—of the same magnitude as the predicted signal due to 'greenhouse' warming.

A similar long-term run with a coupled atmosphere—deep ocean model has been carried out at the Max Planck Institute in Hamburg by Cusbasch *et al.* (1992). CO_2 is allowed to increase rather more rapidly to double after 60 years and produces a global mean warming of 1.3°K, the lowest value so far reported.

The transient responses to the doubling of CO_2 by all three models, ranging from 1.3 to 2.3 K, correspond to about 60% of the expected equilibrium response. This implies a lag of about 30 years due largely to the delaying effect of oceans.

The predicted changes in precipitation, though small on average, are far from uniformly distributed. The UKMO model indicates increases in high latitudes of the Northern Hemisphere throughout the year, in middle latitudes

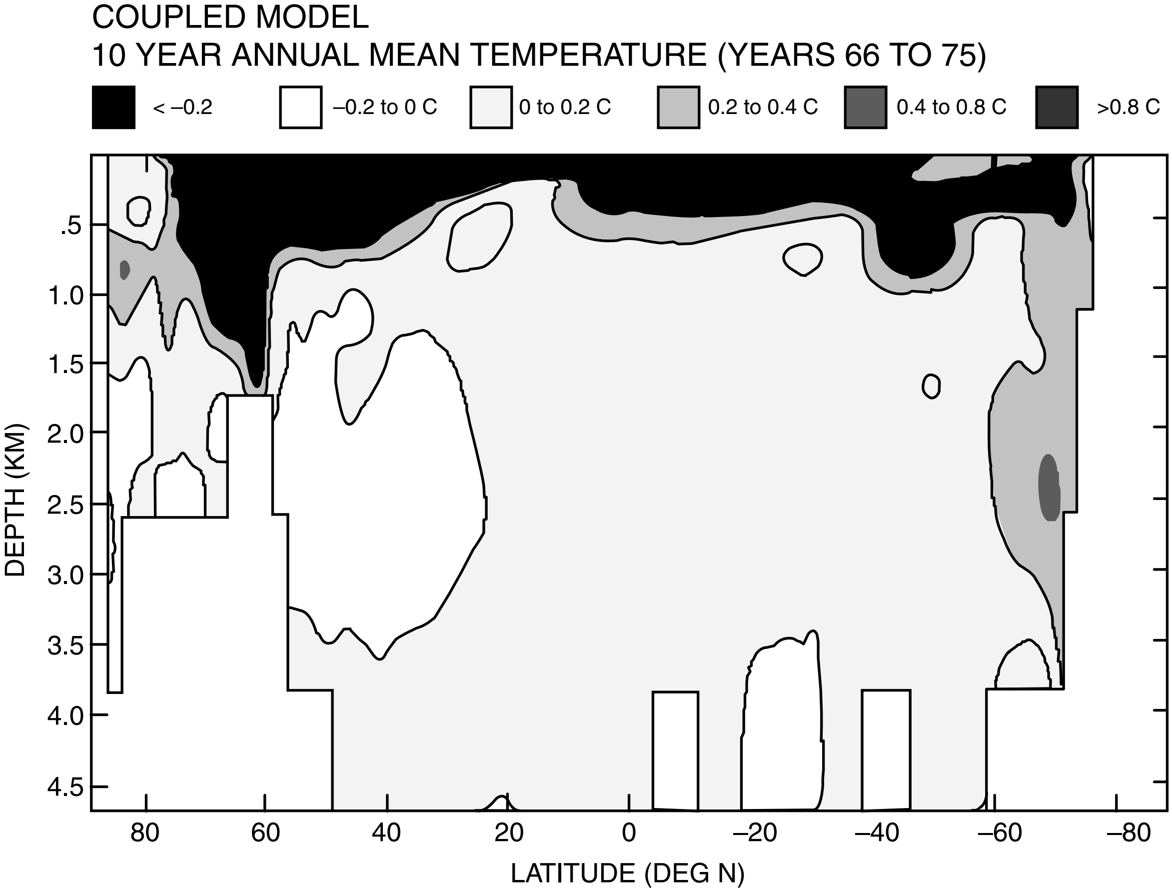

FIGURE 6 Changes in the ocean temperatures averaged around latitude bands and shown as a function of depth after the carbon dioxide has doubled in the model experiment of Figures 4 and 5. These range from about 1°K near the surface to about 0.4 K at 3 km depth near 65°S. (See Color Plate VII)

in winter, and during the S.W. Asian monsoon. In the Southern Hemisphere precipitation increases in the middle-latitude storm tracks throughout the year. Soil moisture is enhanced over the middle latitude continents of the Northern Hemisphere in winter but, in summer, many areas show a deficit mainly because of the earlier retreat of the snow cover under the enhanced temperatures.

Although the four models show broadly similar *global* patterns of response to double CO_2 concentrations, they show marked differences on regional and sub-regional scales, especially in precipitation and soil moisture.

Predictions of globally-averaged changes in temperature, precipitation and soil moisture are of little value in assessing their political, economic and social impact. Although current global models with rather low spatial resolution cannot be expected to provide reliable scenarios in regional and sub-regional scales, the UKMO has been asked to make deductions from its 'transient' CO_2 experiment for Western Europe. The results, which should be treated with caution, may be summarized as follows.

Summer temperatures rise throughout the 70-year experiment, stabilizing at about 0.3°K per decade after year twenty. There is a similar but less steady warming in winter, most pronounced over land. Winter precipitation increases rapidly during the first 30 years (possibly an artefact of an inadequate spin-up period) but thereafter remains rather steady at an average increase of about 0.3 mm/day, the main increases occurring over N. Europe and reductions in S. Europe and the Mediterranean. In summer the precipitation *decreases* by about 0.2 mm/day. The warmer, wetter winters and the slightly warmer drier summers are reflected in the changes of soil moisture.

Since the decadal changes are comparable in magnitude to the decadal variability, the comparable in magnitude to the decadal variability, the confidence in these estimates is low, especially in respect of precipitation and soil moisture changes, which are only marginally significant relative to the variability of the 'control' model, for any single decade.

THE EFFECT OF AEROSOLS

Aerosol particles influence the Earth's radiation balance directly by their scattering and absorption of solar radiation.

They also absorb and emit long-wave radiation but usually with small effect because their opacity decreases at longer wavelengths and they are most abundant in the lower troposphere where the air temperature, which governs emissions, is close to the surface temperature. Aerosols also serve as cloud condensation nuclei and therefore have the potential to alter the microphysical, optical and radiative properties of clouds.

The larger aerosol particles of $d > 0.1$ μm, if produced in large quantities from local sources such as forest fires, volcanoes and desert storms, may significantly influence the radiation balance on local and regional scales, both by scattering and by absorption and emission, especially if they contain carbon particles. However, such particles are rapidly removed from the troposphere by precipitation and are not normally carried long distances. On the global scale, smaller particles of $d < 0.1$ μm are more important, their dominant effect being to cool the atmosphere by scattering solar radiation to space.

Some recent calculations by Charlson *et al.* (1990) of the impact of anthropogenic sulphate particles on the short-wave radiation balance in cloud-free regions conclude that, at current levels, they reduce the radiative forcing over the Northern Hemisphere by about 1 W/m^2 with an uncertainty factor of two. A rather more sophisticated treatment by Kiehl and Briegel (1993) calculated the annually-averaged reductions in radiative forcing due to back-scattering of solar radiation by both natural and anthropogenic sulphate aerosols to be 0.72 W/m^2 in the N. Hemisphere, 0.38 W/m^2 in the southern hemisphere the global value of 0.54 W/m^2 being about half of that calculated by Charlson. However, the high aerosol concentrations over the heavily industrialised regions of the eastern USA, central Europe and South-East Asia produced reduction of >2 W/m^2 that are comparable to the cumulative increases produced by greenhouse gases emitted since the industrial revolution.

In addition to the direct effect on climate, anthropogenic sulphate aerosols may exert an indirect influence by acting as an additional source of effective cloud condensation nuclei, thereby producing higher concentrations of smaller cloud droplets leading to increased reflectivity (albedo) of clouds, especially of low clouds, for solar radiation, which is sensitive to the 'effective' droplet radius

$$r_{eff}\alpha(W/N)^{1/3}$$

where W is the liquid–water concentration of the cloud (in g/m^3) and N is the number concentration of the droplets.

The first calculations of this indirect effect on climate have been made to the UKMO by Jones *et al.* (1994), using their climate model that predicts cloud liquid water and ice content and parameterizes r_{eff} linking it to cloud type, water content and aerosol concentration. The concentration and size distribution of the aerosol, and its spatial distribution are calculated in the same manner as in Kiehl and Briegel but the particles are assumed to consist of ammonium sulphate as being characteristic of aerosol produced in industrially polluted air.

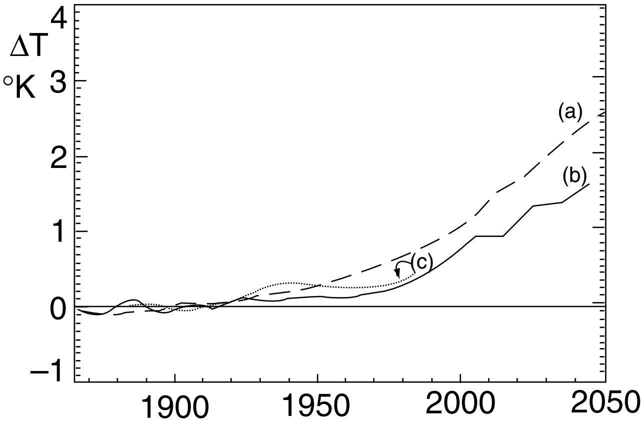

FIGURE 7 Changes in the globally-averaged mean surface temperatures relative to the mean for 1850–1920; dotted curve—observed change since 1880; dashed curve—model computations of the effects of increasing greenhouse gases from 1850–1990 and extrapolated to 2050 AD; solid curve—model predictions of changes caused by both greenhouse gases and aerosols from 1850–2040.

The calculations indicate that the enhanced back-scatter of solar radiation, mainly from low-level clouds in the atmospheric boundary layer, produces an annually-averaged global cooling of 1.3 W/m^2 but that over the highly industrialized regions, where r_{eff} may be reduced by as much as 3 μm, the cooling may exceed 3 W/m^2. However, it must again be emphasized that these calculations contain major uncertainties, probably even larger than those for the direct effect.

Taking them at face value, the calculations of the direct and indirect effects combined, suggest an average global negative forcing of 1.5–2 W/m^2 that may have largely offset the positive forcing of 2.3 W/m^2 by greenhouse gases to-date, and this may be at least part of the reasons for failure to detect a strong greenhouse signal.

The first results of introducing sulphate aerosols into a coupled atmosphere-ocean model come from the UKMO (Mitchell *et al.* 1995). The model, starting from an initial state determined by surface observations in 1860, was run forward to 1990 with no man-made greenhouse gases or aerosols as a control experiment. The model's average global surface temperatures showed realistic inter-annual variations but no overall rise over this period. In the perturbation experiment greenhouse gases were gradually increased from 1860 to reach a 39% equivalent increase in CO_2 by 1990; this resulted in a temperature rise of 1°C compared with an observed rise of only 0.5°C, (Figure 7). The next step was to compute the effects of sulphate aerosols with best estimates of concentration and geographical distribution. The direct effects of increasing the back-scatter of solar radiation was to reduce the warming between 1860 and 1990 to only 0.5°C, very close to the observed, but over and downwind of the highly industrialized regions of North America, Europe and Southern Asia, the aerosols largely nullify the warming caused by the greenhouse gases.

When the coupled model runs were carried forward from 1990 to 2050, increasing the CO_2 by 1% p.a. compound, the effect of aerosols was to reduce the global greenhouse warming from the 0.3°C/decade shown in Figure 5 to only 0.2°C/decade, and to largely offset it in highly polluted regions.

More reliable estimates of the effects of aerosols on climate must await much better observational data on the sources, concentration, size, chemical composition and spatial distribution of both natural and anthropogenic aerosols, including strongly absorbing carbonaceous particles, and dusts, and on the difference between droplet concentrations and sizes in clean maritime and polluted continental clouds. These data will be difficult and expensive to acquire; meanwhile, we are likely to have too many theories and computations chasing too few observations.

When aerosol particles are injected into the stratosphere, they remain there for much longer periods and become much more uniformly distributed than in the troposphere. Concentrations remained consistently high in the 1980s relative to earlier decades, largely due to the El Chichon volcanic eruption in 1982. Recently they were much enhanced by the Mt. Pinatubo eruption in June 1992 which injected about 20 million tons of SO_2 directly into the stratosphere. The consequent reduction in radiative forcing at the top of the atmosphere, estimated at 4 W/m^2, would have required the surface to cool by about 1°C in order to restore equilibrium. The fact that the temperature fell by only 0.3–0.5°C during the following two years may be due partly to absorption of radiation and infra-red emission by the aerosols, to the thermal lag of the oceans and to other negative feedbacks in the system.

SEA-LEVEL RISE

A potentially important consequence of greenhouse warming is the melting of sea-ice and ice sheets on land, only the latter resulting in a rise in sea level. The sea level will also rise as the ocean waters expand in response to the additional warming. Estimates of these consequences involve large uncertainties because of the lack of observations and understanding of the mass balance and dynamics of glaciers and ice sheets. These uncertainties are compounded by the uncertainty in the predicted increases in surface temperature due to greenhouse warming.

Over the past 100 years, the sea level is estimated to have risen about 10 cm. Thermal expansion of the ocean waters has probably been responsible for 4 cm of this rise, melting of mountain glaciers for 4 cm, and melting of the Greenland ice sheet for 2.5 cm. Glaciologists believe that there has been little, if any, overall melting of the Antarctic ice sheet because the air temperatures are too low.

If air and surface temperatures were to increase because of greenhouse warming, thermal expansion of the oceans and melting of mountain glaciers are likely to continue to make the largest contribution to sea-level rise. We have seen that globally coupled atmosphere deep ocean models predict that, when the atmospheric concentrations of carbon dioxide approaches double the present value, the average surface air temperature will increase by 0.3°C/decade. The best estimate of the corresponding rise in seal-level is 4 cm/decade, about half resulting from expansion of ocean waters and half from melting of landbased ice. These estimates, which may conceivably be in error by a factor of two either way, imply serious consequences for low-laying, highly populated areas such as Bangladesh, but they are very much smaller than the wildly exaggerated values that have appeared in the media.

UNCERTAINTIES IN MODEL PREDICTIONS

In summarising the current state of knowledge and understanding of the likely magnitude, timing and impacts of enhanced greenhouse warming, it is virtually certain that the troposphere is warming very slowly in response to the continually increasing concentrations of carbon dioxide and other greenhouse gases, but the signal is as yet barely detectable above the large natural climate variations, probably because it is being delayed by the large thermal inertia of the oceans and has also been masked by the cooling effect of man-made aerosols.

Predictions of the increase in globally averaged temperature that may result from a doubling of carbon dioxide have recently converged towards lower values ranging from 1.3°C to 2.3°C, based on coupled models with a deep ocean. However, this trend may be deceptive because only a small number of 70–100 year simulations have been published and considerable problems and uncertainties remain, both in the atmospheric physics and in the ocean dynamics. These arise largely from the sensitivity of the models to the simulation of clouds and their interaction with the radiation fields, the uncertainty as to how well they simulate the ocean circulation, and the necessity to adjust the ocean surface fluxes in order to ensure that the ocean temperature and salinity remain close to present-day climatology and that the control model climate does not drift during long runs. Long-term drift in the climate of the Southern Hemisphere arises from an imbalance in the heat budget of the Antarctic leading to a spurious slow-melting of the ice. This has now been corrected and changes in the pack-ice are now included. Another important defect of current low resolution ocean models is that they do not capture narrow features such as the Gulf Stream and Kuroshio currents and the regions of strong upwelling off South Africa and South America, all of which play an important role in heat transport. Some tests with higher resolution (1.25° × 1.25°) in the UKMO model improved this situation but only partially. The fact that current models have only limited success in simulating and predicting such a spectacular event as the El Nino is also evidence of defects in the treatment of atmosphere-ocean interactions. There is also a need for an improved representation of atmospheric boundary layer.

Even if the various models agree quite well on the globally-averaged effects, they show larger differences on regional and sub-regional scales, which are politically and economically more relevant. Further improvements in model development will require higher spatial resolution, especially in the oceans, better model physics, much faster computers and, above, all, an adequate supply of global observations from both the atmosphere and the oceans, to feed and validate the models, and to monitor the actual changes in climate that may eventually become evident.

The need for observations from both the surface and the interior of the oceans, and how they might be provided by new and advanced technology, are discussed by Mason (1993).

Despite these uncertainties and the fact that a doubling of CO_2 will cause an increase of only $\backsim$3% in the downward flux of infra-red radiation from the greenhouse gases, future predictions of the resulting globally-averaged temperature rise are unlikely to lie outside the range 1°C to 2.5°C. However, the models provide little guidance as to when these events are likely to occur. Their timing will be determined largely by the very uncertain future global emissions of greenhouse gases and their retention in the atmosphere. We must also realise that no existing climate model incorporates the carbon cycle in which exchanges of CO_2 between the earth's surface and the atmosphere are dominated by terrestrial and especially marine biology, man-made emissions being only about 3% of the natural two-way exchanges. We are always faced with having to compute small differences between large quantities whose magnitudes are uncertain. Given this and the complexity of the models, it is remarkable that they simulate the climate and its variability as well as they do, but there is a tendency to infer more from model predictions than their input data, spatial resolution and simplified physics can justify.

The latest version of the UKMO model has 38 pressure levels in the atmosphere, 20 levels in the ocean, where the horizontal grid spacing is reduced to 1.25° × 1.25°, obviating the need for artificial flux corrections at the ocean/atmosphere interface. Representations of the radiative effects of clouds, of atmospheric convection and of the drag exerted by mountain-induced gravity waves have all been improved. The model now remains stable when run for 1,000 years and shows no long-term drift in the global climate. Changes are calculated at about one million grid points so that computation of one annual cycle of the global climate involves about 10^{15} numerical operations.

When estimates of the radiative effects of greenhouse gases and aerosols prevailing in the years 1860 to 2000 were inserted in the model the predicted increase in the mean global near-surface air temperature T_s was 0.7°C in very good agreement with observation. When the model run was continued to Y2100, during which time CO_2 emissions were assumed to increase from the present value of 6.3 GtC/yr to 13.3 GtC/yr and the atmospheric concentration to almost double from 365 to 620 ppm, T_s was predicted to rise by 3.0°C relative to 1860, or 2.3°C relative to Y2000. The corresponding rise in global sea-level was 34 cm.

If the CO_2 concentration was assumed to increase at 1% pa to double after 70 years to 730 ppm, the predicted rise in T_s was 1.9°C. Similar experiments elsewhere with comparable models gave values between 1.1° and 3.1°C with an average of 1.8°C.

HAZARDOUS GASES: see PREVENTION OF TOXIC CHEMICAL RELEASE

GROUNDWATER RESOURCES

Water plays a vital role in sustaining the existence of all living things. The importance of managing the different aspects of the water, including its quantity, quality, transport processes, utilization, and management becomes apparent when the supply of water, especially potable water, is limited. This article is intended to be an introduction of the subject of groundwater. It includes a historical perspective of development, well hydraulics, the quality aspect, and a number of remediation technologies.

It has been estimated that approximately 300 million cubic miles of water exist on the earth at different locations and in different states phases. From Table 1, it can be seen that the ocean forms about 97% of the earth's water as saline water. The remaining 3% is freshwater. This freshwater supply would be quickly depleted if it were not for its endless interaction and exchange with the ocean. This movement of the earth's waters, known as the *hydrologic cycle,* is shown schematically in Figure 1. Due to the complexity of the hydrologic cycle, not all of the components can be determined easily. A detailed discussion on the subject is presented by the United Nations Educational, Scientific, and Cultural Organization (UNESCO) (USSR National Committee for the International Hydrological Decade, 1978). On a long-term average basis, the total freshwater supply is to be considered constant. Therefore, the budget equation for freshwater can be expressed as:

$$[\text{Total precipitation}] = [\text{Evaporation}] + [\text{Transpiration}]$$

Here, the freshwater is found in the atmosphere as water vapor; on the land as water, dew, snow, and ice; and in the ground usually in the form of water. Approximately 99.5% of all the Earth's water is in a form or location unavailable for use (see Table 1), leaving only about 0.5% of the earth's water remaining for consumption. The largest source of available water is groundwater, which forms an important part of the water supply for municipalities, agriculture, and industry. For instance, in the United States, approximately 50% of the total water usage is from groundwater, while over 90% of the world's potable water supply is derived from groundwater. Thus, groundwater is one of the most important natural resources. Groundwater occurs in the saturated zone of water-bearing soils. However, it may also be found in sedimentary deposits, fissures in igneous rocks, limestone caverns, and other water-bearing sources, which may lie near the surface or hundreds of feet beneath the surface. The subject of groundwater is addressed by a variety of disciplines, including hydrology, geology, and hydraulics.

In general, hydrologists and engineers are concerned with the long-range yield from watersheds and aquifers. Yield is a function of watershed storage capacity and the supply, which fluctuates with time. Typical means of groundwater removal are shown in Figure 2. It is of paramount importance to ensure enough supply to last through drought periods. Currently, accurate prediction of drought phenomena is difficult and unavailable, as indicated by the National Research Council. The subject is still an active research in water-resource engineering. Because of the cost of well drilling, it is desirable to have some assurance that the water-supply well will reach a satisfactory aquifer. In order for the hydrologist or engineer to obtain an appreciation of groundwater flow, he/she must understand that the notion of "safe yield" in groundwater is the quantity of groundwater that can be withdrawn without impairing its quality.

HISTORICAL NOTES

A long time passed in the history of man before the concept of the hydrologic cycle was established. Groundwater has been used since ancient times. Plato wrote about rainfall, runoff, and the infiltration of source water as the source for springs. Aristotle recognized the hydrologic cycle, including evaporation, condensation, streamflow, infiltration, and the reappearance of groundwater as springs. Among the early investigations of the hydrologic cycles and groundwater flow, the contributions of Leonardo da Vinci, Bernard Palissy, Claude Perrault, Edme Mariotte, Edmond Halley, and La Metherie are of particular note.

In 1856, studying the movement of water through sand, Henry Darcy developed the celebrated Darcy's Law, that is, the velocity of percolation as a function of permeability and hydraulic gradient. Darcy's Law provides the basis for a quantitative method used in groundwater evaluation. Most of the developments centered in this period on the problems of well hydraulics and well-field design. A detailed account of Darcy's contributions and life history is presented in a recent publication (Brown, Garbrecht, and Hager, 2003). During the late nineteenth and twentieth centuries, Boussinesq, Dupuit, Theim, Forchheimer, and many others laid an analytical foundation for the subject. Their contributions encompassed a large number of analytical solutions for which equations

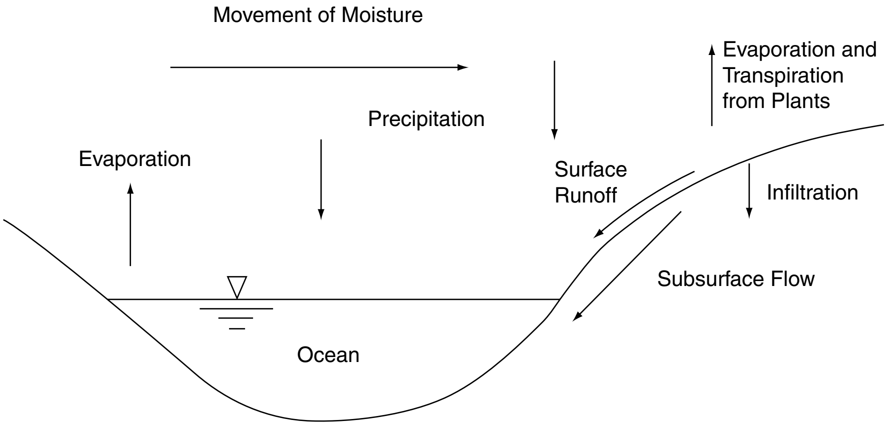

FIGURE 1 The hydrologic cycle.

TABLE 1
World water distribution

Form of Water	Area Covered (km^2)	Volume (km^3)	Share of World Reserves (%)	
			of Total Water Reserves	of Fresh Water Reserves
World ocean	361,300,000	1,338,000,000	96.5	—
Groundwater	134,800,000	23,400,000	1.7	—
Predominantly fresh groundwater	134,800,000	10,530,000	0.76	30.1
Soil moisture	82,000,000	16,500	0.001	0.05
Glaciers and permanent snow cover	16,227,500	24,064,100	1.74	68.7
Antarctica	13,980,000	21,600,000	1.56	61.7
Greenland	1,802,400	2,340,000	0.17	6.68
Artic islands	226,100	83,500	0.006	0.24
Mountain areas	224,000	40,600	0.003	0.12
Ground ice in zones of permafrost strata	21,000,000	300,000	0.022	0.86
Water reserves in lakes	2,058,700	176,400	0.013	—
Freshwater	1,236,400	91,000	0.007	0.26
Saltwater	822,300	85,400	0.006	—
Marsh water	2,682,600	11,470	0.0008	0.03
Water in rivers	148,800,000	2,120	0.0002	0.006
Biological water	510,000,000	1,120	0.0001	0.003
Atmospheric water	510,000,000	12,900	0.001	0.04
Total water	510,000,000	1,385,984, 610	100	—
Total freshwater	148,800,000	35,029,210	2.53	100

bear their names. In the United States, significant works in field, laboratory, and analytical studies were made by Slichter, Meinzer, Theis, Jacob, Hubbert, Hantush, and Muskat, to name a few. The major achievements of the subject, up to the 1950s, have been summarized by Ferris and Sayre (1955).

In the second half of the twentieth century, a considerable body of highly scientific knowledge and sophisticated technology were developed. However, the most important impact is perhaps the invention and proliferation of the digital computer as a tool for performing difficult and tedious computation, which has led to the new computational methods capable of analyzing complex systems. First, an extensive investigation has gone into the different aspects of the chemical processes in groundwater and biodegradation in the subsurface system, among others. Second, a number of solute-transport models have become available, such as the USGS MOC (U.S. Geological Survey method of characteristics) series and the USGS MODFLOW-2000 (modular finite-difference flow model), to name a few. As a result, analysis, planning, and development of large-scale problems can be achieved. Thus far, studies of groundwater resources have made tremendous strides. Major developments include economical use, environmental considerations, and man's effect on the groundwater resource.

WELL HYDRAULICS

Well hydraulics is the most important single element in groundwater-resources engineering. Wells are drilled either for abstraction or observation purposes. Abstraction wells, or pumping wells, are drilled and developed to achieve the optimum output quantity of groundwater, while observation wells are for evaluation of the aquifer characteristics. Equations of well hydraulics under steady and unsteady conditions with specific geologic settings (i.e., confined, unconfined, leaky, and fractured) and their specific boundary conditions can be formulated by fluid-dynamics equations when used in conjunction with Darcy's Law. For practical purposes, most solutions have been reduced to graphical form (Lohman, 1972), tables (Hantush, 1964), or computer programs (Appel and Reilly, 1994). Here, the case of unsteady flow to a well in a confined aquifer (unsteady artesian well) is presented because of its fundamental characteristic and importance in practical applications. A variety of solutions to well hydraulics for other aquifer-pumping and well conditions are available in standard texts (e.g., Todd and Mays, 2005; Bear, 1979).

In the derivation of the nonequilibrium drawdown equation for an aquifer, it is assumed that the release of water occurs instantaneously and that any compaction occurs only in the aquifer. If the aquifer is a limestone formation, such compaction is not too likely to occur. On the other hand, if the aquifer is a clay formation, it will compact quite readily when it loses its moisture content. Thus, before controlled withdrawals are put into effect, the ground levels can subside substantially. For example, the subsidence of Mexico City was caused by the compaction of the clays overlying the limestone formation from which water was drawn. In any case, if compaction does occur, the storage coefficient will vary. Since the variation of the storage coefficient is rather slow, it can be considered a basic property of the soil for most purposes. Assumptions are summarized as follows (see Figure 3):

1. The aquifer is horizontal and infinite in extent in all directions.
2. Pumping starts instantaneously, at a rate Q.
3. Darcy's Law is valid.

The discharge of groundwater flow can be evaluated by Darcy's equation:

$$Q = KiA \tag{1}$$

where Q is the discharge flow rate, ft^3/d; K is the hydraulic conductivity, ft/d; i is the hydraulic gradient; and A is the

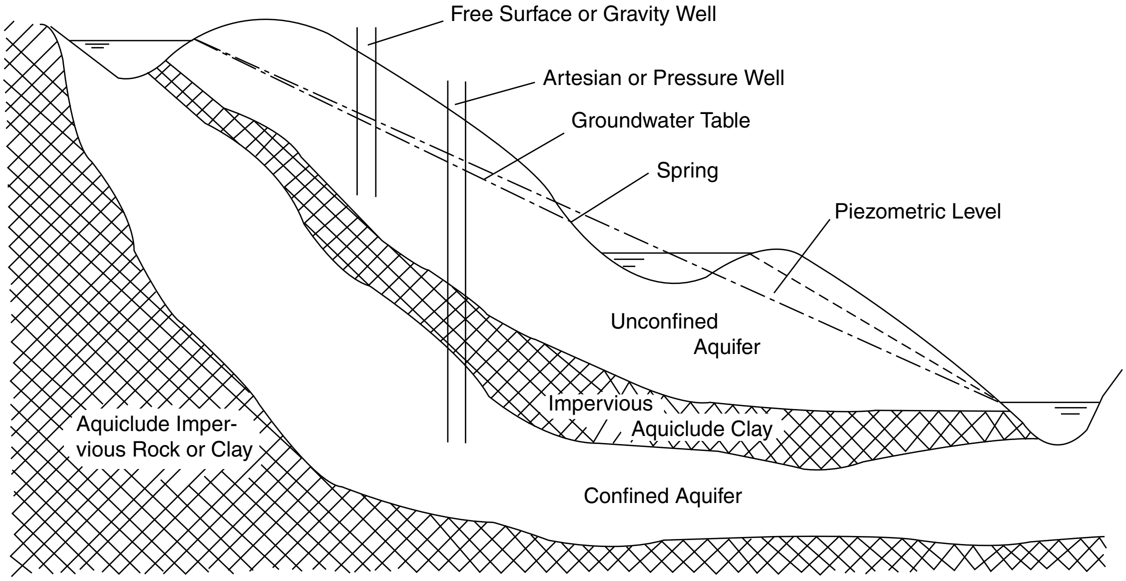

FIGURE 2 Types of groundwater withdrawal.

area through which flow occurs, ft^2. From the basic mass balance equation, the resulting expression of nonequilibrium (transient) flow forward wells can be written as follows:

$$\frac{1}{r}\frac{\partial s}{\partial r}+\frac{\partial^2 s}{\partial r^2}=\frac{S}{T}\frac{\partial s}{\partial t}, \qquad T = Kb \tag{2}$$

where s is drawdown, ft; S is the storage coefficient; T is the transmissibility, ft^3/d per ft; r is the radial coordinator, ft; and t is the time, days. The solution for Equation (2) with the pertinent initial and boundary conditions is given as

$$s=\frac{Q}{4\pi T}\int_{-u}^{\infty}\frac{e^{-u}}{u}\,du=\frac{Q}{4\pi T}W(u), \qquad u=\frac{S}{4T}\frac{r^2}{t} \tag{3}$$

where $W(u)$ is known as the "well function," whose values can be obtained from a standard mathematical handbook. Equation (3) is called the Theis equation and is the expression for the drawdown for radial flow to a well. It is perhaps the most widely used equation for the field determination of transmissibility and the storage coefficient. However, due to the mathematical difficulties involved, several approximate techniques have been developed.

The Theis Method

This is simply the graphical solution of Equation (3), also known as the type-current method. The Theis equation can be rewritten in the form

$$\frac{W(u)}{u}=\frac{16\pi T^2}{QS}\frac{s}{(r^2/t)} \tag{4}$$

By plotting $W(u)$ versus u and s versus r^2/t on log-log scales, respectively, and then overlapping these two curves with

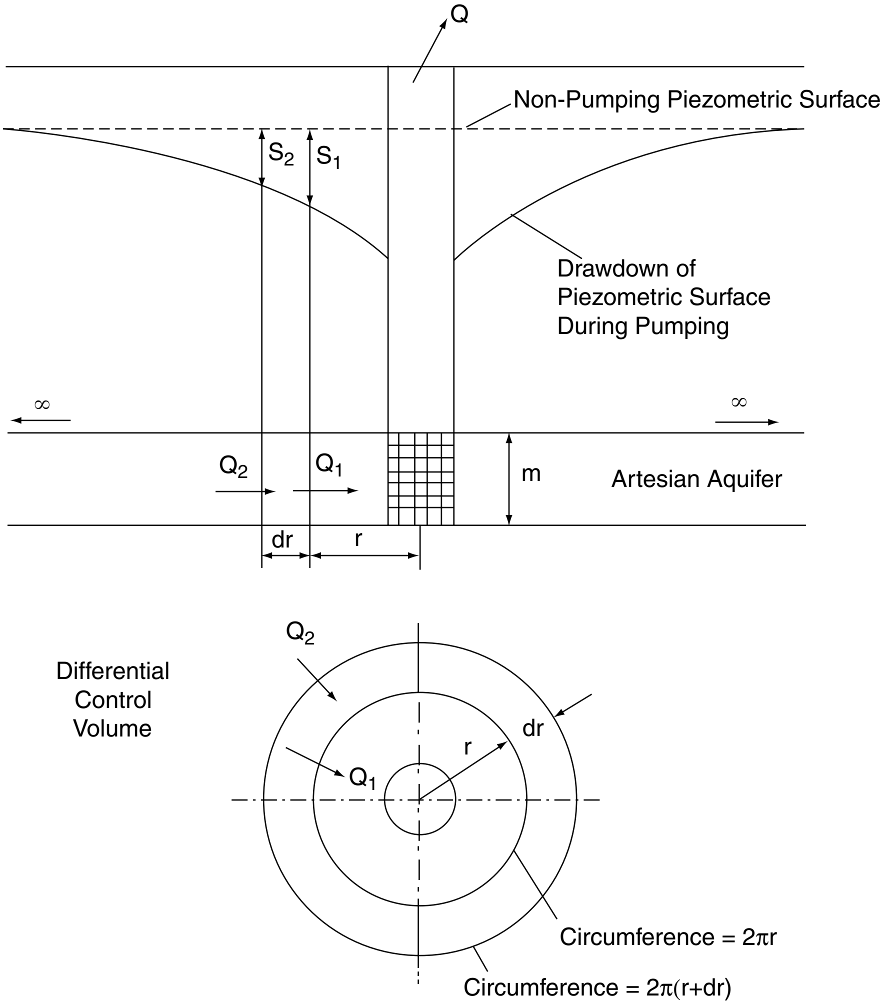

FIGURE 3 Definition sketch for the derivation of the nonequilibrium Theis equation.

their coordinate axes parallel as shown in Figure 4, the values of $W(u)$, u, s, and r^2/t may be obtained for the center of the matching segments. Then, T and S can be calculated as follows:

$$T = \frac{Q}{4\pi s} W(u) \qquad \text{and} \qquad S = \frac{4uT}{(r^2/t)}$$

The Jacobs Method

This method involves a simplification of the well function. Assume that a test well is being pumped at a rate Q with two observation wells located at r_1 and r_2 in a radial direction from the test well. As the test well is pumped, the drawdowns and times of drawdowns are observed for the two observation wells. The difference of drawdowns between the two observation wells can be obtained as follows:

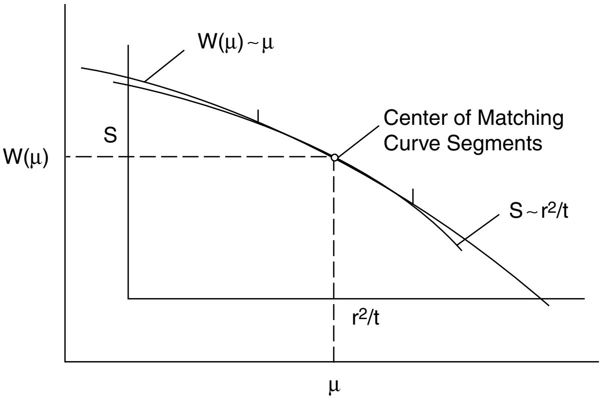

FIGURE 4 Application of Theis method.

$$\begin{aligned} s_2 - s_1 &= \frac{2.3Q}{4\pi T}\left(\log_{10}\frac{0.3Tt_2}{r_2^2 S} - \log_{10}\frac{0.3Tt_1}{r_1^2 S}\right) \\ &= \frac{2.3Q}{4\pi T}\log_{10}\frac{r_1^2/t_1}{r_2^2/t_2} \end{aligned} \tag{5}$$

where the subscripts 1 and 2 refer to the observation wells. Now, if there exists only one observation well (i.e., $r_1 = r_2$), the subscripts now refer to the time at which observations are made and recorded. Then the above equation can be reduced to:

$$s_2 - s_1 = \frac{2.3Q}{4\pi T}\log_{10}\frac{t_2}{t_1} \tag{6}$$

The above equation can be used to evaluate T from field data. For a constant Q, drawdown versus time can be plotted on a semi-log scale as shown in Figure 5. If $t_2/t_1 = 10$, then the transmissivity, T, can be calculated as follows:

$$T = \frac{2.3Q}{4\pi(s_2 - s_1)} \tag{7}$$

If it is assumed the drawdown began at some time, say t_0, the storage coefficient, S, can be determined as

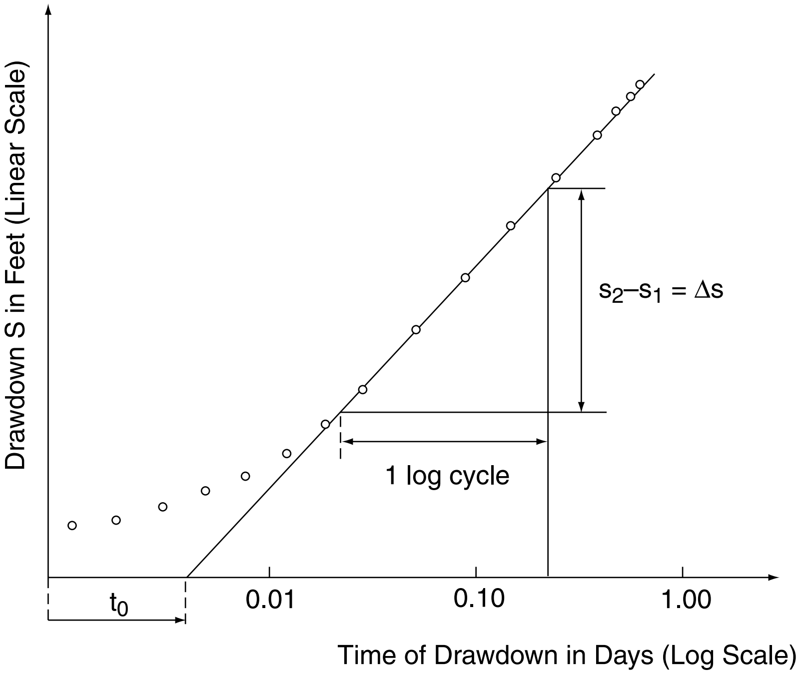

FIGURE 5 Application of semi-log drawdown curve—Jacobs method.

$$S = \frac{0.3Tt_o}{r^2} \tag{8}$$

In order to account for some of the different situations encountered in the field, modification to the basic equations may be necessary by incorporating the well friction losses in the form

$$\text{well friction losses} = kQ^n \tag{9}$$

when $n = 2$ is generally used. The total loss can be expressed as

$$s''_w = s'_w + kQ^2 \tag{10}$$

where

$$s'_w = Cs_w \tag{11}$$

and

$$s_w = \frac{2.3Q}{4\pi T}\log_{10}\frac{0.3Tt}{r_w^2 S} \tag{12}$$

where coefficient C is a gross measurement of the degree of well screen penetration, flow curvature, the radius of the well itself, and the anisotropy of the permeability of the aquifer. It can be evaluated by making field tests at the site.

True equilibrium between the rate of withdrawal and the rate of replenishment is seldom, if ever, achieved. However, a state of quasi-equilibrium can sometimes be attained through several means. For example, replenishment may be by a stream located near the point of withdrawal or, in the case of artesian aquifers, by rain falling on an exposed portion of the aquifer miles away or by rainwater infiltrating to the groundwater in the near vicinity of the well.

QUALITY CONSIDERATION

While the quantity of available groundwater and its movement are still of increasing interest to engineers and scientists, the solutions for well hydraulics represent the quantitative aspect of groundwater resources. It is now recognized that the quality of groundwater is equally important. A major effort has been made by environmental engineers and scientists throughout the world on water quality. In this and the following sections, the quality aspect and remediation considerations are introduced. From a practical standpoint, the quality of any water is a relative term. Water that is of good quality for an industrial-cooling purpose may be of unacceptable quality as a drinking-water source. Generally, water-quality considerations are related to chemical, biological, and radiological content and temperature, and are based on the intended use.

As water moves through the hydrologic cycle, its quality is altered. Rainwater, which was considered a "pure" substance, is not pure at all. When rainfall reaches the ground surface, it contains dissolved gases (CO_2, O_2, N_2, NO_2, NH_3, CO, SO_2, H_2S, etc.) as well as other dissolved materials. The expression "acid rain," for example, is familiar to most people.

As water reaches the soil, its quality changes further. As water percolates through the biologically active soil mantle, organic material, both suspended and dissolved, is removed due to aerobic bacterial action. Filtration occurs, as do ion exchange and adsorption. Thus, by the time water has reached the level of rock, a great deal of the organic material, effectively all of the suspended material, and some of the dissolved inorganic material have been removed. However, inorganic material may also have been added to the water, due to ion-exchange reactions and chemical equilibrium. For example, ammonia dissolved in the rainwater or present in the soil will be oxidized by soil bacteria to nitrate, and the nitrate will be released into the water and carried downward to the water table. As the water moves through rock strata, it picks up inorganic matter as part of dissolution action. This dissolving action is responsible for the relative hardness of most groundwater. It is also responsible for the formation of caves and caverns, especially in limestone ($CaCO_3$) strata. The natural changes in groundwater quality may be seen in Figure 6.

In accordance with their genesis, therefore, there are two different sources of pollutants in the groundwater system: (1) the dissolved chemicals from the geologic formation, and (2) the man-made wastes. The movement of groundwater, as a carrier of the dissolved chemical mass, gives rise to many of the reaction-transport processes that occur in the subsurface. In many geologic processes, groundwater plays a critical role in the formation and dissolution of certain ores and hydrocarbon deposits. For a detailed discussion, the reader is referred to Phillips (1991) and Ingebritsen and Sanford (1998). On the other hand, the dissolved chemicals from man-made waste become a primary source of pollutants in the groundwater system. Groundwater hydrologists are interested in the quality of existing groundwater resources and the effect that human influence will have on the quality of groundwater.

Human influence on the quality of groundwater results primarily from activities that generate wastes. (There are some exceptions, such as nitrates in water due to fertilizers, and saltwater intrusion due to pumping of aquifers.) There are many potential sources of environmental contamination, including agrochemicals, industrial effluents, storage-tank leaks, seepage from disposal sites for toxic substances, and petroleum-product spills. It has been estimated that the amount of hazardous waste generated annually is 264 million metric tons in the United States alone. The enormous amount of hazardous waste that has accumulated over the years makes this figure even more astounding. It is reported that only 10% of the waste generated prior to 1980 was disposed of by practices that would be considered adequate according to current standards. Thus, as much as 90% of the hazardous waste was disposed of at unregulated facilities. These irresponsible disposal practices have created over 22,000 sites containing unregulated hazardous waste in United States. The improper disposal of hazardous waste has caused a number of serious problems that not only result in

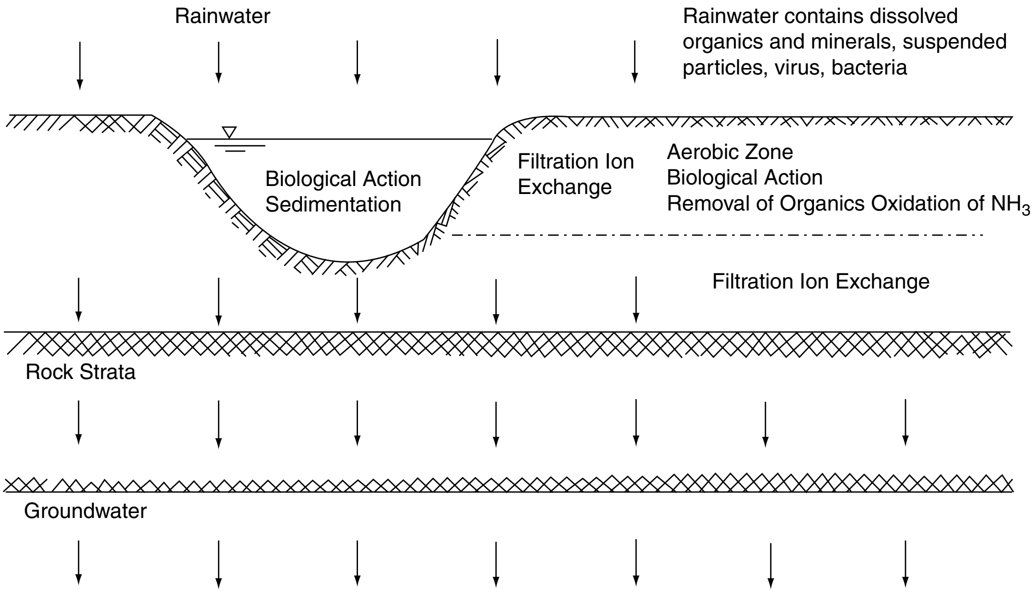

FIGURE 6 Effect of water movement on water quality.

the destruction of the ecological system and natural resources but also present a danger to public health. Pollutants have been broadly classified into eight categories by the U.S. Public Health Service.

1. Oxygen-demanding wastes: These include domestic and industrial wastewaters, leachates from landfill, and any other wastes containing biodegradable organic material. These wastes are stabilized by microorganisms and will remove dissolved oxygen from water.
2. Infective agents: Bacteria, virus, protozoa, and other infectious agents may be present in domestic wastewaters. Those that reach drinking water or even recreational waters represent a health hazard to humans.
3. Plant nutrients: Mineral substances, particularly nitrates and phosphates, stimulate the growth of plants. However, nitrates in groundwater potentially infiltrating through heavily fertilized soil can be a public health hazard.
4. Organic chemicals: Chemicals such as insecticides, pesticides, and detergents are toxic at low concentrations and can cause significant changes in groundwater quality.
5. Other minerals and chemicals: This group consists primarily of materials found in industrial wastes, including chemical residues, petrochemicals, salts, acids, etc. New chemical substances are being created at the rate of 400 to 500 compounds per year. Many of these substances are known to be toxic, although very little is known about their biological action. Almost nothing is known about the possible long-term effects of these chemical compounds.
6. Sediments from land erosion: These materials have little effect on groundwater quality since they would be filtrated out in the first stages of percolation.
7. Radioactive substances: Expected increases in the use of nuclear reactors for power generation indicate that radioactivity may be a serious problem in the future. The extremely long half-lives of some radioactive materials make the disposal of radioactive wastes difficult. Once a radionuclide reaches the groundwater it remains a hazard for a long time. One rule is that a radionuclide is no longer dangerous after nine half-lives.
8. Heat: Heat from industry and power generation is considered a serious pollutant. Its effect on groundwater is limited to reducing the value of a groundwater source for cooling water.

In addition to the eight categories of pollutants used by the U.S. Public Health Service, oil can be considered a ninth category, since oil spills in coastal waters have found their way into groundwater supplies near the coast.

The quality of water required for industrial-process usages varies widely with the type of industry and the type of process used. For example, the recommended total solids concentration in boiler feed waters varies from 50 to 3,000 mg/l depending on the design of the boiler and the pressure of operation. The quality of water used for agricultural operations also varies considerably. Range-cattle-use water

MCLG—maximum contaminant-level goal, a nonenforceable health goal that is set at a level at which no known or anticipated adverse effect on the health of persons occurs and that allows an adequate margin of safety.

MCL—maximum contaminant level, the highest level of a contaminant that is allowed in drinking water. MCLs are set as close to the MCLG as feasible using the best available analytical and treatment technologies and taking cost into consideration. MCLs are enforceable standards.

containing 5,000 mg/l dissolved solids but low concentrations of sodium, magnesium, and sulfate are desirable. The quality required for irrigation water depends on the soil, composition, climate, type of crops, amount of groundwater used, etc.

Groundwater is primarily used as a water source for public and private drinking-water supply, industrial-process and cooling water, and agricultural supply. The acceptability of a groundwater source for use depends on the standards for quality for that use. The Drinking Water Standards for major chemicals are regulated by the U.S. Environmental Protection Agency (EPA) (2004). These standards are shown in Table 2.

REMEDIATION CONSIDERATION

Pollution Control and Remediation Policy

This section briefly describes the major federal environmental laws that control and regulate groundwater quality. In the United States, the protection of groundwater is accomplished through a set of statutes passed at different times. The goal of these laws is to protect the public health and regulate sources of contaminations.

The first and probably most important modern environmental law was enacted in January of 1970, namely the National Environmental Policy Act (NEPA) of 1969. NEPA is a milestone in man's understanding regarding his own survival and the survival of the total ecology that has supported all life of earth. This act dictated that decision makers approach industrial development by balancing the environmental, economic, and technological factors to protect and enhance public health and welfare. Following NEPA, many important statutes were enacted to restrict the improper handling of hazardous wastes. Currently, there are more than 30 laws concerning environmental issues, among which 2 deal directly with water.

The Clean Water Act (CWA) of 1972, although it does not deal directly with groundwater, is the cornerstone of surface-water-quality protection. It established the basic structure for regulating pollutant discharges into the water system as well as regulatory tools to sharply reduce those pollutant discharges. These tools are employed to achieve the broader goal of restoring and maintaining the chemical, physical, and biological integrity of the water system.

The Safe Drinking Water Act of 1974 was established to protect the quality of drinking water in the United States. It focuses on all waters actually or potentially designed for drinking use, including both surface water and groundwater sources. Since their enactment, these statutes have played a very important role in preventing the creation of new contaminated sites. However, they have had no effect on the hazardous-waste sites already in existence. If a healthy environment is to be established, these long-term dangers cannot be ignored.

The cleanup action started with the enactment of the Comprehensive Environmental Response, Compensation, and Liability Act of 1980 (CERCLA, or Superfund), which is a remedial program for cleaning up the nation's worst hazardous-waste sites created by past industrial disposal practices. CERCLA established a hazardous-substance Superfund as well as regulations controlling inactive hazardous-waste sites. Extensive liability has been brought to owners and waste generators alike. As a consequence, the public is more concerned than ever about groundwater contamination. The implementation of Superfund is challenging, both technically and economically.

Remediation

Groundwater cleanup is very expensive and extremely difficult, if not impossible. An important and necessary step is removal of contaminants from the vadose (unsaturated) zone, which in most cases serves as a source of contamination.

The groundwater remediation can never be complete so long as mobile contaminants remain in the vadose zone. Currently, there are two basic approaches for decontamination, namely *ex situ* and *in situ* techniques. *Ex situ* remediation requires excavation with on-site or off-site treatment, while the *in situ* remediation removes (or treats) the contaminants in place, thus minimizing disturbance to the site. Since excavation may not be feasible in many situations, the *in situ* remediation approach, in general, is technically and economically superior. As a result, a number of *in situ* remedial technologies have been developed to treat contamination in the soil. These remedial actions can be grouped into the following general categories based on their characteristics.

Physical Treatment Physical treatment is a relatively simple and safe approach compared with other treatment methods. Since no foreign materials are introduced into the formation, there is little chance that the contamination situation will be worsened.

The soil vapor extraction (SVE) method, known as soil venting, *in situ* volatilization, enhanced volatilization, or soil vacuum extraction, is one of the most popular physical treatment technologies. In this process, a vacuum is applied through extraction wells to create a pressure gradient that induces transport of chemical volatiles through the soil to extraction wells. This technology has been widely used in volatile organic compound (VOC) removal from the vadose zone, and it can also be useful in decontaminating groundwater, since the lowered VOC vapor pressure in the vadose zone will increase volatilization of contaminants in the groundwater. Principal factors governing the applicability of SVE include contaminant distribution at the site, site hydrogeology, and contaminant properties. In general, SVE is an effective process for highly permeable formations such as sand, but is ineffective for low-permeability formations such as silt and clay, since tight formations restrict the airflow through the porous medium.

Pump-and-treat is a physical treatment technology used for the saturated zone in combination with other technologies. Contaminated groundwater is pumped out of the formation and treated either off-site or on-site. This technology is commonly applied to reduce the rate of plume migration, or to confine the plume to a potentiometric low area. In addition, physical containment systems (cutoff walls, reactive barriers, etc.) have been used. The primary objective is to construct a physical impediment to groundwater flow.

Chemical Treatment In general, chemical methods for detoxification of contaminants in the soil are severely hindered by the difficulties of dispersing chemical amendments into the formation. As such, most attempts of chemical *in situ* treatments have been limited to chemical spills or dump sites where near-surface contaminated soil could be treated. Potential chemical reactions of the treatment reagents with the soils and wastes must be considered with all chemical treatments. Since most hazardous-waste disposal sites contain a mixture of contaminants, a treatment approach that may neutralize one contaminant could render another more toxic or mobile. In addition, the chemical amendment introduced into the soils may create new pollution. The general chemical treatments include solidification-stabilization, neutralization, and oxidation-reduction.

The solidification-stabilization method is designed to make contaminants physically bound or enclosed within a stabilized mass. This method includes inducing chemical reactions between the stabilizing agent and contaminants to reduce their mobility. Neutralization involves injecting dilute acids or bases into the ground to adjust the pH. This pH adjustment can serve as pretreatment prior to oxidation-reduction or biological remediation. The oxidation-reduction method consists of using oxidation-reduction reactions to alter the oxidation state of a compound through loss or gain of electrons, respectively. Such reactions can detoxify and solubilize metals and organics. This technology is a standard wastewater-treatment approach, but its application as *in situ* treatment is limited.

Biological Treatment The ultimate goal of biological treatment is to achieve biodegradation of the organic chemicals. From attempts to utilize bacterial cultures to sophisticated genetic-engineering applications, a myriad of biodegradation technologies have been explored. Since a large portion of the hazardous-waste contamination in the United States stems from petroleum-hydrocarbon products that have been discharged or spilled into the soil at petroleum refineries, airports, and military bases, bioremediation has become an accepted, simple, and effective cleanup method. Basically, there are two approaches: stimulating the growth of “indigenous” microorganism populations and adding new “endigenous” microorganisms. Biological treatments may utilize either one or both of these approaches.

Many toxic organic chemicals can be metabolized or degraded to some degree by indigenous soil microorganisms. This natural process can be accelerated by pumping oxygen and nutrients into the contaminated zone to stimulate the resident microorganisms. However, if the infiltration rate is low, remediation may be a very slow process.

In the endigenous approach, genetically endigenous microorganisms are introduced into the formation to clean the contaminants. There are two major difficulties in this approach. First, the dispersal of introduced organisms throughout the contaminated zone is very difficult, since microorganisms tend to be absorbed by solid particles and become clustered. Second, the newly introduced organisms may destroy the microbial balance once the porous medium has become decontaminated, which creates new ecological problems.

Overall, a significant engineering deficiency with *in situ* bioremediation is the absence of proven methods to introduce degrading populations of microorganisms, nutrients, and other chemicals into the subsurface environment for efficient mixing with microorganisms and the contaminants of concern. In addition, the infiltration rate is an important governing parameter to the effectiveness of the process.

Thermal Treatment

Thermal treatment involves introducing extra energy into the contaminated zone to increase the formation temperature. Two different temperature ranges have been employed: high-temperature treatment is used to destroy chemical structures as well as soil constituents to retard chemical movement, while low-temperature treatment is used to increase chemical mobility and removal rates.

The *in situ* vitrification (ISV) technology is a high-temperature treatment designed to treat soils, sludges, sediments, and mine tailings contaminated with organic, inorganic, and radioactive compounds. Heating, applied via electrodes, is used to melt contaminated soils and sludges, producing a glass and crystalline structure (at about 3000°F or 1600°C) with very low leaching characteristics. The glass and crystalline product will permanently immobilize hazardous substances and retain its physical and chemical integrity for geologic time periods. Since the ISV process is costly, it has mostly been restricted to radioactive or highly toxic wastes. The demand for high energy, specialized equipment, and trained personnel may greatly limit the use of this method.

The thermally enhanced SVE process uses steam/hot-air injection or electric/radio frequency heating to increase the mobility of vapors and facilitate SVE. The temperature in this process is controlled in a low range so that there is no chemical destruction.

Enhancement Technologies

The success of *in situ* remediation technologies depends largely upon the transport efficiency of materials in and out of the contaminated zone. Contaminants must be transported out of the formation, while chemical, biological, and other amendments must be transported in. Without enhancement, most *in situ* remediation methods are effective only in relatively permeable formations and are inadequate for fine-grained soils due to the low natural permeability. Enhancement technologies were developed to improve the transport conditions for the current remediation industry.

The hydraulic-fracturing process begins by using a hydraulic jet to cut a disk-shaped notch on the borehole wall. Water (with or without chemicals) is then injected into the notch until a critical pressure is reached and a fracture is formed. A proppant composed of a granular material (e.g., sand) and a viscous fluid (e.g., guar gum and water mixture) is then pumped into the fracture. As a result, the mobility through difficult soil conditions can be increased. However, since water or another liquid is used in the process, the moisture content of the formation is increased during hydraulic fracturing. This additional water or liquid may block the pathway for gaseous transport and subsequently reduce the removal efficiency from fractured formations.

Pneumatic fracturing is a relatively new enhancement technology. This process involves injection of pressurized air into soil or rock formations to create fractures and increase the permeability. The injection is a quick process (e.g., taking within 10 to 20 seconds), and clean air is the only ingredient of the injection fluid. Thus, the potential chemical hazard or disturbance to the formation's chemical constituents is minimal.

As indicated, groundwater remediation is an expensive and difficult task, which requires a comprehensive understanding of the problem, the identifying of remediation technologies, abilities, and the selecting of an appropriate remediation goal. New engineering remediation technologies are being developed and tested; the interested reader is referred to a document by the EPA (1993).

CONCLUDING REMARKS

It has long been recognized that groundwater is one of the most valuable natural resources. The subject of groundwater is vast and encompasses a great variety of disciplines, including hydrology, hydraulics, geology, and chemistry. This article is intended to serve as an introduction to the subject, and as such, the emphasis is on the underlying principles. Discussion on modeling of solute transport in groundwater is omitted here because of its complexity. For an overview of modeling, the reader is referred to Sun (1996), Van der Heijde and Elnawawy (1993), and others. In short, a great many challenging problems in groundwater await solutions.

HAZARDOUS WASTE MANAGEMENT

HISTORICAL OVERVIEW

The development of the Resource Conservation and Recovery Act of 1976 dates to the passage of the Solid Waste Disposal Act of 1965, which first addressed the issues of waste disposal on a nationwide basis. Prior to the 1960s land disposal practices frequently included open burning of wastes to reduce volume, and were controlled only by the general need to avoid creating a public health impact and nuisance, such as a bad smell or visual blight—problems that one could see, smell, taste or touch. At that time, what few landfill controls existed were generally focused only on the basics of sanitation, such as rodent control, and the prevention of fires. The early concept of the "sanitary" landfill was to cover the waste with soil to reduce pests and vermin, create separate chambers of earth to reduce the spread of fire, and control odor and unsightly appearance—the key environmental concerns of the time.

Throughout the '60s and into the '70s, the use of industrial pits, ponds or lagoons on the land were viewed as legitimate treatment systems intended to separate solids from liquids and to dissipate much of the liquids. They were not only intended to store waste, but also to treat it. That is, solids would sink when settling occurred and the liquid could be drained, evaporated, or allowed to percolate into the ground. The accumulated solids ultimately would be landfilled.

Similarly for protection of receiving waters, pollution control laws prior to the mid-1960s were generally concerned with water-borne diseases and nuisances. The concept of water pollution was far more closely linked to the bacterial transmission of disease and physical obstruction or offense than it was to the impact of trace levels of chemicals. Waterways were viewed as natural systems that could handle waste if properly diluted and if the concentrations were within the assimilative capacity of the rivers and streams. The environmental concerns were primarily odor, appearance, oxygen content, and bacterial levels. Individual chemical constituents and compounds, at this time, were not typically regulated in a waterway.

The science of testing for and measuring individual contaminants was unrefined and typically not chemical specific until the 1970s. Water and wastewater analyses were generally limited to indicator parameters, such as Biochemical Oxygen Demand, turbidity, suspended solids, coliform bacteria, dissolved oxygen, nutrients, color, odor and specific heavy metals. Trace levels of individual chemical compounds and hazardous substances as we know them today were not among the parameters regularly analyzed.

"Hazardous waste" became a household word in the late 1970s with the publicity surrounding the Love Canal incident. How much waste has been disposed of is still questionable. Unfortunately, significant amounts were "thrown away" over the past decades and have endured in the environment in drum disposal sites such as "The Valley of the Drums" and in land disposal facilities where they have not degraded.

Throughout the '70s and '80s significant changes were made in the laws governing environmental protection. New laws adopted in the '70s include the Clean Air Act, the Federal Water Pollution Control Act, Safe Drinking Water Act, Resource Conservation and Recovery Act (RCRA), Toxic Substance Control Act, Marine Protection Research and Sanctuaries Act, and in 1980 the "Superfund" (CERCLA) statute. Of all the laws passed in the '70s, RCRA has had the greatest impact on the definition of wastes and the manner in which these wastes were to be managed, treated and handled. RCRA[1] required the US Environmental Protection Agency to establish management procedures for the proper disposal of hazardous wastes. These procedures are part of the Code of Federal Regulations dealing with environmental protection. They cover a "cradle-to-grave" procedure which regulates generators, transporters, storers and disposers of hazardous materials. Regulations for generators and transporters of hazardous wastes may also be found in the Code of Federal Regulations.[2,3]

Subsequent revisions to RCRA in 1984 included the provisions dealing with underground tanks, the restriction of land disposal of a variety of wastes, corrective action requirements for all releases, and the inclusion of a requirement of the EPA to inspect government and privately owned facilities which handle hazardous waste.

Today the law is again being considered for revision, and among the issues that are always under discussion include "how clean is clean" when remediating industrial and landfill sites. The cleanup standards are not consistent among state and federal programs, frequently causing significant discussion among responsible parties and regulators. At this time, risk assessments are used more often in an effort to design remedial programs that are appropriate for the media, and the resources being protected. A risk assessment might provide, for example, the necessary information to set differing groundwater cleanup goals in a sole source aquifer, than in an industrialized area situated above a brackish water-bearing zone where the groundwater will not again be used for potable purposes.

With the preceding paragraphs as general background, the brief discussion which follows on hazardous wastes emphasizes some of the technologies that have been successfully used for the treatment and disposal of hazardous wastes, and remediation of contaminated properties.

HAZARDOUS WASTE DEFINED

Hazardous wastes encompass a wide variety of materials. In 1987, the US EPA estimated that approximately 238 million tons could be classified as hazardous. This number is probably generous but suffice it to say that a great deal of material of a hazardous and dangerous nature is generated and disposed of every year.

The Resource Conservation and Recovery Act defines a hazardous waste as a solid waste that may cause or significantly contribute to serious health or death, or that poses a substantial threat to human health or the environment when improperly managed. Solid waste, under the present guidelines, includes sludges, liquids, and gases in bottles that are disposed of on the land.

From this working definition, a number of wastes have been defined as hazardous. These include materials that are ignitable, corrosive, reactive or explosive or toxic. These characteristic identifiers are further delineated in the regulations.[4] In addition, using these general characteristics and specific tests, the US Environmental Protection Agency has listed materials from processes, such as electroplating, or specific classes of materials, such as chlorinated solvents, or specific materials, such as lead acetate, or classes of compound, such as selenium and its compounds, which must be managed as "hazardous wastes" when they are disposed. This list changes periodically. In many cases disposers have treated materials not on the list as hazardous if they believe them to be so.

Some general classes of materials such as sewage, mining and processing of ore wastes are excluded by law at the present time.

Managing Wastes

Advancements in science and technology have given us opportunities to address environmental contamination issues in ways that are technologically more advanced, and more cost and time efficient than ever before. Technologies that were unknown, unproven and unacceptable to regulatory agencies just a few years ago, now exist and are being implemented at full scale. Regulations have changed, as have government policies governing cleanup and enforcement.

On a technical level, many ideas for hazardous waste treatment and remediation were rejected a few years ago by the engineering, business and regulatory community as being unproven or unreliable. Entrepreneurial scientists and engineers have adapted their knowledge of manufacturing process chemistry and engineering to the sciences of geology and hydrogeology and have refined the necessary equipment and techniques for waste treatment and remediation. Technologies have been tested at bench and pilot scale, and many have proven effective on a large scale. Pressure by the industrial community for engineers and regulators to reach a common ground has driven the process.

Contaminated soil and groundwater remedial techniques have tended toward the "active" end of the spectrum, with the installation of pumps, wells and above ground treatment systems of the capital and labor intensive variety. Progress has been made at the opposite end of the spectrum, ranging from intrinsic bioremediation, which involves no active treatment, to incremental levels of treatment that are far less costly than *ex-situ* pump and treat methods.

Programs like the EPA SITE (Superfund Innovative Technology Evaluation) Program and other Federal test and evaluation facilities, University research organizations and privately sponsored technology incubator and test evaluation facilities have been very successful in testing and establishing new hazardous waste treatment and disposal technologies. Currently, there are several dozen organizations nationally that specifically focus on the development of emerging hazardous waste treatment technologies. The results have been very positive, and many of today's front-edge technologies are the offspring of programs such as these.

On a regulatory/compliance level, the extensive time frame for receipt of approvals led many companies down the path of the traditional treatment and disposal methods, since they were "proven," as well as being approvable by the regulatory agencies. Environmental agencies have become more sophisticated, and cleanup levels are more often based on risk rather than standards set at an earlier data in technical and regulatory development. More than ever, agency personnel are now trained as specialists in the various segments of the environmental industry, including risk assessment, hydrogeology, remediation engineering and personal protection. As a result, the agencies are often more willing to engage in discussions regarding site specific conditions and remedial goals. Further, modifications to state permitting programs have allowed variations on typical operating permits for new and emerging technologies that appear to have promise.

An analysis of Superfund remediation activities indicates that significant progress has been made in the use of innovative technologies for site remediation. The predominant new technologies used at Superfund sites include soil vapor extraction (SVE) and thermal desorption. It is important to note that there are many derivative technologies that will now stand a greater chance of receiving government and industry support as a result.

Remediation technologies that are derived from soil vapor extraction include dual phase extraction and sparing. The two phases are typically a) removal of free product or contaminated groundwater and b) vapor. The *in-situ* addition of certain compounds by sparging into the soil and groundwater has made bioremediation attractive. The addition of the additional components to an earlier technology that was moderately successful has made the modified treatment train much more effective. The new treatment train is therefore more approvable.

On a financial level, methods have been developed for the evaluation of large projects to provide a greater degree of financial assurance. The concept of the "unknown" cost of remediation due to the inability of scientists to accurately see and measure subsurface contamination is diminishing. Probabilistic cost analyses are frequently completed on assignments so that final remediation costs can be predicted within a much narrower range.

Management practices have changed dramatically over the past 20 years at most industries. They have been driven by the improvements in technologies, as well as the laws and regulations. The real estate boom of the 1980s also impacted operating practices, as many properties were bought and sold during this time. The desire of buyers to be assured that they were purchasing "clean" properties, as well as some state environmental property transfer requirements, was the genesis of facility environmental audits as we now know them.

For purposes of discussion, hazardous wastes fall primarily into two categories, organic and inorganic. Some management technologies will apply to both, but in general organic material can be destroyed to relatively innocuous end products while inorganic material can only be immobilized. The key technologies for hazardous waste management include:

- Pollution Prevention
- Recycling and Reuse
- Waste Minimization
- Chemical Treatment and Detoxification
- Destruction
- Stabilization
- Land disposal

Of these, land disposal is the least attractive alternative from the standpoint of long-term liability exposure and environmental impact.

Waste Concentration—A Key Where a waste must be ultimately disposed of, concentration or volume reduction is beneficial. The simplest approach to this is to separate wastes at the source; that is, at the place of origin. This will increase handling costs and effort, but will more than pay dividends in minimizing analytical and disposal costs. First, it will mean that analysis must be done less frequently. Second, waste can be disposed of at the lowest degree of care consistent with the most hazardous contaminant, thus minimizing the volume of waste that must get a greater degree of care because of slight cross-contamination by a more toxic material. This is true whether the material is in the liquid or solid state.

Another method of reducing volume is concentration. For liquids, this generally means distillation or evaporation. Evaporation to date has been acceptable, however, with increased emphasis on the presence of volatile hazardous materials in the atmosphere, evaporation ponds, will, in all probability, no longer meet the necessary standards for waste control and management. In addition, ponds must be permitted under RCRA, which imposes additional financial and operating requirements on the waste concentrator. Double and triple effect evaporators and distillation units will be acceptable but are very energy-expensive. Innovative techniques will be required because of the high energy of the traditional liquid separation systems.

Where a material is dissolved in water or an organic solvent, precipitation may be advisable. The solid can then be separated out from the majority of the liquid by filtration or other liquid/solid separation technology. Typical of this would be the precipitation of lead by the use of a sulfide salt, resulting in lead sulfide which has extremely low solubility. The solid may be suitable for reclamation at present or be stored in a secure landfill in a "non- or less-hazardous form" for eventual reuse.

Pollution Prevention The passage of Pollution Prevention Laws has driven many industries toward better utilization of their resources. Many companies now actively participate in the preparation and update of a pollution prevention program, designed to guide personnel toward goals established to improve waste generation and disposal practices.

Traditional environmental quality and pollution control programs typically focus on an end-of-pipe approach. The pollution prevention plan approach typically begins earlier in the "equation" by reviewing an operation and making modifications that will positively impact a facility. Some examples include reducing harmful chemical purchases, increasing operation efficiencies, and ultimately generating a smaller quantity of waste.

The pollution plan approach will include involvement by a wider range of facility personnel than the traditional environmental management approach. Purchasing, accounting, production and engineering all participate. Proponents suggest that a program is easy to implement, although corporate personnel involved in the effort know that it is an effort which requires broad-based management support, is time consuming, and not necessarily inexpensive to implement. The benefits are potentially significant, as reduced emissions make it easier to comply with discharge standards, and will reduce long-term liabilities.

Recycling and Reuse In many cases, in addition to economically attractive alternatives, a very attractive alternative will be recycling or reuse of hazardous wastes. The economic realities of the regulations, where disposal of a barrel of waste can demand a 5–$10 per gallon, and up to $1,200 per ton or greater fee, may make processing for recycling and/or reuse the best practice. In the present context, we are defining recycling as internal to the plant, and reuse as external to the plant. This is not a legal definition which defines recycling as essentially both internal and external, but it is helpful in this discussion.

Internal recycling will require, in general, high efficiency separation and potential additional processing. Thus, if a solvent is being recycled, impurities such as water, by-products, and other contaminants must be removed. Depending on the volumes involved, this may be done internally to the process or externally on a batch basis.

Reuse involves "selling" the waste to a recycle and reclaimer. The reclaimer then treats the waste streams and recovers value from them. The cleaned-up streams are then his products for sale.

From a regulatory, liability perspective, there are advantages to reuse as the liability for the waste ends when it is successfully delivered to the reclaimer. Because he processes the material, he then assumes responsibility for the products and wastes that are generated. If the material is internally recycled, then the recycler, that is the plant, maintains responsibility for any wastes that are generated as a result of the recycling operation.

In some cases, it may be desirable to dispose of wastes directly to the user. This is particularly true when there are large quantities involved and a beneficial arrangement can be worked out directly. Waste exchanges have been organized to promote this type of industrial activity. Detailed discussions of their mode of operation can be obtained directly from the exchanges.

Waste Minimization The alternative scenario development will be not only site, but substance specific. Two basic approaches to hazardous waste management are:

1) In-process modifications
2) End-of-pipe modifications

Each will have advantages and disadvantages that are processes, substance, and site specific.

In-process alternatives include changing process conditions, changing feedstocks, modifying the process form in some cases, or if necessary eliminating that process and product line.

In-process modification is generally expensive and must be considered on a case-by-case basis. There are some potential process modifications that should be considered to minimize the production of toxic materials as by-products. These include minimization of recycling so side-reaction products do not build up and become significant contributors to the pollution load of a bleed stream. For example, waste must be purged regularly in the chlorination of phenols to avoid the build-up of dioxin. It may also be desirable to optimize the pressure of by-products. For example, phenol is produced and found in condensate water when steam-cracking naphtha to produce ethylene unless pressures and temperatures are kept relatively low.

It may be desirable to change feedstocks in order to eliminate the production of hazardous by-products. For example, cracking ethane instead of naphtha will yield a relatively pure product stream.

Hydrazine, a high energy fuel, was originally produced in a process where dimethylnitrosamine was an intermediate. A very small portion of that nitrosamine ended up in a waste stream from an aqueous/hydrocarbon separation. This waste stream proved to be difficult, if not impossible, to dispose of. A new direct process not involving the intermediate has been substituted with the results that there are no noxious wastes or by-products.

In the ultimate situation, production of a product may be abandoned because either the product or a resulting by-product poses an economic hazard which the corporation is not willing to underwrite. These include cases where extensive testing to meet TSCA (Toxic Substances Control Act) was required. They include the withdrawal of pre-manufacturing notice applications for some phthalate ester processes. However, production of certain herbicides and pesticides was discontinued because a by-product or contaminant was dioxin.

Treatment/Destruction Technology

Chemical Treatment/Detoxification Where hazardous materials can be detoxified by chemical reaction, there the molecule will be altered from one that is hazardous to one or more that are non-hazardous, or at least significantly less hazardous. For example, chlorinated hydrocarbons can be hydro-dechlorinated. The resulting products are either HCl or chlorine gas and nonchlorinated hydrocarbons. A number of these processes are being developed for the detoxification of PCB (polychlorinated biphenols) and are being demonstrated as low concentrations of PCB's in mineral oil. The end products, if concentrated enough, can be useful as feedstocks or the hydrocarbons may be used as fuel.

Cyanide can be detoxified using any number of chemical reactions. These include a reaction with chlorine gas to produce carbonate and chlorine salt. Cyanide can also be converted to cyanate using chlorine gas. In addition, ozone can be utilized to break up the carbon-nitrogen bond and produce CO_2 and nitrogen.

Hexavalent chromium is a toxic material. It can be reduced to trivalent chromium which is considerably less hazardous and can be precipitated in a stable form for reuse or disposal as a non-hazardous material. Chromium reduction can be carried out in the presence of sulfur dioxide to produce chromium sulfate and water. Similar chemistry is utilized to remove mercury from caustic chlorine electrolysis cell effluent, utilizing sodium borohydride.

Lead, in its soluble form, is also a particularly difficult material. Lead can be stabilized to a high insoluble form using sulfur compounds or sulfate compounds, thus removing the hazardous material from the waste stream.

Acids and bases can most readily be converted to nonhazardous materials by neutralizing them with appropriate base or acid. This is probably the simplest chemical treatment of those discussed and is widely applicable; care must be taken, however, to insure that no hazardous precipitates or dissolved solids forms.

Incineration Incineration has been practiced on solid waste for many years. It has not, however, been as widely accepted in the United States as in Europe where incineration with heat recovery has been practiced for at least three decades. Incineration of industrial materials has been practiced only to a limited extent; first, because it was more expensive than land disposal, and second, because of a lack of regulatory guidelines. This has changed because landfills are not acceptable or available, costs for landfilling are becoming extremely high, and regulatory guidance is available. Equipment for incineration of industrial products has been, and is available, however, it must be properly designed and applied.

Incineration is the oxidation of molecules at high temperatures in the presence of oxygen (usually in the form of air) to form carbon dioxide and water, as well as other oxygenated products. In addition, products such as hydrogen chloride are formed during the oxidation process. The oxidation, or breakdown, takes place in the gaseous state, thus requiring vaporization of the material prior to any reaction. The molecules then breakdown into simpler molecules, with the least stable bonds breaking first. This occurs at relatively lower temperatures and shorter times. It is followed by the breakdown of the more stable, and then the most stable bonds to form simple molecules of carbon dioxide, water, hydrogen chloride, nitrogen oxides, and sulfur oxides, as may be appropriate.

Thus, the primary considerations for successful oxidation or destruction are adequate time and temperature. Good air/waste contact is also important. Regulatory guidelines require a destruction and removal efficiency (DRE) of 99.99% thus, time and temperature become all the more important. For the most refractory compounds, such as PCB's, residence times in excess of three seconds and temperatures in excess of 1000°C are required. These temperatures may be reduced in light of special patented processes utilizing oxidation promoters and/or catalysts. As a result of the high required DRE, a test burn is required to demonstrate adequate design.

In addition to time and temperature considerations, there are other important factors which must be considered when designing or choosing equipment to incinerate industrial waste. Most important is adequate emission gas controls. Where materials which contain metals, chlorides, or sulfides are to be incinerated, special provisions must be made to minimize emission of HCl, SO_2, and metal oxides. Usually a scrubber is required, followed by a system to clean up the scrubber-purge water. This system includes neutralization and precipitation of the sulfur and metal oxides. In addition, where high temperature incineration is practiced, control of nitrogen oxides to meet air quality emissions standards must be considered. These substances do not present insurmountable technological challenges, as they have been handled satisfactorily in coal-fired power plant installations, but they do present added economic and operating challenges.

Several types of incineration facilities should be considered. Unfortunately, the standard commercial incinerator utilized or municipal waste will generally not prove adequate for handling industrial waste loads because the temperatures and residence times are inadequate. Municipal incinerators are designed to handle wastes with an energy content below 8000 Btu/pound, while industrial wastes can have heating values as high as 24000 Btu/pound. Municipal incinerators are generally not designed to accept industrial wastes.

A number of incinerator facilities have been built for industrial wastes. Small, compact units, utilizing a single chamber with after-burner, or two-stage, multi-chamber combustion are available. In general, a single-state unit will not suffice unless adequate residence time can be assured.

Rotary kiln incinerators are of particular interest for the disposal of industrial materials. Generally, they are only applicable for large-scale operations, and can handle a large variety of feedstocks, including drums, solids and liquids. Rotary cement kilns have been permitted to accept certain types of organic hazardous materials as a fuel supplement.

Of increasing interest for industrial incineration is the fluid bed incinerator. This has the additional advantage of being able to handle inorganic residues, such as sodium sulfate and sodium chloride. These units provide the additional advantage of long residence time, which may be desirable when the waste is complex (e.g., plastics) or has large organic molecules. On the other hand, gas residence times are short, and an after-burner or off-gas incinerator is often required in order to achieve the necessary DRE.

Incineration has been used successfully for the disposal of heptachlor, DDT, and almost all other commercial chlorinated pesticides. Organo-phosphorous insecticides have also been destroyed, but require a scrubbing system, followed by a mist eliminator, to recover the phosphorous pentoxide that is generated.

Some special incineration applications have been implemented. These include:

- An ammonia plant effluent containing organics and steam is oxidized over a catalyst to form CO_2, water and nitrogen;
- Hydrazine is destroyed in mobile US Air Force trailers which can handle 6 gpm of 100% hydrazine to 100% water solutions, and maintain an emission has which contains less than 0.03 pound/minute of NO*x*;
- Chlorate-phosphorous mixtures from fireworks ammunition are destroyed in a special incinerator which has post-combustion scrubbing to collect NO*x*, P_4O_{10}, HCl, SO_2 and metal oxides;
- Fluid bed incinerators which handle up to 316 tons per day of refinery sludge and 56 tons of caustic are being utilized.

Wet Air Oxidation Although not strictly incineration, wet air oxidation is a related oxidation process. Usually air, and sometimes oxygen, is introduced into a reactor where hazardous material, or industrial waste, is slurried in water at 250° to 750°F.

Operating pressures are as high as 300 psig. Plants have been built to treat wastes from the manufacture of polysulfite rubber and other potentially hazardous materials. Emissions are similar to those obtained in incineration, with the exception that there is liquid and gaseous separation. Careful evaluation of operating conditions and materials of destruction are required.

Pyrolysis Pyrolysis transforms hazardous organic materials by thermal degradation or cracking, in the absence of an oxidant, into gaseous components, liquid, and a solid residue. It typically occurs under pressure and a temperature above 800°F.

To date, the process has found limited commercial application but continues to be one that will eventually be economically attractive, the prime reason being the potential for recovery of valuable starting materials. A great deal of experimentation has been carried out both on municipal and industrial wastes. For example, polyvinyl chloride can be thermally degraded to produce HCl and a variety of hydrocarbon monomers, including ethylene, butylene, and propylene. This is a two-stage degradation process with the HCl coming off at relatively low temperatures (400°C) and the hydrocarbon polymer chain breakdown can be obtained with Polystyrene, with styrene as the main product, and most other polymers. Experimental work carried out in the early 1970s by the US Bureau of Mines, indicates that steel-belted radial tires can be pyrolyzed to reclaim the monomers, as well as gas and fuel oil.

Other target contaminant groups include SVOCs and pesticides. The process is applicable for the treatment of refinery, coal tar, and wood treating wastes and some soils containing hydrocarbons.

Disposal Technology

Land Storage and Disposal Disposal of hazardous materials to the land remains the most common practice. It is highly regulated and a practice which has been limited because of public pressure and federal rules which require the demonstration of alternate means of disposal. The design of secure landfills for the acceptance of hazardous materials must be such that ground waters, as well as local populations are protected. The US Environmental Protection Agency has implemented strict landfills. In practice all landfills accepting hazardous wastes must insure that the wastes stored in close proximity are compatible so that no violent reactions occur should one or more waste leak.

Federal and State regulations prohibit the disposal of liquids in landfills. Of equal importance to the disposal of hazardous wastes, whether solid or semi-solid, is the assurance that material will not leach away from the landfill or impoundment. This assurance is provided by the use of "double-liners" with a leak detection system between the liners, a leachate collection system for each cell, and a leachate treatment system designed and operated for the facility.

In dilute form liquid wastes can be "landfarmed" where microbial action will decompose the compounds over time. This methodology has been utilized over many years for hydrocarbons and has worked well. For highly toxic compounds, such as chlorinated organics, it is less attractive even though decomposition does occur. Land treatment of PCB contaminated soils has been tested with some success.

Stabilization The stabilization of hazardous materials prior to land disposal is frequently practiced. Generally, the stabilization is in the form of fixing the hazardous material with a pozzolanic material, such as fly ash and lime, to produce a solid, non-leachable product which is then placed in land disposal facilities. Typically, this methodology is applicable to inorganic materials. Most of the commercial processes claim that they can handle materials with some organic matter.

Polymer and micro-encapsulation has also been utilized but to a significantly lesser extent than the commercially available process which utilize pozzolanic reactions. Polymers which have been utilized include polyethylene, polyvinylchloride and polyesters.

Grube[9] describes a study of effectiveness of a waste solidification/stabilization process used in a field-scale demonstration which includes collecting samples of treated waste materials and performing laboratory tests. Data from all extraction and leaching tests showed negligible release of contaminants. Physical stability of the solidified material was excellent.

Remediation Technologies

Natural Attenuation and Bioaugmentation The concept of natural attenuation, or intrinsic bioremediation, has gained a greater acceptance by the regulatory community as data presented by the scientific community have demonstrated the results of natural attenuation, and the costs and time frames associated with traditional remedial methods.[1] This approach is most appropriate for the dissolved phase groundwater contamination plume. It is still necessary to remove or remediate the source zone of an affected aquifer, after which natural attenuation may be a reasonable approach to the dissolved phases.

Natural attenuation should not be considered "No Action." It requires a solid understanding of the contaminant, geologic and aquifer characteristics, and a defined plan of action. The action involves demonstrating that the contaminants will breakdown, will not migrate beyond a specified perimeter, and will not impact potential receptors. It may involve the stimulation of microorganisms with nutrients or other chemicals that will enable or enhance their ability to

---

[1] Example of traditional remediation methods are *ex-situ* treatment of soil and groundwater, such as soil excavation/disposal, groundwater pump-and-treat using air stripping and granulated carbon polishing.

degrade contaminants. Some limitations may include inappropriate site hydrogeologic characteristics (including the inability of the geostrata to transport adapted microorganisms) and contaminant toxicity. Monitoring and reporting is required, and a health-based risk assessment may be required by regulators.

Natural attenuation is frequently enhanced by several components, such as the creation of a barrier or the addition of a chemical or biologic additive to assist in the degradation of contaminants.

The overall economics of this approach can be significantly more favorable than the typical pump-and-treat approach. One must be careful to consider, however, that the costs of assessment will equal or exceed that necessary for other methods, and the costs associated with sentinel monitoring will be borne for a longer period of time.

Barriers This has been used in instances where the overall costs of the remedial action is very high, and the geologic features are favorable. It involves the installation of a physical cut-off wall below grade to divert groundwater. The barriers can be placed either upgradient of the plume to limit the movement of clean groundwater through the contaminated media, or downgradient of the plume with openings or "gates" to channel the contaminated groundwater toward a remedial system. This technology has proven to be more efficient and less costly than traditional pump and treat methods, but also requires favorable hydrogeologic conditions. It allows for the return of treated groundwater to the upgradient end of the plume with a continuous "circular" flushing of the soil, rather than allowing the dilution by groundwater moving from the upgradient end of the plume. The result is greater efficiency, and a shorter treatment time period. While the cost of the cutoff wall is significant, it is important to conduct a proper analysis of long-term pump-and-treat costs, including the operation and maintenance of a system that would otherwise be designed to accept a much larger quantity of groundwater.

The creation of a hydraulic barrier to divert upgradient groundwater from entering the contaminant plume allows the pumping of groundwater directly from the affected area and often allows the reinjection of the treated water back into the soils immediately upgradient of the plume. This allows for the efficient treatment of the impacted area, without unnecessary dilution of the contaminated groundwater plume. It does, however, require an accurate assessment of the groundwater regime during the assessment stage. This promising concept is not radical, but its use in connection with natural remediation is growing rapidly.

Passive Treatment Walls Passive treatment walls can be constructed across the flow path of a contaminant plume to allow the groundwater to move through a placed media, such as limestone, iron filings, hydrogen peroxide or microbes. The limestone acts to increase the pH, which can immobilize dissolved metals in the saturated zone. Iron filings can dechlorinate chlorinated compounds. The contaminants will be either degraded or retained in concentrated form by the barrier material.

Physical Chemical Soil Washing Soil is composed of a multitude of substances, with a large variance in size. These substances range from the very fine silts and clays, to the larger sand, gravel and rocks. Contaminants tend to adsorb onto the smallest soil particles, as a result of the larger surface per unit of volume. Although these smaller particles may represent a small portion of the soil volume, they may contain as much as 90% of the contamination.

Soil washing involves the physical separation, or classification, of the soil in order to reduce the volume requiring treatment or off-side disposal. It is based on the particle size separation technology used in the mining industry for many decades. The steps vary, but typically begin with crushing and screening. It is a water-based process, which involves the scrubbing of soil in order to cause it to break up into the smallest particles, and its subsequent screening into various piles. The fraction of the soil with the highest concentration of contamination can be treated using technologies frequently used by industry. The goal is to reduce the quantity of material that must be disposed. The clean soil fractions can often be returned to the site for use as fill material where appropriate.

The use of soil washing technology has some limitations, including a high initial cost for pilot testing and equipment setup. It will be most useful on large projects (requiring remediation of greater than 10,000 cubic yards of soil). Sites with a high degree of soil variability, and a significant percentage of larger particles will show the greatest economic benefit.

Soil Vapor Extraction Soil Vapor Extraction (SVE) is an effective method for the *in-situ* remediation of soils containing volatile compounds. Under the appropriate conditions volatile organic compounds will change from the liquid phase to the vapor phase, and can be drawn from the subsurface using a vacuum pump. There are several factors necessary for the successful use of this technology, including 1) the appropriate properties of the chemicals of concern (they must be adequately volatile to move into a vapor phase), and 2) an appropriate vapor flow rate must be established through the soils.

Air is drawn into the soils via perimeter wells, and through the soils to the vapor extraction well. It is drawn to the surface by a vacuum pump and subsequently through a series of manifolds to a treatment system such as activated carbon or catalytic oxidation.

A concentration gradient is formed, whereby in an effort to reach equilibrium, the liquid phase volatile contaminants change into the vapor phase and are subsequently transported through the soils to the treatment system.

This technology is particularly effective for defined spill areas, with acceptable soils. It is most effective in remediating the soils in the vadose zone, the area that is in contact with the fluctuating groundwater table. Groundwater contaminated with these compounds and similar soil conditions can be remediated using air sparging, a variation of soil vapor extraction.

A variation of this technology is thermal enhanced SVE, using steam/hot air injection or radio frequency heating to increase the mobility of certain compounds.

Air Sparging Air sparging is the further development of soil vapor extraction, wherein that process is extended so that soils and groundwater in the capillary fringe can be effectively treated. Air sparging involves injecting air or oxygen into the aquifer to strip or flush volatile contaminants from the groundwater and saturated soils. As the air channels up through the groundwater, it is captured through separate vapor extraction wells and a vapor extraction system. The entire system essentially acts as an *in-situ* air stripper. Stripped, volatile contaminants usually will be extracted through soil vapor extraction wells and usually require further treatment, such as vapor phase activated carbon or a catalytic oxidation treatment unit. This technology is effective when large quantities of groundwater must be treated, and can provide an efficient and cost-effective means of saturated zone soil and groundwater remediation.

The biological degradation of organic contamination in groundwater and soil is frequently limited by a lack of oxygen. The speed at which these contaminants are degraded can be increased significantly by the addition of oxygen in either solid or liquid form. Air sparging is often combined with *in-situ* groundwater bioremediation, in which nutrients or an oxygen source (such as air or peroxide) are pumped into the aquifer through wells to enhance biodegradation of contaminants in the groundwater.

Oxygen Enhancement/Oxidation In this *in-situ* process, hydrogen peroxide is used as a way of adding oxygen to low or anoxic groundwater, or other oxidative chemicals are added as an oxidant to react with organic material present, yielding primarily carbon dioxide and water. The application of this technology is typically through the subsurface injection of a peroxide compound. It has been injected as a liquid, above the plume, and allowed to migrate downward through the contaminated plume. Alternately, it has been placed as a solid in wells located at the downgradient edge of the plume; in this fashion it can act as a contamination "barrier," limiting the potential for contaminated groundwater to move offsite. As the organic contaminated groundwater moves through the high oxygen zone, the contaminant bonds are either broken, or the increased oxygen aid in the natural biodegradation of the compounds.

The process is exothermic, causing a temperature increase in the soils during the process. This acts to increase the vapor pressure of the volatile organic compounds in the soil, and subsequently increases volatilization of the contaminants. This process can be utilized in connection with a soil vapor extraction and/or sparging system to improve remediation time frames.

It does not act, however, on the soil groundwater vadose zone. This may not be a critical flaw, however, since the strategic placement of the wells may positively impact the contaminant concentrations adequately to meet cleanup standards.

Dual Phase Extraction Dual phase extraction is an effective method of remediating both soils and groundwater in the vadose and saturated zones where groundwater and soil are both contaminated with volatile or nonvolatile compounds. It is frequently used for contaminant plumes with free floating product, combined with known contamination of the vadose zone. This technique allows for the extraction of contaminants simultaneously from both the saturated and unsaturated soils *in-situ.* While there are several variations of this technique, simply put, a vacuum is applied to the well, soil vapor is extracted and groundwater is entrained by the extracted vapors. The extracted vapors are subsequently treated using conventional treatment methods while the vapor stream is typically treated using activated carbon or a catalytic oxidizer.

The process is frequently combined with other technologies, such as air sparging or groundwater pump-and-treat to minimize treatment time and maximize recovery rate.

Chemical Oxidation and Reduction Reduction/oxidation reactions chemically convert hazardous contaminants to nonhazardous or less toxic compounds that are more stable, less mobile and/or inert. The oxidizing agents typically used for treatment of hazardous contaminants are ozone, hydrogen peroxide, hypochlorites, chlorine and chlorine dioxide. These reactions have been used for the disinfection of water, and are being used more frequently for the treatment of contaminated soils.

The target contaminant group for chemical reduction/oxidation reactions is typically inorganics, however hydrogen peroxide has been used successfully in the *in-situ* treatment of groundwater contaminated with light hydrocarbons.

Other Technologies Many other technologies are being applied with increasing frequency. The following is only a very brief description of several that have promise.

- *Surfactant enhanced recovery* Surfactant flushing of non-aqueous phase liquids (NAPL) increases the solubility and mobility of the contaminants in water, so that the NAPL can be biodegraded more easily in the aquifer or recovered for treatment aboveground via pump-and-treat methods.
- *Solvent extraction* Solvent extraction has been successfully used as a means of separating hazardous contaminants from soils, sludges and sediments, and therefore reducing the volume of hazardous materials that must be treated. An organic chemical is typically used as a solvent, and can be combined with other technologies, such as soil washing, which is frequently used to separate, or classify, various soil particles into size categories. The treatment of the concentrated waste fraction is then treated according to its specific characteristics. Frequently, the larger volume of treated material can be returned to the site.
- *Bioremediation using methane injection* The method earlier described for the injection of hydrogen peroxide into wells has also been successfully utilized using methane. It is claimed that this bioremediation process uses microbes which co-metabolize methane with TCE and other chlorinated solvents,

potentially cutting treatment costs and time frames by 30 to 50%.

- *Thermal technologies* The EPA has conducted tests of thermally-based technologies in an evaluation of methods to treat organic contaminants in soil and groundwater. Low temperature thermal desorption is a physical separation process designed to volatilize water and organic contaminants. Typical desorption designs are the rotary dryer and the thermal screw. In each case, material is transported through the heated chamber via either conveyors or augers. The volatilized compounds, and gas entrained particulates are subsequently transported to another treatment system for removal or destruction.

Mobile incineration processes have been developed for use at remedial sites. While permitting is frequently a problem, the economics of transporting large quantities of soil can drive this alternative. One method is a circulating fluidized bed, which uses high-velocity air to circulate and suspend the waste particles in a combustion loop. Another unit uses electrical resistance heating elements or indirect-fired radiant U-tubes to heat the material passing through the chamber. Each requires subsequent treatment of the off gases. Also certain wastes will result in the formation of a bottom ash, requiring treatment and disposal.

In summary, the current business and regulatory climate is positive for the consideration of alternate treatment technologies. The re-evaluation of ongoing projects in light of regulatory and policy changes, as well as new technological developments may allow cost and time savings. The arsenal of techniques and technologies has developed substantially over the years, as has our knowledge of the physical and chemical processes associated with the management of wastes. Effluents and contaminated media are now easier to target with more efficient and cost-effective methods.

HAZARDOUS WASTES

A hazardous waste is a solid waste than may (1) cause or significantly contribute to an increase in serious irreversible or incapacitating reversible illness, or (2) pose a substantial threat or potential hazard to human health or the environment when improperly treated, stored, transported, or disposed of, or otherwise managed. Hazardous wastes are managed under two categories: (1) waste material currently being generated and subject to control by the Resource Conservation and Recovery Act (RCRA), and (2) wastes that have accumulated at inactive or abandoned sites or wastes resulting from spills that require emergency response. Both are addressed by the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), commonly known as Superfund.

The RCRA identifies hazardous wastes based upon lists of specific wastes and four characteristics. All waste generators are required to determine if any of these four characteristics are exhibited by their wastes.

SOLID WASTES

Hazardous wastes are managed as part of solid wastes; therefore, a discussion of the legal definition of solid waste is necessary. The word "solid," in this case, is misleading, because solid wastes can include liquids and contained gases. Thus, the important term is "waste," which is any material that is discarded—for example, discarded military munitions are considered solid wastes. Recycling has become a major factor in waste management, and the manner in which a waste is recycled determines whether it is to be treated as a solid waste. Material in a waste stream that is recycled by introducing it directly as an ingredient in a production process is not a solid waste, nor is it a solid waste if it is used as a substitute for a commercial product. On the other hand, waste disposed of by burning as a fuel, or in fuels, is a solid waste, as is material containing dioxin. If wastes are stored for recycling but are not 75% recycled in a calendar year, they are solid wastes.

Certain specific types of wastes, such as untreated domestic sewage, industrial wastewater discharges, irrigation return flows, and nuclear materials as defined by the Atomic Energy Act of 1954, are excluded from the definition as solid wastes.

HAZARDOUS WASTES

The growth of industry during World War II was accompanied by a great increase in the generation of hazardous wastes. It is estimated that this increase was accelerated after the war from half a million metric tons per year to almost 280 million metric tons by 1995. This phenomenal rate of growth caused Congress to react by passing the RCRA in 1976 as an amendment to the Solid Waste Disposal Act (SWDA) of 1965. The RCRA itself has been amended several times, most significantly in 1984 by the Hazardous and Solid Waste Amendments (HSWA) of 1984. The management of underground storage tanks (USTs) was included among the amendments.

There are three subtitles in the RCRA that have special significance to hazardous wastes. Subtitle C describes the hazardous-waste program, and Subtitle I describes the underground storage-tank problem. Subtitle D, which pertains to solid wastes, is important because a hazardous waste must first be identifiable as a solid waste.

As directed by Congress, the Environmental Protection Agency (EPA) has defined hazardous wastes by listing certain specific solid wastes as hazardous and by identifying characteristics of a solid waste that make it hazardous.

Is a waste Hazardous?

1. Is the waste excluded? (40 CFR 261.4) Code of Federal Regulations

If not,

2. Is it listed? (40 CFR 261, Subpart D)

F	Non specific sources such as spent solvents.
K	Source specific wastes.
P - U	Discarded products, off-spec material, container or spill residues.

If not,

3. Is it a characteristic waste? (40 CFR 261 Subpart C)

All of the wastes on these lists are assigned an identification number. All listed wastes are presumed to be hazardous regardless of their concentration and must be handled according to Subtitle D of RCRA.

Hazardous-Waste Characteristics

A waste that falls into one of the lists must still be examined to determine if it exhibits one or more of these characteristics: ignitability, corrosivity, reactivity, or toxicity. If it does, it is considered to represent an additional hazard and may necessitate special regulatory precautions.

Ignitability: Liquid wastes with a flash-point test less than 60°C and nonliquids that spontaneously catch fire through friction or by reaction with moisture and materials that meet the Department of Transportation definition of an oxidizer

Corrosivity: Aqueous wastes with a pH greater than or equal to 12.5 or less than or equal to 2, and liquids that can readily corrode or dissolve flesh, metal, or other materials (liquids that corrode steel at greater than 0.25 in. per year at 55°C)

Reactivity: Wastes that readily explode or undergo violent reactions, for example, sodium hydride

Toxicity: Wastes likely to leach chemicals into groundwater when discarded, for example, in a municipal landfill

The EPA designed a procedure called the toxicity characteristic leaching procedure (TCLP) to be used to determine the leachability of a waste. If the leachate contains an amount of any of 40 different toxic chemicals above its regulatory level, the waste is given the waste code associated with that compound or element.

Excluded Wastes (40 CFR 261.4)

Certain wastes have been excluded from hazardous wastes for practical or economic reasons. Wastes are excluded because:

- They fall within 19 categories that are listed as not solid wastes
- They fall within 17 categories that are listed as not hazardous wastes
- They are regulated under other laws, such as the Clean Water Act or the Atomic Energy Act
- They are generated in laboratory experiments or waste-treatability studies
- They are generated in raw material, product storage, or manufacturing units

Examples:

Domestic sewage discharged into a sewer to a municipal wastewater treatment plant, regulated under the Clean Water Act

Certain radioactive materials that are regulated by the Atomic Energy Act

Scrap metal that has been processed to make it easier to handle

Circuit boards that have been shredded and are free of potentially dangerous materials

Household wastes generated by normal household activities that could technically be considered hazardous wastes

Certain wastes from the exploration and production of oil, gas, and geothermal energy

Treated wood containing hazardous materials such as arsenic that is discarded by end users

Dredge materials subject to the Marine Protection, Research, and Sanctuaries Act of 1972

Underground Storage Tanks The greatest potential hazard from underground tanks is leakage that will contaminate groundwater. The EPA estimates that about 25,000 tanks out of 2.1 million regulated tanks contain hazardous materials. In 1984, Congress added Subtitle I to the RCRA to initiate a program to protect the environment from underground tanks leaking petroleum products and other hazardous materials.

For practical and economic reasons, many tanks are excluded from meeting federal requirements (but not necessarily state or local):

- Tanks of 1,100 gallons or less used to hold motor fuels for noncommercial purposes on farms and residences
- Tanks for heating oil used on the premises where tank is stored
- Tanks in basements or tunnels
- Septic tanks and storm and wastewater collectors
- Tanks with a capacity of 110 gallons or less

The nature and complexity of the program led the federal government to allow approved state programs to act in its place. Inasmuch as state regulations can be more stringent, it is important that anyone concerned about underground storage tanks be familiar with state requirements. The Petroleum Equipment Institute Web site presents a map showing which states regulate tanks; however, it is recommended that your local regulatory agency be consulted.

LUST, the program for leaking underground storage tanks, is funded by a 0.1-cent federal tax on every gallon of motor fuel sold in the country.

Accumulated Wastes

Past practices have left huge quantities of hazardous wastes deposited in landfills, ponds, fields, and storage in a manner that threatens our health and environment. Surface and groundwater supplies of drinking water are especially sensitive to contamination by these accumulations, which can take thousands of years to clean themselves. Depending on the type of contamination, treatment may be impractical or prohibitively expensive.

The federal government response to the problem of accumulated wastes and emergencies that release hazardous wastes was CERCLA, commonly referred to as Superfund. This law was enacted by Congress December 11, 1980, and amended by the Superfund Amendments and

TABLE 1

Toxicity-characteristic waste

The D List

If your waste contains one or more of these contaminants at or above the regulatory level, it is a hazardous waste.

Maximum Concentration of Contaminants for the Toxicity Characteristic

EPA Waste #	Contaminant	CAS No.	Regulatory Level (mg/l)
D004	Arsenic	7440-38-2	5.0
D005	Barium	7440-39-3	100.0
D018	Benzene	71-43-2	0.5
D006	Cadmium	7440-43-9	1.0
D019	Carbon tetrachloride	56-23-5	0.5
D020	Chlordane	57-74-9	0.03
D021	Chlorobenzene	108-90-7	100.0
D022	Chloroform	67-66-3	6.0
D007	Chromium	7440-47-3	5.0
D023	o-Cresol	95-48-7	200.0*
D024	m-Cresol	108-39-4	200.0*
D025	p-Cresol	106-44-5	200.0*
D026	Cresol	—	200.0*
D016	2,4-D	94-75-7	10.0
D027	1,4-Dichlorobenzene	106-46-7	7.5
D028	1,2-Dichloroethane	107-06-2	0.5
D029	1,1-Dichloroethylene	75-35-4	0.7
D030	2,4-Dinitrotoluene	121-14-2	0.13
D012	Endrin	72-20-8	0.02
D031	Heptachlor (and its epoxide)	76-44-8	0.008
D032	Hexachlorobenzene	118-74-1	0.13
D033	Hexachlorobutadiene	87-68-3	0.5
D034	Hexachloroethane	67-72-1	3.0
D008	Lead	7439-92-1	5.0
D013	Lindane	58-89-9	0.4
D009	Mercury	7439-97-6	0.2
D014	Methoxychlor	72-43-5	10.0
D035	Methyl ethyl ketone	78-93-3	200.0
D036	Nitrobenzene	98-95-3	2.0
D037	Pentachlorophenol	87-86-5	100.0
D038	Pyridine	110-86-1	5.0
D010	Selenium	7782-49-2	1.0
D011	Silver	7440-22-4	5.0
D039	Tetrachloroethylene	127-18-4	0.7
D015	Toxaphene	8001-35-2	0.5
D040	Trichloroethylene	79-01-6	0.5
D041	2,4,5-Trichlorophenol	95-95-4	400.0
D042	2,4,6-Trichlorophenol	88-06-2	2.0
D017	2,4,5-TP (silvex)	93-72-1	1.0
D043	Vinyl chloride	75-01-4	0.2

[*] If the o-, m-, and p-cresol concentrations cannot be differentiated, the total cresol (D026) concentration is used. The regulatory level of total cresol is 200 mg/l.

Reauthorization Act (SARA) on October 17, 1986, creating a hazardous-waste-site response program and liability scheme that authorizes the government to hold persons who caused or contributed to the release of hazardous substances liable for the cost or the cleanup of affected sites. The president or the delegated agency is authorized to draw funds from a revolving trust fund (Superfund) to respond to releases of hazardous substances: (1) the EPA can take action at the site using Superfund money that it can recover from potentially responsible parties (PRPs), (2) the EPA can order PRPs directly or through a court to clean up a site, and (3) the EPA can enter into settlement agreements with PRPs that require them to clean up or pay for the cleanup of a site.

Superfund money can be used for sites that meet the following criteria:

(1) The site is listed on the National Priority List (NPL).
(2) The state in which the site is located either contributes or provides financial assurances for 10% of any remedial costs incurred.
(3) The remedial action is not inconsistent with the National Oil and Hazardous Pollution Contingency Plan (NCP). The NCP was revised in 1994 to reflect the oil-spill provisions of the Oil Pollution Act of 1990 (OPA).

To establish that a person is liable under CERCLA, the EPA must prove that a hazardous substance was released from a facility that caused the government to incur costs in responding. CERCLA imposes liability on current and former owners and operators of a facility, persons who arranged for treatment or disposal of hazardous substances, and transporters of hazardous substances who selected the disposal site.

Planning Ahead

The Toxic Substances Control Act (TSCA), which became law on October 11, 1976, authorizes the EPA to secure information on all new and existing chemical substances and to control any that were determined to be unreasonable risks to public health or the environment. The Asbestos Hazard Emergency Response Act (AHERA) amended the TSCA on October 22, 1986, and the Radon Reduction Act amended it in October 1988. In 1990 AHERA was amended by the Asbestos School Hazard Abatement Reauthorization Act, which required accreditation for persons conducting asbestos inspection and abatement activities in schools and commercial and public buildings. The TSCA was amended in October 1992 to add the Lead-Based Paint Exposure Reduction Act.

All manufacturers and importers, processors, distributors, and users of chemical substances may be subject to TSCA reporting, record keeping, and testing requirements. Penalties for noncompliance may be up to $27,500 per violation per day. The demand for greater environmental protection at less cost led the EPA to recommend a one-stop approach toward controlling the release of pollutants from different types of facilities in the May 10, 1996, Federal Register. This Public Performance-Based Permitting Program (P3) is oriented toward identifying the actual impact on the environment, the compliance over time, and how well the enforcement agencies perform.

The ultimate approach to the prevention of exposure of the public and contamination of the environment by hazardous wastes is to find ways to produce what we need while minimizing the hazardous side products. The flood of legislation and its costs in money and time to industry has helped to generate a movement sometimes known as “green technology” that introduces environmental consciousness at the early stages of product development. Industry’s aim for a maximum yield is being tempered by the necessity to minimize unwanted and costly-to-dispose-of materials that must be classified as hazardous wastes.

The Control of Exposures

Certain factors must be understood and managed in controlling exposures to hazardous materials:

- Where in the environment have hazardous materials accumulated or are currently being introduced as a result of ignorance, carelessness, or criminal disregard for human health or the welfare of the environment?
- How much hazardous material has accumulated or is being released?
- What are the environmental pathways and mechanisms by which these materials reach human receptors?
- How hazardous are specific materials and how can their risks be estimated?
- How can their generation be minimized?
- How can their impact be minimized?
- How best can the public be informed about the important aspects of hazardous material control?
- How can the credibility of the agents responsible for informing and protecting the public be established?
- How can the priority for control of hazardous materials be determined within the complex structure of society’s problems?
- How can public outrage, often generated by media treatment of environmental problems, be managed so that priorities and resources are directed to where they are most needed?

The Effects of Exposures

The prime motivation for continuing generation of laws to control exposures to hazardous materials has been the fear of cancer; however, it should be noted that there are other health perils inherent in exposures. Environmental exposures pertinent to carcinogenesis include not only hazardous materials but also diets, infectious agents, and even social behavior, as illustrated by the summary prepared in 1981 by the Office of Technology Assessment of the Congress of the United States (Table 2).

Determining the probability of cancer being caused at the concentration levels of a substance encountered in the environment is very difficult. Testing on human beings is not to be considered; therefore, accidental exposures are an important source of information, but the actual exposures and doses are usually poorly documented and existing records can be misleading. As a result, the use of animals as surrogates is the usual alternative, with the size of the doses used and the difference in response between humans and animals as serious complicating factors.

Toxicity and Risk Assessment

Three elements must be present for a situation to have toxicological implications:

1. A chemical or physical agent capable of causing a response
2. A biological system with which the agent interacts to produce a response
3. A response that can be considered deleterious to the biologic system
