For butt welds in piping and fabrication welds in tanks and vessels, no such cold-work is feasible. Instead, an overmatching rod is used to confer higher resistance to the weld itself, for example, alloy 254SMO (S31254) to weld S31603 or S31703 or alloy 625 (N06625) to weld S31254.

Stress Corrosion Cracking

The predominant form of environmental stress cracking (ESC) in the 18-8 varieties of stainless steels is anodic stress corrosion cracking (SCC) under either applied or residual tensile stress. Compressive stress will not cause SCC, and indeed application of *compressive* surface stress, as by shot-peening, is sometimes used as a palliative surface treatment against SCC. Only the martensitic grades are subject to hydrogen-assisted cracking (HAC), a form of ESC found, for example, in "sour" service due to hydrogen sulfide effects.

The most common form of SCC of 18-8 austenitic grades is caused by chloride contamination. The ubiquitous chloride is sodium chloride (NaCl, table salt), as found in water and atmospheric exposures. NaCl usually causes SCC only between about 50 °C (120 °F) and 200 °C (390 °F). However, SCC can occur at room temperature and even at cryogenic temperatures in the presence of other chlorides, such as ferric chloride, sulfuric–NaCl mixtures, aqueous solutions of hydrogen sulfide–NaCl, and hydrogen chloride (HCl). For boldly exposed surfaces, there are rough correlations between pH and chloride concentration at which SCC may be anticipated. There is no minimum chloride concentration below which SCC will not occur if there is any possibility of concentration, either by evaporation or by occlusion or adsorption in films adhering to the stainless surface (e.g., mill scale, heat tints, welding slag, rust deposits, calcareous deposits, biomasses).

External stress corrosion cracking (ESCC) occurs when chlorides from the atmosphere, water leaks, or insulation concentrate on the surface of an 18-8 type stainless steel pipe or vessel. This is best combatted by coating vessels and piping that are more than 4 in in diameter and that operate between 60 and 200 °C, using a zinc-free and chloride-free paint system (4,5).

Hot caustic can also cause SCC of 18-8 stainless steels, as frequently happens when high-pressure steam is contaminated by carryover of alkaline boiler-treating chemicals. This is a potential problem in steam lines and during sterilization procedures. Use of nickel-base alloys such as N06625 or better (but not N08800 or N08825) is effective against caustic SCC.

Rouging in High-Purity Water

Austenitic stainless steels are subject to superficial rusting under some circumstances, either because of tramp iron embedded in the surface or from chloride contamination by corrosive atmospheres or water environments. The former problem is addressed through standard cleaning and passivation techniques described further next.

An apparently separate problem, "rouging," is sometimes observed with clean stainless steels in high-purity water at about 80 °C (175 °F) (6). Strictly speaking, rouge consists of a thin red deposit of α-Fe_2O_3 which is usually loosely adherent, wiping off easily. Generally, very little corrosion of the surface is evident. Typically, rouging is experienced in high-purity deionized water such as WFI ("water for injection") in the pharmaceutical industry, and UHPW ("ultrahigh-purity water") in the electronics industry and in nuclear reactor systems. When the U.S. Food and Drug Administration and solutions for human injection are involved, the presence of red-colored oxide on the surfaces of stainless steel equipment is not acceptable. Also, the standards for ultrahigh-purity water in the electronics industry do not permit this sort of condition.

One explanation that has been advanced to explain the fairly recent development of this phenomenon relates to modern steel-making processes. The AOD process itself gives a precise control that permits the manufacturer to work at the lowest ranges permissible for alloying elements, for example, chromium, within the nominal range specified. During long-time hot-working and annealing, the stainless steels form a chromium oxide scale that depletes the metal substrate of Cr. Modern short-time "spray pickling" may not be adequate to dissolve the depleted layer, leaving a surface of somewhat lesser corrosion resistance than the nominal analysis. However, even minor mechanical abrasion restores the proper surface chemistry, and electropolishing, although not simple nitric acid "passivation," which does not attack alloys with as little as 11% Cr, also does so.

A rouge of loose ferric oxide has been developed on Type 304L in laboratory tests in deionized water at 250 °C, simulating a reactor loop. When the water was cooled for sampling and filtered through a 0.1-μm PTFE filter supported on a 0.2-μm silver filter, no deposits were found on the PTFE but large crystals of spinel ferric oxide (with traces of Cr and Ni) had developed on the silver filter and grown back into the PTFE from the backside. This reaction suggests either soluble or colloidal iron in the nearly supercritical (288 °C or higher) water. Loose rouge has also been observed in hot aggressive waters (e.g., WFI) as low as 80 °C (175 °F) from sterilizing procedures with stainless steels in the pharmaceutical industry. Some operators have used solutions of sodium hydrosulfite ($NaHSO_3$) to reduce and remove rouge from their systems.

Some authorities state that the term *rouging* is a misnomer because the films may be either the powdery red iron oxide or adherent films of various colors including gray, black, purple, blue, and even yellowish green. In practice, it is often difficult to distinguish between superficial corrosion (involving a black substrate under a reddish-brown crust, associated with craters and white debris) and extraneous deposits (7). Heat tints and similar films exhibit colors related to their thickness and, although they can occlude and concentrated corrosive species such as chlorides, should not be considered rouge.

In one case, an electropolished Type 316L filter plate developed a blue-black tint, with no apparent corrosion of the parent metal, in ultrahigh-purity water of reportedly ambient temperature or at least not more than about 55 °C (130 °F). Analysis determined that the film contained more than 85% iron as a black oxide, probably derived from equipment upstream and entering the system, perhaps during regeneration of the mixed ion exchange beds.

FACTORS CONTRIBUTING TO LOCALIZED CORROSION

Some factors that contribute to the occurrence of localized corrosion in the stainless steels are surface defects or foreign matter. Surface defects are undercut welds, scratches, and grinding marks, which can initiate localized attack.

Foreign matter constitutes embedded iron or iron oxides (usually from mill or shop contamination of the stainless steel surface), the bluish heat tints adjacent to welds, weld splatter or arc strikes, and paint or crayon markings. Iron oxides and heat tints can occlude and concentrate chlorides and are themselves susceptible to corrosive attack. Weld splatter and arc strikes weaken the surface film and may constitute crevices for the initiation of attack. Paints and crayon markings may contain organic chlorides, which can hydrolyze or thermally degrade to release traces of hydrochloric acid and promote localized attack.

Bacterial effects in unsterile water, for example, residual hydrotest water, can also cause localized attack. The production of traces of hydrogen sulfide by sulfate-reducing bacteria (SRBs) and the excretion of iron or manganese oxides by aerobic strains can cause serious pitting in a very short time. Sulfides compete with oxygen and weaken the passive film, contributing to pitting and SCC. Microbiologically induced corrosion (MIC) has attracted increasing interest in the process industries.

PREVENTION OF LOCALIZED ATTACK

To prevent or minimize the possibility of localized corrosion, a specific sequence of events must be established. The methodology for this starts with proper materials and design and the establishment of certain procurement details in the materials selection, specification, and inspection phases, plus postfabrication cleanup and preservice sanitizing or other preparatory steps.

Materials

Materials must be properly chosen for the expected conditions of fabrication and service. The alloys chosen should be indicated by the proper alloy designation or corresponding UNS number, and these should be allied with an appropriate ASTM or ASME specification and any necessary supplements.

For best results, cast components, such as pumps and valves (which are predominantly CF8M and CF3M, the cast equivalents of types 316 and 316L), should be purchased to ASTM A743 with a special annealing temperature requirement. Annealing at about 1,120 °C reduces the tendency toward molybdenum gradients within the casting, ensuring a more uniform corrosion resistance.

To avoid materials mixups, such as may occur either at the manufacturer's plant or in warehousing, the composition of the alloy should be verified not only by checking the mill analysis but also by spot-test or nondestructive metal identification procedures; this is particularly necessary when a molybdenum-bearing alloy has been chosen. Inadvertent substitution of Type 304L for 316L has caused many problems in process applications. The fact that a piece of stainless steel is clearly marked as Type 316L, Heat No. *X*, is not a guarantee.

Finally, special finishes may be required. The several commercial finishes (in decreasing order of surface roughness) are numbered 1 (hot-rolled, annealed, and pickled) through 8 (a mechanically polished and buffed specular finish, with no visible abrasive scratches). For bioprocessing applications, a number 2B finish (cold-rolled, annealed, pickled, and temper-rolled) or a number 4 (which adds a 150-grit abrasive belt grinding to the 2 B finish) is usually specified.

For extra smoothness in special nonstick applications or to facilitate removal of bacterial contaminants, stainless steel may be electropolished to a mirror finish in lieu of a number 8 finish. Electropolishing aids surface homogenization and autopassivation, and an actual anodizing can be added as the final step to enhance the passive film.

Design

Because localized corrosion causes about 90% of the failures experienced with stainless steels in process applications, vessels, piping, and ancillary equipment must be designed, purchased, and maintained to minimize the risk of such attack. This requires that crevices, pockets, and traps should be avoided, thereby minimizing the probability of localized corrosion.

All fabrication steps, such as bending, forming, and welding, should conform to standard procedures. The welds must be full penetration to prevent crevice corrosion in incompletely fused joints. Fillet welds should be smooth and continuous, with no undercutting. Butt welds should be smooth and corner welds should be avoided if possible; side-wall welds in tanks are preferable. Lines and vessels should be sloped and self-draining, and top nozzles, side ports, and bottom nozzles must be accessible for cleaning.

A postweld chemical cleaning with an ammoniated citric acid solution, as described next, will remove the heat tints from the welded heat-affected zones (HAZ).

REMEDIAL MEASURES

Pickling

Because stainless steels are chosen for appearance, corrosion resistance, and freedom from product contamination

in storage and shipment, pickling (to remove contaminants) or passivation (to augment the naturally occurring surface film) is often required. A surface of assured cleanliness, uniformity, and corrosion resistance is desirable and, in some services, absolutely required.

During fabrication, stainless steels are subject to contamination by embedded steel particles or iron oxides, as well as heat tints caused by welding. The alloy surface may be cleaned with acid solutions or pastes, mechanically cleaned with a stainless steel wire brush or a clean abrasive disk, or hydroblasted with high-pressure water of potable water quality (i.e., <250 ppm Cl^-). ASTM A 380, "Cleaning and Descaling Stainless Steel Parts, Equipment, and Systems," provides detailed procedures. Demineralized water is usually specified for critical services, but a 25-ppm maximum chloride limit should be adequate.

Embedded iron is subject to air oxidation to hydrated ferric oxide ($Fe_2O_3 \cdot H_2O$). Foreign rust particles or mill scale (Fe_3O_4) may also be present. "Pickling" (see following) is intended to effect the desired cleanliness while simultaneously homogenizing the surface. A solution of 10–15% nitric acid and 1–3% hydrofluoric (HF) acid has been used as a "bright pickle" to remove visible oxides, while pastes of similar composition are available for localized application. Such solutions and pastes constitute somewhat of a safety hazard to personnel, as well as potential disposal problems, but are very effective. (Note: There is increasing resistance to using HF mixtures today because of the safety concerns and disposal problems related to environmental considerations.)

A HNO_3–HF mixture, unlike nitric acid itself, is a reducing acid intended to remove iron oxides and other metallic oxides by chemical reduction. This mixture is not a passivating medium, and corrosion rates are high during the actual exposure. However, a uniform passive oxide film will reform over the freshly cleaned surface after removal of the pickling environment by autopassivation.

Heat tints from welding tend to adsorb chlorides, with attendant pitting or stress corrosion cracking. They may be removed by abrasive disks or with a nitric–HF paste. Citric acid solutions, such as a 5% solution adjusted to pH 3.5 with ammonia and used at about 80 °C, are very effective and are to be preferred for removing heat tint from bioprocessing equipment. This solution is a chelating agent as well as an acid cleaning medium. Unlike the nitric–HF materials, citric acid solutions are benign and quite readily disposable from the environmental standpoint. However, chelants incorporate the metal ions within a clawlike ringed structure that may pass through conventional waste treatment systems. When heavy metals (i.e., chromium, copper, nickel, and zinc) are involved, special waste treatment systems, rather than simple sanitary drain systems, may be employed.

Antisplatter pastes are sometimes used to minimize weld-splatter sticking. If such splatter has adhered to the adjacent areas, it should be removed by a flapper wheel, wire-brushing, or hydroblasting. A cleaning operation with organic reducing acids may be followed with an alkaline sodium nitrite neutralizing–oxidizing rinse. (Note: Adequate provision must be made for proper disposal of the chemical solutions in accordance with environmental regulations.)

Electropolishing, in which the work serves as the anode during electrochemical dissolution to produce a highly polished nonstick and uncontaminated surface, is a specialized form of chemical cleaning in which the surface is actively corroded during the operation. Although the stainless steel surface will passivate on rinsing and exposure to air, many users specify a final anodizing step, which is tantamount to chemical passivation.

Passivation

Cleaning and pickling, as described, and passivation of stainless steels, particularly in the widely used austenitic 300 series, for example, Types 304 (S30400), 304L (S30403), 321 (S32100), 347 (S34700), 316 (S31600), 316L (S31603), and 317L (S31703), are widely misunderstood.

Cleaning and pickling are intended to remove foreign materials and permit the surface to equilibrate or homogenize, effecting an electrochemically uniform surface for resistance to localized corrosion. Passivation has been defined as a reduction in the rate of the anodic reaction of an electrode involved in corrosion, as by formation of a protective oxide film.

As previously noted, stainless steels are self-passivating on exposure to air and moisture as the result of their high chromium content (i.e., $>11\%$). Passivation treatment consists of augmenting the naturally occurring protective oxide film by chemical or electrochemical methods. The enhanced passive film is somewhat thicker and more persistent than that formed by autopassivation. For example, in some iron-sensitive organic chemicals (e.g., acetoacetanilide, glyoxal), stainless steel vessels are specially passivated and repassivated at intervals thereafter whenever chromophoric corrosion products are detected in the chemical product. This practice suggests a gradual diminution in thickness (or localized weakening of) the passive film with time in some services. Passivating is accomplished by treatment with oxidizing solutions, such as warm dilute nitric acid (not nitric-HF), ammonium persulfate (which is very safe to handle), dilute hydrogen peroxide, and citric acid–sodium nitrate mixtures.

Table A2.1 of ASTM A 380, Part II, recommends passivation with 20–50% nitric acid at 49–71 °C (120–160 °F) for 10–30 min or 21–38 °C (70–100 °F) for 30–60 min for dull or nonreflective surfaces. In the latter case, a 10% caustic–4% potassium permanganate solution is suggested for smut removal after the final rinse. A 20–40% nitric acid with 2–6% sodium dichromate is suggested for bright-machined or polished surfaces, instead of straight nitric acid. Such solutions are also used for precipitation-hardening (PH) grades, 12–14% chromium grades, and high-carbon martensitic grades, such as Type 440 (S44000). However, chromates are not compatible with pharmaceutical products. (Note: In chemical plants, large tanks or vessels are usually passivated with 10–15% nitric acid at 66 °C (150 °F) for about 4 h.) A 1% citric acid–1% sodium nitrate solution at 21 °C (70 °F) is discussed in ASTM A 380, Part III. The dairy industry has used a 0.5–1.0% nitric acid for 10 min at 65–82 °C (150–180 °F).

A special sequence of alkaline–acid–alkaline (A-A-A) treatment is recommended for free-machining grades (8). Because oil or grease interferes with passivation and because attack on sulfur or selenium inclusions in Type 303 (S30300) and its variants can leave minute pits with residual corrodents on the metal surface, the machined parts are (*1*) degreased for 30 min in 5% sodium hydroxide at about 70–80 °C (160–180 °F) and rinsed, (*2*) immersed in 20% nitric plus 3 oz. per gallon sodium dichromate at 50–60 °C (120–140 °F) for 30 min and rinsed, and finally (*3*) neutralized in the original caustic solution.

Because oil or grease can interfere with self-passivation by preventing ready access of water and oxygen to the metal surface, degreasing may be required. Such contamination occurs primarily from machining operations and should be removed by degreasing with nonchlorinated solvents before passivation is attempted. (Note: Chlorinated solvents may introduce inorganic chloride ions, Cl^-, by hydrolysis or by thermal degradation, and are proscribed.)

Note that nonoxidizing solutions, such as ammonium citrate, hydroxyacetic–formic acid mixtures, and EDTA (ethylenediaminetetraacetic acid) instead of a nitric acid passivation are described in ASTM A 380, Part III. The dairy industry uses a 0.5–1.0% phosphoric acid solution at 65–82 °C (150–180 °F) for 10 min. These nonoxidizing solutions used to remove iron or iron oxides only equilibrate the surface, facilitating autopassivation. They do not actually enhance the film as do the true passivation procedures.

Sanitizing

As a final step (or between batch operations), it is frequently desirable or even necessary to sterilize stainless steel equipment. Sodium or calcium hypochlorite is most frequently utilized, but the oxidizing capacity and chloride content pose serious potential dangers for pitting or crevice corrosion. The conditions and time of exposure and the proper steps to flush the hypochlorites from the system, including low spots, is of paramount importance. Serious failures have occurred in numerous stainless steel installations when adequate measures to preclude attack during treatment or by residual hypochlorites were not taken. Treatment with ozone or dilute hydrogen peroxide, as well as by ultraviolet light, seems to provide useful alternatives.

STANDARD OPERATING PROCEDURES

To summarize, the recommended sequence of treatment of fabricated stainless steel equipment for pharmaceutical applications should embrace the following steps:

1. A pretreatment with solvent or detergent to remove oil, grease, and the like
2. A rinse with water of suitable quality (deionized water being preferred)
3. Necessary pickling or other cleaning operations
4. Passivation
5. Water rinsing
6. Sanitizing
7. Final water rinse; drain and dry

A proper understanding of service conditions and requirements is essential if the several possible cleaning, pickling, and passivation treatments are to be successfully employed for their respective end purposes.

The most valuable resources for practical information on corrosion and corrosion prevention of stainless steels are as follows:

- NACE International (standards and publications), Houston, Tex.
- The Nickel Development Institute (AISI, INCO, and NiDI publications), Toronto, Ontario, Canada
- ASTM International (specifications), Barr Harbor, Pa.
- The Materials Technology Institute of the Chemical Process Industries, Inc. (publications), St. Louis, Mo.

OUTLINE

INTRODUCTION

The intensification of transfer processes in bioreactors using techniques that do not require additional energy costs is of great interest in biotechnology. Traditionally, most bioprocesses, especially aerobic fermentations, are conducted in stirred-tank bioreactors, which require considerable power input to attain adequate oxygen transfer rates. Besides the conventional mechanically agitated fermenters, other types of gas–liquid contactors are used, as pneumatic or jet bioreactors with or without a loop. Advantages of these nonmechanically agitated bioreactors are known to include efficient use of energy for aeration, simple design, and construction. To improve transfer processes in these bioreactors, considerable efforts have been made to study all the essentials of the major relationship for flow, mass and heat transfer over plates, cylinders, baffles, and spheres as well as through sieves and trays. These are the simplest and the oldest contacting bodies, and also are the basic shapes for other contacting devices of practical interest. Both theoretical and experimental studies on flow around these internals together with heat and mass transfer approaches are available (1–4).

Recently, new constructive types of internals known as static mixers or motionless mixers have been developed that supply spectacular effects concerning transfer rate increase. The first of these unconventional mixers was developed for viscous fluids about 30 years ago (5). After a slow start, the development of static mixers has been proceeding since 1970. Static mixers are applied in many operations in heterogeneous systems that require larger contact areas, thermal homogenization, and mass transfer. Today, these devices placed in column bioreactors are increasingly considered for use in fermentation industries, sometimes replacing the traditional mechanically agitated bioreactor design. Static mixers are suitable particularly for use in shear-sensitive cell cultures because of their lower shear rates, compared to those in mechanically agitated bioreactors. They proved to consider some specific criteria in the design of a bioreactor system for a definite process: population damage, energy distribution, and oxygen demand of a culture. The relatively numerous investigations and works that refer to static mixers are concerned with their influence on different process transfer parameters not only in fermentation systems, most of them being performed in model systems, in monophasic and polydispersed laminar or turbulent flow (usually gas–liquid dispersions), using low and viscous liquids, with Newtonian or non-Newtonian rheological behavior.

Static mixers frequently require no additional space (in-line assembly) and can be used as compact inserts or with a distance between the elements. They act on hydrodynamic conditions for turbulence development, the increase of contact areas, or the intensification of driving forces, separately or simultaneously. In all cases, the energy for process intensification is extracted from the fluid flowing through the mixers.

STRUCTURAL TYPES AND CONSTRUCTION

Static mixers can be of numerous constructive types, made of tubes, sheets, helixes, or wire matrix. They can be manufactured by steel, ceramic, or plastics. Their effect depends on the construction of the mixing element and the capacity to produce continuous separation, distribution, and reuniting the fluid stream. Besides their multiple advantages, static mixers often have the difficulty of a complicated structure. At the present time, most of the problems in the construction of static mixers have already been solved, and a number of different types of static mixing systems are being manufactured on an industrial scale, so that about 30 types of static mixers are known today. One of the most important moments in static mixing presentation was the ACHEMA '79 Exhibition in Frankfurt/Main (5). This section discusses some of the most interesting, familiar and, at the same time, most structurally dissimilar static mixers.

Static Mixers from Tubes or Short Pipes

Static mixers from tubes or short pipes generally affect the spatial distribution of the fluid by twisting, distorsion, and expansion of fluid elements in specially designed flow arrangements. For instance, the Ross-ISG static mixer (Aachener Misch- und Knetfabrik) is made by elements turned through 90°, placed one behind other. Over the cross-section of an element there are four obliquely sloped channels twisted with an angle of 120° (Fig. 1**a**), forming a tetrahedral space between elements. The PRM mixer (Prematechnik, Frankfurt/Main) consists of a tubular packet containing obliquely arranged partial tube sections (Fig. 1**b**), which change the direction of the fluid stream (5). Another static mixer used in laminar flow conditions, especially to equalize the distribution of the flow residence time, consists of six guiding holes, directed in the direction of flow (Fig. 1**c**). A portion of the fluid stream, which flows through the central section in front of the device, has a

higher mean velocity and crosses the channels that direct it to a zone with a low mean velocity. Other parts of the fluid stream that flow near the pipe wall cross over the channels that direct them to the central zone of the pipe behind the static mixer. Therefore, the positions of the fluid streams that flow with different velocities are inverted (6–8).

Static Mixers of Plates or Sheets

The effects of these static mixers depend on the continuous cutting, subdividing, distribution, and reuniting the stream of fluid. The PSM mixer (Petzhold, Frankfurt/Main) (Fig. 2**a**) contains rectangular and conical channels combined with conical holes resulted from a special arrangement of individual plates. The fluid flows from the entry to the exit of the static mixing element, being subdivided through a central hole, a conical space created by tangentially arranged slots and furthermore through other channels and openings (5). Sulzer mixers (Sulzer Brothers Ltd., Switzerland) are adequate for both laminar and turbulent regimes. They are constructed in many different ways (SMV, Fig. 2**b**; SMX, Fig. 2**c**) from stacks of corrugate sheets with open crossing channels. The SMX mixer consists of strips inclined to one another that form frameworks with the axis perpendicular to the column axis. The mixing elements are arranged successively in the column turned through 90° one to another. The SMLX mixer type is constructed from corrugate sheets with a distance between the strips increasing in the flow direction. The crossing angle of the sheets is 60°. These static mixers made of corrugate sheets can be mounted in packed form in compact arrangement or with distance between packets in different nonmechanical bioreactors (9). The Komax mixer (Long Beach, Calif.) contains triangular-shaped channels, made by the bent ends of the slotted sheets that form the mixing element (Fig. 2**d**). The Koch mixer (10,11) contains a numer of in-line elements mounted alternately at right angles to each other. The mixing elements are made from layers of corrugate metal sheets joined one to another, forming opened intersecting channels. C_1 and C_2 mixer types (12) (Figs. 2**e** and **f**, respectively) developed in the Central Institute of Physical Chemistry of the German Academy of Sciences and the Pyrapak 480 type developed at the CLG Leipzig-Grimma were also manufactured out of metal sheets.

Helical Static Mixers

The Kenics mixer (Ott Vertriebsgeselschaft, Leonberg) is made of counterclockwise and clockwise rotational elements twisted at 180°, being mounted in tubes alternating left and right with perpendicular leading edges (Fig. 3**a**). A particular form of this helical static mixer consists of an unbroken continuous helical surface that may have the diameter of a screw identical or smaller than the inner di-

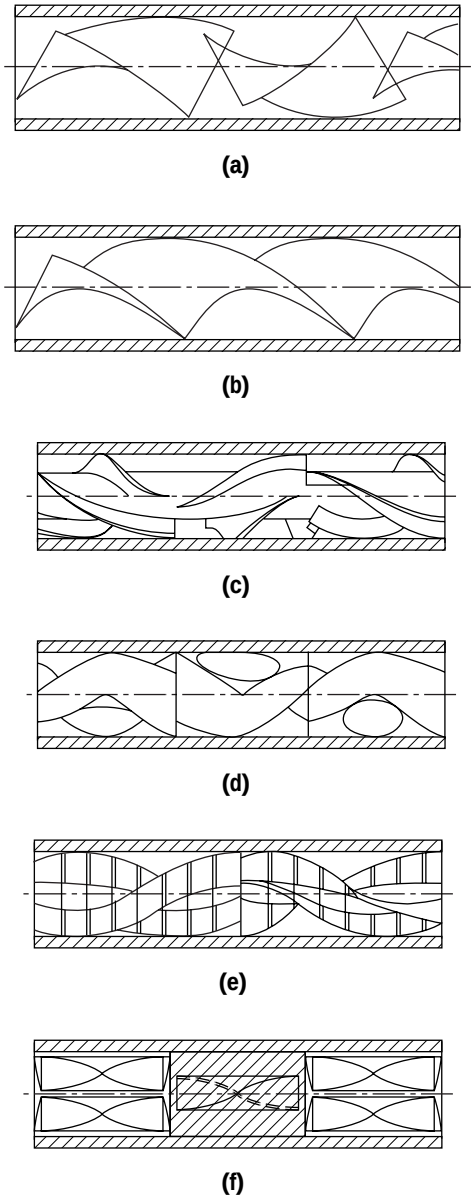

Figure 3. Helical static mixers. *Source*: Reprinted from Ref. 5, with permission from VCH Verlagsgesellschaft mbH, and from Ref. 7, with permission from Wiley-VCH.

ameter of the tube (13) (Fig. 3**b**). Helical static mixers can be disposed in columns as in-line elements or in packed form (14). The Erestat mixer (Yxzet, Dr. Karg GmbH, Affalterbach) consists of four baffles twisted in an alternate manner arranged in a left- or right-handed arrangement on an inner support (Fig. 3**c**). This assembly creates various flowing channels. The N-shaped mixer (Bran and Lübbe, Norderstadt) consists of twisted mixing elements (Fig. 3**d**) that determine variable cross-sectional areas, owing to the formation of variable channels. The Lightin type (Lightin, Rochester, NY) combined in-line mixers obtained by assembling three-bladed elements to form helixes with different senses of rotation (Fig. 3**e**). The HI mixer (Toray, Tokyo) is constructed by helixes twisted at 180°, fitted into holes performed parallel to the axis in a solid cylinder (Fig. 3**f**).

Wire Matrix Turbulators

The Heatex inserts (15) consist of a central wire core onto which are wound a series of wire loops. Each loop is inclined at a certain angle to the core. These inserts are pulled into a tube, the loops being so inclined as to be oversized for the tube and come into a close contact with the tube wall in the form of an arc (Fig. 4). A degree of resistance is offered as the insert is pulled into the tube, indicating that some wall contact is achieved and that the insert is self-supporting. Heatex inserts may have different loop densities, characterized by the number of tube wall contacts achieved per unit insert length.

EFFECTS OF STATIC MIXERS ON MOMENTUM TRANSFER

Flow Structure

Static mixers produce variations in the flowing cross-sectional area that result in modifications of velocity profiles. The fluid is split into individual streams at the open intersecting channels of the mixing element. At each intersection, a partial quantity is sheared off into a crossing channel and stagnant zones are usually eliminated. Also, most of the static mixers divide and reunite continually the main fluid stream and give rise to the formation of elementary layers of fluid. The number of n elementary layers or partial streams produced in laminar flow over a static mixer resulted through assembly of N mixing elements can be calculated from the following expression (16):

$$n = ca^{N} \tag{1}$$

where c and a are parameters characteristic for the static mixer in discussion that are usually given in the literature (16). In the laminar regime, the flow profiles are modified by cutting and twisting, displacement and distortion, or separation and expansion. In the turbulent flow, additional effects occur (5). For instance, the fluid streams are alternating directed from the center to the wall of the column

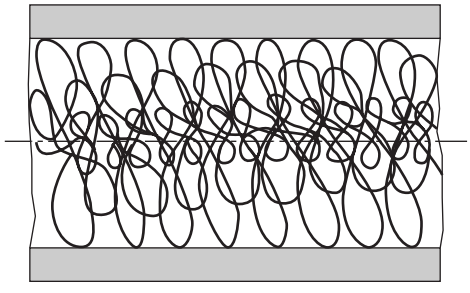

Figure 4. Static mixers of wire matrix. *Source*: Reprinted from Ref. 7, with permission from Wiley-VCH.

and from the wall to the center in the Ross-ISG mixer (Fig. 1**a**) or in the static presented in Fig. 1**c**. The presence of Heatex inserts (Fig. 4) causes a tube wall–fluid disturbance, and radial mixing is expected to be produced as the fluid flows through the mesh of loops nearer the pipe axis (15). In a Kenics mixer (Fig. 3**a**) a tracer injected below the first element in a certain point can perform a helical rotation strictly geometrically and reach the element edge in an opposite point situated on the same diameter, or it flows along a shortened path after a distortion and arrives at the end of the helix in a intermediate position on the diameter (5). The flow pattern in a Sulzer SMV mixer was presented by Pahl and Muschelknautz (5) using a model that consists in two triangular opened ducts crossing at 90° (Fig. 5) forming two intersected channels. Tracer introduced at the entrance of the channel I flows up to the intersection of the channels, and then about two-thirds of the tracer stream takes the shortest path flowing into duct II owing to the displacement that is produced at the crossing point. The trajectory of the tracer is also distorted; the fluid that exists along the left cathetus of the triangle representing the cross-section of the duct I shifts to the right side of duct I at the exit, performing a rotation. Also, the stream that starts from the opposite position at the entrance of duct I is greatly distorted at the crossing point and flows into both ducts I and II. In gas–liquid dispersions, a reasonably uniform distribution of the gas velocity over the cross-section of a column with static mixers is one of the favorable results. An equalizing effect is achieved by the resistance to flow, which forces the gas to spread out gradually in the direction of flow. This fact is very important in bioreactors with viscous non-Newtonian fermentation fluids, where the bubbles coalesce in the sparged vertical columns, leading to the formation of large bubbles, even at very low gas flow rates. In absence of static mixers, these bubbles rose with large velocities and their size distribution is controlled by bubble coalescence. The velocity profile of a fluid flowing through a tube containing motionless mixers is also considerably altered. There are some works in the literature that give information about radial and axial velocity profiles in the presence of static mixers (13,17,18). The axial and radial velocity profiles in a Kenics mixer change periodically owing to the use of alternating elements of right- and left-hand pitch that results in more intensive mixing of fluids. The screw having the form of a continuous helical surface divides the inside of the tube into two parallel channels, which causes a secondary motion of the fluid in the tube (13). In these motionless mixers, circulating flow occurs in the r-θ plane (r and θ being radial and tangential coordinates, respectively), which is caused by a slow twist in the partitioning chord so that it forms a helix. The actual velocity profiles can be calculated using a complex procedure (17), but an approximation can be made, leading to the following expressions:

$$v_r = \frac{dr}{dt} = \beta r(1 - r^{\upsilon}) \sin 2\theta \tag{2}$$

$$v_\theta = \frac{d\theta}{dt} = \beta[2 - (2 + \upsilon)r^{\upsilon}] \sin^2\theta \tag{3}$$

where

$$\upsilon = \left(\frac{11}{3}\right)^{0.5} - 1 \tag{4}$$

and β is a parameter that governs the intensity of circulation (17).

Pressure Drop

The changes in the velocity field caused by the static mixers cause modifications in the pressure loss as well. The pressure drop in static mixers depends very strongly on the geometrical arrangement of the packed elements, the nature of the flowing fluids, and the flow regime (19,20). A simple form representing the pressure loss equation can be referred to the empty tube, together with a geometrical correction factor (5,7,13). For Newtonian media, the equation for calculating the pressure drop is in the following form:

$$\frac{\Delta p_M}{\rho v_{SL}^2}\frac{2D}{L} = f_D(Re_D, \text{geometry}) \tag{5}$$

The mean liquid superficial velocity $\mathbf{v}_{SL}$ can be calculated on the basis of the empty tube cross-section as follows:

$$v_{SL} = \frac{4\dot{V}_L}{\pi D^2} \tag{6}$$

In laminar flow, $f_D\ Re_D$ = constant. Rearranging equation 5, a relationship is obtained whose denominator becomes the pressure drop for laminar flow through an empty pipe:

$$\frac{\Delta p_M}{\Delta p_L} = \frac{\Delta p_M}{32\eta v/D^2} \tag{7}$$

Defining a pressure drop factor as

$$z = f_D \frac{Re_D}{64} \tag{8}$$

it follows that

$$\Delta p_M = z\Delta p_L \tag{9}$$

In Figures 6 and 7, the pressure drop and friction factors for different static mixers are presented (5,7). The plot

$f_D - Re_D$ could be also used for comparing static mixers in the turbulent flow regime, since f_D is then approximately independent of the Reynolds number (Fig. 7). Compared with an empty tube, the pressure drop in static mixers is 7 to 200 times greater for laminar flow and 100 to 600 times greater for turbulent flow. Kenics mixers show the smallest pressure drop, and the Ross-ISG affords the largest pressure drop (5,16). Also, the pressure losses in a tube containing continuous screws calculated using equation 5 are lower than those corresponding to a tube containing Kenics mixers for the same value of the parameter h/d. The following analytical expressions were developed for the different types of helical static mixers (13). For Kenics type (for $15 \le Re_D \le 1{,}200$):

$$f_D = \frac{213.5 + 224.0(h/d)^{-1}}{Re_D} + [-0.549 + 4.775(h/d)^{-1}] \tag{10}$$

For static mixer with a continuous screw surface for $15 \le Re_D \le 90$,

$$f_D = \frac{191.3 + 229.0(h/d)^{-1}}{Re_D} \tag{11}$$

for $90 \le Re_D \le 5{,}000$,

$$f_D = \frac{79.8}{Re_D^{0.839 - 0.454(h/d)^{-1}}} \tag{12}$$

With increasing of h/d, the pressure loss decreases for any given type of fittings (Fig. 8). The specification of notation is given in Table 1.

In Newtonian liquids, the presence of wire matrix turbulators caused an increase in pressure drop by factors up to 20 compared with the empty tube case (15). In non-Newtonian fluids, the pressure drop in a static mixer assembly can be correlated as follows:

$$\Delta p_M = \frac{A}{Re_D} + \frac{B}{Re_D^m} \tag{13}$$

where the values of A, B, and m are dependent on rheological behavior of the liquid phase (7,21). Olivier and Oosterhuis (22) studied the pressure drop in the laminar flow regime for a Sulzer-SMV-type in the xanthan fermentation and found that the pressure drop is approximately 15 times greater than that in an empty tube. Fan et al. (23) studied the pressure drop in a gas–liquid system in a bubble column packed with Sulzer-Koch mixing elements and observed that the ratio of the pressure drop through the packed column to that of the empty one was slightly greater than 1. Data referring to the pressure drop in a column equipped with a static mixer of the Kenics type were obtained for a single (gaseous) phase and two-phase countercurrent flow, respectively (14,24). For one mixing element, the pressure drop, which is a function of the Reynolds number for the gaseous phase, Re_G, is assessed as follows:

$$\Delta p' = \frac{\Delta p_M}{N} \tag{14}$$

The pressure drop in the system was calculated using the gas dynamic pressure for the single phase as

$$\Delta p' = f_{Do}\rho \frac{v_{SG}^2}{2} \tag{15}$$

and for the diphasic flow:

$$\Delta p'_{TP} = f_{DTP}\rho \frac{v_{SG}^2}{2} \tag{16}$$

The plots show three domains with different slopes (Fig. 9). The friction factor also differs in the domains. For a single phase flow, it was correlated as follows:

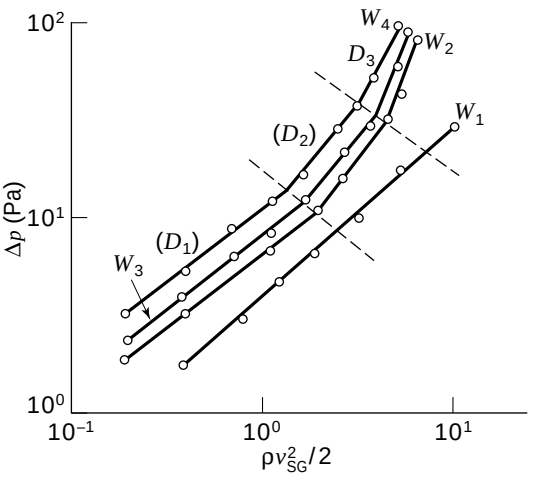

Figure 9. Pressure drop through a single static mixing element as a function of the dynamic pressure of the gaseous phase for different spraying intensities. $W_1 = 0$; $W_2 = 60.93$ m^3/m^{2}h; $W_3 = 81.24$ m^3/m^{2}h; $W_4 = 101.56$ m^3/m^{2}h. *Source*: Reprinted from Ref. 7, with permission from Wiley-VCH.

$$\text{Domain D}_1: \quad f_{Do} = 12.86 Re_G^{-0.1708} \tag{17}$$

$$\text{Domain D}_2: \quad f_{Do} = 1.039 Re_G^{0.1062} \tag{18}$$

$$\text{Domain D}_3: \quad f_{Do} = 0.9742 Re_G^{0.1137} \tag{19}$$

For a diphasic flow, the following relation was established (24):

$$\frac{\Delta p'_{TP}}{\Delta p'} = B'^{W(1+b'Re_G)} \tag{20}$$

The values of the spraying intensity, B', and of the parameter b', are different in the three domains of the curves (Table 2) (24).

For a two-phase flow, Shah and Khale (21) applied a correction factor for the manometer reading, assuming the gas holdup to be proportional with $\dot{V}_G/(\dot{V}_G + \dot{V}_L)$. For an empty tube, the correction factor was found to be 0.83. They presented their data in the form of a Lockhart-Martinelli correlation for three types of static mixers, Kenics, Sulzer, and Komax, for two-phase non-Newtonian liquid–air systems in the following form:

$$\Delta p_{TP} = \varphi_L^2 \Delta p_L = \varphi_G^2 \Delta p_G \tag{21}$$

$$\varphi_L^2 = 1 + (c'/X) + (1/X^2) \tag{22}$$

$$X = (\Delta p_L/\Delta p_G)^{0.5} \tag{23}$$

with $c' = 2.5 \pm 0.3$ for glycerol solution–air and $c' = 3.27 \pm 0.1$ for CMC solution–air diphasic systems, respectively. Generally speaking, the pressure drop in the gas–liquid systems decreases as the gas flow rate increases (10).

Gas-Holdup

In tower bioreactors with or without a loop (bubble columns, airlifts, jet contactors), liquid flow and gas holdup

are of basic importance in the determination of their performance (25). Because microbial aerobic cultures often behave as non-Newtonian fluids, much attention was directed toward the performance of these gas–liquid contactors equipped with static mixers, especially when they handle non-Newtonian fermentation liquids. The rheological behavior of biofluids plays an important role in bubble coalescence and breakup, because the large velocities of coalesced bubbles lead to gas holdup decreasing (26). The presence of static mixers in diphasic flow diminishes the bubble coalescence rates owing to their shear effect. Therefore, the average bubble size should decrease and gas holdup is enhanced (7,10) (Fig. 10). The results of MacLean et al. (27) confirm these findings, suggesting that the motionless mixers help to retain more gas in the column. Similar effects can be obtained in triphasic sparged reactors (28). By using Ross-LPD and Sulzer SMV static mixers, larger gas holdup values resulted, compared with the empty contactor (Fig. 11). Kenics mixers mounted in an airlift bioreactor contribute to increase gas holdup values during the batch fermentation of a yeast culture (29). Gas holdup in downcomer (annular section) decreased because of a lower liquid recirculation rate, which implied a more intense gas disengagement at the upper part of the bioreactor, reducing the quantity of the recirculated gas. In the region of greater airflow rates (the riser), gas holdup values are, however, improved. This behavior had a favorable influence on oxygen transfer rates (29,30). The presence of static mixers does not change the correlation between gas holdup and gas superficial velocity, which was established in the following form:

$$\varepsilon_G = a v_{SG}^b \tag{24}$$

For example, static mixers manufactured through assembly of corrugated stainless steel sheets and mounted in the riser section in an external-loop airlift bioreactor can contribute to gas holdup intensification at any given gas flow rate and liquid phase properties, relative to bioreactor configuration without static mixers (Fig. 12), also proved by the modified values of the parameters a and b in equation 24. This effect is found in low-viscous Newtonian and viscous non-Newtonian liquids as well (Table 3) (25). It is evident from Table 3 that static mixers show an increased efficiency in more viscous liquids. Also, they affect the values of the coefficient a in equation 24 in a greater measure than those of b. Therefore, larger values of gas holdup in columns with static mixers resulted because of smaller bubble sizes and hindering action of the packing, which contribute to increasing the gas phase residence time (21,31).

Liquid Velocity

The presence of static mixers changes the liquid circulation rates, because they act as supplementary resistances in the flow path. Besides changes in gas flow pattern, the presence of static mixers in gas–liquid contactors having a net liquid flow (continuous bubble columns, airlifts, con-

tactors with a liquid jet) changes the liquid circulation velocities, their effects being complementary to those of several other parameters, including gas superficial velocity, gas holdup, liquid phase viscosity, pressure drop along the flow path, reactor geometry. For instance, the static mixers mounted in an external-loop airlift bioreactor diminish the liquid superficial velocity in the riser section both in Newtonian and non-Newtonian liquids. The parallel lines in the diagram presented in Fig. 13 show that in all cases the liquid velocity increases with gas superficial velocity. This behavior can be expressed by the following mathematical expression as:

$$v_{SL} = f v_{SG}^{m} \tag{25}$$

In non-Newtonian liquids, it was found that the presence of static mixers affects f and m values, dependent on consistency index values (25) (Table 4).

The relationship between the ratio of f values with and without static mixers, respectively, and the consistency index in an airlift contactor can be represented by the following relationship (25):

$$\frac{f_M}{f} = 0.85K^{0.008} \tag{26}$$

The effects of the consistency index on the liquid velocity could be considered as being less significant proving that static mixers are effective in viscous liquids. Popovic and Robinson (32) found that the circulating liquid velocity in the riser section of an airlift reactor is dependent mainly on the downcomer-to-riser cross-sectional areas ratio, A_D/A_R, the apparent viscosity, η_{ap} and gas superficial velocity, as described by the following correlation:

$$v_{SLR} = c' v_{SGR}^{0.32} (A_D/A_R)^{0.97} \eta_{ap}^{-0.39} \tag{27}$$

Considering that equation 27 correlates well a large number of experimental data, it was found that the differences in the values of v_{SLR} should be treated as particular cases of diminuation up to 40% of the geometrical parameter A_D/A_R, as a result of the presence of static mixers (25).

Mixing

As shown, homogenization in static mixers is attained by means of motionless elements using the flow energy of the fluids. The mixing effect depends on the continuous separation, distribution, and reuniting streams of material (5,7). The energy requirements of static mixers when used for mixing are lower than those of conventional dynamic mixers and, moreover, they are of simple construction. In the case of two components, the two quantities are related to each other by the volumetric flow rate ratio, $\dot{V}_2/\dot{V}_1$. The degree of mixing may be described using the variation coefficient $s/\bar{C}_V$ or the relative standard deviation s/τ_0 (5). For component 1, the following expression held:

$$s_1/\bar{C}_V = \sqrt{\dot{V}_2/\dot{V}_1}\, s_1/\tau_0 \tag{28}$$

where

$$s_1^2 = \frac{1}{n-1}\sum_{i=1}^{n}(C_{V_i} - \bar{C}_{V_1})^2 \tag{29}$$

$$\tau_0 = [\bar{C}_{V_1}(1 - \bar{C}_{V_1})]^{0.5} \tag{30}$$

$$\bar{C}_{V_1} = \frac{1}{n}\sum_{i=1}^{n} C_{V_{1,i}} \tag{31}$$

$$C_{V_{1,i}} = \dot{V}_{1,i}/(\dot{V}_{1,i} + \dot{V}_{2,i}) \tag{32}$$

The degree of mixing is strongly dependent on the static mixer type and normalized mixing length, L/D (Fig. 14). It can be seen that the Sulzer-SMX mixer and HI-mixer require shorter homogenization lengths. Also, the degree of mixing is dependent on the entry point of fluids to be mixed as well as by the operation scale (5). Static mixers achieve rapid mixing of fluids with low energy requirements, and the fluids may have either similar or different viscosity. Operation in fermentation processes involves very viscous fluids, and the flow will be predominantly in the laminar region for both liquid and gaseous phases. Suitability of static mixers to mix fluids of different viscosities was investigated in the literature (12,22,33,34).

Mixing behavior is usually described by mixing time, t_M, which is defined as the time required to achieve a definite degree of homogeneity after a trace pulse has been injected into the reactor (35). The mixing time is highly dependent on the presence of static mixers (34). In gas–liquid dispersions, the mixing time is dependent to a great extent on the gas superficial velocity and the presence of static mixers and to a low extent on the liquid phase properties. In Figure 15 the mixing time in water and starch solutions is plotted against superficial velocity. With static mixers, mixing times at a given superficial velocity are essentially

Figure 14. up to 50% shorter than in the reactor without static mixers. The dependence of mixing time on gas superficial velocity can be expressed by the following equation:

$$t_M = k v_{SG}^q \tag{33}$$

The presence of static mixers does not affect q very much, but significantly influences k. Mixing times increase with increasing pseudoplasticity, but not very greatly (Fig. 15). In non-Newtonian systems, the consistency index had no significant influence on these parameters in the presence of static mixers (Fig. 16).

Other properties of a suitable static mixer are good radial mixing on as short as possible flow path and as low as possible axial mixing. Some static mixers contribute to diminish axial dispersion and influence the residence time distribution in laminar monophasic liquid flow, dependent on the Reynolds values (6). In the presence of static mixer seen in Figure 1**c**, the pulse response at the tube exit indicates a smaller axial dispersion (Fig. 17) (6). Also, the dead zones are diminished, and the distribution function of the elements of fluids with ages less than the residence time indicates an evident equalization of the residence times in laminar flow (Fig. 18) (6). In turbulent flow regimes, this effect is not very important. A good radial mixing of a static mixer does not imply in all cases also low axial mixing. The individual static mixers display a different dependence of the axial dispersion on the flow rate of the phases both for single and two-phase flow system. A good static mixer from the standpoint of axial dispersion in single-phase flow does not necessary display a low axial dispersion in two-phase flow (12). Data on axial mixing for the individual types of static mixers are usually missing in the literature. Fialova et al. (12) presented the value of the Péclet number given by Sulzer for its SMX product (*Pé* > 110, d = 0.1 m; L/D = 22). These properties can be ascertained by experimental means.

MASS TRANSFER IN PRESENCE OF STATIC MIXERS

The application of the static mixers built in nonmechanically bioreactors, especially in aerobic bioprocesses, should lead to attain the most extensive transport rate of oxygen into the liquid phase at the low possible energetic requirement. The influence of static mixers on hydrodynamic behavior has an important impact on mass and heat transfer characteristics and transfer rate intensification. The improvement of the oxygen mass transfer in bioreactors depends on a number of factors, such as bubble formation, bubble size distribution, bubble shear, gas holdup, rate of coalescence, and breakup. Also, bubble or drop coalescence behavior in gas–liquid dispersions, especially in viscous fluids, demonstrates the necessity for redispersing the gaseous or liquid phase to prevent the reduction of interfacial

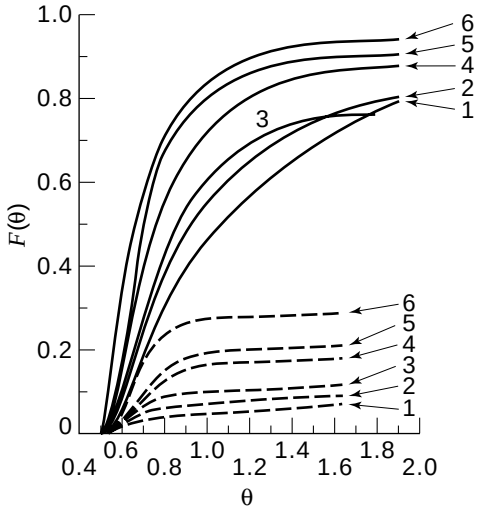

Figure 18. The distribution function of the fluid elements with the age less than the residence time versus Reynolds number in the tube without and with the static mixer from Figure 1**c**. 1 = Re_D = 630; 2 = Re_D = 950; 3 = Re_D = 1,260; 4 = Re_D = 1,580; 5 = Re_D = 1,890; 6 = Re_D = 2,2000. - - - - - - = without static mixer; — = with static mixer.

areas and mass transfer rates. A general solution to the mass transfer problems that appear in gas–liquid systems can be the use of static mixers installed at different intervals for increasing the degree of the gas dispersion and mass transfer rates (7,33,36). Usually, the intensity of oxygen transfer is characterized by its volumetric mass transfer coefficient, *Kla*. Static mixers improve *Kla* at any given gas flow rate relative to the bioreactor configuration without static mixer (7). The mass transfer rates are very high during bubble formation, and the values of mass transfer coefficient vary significantly being associated with large surface renewal rates. Coalescence and break-up, bubble formation, bubble shear, and turbulent liquid surface are examples of conditions where mass transfer coefficient is large. The introduction of static mixers has two important roles in *Kla* enhancement:

1. Bubble redispersion produces increased values of interfacial areas, *a*.
2. The interfacial turbulence during bubble coalescence and redispersion increases *Kl*.

At low gas flow rates, the latter mechanism becomes important (37). Small bubble size can be obtained with a homogeneous bubble distribution over the column cross-section and with a narrow size distribution. However, small rigid bubbles less than 2 mm in diameter have frequently been found to have much smaller mass transfer coefficients (38). Several studies were presented concerning the influence of the Sulzer type (22,33,36,39), Koch (10,11,20,24,40), Kenics (29,30) on *Kla* in bubble columns and external-loop airlift bioreactors in waterlike fluids as well as in non-Newtonian pseudoplastic media. Static mixers significantly enhance the mass transfer rates in waterlike fluids (Fig. 19). In non-Newtonian systems, the improvement in *Kla* due to static mixers depends on the rheological parameters. Stejskal and Potucek (30) and Chisti et al. (39) mounted static mixing elements in the risers of internal- and external-loop airlift reactors that

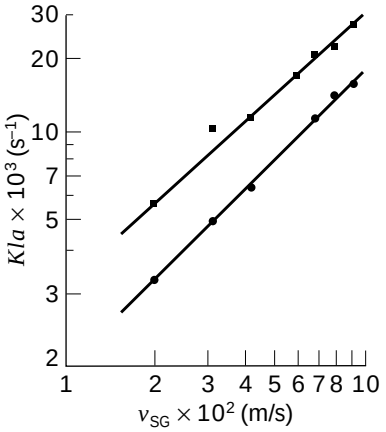

Figure 19. Effects of static mixers on the mass transfer coefficient in aqueous salt solutions. ● = without static mixers, ■ = with static mixers. *Source*: Reprinted from Ref. 7, with permission from Wiley-VCH.

enhanced mass transfer in viscous pseudoplastic CMC aqueous solutions that simulated the rheological behavior of filamentous biofluids. In pseudoplastic liquids, the thicker the fluid was, that is, the higher its value of the consistency index, *K*, the greater the effect of the static mixer was on *Kla* (36,39). Usually, the accumulation of biomass or product in the culture medium leads to increased viscosity and non-Newtonian flow characteristics that contribute to diminish *Kla* (26). This leads to a drastic decrease in oxygen transfer capability, and the aerobic culture eventually becomes oxygen limited (33,41). The significant decrease in *Kla* is mainly attributed to the formation of large bubbles and a decrease in specific interfacial areas that can be counterbalanced by the static mixers presence. The values of *Kla* can be correlated with the gas superficial velocity, v_{SG}, in tower bioreactors as

$$Kla = u v_{SG}^{t'} \tag{34}$$

The presence of static mixers affects u and t' values. They do not affect t' very much, but significantly enhance u dependent on the consistency index (Fig. 20) (36). The degree of *Kla* enhancement depends on the fluid viscosity and the pattern of fluid circulation through the reactor. The results of Hsu et al. (20) also show that mass transfer coefficient in a bubble column in the presence of Koch type static mixers is improved. A comparison of the oxygen transfer efficiency in terms of kilograms of oxygen transferred per kilowatt hour consumed at low flow rates indicated that the Koch mixed column was almost twofold as efficient as the empty column. However, at high gas flow rates, the efficiency was about the same for the two columns. Also, the ratio Kla/P_G can be used to characterize the efficiency of energy utilization for mass transfer per unit volume of the liquid phase or dispersion. Potucek (29) found that an airlift bioreactor with static mixers showed higher Kla/P_G values for absorption of oxygen in water or polyacrylamid solutions in the region of gas velocities of $v_{SGR} = 0.01 - 0.06$ m/s. Also, in the batch yeast cultivation, Kla/P_G was larger than in the witness bioreactor; gas superficial velocities ranged from $v_{SGR} = 0.03 - 0.06$ m/s, whereas with $v_{SGR} = 0.01 - 0.03$ m/s, lower values of Kla/P_G were obtained. As energy costs increase, more capital should be allocated to motionless mixers that increase the mass transfer efficiency. Olivier and Oosterhuis

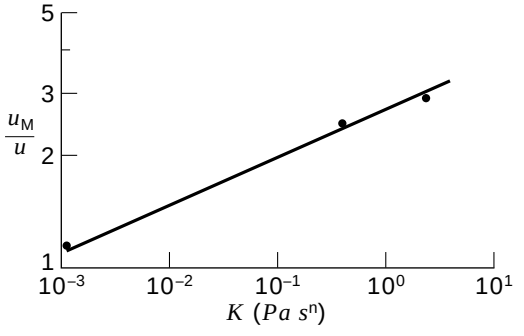

Figure 20. Variation of the ratio u_M/u with the consistency index.

(22) considered that by keeping liquid and gas velocities as well as the volume ratio of empty tube parts and internals constant, the oxygen transfer would be higher and nearly independent on the scale. They also considered that oxygen transfer takes place not only in the internals, but also in the empty tube parts, and correlated the overall oxygen transfer coefficient as (22):

$$Kla = \frac{(Kla\ V_M)_{\text{internals}} + (Kla\ V_E)_{\text{empty tube}}}{(V_M)_{\text{internals}} + (V_E)_{\text{empty tube}}} \quad (35)$$

The results obtained in different gas–liquid contactors show larger interfacial areas in the systems with static mixers (42) (Fig. 21). Data also indicate that the static mixer contactors are superior to other nonmechanically contacting devices, regarding mass transfer coefficient. Hsu et al. (20) investigated mass transfer in a bubble column with Koch mixers comparative to that with sieve trays. They found a different dependence of Kla on gas superficial velocity:

$$\text{for KOCH mixed column:} \quad Kla \approx v_{SG}^{0.95} \quad (36)$$

$$\text{For sieve-tray bubble column:} \quad Kla \approx v_{SG}^{0.89} \quad (37)$$

Also, data presented by Atkinson and Mavituna (42) show that in static mixed gas–liquid contactors a larger range of high Kla/V values was obtained, compared to those resulted in other gas–liquid contacting devices (Fig. 22).

The optimization of the number of motionless mixing elements and their positioning can enhance the mass transfer rates.

HEAT TRANSFER USING STATIC MIXERS

The role of the static mixers in heat transfer to flowing homogeneous or heterogeneous or heterogeneous fluids consists in fetching fresh fluid to the surface of the heat exchanger by promoting secondary flow, mixing, and turbulence (15). Most heat exchanger performances depend on hydrodynamics, and there are evident advantages that heat transfer may be enhanced by using built-in elements that change the velocity fields inside the tubes. Several studies investigated the heat transfer enhancement by using twisted strip inserts (43), helical static mixers (44,45), and wire matrix (15). The static mixers mostly used for heat transfer enhancement were helical static mixers, which promote a secondary motion in the fluid, increasing the heat transfer between the fluid and the tube wall by convection.

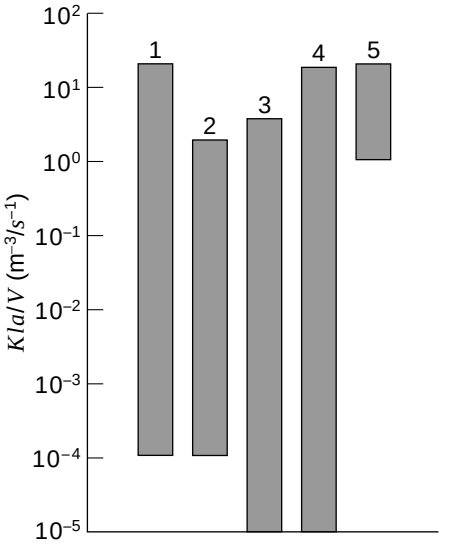

Figure 22. Comparison of different gas–liquid contacting devices regarding Kla/V values (significance of numbers as in Figure 21. *Source*: Data from Ref. 42.

The heat transfer performances of a given piece of equipment is usually estimated in terms of a Nusselt number, Nu, which is then related to the fluid properties and the Reynolds number, Re, characterizing the fluid environment. For instance, the individual heat transfer coefficient α_1 for the inside surface of a tube equipped with a helical static mixer is assessed from the following expression (44):

$$Nu_1 = \frac{\alpha_1 D}{\lambda_1} = \Phi(Re_1, Pr_1, h/d, \eta W_1/\eta_1) \quad (38)$$

with

$$Re_1 = \frac{D v_1 \rho_1}{\eta_1} \quad (39)$$

$$Pr_1 = \frac{c_{p1}\eta_1}{\lambda_1} \quad (40)$$

The overall heat transfer coefficient, K_T, of a tubular heat exchanger is related to the individual coefficients as follows:

$$K_T = \frac{1}{\frac{1}{\alpha_1}\frac{D_e}{D} + \frac{D_e}{2\lambda_s}\ln\frac{D_e}{D} + \frac{1}{\alpha_2}} \quad (41)$$

The values of K_T in a double-tube heat exchanger with hot water flowing through the annular space and cold water–glycerol solutions circulating through the inner tube containing helical static mixers were determined using the individual heat transfer coefficients calculated with the following equations (44): For the tube ($90 \leq Re_1 \leq 5800$; $6 \leq Pr_1 \leq 5800$);

$$\mathrm{Nu_1} = 1.86\left(\mathrm{Re_1 Pr_1}\frac{\mathrm{d}}{\mathrm{L_T}}\right)^{0.33}\left(\frac{\eta_1}{\eta_{W_1}}\right)^{0.14} \quad (42)$$

For the annular space ($Re_2 = 1520$):

$$Nu_2 = 1.02 Re_2^{0.45} Pr_2^{0.50}\left(\frac{D_e - D}{L_T}\right)^{0.40} \cdot \left(\frac{D_e}{D}\right)^{0.80} Gr^{0.05}\left(\frac{\eta_2}{\eta_{W_2}}\right)^{0.14} \quad (43)$$

Lecjacks et al. (44) reported the following relationship for helical elements of continuous and Kenics type:

$$Nu_1 Pr_1^{-1/3}\left(\frac{\eta_{W_1}}{\eta_1}\right)^{0.14} = a_1 Re_1^{n_1} \quad (44)$$

with

$$a_1 = \Phi_a\left(Re_1, \frac{h}{D}\right)$$

and

$$n_1 = \Phi_n\left(Re_1, \frac{h}{D}\right)$$

Also, they extended their investigations in the turbulent flow regime, which allowed them to assess the favorable effect of the built-in elements on heat transfer, especially in the laminar regime, for low values of h/d in Kenics static mixer. In the continuous helical static mixer, an increase in friction factor and heat transfer coefficient of 4.4% and 5.3% was obtained, whereas in the Kenics insert this increase was of 19.3% and 10.2%, respectively, comparative with the empty tube (45). Therefore, the heat transfer coefficient was found to be dependent on the flow conditions and geometrical properties of the internals. Olivier and Aldington (15) found a noticeable heat transfer enhancement by factors up to five in round tubes containing wire matrix turbulators, comparative to the empty tube, in laminar regime. Also, the wires caused the falling of the effective viscosity in non-Newtonian solutions at high liquid flow rates. Static mixers are used for thermal homogenization when a breakdown can occur on the heat transfer surface, especially in viscous media. Shear-thinning fluids should give good heat transfer/pressure drop behavior in the presence of tube inserts because the viscosity is reduced in the higher shear rates that are obtained. Static mixers are insensitive and nonresponsive to temperature. They can be well sealed against the surroundings. Maintenance and wear are small, and they are very economical, because they do not require additional space (in-line disposed).

SCALE-UP CONSIDERATIONS

Static mixers are used for many monophasic or gas–liquid, two-phase operations, which involve momentum, mass, and heat transfer. They are largely used in biotechnology and other applications such as processing of natural gases, wastewater treatment, dissolution of gases, continuous mixing of mutually soluble fluids of different viscosities, and so on. It is widely agreed that static mixers are suitable to mix fluids of very widely different viscosities, being especially effective for use with highly viscous fluids. They also could remove any mistakes made by the equipment designed for heat and mass transfer.

As shown in the fermentation field, factors taken into consideration on the choice and the design of an equipment for a definite process, besides the general factors, should include the population safety and damage, the uniform distribution of the phases and energy in phase transfers, the oxygen demand of the aerobic cultures, and so on (4,7). Static mixers can fulfill these objectives. Their action gives rise to elementary fluid layer formation. The maximum thickness of an elementary layer is given by the following expression (16):

$$\delta = \frac{D}{n} = \frac{D}{ca^N} \quad (47)$$

As in the case of any apparatus, the static mixer behavior is tested first in small-scale equipment and then designed for large-scale operation, on the basis of the experimental data acquired for the model. For geometric similarity between the model and the actual mixer, the same degree of mixing means that (16):

$$\delta_m = \delta_a \quad (48)$$

or

$$\frac{D_m}{ca^{N_m}} = \frac{D_a}{ca^{N_a}} \quad (49)$$

Boss and Czastkievicz (16) introduced a linear scale-up coefficient, expressed as follows:

$$S = \frac{D_m}{D_a} \quad (50)$$

when equation 49 becomes

$$N_a = N_m + \frac{lgS}{lga} \quad (51)$$

This reasoning is valid in the laminar flow regime. For

constant physicochemical properties of the fluids that flow through the model and the actual mixer, the changes in Reynolds number for the actual mixer relative to the model can be attributed to modifications occurring in the flow rate of the fluids or in the diameter of the static mixer. The relationships between the volumetric flow rates and Reynolds numbers in the model and the actual mixers, respectively, are as follows (16):

$$\dot{V}_a = \frac{z_m}{z_a} \frac{S^3}{1 + \lg S/N_m lga} \dot{V}_m \quad (52)$$

$$Re_a = \frac{z_m}{z_a} \frac{N_m}{N_a} S^2 Re_m \quad (53)$$

These general equations, applicable to scale-up of mixing processes in static mixers, are inferred starting from the pressure drops associated with laminar flow of a Newtonian fluid through circular pipes, which are taken into account by the pressure drop coefficient z, defined in equation 9. Boss and Czastkievicz (16) gave several examples of scale-up calculations for some types of static mixers, namely Kenics, Ross-ISG, and Sulzer.

CONCLUDING REMARKS

An overview of the published results on transfer processes in fluid flow through static mixers has been presented in the preceding pages. The velocity fields inside a tube containing motionless mixers can be modified using static mixers. As a result, a significant enhancement in mixing, mass, and heat transfer are achieved. Static mixers can be used in chemical and biochemical processes to perform a rapid mixing of monophasic, diphasic, and poliphasic systems with low energy requirements, and the fluids may have similar or different viscosities. The energy for mixing is extracted from the fluid flowing through the mixers. Static mixer effects result from specially designed flow arrangements, cutting and twisting, displacement and distortion, or separation and expansion. Significant efforts are devoted by specialists for developing new static mixers and optimal strategies for using minimum number of static mixers located at different positions in tubes, to ensure greater efficiency on transfer processes intensification, especially mixing and oxygen transfer in aerobic fermentation processes.

NOMENCLATURE

A	Cross-sectional area [m^2] (1 in^2 = 6.4516.10^{-4} m^2; 1 ft^2 = 9.290304.10^{-2} m^2)
a	Specific interfacial area [m^2/m^3]
c_p	Specific heat at constant pressure [J/kg °K] (1 ft pdl $°R^{-1}$ lb^{-1} = 0.1672255 J/kg °K)
D	ID of the tube [m] (1 in = 2.54.10^{-2} m; 1 ft = 3.084.10^{-1} m)
D_e	Outside tube diameter [m]
d	Diameter of static mixing element [m]
f_D	Friction factor
Gr	Grashof number
h	Height (length) of a static mixing element [m]
K	Consistency index in power-law rheological model [Pa s^n] (1 lb s ft^{-2} = 1.488163944.10 Pa s)
K_T	Overall heat transfer coefficient [W/m^2 °K] (1 lb s^{-3} $°R^{-1}$ = 0.816466266 W/m^2 °K)
L	Length of the tube [m]
N	Number of static mixing elements
Nu	Nusselt number
n	Number of elementary layers produced in laminar flow over a static mixer
Pr	Prandtl number
Δp	Pressure drop [Pa] (1 lb in^{-2} = 6.89476.10^{-3} Pa)
Re	Reynolds number
Re_D	Reynolds number in a tube with inner diameter D
t_M	Mixing time [s]
V	Volume [m^3] (1 ft^3 = 2.83168 10^{-2} m^3)
$\dot{V}$	Volumetric flow rate [m^3/s] (1 ft^3 s^{-1} = 2.83168.10^{-2} m^3/s)
$\mathbf{v}_S$	Superficial velocity ($\mathbf{v}$ = $4\dot{V}/\varphi D$) [m/s] (1 ft s^{-1} = 3.048 m/s)
α	Individual coefficient of heat transfer [W/m^2 °K]
ϵ_G	Gas holdup
δ	Maximum thickness of an elementary layer [m]
λ	Thermal conductivity [W/m °K] (1 ft lb s^{-3} $°R^{-1}$ = 0.248858918 W/m °K)
η	Dynamic viscosity [Pa s]
ρ	Density [kg/m^3] (1 lb ft^{-3} = 1.60185 10 kg/m^3)

OUTLINE

INTRODUCTION

Sterilization-in-place (SIP) refers to the practice of sterilizing process equipment or materials in process at their place of use or installed location. Sterilization can be simply defined as a procedure for rendering a system free of living organisms. SIP is a very important technology, needed for microbiological control during production. Although the process of microbial sterilization is a well-studied area of science, SIP varies widely in its interpretation and industrial application. Steam is usually employed as the sterilizing agent, although many sterilizing methods are conceivable. The term SIP in some places is used loosely for a sanitization process whereby the goal is not necessarily achievement of a high assurance level of sterility (SAL).

APPLICATIONS

SIP supplements or replaces the use of process equipment whose purpose is to sterilize materials such as autoclaves, sterilization tunnels, and ovens. Introduction of the equipment into a sterilization chamber often is not practical. SIP is also preferred when several components can be sterilized together via SIP rather than separately treated and subsequently connected under aseptic conditions.

Clean piping systems, such as a water for injection (WFI) supply ring, will usually be sterilized in place before start-up and after service interruptions. Here, the goal is to begin or resume microbiological control but not achieve a specified sterility assurance level. Fermentors, especially those used to culture genetically altered cells, need to be sterilized before innoculation, which can be achieved to a high level of assurance by SIP. Fermentation media are sometimes first introduced into the fermentor and then sterilized with the fermentor. Aseptic manufacture of parenteral drugs and devices requires sterile process equipment, which is usually achieved by SIP. For example, modern filling equipment often undergoes an SIP of the filling lines and nozzles. It is also a current Good Manufacturing Practice (cGMP) standard that lyophilizers for parenteral products be outfitted with an SIP cycle to sterilize the drying chamber and process connections that are open to the product. Finally, as part of biocontainment practice (especially when using recombinant or hazardous organisms), processing equipment may receive an SIP after use but before opening to inactivate any residual microorganisms and prevent their release into the environment.

STEAM-IN-PLACE TECHNOLOGY

The use of saturated steam for sterilization has been relied on for many years. It is natural that SIP would evolve from this experience. One of the first publications on the use of steam for SIP was provided by Myers and Chrai (1) and later reviewed by Agalloco (2). The preference for steam as the sterilizing agent can also be attributed to its advantages in heat transfer, which are elaborated in the following.

Sterilization in general is a kinetic process and is a subject of sufficient breadth for textbooks (3). It follows first-order kinetics for individual microbial populations, whereby the rate constant is species specific as well as being dependent on the sterilizing conditions. When only water is present at the saturated steam condition, the temperature alone is sufficient for completely defining these conditions and hence the rate constant for a particular organism. The rate constants are exponentially dependent on temperature, and the dependencies are significant for temperature variations as small as 1 °C.

For scientific studies, sterilization processes are usually quantified in terms of the D and F values. The D value provides the kinetic information and is simply related to the rate constant. It is species and temperature dependent, and its value is the time in minutes for a 10-fold reduction in the population. The F value gives the time in minutes for a desired reduction in the population, as calculated by $F = (\log N_0 - \log N)\, D$, where N_0 is the starting count and N is the desired count.

The F_0 value has become a standard for defining and comparing sterilization processes. It is based on the sterilization kinetics that have been found for heat-resistant organisms, such as *Bacillus stearothermophilus*. The F_0 value can be calculated from thermal data using the following integral equation, $F_0 = \int 10^{(T-121.1)/10}\, dt$, where T is the sterilization temperature in degrees Celsius and t is the sterilization time in minutes. SIP operations typically should demonstrate an F_0 value in the range of 8 to 20 min, depending on the application.

Steaming conditions other than with pure saturated steam have been found by experience to be less effective (3). Apparently, the presence of both phases, liquid and gas, is important because superheated steam at the same temperature is not as lethal. Also, the presence of air reduces sterilization effectiveness. If air is present, and the sterilizing pressure is kept constant, then the contribution of air to the total pressure lowers the partial pressure of the steam and hence its saturation temperature. The lower temperature has a direct effect on the kinetics. If an outside heating source raises the temperature, the system departs from saturated steam conditions; that is, water is present then only as superheated steam. If the total pressure is raised, so that the steam saturation temperature is maintained, such as with an overpressure autoclave cycle, then the kinetics predicted with saturated steam are followed.

Validation Issues

Important validation issues arise with SIP. The general problem is the estimation of sterility, but the additional

process complexities associated with an SIP operation often add problems of control for the process parameters. Validation is needed to provide assurance that the probability of surviving organisms is small enough to be of insignificant risk to the operation. Because the initial bioburden (number and type of microorganisms) can only be partially known from past monitoring experience, kinetic models cannot predict with accuracy the outcome of SIP. Measurements of sterility are in general destructive tests; that is, they violate the integrity of the enclosed sterile system.

Accurate temperature and pressure measurement and control is of special concern for steam-in-place processes. It is especially important to know the location of the coldest points in the system to estimate conservatively the sterilization effect. An accurate measurement of pressure is needed to verify saturated steam conditions. Validation testing include extensive thermal measurements, the use of biological indicators (e.g., spore strips) and often sampling methods via swabbing or media contact. Such testing should yield consistent, favorable, and reproducible results to give such assurance.

Reflecting the uncertainties and risks associated with a sterilization process, regulatory bodies, such as the U.S. Food and Drug Administration (FDA) (4), have specified relatively severe process parameters to meet for general use. These conditions are often termed overkill. In the cited reference, 121.5 °C is to be maintained with saturated steam for 20 min, or equivalency to these conditions must be demonstrated as by achieving the same F_0 value. Using the formula provided, this value would be $F_0 = 21.9$ min.

Process Description

A technical description and a theoretical modeling of the steam-in-place process can be found in Ref. 5 and is relied on here. A steam-in-place process follows the general operations of an autoclave, which have the following cycle steps:

1. Air purge
2. Heat-up
3. Sterilization holding period
4. Displacement and collapse of the steam with sterile air

SIP of a vessel or piping system usually accomplishes the air purge step by displacing the air with steam. The air exits the system through drain and vent openings, which are usually equipped with steam traps.

A residual presence of air is to be avoided because it introduces a poorly controllable heat transfer resistance, which is described next. Its contribution to the total gas pressure also lowers the effective steam pressure and hence saturation temperature, which affects directly the sterilization kinetics. Therefore, this first step is critical to the reproducibility and success of the operation. Unfortunately, displacement of air with steam is often not very effective. Some autoclaves utilize a series of vacuum pump-outs followed by steam repressurization to remove the air from the chamber. Vacuum pump-outs are seldom part of an SIP operation unless an efficient vacuum system is already present for process needs, as with freeze dryers.

Convective displacement of air with steam always results in some mixing of air with the steam. In branched piping systems with poor flow distribution or in large vessels, this mixing can be extensive. In theory (5), turbulent steam flow is desirable because the additional kinetic energy helps to break up any air pockets and transport the air (with steam) out. The air purge step can be successful when the piping design meets appropriate criteria (to be described later) and restrictions to flow are minimized such that maximal steam flow can be reached.

Using steam to heat an enclosure combines both heat and mass transport phenomena. In the gas phase, a comparable situation (condensation of vapor in the presence of a noncondensable gas) has been analyzed and modeled for psychrometric calculations (6). Geometric complications prevent an exact analysis of a typical SIP application. Additionally, steam-in-place must consider transport in the condensed phase as well as heat transport in the walls of the system.

The combined heat and mass transport created by steaming yields important advantages for heat transfer. When saturated steam contacts a colder surface, it condenses, and the resulting void created by the collapse of water vapor molecules into a condensed phase drives more steam to the region of the colder surface. The pumping effect of the condensation helps bring steam heat to the colder regions of the enclosure and thereby improves the heat transfer. Reliance on latent heat also reduces temperature drops, which are otherwise needed for sensible heat transfer.

During the heat-up step, the system pressure is allowed to build up to the steam supply pressure by restricting any vents or drains or via the functioning of the installed steam traps. Any trapped air left will be largely swept to the cold boundaries by the dragging effect of the moving steam. Thus, the residual air will not be uniformly distributed but will be concentrated near the colder boundaries. As a stagnant layer, through which the steam must pass to condense on the walls, residual air can bring a significant resistance to heat transfer. Enclosures with a large volume-to-surface ratio, such as tanks, are particularly prone to interference from trapped air. In Ref. 5, temperature drops of the order of 1 °C are predicted from residual amounts of air equivalent in some cases to less than 0.1% of the original volume. Such exquisite sensitivity is possible in piping dead legs (to be described later) and is greatly amplified when the equipment is not thermally insulated. Insulation reduces heat transport requirements and thereby mitigates the sweeping of air into stagnant boundary layers.

Condensate removal during steam-in-place is a serious concern. Condensate forms on all cold surfaces and will subcool if allowed to accumulate. Because of its low thermal diffusivity, liquid water can maintain a substantial temperature difference between the steam phase and the equipment walls. Condensate layers will collect at all low points. Flow in these layers to the next steam trap is usually laminar. A one-dimensional analysis (5) is useful to predict order-of-magnitude effects. In an insulated pipe, a

condensate layer 1 mm in depth will have a temperature drop of the order of 0.5 °C. Without insulation, only a 0.2-mm depth would show such a temperature drop.

The boundary layer phenomena discussed here are not usually observable without extensive temperature monitoring, which may only be performed during validation as a thermal mapping activity. From this study the coldest locations are identified. Thermal data from these locations are then used to define a sterilization holding period to achieve equivalence to the overkill process, or a predefined F_0. In normal operations only one or a few sensors, which for practical reasons sometimes cannot be positioned at the coldest locations, are used to monitor temperature. Temperature nonuniformities bring an uncertainty into the estimation of the sterilization effect; their existence demonstrates the presence of heat transfer resistances, usually resulting from boundary layer phenomena, which are not under direct control. Statistical analysis of temperature data during process validation will be used to add additional time to the holding period to provide the desired degree of sterility assurance.

On completion of the sterilization process, the steam supply is shut, and the equipment can be cooled either actively or passively before use. The collapse of residual steam will ultimately create a vacuum in the enclosure, which is to be avoided because a vacuum increases the risk of recontamination of the system. Therefore, the steam is usually displaced with sterile-filtered process air while there is still overpressure present.

Equipment Design

Process requirements for steam-in-place operations have determined to a large degree the special equipment design specifications associated with bioprocesses. The sterilization conditions usually chosen are 121 °C or greater, resulting in a saturated steam pressures above 1 bar gauge. Materials of construction and construction methods must be suitable for these conditions.

Materials of Construction. 316L stainless steel is usually chosen because of its strength and chemical resistance to the high-purity steam used. Vessels need to be pressure rated for these conditions and protected with safety relief valves or rupture disks.

Specifications for surface finishes and construction methods have the purpose of reducing the potential for the buildup of soil and deposits on the equipment surfaces. Surface deposits provide an additional barrier to the transport of heat and steam. They may also introduce an uncontrolled bioburden level. A high degree of polish will be required; electropolished is preferred. Corners and joints should meet with a generous radius of curvature. Ideally, sealing methods would be seamless. For this reason, welding is preferred, but the welds must be polished and passivated. Seiberling (7) provides general specifications of equipment to receive SIP.

All low points inside the enclosures must have drains; these are needed to drain the condensate and are also required to effectively clean the equipment so as to prevent soil buildup. Thermal insulation of the equipment is needed to reduce the temperature variations in the system. If the equipment is located in a clean room, the insulation must be clad with a housekeeping skin, so that particles from the insulation do not enter the clean rooms and the surfaces can be maintained clean. Stainless steel sheathing is usually used on vessels, and plastic is easier to install on piping. The enclosed insulation must not chemically release agents that would attack the equipment, such as chlorides, which are known to attack stainless steel.

Piping Design. Piping particularly should be thermally insulated because of its large surface-to-volume ratios. All piping must be sloped to drain condensate. Because the mass transport of steam and condensate are driven by heat transport and gravity, respectively, and not by large pressure gradients, it is important in the piping design to remove any uncertain flow paths. A clear example of this concern can be made with parallel flow arrangements. If two or more identical items such as heat exchangers are steamed in parallel, it is likely that one item will not receive the proper treatment because of poor steam distribution. In an extreme case, one item may stay filled with air or become blocked with accumulated condensate, effectively stopping the flow of steam.

Dead legs are to be avoided, but this is not usually possible. Dead legs are commonly understood to be sections of piping with no outlet. Connections that are closed with a valve during SIP are typical dead legs. Instrument ports can be another. Dead legs also need to be sloped to allow for draining. Depending on their length, flow of steam in and air out can be largely a diffusive process. Dependence on diffusion means some air is always trapped in dead legs during SIP, contributing to the difficulty of their sterilization (8). General design guidelines (7,9) limit dead legs in length by a scale factor expressed in terms of pipe diameters, but this rule cannot be defended in theory (5). The best guideline is to minimize their length because they will usually be the most difficult locations to sterilize. Practically, dead legs can easily be limited to four pipe diameters with commonly available pipe fittings.

Dead leg–free valves are commercially available (Fig. 1); they function by using the pipe wall on one side as the valve seating surface. The seating design employs a flexible diaphragm or membrane, which is pushed into the flow path to press against the seating surface. Such valves belong to a type, commonly referred to as diaphragm or membrane valves, which are preferred for equipment that receives SIP or clean-in-place (CIP). Such valves have no dynamic seals for moving parts such as valve stems that may enter or leave the sterile side of the valve. Dead leg–free valves are only such on one side of the valve. On the other side, the valve body itself is a short dead leg.

Instrumentation and Monitoring. The critical parameters to monitor are temperature and pressure. By measuring both, one can confirm that saturated steam conditions are present. Instrumentation must be of a sanitary design, which follows the general considerations given earlier. Temperature is usually measured with resistance temperature detectors (RTD) because their signal can be recorded, they are robust, and they can be accurately cali-

brated. A calibration accuracy of no more than ± 0.5 °C is recommended because such variations significantly affect the sterilization effectiveness.

Clean Steam Supplies. If the SIP application is for parenteral pharmaceutical products, high-purity steam, commonly known as clean steam, must be specified. Product contact surfaces in such applications must meet only strictly controlled media. Clean steam is usually defined by the purity of its condensate, and this must usually have WFI quality. Normal plant steam will contain more dissolved solids and potentially also some suspended debris. From these discussions, the steam supply should in any case be free of air, which is normally the case even with plant steam.

The steam supply system (boiler and distribution headers) normally is at higher pressure than the desired steam sterilization pressure. The steam connection to the equipment will then include a pressure-regulating valve to reduce the pressure. This design is preferred because the supply system then has reserve to supply large amounts of steam, without a serious loss of steam pressure. Too large a pressure reduction should not be expected from the pressure regulation valve, however. When too large a reduction is made just before entering the equipment, the steam acquires significant superheat. Superheated steam is known to be less effective as a sterilizing agent and as a heat transfer medium. Its presence affects the sterilization kinetics but is not easily observable. An industrially based guideline is to design the pressure reduction for 2:1 (10).

Sizing the steam supply for a steam-in-place is not straightforward, and there is no consensus in the industry. The greatest demand for steam occurs during the air purge and subsequent heat-up phases. The demand during the air purge is really determined by the restrictions to flow, often created largely by the vents and drains, as is discussed in the next section. During the heat-up step, the capacity of the steam supply could limit the heat-up rate, but the actual rate is not normally considered a critical variable.

Steam Traps and Vents. From the previous process description, it is clear that these components are critical to a successful steam-in-place operation. Steam traps are devices that are designed to not pass steam but rather air and condensate. There are many types available (11), and some models have been created especially for the biotech industry (Fig. 2). These devices operate as valves that are self-actuating, can sense by physical property differences whether they are passing steam, air, or water, and thus open or close appropriately. For steam-in-place applications, it is critical that they remove air and condensate. However, the steam trap designs that have evolved from other industries have the major goal of conserving steam. The types commonly selected for biotechnological applications allow some accumulation of condensate to occur upstream and may bring a significant restriction to the flow of air out of the system.

As a consequence, pharmaceutical companies have in the past dispensed with the use of steam traps and employed their own simpler solutions. The simplest solution

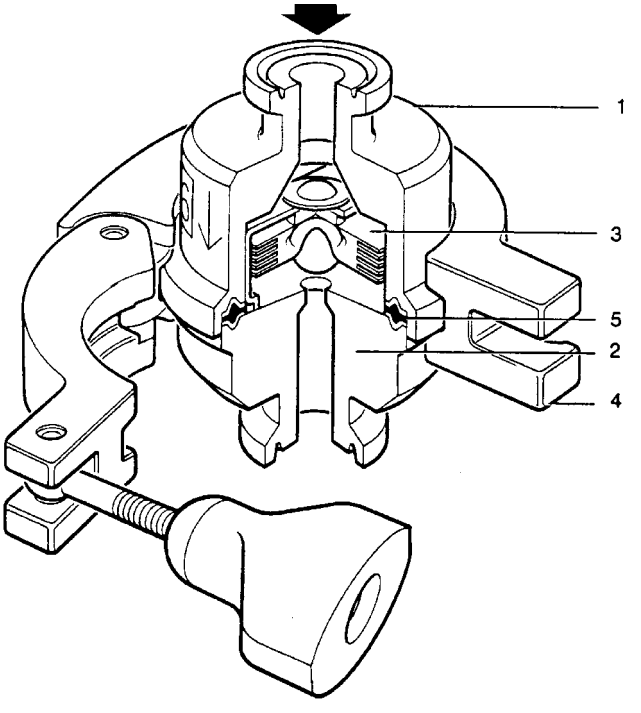

Figure 2. Sanitary blanced pressure steam trap. *Source*: Reproduced with permission of Spirax Sarco GmbH, Konstanz, Germany.

is to install manual valves instead of the steam traps, which must then be manually adjusted during the course of the procedure. During the air purge step, the valves may be fully opened. They are subsequently throttled, but only so far that steam continues to emerge, that is, condensate does not back up. A more automated approach is to employ restriction orifices instead (Fig. 3). During the air purge step, the orifice is bypassed with an open isolation valve to allow a relatively unrestricted flow of air and condensate. During the subsequent steps in the process, the isolation valve is closed, forcing remaining flow through the orifice. The orifice must be custom sized to ensure is large enough to allow all condensate to freely drain. Correctly sized, the orifice will be continuously passing (and wasting) steam and will prevent any buildup of condensate.

It is usual now to encounter sanitary steam traps of the type illustrated in Figure 2. Provided one realizes their limitations, successful steam-in-place operations can be performed with them. Typically, the steam traps are placed a significant piping distance from the limits of the system to be sterilized. The limit is usually an isolation valve, which will close immediately on completion of the operation. The piping downstream of this valve should then be noninsulated to allow for a sufficient condensation of steam and subcooling of condensate to keep the steam trap open. Steam traps must also be selected for the ability to pass air, and a sufficient number must be planned to allow for a successful air purging operation and condensate removal.

Filters. Sterilizable enclosures are almost always equipped with sterile filters, acting as barriers for sterile exchange of air or other media with the outside. Sterile vent filters are needed for pressure equalization, and process liquids are introduced though sterilizing liquid filters. Sterile filter installations are often sterilized together with the enclosure, although there is also no consensus on this practice. The filter element and enclosure may also be sterilized separately, but this raises concerns about ensuring that the separately sterilized components can subsequently be connected together aseptically.

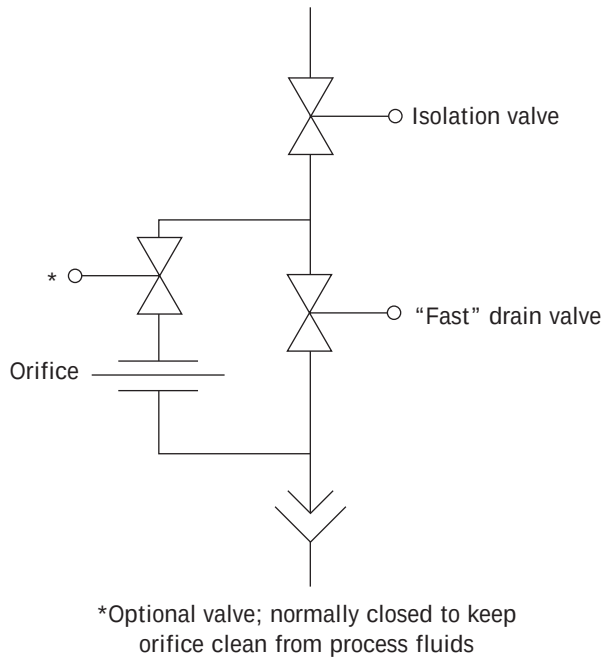

Figure 3. Use of orifices in place of steam traps.

The steaming-in-place of filters is not straightforward (12). Of special concern is the passage of steam, air, and condensate through the filter element. Also, the pressure drop across the filter element is limited by design. These concerns result in special piping designs and controls to ensure that both sides of the filter receive sterilizing conditions. It is not practical to attempt only a sterilization of the future sterile side of the filter, because without flow through of steam the filter will not be air purged successfully.

When steaming-in-place an enclosure, the vent filter will not be employed as the major vent for the air purge operation nor will it be used as the connection to the steam supply because it is typically too limited in flow capacity. It usually receives a secondary source of steam from the vessel during the sterilization process. Vent filter elements are typically nonwetting, which allows them to be quickly functional after steaming. A sterilizing liquid filter is sometimes steamed through to the enclosure (i.e., becomes the source of steam for the enclosure). Because of its limited ability to pass steam, the enclosure downstream is limited in size, often only piping. Liquid filters do not easily pass air after steaming because their hydrophilic pores become blocked with condensate.

ALTERNATIVE SIP TECHNOLOGIES

Equipment design requirements for steaming-in-place constrain opportunities for applying SIP, which raises interest in alternative technologies that are less demanding on mechanical designs. By employing chemical agents, sterilizing conditions can be reached without elevated temperatures or pressures. Sterilizing methods using radiation are not usually considered for SIP applications because the distribution of radiation throughout an extended enclosure is not practical.

When a new alternative SIP technology is chosen, a large amount of development work follows to make it a reliable industrial process. Much of this work involves scientific studies of the sterilization effect on the diverse microflora potentially present. A large amount of work is needed to develop monitoring and testing procedures for the validation and subsequent monitoring studies. Chalumeau has outlined the concerns raised with alternative sterilization methods in general (13). Some representative SIP methods receiving industrial attention are now used as examples for the technical issues encountered with alternative methods.

SIP with Superheated Water

The application of superheated water is an obvious extension to the use of saturated steam. This method can rely largely on the scientific knowledge base of the thermal

sterilization effect with saturated steam. Häggström has reported its effectiveness (14), but it has not been widely practiced. The advantage of using superheated water over steam is that it can be pumped and reheated to distribute the thermal conditions needed. Häggström claims that no steam traps or vents are needed and that a more uniform temperature distribution is attained.

A theoretical analysis (15) points to a fundamental weakness of the technology when compared with steaming-in-place. Heat transport by conduction through water is less effective than the combined heat and mass transport occurring in steam. The analysis considered heat transport in dead legs of hot WFI systems, where significant temperature drops of the order of 10 °C were predicted for typical dead legs. Although acceptable for WFI operation, such temperature variations are very unattractive for SIP. The advantages of superheated water have no benefit for the dead legs in the system, which are typically the most difficult to SIP. Also, to properly heat an enclosure with superheated water, it must be completely filled, or the headspace must be purged of air as in a classical steam-in-place process; this means that steam traps and vents are still required, although fewer would be needed. When the technical features are considered that would be needed to prepare and then discard large amounts of superheated water, it is not surprising that this method has not gained popularity.

SIP with Chemical Agents in a Liquid Phase

Chemical agents used for desinfection or sanitization are sometimes considered for SIP. Sanitizing solutions are not generally useful as sterilizing agents for SIP. To be useful they would have to have biocidal activity against the full spectrum of microorganisms yet be relatively noncorrosive and safe to handle. Commercially available agents that approach this ideal are often termed cold sterilants but still require many hours of exposure to achieve sterilizations.

In general, one must design a system to uniformly distribute the agent, monitor the operation for the proper exposure, and finally remove the agent, so that the equipment can be put back in operation. Monitoring of the operation must consider all parameters that can significantly affect the chemical reactions that determine the sterilization kinetics. Temperature may be important, but the concentration of the agent certainly is. Other material components or chemicals present can potentiate or interfere with the desired reactions. Unless a sensor is available, routine sampling and subsequent chemical analysis are required to verify sterilizing conditions.

High-purity water systems, such as those claiming to be sterile, have been reported using ozone as a circulating agent (16). Ozone has many advantages as a sterilant. It is extremely effective even at low concentrations because of its high reactivity, and it is easily generated electrically from ambient oxygen. In water systems, its decomposition product is also oxygen, which is usually not considered a contaminant. Before use of the media, residual ozone is catalytically decomposed with the aid of ultraviolet radiation. Widespread acceptance of this agent, even for simple microbiological control, has not been reached because of some underlying problems. First, it is an extremely aggressive agent that will degrade the piping system, especially gaskets. Second, it is difficult to remove it to levels sometimes desirable for end use. (See analyses in Ref. 15. Finally, penetration of chemical agents such as ozone into dead legs can be a difficult problem. Where diffusion dominates the transport, the relatively low liquid-phase diffusivities coupled with the low bulk concentrations result in very slow penetration of agent into dead legs (15).

At another extreme, caustic (sodium hydroxide) at relatively high concentrations can be considered as a sterilizing agent. Caustic is often used as a cleaning agent, such as in a CIP operation. If the concentration is high enough, it can be used as a sterilizing agent. Validation of the sterilization effect can be difficult because of the lack of scientific knowledge regarding such use of this agent with microorganisms. Also, the agent must be washed from the installation with large amounts of sterile water. However, it can be appropriate if the goal is to inactivate a biological agent left in equipment or in a waste stream before opening to the environment. Here, the removal of caustic after the operation is not critical; it will be subsequently removed in a washing step.

SIP with Chemical Agents in a Gaseous Phase

The use of gaseous chemical agents is probably the most active area of interest for alternative SIP technologies. Unlike liquid-phase agents, gaseous agents are easier to distribute and remove. There is also a long history of use, and consequently a significant knowledge base, with some of the biocidal gases. Formaldehyde and ethylene oxide have long been used for room and equipment disinfections in hospitals. As with all chemical agents, their use requires measurements of all important reaction conditions for the sterilization. One must also determine their reactivity with any system components and the ultimate fate of their decomposition products.

Both formaldehyde and ethylene oxide have become restricted in their use because of their toxicity and their activity as carcinogens. Ethylene oxide also has physical hazards; not only is it flammable, its chemical instability can lead to explosive decompositions. Recently, vaporized hydrogen peroxide as a sterilizing agent has been developed (17) to the point of a commercially available generator for SIP applications (Fig. 4). Its commercial success has been spurred by the active interest in the use of isolator technology for aseptic processing. Haas (18) has reviewed isolator design issues and listed gaseous agents that have been attempted for their SIP. At present, there does not appear to be a more promising chemical sterilant than hydrogen peroxide, which is likely to become the method of choice for pharmaceutical applications.

The AMSCO VHP™ systems have a basic three-step cycle: dehumidification, sterilization, and sterilant removal. Their commercial systems perform these functions on an attached isolator or enclosure. Often the isolator has operating components that assist the process. The reader is directed to the vendor for specific details on the operation of the commercial AMSCO VHP™ systems; the basic physical and chemical phenomena are considered here.

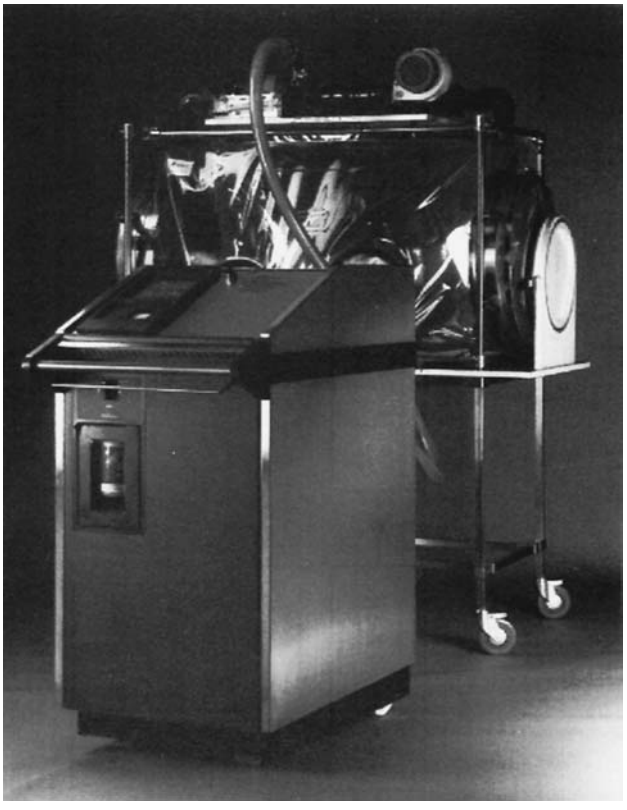

Figure 4. Vaporized hydrogen peroxide generator. *Source*: Reproduced with permission of AMSCO Scientific, Apex, North Carolina.

Hydrogen peroxide solutions have long been recognized for their disinfecting value. The greater lethality of vaporized hydrogen peroxide is a more recent discovery (17). H_2O_2 is an unstable material, available commercially in aqueous solutions up to 70%. High concentrations of H_2O_2 require proper handling because it can explosively decompose or cause fires (19). Its decomposition products are water and oxygen, and it will react with any oxidizable substance, particularly organic materials. Aqueous solutions of H_2O_2 are corrosive, but they have been found to be relatively benign to materials when only vapors are present (17).

A relatively safe solution concentration of 30% is usually the raw material consumed by a H_2O_2 generator. H_2O_2 has a lower vapor pressure than water, and considerable water vapor will also be generated when a 30% solution is vaporized. The water vapor released with the H_2O_2 limits the gas concentration of H_2O_2 achievable because water can easily reach saturation conditions in air. When water condenses, H_2O_2 is also lost from the gas phase because it will dissolve readily in the condensate. SIP with vaporized hydrogen peroxide must therefore control not only the concentration of H_2O_2 but also water in the air when the solution is vaporized. The first step in such an SIP is usually to dehumidify the enclosure so that reproducible initial conditions are established. The temperature of the isolator and the air within is also important because this has a strong effect on the relative humidity. The kinetics of the sterilization reaction do not appear to be strongly a function of temperature.

During the sterilization step, the H_2O_2 reagent is vaporized, and the vapors are introduced into the chamber. The chamber must be leak-tight to prevent emissions and exposures to personnel. Forced convection is needed to distribute the vapors throughout the enclosure and ensure a uniform exposure to, and concentration of, H_2O_2. To maintain the gas concentration, additional H_2O_2 must usually be generated for the duration of the sterilization to replace H_2O_2 that has decomposed. The sterilization step is timed to achieve the desired level of assurance of sterility. This activity on a closed system results in a steady rise in both water vapor content and air temperature. The commercial generators are successful in part because they continuously remove water vapor from the returning gas stream, as they are generating more H_2O_2 in the supply stream. They are thus able to achieve and maintain the necessary H_2O_2 concentrations needed for a rapid sterilization (0.5–2 mg/L) while avoiding reaching water saturation conditions.

As the air temperature rises during the sterilization, a temperature difference develops between the air and the enclosure and its fixtures. Saturation conditions are likely to occur at these surfaces, and process development efforts must focus on avoiding this condition by parameter adjustment. SIP with gas requires good gas circulation to achieve a uniform exposure. Modern isolator designs (18) usually have the necessary vigorous air circulation needed because they employ it to also remove airborne particles via HEPA filtration. Fixtures inside an isolator may have restricted spaces where air circulation is ineffective. Transport of biocidal gas into these spaces then is dependent on diffusion, and dead leg effects for transport can be expected.

Graham et al. (17) reported sterilization conditions could be reached up to 60 pipe diameters into a dead leg with a pulsed cycle, which included a vacuum pulldown between cycles. The vacuum pulldown ensures that transport into the dead leg is not entirely dependent on diffusion because breaking the vacuum with sterilant creates a pressure difference for convection up the tube. Most isolators are not designed for vacuum conditions, and reliance on diffusion reduces this impressive penetration result.

The analysis of diffusional transport of H_2O_2 into dead legs can be modeled analogously to the transport of ozone into dead legs (15). In the gas phase, diffusional transport is much more rapid, but the decomposition kinetics of H_2O_2 are also larger than for ozone. The diffusivity of H_2O_2 in air is reported to be 0.188 cm^2/s at 60 °C. For such gas systems, the temperature dependence of the diffusivity should be of the order of $T^{1.5}$. This corresponds to a value of 0.167 cm^2/s at 35 °C. In comparison to ozone in water, such gas-phase diffusivities are four orders of magnitude larger. The defining parameter for penetration is the diffusivity divided by the rate constant for decomposition (15). Because H_2O_2 decomposition is observable in terms of minutes and ozone decomposition in hours, one would expect that the penetration of H_2O_2 into dead legs would be dramatically better than predicted for ozone in water (15). An industrial guideline to use for limiting dead leg

lengths with H_2O_2 has not yet evolved but would be strongly affected by the specific conditions created by the enclosure, the sterilization cycle, and the material of the dead leg, and hence not generally useful.

Finally, it must be realized that the SIP of an enclosure or isolator has the main goal of sterilizing the exposed surfaces. The air in the enclosure is usually recirculated through a sterilizing HEPA filter to keep microbes out of the air, and it therefore does not have the major bioburden. Surfaces must be clean. Microorganisms encased in dirt or a biofilm will not be exposed to the gas-phase H_2O_2 concentration because of transport resistance through the film and decomposition reactions occurring with the film. Reactive surface materials will in general reduce the local concentration of agent at the surfaces.

After the sterilization step, a H_2O_2 removal step is needed before normal operations can resume. The AMSCO VHP™ systems employ a catalytic reactor in the recirculating air stream to the enclosure to accelerate the decomposition and removal of H_2O_2. Plastic components are generally porous to H_2O_2, and thus a significant length of the cycle time often is devoted to removing the outgassing amounts of H_2O_2. This phase is again a diffusional process; but now in a solid phase and hence relatively slow.

The permeability of plastics to biocidal gases, notably ethylene oxide, has been relied on to sterilize materials sealed in plastic bags via exposure from the outside. This method has also been tested successfully with H_2O_2, but a vacuum pulsed cycle is needed (17); this step is not normally considered an SIP operation. A sterilization chamber, similar in concept to an autoclave, would be needed to alternatively evacuate the air and introduce H_2O_2.

OUTLINE

INTRODUCTION

Mammalian cells can be distinguished by their requirement to grow attached to a surface (anchorage dependence) or in free suspension. The ability to grow in suspension is frequently associated with cell lines that demonstrate an "immortal" or infinite lifespan phenotype. Suspension culture systems are preferred for most large-scale manufacturing processes because scale-up is more straightforward. Relatively homogeneous conditions can be achieved in a suspension bioreactor, allowing efficient monitoring and control of key process parameters.

Suspension culture technology for animal cell culture started in the 1950s with the demonstration that several types of cell could be grown in simple agitated systems such as tumbling tubes and shaken flasks (1,2). By the end of the decade methods had been developed for growing cells in magnetically stirred spinner vessels (3,4) and in fermenter vessels similar to those used for microorganisms (5,6). By the 1960s pilot plant reactors at scales of hundreds of liters were in operation (7).

The initial drive to develop an industrial process based on mammalian cell suspension culture came from the need to produce very large volumes of vaccines against foot-and-mouth disease (FMD). Processes were developed using baby hamster kidney (BHK) cells growing in stirred-tank reactors up to 3,000 liters (8–10). Subsequently stirred-tank reactors of up to 8,000-L were used for the production of interferon α from human Namalwa cells (9). The industrial application of animal cell culture has increased dramatically over the last 20 years, driven by the need to produce monoclonal antibodies and recombinant proteins in addition to vaccines. It is the demonstration that these products can be made safely in immortal cell lines that has made possible their large-scale manufacture. Very large scale suspension processes (up to 10,000-L) have been described for the production of proteins such as tissue plasminogen activator (tPA) (11).

CELL TYPES USED FOR LARGE-SCALE PRODUCTION IN SUSPENSION CULTURE

A very wide range of cell types can be grown in suspension culture. The most important cells for industrial processes are Chinese hampster ovary (CHO), BHK, hybridomas, and mouse myelomas; these are discussed in more detail later. Other cell types grown on a large scale include insect cells (for example, see Ref. 12), especially for the production of research materials. Human cell lines such as the human kidney 293 cell line are becoming increasingly important for the production of virus vectors for gene therapy (13).

CHO Cells

The cell type most commonly used for recombinant protein production is the CHO line. CHO cells have been used to produce a wide range of therapeutic proteins (hormones, growth factors, thrombolytics, blood clotting factors, immunoglobulins). The choice of the CHO cell is based on several factors: compatibility with efficient gene expression systems leading to good productivity, ability to carry out important posttranslational modifications of proteins, and freedom from detectable pathogenic agents. In addition the cell type can be grown in large-scale suspension bioreactors. CHO cells can also grow as attached cultures, and in fact, growth in suspension generally requires a period of adaptation after the production cell line has been created. This requirement for adaptation, which can take several weeks, or months, can be circumvented by using host cells for gene transfection that have been preadapted to grow in suspension (14). Kurano et al. (15) isolated several anchorage-independent sublines of CHO, one of which grew in suspension even in static flasks. A different approach was taken by Renner et al. (16) who demonstrated that expression of recombinant cyclin E (a cell cycle regulator) in CHO cells prevented surface attachment and additionally permitted growth in protein-free medium.

BHK Cells

BHK cells have been used for large-scale production of foot-and-mouth disease vaccine because of their ability to propagate the virus and their capacity to grow in large-scale suspension culture (10). Rabies vaccine for veterinary use is also manufactured in BHK cells (17). BHK cells are also used (albeit less frequently than CHO) for production of recombinant proteins such as factor VIII (18).

Hybridomas and Myeloma Cells

Rodent monoclonal antibodies are typically produced in hybridoma cells, which can readily be grown in suspension culture (see, for example, Ref. 19). Increasing therapeutic use is being made of genetically engineered antibodies that have been "humanized" to reduce their immunogenicity in humans. Engineered antibodies can be made in CHO cells (20), but rodent myeloma cells (e.g., the mouse NSO line) are also frequently used (21), and like hybridomas, these can be grown in large-scale reactors (22).

Cells such as CHO and BHK, which can grow as attached cultures, have a tendency to form aggregates when grown in suspension (23). Aggregation can be reduced by rigorous adaptation to suspension culture and by design of culture media. Boraston et al. (24) showed that aggregation of CHO cells was reduced by adjusting the inorganic salt and amino acid composition of the culture medium. When developing cell lines for suspension culture, careful screening in an appropriate system (e.g., shake-flask culture) is essential. Brand et al. (25) compared the specific production rate in attached and in suspension culture of six closely related CHO cell lines, all making the same monoclonal antibody. Production rates were higher, lower, or the same depending on the particular cell line. The same authors found similar results with NSO myeloma cells; measurement of specific production rate in static culture for clones from the same transfection was of limited value in predicting results in suspension culture.

SUSPENSION CULTURE REACTORS

Stirred Reactors

The most commonly used systems for suspension culture are based on stirred reactors used in both batch and per-

fused configurations (Table 1). Typically reactors are stainless steel with height-to-diameter ratios in the range 1:1 to 3:1. In some cases mammalian cell bioreactors have been developed by retrofitting microbial vessels, usually by changing the agitators and aeration system. Backer et al. (19) described the retrofitting of 150- and 1,300-L reactors. Rushton impellers were replaced with marine propellers, and the agitator drives were altered to allow operation between 25 and 250 rpm. Air was sparged through a sintered stainless steel sparger with 10-μm pore size. Garnier et al. (12) describe the retrofitting of a 150-L microbial bioreactor (height-to-diameter ratio 3). They used two large pitched-blade impellers (45°), three surface baffles, and a polypropylene porous sparger (80-μm pore size). Agitation was controlled at 60–120 rpm. Nienow et al. (29) found that Intermig impellers improved mixing times in a mammalian reactor compared with the Rushton turbines commonly used in microbial reactors. Impellers may be directly driven via a shaft or indirectly driven through a magnetically coupled drive (30,31). Magnetic drives remove the potential for microbial ingress through mechanical shaft seals. The operation of mammalian reactors differs from that of microbial reactors in one very important respect: power inputs are very low to minimize the risk of damage to cells. For an 8,000-L reactor it has been reported (29) that a maximum agitator speed of 1.5 rev/s is used, giving a maximum power input of 30 W/m^3. This is around two orders of magnitude less than the value typically achieved in microbial fermentations. Similarly very low aeration rates are used in animal cell reactors compared with microbial cultures. This combination of low power input and low aeration rate means that particular attention has to be paid to the design of vessels to ensure good bulk mixing and adequate mass transfer of gases (especially oxygen and carbon dioxide). Nienow et al. (29) describe a study of mixing characteristics and oxygen uptake rates in an 8,000-L reactor and discuss ways of improving reactor performance.

Airlift Reactors

The airlift reactor is used less commonly than the stirred reactor for cell culture and was originally developed for microbial fermentation. Sparging of air or other gas mixtures is used to aerate the culture and to provide mixing. Mixing is achieved by separating the vessel into riser and downcomer sections using a draught tube, divider plate, or external recirculation loop. The presence of gas bubbles in the riser section creates a density difference between riser and downcomer that causes the fluid to circulate, providing mixing. Airlift reactors tend to have larger height-to-diameter ratios than stirred reactors (typically as high as 10:1). Their advantage is simplicity (no mechanical agitators) combined with good mass transfer and low shear characteristics (32,33). The basic design features of airlift reactors have been described in reviews (34,35). Airlift reactors have been used for the culture of BHK and human lymphoblastoid cells (36), insect cells (37), and at scales up to 2,000 L for a variety of cell types including CHO, hybridomas, and myelomas (38,39) (Fig. 1). Growth and productivity profiles for a GS-NSO cell line making a recombinant antibody in an airlift reactor are shown in Figure 2 (from Ref. 40).

Operational Considerations

While the type of vessel used for suspension culture is usually a stirred reactor (occasionally airlift), the mode of reactor operations can vary significantly. Production methods have been developed based on batch, fed-batch, and continuous (perfusion) systems. The choice of process will be dictated by several factors. Batch and fed-batch culture have the advantage of simplicity, reliability, flexibility, and reduced timescales for development and validation (compared with continuous systems). On the other hand continuous systems may have significant economic advantages, particularly for high-volume products, and thorough cost modeling is necessary to determine the most appropriate route for a given product. Griffiths (41) has reviewed the benefits of continuous processes.

Batch and Fed-Batch Culture

Batch culture is very commonly used in industry. Cells and medium are added to the reactor, and the culture is harvested after an appropriate period of culture. The time of harvest will depend on the kinetics of product accumulation and, in some cases, on the stability of product within the reactor. A commonly used variation on this type of culture is repeated batch or "draw and fill" culture. This is a batch culture in which a proportion of the culture is retained in the reactor as an inoculum, and fresh medium is added. This allows repeated batch growth cycles within the reactor, obviating the need to repeatedly clean, sterilize,

Table 1. Examples of Industrial-Scale Mammalian Cell Suspension Culture Processes

Product	Cell Line	Reactor	Reference
Foot-and-mouth disease vaccine	BHK 21	3,000 L	Pullen et al. (9)
Interferon	Namalwa	8,000 L	Pullen et al. (9)
Tissue plasminogen activator (tPA)	CHO	10,000 L	Lubiniecki et al. (11)
Factor VIII	BHK 21	Perfused 500-L reactor with cell recycle system	Bödeker et al. (18)
Factor VIII	CHO	2,500-L batch refeed	Adamson (26)
Monoclonal antibodies	Hybridoma/myelomas	Perfused 500-L spin filter reactor	Deo et al. (27)
Monoclonal antibody	NSO myeloma	2,000-L fed-batch reactor	Ray et al. (22)
Monoclonal antibody	Hybridoma	1,300-L batch, draw and fill	Backer et al. (19)
Monoclonal antibody	Myeloma	2,000-L airlift reactor	Brown et al. (28)

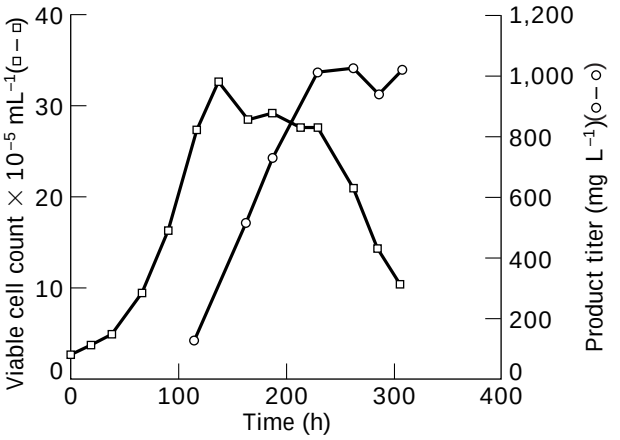

Figure 1. Growth and productivity of a GS-NSO cell line making a recombinant antibody in airlift culture. *Source*: From Ref. 40.

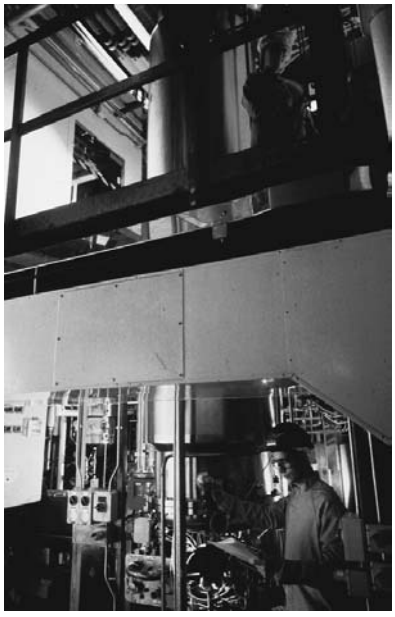

Figure 2. A 2,000-liter airlift bioreactor.

and reinoculate the vessel. Backer et al. (19) described such a system, which was operated for several months at a time, for monoclonal antibody production in a 1,300-L reactor. Every 84 h, the reactor was harvested leaving, 10% of the culture in the reactor as inoculum for the next culture.

A further commonly used variant on batch culture is fed-batch culture in which small volumes of selected nutrients are fed to the culture during the growth cycle to improve productivity. Bibila and Robinson (42) and Bibila et al. (43) describe the optimization of a feeding strategy for production of monoclonal antibodies. The use of a multinutrient feed to increase cell culture longevity resulted in antibody titers in the range of 1 to 2 g/L. A similar feeding strategy led to a 10-fold increase in productivity for large-scale myeloma cultures producing recombinant mouse and rat growth hormones (44). Ray et al. (22) described the fed-batch culture of GS-NSO cells making a humanized monoclonal antibody in a 2,000-L stirred-tank bioreactor, using a supplemental feed containing glucose and amino acids. Xie and Wang (45–48) have developed a feeding strategy based on a stoichiometric model of the demands of nutrients for growth and product formation. The strategy is aimed at preventing nutrient depletion while reducing the formation of toxic products of metabolism such as ammonia and lactate (by avoiding excess concentration of the nutrient precursors of these products). Application of this strategy in 2-L fed-batch cultures of hybridoma cells (45) resulted in very high cell densities (1.7×10^7 cells/mL), extended culture span (550 h), and a final monoclonal antibody concentration of 2.4 g/L. This approach clearly demonstrates the potential for improving the productivity of suspension culture processes. It may ultimately be possible to use on-line measurement to estimate nutrient utilization rate and feed stoichiometric amounts of nutrient to support growth and reduce accumulation of toxic metabolites. Zhou et al. (49) demonstrated such a system using on-line measurement of oxygen uptake rate to automatically control the feed to a 500-mL hybridoma culture. Maximum cell concentrations were increased from 2×10^6/mL in batch culture to 1.36×10^7/mL in the fed culture. Kurokawa et al. (50) used on-line measurement of glucose and glutamine, using HPLC, to control the concentration of these nutrients in fed batch culture at low levels (0.2 and 0.1 g/L, respectively). This strategy reduced the accumulation of lactate and ammonia and gave an approximately twofold increase in cell growth and antibody production.

Continuous Culture Systems

Continuous (perfusion) suspension culture systems are now being used for large-scale manufacturing operations. For a discussion of perfusion culture technology and the engineering issues involved in designing and operating such systems, the reader is referred to the review by Ozturk (51). Perfusion culture uses a continuous supply of culture medium to the reactor and a continuous offtake of spent culture fluid containing product. By retaining cells in the reactor (by preventing them leaving the vessel or by an external recycle device), very high cell densities and consequently very high product throughput can be achieved. The earliest device of this kind was the spin filter culture developed by Himmelfarb et al. (52). A spinning filter within the reactor allowed cell retention, and with continuous perfusion of culture medium, cell densities approaching 10^8/ml were achieved.

Several groups have described production systems based on the spin filter principle. Avgerinos et al. (53) described a 20-L perfused bioreactor for production of a plasminogen activator from CHO cells. Deo et al. (27) described the design and operation of a 500-L perfused spin filter reactor for monoclonal antibody production. They note that continuous perfusion generally gives an approximately 10-fold greater volumetric productivity in comparison with batch and fed-batch processes. Hence less reactor capacity is required. At an antibody titer of 400 to 500 mg/L the 500-L reactor is capable of producing greater than 1 kg of

antibody per week, which they estimate would require a 5,000- to 10,000-L bioreactor operating in batch or fed-batch mode. Successful operation of spin filter systems depends on careful optimization of the filter system to prevent fouling (27,54).

Other cell retention devices have also been described in the literature. Roth et al. (55) describe an external vortex flow filtration device used with perfused 3-L cultures of CHO, HEK 293, HeLa, and Sp2 cell lines. Hülscher et al. (56) describe the use of a settling tank for cell retention in a perfused 5.4-L airlift loop reactor. Pui et al. (57) have developed an acoustic resonator to cause cell aggregation and sedimentation back into the culture. At industrial scale Bödeker et al. (18) (Table 1) have used a perfused 500-L bioreactor with an external cell retention/recycle system to manufacture recombinant factor VIII from BHK cells. This is apparently the first approved biopharmaceutical from recombinant mammalian cells made using perfusion culture. The authors discuss the advantages of this process for factor VIII production, which requires the generation of greater than one million liters of harvest. These advantages are a high degree of culture control compared with batch operation (operates in steady-state conditions) and reduction in reactor size (hence easier to operate, clean, and sterilize). The main disadvantage reported was the extended process validation required. This validation included process stability, stability of product characteristics, and genetic stability of the cell line over the duration of the culture, which was up to 185 days. Several full-length campaigns were run to establish process consistency.

An alternative approach to continuous culture is to use a chemostat in which growth rate is controlled by the supply of a single limiting nutrient. The advantage of this system is that true physiological steady-state conditions can be maintained indefinitely, allowing very precise control of culture conditions, and this can be extremely valuable in a variety of research applications for studying cell physiology (see for example Refs. 58–60). To date, however, the technique has not been applied in industrial processes.

Process Monitoring and Control

The key parameters that are usually monitored and controlled in industrial-scale suspension cultures are pH, temperature, and dissolved oxygen. There is also increasing interest in the use of devices, which are now available, that allow real-time monitoring of biomass concentration (61). Such devices will allow improved monitoring and control of fermentations, particularly where fed-batch and perfusion strategies are adopted.

pH Control. Mammalian cell growth metabolism and productivity can be profoundly influenced by even small changes in pH of the culture. Ozturk and Palsson (62) found that the growth rate for a hybridoma was optimum at pH 7.2 but that the specific antibody production rate increased twofold at pH values below 7.2. They also showed that glucose and glutamine uptake rates and production rates for lactate and ammonia increased at higher pH values. Wayte et al. (63) reported that differences in pH of as little as 0.1 unit could profoundly affect cell growth and/or productivity of hybridoma and myeloma cell lines. The effects observed were cell line specific. pH may also influence product characteristics, especially glycosylation. Borys et al. (64) showed that pH affected the glycosylation pattern and specific expression rate of a recombinant lactogen protein made in CHO cell culture. Hence it is essential to establish the optimum pH for a given cell line and to measure and control pH precisely. pH is typically controlled at a value in the range 7.0 to 7.5. Most cell culture media rely on a bicarbonate-CO_2 buffering system. Hence when a bioreactor is sparged with air the pH can be controlled by injecting a controlled flow of CO_2 on demand to maintain a constant pH value. It is frequently found that lactic acid accumulates to levels that cannot be controlled by sparging with air and CO_2; it is then common practice to control the pH by addition of a sterile base solution such as sodium bicarbonate (19) or sodium carbonate (29). Care is needed in designing bioreactors to avoid pH gradients during addition of base solution. Regions of high pH may arise, especially if base is added to a poorly mixed zone (often the upper region) in both stirred reactors (29) and airlift reactors (63). The problem can be minimized by adding base to a well-mixed region of the reactor.

Dissolved Oxygen Concentration. Animal cells have an absolute requirement for oxygen. Their are several ways in which it can be provided to cultures, but the most common method is to bubble or "sparge" air or oxygen into the reactor. A less commonly used method involves gas exchange across gas permeable membranes inside or outside the reactor (51,65). Dissolved oxygen concentrations can be measured in situ with a dissolved oxygen electrode and controlled automatically by adjusting the flow rate of air or oxygen to the reactor. The optimum dissolved concentration varies from one cell line to another, although most cell types will grow over quite a wide range of dissolved oxygen concentrations. Boraston et al. (58) found that growth of a hybridoma cell was relatively unaffected over the range 8–100% air saturation. Ozturk and Palsson (62) showed that growth rates of hybridoma cells were not influenced at dissolved oxygen concentrations in the range 20–80% air saturation. Specific death rates were lowest in the range 20–50% air saturation. Nienow et al. (29) found that a CHO cell line producing recombinant interferon γ grew well and had similar productivity over the range 20–80% saturation, but growth and productivity were reduced at 5 and 100% saturation. The oxygen uptake rate of animal cells is typically in the range 0.05 to 0.5 mmol $O_2/10^9$ cells/h (66). It is of course necessary to ensure that oxygen transfer into the culture is sufficient to meet the uptake rate of the cells, and this becomes an increasingly important issue as higher cell densities are achieved through improvements in process design. Factors influencing oxygen transfer include height-to-diameter ratio for the vessel, sparger and impeller designs, and gas flow rates. Tramper (67) has pointed out that gradients of dissolved oxygen concentration may occur in large bioreactors. It is not clear what impact such gradients have in practice, but they should be borne in mind and minimized when design-

ing reactors. Aeration in cell culture bioreactors has been reviewed in detail by Aunins and Henzler (65).

Dissolved Carbon Dioxide Concentration. In addition to CO_2 added to the culture as part of the pH buffering system, account must be taken of CO_2 generated by cell metabolism. Although systems for in situ monitoring and control of CO_2 are not yet commonly used, it is useful to measure CO_2 levels off-line, for example, using a clinical blood gas analyser. In recent years it has become apparent that in some large-scale processes CO_2 can accumulate to levels that inhibit cell growth and recombinant product formation (12,65–69). It has been suggested (65) that CO_2 accumulation may be the factor that will ultimately limit the reactor scale for some processes. Kimura and Miller (70) point out that inhibition may be caused by an effect of CO_2 on intracellular pH (even if the culture pH is controlled) and may also be caused by an increase in osmolarity caused by the additional base required to maintain pH.

Gray et al. (69), working with CHO cells in a high density perfused process, showed that productivity of a recombinant product was maximized when CO_2 was maintained in the range 30–76 mm Hg. Levels greater than 105 mm Hg resulted in inhibition of growth and productivity. CO_2 concentration may also influence glycosylation of recombinant proteins (70). Aeration systems designed for efficient oxygen transfer will not necessarily be efficient at stripping out CO_2. Gray et al. (69) found that sparging with microbubbles of pure oxygen gave very efficient oxygen transfer but was inefficient for CO_2 removal because the bubbles dissolved before reaching the surface of the culture. Sparging with large bubbles (2–3 mm diameter) improved CO_2 removal while retaining adequate oxygen transfer. Zhou et al. (44), working with GS-NSO cell lines making recombinant mouse and rat growth hormones in a 250-L fed batch reactor, also found that use of a sintered steel frit delivering pure oxygen gave good oxygen transfer, but CO_2 accumulated to 200 mm Hg, depressing cell growth. By using a less efficient sparger (12-mm $\times$ 1.5-mm orifice ring sparger) CO_2 accumulation was reduced to a noninhibitory level.

Temperature. Temperature is typically controlled at around 37 °C. Bloemkolk et al. (71) studied the effect of temperature on growth and antibody production of a hybridoma in suspension culture; 37 °C was the optimum temperature for cell growth and antibody production. At 39 °C growth was completely inhibited. In some instances the optimum temperature for product accumulation may be below 37 °C (72).

Culture Media for Suspension Culture

In general media for suspension culture are similar to those used for other processes, with the exception that an agent to protect against mechanical damage is frequently added (see later section on mechanical damage). For reactors that are aerated by sparging it may also be necessary to use an antifoam agent, which is usually a silicone emulsion (65,73). In some instances changes in nutritional requirements have been observed in suspension as opposed to static culture. For example, Murakami (74) showed that a myeloma cell line in suspension culture had a requirement for a phospholipid component that was not required in static culture.

Significant progress is being made in the optimization of media composition as well as of nutrient feeds for fed-batch culture (see earlier section). Brown et al. (28) described how an iterative program of medium development gave a six- to sevenfold improvement in productivity of antibody from a recombinant NSO myeloma cell line. Addition of a feed gave a further twofold increase in productivity. Jo et al. (75) increased maximum cell concentrations significantly for several cell lines by increasing the nutrient concentrations in RPMI 1640 medium.

There is an increasing drive to remove animal-derived raw materials from cell culture processes to reduce the risk of inadvertently introducing adventitious agents. Encouraging progress has been made, and there are now several examples in the literature of industrially important cell lines being grown in chemically defined protein-free medium. Keen (76) described the growth of myeloma and hybridoma cell lines in a protein-free medium in shake flask culture. Zang et al. (77) showed that CHO cell lines making recombinant proteins could be grown in protein-free culture medium.

PREVENTION OF CELL DAMAGE IN BIOREACTORS

Two mechanisms have been identified that can potentially cause cell damage in bioreactors; the first is the interaction of cells with bubbles in sparged reactors, and the second is the stresses created by impellers at high agitation rates in stirred reactors. In practice, given the low impeller speeds used in animal cell reactors, interaction with bubbles is the only likely source of damage in aerated cultures (65,78). The problem is readily overcome by incorporation of a protective polymer such as the nonionic surfactant Pluronic F68 into the culture medium. For a review of protective additives see Ref. 78. The role of these polymers is not totally clear. They may act by preventing cells from attaching to bubbles, by altering the way in which bubbles burst when they disengage at the surface of the culture, or by adsorbing to the surface of cells and strengthening them (65,79,80).

CONCLUSIONS

Large-scale animal suspension cell cultures have become an extremely important source of biopharmaceutical products, and with the steadily increasing number of biotechnology products in clinical trial (81), this trend seems set to continue. New areas of medical development, for example in gene therapy, give rise to new process development challenges that will lead to new uses for large-scale

suspension culture. The requirement for large volumes of some animal-cell-derived pharmaceuticals drives the need to develop processes that are highly productive and cost efficient. Currently two approaches are being adopted: the use of very large bioreactors (to benefit from economies of scale), and the use of continuous (perfusion) culture using high-density cell culture at smaller scale. Advances in reactor design and operations are being complemented by the use of efficient gene expression technology and by continuing improvement in the design of culture media, especially chemically defined media.

OUTLINE

INTRODUCTION

Recombinant therapeutic proteins have emerged as important pharmaceuticals for a wide variety of indications in a number of clinical disciplines. These include immunoregulatory proteins, peptide and protein hormones, growth factors, and immunoglobulins. Developing stable formulations of proteins offers challenges related to the inherent instability of their native three-dimensional structures that must usually be maintained for biological function (1,2). The pharmaceutical aspects of developing stable protein formulations include designing ways to preserve their chemical and conformational integrity as measured by sensitive, stability-indicating assays.

Protein inactivation can occur by either or both of two distinct pathways: chemical degradation, including hydrolytic and proteolytic clipping, and physical inactivation, including global unfolding, a more subtle local conformational change involving a functionally critical site. Protein stability studies must include assays that can quantitatively determine the extents of physical and chemical changes as well as changes in biological activity that may result from perturbations introduced by storage, handling, and formulation conditions. A well-designed study using various biophysical and biochemical techniques is essential to monitoring protein structure and activity as a function of formulation processing. Protein conformational stability studies under various stress conditions have been widely applied in protein formulation research. The techniques include both thermal, pH, and denaturant induced unfolding. In this article, we discuss specifically the application of thermal unfolding studies to formulation development of protein-based pharmaceuticals.

MECHANISMS OF PROTEIN UNFOLDING

The native or functional structure of a protein is a minimum energy state that is held together by an intricate balance of a multitude of covalent and noncovalent interactions. Perturbations of these interactions can lead to unfolding of the native conformation and will usually lead to the loss of biological activity. In general, there are two major types of noncovalent interaction contributing to the stability of a folded protein structure: hydrophobic interactions between apolar side chains that prefer to exclude water and electrostatic or polar interactions mediated by water. The latter includes hydrogen bonding and salt bridges. Although from a macroscopic point of view a protein molecule may appear to be in a completely folded state, the so-called native protein conformation is in fact in a fast exchange between folded or native (N) and unfolded (U) states in a dynamic equilibrium, with an overwhelming majority of the population being in the folded state. The equilibrium constant, K, describing the population distribution in these two states, is strongly dependent on the environment of the protein and is correlated to the Gibbs energy, ΔG, of the protein molecule through relation $\Delta G = -RT\ln K$.

Protein unfolding occurs when the balance of forces between the intramolecular interactions in the protein and the protein's interaction with its environment is disrupted. This may be a result of perturbation of normal water struc-

ture around the protein. The conformational stability of most proteins is sensitive to temperature. Increased temperatures lead to increased thermal motions in proteins, which, in turn, perturb intermolecular interactions as well as solvent–protein interactions. When the environment of a protein is altered because of changes of temperature, pressure, pH, or solvent polarity, the equilibrium balance between unfolded and native states is altered, and a new equilibrium is reached in which the unfolded state may be favored. However, this population redistribution is not significantly noticeable until an apparent conformational transition is approached in the unfolding process.

Disruption of Secondary and Tertiary Structure

It is important to understand the mechanism of the disruption of protein secondary and tertiary structures when the protein is exposed to stress conditions. The secondary structure of a protein refers to the spatial arrangement of amino acid residues that are near one another in the linear sequence (3–6). Some of these steric relationships manifest a regular repeat pattern, giving rise to periodic structures. The α-helices, β-sheets, turns, and random coils are elements of secondary structure. Tertiary structure refers to the overall three-dimensional architecture of the spatial arrangement of amino acid residues, including those that may be far apart in the linear sequence (3–6). This spatial arrangement is also referred to as the packing assembly of secondary structure units.

The net stabilization free energy that maintains the native folded structure of a globular protein is in the order of only 2 to 20 kcal/mol. Therefore, a few kcal of additional energy gained from the interaction changes of the protein with the environment can result in the destabilization of the protein molecule resulting in either local or global conformational changes (7). Information about obtaining the ΔG value of a protein is available (8).

It is necessary to point out that thermodynamic analysis of the free energy of protein conformational change is limited to reversible conformational change or unfolding, because the relation $\Delta G = -RT\ln K$ is only valid when the mass balance is retained for all species involved in the conformational change. For a thermally induced reversible unfolding transition, the dependence of ΔG on T (and hence the dependence of K on T) is given by $\Delta G = \Delta H - T\,\Delta S$. ΔH and ΔS are, respectively, the enthalpy and entropy differences between U and N states. The values of ΔH and ΔS are dependent on temperature through a positive heat-capacity change, ΔCp. The positive ΔCp is thought to be related to the hydrophobic exposure of apolar side chains as a result of unfolding of globular proteins.

Two-Step versus Multistep Unfolding

The simplest model for the unfolding of a protein is the two-state model in which transition from N state to U state occurs in a cooperative process, that is, in a single unfolding transition step N ↔ U (4,9,10). A typical two-state unfolding of a protein follows a sigmoidal shaped unfolding curve, as shown in Figure 1 (for a review see Ref. 11). The N state is generally considered to have a narrow distribution of conformations, which are relatively ordered (low in entropy), whereas the U state involves a broader distribution of microscopic conformational states, which are relatively disordered (high in entropy). In recent years, protein biochemists have focused on the multistep unfolding model, in which protein unfolding proceeds from N to U by passing through one or more intermediate (I) states:

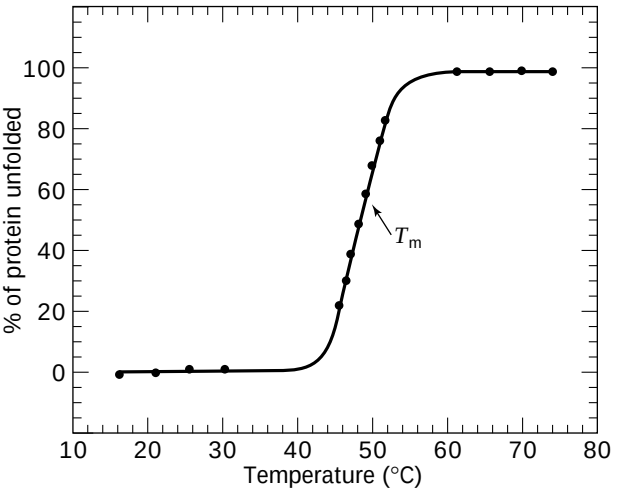

Figure 1. Two-state protein unfolding curve: Ribonuclease T1 thermal unfolding as measured by specific optical rotation at 295 nm. Data were adapted from reference 10 with permission.

$$N \leftrightarrow I \leftrightarrow \ldots \leftrightarrow U \quad (1)$$

If an I state is stable in the unfolding process, both N ↔ I and I ↔ U transitions can be characterized biophysically from equilibrium and kinetic unfolding studies (12–14). Several features of a partially unfolded state as a folding intermediate have been identified:

1. Relatively well-defined secondary structure (15,16) folded in a compact globular shape (17)
2. A non-cooperative folding/unfolding pathway (18)
3. Weak tertiary contacts and substantial solvent exposure of hydrophobic groups (18,19)
4. Relatively high affinity for hydrophobic ligands and tendency to aggregate (17,19)

For a multidomain protein, each individual domain may unfold sequentially or simultaneously (13).

Protein unfolding can lead to either reversible or irreversible loss of the folded structure. By definition, proteins denatured by a reversible pathway can regain their native structures and biological functions. An example of this process is the refolding of a protein after solubilization from inclusion bodies using denaturing conditions. Irreversible denaturation often leads to protein aggregation and results in loss of biological function (20,21).

APPLICATION OF THERMAL UNFOLDING STUDIES TO DEVELOPMENT OF STABLE PROTEIN FORMULATIONS

The unfolding of a protein during storage could be induced by perturbations such as elevated temperatures, surface

adsorption, and physical agitation. A successful formulation of a protein pharmaceutical would require the development of a dosage form in which the physicochemical properties and biological activity of the protein are maintained during storage. The design of a pharmaceutical formulation should be biocompatible, possess pharmaceutical elegance, and be suitable for commercial scale-up. The development of a stable formulation requires a thorough understanding of the causes and mechanism of inactivation, including both physical and chemical pathways. In approaching this goal, thermal unfolding studies are frequently used in the following ways. Intrinsic conformational stability data such as unfolding transition temperature can be obtained. If the transition is reversible, thermodynamic information such as ΔCp can be derived, and the results obtained from these accelerated stability measurements can often be extrapolated to make reasonable predictions about stability at different temperatures. Thermal unfolding studies can be used to investigate the mechanism of inactivation. The inactivation process is generally accelerated at an elevated temperature. Potential stabilizers can be screened by observing their effects on the thermal unfolding transition. An excipient that provides protection against temperature-induced denaturation or inactivation of a protein is often effective in prolonging its shelf life at refrigeration temperature (22). For example, an unstabilized respiratory syncytial virus (RSV) preparation lost most of its infectivity at −86 °C within 2 to 3 weeks, at 37 °C within 24 h, at 56 °C within 3 min. This study aided the development of a stabilized RSV formulation that was stable at −86 °C for 3 years, at 37 °C for 3 days, and at 56 °C for 6 min (23).

Compared to pH or denaturant-induced unfolding studies that also address the conformational stability of a protein, thermal unfolding studies are more direct and avoid the use of nonnative solution conditions (denaturants). In most cases, proteins and vaccines are likely to be exposed during handling to temperatures higher than the temperature usually recommended for their stable storage (e.g., 2 to 8 °C). Monitoring biological activity and structure of proteins as a function of increasing temperatures is the most convenient method to perform an accelerated stability study, although cold denaturation and freezing-induced aggregation of proteins have been studied as well (24–28). A major benefit of the accelerated stability studies is to expedite the process of screening suitable excipients for development of a stable formulation.

There have been many recent developments in using the approaches of stabilizing proteins by stabilizing the folded state, destabilizing the unfolded state, and altering the kinetics of unfolding. The factors that affect stability of a folded state versus the unfolded state as well as factors affecting rates of folding and unfolding play a role in maintaining stability (29). More detailed information on approaches to minimize inactivation and develop stable formulations of proteins are available (1,4,20,22,28–33).

PROTEIN STABILITY EVALUATED BY MEASUREMENT OF THERMAL UNFOLDING TRANSITION

The denaturation transition temperature (T_m) has been widely used as a reference to evaluate the thermal stability of proteins and polynucleotides (34–43). T_m is defined as the temperature at the midpoint of protein unfolding transition (Figs. 1 and 2). At T_m, 50% of the total protein is unfolded (1,10). Therefore, for a reversible two-state unfolding process, at T_m, the unfolding equilibrium constant K is 1 and the Gibbs free energy ΔG is 0. Based on the complete unfolding curve, a two-state or multistate unfolding process can be suggested. For well-resolved, reversible, multiple transitions, the transition midpoint between states and the apparent unfolding ΔG can be determined for each transition under various conditions (37). The fractions of different conformational states at equilibrium can also, in such ideal cases, be determined from the unfolding transition curves (10,37,44).

There are several methods to determine T_m of protein unfolding with reasonable accuracies. (1) The first derivative of the unfolding curve yields T_m as the sharp peak in the middle of the unfolding transition (Fig. 2**a**). (2) A plot of K values against temperature yields T_m at the temperature at which $K = 1$ (Fig. 2**b**). (3) A plot of ΔG value against temperature yields T_m at the temperature at which $\Delta G = 0$ (Fig. 2**c**).

An increase in T_m is indicative of structural stabilization of a protein in solution. The stabilization or destabilization effect of an excipient can be studied by measuring the change in T_m upon the addition of the excipient. For example, addition of heparin, a sulfated polysaccharide, to a solution of acidic fibroblast growth factor (aFGF) causes a dramatic increase in the T_m for aFGF unfolding, as measured by circular dichroism (CD) and fluorescence spectroscopy (31,45). A related study shows that the binding of heparin results in about 2.5 kcal/mol of stabilization for the native form of aFGF (46). Another example is the differential scanning calorimetric studies of the addition of osmolytes such as glycine, sarcosine, *N*,*N*-dimethylglycine, and betaine to ribonuclease A and lysozyme. The data indicate a 22 to 23 °C increase in T_m of the proteins upon the addition of the osmolytes (43). For ribonuclease, the 22 °C increase in T_m corresponds to an increase in stabilization free energy of 7.2 kcal/mol. Changes in T_m as a function of pH, salt, and osmolyte concentrations have been used to monitor thermal stability of proteins under different conditions (43,47,48). The T_m of tissue-type plasminogen activator (TPA) in phosphate buffer is approximately 66 °C. The addition of arginine (the stabilizer selected for the formulation) shifts the T_m up to 71 °C (28). Binding of nucleotides and substrates plays an important role in the thermal stabilization of a 70-kDa heat shock protein. Addition of nucleotide (ATP and/or ADP) or substrate protein (unfolded protein or peptide) to the solution increased the T_m of DnaK by 10 to 20 °C (38,49).

Protein unfolding can facilitate aggregation or chemical degradation (Scheme 1). Where U is fully or partially unfolded protein, I_d is the protein inactivated by degradation and I_a is the protein inactivated by aggregation. Unfolding could be a reversible process, but inactivation is normally an irreversible process. Study of the correlation of protein unfolding T_m with the rate of protein inactivation could provide useful information in understanding the mechanism of the inactivation process (7,33). In the case of reversibly denaturing of protein, the shift of T_m upon the addition of excipient is often related to the difference be-

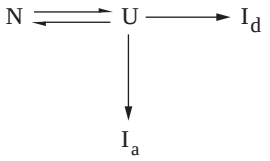

Scheme 1. Protein unfolding related inactivation pathways.

tween the binding affinities of the excipient for native and denatured states (50). For example, heparin increases the T_m of antithrombin III by 7 °C through a preferential binding to the native state of the protein (51).

Protein preparations are well known to be more stable in the dried state. Conformational flexibility is believed to be restricted in the dry state because interactions with water molecules are minimized. However, unfolding of proteins during the process of freeze-drying has been observed with FTIR spectroscopy. Many sugars and even some polymers, such as poly(vinylpyrrolidone) have been found to inhibit lyophilization-induced unfolding (24,52).

Many proteins irreversibly aggregate as they start to unfold with increasing temperature, making it difficult to obtain a complete thermal unfolding curve, and therefore the unfolding data can not be used to calculate thermodynamic parameters such as ΔG (31). As an alternative means for obtaining thermodynamic parameters, unfolding by urea or guanidine hydrochloride is frequently used, provided that these processes are reversible. These denaturants help to maintain the solubility of unfolded forms of these proteins. For the same reason, when performing the thermal unfolding studies of such proteins, a relatively low concentration (0.2 to 1 M) of chemical denaturants such as urea or guanidine hydrochloride could be added to the protein solution to prevent fully or partially unfolded protein from falling out of the solution because of aggregation (53). When this is the case, the contribution of the added denaturant to the apparent unfolding T_m should be taken into consideration. Normally, unfolding should be carried out at a series of denaturant concentrations, and T_m and other thermodynamic parameters can be obtained by extrapolation to zero denaturant concentration. A two-dimensional protein unfolding (thermal unfolding profile under various guanidine hydrochloride concentration conditions) study aimed at elucidation of biomolecular energetics has been carried out by Straume (54).

PROTEIN STABILITY EVALUATED BY KINETICS OF TEMPERATURE-INDUCED PROTEIN INACTIVATION OR UNFOLDING

Another approach to quantitative characterization of the stability of a protein is to study the protein unfolding kinetics and inactivation rate (29,55,56). Rapid unfolding, aggregation, or inactivation at high temperature indicates a less-stable protein product. A formulation that can slow down these denaturation and inactivation processes at el-

evated temperatures may be able to increase the stability of the protein product at storage temperature.

Arrhenius Relationship

For most proteins, unfolding can be simplified as a first-order kinetic process displaying single-exponential unfolding kinetics. The equilibrium unfolding curve can be predicted from the rate constant assuming a two-state kinetic model. The unfolding rate can be expressed by the decrease in population of the native structure with time as

$$-d[\mathrm{N}]]/dt = k[\mathrm{N}] \quad (2)$$

where [N] is the population of the structure remaining native at time t during unfolding, and the proportionality constant, k, is the apparent rate constant of the unfolding. The population of the native structure remaining can be expressed as

$$[\mathrm{N}] = [\mathrm{N}]_0 \exp(-kt) \quad (3)$$

where $[\mathrm{N}]_0$ is the population of native structure at time zero. Arrhenius in 1889 suggested that a reasonable equation for relating the rate constant, k, with an activation energy term (Ea) for the forward part of a reversible reaction is

$$d\ln k/dT = Ea/RT^2 \quad (4)$$

where R is the gas constant, and T is temperature. At temperature T, the above equation can be expressed as

$$k = A\exp(-Ea/RT) \quad (5)$$

where A is a frequency factor or preexperiential factor that can be determined by performing a multimeasurement of k at various temperatures (assuming A and Ea are independent of temperature). Equation 5 shows that for a reaction with a positive activation energy, the reaction rate increases with temperature.

The goal of a stable formulation is to minimize unfolding and other degradative pathways. According to equation 5, this can be achieved by either decreasing storage temperature or increasing the activation energy (Ea) for unfolding. The apparent activation energy, Ea, of unfolding determines the rate of the transition between the folded and unfolded states. This can be affected by altering solution conditions. Stabilizing excipients will increase the activation energy of unfolding and will, therefore, reduce the rate of unfolding under the formulation condition. The calculation of Ea requires measurement of a structural or functional property of the protein that directly reflects unfolding at several different temperatures. The Arrhenius plot of ln k versus $1/T$ should be linear (the slope of which yields the activation energy), and this may be true only over a limited temperature range. For example, the amount of aggregated protein might increase beyond a certain temperature to the point of causing interference with rate measurements. A biphasic Arrhenius plot in the absence of aggregation would indicate either a change in the pathway by which temperature affects the protein structure or the breakpoint that occurs at the temperature at which pathway changes. Measurement of unfolding activation energy has been applied to protein stability studies (22,28).

Experimental Approaches

Careful considerations must be given to the selection of methods for measuring the unfolding rate. Far-UV CD detects changes in secondary structure, but subtle and functionally important changes might remain undetected. Near-UV CD and tryptophan fluorescence measurements are well suited to monitor tertiary structural changes. The active sites of proteins, including receptor-binding sites, catalytic sites, and antigen-binding sites, would often be perturbed (locally) before a global unfolding occurs. In such cases, the unfolding rate will be slower than inactivation rate. A good strategy is to use a number of different techniques, for example, CD and fluorescence spectroscopy to monitor the unfolding rate and hydrodynamic methods to monitor rate of aggregation.

APPLICATION OF ACCELERATED PROTEIN STABILITY STUDIES TO FORMULATION DEVELOPMENT

Although the expiration dating of a biological product is based on real-time and real-temperature storage stability data, accelerated stability studies of biological products under stress conditions usually constitute an important part of the stability data package (57). It is common to determine the degradation rate of a chemical compound under a stress condition, for example, an elevated temperature (37 °C or higher), and then extrapolate the results to a lower (storage) temperature (22). When exposed to sufficiently elevated temperatures, all proteins will lose biological activity within limited a time.

Thermal stability studies include two main approaches: temperature-induced conformational change and kinetics of unfolding and degradation at elevated temperatures. The first approach is to follow the unfolding transition temperature to test, for example, effects of various excipients on T_m. The second approach is to accelerate the process that may result in the destabilization of the protein samples. At elevated temperatures, protein unfolding rate increases and most chemical interactions become faster compared to lower temperatures (37). Under these conditions, various formulations could be screened for their ability to inhibit the inactivation process. Under accelerated stability study conditions, the intrinsic stability of protein pharmaceuticals is often decreased dramatically. The addition of various excipients or stabilizers may enhance the stability of the protein pharmaceuticals under the same condition. For example, a properly buffered solution of acidic FGF (aFGF) complexed with heparin is stable at 5 °C for 1 year, but the protein is inactivated when stored at 30 °C for 2 to 4 months. Addition of 0.15 mM EDTA to the formulation enhanced storage stability at 30 °C to be roughly equivalent to that at 5 °C, and more than 70% of the protein mass remained after 1 year of storage at 30 °C (58).

Questions have been raised about the validity of accelerated protein stability studies in defining stable formulations. There are two simple but critical questions that deserve attention. One is the question of reliability of extrapolating results obtained at elevated temperatures to a lower storage temperature, such as 5 °C (22). Another question is how high the temperature for an accelerated condition could be pushed to. So far, there is no generally correct answer to the first question. The answer to the second question is that for quantitative extrapolation of kinetic data to low temperatures, the accelerated studies should be kept well below the lowest protein unfolding transition temperature (T_m). Pearlman and Nyguyen (59) were able to successfully extrapolate data obtained in an accelerated stability study at 40 °C down to 5 °C.

If protein unfolding is a first-order kinetic process, the unfolding activation energy could be obtained by carrying out the unfolding measurement at two or more different temperatures, and then using the temperature coefficient of kinetics to calculate the unfolding rate of the protein at storage temperature. Recently, Eberlein et al. (60) used a turbidity test for 15 h at 30 to 40 °C by UV spectrophotometry to predict storage stability of recombinant human bovine fibroblast growth factor (rhbFGF) with 95% confidence. Figure 3 shows a theoretical calculation for different activation energies of a first-order inactivation process using the Arrhenius equation. The results indicate that the storage stability increases as a function of activation energy of the unfolding and inactivation process. The higher the activation energy, the longer the shelf life is expected to be.

TECHNIQUES USED IN THERMAL UNFOLDING STUDIES

The spectral property of a protein molecule is sensitive to the molecular environment and the mobility of its chromophores. Far-UV CD (180–250 nm) and amide I Fourier transform infrared (FTIR) (1600–1700 cm^{-1}) are convenient spectroscopic tools for monitoring changes in the secondary structures of proteins (61,62). Fluorescence and near-UV CD (250–320 nm) are used to monitor environmental changes around aromatic chromophores of proteins and can often detect subtle changes in tertiary structure even in the absence of a global structural change in a protein (1,44,63,64). Differential scanning calorimetry (DSC), which measures changes in heat capacity, provides a direct method for monitoring thermal stability of proteins (43,65–67). Changes in hydrodynamic properties of proteins, such as aggregation, often induced at elevated temperatures, are monitored by techniques such as dynamic light scattering (DLS), small-angle X-ray scattering, analytical ultracentrifugation, and size exclusion chromatography (SEC). Specific applications of some of the more commonly used techniques that readily provide useful information are described in this section.

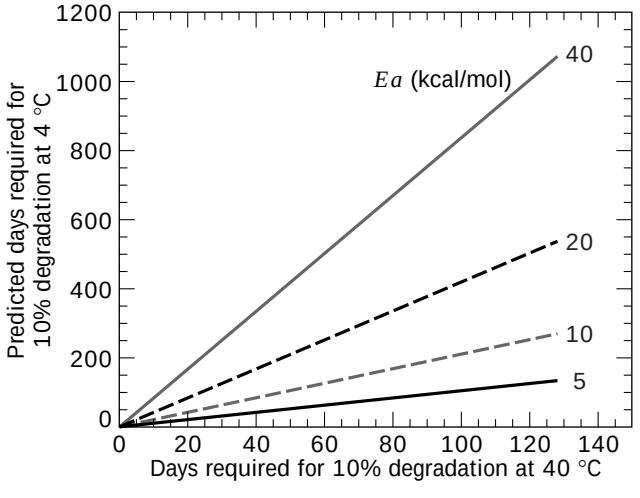

Figure 3. Theoretical prediction of 4 °C shelf-life time based on stability data at 40 °C.

Spectroscopic Methods

Tryptophan and tyrosine residues are the most commonly used intrinsic aromatic chromophores and fluorescence probes of proteins. Phenylalanine fluorescence exhibits a low quantum yield and has not found much use in protein unfolding studies. Tryptophan fluorescence spectral maxima of proteins typically range from 315 to 345 nm, and a fully water-exposed tryptophan manifests maximal fluorescence around 355 nm. The intrinsic fluorescence of tryptophan residues of most proteins is very sensitive to changes in the polarity of their immediate environments. Protein unfolding is usually accompanied by a change in the fluorescence (emission) spectrum of tryptophan, caused by increased exposure of the tryptophan residue(s) to solvent. The spectral maxima of tyrosine fluorescence are limited to a relatively narrow range (~300 to 310 nm), and they often do not manifest significant shifts upon unfolding. However, changes fluorescence intensity can provide valuable information. In proteins containing tryptophan and tyrosine residues, energy transfer from tyrosines to tryptophans can occur, and this process may be affected because of unfolding-induced changes in the distances between these residues. For most proteins containing tyrosine and tryptophan residues, excitation at or near 280 nm (close to the absorption maxima for both residues) results in tryptophan fluorescence. Fluorescence from the phenolic side chain of tyrosines in proteins is often quenched because of different mechanisms, including energy transfer to tryptophan. However, in a number of proteins, tyrosines contribute significantly to the fluorescence spectrum in the 300 to 350 nm wavelength range. To selectively observe tryptophan fluorescence in such proteins, excitation at the red edge of the tryptophan absorption spectrum (typically 295 to 300 nm) is used (68). Although this reduces the sensitivity of excitation (and consequently of emission), the differential absorption between tryptophan and tyrosine is high at these wavelengths where tyrosine absorption is minimal. For aFGF in its properly folded form, the fluorescence intensity of its single tryptophan residue is dramatically quenched, presumably because of electrostatic interactions with charged residues, and can only be observed, with a very low quantum yield, upon red edge excitation (69). When excited at 280 nm, folded aFGF man-

ifests tyrosine fluorescence and no detectable tryptophan fluorescence. As the temperature is raised and the protein starts to unfold, tryptophan fluorescence begins to emerge with a maximum wavelength characteristic of solvent-exposed tryptophan. Changes in tyrosine and tryptophan fluorescence intensities were simultaneously monitored as a function of temperature to study thermal unfolding of aFGF (55,69). These measurements have helped identify a number of polyanionic stabilizers of aFGF.

The relatively simple measurements of steady-state intrinsic fluorescence spectra of proteins, as described above, can provide a wealth of information about protein unfolding and aid in developing stabilizing formulations of proteins. Extrinsic probes such as anilinonaphthalene sulfonic acid (ANS) and (p-toluidiny)naphthalene sulfonic acid (TNS) that noncovalently bind to hydrophobic surfaces have also been widely used in protein unfolding studies, especially in the context of studying partially unfolded intermediates (70). These and other applications of fluorescence spectroscopy to unfolding and thermal stability studies, such as nonradiative energy transfer measurements, have been recently reviewed (32). It should be noted that light-scattering artifacts make it difficult for fluorescence spectroscopy to be used for protein formulations that are not clear solutions or that contain large aggregates or particles. Front face fluorometry or alternative detection geometries, coupled with careful light scattering corrections, can still yield valuable information in such cases (31).

Near-UV CD signals in the 250 to 300 nm range result from asymmetric environment experienced by aromatic amino acid side chains and in the tertiary structures of folded proteins. Unfolding creates increased mobility and decrease or loss of induced asymmetry. This technique is, therefore, complementary to fluorescence in monitoring subtle changes in tertiary structure of proteins. Phenylalanine, tyrosine, and tryptophan are usually well resolved. For guanidine-hydrochloride-induced unfolding of a chimeric protein, TP40, with potentially chemotherapeutic activity, near-UV CD, and fluorescence of tryptophan residues produced comparable unfolding transitions (63). The sensitivity of this technique, in terms of sample concentration requirement, is lower than that of fluorescence. Furthermore, the extraction of quantitative information from near-UV CD spectra is often cumbersome. Theoretically, a quantitative description of a protein's tertiary structure based on its near-UV CD spectrum is attainable, but it is rarely done because detailed information of transition dipole moment orientations, interactions, and environments are not available.

Far-UV CD spectroscopy is frequently used as a powerful technique to monitor changes in the protein's secondary structure that might arise from thermal and other kinds of perturbation. Each element of the secondary structure of a protein's peptide backbone, that is, α-helices, β-sheets, turns, and random coils, manifests different but overlapping spectral features. Protein unfolding results in a decrease in the amount of ordered secondary structure, for example, α-helices and β-sheets, which, for thermal unfolding, can be conveniently monitored by measuring the CD signal at one or more wavelengths as a function of temperature. For an accurate description of the thermal unfolding transition, careful baseline correction may be necessary. This has been achieved by simultaneously monitoring, as a function of temperature, the background signal at a wavelength where proteins do not manifest CD (71,72).

Amide I FTIR spectroscopy is complementary to CD in monitoring the secondary structure of the peptide backbone. The biggest advantage of FTIR, especially in the context of protein formulation, is that the protein sample does not have to be in a clear solution state. Samples in different physical states can be studied, including solids, gels, suspensions, and solutions. Different sample geometries may be used, including transmission, attenuated total reflection, and diffuse reflectance. The choice of the experimental design often depends on the physical state of the sample being used (62). For example, lyophilized samples can be directly studied in the dry form using the diffuse reflectance technique. Although KBr pellets of dry protein samples have often been used to make transmission measurements, it should be recognized that KBr is a chaotropic agent and may cause perturbation of the protein structure, although chances for protein unfolding are reduced in the dry state. The effect of freeze-drying on structures of proteins has been studied by FTIR spectroscopy and potential stabilizers against freezing-induced structural damage have been identified (52). Infrared spectroscopy has also been used to evaluate the effectiveness of formulations in protecting the secondary structural integrity of proteins both in solution and in dried states. This necessitates making quantitative comparisons of the overall similarity of infrared spectra in the conformational sensitive amide I region. The study of temperature-induced protein unfolding using FTIR is generally performed by following spectral change with temperature at a fixed absorption band (e.g., amide I or I′) or wavelength (e.g., 1,640 cm^{-1}). The plot of FTIR intensity at a fixed wavelength versus temperature should yield the protein unfolding transition temperature (73). Detailed discussions on the application of FTIR to study protein conformational stability and thermal unfolding are available elsewhere (62,74–81). Protein aggregation as a result of thermal unfolding can also be detected by appearance of bands around 1,610 and 1,685 cm^{-1}, as demonstrated for chymotrypsinogen (82). The major disadvantages of FTIR are (*1*) In solution, water signal interferes with the amide I signal and must be carefully subtracted or moved away from the spectral range of interest by dialyzing the sample into D_2O. (*2*) Deconvolution of the rather broad amide I band can, to some extent, be subjective. (*3*) There is significant spectral overlap between peptide bonds in random coil and α-helical conformation. (*4*) The sensitivity for aqueous protein samples is approximately two orders of magnitude lower compared to far-UV CD. As for all the biophysical techniques described here, FTIR should be used for monitoring changes in conformation as a result of a perturbation, such as temperature, and should not be viewed as a technique to determine structure contents in absolute terms. To this end, second-derivative FTIR spectroscopy has been shown to be a valuable comparative tool, and second derivatives of amide I spectra have been particularly useful in monitoring structural changes.

It should be noted that temperature-induced protein unfolding can often be monitored by simply following UV absorbance changes in the far-UV (peptide bond absorption) and near-UV (aromatic side chains) regions. This was demonstrated for ribonuclease A and equinatoxin II by Fink and Painter (83) and Poklar et al. (84). However, this is not as commonly used a method as fluorescence and CD because (*1*) the magnitude of UV absorbance change between folded and unfolded protein states is usually much smaller than the change observed by fluorescence and CD and (*2*) the potential light scattering contribution resulting from protein aggregation that often accompanies unfolding can introduce significant inaccuracy. The resolution of near-UV absorbance spectroscopy, which is inherently a low-resolution technique, can be significantly improved by using second-derivative analysis (85). In addition, UV spectrophotometry offers a simple method to monitor temperature-induced protein aggregation. This method, which is usually called the turbidity assay and frequently used in accelerated thermal stability studies, takes advantage of the increase in total optical density resulting from light scattering as large protein aggregates are formed. The intensity of light scattering is proportional to the inverse fourth power of the wavelength of light so that greater sensitivity in measuring light scattering is achieved at lower wavelengths. Typically, a satisfactory balance between measurable light-scattering intensity and minimal protein absorbance is accomplished in the 300 to 350 nm wavelength range (4). The turbidity assay was one of the methods used to study thermal stabilization of basic and acidic FGF (45,56).

The need to use multiple techniques to study thermal unfolding of proteins cannot be overemphasized. When different techniques yield different T_m values, the pathway of unfolding most likely involves one or more partially folded intermediates. For aFGF in the presence of the stabilizer, heparin, fluorescence, CD, and DSC measurements yielded apparent T_m values of 62 °C, 72 °C and 71 °C, respectively (31). This suggests that local unfolding in tertiary structures precede a more global unfolding in which the ordered secondary structure of the peptide backbone is disrupted. For another potentially therapeutic protein, TP4O, produced as chimera of a truncated form of *Pseudomonas exotoxin* and transforming growth factor-α, tryptophan fluorescence, far-UV CD, and DSC gave apparent T_m values of 42, 55, and 48 °C. In this case also, a local unfolding in one or more parts of the tertiary structure precedes global unfolding. The in vitro cell killing activity of the protein was found to be irreversibly lost at 50 °C, and the hydrodynamic radius was increased to 12 nm, compared to 4 nm at 23 °C as measured by dynamic light scattering, suggesting aggregation (71,86).

Calorimetry

Differential scanning calorimetry (DSC) is another frequently used method in protein structural stability studies. Changes in heat capacity as a function of temperature, obtained from DSC measurements, provide a direct description of the thermal unfolding transitions of proteins. A good example (Fig. 4) is the study of the effects of various

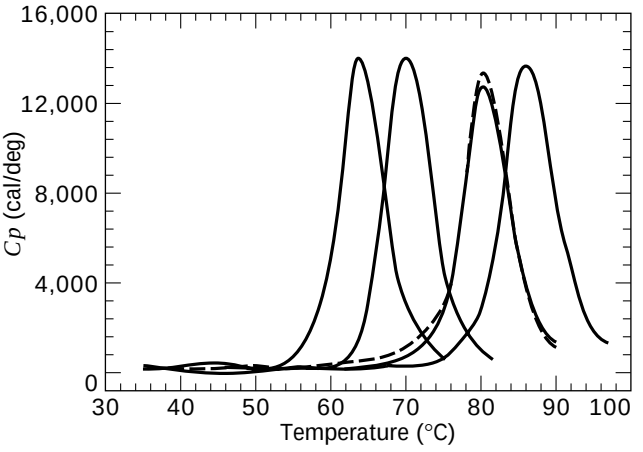

Figure 4. DSC determination of sarcosine effect on the thermal unfolding transition (T_m) of ribonuclease A. Endotherms from lower to higher T_m represent sarcosine concentrations of 0.0, 2.0, 5.5, and 8.2 M. Both of first scan and the rescan are shown for sample with 5.5 M sarcosine (solide and dashline). Data were adapted from reference 47 with permission.

excipients on thermal unfolding transitions of ribonuclease A (43,47,48). The rescanned heat flow profile indicates that thermal unfolding of ribonuclease A is a reversible process (43). In theory, calculation of thermodynamic parameters such as Gibbs free energy can only be made for reversible transitions (66,87). Thermal unfolding of proteins is often irreversible because of aggregation of the unfolded or partially unfolded states. Nevertheless, in protein formulation studies, potential stabilizers can be screened by monitoring their effects on the heat flow profile of a protein scanned from low to high temperature. For example, DSC studies provided critical data in support of stabilizing effects of heparin and osmolytes against thermal unfolding and (irreversible) aggregation of aFGF and lysozyme (43,45,48).

Hydrodynamic Measurements

Unfolding of a protein is usually associated with an apparent increase in its hydrodynamic size and changes in sedimentation and diffusion coefficients. In addition, if the partial or fully unfolded protein states are unstable and form aggregates, the overall hydrodynamic properties of the protein in the solution will change. The techniques for monitoring changes in hydrodynamic properties of proteins include capillary electrophoresis (CE), SEC-HPLC, analytical ultracentrifugation, dynamic light scattering (DLS), and small-angle X-ray scattering (SAXS).

With the recent introduction of a compact and easy-to-use analytical ultracentrifuge that offers both optical absorption and interferometric optics for real-time monitoring of sedimentation, interest has grown exponentially in using equilibrium and velocity sedimentation techniques to measure self-association of proteins (88–90). Equilibrium sedimentation offers a thermodynamically rigorous way of determining molecular weights. The sedimentation

properties (sedimentation coefficient) of a protein sample are controlled by several physical factors of the protein and protein complex with other solution components. These factors include protein mass, geometry, and density and are affected by protein oligomerization, aggregation, unfolding, and degradation. Both velocity and equilibrium sedimentation experiments can provide information about protein hydrodynamic properties (33,71). Velocity sedimentation experiments can be performed in only a few hours, although diffusion coefficient is required for obtaining a semiquantitative measure of mass change caused by aggregation.

Based on the difference between the electrophoretic mobility of the native protein and that of the unfolded one, the temperature-induced unfolding transitions of proteins can be analyzed by CE. This technique offers the advantage of very high sensitivity, although it has not yet found wide usage in protein unfolding studies. Ishihama et al. (91) used an in-column incubation method to monitor thermal unfolding of nanogram quantities protein. The thermodynamic parameters of the unfolding transition process were obtained by analyzing the temperature dependence of the electrophoretic mobilities. More information on the application of CE in protein analysis can been found in literature (91–93).

SEC allows separation of proteins based on their molecular shape and size. An unfolded or aggregated protein generally possesses a larger hydrodynamic size than the native protein and is eluted out of the column earlier (i.e., with a smaller elution volume) than the native protein. This method has been used to estimate molecular sizes of proteins under different denaturing conditions (13,63,94). The application of various signal detection techniques in protein gel–filtration analysis has been discussed (32).

Static light scattering (SLS), DLS, and SAXS from protein solutions can all be applied to the measurement of changes in the molecular sizes of proteins induced, for example, by thermal unfolding. SLS measurements normally permit reliable data of molecular weights and radii of gyration for relatively small particles since light scattering of large particles is a very complex function of particle shape and sensitive to detection angle. DLS measures the time-dependent intensity fluctuations of scattered light. The correlation of these fluctuations is related to the diffusion coefficient of the scattering particle, a quantity linked to the hydrodynamic radius through the Stokes-Einstein equation (95). SAXS is a very useful, but underused, technique for characterizing size, compactness, and shape of protein molecules in solution. In addition to determining the overall radius of gyration and the maximum dimension, SAXS can quantitatively describe the globular conformation of a protein molecule, as well as denaturant- and ligand-induced conformational changes in solution (96–98). Detailed discussions on the applications of SLS, DLS, and SAXS on protein conformational change and unfolding are available in the literature (27,32,99–102).

Kinetic Techniques

For a complete description of the thermal unfolding kinetics, a fast time resolution may be necessary. Stopped-flow instrumentation with absorption and fluorescence optics allows studies of unfolding kinetics with a dead time of about 2 ms. Stopped-flow CD instrumentation is also available. The instrumentation of time-resolved CD (TRCD) has been reviewed by Lewis (103). Time-resolved FTIR spectroscopy (104) can complement kinetic CD studies in identifying the faster phases of folding or unfolding of a protein's secondary structure. Techniques for studying fast protein structural change at an atomic level include hydrogen–deuterium exchange in combination with multidimensional NMR, electron spray mass spectrometer, and FTIR spectroscopy (105,106). These techniques monitor the spectral and mass changes induced by exchange of amide protons with deuterium during the folding or unfolding process.

CONCLUSION

Thermal unfolding studies provide formulation scientists a way to evaluate the intrinsic stability of pharmaceutical proteins and to screen excipients that might lead to stabilizing formulations during storage, handling, and administration. The data obtained from thermal unfolding studies can support the design and execution of the formulation processing steps leading to pharmaceutical products. Because temperature is one of the most practically important parameters in testing stability of a protein from small- and large-scale production, detailed information of a protein's conformational stability at various temperatures is critically needed. A rational approach to stable formulation development requires a thorough understanding of the mechanism of protein inactivation. Normally, thermal unfolding experiments provide an understanding of both the physical and chemical events leading to protein inactivation, thereby opening up a faster path to development of stabilizing formulations for protein-based pharmaceuticals and vaccines.

Thermolysin

OUTLINE

INTRODUCTION

Thermolysin (EC 3.4.24.4) is a thermostable metalloprotease produced by *Bacillus thermoproteolyticus* Rokko (1). It is the most thermostable protease currently produced for industrial use. Thermolysin and similar microbial metalloproteases require a metal ion, usually Zn^{2+}, for their catalytic activity. Formerly, they were called neutral proteases because their optimum pH is around pH 7. They also have a common property of substrate specificity in hydrolyzing peptide bonds involving an amino group of hydrophobic and bulky amino acid residues such as Leu or Phe (2). Among these proteases, thermolysin has been extensively studied regarding its structure and catalytic mechanism (3–6). Currently, we can easily obtain structural data of thermolysin from the Protein Data Bank. Although metalloproteases have been produced not only for laboratory use but also for industrial use, the market size has been small, because their substrate specificity is narrower compared to that of other proteases such as serine proteases or cysteine proteases. Their use has been restricted to hydrolysis of proteins that cannot be hydrolyzed by other proteases, for example, that of barley protein, which contains a specific inhibitor toward serine protease (7). Recently, however, thermolysin has been used extensively in aspartame (APM) production at Holland Sweetener Company (HSC), a joint venture of TOSOH (Japan) and DSM (the Netherlands). APM, L-α-aspartyl-L-phenylalanine methyl ester, is an artificial sweetener that is 200 times sweeter than sucrose. In APM production, thermolysin plays an important role because it catalyzes the synthesis of an APM precursor, *N*-benzyloxycarbonyl-APM (Z-APM), from Z-L-Asp and L-Phe methyl ester (L-PheOMe).

$$\text{Z-L-Asp} + \text{L-PheOMe} \xrightarrow[\text{thermolysin}]{} \text{Z-L-Asp-L-PheOMe}$$

Because the coupling reaction is the key step in APM production, improvement of this reaction is highly desired. Immobilization of thermolysin has been attempted as one of the improvements to establish efficient recycling of thermolysin (8,9). We sought to improve thermolysin activity by site-directed mutagenesis, that is, by protein engineering, because such activity enhancement not only results in the reduction of enzyme consumption but also circumvents the enzyme recovery step, if enzyme cost is reduced to a negligible amount. It thus also can affect the fixed cost of APM production. In this article, we explain the results of our study to improve thermolysin.

ENHANCEMENT OF THERMOLYSIN ACTIVITY

Before introduction of our improvement study, several other reports regarding activity enhancement of thermolysin are described herein (Table 1). It is well known that enzyme activity is affected by additives in the reaction mixture, such as salts and organic solvents. Thermolysin is also affected by additives, which results in either enhancement or reduction of the activity. Thermolysin activity is enhanced by almost all salts consisting of monovalent anions and cations (10,11). In the case of alcohol, *n*-pentanol at concentrations below saturation enhances activity while *n*-butanol is inhibiting (12). The effect of alcohol is highly dependent on physicochemical properties such as log P or ϵ (13). Pressure is known to be another factor that enhances activity (14). The mechanism of the activation by salts, organic solvents, or high pressure is not clear, although a slight structural change of the enzyme by salts has been observed spectrophotometrically (10). We thought that activity enhancement by these methods on an industrial scale is not feasible from the economical point of view, because expensive equipment would be required to avoid corrosion by salts or explosion of solvents or to resist high pressure. Additionally, such additives result in the increase of industrial wastes.

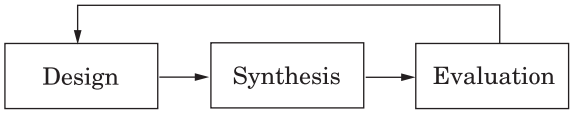
Kubó et al. (15) demonstrated activity enhancement of thermolysin for casein hydrolysis (Table 1). Mutant enzymes can be expected to be more effective for industrial use compared to salts, organic solvents, or high pressure. However, activity for casein hydrolysis does not correlate with that for hydrolysis or synthesis of dipeptide derivatives as described later. Two thermolysin mutants, Y110W and Y211W, have not been evaluated for their activity for Z-APM hydrolysis or synthesis.

IMPROVEMENT BY PROTEIN ENGINEERING

As described, thermolysin activity can be enhanced by additives. However, we preferred improvement by protein engineering because the use of thermolysin mutants is more cost effective. The strategy, method, and results of our study are described next.

Strategy

In recent protein engineering studies, thermal stability of proteins can be enhanced by introducing or reinforcing one or more of several physicochemical intramolecular interactions, such as hydrogen bonding, S–S bridges, and so forth. Most attempts to modify the activity, however, have resulted in suppression of biological activity. To find a novel strategy for producing more active enzymes, we conducted a "protein engineering cycle" consisting of three elements—design, synthesis, and evaluation—as shown in the following scheme:



In this scheme, feedback from evaluation to design is highly important. Feedback can revise our working hypothesis for the structure–function relationships. Working with this cycle will not only give us novel useful proteins

Table 1. Activity Enhancement of Thermolysin by Additives, Pressure, and Site-Directed Mutagenesis

Additive	Condition	Substrates	Reaction	Relative activity[a]	Reference
NaCl	4 M	Z-APM	Hydrolysis	9.0	10
NaCl	2.7M	Z-APM	Synthesis	4.2	10
NaCl	4 M	FaGLa	Hydrolysis	13	11
N-Pentanol	60% saturation	Z-FFM	Synthesis	4.7	12
Pressure	1,000 psi	FaGLA	Hydrolysis	4.5	14
Mutation	Y110W	Casein	Hydrolysis	1.6	15
Mutation	Y211W	Casein	Hydrolysis	1.5	15

[a]Relative activity compared with activity in absence of the additives.

as products but also gives us worthwhile knowledge about the mechanisms underlying the relationship between protein structure, properties, and functions.

Although enzymes do not change the thermodynamic equilibrium between starting materials and products, they accelerate reaction rates by stabilizing the transition state of the reaction. This stabilization is realized enthalpically or entropically, and the Gibbs energy of the transition state is decreased. It is well known that one of the stabilization forces for the transition state is electrostatic interaction (including hydrogen bonding) between an enzyme and its ligand. Several ionizable amino acids such as Asp, Glu, and His play an important role in this stabilization. The equilibrium between the protonation and deprotonation states of these residues, which is mainly determined by electrostatic interaction, controls enzyme activity. Usually the change of protonation state from its active form completely eliminates activity. The pH profile of enzyme activity is generally thought to reflect the protonation state. Therefore, changes in electrostatic potential at the active site may affect both the stability of the transition state and the protonation equilibrium. The optimum pH for the activity of thermolysin is known to be around 7 (1). The synthesis of Z-APM is, however, carried out industrially under a more acidic pH because the methyl ester of the substrate, phenylalanine methyl ester, and the product are hydrolyzed rapidly above pH 7 (16). If the optimum pH can be shifted to the acidic pH region, enzymatic activity in this region may be enhanced. To accomplish this we decided to change the electrostatic potential around the active site.

Design for Higher Activity

There are two residues, Glu 143 and His 231, and zinc ion, Zn^{2+}, in the active site of this enzyme (5,6). We decided to change first the electric charge of Gln 119 to affect the electrostatic potential at Glu 143 (17,18). Gln 119 is known to form a hydrogen bond to the side chain of Ser 103. When Gln 119 is replaced by other amino acids, that hydrogen bond is broken, thereby affecting dynamic properties and stability of the enzyme.

Synthesis of Thermolysin Mutants

The site-directed mutagenesis at the 119th site was performed by the overlap extension method (18,19) using the polymerase chain reaction. The mismatched primer and its complementary sequence were synthesized and used as inside primers, which anneal to the same segment of *npr*M gene coding for thermolysin. The mismatches lead to random sequence alteration in the 119th amino acid residue. The amplified DNA fragment containing random mutation was digested with *Bam*HI and *Sph*I, and substituted for the same region of the native *npr*M gene in pUBTZ2. The *npr*M gene was cloned from *Bacillus stearothermophilus* MK232, which was isolated by TOSOH from soil to provide a protease for APM production (20).

In the early stages of investigation of this metalloprotease, it was believed that its primary structure was different from that of thermolysin at the 37th and the 119th sites (21), because the amino acid sequence of thermolysin was reported to be Asp at the 37th site and Glu at the 119th site by Titani et al. (4). More recent studies, however, revised the sequence of thermolysin as Asn at the 37th and Gln at the 119th (22,23), exactly the same as the metalloprotease from *npr*M gene. The *npr*M gene was first cloned by Kubo et al. (20) in *Bacillus subtilis* MT-2 whose genotype is *trp*C2 *leu*C7 *hsd*R *hsd*M Npr^- (24). Expression plasmid pUBTZ2, which is a shuttle vector between *Escherichia coli* and *B. subtilis*, was constructed from pUC9, pUB110 (25), and a fragment of pMK4 (26) involving *npr*M. The thermolysin mutants were expressed in *B. subtilis* MT-2 by cultivation in 2 L broth (10 g of yeast extract, 20 g of Bacto peptone, and 5 g of NaCl in 1 L of H_2O) containing 20 μg/mL kanamycin at 37 °C for 20 h in a culture flask. The mutants were recovered by ammonium sulfate precipitation of culture supernatant and further purified by two-step column chromatography with Butyl Toyopearl 650 M (Tosoh, Japan) and TSK gel G2000SW (Tosoh, Japan).

Evaluation of Thermolysin Mutants

The amino acids at the 119th site were confirmed by sequencing the plasmid DNA. The purity and the isoelectric point were determined by gel isoelectric focusing using Phast System (Pharmacia, Sweden). The *pI* value of three mutants, namely Lys mutant (Q119K), Arg mutant (Q119R), and Met mutant (Q119M), is 5.3 while that of the other mutants and the wild type (WT) is 5.0. The difference in pI was thought to result from a change in one electric charge of the mutant, judging from the *pI* calculation of the amino acid composition.

The hydrolytic activities were evaluated by measuring hydrolysis of *N*-(3-{2-furyl}acryloyl)-glycyl-L-leucine amide (FaGLa) and *N*-(3-{2-furyl}acryloyl)-L-aspartyl-L-phenyl-

alanine methyl ester (Fa-APM). The theoretical curve of an integral Michaelis–Menten equation (27) fitted well with all experimental data within experimental error (10^{-3} optical density). The decrease in absorbance at 345 nm was monitored by a spectrophotometer (UB-35; Jasco, Japan) connected to a thermostat circulator (EL-15; Taitech, Japan) and a personal computer (PC9801; NEC, Japan) for data acquisition. The stored data were fitted with an integral Michaelis–Menten equation by a nonlinear least-squares method to determine k_{cat} and K_m. All measurements were done under a solution condition of 200 mM Tris-maleate buffer with 10 mM $CaCl_2$ at 37 °C. The concentrations of substrate and enzyme were about 1–2 mM and 1 nM, respectively.

Protein concentration was determined by photometry with an extinction coefficient of 1.67×10^4 OD g/mL. The computer program was described in BASIC on PC9801 and FORTRAN with a program package SALS on a workstation (Titan 750; Kubota Computer, Japan). Fa-APM was synthesized using *N*-(3-{2-furyl}acryloyl)-L-Asp and L-PheOMe following a modified method of Oyama et al. (28). To check the electrostatic effect of the 119th site on activity, we selected the potentially positively charged residues, His, Lys, and Arg, and the potentially negatively charged residues, Glu and Asp. In contrast to the expectations based on the electrostatic effect, hydrolytic activity of all mutants was higher than that of WT, indicating that the main reason for the activity enhancement is not the electrostatic effect. We therefore decided to generate all mutants at this site.

The hydrolytic activity toward FaGLa of the mutants depending on pH is presented in Figure 1. The mutant Q119E exhibited the highest activity, five times higher than WT. It should be noted that the hydrolytic activities of almost all these mutants exceeded that of the WT, indicating that the amino acid at this position is selected by nature to show the lowest activity.

We then substituted Ala and Gly for Ser 103, expecting to cause the disruption of the hydrogen bond between this site and the 119th site. These two mutants, S103A and S103G, showed activity 3.0 and 2.6 times higher, respectively, than that of the WT. The similar increase in activity observed as a result of amino acid substitution at the 103rd site indicates that disruption of hydrogen bond is the main cause of activity enhancement.

We found low K_m values for another substrate, Fa-APM, and this enabled us to determine k_{cat} and K_m values separately. The $1/K_m$ values of the mutants showed a strong correlation to k_{cat}/K_m value, while k_{cat} values showed little change from the WT (18). This result indicates that the mutation increases the affinity of the substrate so that it enhances k_{cat}/K_m for FaGLa and Fa-APM (18). The hydrogen bond of Gln 119 seems to fix the part of the β sheet from the 112th to 128th residues to the other strand. Judging from the three-dimensional structure, the strand from the 112th to 118th residue is considered to contact the pep-

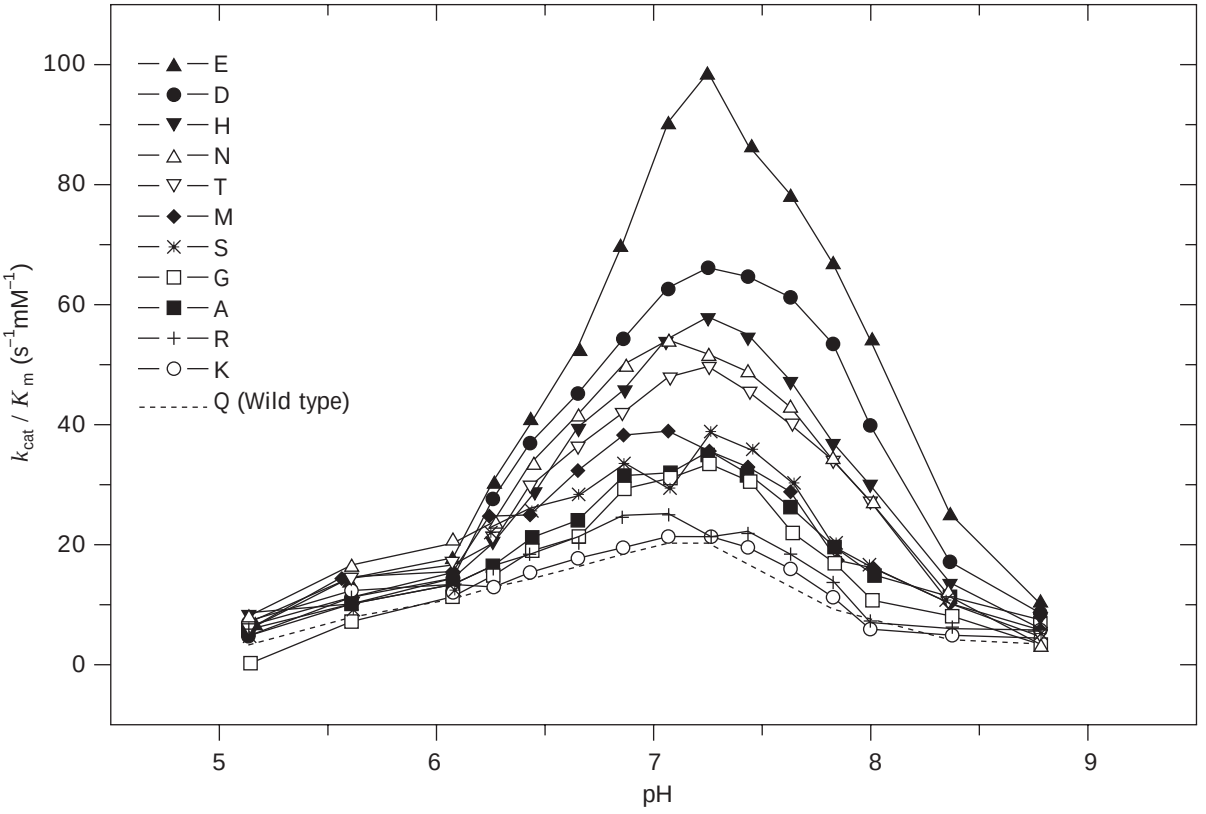

Figure 1. pH dependence of the hydrolytic activity of thermolysin and its mutants at the 119th position in 200 mM Tris-maleate buffer with 10 mM $CaCl_2$ at 37.0 °C.

tide chain of the substrate directly. The flexibility of the β strand may be increased by breakage of the hydrogen bond, thereby causing an increase in affinity of the binding site to the substrate. When flexibility is increased, it is usually observed that the thermal stability of a protein is decreased (18). In this case, a negative correlation between activity and stability is seen. If we assume that the activity is enhanced by flexibility, then there is negative correlation between flexibility and stability. Two mutants, Q119K and Q119R, however, markedly deviated from the negative correlation. From the shift of the *pI* values of these mutants, the Lys and Arg at the 119th site were supposed to be positively charged. The positive charge at this site may suppress the activity. It is reasonable that this change in electric charge affects the activity because this site is selected as a site that affects the electrostatic potential of Glu 143. Measurement of *pI* values of Q119D and Q119E showed the Asp and Glu at this site to be neutral (protonated) around pH 5.0.

From these results, we concluded that flexibility around the substrate-binding site plays an important role in enhancing the activity. The electrostatic potential also influences the change of activity. Measurement of the synthetic activity of these mutants, however, disclosed that synthetic activity of the 119th series mutants did not exceed that of WT (see Table 2). Under the conditions for the coupling reaction, the concentration of the substrates is very high so that the K_m value, which represents the affinity to substrate, does not affect the reaction rate. The important factor for enzymatic activity under the synthetic conditions, therefore, is not the K_m value but the k_{cat} value.

Reiterating the Protein Engineering Cycle

The 213th and 227th sites were then selected as two of the sites possibly most effective in changing the electrostatic potential of His 231 at the active site. Mutations of *npr*M at the 213th and 227th sites were performed by the M13 phage mutagenesis method (29).

In the case of Asp 213 mutants, four mutations, D213N, D213H, D213K, and D213R, were introduced in thermolysin. The hydrolytic activity of these mutants against FaGLa became lower than that of the WT, which led to a negative correlation between the activity and *pI* value of the mutants (30). Considering the three-dimensional structure and electrostatic calculations, it was concluded from these experimental data that the contribution of the pK shift of residues other than the His 231 and the 213th residue must be taken into account in explaining the change in activity.

The mutant N227H, in which a positively charged residue His is introduced instead of Asn 227, showed higher hydrolytic and synthetic activities (Table 2). In contrast, in the mutant N227D, where a negatively charged residue, Asp, is introduced at this site, lower hydrolytic and synthetic activities were seen. The positive charge enhanced enzymatic activity at this site, while the positive charge at the 213th site suppressed the activity. The mechanism of enhancement and suppression of activity by electrostatic interaction seems to be complex and cannot be explained by a simple model. Further theoretical and experimental research is necessary to explore this process.

The Asp 150 was replaced by neutral Asn or by positively charged His so as to influence the electrostatic potential of the Zn ion at the active site. The mutations were performed by PCR (31). In this case the k_{cat}/K_m for hydrolysis of Fa-APM decreased (both k_{cat} and K_m are increased) below that of WT. However, these mutants, D150N and D150H, respectively, exhibited increased activity for Z-APM synthesis (Table 2).

As shown in the Q119 series mutants, flexibility around the active site may have a great effect on the activity. To modify the flexibility, we searched for cavities in the protein molecule using its three-dimensional structure. Figure 2 shows the density map of a cross section of thermolysin; the darker and lighter portions represent higher and lower densities, respectively. As can be seen, the central part of the N-terminal domain has lower density than the surrounding part, clearly indicating the presence of a cavity. Computer graphics suggested that the size of the cavity can be easily modified by replacing several amino acids such as Leu 144. This cavity was also remarked by Vriend and Eijsink in stabilization of thermolysin-like metalloprotease from *B. stearothermophilus* CU21 (32), although the Phe mutant at Leu 144 (L144F), designed to fill the cavity, did not show an increase in thermal stability. We introduced mutation at the 144th site by PCR. It was found that several mutants, such as the Ser mutant (L144S), showed higher hydrolytic and synthetic activities than WT (Table 2).

Based on the three-dimensional structure, several single-point mutants having higher synthetic activity for Z-APM were prepared. We combined these single mutations to obtain more active enzymes, and their synthetic activities are shown in Table 2. We obtained fivefold higher synthetic activity for a triple mutant, L114S-D150H-N227H (33).

Table 2. Activity of Thermolysin Mutants with Z-APM and Casein as Substrates

	Z-APM[a]		
Thermolysin mutant	Synthesis (kat/mol): pH 6.0	Hydrolysis (kat/mol): pH 7.0	Casein[b] (U/mg): pH 7.2
Wild type	0.06 (1.0)	3.5 (1.0)	9,200 (1.0)
Q119E	0.07 (1.1)	5.6 (1.6)	4,000 (0.4)
L144S	0.09 (1.5)	6.3 (1.8)	4,600 (0.5)
D150H	0.12 (2.0)	6.3 (1.8)	9,200 (1.0)
D150W	0.26 (4.3)	11.9 (3.4)	7,400 (0.8)
N227H	0.09 (1.5)	7.4 (2.1)	7,400 (0.8)
L144S-D150H	0.14 (2.4)	6.4 (1.8)	2,700 (0.3)
L144S-N227H	0.11 (1.8)	10.5 (3.0)	3,800 (0.4)
D150H-N227H	0.21 (3.5)	11.3 (3.2)	9,800 (1.1)
D150W-N227H	0.45 (7.5)	22.6 (6.5)	6,700 (0.7)
L144S-D150H-N227H	0.30 (5.0)	21.5 (6.1)	3,200 (0.4)
L144S-D150W-N227H	0.63 (10.5)	37.4 (10.7)	1,900 (0.2)

Note: Numbers in parentheses are activity relative to wild type.

[a]The activity for Z-APM, that is, the synthesis or hydrolysis of 1 mol Z-APM in 1 s, was defined as 1 katal (kat).

[b]The activity for casein, that is, the release of acid-soluble peptides corresponding to the absorbance of 1 μg of tyrosine in 1 min, was defined as 1 unit (U).

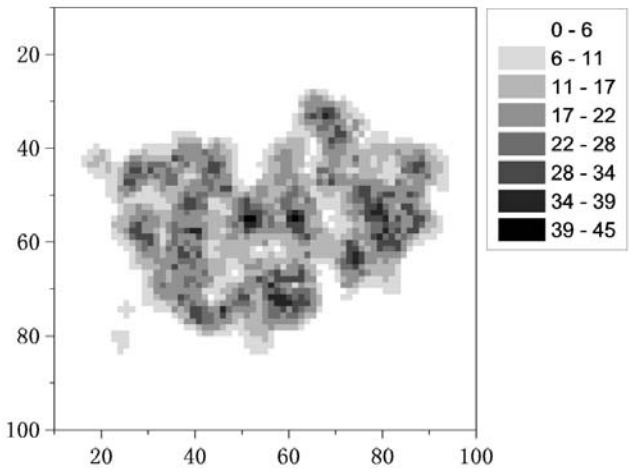

Figure 2. Cross section of average number–density of thermolysin. The density is represented by shading, the highest density being represented by black. *N*-terminal domain is plotted on the left.

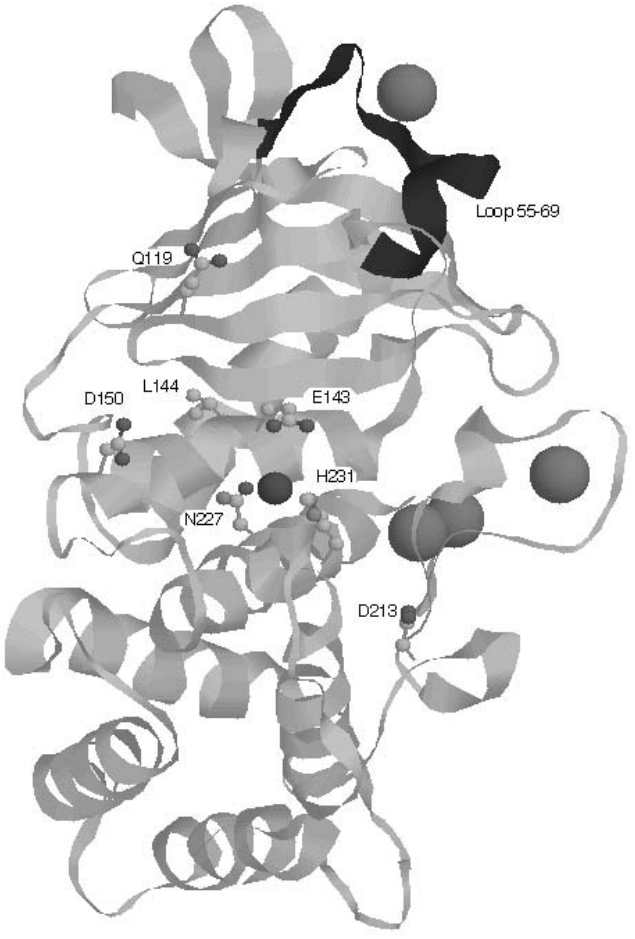

Figure 3. Three-dimensional structure of thermolysin. The peptide chain is represented by a ribbon model. The small ball in the center of this model represents the zinc ion, which is essential for catalytic activity. The four larger balls represent the calcium ion required for stabilization of the three-dimensional structure. E143 and H231 are essential for the catalytic activity. Mutated residues are located as shown here. Loop 55–69 is the dominant region in the stability of thermolysin (38).

Activity for the Aspartame Precursor Z-APM

The activity of the thermolysin mutants for Z-APM synthesis is described in detail in this section. Because mutants at Gln 119, Leu 144, Asp 150, and His 227 sites, specifically the Q119E, L144S, D150H, and N227H mutants, exhibited higher activity for FaGLa or Fa-APM hydrolysis, we examined their activity for Z-APM synthesis. Positions of these sites are indicated in Figure 3. Z-APM synthetic activity was evaluated with 0.1 M Z-L-Asp and 0.1 M L-PheOme as substrate in 0.1 M Tris-maleate buffer at pH 0.6 at 35 °C. After 30 min incubation, the reaction was terminated by addition of EDTA. Z-APM in the mixture was measured by a HPLC system (Tosoh, Japan) equipped with an ODS column (Nacali Tesque, Japan). Z-APM hydrolytic activity, the reversal of Z-APM synthesis, was also analyzed according to the modified method of Inouye (10) by monitoring absorbance at 224 nm at 35 °C with 1 mM of Z-APM as substrate in 0.1 M Tris-HCl buffer (pH 7.0) containing 10 mM $CaCl_2$.

L144S, D150H, and N227H exhibited enhancement of activity both for synthesis and hydrolysis of Z-APM while Q119E only exhibited enhancement in the hydrolysis (see Table 2). The greatest effect on the activation was obtained by D150H wherein synthetic activity was 2-fold higher than for WT; activities of both L144S and N227H were only 1.5-fold higher. The combination of L144S and another mutation enhanced the activity by simple addition of the effects of each mutation. The activity of the double mutants L144S-D150H and L144S-N227H were 2.5-fold and 2-fold higher than WT, respectively. However, when D150H and N227H were combined, the resulting activity was higher than the simple addition of the effect of each mutation. For example, if the enhancing effect were caused by simple addition, the activity of the double mutant D150H-N227H would be 2.5-fold higher than WT, instead of the observed 3.5-fold higher activity (Table 2). The triple mutant, L144S-D150H-N227H, exhibited the highest activity, which was 5-fold higher than WT. We called this thermolysin mutant TZ-1, and its efficiency was further evaluated by small-scale production under the production conditions of the HSC plant; see also ASPARTAME.

These mutants did not always exhibit enhanced activity for other substrates. For example, the activity for casein hydrolysis, analyzed following the method of Endo (1), was decreased in two mutants, Q119E and L114S, while the activity of D150H and N227H was the same as that of the WT (Table 2).

The kinetic parameters of Z-APM synthesis were examined at various concentrations of Z-Asp and 800 mM of L-PheOMe. The reaction rate increased with increasing concentration of Z-Asp up to 100 mM and then declined. This inhibition of the synthetic reaction at high concentration of Z-Asp was also reported by Nagayasu et al. (34) when the reaction was performed with immobilized ther-

molysin in MES buffer saturated with ethyl acetate. Nagayasu reported that the K_m value of the reaction was 2.8 mM and 250 mM for Z-Asp and PheOMe, respectively, and the K_i value for Z-Asp was 100 mM. Although we have not calculated the K_i value of the condensation reaction, k_{cat} and K_m values of the reactions were calculated from Lineweaver–Burk plots at the range of Z-Asp concentration in which no inhibition is observed (Fig. 4a). The kinetic parameters for Z-Asp are summarized in Table 3.

In our results, the K_m of WT for Z-Asp was 13 mM, which is four to five times higher than the results obtained by Nagayasu et al. (34), apparently because of differences in reaction conditions such as solvent, concentration of substrates, or immobilization of enzyme. L144S decreased the K_m value significantly with slight increase of k_{cat} value, D150H increased both k_{cat} and K_m, and N227H increased k_{cat} without affecting K_m. These results, except for the k_{cat}/K_m value of D150H, were similar to the kinetic parameters obtained when Fa-APM is the substrate. In Z-APM synthesis, the k_{cat}/K_m value of D150H increased while there was a decrease for Fa-APM hydrolysis. This change was caused by the greater effect of this mutation on K_m for Fa-APM than that for Z-APM and the difference of the Fa group and Z group at the N-terminal of APM. The Fa group is less hydrophobic than the Z group.

When k_{cat}/K_m values for Z-Asp of TZ-1 and WT were compared, the efficiency of the former was seven times higher. We were not able to estimate the K_m value for PheOMe in Z-APM synthesis because the Lineweaver–Burk plot at 100 mM Z-Asp and variable PheOMe passed through the graph origin (Fig. 4b), suggesting that the K_m values for PheOMe were greater than 900 mM under this reaction condition.

Optimization of Amino Acids at the 150th, 144th, and 227th Sites

Because D150H exhibited the greatest activity in the complete set of mutants tested, we further examined the substitution of other amino acids for Asp 150. The mutations were introduced by PCR using a random primer. In the complete set of 19 mutants at this site, the Trp mutant (D150W) exhibited the highest activity both for synthesis and for hydrolysis of Z-APM (Table 2) (35), about four times higher than the activity of the WT. The activity of the series of the mutants apparently exhibits correlation with hydrophobic parameters (33), such as the π value (36) or ΔH value (37) of substituted amino acids. From the analysis of three-dimensional structure, we assumed that the enhancement of activity might result from reinforcement of the hydrophobic interaction between the Z group of the substrate and the amino acids at the 150th site.

We also evaluated the substitution of other amino acids for Leu 144 and Asn 227 by random mutation. In the 12 variants of the mutants obtained at the 227th site, that is, Asp, Glu, His, Lys, Arg, Thr, Ala, Met, Trp, and Leu mutants, only N227H exhibited apparent activity enhancement. We could not find any relationship between activity and the physicochemical properties of amino acids at the 227th site. The activation mechanism of N227H is not yet clear, but it is believed that the electrostatic effect caused by the positive charge of His might be the main cause of the activity enhancement. In case of the 144th site, 10 variants of mutants, that is, the Glu, Asn, Gln, Ser, Thr, His, Cys, Ala, Tyr, Phe, and Trp mutants, were obtained. Although this series of mutants exhibited almost the same activity for Z-APM synthesis, activity for the hydrolysis of Z-APM exhibited a negative correlation with the hydrophobic properties of the substituting amino acids. This result seems to support our hypothesis described in the previous section; that is, the activity is affected by the flexibility of the enzyme molecule, which thereby influences the cavity in the center of thermolysin. Hydrophilic amino acids at the 144th site appear to contribute not only to cavity expansion but also to weakening hydrophobic interactions within the thermolysin molecule.

Finally, the triple mutant obtained, L144S-D150W-N227H (named TZ-5), exhibited about 10-fold higher activity for Z-APM synthesis and hydrolysis (Table 3) (35). D150W apparently enhanced the k_{cat} value of the reaction without an effect on K_m value. The k_{cat}/K_m value of TZ-5 was 11 times higher than that of WT.

STABILIZATION OF THERMOLYSIN

Recently, Van den Burg et al. (38) reported remarkable stabilization of thermolysin-like metalloprotease in boiling conditions (100 °C) by site-directed mutagenesis at eight sites (Table 4). This protease (TLP-ste) from *B. stearothermophilus* CU21 differs from thermolysin at 44 sites in its sequence and is less stable than thermolysin. Five mutations, A4T, T56A, G58A, T63F, and A69P, are substitutions of thermolysin-type residues for TLP-ste. In these mutations, G58A was originally suggested by Imanaka et al. (39). In a previous study, Van den Burg et al. (40) replaced almost all residues of TLP-ste by thermolysin-type amino acids and found that substitutions in the N-terminal domain are more effective than those in the C-terminal domain. They presented a hypothesis that local denaturation at the 55–69 loop in the N-terminal domain determines thermal denaturation of TLP-ste (41,42). The region corresponding to the 55–69 loop in thermolysin is shown in Figure 3. The three mutations, S65P, G8C and N60C, were rationally designed to fix the flexible region by substitution of Pro (42) and by introduction of an S–S bridge between the 8th and the 60th sites (38). Thus, the resultant 8-point mutant exhibited a half-life 170 times longer than thermolysin at 100 °C. These mutations did not affect the specific activity of TLP-ste (38). This result suggests that a highly active and extremely stable thermolysin mutant is possibly produced when their mutations are combined with our mutations. Three of these mutations, S65P, G8C, and N60C, can be introduced into thermolysin. Other mutations that stabilize thermolysin (15) are also summarized in Table 4. Thermolysin will be further stabilized when this mutation is combined with others.

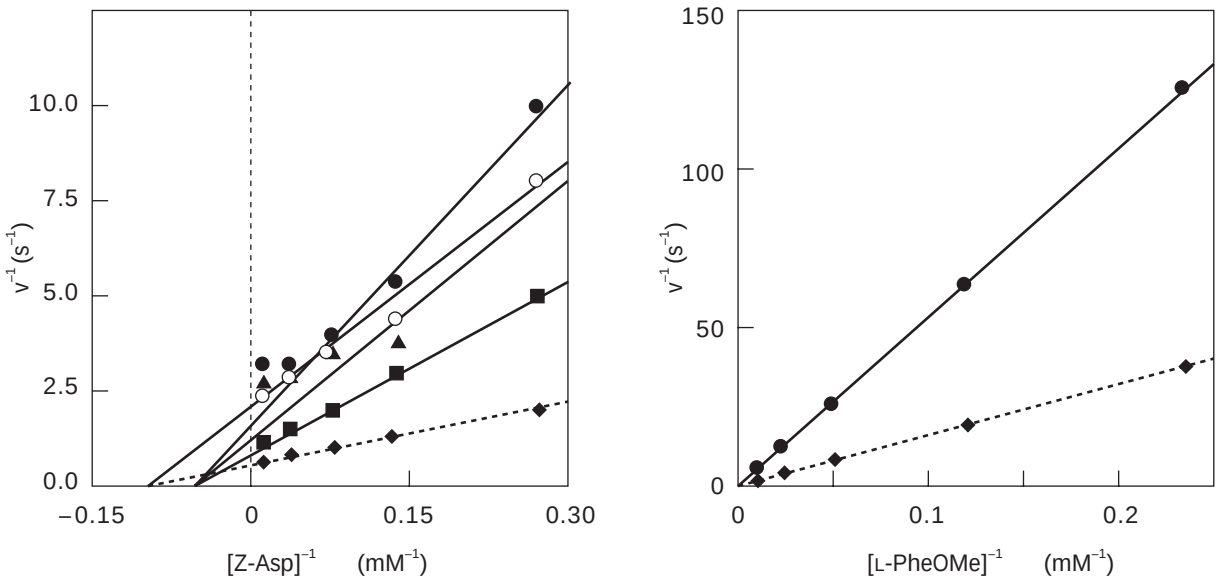

Figure 4. Lineweaver–Burk plots of the condensation reaction of Z-L-Asp (**a**) and L-PheOMe (**b**) catalyzed by thermolysin mutants. The reactions were performed at a constant concentration of L-PheOMe and various concentrations of Z-L-Asp (**a**) or at constant Z-L-Asp and various L-PheOMe (**b**) at pH 6.0 and 35 °C. Closed circles, open circles, squares, triangles and rhombuses represent wild type, L144S, D150H, N227H, and L144S-D150H-N227H, respectively.

CONCLUSION

In designing thermolysin mutants, we started by influencing the electrostatic environment around the active site. It was found during the protein engineering cycle that two additional factors influence thermolysin activity, namely, molecular flexibility and the hydrophobic interaction between the N-protective group of the substrate and the side chain of the 150th site of the enzyme. We were able to locate sites that effectively influence the activity of thermolysin, although some of the mutants at the sites do not enhance the activity, the reasons being only partly inter-

Table 3. Kinetic Parameters for Z-APM synthesis

Thermolysin variant	k_{cat} (s^{-1})	K_m (mM)	k_{cat}/K_m (s^{-1} mM^{-1})
Wild type	0.4	13	0.03
L144S	0.4	9	0.04
D150H	0.9	16	0.06
D150W	1.5	12	0.12
N227H	0.6	13	0.05
L144S-D150H-N227H	1.6	8	0.20
L144S-D150W-N227H	3.0	9	0.33

The kinetic parameters were determined by Lineweaver–Burk plots at 3–100 mM Z-Asp and constant L-PheOMe concentration (800 mM).

Table 4. Stabilization of Thermolysin and Thermolysin-Like Metalloprotease from *Bacillus stearothermophilus* CU21 by Site-directed Mutagenesis

Enzyme	Mutation	Half-life[a] (min)	$T_{1/2}$[b] (°C)	Incubation time/temp.	Reference
TLN	Y93S/G	+36/24	—	80 °C	15
TLP-ste[c]	A4T	—	+1.8	30 min	32
TLP-ste	T56A	—	+1.5	30 min	32

preted (30). Further studies, integrating up mutations and down mutations, must be carried out to establish a more reliable design principle. Apart from the theoretical aspect, we found it quite successful to enhance the synthetic activity of thermolysin by 10-fold. The production cost of APM will be lowered when the thermolysin mutant is applied in the actual industrial process.

ACKNOWLEDGMENTS

The improvement of thermolysin activity was supported by Holland Sweetener Company. We are grateful to Drs. Hiromasa Nagao, Toshio Miyake, Atsuo Aoyama, Takashi Yoneya, Ken-ichi Kai, Seigo Ooe, Yoshikazu Tanaka, You-ichiro Miki, and Kimiko Endo for preparation and evaluation of thermolysin mutants. We thank Dr. Kakidani and Dr. Dionisio-Sese for their critical reading of this manuscript. We would like to express special thanks to Dr. Kiyotaka Oyama, Mr. Ichiro Hiraki, Mr. Akira Tokuda, and Prof. Akiyoshi Wada for the organization of this work.

OUTLINE

INTRODUCTION

It has been 25 years since it was first reported by Brock et al. (1) that microbial life was indeed possible above 80 °C and in that time the number and diversity of known thermophilic, or heat loving, microorganisms has continued to expand. The so-called extreme thermophiles, defined here as organisms having an optimal growth temperature of at least 75 °C, can be found in a variety of geothermal sites ranging from terrestrial hot springs to seeps associated with volcanic activity to deep sea hydrothermal vents (2). The most thermophilic of these will be referred to as *hyperthermophiles* (growth at temperatures of 90 °C or above), some of which prefer to grow at temperatures of 100 °C or higher (3). Much has been accomplished in developing protocols for culturing these novel organisms in laboratory settings (4,5). As such, their physiological and metabolic characteristics have been examined (6,7), and numerous highly thermostable proteins have been purified and studied (8,9). Efforts have also begun to address the genetic manipulation of certain extreme thermophiles, not only to probe the intracacies of their replication apparatus, but also to develop cloning and expression systems that are functional at elevated temperatures (10,11).

The driving force to study extremely thermophilic microorganisms is based on both scientific and technological possibilities. The origin of life on earth has been proposed to be traced to this group of microorganisms (12), and prospects for extraterrestrial life have been fortified by the increasing variety of inhabitable environments on this planet, which were long thought to be barren of life. If one accepts the premise that among this group are the most primitive of all known life forms (13), the templates for all existing metabolic strategies and bioenergetic processes can be identified and examined for clues to not-yet-understood cellular phenomena. Fundamental insights into the basis for biomolecular stability, particularly proteins, have been sought through the study of extreme thermophiles (8,14). Encouraged by the incredible utility of DNA polymerases from extreme thermophiles in the polymerase chain reaction (15), commercial interest in enzymes from these organisms is high. Biocatalyst instability often has been a major drawback in many existing applications, and it also diminishes enthusiasm for untried enzymatic routes to new products. Extreme thermophiles represent a fertile source of robust biocatalysts that may change this perspective.

Bioprocessing has proved to be an enabling expertise in the study of extreme thermophiles and will be central to the eventual use of these organisms or their products for commercial purposes. The earliest efforts in this field of inquiry were facilitated by the development of unusual bioreactors and cultivation protocols to provide biomass for characterization (16,17). Imaginative approaches for using extreme thermophiles, ranging from mixed communities of viable cells to thermostable enzymes catalyzing multiple step reactions, will be required in future years. As such, bioprocess engineering and technology will have to accommodate the anticipated application of extreme thermophiles and their constituent biomolecules.

In this review, the physiological and metabolic characteristics of extremely thermophilic microorganisms are discussed with regard to bioprocessing issues that arise in their cultivation. The physiological and phylogenetic diversity of currently known members of this group is covered in addition to efforts to define the untapped microbial content of geothermal locales. In a separate review in this volume, the characteristics of enzymes from extreme thermophiles are examined.

OBTAINING EXTREMELY THERMOPHILIC MICROORGANISMS FROM GEOTHERMAL SITES

A variety of natural biotopes associated with geothermal activity have yielded extremely thermophilic microorgan-

isms (18–20). Samples from these sites (in the form of hot water, sediments, or solid rock or even from intestines of animals inhabitating these sites [21]), inoculated into various types of liquid growth media at temperatures below approximately 120 °C and pH between 0 and approaching 11, can contain one or more culturable species of extreme thermophiles. In fact, it has been demonstrated that samples from geothermal sites can contain any number of microorganisms whose cultivation in a laboratory setting may be difficult at best (22,23). Obtaining samples containing extreme thermophiles from geothermal biotopes can be as simple as drawing liquid into a syringe at the edge of a hot spring, as has been done at Yellowstone National Park (19), or as difficult as having to dive in a submersible several kilometers into the ocean and then expertly manipulate external sampling equipment to procure material that cannot be contaminated by the cold surrounding seawater (3).

Although no connection has been found between the degree of difficulty in sampling or remoteness of location to the isolation of the most unusual organisms, sites that have unique characteristics are continually sought. Table 1 lists some examples of geothermal locations from which extreme thermophiles have been isolated and some characteristics of these sites. As more geothermal locales are investigated, it has become clear that similar organisms may be isolated from locations that have very different physicochemical characteristics and are geographically distant. For example, members of the hyperthermophilic genus *Thermococcus* have been found in shallow marine settings (36), deep sea vents (37), and terrestrial surface waters (32) and petroleum reservoirs of various depths (38). The ubiquity of certain extreme thermophiles may reflect evolution under similar environmental conditions or a common source manifested through global volcanic activity.

Enrichment cultivation of samples taken from geothermal sites to isolate extreme thermophiles follows methodology used for less thermophilic microorganisms, with several key exceptions (18,19,39). For aerobic thermoacidophiles, typically growing optimally at temperatures of approximately 75 °C and pH 2.0, iron pyrite or elemental sulfur may be added to the medium to support chemolithotrophy (1). Many of these organisms grow better in the presence of added complex media such as yeast extract, although the nutritional requirements met by particular complex media are often unclear. Most hyperthermophiles, which grow above 90 °C, are anaerobic and thus require careful attention to ensure that oxygen is eliminated from the media. Fortunately, the reduced solubility of oxygen at such high temperatures somewhat simplifies anaerobic technique to the extent that glove boxes are usually unnecessary. Enrichment media for hyperthermophiles typically contain an array of trace elements, basic salts, oligosaccharides, complex substrates (e.g., yeast extract, tryptone, etc.), and elemental sulfur (18). Adams et al. demonstrated the importance of tungsten as a trace element for several hyperthermophiles that incorporate this metal into specific oxidoreductases (40). For example, a threefold stimulation of cell density levels of one hyperthermophile, *Pyrococcus furiosus*, was noted in the presence of trace amounts of tungsten (41). Although there have been reports of chemically defined growth media for certain hyperthermophiles, such media often result in sig-

Table 1. Examples of Geothermal Sites Yielding Extreme Thermophiles

Site	Location	Geothermal characteristics	Examples of extreme thermophiles found
Yellowstone National Park	Wyoming, Montana, Idaho	Varied; includes alkaline and acid hot springs	*Sulfolobus acidocaldarius* (1)
Vulcano Island	Mediterranean Sea, off western coast of Italy	Geothermally heated sediments and shallow marine hot springs	*Pyrococcus furiosus* (24), *Staphylothermus* sp. (11), *Thermococcus* sp. (25)
Juan de Fuca Ridge	Off coast of Washington, Oregon	Deep sea hydrothermal vents	*Pyrococcus endeavori* (ES4) (26)
Macdonald Sea Mount	Polynesia	Erupting submarine volcano	*Pyrodictium occultum* (27), *Archaeglobus fulgidus* (28), *Pyrococcus furiosus* (24), *Thermococcus celer* (25)
Icelandic hot springs	Various locations in interior Iceland	Varied; includes alkaline and acidic hot springs	*Desulfurococcus mucosus* (29), *D. mobilis* (29)
East Pacific Rise	21 °N, depth 2,610 m	Deep-sea hydrothermal vent	*Methanococcus jannaschii* (30)
Oil reservoirs	3,000 m below the bed of the North Sea	Deep oil-bearing strata	*Archaeoglobus* and *Thermococcus* species (31)
Shallow hot springs	New Zealand (central North Island)	Thermal pools, samples taken from 1-m depth	*Thermococcus* ANI (32)
Solfatara fields	Various terrestrial locations; many in Iceland and Italy	Acidic, sulfur-rich	*Acidianus brierleyi*, *A. infernus* (33), *Thermofilum pendens* (34)
Guaymas Basin	Off the coast of Guaymas, Mexico in Gulf of California	Deep-sea hydrothermal vent	*Methanopyrus kandleri* (35), *Methanococcus* strains, *Pyrococcus* sp., *Archaeoglobus profundus* (18)

nificantly lower growth yields (42). Thermal lability of many medium components is always a concern (43), especially for amino acids, such as glutamine and asparagine (42), certain vitamins, and some monosaccharides. Maltose and cellobiose, however, serve as excellent carbon and energy sources for *P. furiosus* growing at 98 °C, although glucose does not.

Extreme thermophiles can be very difficult to establish in pure, laboratory culture, whether the inoculum is directly from isolation efforts or even from storage. This is especially true for some of the hyperthermophilic, sulfur-reducing chemolithotrophs, such as *Pyrodictium occultum* (44), which grow to very low cell densities and are highly sensitive both to shearing forces and the presence of various metals (Schicho and Kelly, unpublished observation). Problems with culture stability can be encountered; cultures that have transferred successfully for long periods of time will abruptly stop growing and may require reinoculation from stock cultures.

Cultures can be stored in various ways. In some cases, extreme thermophiles will remain viable for years in liquid media. Attempts to freeze-dry cultures for long-term storage have met with mixed success (Rinker and Kelly, unpublished data); this may have something to do with the unusual cell membrane characteristics that members of the archaea possess. Lyophilization has been used successfully for some hyperthermophilic archaea, although there are also reports of limited storage times for organisms stored in this way (45). *P. furiosus* (24) can be stored in dimethyl sulphoxide (DMSO) for extended periods in glass capillary tubes over liquid nitrogen, although plastic cryotubes were found to be too permeable to oxygen and thus ineffective for extended storage (45,46).

The inability to use standard microbiological techniques on solid media has been a limitation in establishing genetic systems for extreme thermophiles. However, plating techniques for *Thermotoga* species (47,48), *Aquifex pyrophilus* (49), *P. furiosus* (50), and *Sulfolobus* strains (51) have been reported. Methodology to carry out mutagenesis experiments for the hyperthermophilic pyrococci has been developed and used to produce a uracil auxotrophic mutant of *Pyrococcus abyssi* (52).

BIODIVERSITY OF EXTREMELY THERMOPHILIC MICROORGANISMS

There are now more than 50 different species of extreme thermophiles that are classified into 25 genera and 11 orders (2); these are summarized in Table 2. The pioneering work of Carl Woese and co-workers, using a 16S rRNA-based phylogenetic tree, helped to distinguish the domain Archaea (which contains most extreme thermophiles) from the domains Bacteria and Eucarya (13). On this basis, new extremely thermophilic isolates can be compared to those already discovered on the basis of 16S phylogeny, in addition to distinguishing them by physiological differences. By using both phylogenetic and physiological yardsticks, a framework for differentiating among the many extreme thermophiles that are known and are newly isolated can be established. This is important not only for scientific reasons, but because it also helps directing attention to a certain species that may contain particular enzymes of interest or has desirable physiological characteristics for application as a whole cell.

Phylogenetic Diversity

Using the sequence of 16S rRNA as a chronometer, evolutionary trees showing the relationships among extreme thermophiles can be developed, and such sequenced-based maps of biodiversity have proved to be valuable tools in studying these microorganisms (23). Figure 1 shows one such representation. The extreme thermophiles include two genera that group with the Bacteria: *Aquifex* and *Thermotoga*. The rest are of the extreme thermophiles are found within one of two archaeal kingdoms: the Crenarchaeota and the Euryarchaeota. It should be pointed out that the Archaea include members that are not thermophilic, such as certain methanogens and the halophiles.

In some cases, it can be difficult to sort out members within a given extremely thermophilic genus based strictly on 16S RNA sequence. Within the genus *Thermococcus*, for example, differences of only a few bases may exist between species that have otherwise distinguishing physiological characteristics (83). Whether these differences are in phenotype or genotype are not completely clear, and this issue will remain unresolved until the genomes of the species being compared are examined. In view of the fact that 16S sequence alone is not sufficient in some cases for phylogenetic differentiation of microorganisms, more detailed bases for such differentiation have been proposed, including using DNA polymerase restriction fragment length polymorphisms (RFLP) (102) and using 16S/23S rRNA spacer regions (103). Of course, the best approach is to combine elements of phylogeny with classical approaches to taxonomy and growth physiology.

Physiological Diversity

The extreme thermophiles are a physiologically diverse group of microorganisms that share a common dependence on high temperatures for growth. Within this group are fermentative anaerobes, methanogens, extreme acidophiles, and to a lesser extent thus far, nitrate reducers and sulfate reducers. Some details on these classifications are provided in this section.

Fermentative Anaerobes. Geothermal sites, both terrestrial and marine, have yielded an array of fermentative microorganisms that use a variety of organic carbon and energy sources and reduce sulfur as a consequence of growth. Most of these fermentative heterotrophs require sulfur for growth, with the exception of some species in the genera *Pyrococcus*, *Thermococcus* and *Thermotoga*. Of these fermentative anaerobes, species of the archaeal genus *Pyrococcus* and of the bacterial genus *Thermotoga* have been the most carefully studied. As such, species from each of these will be discussed in more detail to illustrate the current level of understanding the physiology of extremely thermophilic fermenters.

Pyrococcus furiosus, A Hyperthermophilic Archaeon. Members of the genus *Pyrococcus* typically ferment pep-

tides and saccharides to CO_2, H_2, and fatty acids (24). Alanine is also produced in significant amounts in the absence of sulfur (104). Hydrogen sulfide will be produced in copious amounts, if a polysulfide source (e.g., elemental sulfur) is present in the growth medium (105). *Pyrococcus furiosus*, the type strain in this genus, was first isolated from geothermally heated sediments near Vulcano Island, Italy (24), and has been the subject of a number of physiological, enzymatic, and bioenergetic studies (6,7). *P. furiosus* seems to grow best on α-linked polysaccharides, such as starch and glycogen (106), and the disaccharides maltose (41) and cellobiose (104). Growth on β-linked polysaccharides larger than cellobiose has not been reported. Although *P. furiosus* will grow on pyruvate (107), it will not grow on glucose even though it has been shown to take up and metabolize this substrate (108). Defined media for this organism have been difficult to develop (105), but one such successful attempt has been reported (43). The significance of sulfur in the bioenergetics of this organism is not completely clear. Schicho et al. (109) showed that sulfur addition led to a twofold improvement in maximum growth yield of *P. furiosus* grown in continuous culture on maltose. Ma et al. (110) showed that the hydrogenase from *P. furiosus* also catalyzes sulfide formation from polysulfide, implicating this enzyme in both sulfur and nonsulfur growth. It was later shown that *P. furiosus* produces significant amounts of alanine in the absence of sulfur (104), which is seemingly an energetically inefficient alternative to acetate formation. This organism may use sulfur as a more productive electron acceptor in that alanine formation decreases in its presence. It remains to be seen why *P. furiosus* is capable of growth in the absence of sulfur, which is an unusual feature among hyperthermophilic heterotrophs.

There has been progress in elucidating the central metabolic pathways of *P. furiosus*, and this has served as a basis for examining other heterotrophic hyperthermophiles (6,7). Studies on glycolysis have shown that this microorganism possesses a version of the Embden-Meyerhof-Parnas (EMP) pathway, which has some interesting alterations compared to the one found in bacteria (Fig. 2). For example, this pathway involves ADP-dependent kinases, glucokinase, and phosphofructokinase (7). Although ADP and ATP have similar thermodynamic properties in regard to the free energy released upon hydrolysis, it is not clear why AMP-forming enzymes are involved (7). Another interesting feature in this modified pathway is the presence of a tungsten-based glyceraldehyde-3-phosphate–ferredoxin oxidoreductase (111), which appears to oxidize glyceraldehyde-3-phosphate to 3-phosphoglycerate directly. Yet another apparent difference that appears to be present in all archaea is the direct conversion of acetyl-CoA to acetate by means of an acetyl-CoA synthetase (ADP forming) (112). The transfer of reducing equivalents generated by glycolysis have been traced to several potential sinks. From ferredoxin (113), electrons may go to the formation of H_2, when growth is in the absence of sulfur, or to polysulfides that can be formed upon nucleophilic attack of elemental or colloidal sulfur (105). Ferredoxin seems to supplant the need for large pools of NAD^+/NADH in *P. furiosus*, which may be a strategy to offset the thermal lability of this coenzyme.

P. furiosus is an attractive candidate for enzymological studies because of its rapid growth rate (doubling time of ~40 minutes, in some cases), its ability to grow in the absence of sulfur, and the cell densities that can be achieved (more than 10^9 cells/mL) (43). Thus, biomass yields of over a kilogram have been reported from 600-L fermentations (8). A number of enzymes spanning most known classifications have been purified from *P. furiosus* and characterized; these are shown in Table 3. An effort is underway to sequence the entire genome of this organism, which will a valuable tool in further examining its physiological and metabolic characteristics (141).

***Thermotoga maritima* and *Thermotoga neapolitana*, Hyperthermophilic Bacteria.** The genus *Thermotoga* contains obligately anaerobic bacteria with optimum growth temperatures of up to about 80 °C, with some species capable of growth up to 90 °C (98). Species of *Thermotoga* have been found in high-salt, marine environments and low-salt, terrestrial settings. A sheathlike outer structure envelopes these rodlike organisms and balloons over the ends, hence the designation *toga* (66,98). During the stationary phase, cells may become spherical but remain within the *toga*. Nutritionally, *Thermotoga* species are very diverse and can use peptides, simple sugars, and polysaccharides, such as starch (98), xylan (142), and galactomannan (143), as carbon and energy sources.

Thermotoga maritima (98), the type species, has been studied to the greatest extent in terms of its physiological and metabolic characteristics, and *Thermotoga neapolitana* (99) has also been studied in some detail. *T. maritima* ferments sugars to CO_2, acetate, lactate, and H_2 by a standard EMP pathway (144,145); hydrogen sulfide appears to replace H_2 as a product in the presence of polysulfide. Alanine is also produced from sugar fermentation (146). For *T. neapolitana*, sugar transport was found to involve substrate level phosphorylation (147), which is presumably also the case for *T. maritima* species. *T. maritima* and *T. neapolitana* appear to be inhibited by H_2 produced during fermentation; this inhibition is minimized or avoided in the presence of elemental sulfur or if paired with a complementary extremely thermophilic methanogen (148). Both *T. maritima* and *T. neapolitana* are able to reduce thiosulfate to sulfide, which appears to improve growth rates and yields (146). *T. maritima* has been shown to be motile and migrates at a speed that is proportional to temperature (149).

Because *T. maritima* and *T. neapolitana* can be cultured in the absence of sulfur and are nutritionally diverse, these species have been examined for the presence of an array of enzymes (Table 4). In particular, several glycosyl hydrolases have been characterized from these and other Thermotoga species. These include amylases (176), xylanases (142), mannanases (143), galactosidases (143,152), and glucanases (150). The localization of these activities is interesting because some have been found to be associated with the toga (176).

Methanogens. Biotic methane generation is characteristic of many anaerobic geothermal environments, even at

the most extreme temperatures. Methanogenic microorganisms have been isolated from such environments. For example, *Methanococcus jannaschii* was isolated from the base of a deep-sea white-smoker chimney on the East Pacific Rise and found to grow optimally at 85 °C with a doubling time of 26 min (30). Subsequent work with this organism found it to be barophilic with elevated pressures, even higher than those associated with its isolation habitat, promoting both increased growth rate and methane production (177). *M. jannaschii* grows well when

cocultured with hydrogen-producing extreme thermophiles (148,178), which may reflect its ecological role. A novel group of rodlike methanogens have also been isolated from marine geothermal systems that do not appear to belong to the three main methanogenic linkages defined by 16S rRNA phylogeny. *Methanopyrus kandleri*, the type species of the novel methanogenic genus, grows optimally at 98 °C and up to 110 °C and has some unusual cell wall features, including a new type of pseudomurein containing ornithin (35). Both *M. jannaschii* and *M. kandleri* exhibit rapid growth rates under optimal conditions (less than 1 h doubling times) relative to many mesophilic methanogens,

which suggests dynamic interspecies hydrogen transfer in geothermal systems (148). To date, only hydrogenotrophic methanogens have been found among the extreme thermophiles. The isolation of a rapidly growing, acetate-using species would be interesting in view of attempts to accelerate mesophilic and moderately thermophilic anaerobic digestion processes.

Extreme Thermoacidophiles. Brock's pioneering work in investigating microbial life in hot springs in Yellowstone National Park revealed the existence of thermoacidophiles that grew in temperatures in excess of 70 °C and at pH under 2.0 (19). Subsequently, a number of thermoacidophilic genera have been described (Table 2), and organisms that grow at a pH below 1.0 have been reported (179). The metabolism of these organisms is complex and may involve the mixotrophic utilization of both organic carbon and CO_2. Extreme thermoacidophiles typically require some complex organic carbon source, but it is not always clear as to what components of this source are being used to fulfill carbon and energy requirements. Many thermoacidophiles oxidize reduced metal and inorganic sulfur species and have, thus, been evaluated for use in the desulfurization of coal and the recovery of metals from ores (180).

Sulfolobus acidocaldarius was first isolated from Locomotive Spring (pH 2.4, 83 °C) in Yellowstone National Park and subsequently found to be distributed widely in hot, acidic geothermal environments (1). Although the pH optimum is very acidic, *S. acidocaldarius* was also found to grow at a pH up to 5.8. Another member of the order Sulfolobales, *Metallosphaera sedula* grows optimally at pH 2.0 and 75 °C (61). Unlike *S. acidocaldarius*, this organism does not use saccharides as a carbon or energy source, but will grow on peptide-based media supplemented with ferrous iron or elemental sulfur. *M. sedula* will solubilize metals from ores very rapidly, even though its optimal doubling time is more than 5 hours (61).

The identification of an HSP60-like heat shock protein (designated TF 55) from *Sulfolobus shibatae* (181) has led to studies focusing on heat shock in the extreme thermoacidophiles. Although survival rates for *S. shibatae* at supraoptimal temperatures could be increased by thermal acclimation (181), similar experiments with *M. sedula* revealed that thermotolerance was fleeting, and no residual thermotolerance was observed once cultures were returned to normal growth temperature ranges (182). Thermal stress in *M. sedula* appears to result in damage to the proton pumping system or leakage of protons caused by membrane damage. This caused the cytoplasmic pH to drop from around 6 to lethal levels of 4 or below upon extended exposure to supraoptimal temperatures (183).

Other Extremely Thermophilic Physiologies. ***Sulfate Reduction.*** Although the reduction of sulfate to sulfide appears to be a physiological feature of less thermophilic microorganisms, the hyperthermophilic archaeon *Archaeglobus fulgidus*, isolated from Italian geothermal systems, will use sulfate, sulfite, and thiosulfate, but not sulfur, as electron acceptors (31). This organism is a facultative autotroph, growing heterotrophically on a variety of complex media or only on H_2, CO_2, and thiosulfate. *A. fulgidus* grows optimally at 83 °C.

Nitrate Reduction. Nitrate reduction, although rare to this point among the extreme thermophiles, has been observed to occur in both a hyperthermophilic archaeon and a hyperthermophilic bacterium. *Pyrobaculum aerophilum*, isolated from a marine water hole in Ischia, Italy, grows optimally at 100 °C and pH 7.0 by dissimilatory nitrate reduction forming dinitrogen as a product (68). This same organism also grows microaerophically on organic and inorganic compounds by aerobic respiration. In either growth mode, elemental sulfur was inhibitory. Similarly, a hyperthermophilic bacterium, *Aquifex pyrophilus*, isolated from Icelandic hot springs, a strict autotroph, also was found to grow by nitrate reduction or under low concentrations of oxygen (49). Molecular hydrogen, thiosulfate, and elemental sulfur were used as electron donors, forming either sulfuric acid or H_2S, depending on whether growth was aerobic or anaerobic. For *A. pyrophilus*, growth was optimal at 85 °C, with a doubling time of 75 min (49). Of further interest, *A. pyrophilus* represents the most deeply rooted bacterial genus on the 16S rRNA phylogenetic tree (49).

CULTIVATION METHODOLOGY FOR EXTREMELY THERMOPHILIC MICROORGANISMS

The cultivation of extremely thermophilic microorganisms for physiological studies or for generation of biomass has relied on methodology previously developed for mesophiles (138). Modifications have been made to equipment and protocols to accommodate the requirement of high temperature and other extreme conditions, such as pressure and pH. In some cases, specialized bioreactors and approaches have been developed to deal with the unusual bioprocessing conditions. For example, because most of these organisms either reduce (anaerobes) or oxidize (aerobes) sulfur, the highly corrosive conditions created by high levels of hydrogen sulfide or sulfuric acid make materials of construction an important issue. Gaseous products and substrates associated with these organisms also include H_2 and CH_4, so explosive conditions can exist. In any case, many extremely thermophilic microorganisms have been successfully cultivated, in some cases producing in excess of a kilogram of biomass (wet) from a single fermentation (184). Table 5 illustrates some of the reactor types used in the bioprocessing of extreme thermophiles.

Batch Cultivation

Batch cultivation of extreme thermophiles has been done in a variety of ways and on different scales. Hungate tubes or serum bottles are often used for small scale culture, which are made anaerobic by addition of reducing agents and degassing procedures when required. Aerobic thermoacidophiles are often grown at pH of approximately 2.0, making contamination problems minimal, although the cultures must be oxygenated in some way. Details on the types of media used and protocols for establishing cultures have been described elsewhere (4,5,18,89).

Table 5. Bioreactors for Growth of Extreme Thermophiles

Reactor characteristics	Operating mode(s)	Examples of organisms grown	Volume (L)	Operation
Serum bottle	Batch	Most extreme thermophiles	~0.1	Sparge with inert gas before inoculation for anaerobes
Glass resin flask; with 4-5 ports; condenser	Batch, fed-batch, continuous	*Pyrocccus furiosus* *Thermococcus litoralis* *Thermococcus barossii* *Thermotoga neapolitana* *Methanococcus jannaschii* *Metallosphaera sedula*	1–10	Sparge with inert gas H_2S scrubbed with alkali for S^0 growth Can be agitated with magnetic mixing bar or impeller
Glass fermenter; with stainless steel heating mantle; condenser; baffles	Batch, fed-batch	*Pyrocccus furiosus* *Thermococcus litoralis* *Thermococcus barossii* *Thermotoga neapolitana* *Methanococcus jannaschii*	4–18	Sparge with inert gas H_2S scrubbed with alkali for S^0 growth
Ceramic-lined fermenter	Batch	Most extreme thermophiles	50–500	Sparge with inert gas
Stainless steel fermenter	Batch	*Sulfolobus* species *Pyrococcus furiosus* *Thermococcus litoralis* *Thermotoga maritima* *Pyrococcus endeavori* (ES4)	100–600	Sparge with inert gas Mostly non-S^0 growth Carefully clean after S growth to prevent corrosion Can be used for themoacidophile cultivation
High pressure reactor (hyperbaric)	Batch	*Methanococcus jannaschii* *Pyrococcus endeavori* *Sulfolobus acidocaldarius*	~1	Use He for gas phase + substrate gases
High pressure reactor (hydrostatic)	Batch	*Pyrococcus endeavori* (ES4)	~0.5	Flexible gold bag used to contain sample Can be subsampled
Gas-lift reactor	Fed-batch, continuous	*Pyrococcus furiosus*	2	Low hydrodynamic stress
Dialysis membrane reactor	Batch, fed-batch	*Pyrococcus furiosus*	1.2	Both outer and inner chambers are flushed Very high cell yields

Fermenters with modifications for high-temperature operation have be used to culture anaerobic extreme thermophiles. Glass vessels with working volumes up to approximately 20 L (0.7 ft^3) must also have provision for condensing large amounts of water that vaporize because of the high operating temperatures. Although mixing is important to suspend many medium components that are sparingly soluble (e.g., polysaccharides, elemental sulfur), many cultures are sensitive to even modest shearing forces. Also, glass fermenters that have heating mantels or baffle cages that are metallic can be susceptible to corrosion. In some cases, enough metal is leached from stainless steels to inhibit the growth of certain hyperthermophiles.

Growth at High Pressure

Many extremely thermophilic archaea have been isolated from ocean depths of up to 3,000 m (pressures of about 200 atm) and from within temperature gradients that go from 350 °C to 4 °C over distances much less than 1 m. Nonetheless, most isolates are enriched at atmospheric pressure or low hyperbaric pressure (less than 3 atm) and temperatures below 115 °C (78) for experimental convenience. It has been shown that there is a trend toward barotolerance and barophily at pressures greater than those encountered in the native environment (185), and this has spurred efforts to understand the interaction of pressure and temperature as parameters influential to microbial growth (186). It should be noted that special precautions must be used at high pressures to ensure that changes in growth or gas production are actually coupled to increased pressure and not a side effect related to other factors, such as protonation and deprotonation or gas solubility differences (185).

For hydrostatic pressure, a hydraulic fluid must be used to provide overpressures; often distilled water or growth media is sufficient for these purposes (78). Pressure is controlled manually during heating by adjusting hydraulic fluid volume. Hydrostatic pressure bioreactors may be as simple as a syringe or a metal cannister (89). To ensure proper sampling and mixing within the hydrostatic chamber, more sophisticated systems have been developed. A compressible gold bag, fitted with sampling ports and placed in an hydrostatic chamber within a heating mantel, has been used to culture extreme thermophiles (16). This system can be operated semicontinuously by adding and removing material through syringe pumps and rocked to promote mixing. Using such a system, Reysenbach and Deming (78) found that two hyperthermophilic strains showed tolerance to pressures up to 440 atm, and in one case, an improvement in growth rate was observed. In addition, cells grown under pressure appeared to have more

uniform size and were less irregular in shape compared to the same cells grown at low pressure (78).

In a hyperbaric pressure reactor, pressure is transmitted to the culture by the gas phase. Miller et al. (187) developed a hyperbaric pressure reactor that was constructed from a transparent sapphire cell, allowing visual observation of the culture medium during growth experiments. The reactor and a recirculating pump were both contained in an oven to facilitate experiments with extreme thermophiles. One version of this system could be operated at pressures of over 100 bar, with a 10-mL working volume. A magnetically operated pump was used to sparge inert gases through the medium, providing some degree of agitation and promoting thermodynamic equilibrium between vapor and liquid phases. The culture medium was supplied directly from a glove box into the cell, and a gas chromatograph, used to measure volatile products of growth, was directly interfaced to the reactor. The sapphire cell could be replaced with a 167-mL stainless steel vessel, which was then suitable for pressures up to 1,000 atm (177). With the larger volume system, a more powerful pneumatic pump was necessary to achieve desired flow rates to the reactor. Growth of the extremely thermophilic methanogen *M. jannaschii* in the 10-mL hyperbaric bioreactor demonstrated that increases of pressure from 7.8 to 100 bar resulted in accelerated production of biomass and methane and extended the maximum growth temperature from 90 to 92 °C (187). In the stainless steel reactor, the high-temperature limit for methanogenesis was increased to 98 °C by hyperbaric helium pressures up to 750 atm (177).

Continuous Culture

In fed-batch or continuous culture systems used for the growth of extreme thermophiles, the same considerations must be taken as those described for batch systems. Internal parts are typically glass or Teflon-coated to avoid corrosion. Media feedstreams are heat sterilized before use, or in some cases, in situ, given the normally high growth temperatures of these microorganisms. Inorganic feedstreams are filtered through a 0.2-μm porous filter to avoid contamination. Continuous culture systems have been described in some detail for *M. sedula* (182) and *P. furiosus* (41,108). Figure 3 illustrates both a schematic of and an actual continuous culture system.

The gas-lift bioreactor is an alternative type of continuous culture and has been demonstrated for the extreme thermophile *P. furiosus* (50,189). A protocol for setup and operation of an anaerobic gas-lift reactor is described in the work by Sharp and Raven (89). As mentioned previously, some hyperthermophiles are sensitive to high shear rates during growth. Gas-lift systems characteristically have low shearing forces in conjunction with high rates of mass transfer and are well suited for cultivation of extreme thermophiles (189). Such reactors for extreme thermophile growth have been constructed of glass components, with a gas distribution tube for inert gas (filtered with 0.2 μm) supply. The glass vessel can be heated through a heat transfer fluid-containing jacket; an oversized condensor is used to recover water vapor from the exhaust. Both pH and temperature can be controlled continuously. Experiments by Raven et al. (189) have shown that nitrogen is the preferred inert gas to use for sparging, allowing higher cell densities under otherwise equivalent conditions with other gases. The optimal dilution rate for cell mass production of *P. furiosus* was found to be 0.4 h^{-1}, at which point the bioreactor generated more than 1.5 g (wet weight) cells l^{-1} (189). A defined medium was optimized for *P. furiosus*, resulting in reported cell densities of 10^{10} mL^{-1} (50).

Dialysis Membrane Reactor

The impetus for using a membrane bioreactor is twofold: carbon and energy sources can be supplied directly to the cells through the membrane, and inhibitory or toxic end products of fermentation can be removed through the membrane, improving cellular growth rate and cell yield. The dialysis reactor described by Krahe et al. (43) is composed of two reactor chambers of unequal volumes, separated by a membrane. Both of these compartments can be sparged and agitated. The chamber that houses the cells is typically several times smaller than the chamber that contains the dialysing medium. Using complex media for both chambers, a 100-fold increase (as compared to serum bottles) in cellular concentration of *P. furiosus* has been reported, along with a 10-fold higher cell density at stationary phase where cell lysis can be significant and lead to loss of whole cells for subsequent recovery steps.

NEW DEVELOPMENTS IN THE ISOLATION AND STUDY OF EXTREMELY THERMOPHILIC MICROORGANISMS

The recognition that the number of extreme thermophiles isolated to date is but a small fraction of those inhabiting geothermal environments has become apparent from analysis of 16S rRNA signatures from geothermal samples (23). Although phylogenetic diversity may not correlate well with physiological diversity, it nonetheless illustrates the untapped potential that exists for new types of microorganisms that have proved difficult to isolate into pure culture.

Molecular phylogeny has been the basis for recent methods to isolate extreme thermophiles. Single cultures of archaea containing 16S rRNA signatures, previously identified from in situ analysis of samples from hot springs, were obtained by the use of optical tweezers (190,191). This method makes use of an inverse microscope and an infrared laser to pull a single cell with a particular 16S rRNA signature into a separate section of a capillary and then put it into cultivation media, where it can be cloned and characterized (192). If effective, this short-circuits the often laborious methods of serial dilution, from which the result might be an organism that has already been isolated and characterized.

Whole genome sequencing efforts have thus far focused to a significant extent on extreme thermophiles. Table 2 indicates which of the genomes of extreme thermophiles are currently being sequenced or are finished. The Institute for Genomic Research (TIGR) maintains a list available on-line of current sequencing projects. In general, extreme thermophiles are an attractive target for sequencing

efforts given their evolutionary significance, their commercial potential, and the fact that their genomes are relatively small. The first genome sequence for an extremophile to be completed was that of *M. jannaschii* (193), undoubtedly many more will soon follow. Not only does this present an important new approach to assessing metabolic diversity, but it provides a tool to study the regulation of key pathways within a given organism and a means to study genetic, biochemical, and physiological differences and similarities among this group. The explosive increase in sequence information provides yet another challenge in that mechanisms to use these data must be developed.

SUMMARY

This review illustrates the progress that has been made during the past two decades in exploring the basis for life at extremely high temperatures. Bioprocessing has made important contributions to this effort in developing ways in which extreme thermophiles can be grown for purposes of biomass generation and physiological study. The remaining challenges include developing methods for culturing extreme thermophiles that have, thus far, not been cultured under laboratory conditions; this includes establishing mixed cultures that might be used for particular biotransformations, such as bioremediation. In the future, bioprocessing may even find a role in determining the prospects for life on the subsurface of other planets and moons that may harbor extreme thermophiles not unlike those inhabiting volcanic subsurface environments on earth. The development of bioreactors mimicking such environments will be an important contribution in this regard.

Modified agitators

OUTLINE

INTRODUCTION

The dispersion of gases and solids in liquids is one of the most commonly applied processes of chemical engineering, and the fully baffled stirred vessel is one of many types of equipment used for this purpose. The hydrodynamic regime of the impeller controls the mixing performance of the whole reactor, as is reflected in phases of homogenization, the intensity of local energy dissipation distribution in the region of severe shear conditions, the retained gas fraction, bubble size, solid concentration distribution, mass transfer, and heat transfer (1–3). Good understanding of the dispersion mechanism of the impeller is indispensable for a reliable prediction of the behavior of the multiphase system flow in the reactor as a whole.

In multiphase processes carried out in stirred vessels, interphase mass transfer is often an important step and may be rate determining for the overall process. In aerobic fermentation systems, the oxygen transfer from the gas phase to the surface of the microbial cells is of primary importance, especially at high cell densities when microbial growth is likely to be limited by the availability of oxygen in the liquid phase (4–6). For many years, a set of radial flow Rushton disk turbine impellers of roughly one-third of the standard reactor diameter has been considered the optimum design for the multiphase system mixing, including fermentation processes. Mass transfer cannot be improved by increasing the specific power consumption or the aeration rate above certain limits, both of which lead to increased overall costs, but only by a modification of the blades of the impellers or by the development of impellers that allow a better bulk mixing with a minimum power consumption.

It has been reported (7) that a simple modification of the blades of a Rushton turbine through increase in the blade height simultaneously with perforation of the blade surface could significantly diminish power consumption and improve oxygen transfer efficiency in either a non-biological system or in an antibiotic biosynthesis process.

DESCRIPTION OF THE MODIFIED RUSHTON TURBINE AGITATORS

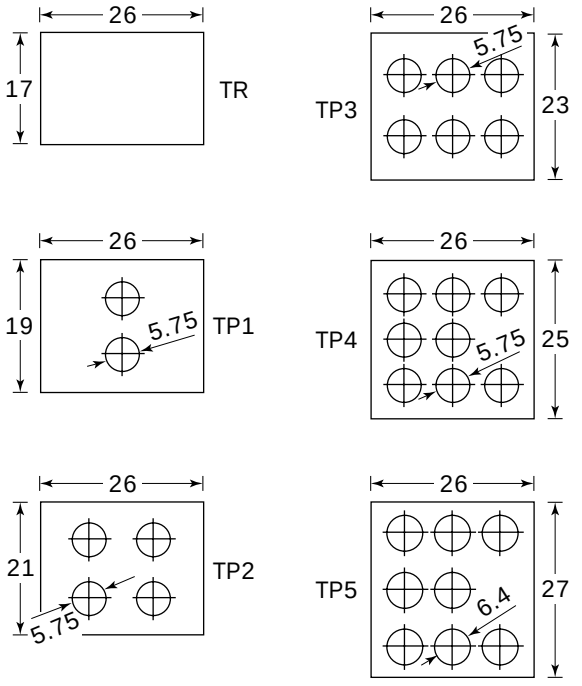
The modified blades were obtained by increase in the conventional (standard) blade height simultaneously with perforation of the blade surface. Five modified blade turbine types (denoted TP1–TP5) were investigated; these are characterized by the fact that the number of perforations and their size varied and that the filled surface of the modified blades is equal to the blade surface of the standard Rushton turbine (TR) (Fig. 1) (7,8).

The application of perforations to the modified blades decreases the pathway between successive shearing actions on the liquid streams, increasing the number of times that the fluid is sheared. This effect has direct implications on local bubble size distribution in a gas–liquid mixture, which develops as a result of the balance between the complementary processes of dispersion and coalescence. The surface fraction of the perforations, defined as the ratio between the area S_G of the perforations on the surface and the full surface area S_C of the blade is in the range of 0 to 0.588. The modified blade turbines do not require any modification in the electrical motor and drive assemblies and are simple to manufacture. The experiments were carried out in a transparent vessel of inside diameter $D = 0.25$ m, with a flat bottom and four symmetrical wall baffles of width $w = 0.1\,D$. Fluid mixing was carried out by conventional and modified blade turbines, positioned singly (1TR, 1TP1–1TP5) or doubly (2TR, 2TP1–2TP5) on the same shaft.

MULTIPHASE SYSTEM HYDRODYNAMICS

Gas–Liquid Dispersing Characteristics

The hydrodynamic regimes were defined by reference to the distribution of the gas phase in the vessel. For an air–water system, the flow regimes were detected through visual observation of the zone close to the outer edge of the TR and TP1–TP5 turbines (8). In the single-turbine configurations, the three classical regimes (9,10) were observed: flooding (F), loading (L), and complete dispersion (CD). For



Agitator	TR	TP1	TP2	TP3	TP4	TP5
S_G/S_C	0	0.117	0.235	0.353	0.470	0.588

Figure 1. Schematic representation of the standard (TR) and modified (TP1–TP5) blades of the Rushton turbine. (*Source*: From Ref. 8, with permission.)

a double-turbine system, two hydrodynamic configurations were defined in the upper zone: ineffective dispersion (DI) and effective dispersion (DE), respectively; the transition between the hydrodynamic regimes corresponds to the rotational speed at which the bubbles have a radial velocity sufficient to reach the vessel wall. The gassed power consumption, P_g, is usually determined by varying the operational parameters: the volumetric flow rate, Q_g, and the impeller speed, N.

The curve representing the ratio P_g/P as related to the gas flow number presents maximum and minimum points when the volumetric gas flow rate is kept constant. Each of these extreme points corresponds to a gas–liquid hydrodynamic regime in the impeller region. The power curves change notably when the power consumption is expressed as a power number. Interesting results were obtained by plotting the gassed power number $(Ne)_g$ against the impeller speed N, when the aeration rate Q'_g, expressed as volumetric flow rate of gas per minute/volume of liquid (vvm) was kept constant. These results are presented in Figures 2 and 3 for mixing systems having one or two turbines, respectively. Table 1 explains the symbols used in Figures 2 and 3.

In the range of low N values, the power number for a single turbine decreased with increasing impeller speed until a certain point: subsequently, it increased suddenly in the case of the standard blade turbine and slowly in the case of the modified blade turbines. The impeller speed at which the transition between these two zones occurred was very close to the transition impeller speed between flooding and loading of the turbine. For two turbines on the same shaft, clear delimitation between the two zones of the impeller speed was not apparent (Fig. 3). The $(Ne)_g$ values decreased slowly with increasing impeller speed until the agitation system exceed the flooding state of the bottom turbine. In the range of large N values, when the gas dispersed uniformly through the entire vessel section, the gassed power number became independent of the impeller speed, as it was a function of aeration rate and geometrical configuration of the mixing system only. The variation in the power number depending on the surface fraction of the perforations, which indicates the geometry of the mixing system, is presented in Figure 4.

The range of power number for an individual Rushton turbine reported in the literature (11) is Ne = 4.8 − 6.3 for $Q'_g = 0$. In our case, the value Ne = 5.5 for a single Rushton turbine is in good agreement with these data. The Ne values for Rushton turbines are dependent on a scale (12), and for a mixing system in which the geometrical symplexes deviate from the standard values, the introduction of a correction factor of the power number is recommended (13,14). The Ne and $(Ne)_g$ values for all the modified blade turbines are smaller than those for the Rushton turbine, as a result of the change in fluid flow around and over the blades and of the minimization of the drag forces associated with the motion of blades such that the energy losses due to form drag are very low. These results imply that it is possible to rotate the modified blade turbines much faster than the standard Rushton turbine at an equal specific power consumption. The TP3 modified blade turbine, with the surface fraction S_G/S_C of the perforations equal to 0.353, has the smallest gassed and ungassed power number values, these being reduced by approximately 50% in comparison with the standard Rushton turbine. The increase in the surface fraction of the perforations over $S_G/S_C = 0.353$ is not justified on the basis of the power consumption.

For double turbines, the power number values are approximately twice those obtained for the single turbines, irrespective of the turbine type, at constant aeration rate Q'_g. This shows that, in the case of two identical turbines, the power consumption P_g is twice that obtained using a single turbine: this is possible because, if Q'_g is kept constant, the volumetric gas flow rate, Q_g, ($m^3\ s^{-1}$) is 60% higher when the liquid volume is higher (Table 1). Also, the power consumption of two TP3 modified turbines is reduced by 50% in comparison with the double standard Rushton turbines. Because the surface of each modified blade increases simultaneously with the S_G/S_C ratio, it is to be expected that a larger gas volume is retained in the ventilated cavities behind the modified blades and dispersed afterward. Therefore, the modified blades have a greatly increased gas-handling capacity: the TP3 turbines handle more than 35% more gas than do the standard Rushton turbines at the same specific ungassed power consumption, before flooding or ineffective dispersion.

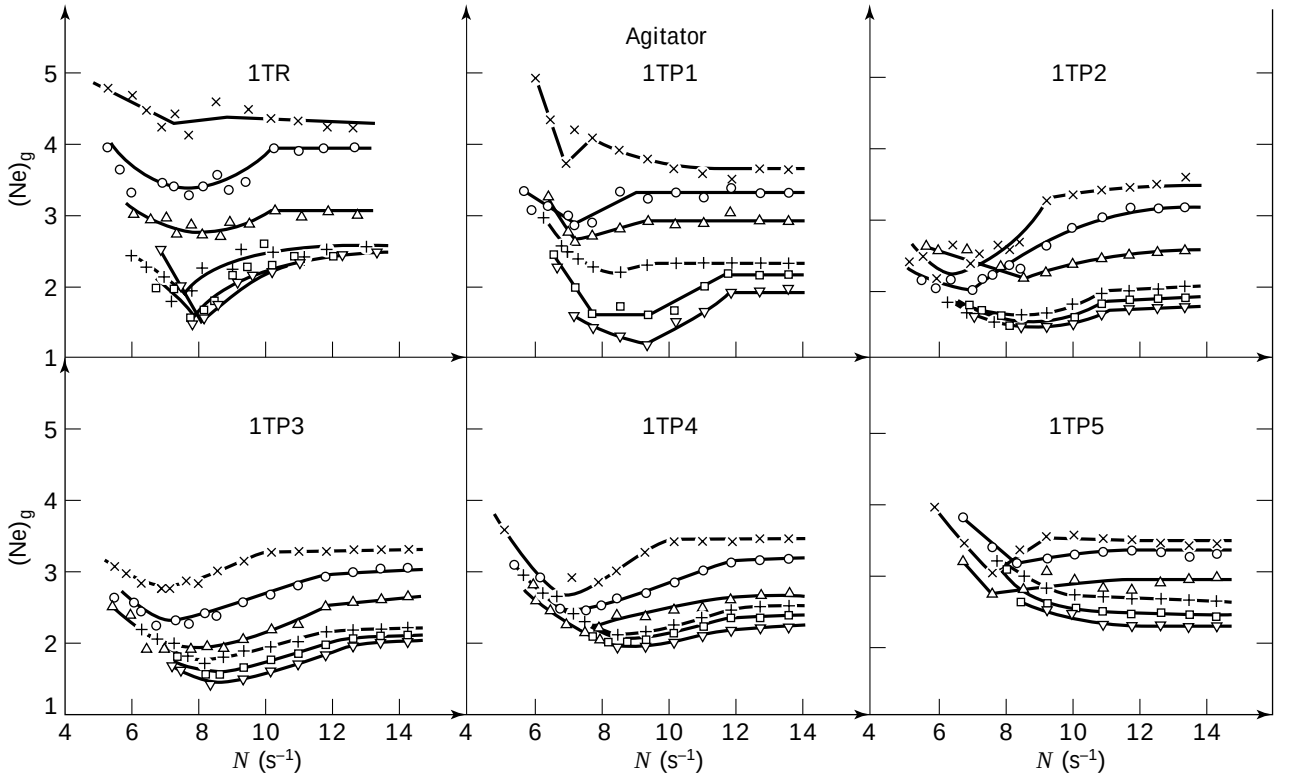


Figure 2. Variation in the gassed power number $(Ne)_g$, depending on the impeller speed (N) at various gas flow rates for single standard and modified Rushton turbines (symbols are defined in Table 1). (*Source:* From Ref. 8, with permission.)

Suspension of Solid Particles in Liquid

Three suspension states can be defined, as follows (15):

1. Incomplete suspension, in which a part of the solid phase is deposited on the bottom of the vessels
2. Complete suspension, in which all particles are in suspension
3. Homogeneous suspension, in which the particle concentration is uniform throughout the vessel

Many earlier investigations concentrated on the impeller speed for complete suspension, when the maximum surface area available for processing is achieved (15–18). The most widely used criterion to describe solids suspension in mechanically agitated vessels is the just-off-the-bottom suspension condition, first described by Zwietering (19).

In this section, an attempt is made to understand the effects of the physical and rheological properties of the suspensions and number and turbine types on the complete suspension speed and on the power dissipation at complete and homogeneous suspension states of the solid particles (20). The solid particles used are $CaCO_3$, a cation exchange resin (Amberlite IR-120 type), and an anion exchange resin (Amberlite IRA-410 type). A range of density differences $\Delta\rho = (\rho_s - \rho_L)$ between 150 and 1,200 kg/m^3 was examined. The ion exchange resin particle shape is spherical, the particle size distribution being measured by a microscopic method. The change in particle size during the experimental run was negligible. The surface-to-volume (Sauter) mean diameter of the particles, d_p, was calculated for the ion exchange resin particles. In the $CaCO_3$ suspension, the mean diameter of the particles was 15 μm (21). The particle concentration, X, was between 20 and 150 kg/m^3 for each particle type used. The physical properties are given in Table 2. The suspensions used are pseudoplastic in behavior. The rheological properties of suspensions depend on the particle size and the concentration of solids. Rheological data of the suspensions were obtained with a rotational cylinder viscosimeter (Rheotest-2.1) and were fitted according to the power law model (22). The rheological parameters, consistency index, K, and flow behavior index, n, are also presented in Table 2. The definition of complete suspension speed, N_{js}, was taken as the speed at which no particles were visually observed to remain at rest on the vessel bottom for more than 1 or 2 s (19). The last particles to be suspended were located near the center of the vessel base and also behind the baffles. The experimental relationships between complete suspension speed and solid concentrations are shown in Figure 5 for each of the five particle types and for modified and standard turbines positioned singly or doubly on the same shaft.

For the same operation conditions, the N_{js} values for the TP3 modified turbine are slightly higher than those for the standard turbine. Also, Figure 5 shows that, independent of the agitator type, N_{js} actually is increased when two turbines are used, as was also observed by Armenante (23). Although the phenomenon of solid suspension off the vessel bottom is largely dominated by the lower impeller, the presence of two turbines modifies the flow pattern in the vessel.

In all geometrical systems, the N_{js} values are found to increase with solid concentration. This increase of the N_{js} value may result from an increase of probability to find particles at rest on the bottom as the number of particles in suspension increases. It was observed that at N_{js} the concentration of the solid particles in the zone near the bottom is considerably higher than the average value in the vessel. The physical background of the concentration effect is the increased power dissipation by presence of solid particles in the turbulent field (24). The particles can interfere with the turbulent field via two routes. (*1*) Because of their inertia, particles do not follow the motion of the liquid. Consequently, the kinetic energy of a particle

Source: Ref. 20.

changes continuously. Acceleration of a particle occurs at the expense of energy from the turbulent eddies, whereas deceleration leads to energy dissipation in the form of heat. (*2*) At high solids concentration, the particles will also interfere with each other (collison and/or hindrance). In a similar way, this will lead to increased dissipation of the energy of the turbulent eddies. Thus, for the point of complete suspension to be maintained, a higher solid concentration requires a higher power input to the systems.

Figure 6, where the power consumption expressed as power number for complete suspension condition $(Ne)_{js}$, is plotted against the Reynolds number Re, demonstrates that in the vessel equipped with the modified blade turbines, single or double, the $(Ne)_{js}$ values are approximately 30% lower than those in the standard vessel. In these plots, $(Ne)_{js}$ and Re numbers are calculated using the properties of the suspensions. The $(Ne)_{js}$–Re representation based solely on liquid properties is inadequate (25), because at the highest solids concentration laminar or transition range appear to persist up to very high Reynolds numbers. By using a suitable apparent viscosity for the solid–liquid suspension, it is possible to condense all the data in the adequate range. In our case, the Reynolds number values for complete suspension condition are in the transition range ($Re < 1000$); the $(Ne)_{js}$–Re dependency has a negative slope.

The main reason for the smaller power number of modified blade turbines is the change of suspension flow around and over the blades. The fluid flow around the blades of the standard Rushton turbine was studied by Vant' Riet (26). Dead zones behind each turbine blade are formed. From these dead zones with the stagnation lines, the trailing vortex pair originates as a combined effect of the vortex motion at the rear of the vertical inner edge of the blade and the wrapping of the vortex sheets behind both horizontal edges. In the case of the modified blade turbines, the fluid jets penetrating the perforations, eliminate the stagnation lines and change the conditions of the trailing vortex formation.

When all the observation are combined, the following correlation is evident between complete suspension speed and the physical and rheological properties of the solid particles:

$$N_{js} = c d_p^{0.2} \Delta\rho^{0.45} X^{0.13} K^{0.1} \quad (1)$$

The exponents of d_p, $\Delta\rho$, and X are essentially the same as those reported by Zwietering. The correlation, equation 1, includes the consistency index K as a pseudo-viscosity of the suspensions. The value of the dimensionless constant, c, is specific for each of the geometrical configurations studied. The influence of the turbine type and number of the turbines on N_{js} can be expressed by incorporation of two dimensionless groups, namely $(1 + S_G/S_C)$ and $n_p/6$ (S_G/S_C is the surface fraction of the perforation and n_p is the number of blades of the mixing system). Using nonlinear least squares regression, the following correlation was established:

$$N_{js} = 1.1 d_p^{0.2} \Delta\rho^{0.45} X^{0.13} K^{0.1} (1 + S_G/S_C)^{0.2} (n_p/6)^{0.25} \quad (2)$$

In the turbulent range ($Re > 1000$), when $N > N_{js}$, the particle concentration is uniform throughout the vessel, and power number in solid–liquid system, $(Ne)_s$, is constant.

In the vessel equipped with a standard turbine, the maximum value of the Reynolds number is 1,800; for the modified blade turbine, the maximum Reynolds number is

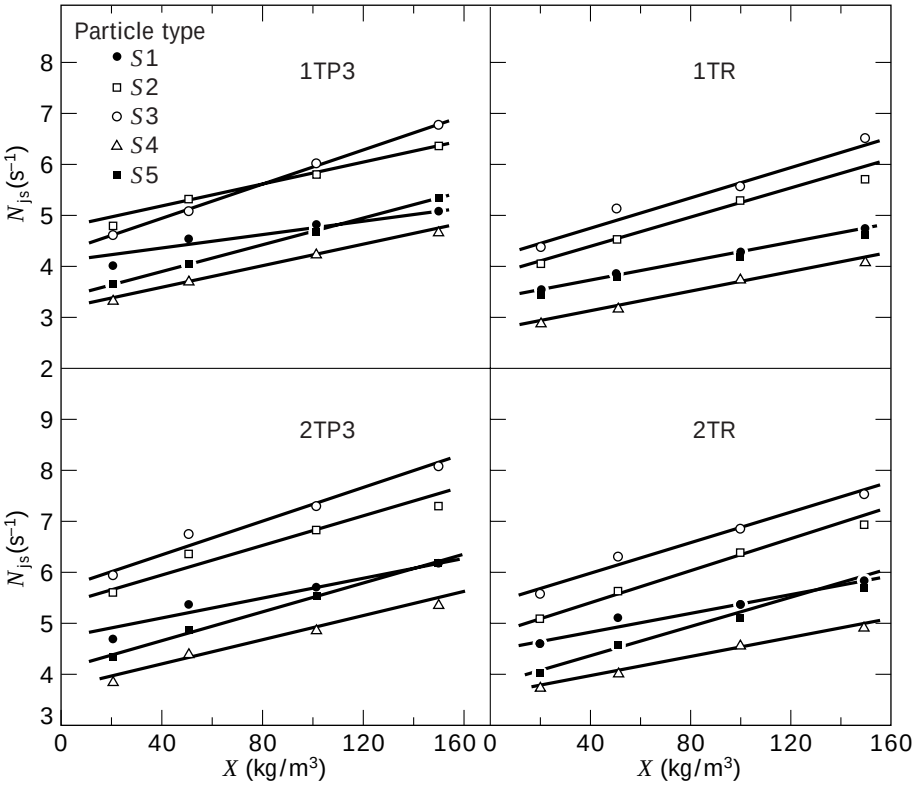

Figure 5. Effect of solid concentration on complete suspension speed for standard and modified Rushton turbines, positioned singly or doubly on the same shaft. S1–S5, particle types (see Table 2). (*Source*: From Ref. 20, with permission.)

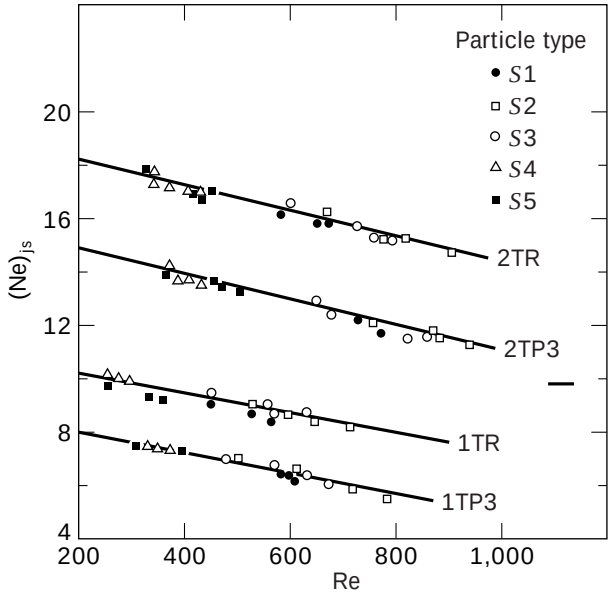

Figure 6. Relation between the power number and Reynolds number (Re) at the complete suspension state, for standard and modified Rushton turbines, single or double. (*Source*: From Ref. 20, with permission.)

2,400. This is possible because the modified blade turbine rotates much faster than the standard turbine at an equal specific power input (11). The relation between the mean values of the power number and the physical properties of the solid particle, in the turbulent range, is

$$(\mathrm{Ne})_3 = 5.6175(n_p/6)(1 + S_G/S_C)^{-1.3867} \cdot (1 + 10d_p^{0.2}\Delta\rho^{-0.45}) \quad (3)$$

The estimated error using equations 2 and 3 lies within ±10%.

Effect of Particles on Gas–Liquid Hydrodynamics

Establishment of the major interactions between gas dispersion and particle suspension mechanisms is a basis for examining in detail the effect of the major variables on the minimum agitator speed for particle suspension under gassed conditions and on the minimum agitator speed for gas dispersion to all parts of the vessel in the three-phase systems.

The manner in which the presence of the particles affects the gas dispersion is inferred from the variation of the relative power consumption P_{gs}/P_s (P_{gs} and P_s are power consumption in gas–liquid–solid and solid–liquid systems, respectively), with gas flow rate, Fl, which is associated with different stages of cavity growth behind the impeller blades. In the curves presented in Figure 7, for various volumetric gas flow rates and concentrations of the S5 type solid particles for 1TR and 1TP3 turbines, the transition to complete gas dispersion is obtained when a minimum occurs in P_{gs}/P_s and the cavity sizes are maximum (27). For the 1TR turbine, the maximum values of P_{gs}/P_s are between 0.5 and 0.3 for all solid concentrations and depend on the volumetric gas flow rate. The 1TP3 turbine shows a behavior similar to that of 1TR turbine but only at $X = 20$ kg/m^3 and $X = 50$ kg/m^3. At $X = 100$ kg/m^3 and $X = 150$ kg/m^3, the minimum values of the P_{gs}/P_s for

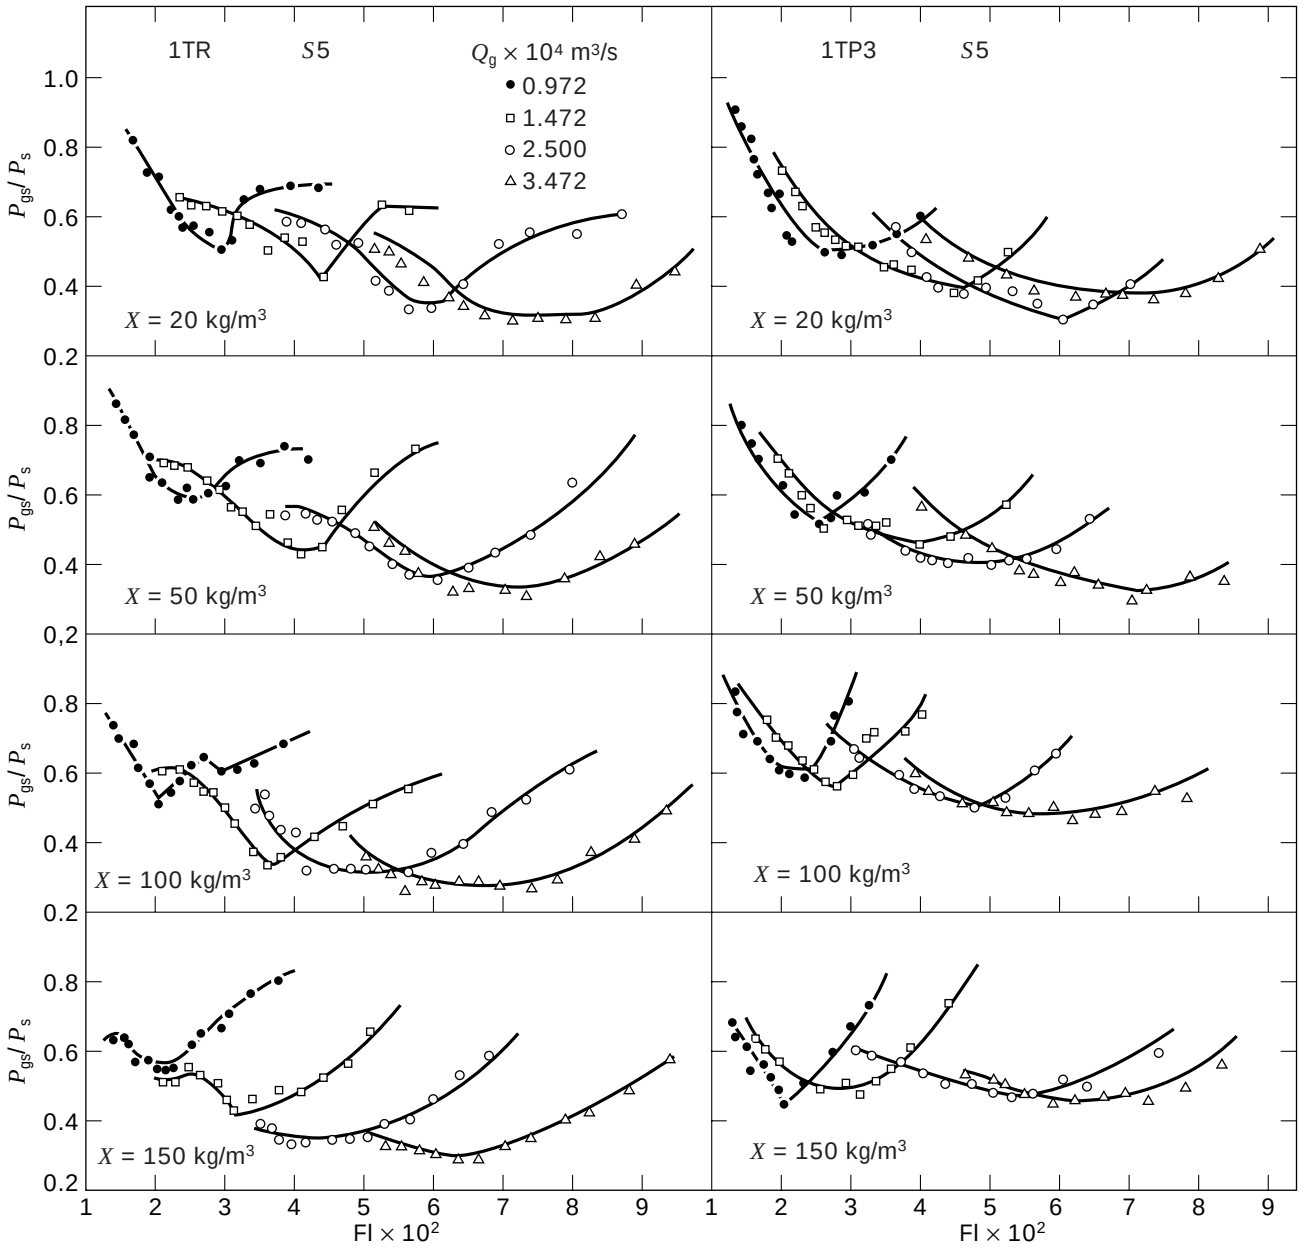

Figure 7. Relation between relative power consumption (P_{gs}/P_s) and gas flow number (Fl) for the S5 particles using single standard and modified turbines. (*Source*: From Ref. 27, with permission.)

1TP3 are approximately 0.5, irrespective of the volumetric gas flow rate. This confirms previous observations (8) as regards the fact that the modified blades have a greatly increased gas-handling capacity.

Effect of particle concentration on power number in a three-phase system, $(Ne)_{gs}$, at constant superficial gas velocity is presented in Figure 8 for the S2 type ion exchange resin, in modified turbines, single or double. A decrease in power number at $N < N_{jsg}$ (jsg is the moment of complete solid suspension) is due to the "false bottom" formed by the particles effectively reducing impeller clearance at low speeds. As the agitator speed N tends to N_{jsg} (as indicated in Fig. 8), the particles were suspended, the false bottom removed, and the power number tended to the common value. The power number generally increased as particle concentration increased before complete particle suspension had been obtained.

In the case of the 1TP3 turbine, the moment of the complete gas dispersion N_{CD} shifts into the range of smaller gas flow rates when the particle concentration increases. For two turbines (2TP3), the variation $(Ne)_{gs} = f$ (Fl) showed the following transition points: the transition to effective dispersion of the gas at the upper impeller (minimum point of the each curve) and also the flooding–loading transition of the bottom impeller (maximum point of each curve). The transition at complete gas dispersion

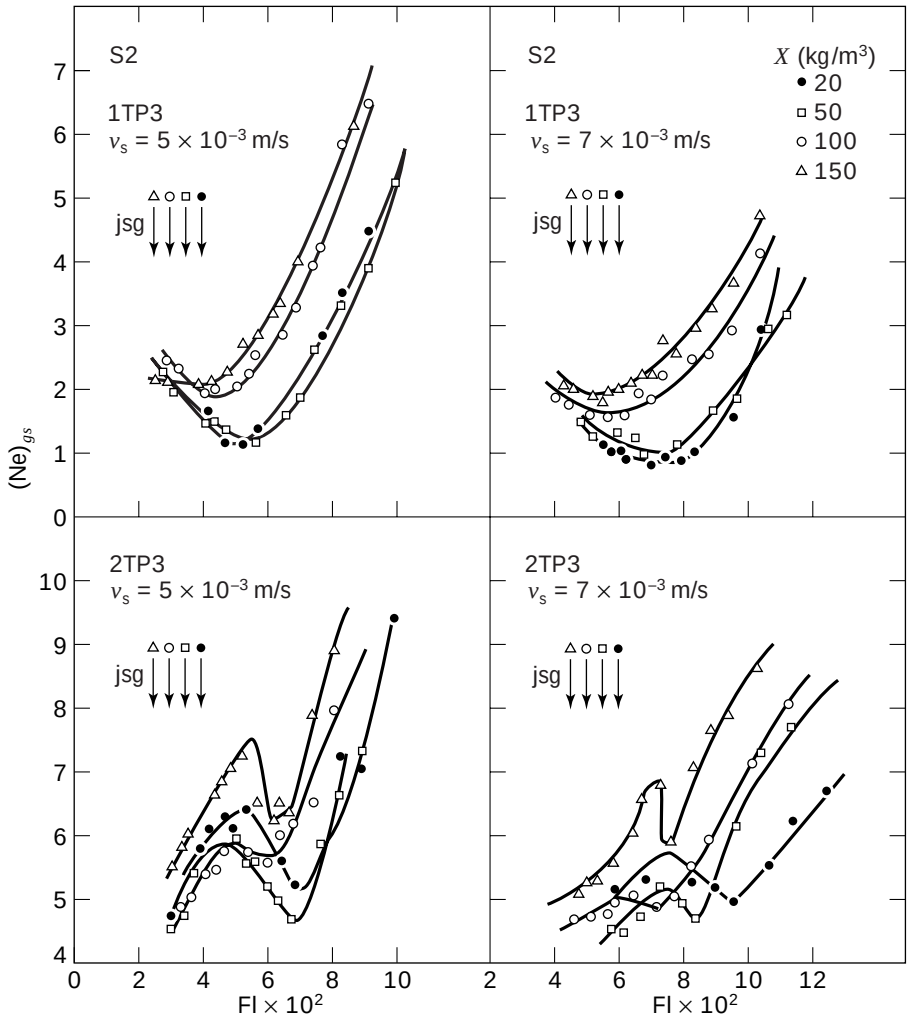

Figure 8. Variation of the power number with gas flow number for the S2 particles using modified turbines, single and double. (*Source*: From Ref. 27, with permission.)

does not show in Figure 8, probably because, once the particles are suspended, the increasing suspension density in the impeller region (and of the power consumption) compensates the decrease in power consumption because of large cavity formation.

The examination of the experimental data in correlation with the Reynolds number shows the following (27):

- For Re $<$ 1,000, mixing is in the transition range, in which the $(Ne)_{gs}$–Re dependence has a negative slope.
- In the range 1,000–1,400 of the Reynolds number, the $(Ne)_{gs}$ values for 1TR attain a minimum point more pronounced for the lower solids concentration. In the case of the 1TP3 turbine, the variation of $(Ne)_{gs}$ with Re is negligible, as a result of the change in fluid flow around and over the perforated blade. The formation of the ventilated cavities behind the modified blades was influenced by the impact of the jets that come through the blade perforations.
- For Re $>$ 1,400, $(Ne)_{gs}$ becomes independent of the Reynolds number, but depends on particle and agitator types. The mixing is in the turbulent range and the phases are uniformly dispersed within the entire vessel section.

The relation between the power number and the physical and rheological properties of solid particles is presented in Figure 9 for the 1TR turbine at various aeration conditions and for 1TP3, 2TP3, and 2TR turbines at constant aeration rate. For the same operation conditions, the modified blade turbines are more efficient, the power number $(Ne)_{gs}$ being reduced by 50% in comparison with the standard Rushton turbine.

Effect of Gas on Solid–Liquid Hydrodynamics

The effect of gas on solid–liquid hydrodynamics in mixing vessels was studied to determine the agitation speed required to just completely suspend all the particles under gassed conditions, N_{jsg} (28). The introduction of a small amount of gas into a solid–liquid system, for the just-suspended condition, causes slight sedimentation such that, for the same impeller speed, the particles were no longer just suspended (i.e., $N < N_{jsg}$). Further increases in the volumetric gas flow rate led to more sedimentation because the pumping capacity and ability of the impeller to circulate fluid and the power input decrease. Any decrease in pumping capacity and power input will decrease all the parameters that cause particle suspension: drag forces, energy dissipation, and associated turbulent eddies. An in-

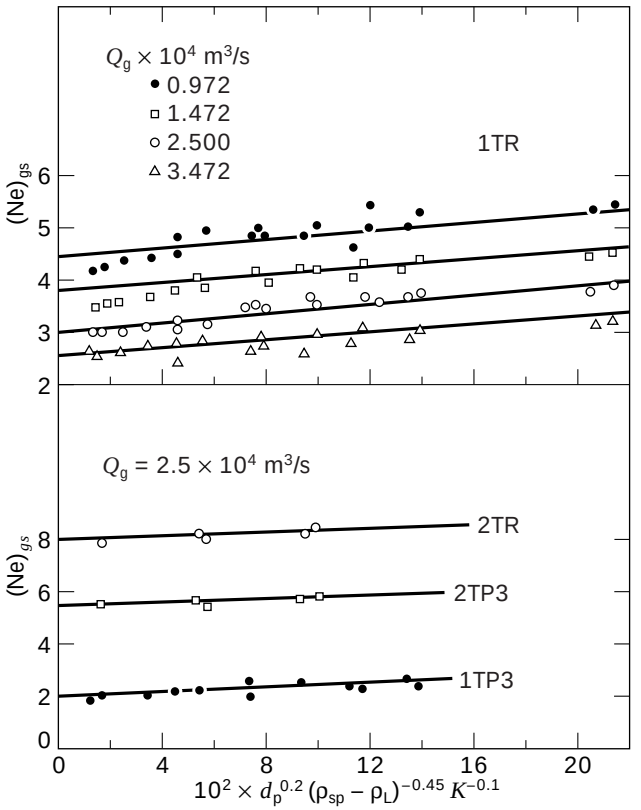

Figure 9. Relation between the power number and the physical and rheological properties of the suspension agitated by various agitator geometries. (*Source*: From Ref. 27, with permission.)

crease of the agitator speed to N_{jsg} ensured complete resuspension. Similarly, under gassed conditions, if $N < N_{jsg}$, a reduction in volumetric gas flow rate gave complete resuspension. In fact, there is a unique combination of gas rate and impeller speed at which the just-suspended condition is achieved and which depends on the agitator type used.

If N_{jsg} is plotted against superficial gas velocity, v_s, the form of the curves is slowly parabolical, for any particle concentration (Fig. 10). At superficial gas velocity of approximately 4×10^{-3} m/s, the slope of the dependence $N_{jsg} = f(v_s)$ decreases, demonstrating that the mechanism of the solid suspension changes. Indeed, this value of the superficial gas velocity is found around a gas flow number Fl = 0.03, when in gas–liquid systems, transition occurs between the clinging cavity regime and the large cavity regime (29,30). The presence of particles has no measurable effect on the formation of the gas-filled cavities.

As showed previously, for complete suspension to be maintained, a higher solid concentration requires a higher power input to the systems. The presence of the gas amplifies the effects mentioned, such that with increasing aeration rate, associated with increasing particle concentration, the agitator speed N_{jsg} must be larger (Fig. 11). The relationship for evaluation of the agitation speed required to just completely suspend all the particles under gassed conditions, N_{jsg}, takes into account the physical and rheological properties of suspensions, the aeration rate, and the equipment configuration (28).

MASS TRANSFER

The mass transfer process from the gas phase to the liquid phase is usually expressed in terms of the volumetric mass transfer coefficient, Kla. The determination methods of the volumetric oxygen transfer coefficient are divided by Rainer (31) into indirect methods, applied without biological system (gassing-out, electrode momentum, sulfite oxidation, carbon dioxide, and glucose oxidase methods), and direct methods (method of gas balance, dynamic method, continuous culture method). The Kla values in mechanically agitated reactors depend on various parameters such as system properties, vessel and stirrer dimensions and arrangement, and operating conditions (32). To examine the behavior of the modified turbines regarding mass transfer, the Kla coefficients were determined in the presence and absence of the solid particles by the sulfite oxidation method.

Gas–Liquid Mass Transfer Characteristics

Figure 12 shows the measured Kla values as a function of gas flow number, Fl, for single and double turbine agitator

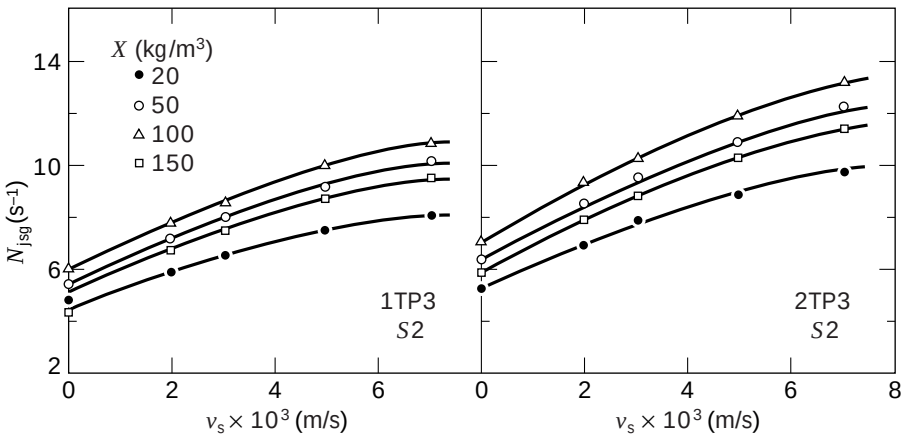

Figure 10. Relation between N_{jsg} and the superficial gas velocity (V_s) for the S2 suspension mixing with modified turbines. (*Source*: From Ref. 28, with permission.)

of TP3 type, having as parameter the agitator speed (curves indicated in Fig. 12 by the continual line) or the aeration rate (curves indicated by the dotted line). The same variation, Kla = f(Fl), was also observed for the other modified turbines and the Rushton turbine (33). The dependence of Kla on Fl, when N is constant, is greater at lower gas flow rates (lower gas flow numbers). At higher gas flow numbers, the curves tend to constant Kla values for all agitator speed values and single turbine types (Fig. 12a). In the case of double turbines (Fig. 12b), this tendency of the curves Kla = f(Fl) appears only at values $N < 10\ s^{-1}$. This dependence of Kla on Fl can be explained by the prism of various hydrodynamic regimes, considering the value Fl = 0.03 as the transition point between the vortex-clinging cavity regime and large cavity regime (33). When the Kla values are represented depending on the gas flow number at a constant aeration rate (curves indicated by the dotted line in Fig. 12), these increase slowly once with increasing the rotational speed when the agitator works in flooding regime (below line noted F/L in Fig. 12). When the agitator works in the loading regime (over line F/L), the volumetric oxygen mass transfer coefficient increases considerably with the decreasing gas flow number.

One procedure for evaluating the volumetric oxygen mass transfer coefficient is based on knowledge of the specific power consumption (P_g/V) and the superficial gas velocity (v_s) (34):

$$\mathrm{Kla} = c(P_g/V)^{0.95}(v_s)^{0.67} \tag{4}$$

The relationship between Kla and the product of the variables $(P_g/V)^{0.95}$ $(v_s)^{0.67}$ for all turbine types and their geometrical disposition is linear, the average value of the dimensional constant c being specific for each of the geometrical configurations studied.

The influence of the mixing system geometry on gas–liquid mass transfer is quantified by including, in equation 4, the geometrical elements $(n_p/6)$ and $(1 + S_G/S_C)$, which indicate the number of turbines and their type. The following correlations were obtained for the evaluations of the volumetric mass transfer coefficient:

$$\mathrm{Kla} = 7.2202 \times 10^{-4}(1 + S_G/S_C)^{1.753}(n_p/6)^{-0.126} \cdot (P_g/V)^{0.95})(v_s)^{0.67} \text{ for } S_G/S_C \leq 0.353;\ r = 0.9843 \tag{5}$$

$$\mathrm{Kla} = 2.721 \times 10^{-3}(1 + S_G/S_C)^{-2.73}(n_p/6)^{-0.141} \cdot (P_g/V)^{0.95}(v_s)^{0.67} \text{ for } S_G/S_C > 0.353;\ r = 0.9629 \tag{6}$$

To obtain the same value of the volumetric mass transfer coefficient, the power consumption in the vessel equipped with the TR agitator is higher than that in the vessel equipped with the TP3 agitator. Therefore, the oxygen transfer efficiency E (m^3O_2/W h) (the oxygen volume transferred into the liquid phase for 1 W h of energy consumption for mixing) for one and two TP3 modified Rushton turbines, for any value of the aeration rate (Fig. 13), is more than 30% higher than those obtained with the TR turbines. The TR and TP5 turbines are similar as regards mass transfer efficiency.

Effect of Particles on Gas–Liquid Mass Transfer

It has been observed that the addition of solids has an influence on gas–liquid mass transfer characteristics, even if these particles are not reactive and do not show increased adsorption of dissolved gases. The inert solid particles used in our work are $CaCO_3$ (S1) and cation exchange resin Amberlite IR-120 type (S3) (35). The experiments were carried out in the range of three-phase homogeneous mixing. The presence of the solid phase, with the concentration between 20 and 50 kg/m^3, influences the gas–liquid mass transfer as shown in Figure 14 for the standard (TR) and modified (TP3) turbines, single or double, at various values of superficial gas velocity. All curves show the same general trend.

For $CaCO_3$ particles (S1 solid), a very slight increase of the Kla coefficient is observed until $X = 50$ kg/m^3, while the addition of the cation exchange resin in a proportion of 20 kg/m^3 leads to a pronounced increase of the Kla value, particularly at $N = 11.667\ s^{-1}$ and at higher values of the superficial gas velocity. This trend of the Kla coefficient to increase in the range of small solid concentration was explained by Brehm (36) that at the moderate agitator speed ($N < 15\ s^{-1}$) the solid particles can move independently of fluid elements and break up the gas–liquid interface, which leads to decreasing thickness of the boundary layer. When increasing the solid concentration beyond the values mentioned, the Kla coefficient gradually decreases toward values smaller than those obtained in gas–liquid systems.

Two main factors are responsible for this reduction of the Kla values (37): one factor is the change of the rheological properties of the suspensions and the other is enhanced bubble coalescence, which is caused by turbulence intensity damping. The higher Kla values for mixing with two turbines (Fig. 14) are due to the their higher power consumption for the same operation conditions.

In the three-phase system, the oxygen transfer efficiency, E, decreases with increase of solid concentration, irrespective of the agitator type (Fig. 15), but for mixing with the TP3 modified turbines, the E values are more than 45% higher than those obtained using TR turbines. The experimental data regarding the mass transfer in gas–liquid suspensions demonstrate that the Kla values depend on the physical and rheological properties. The effect of the solid particles on Kla value is given by the group $K^{-0.15}X^{-0.1}$, which includes the consistency index K as a pseudo-viscosity of the suspensions. Therefore:

$$\mathrm{Kla} = 7.2202 \times 10^{-4}(1 + S_G/S_C)^{1.753}(n_p/6)^{-0.126} \cdot (P_g/V)^{0.95}(v_s)^{0.67}K^{-0.15}X^{-0.1} \tag{7}$$

Equation 7 describes the experimental data with an average error of 20%.

PERFORMANCE OF THE MODIFIED AGITATORS IN BIOSYNTHESIS OF ANTIBIOTICS

The transport phenomena in submerged aerobic fermentation involve mixing and mass and heat transfer in three-phase systems consisting of gas bubbles and suspended microorganisms in a liquid phase and are strongly influenced by the rheological properties of the medium used. The rhe-

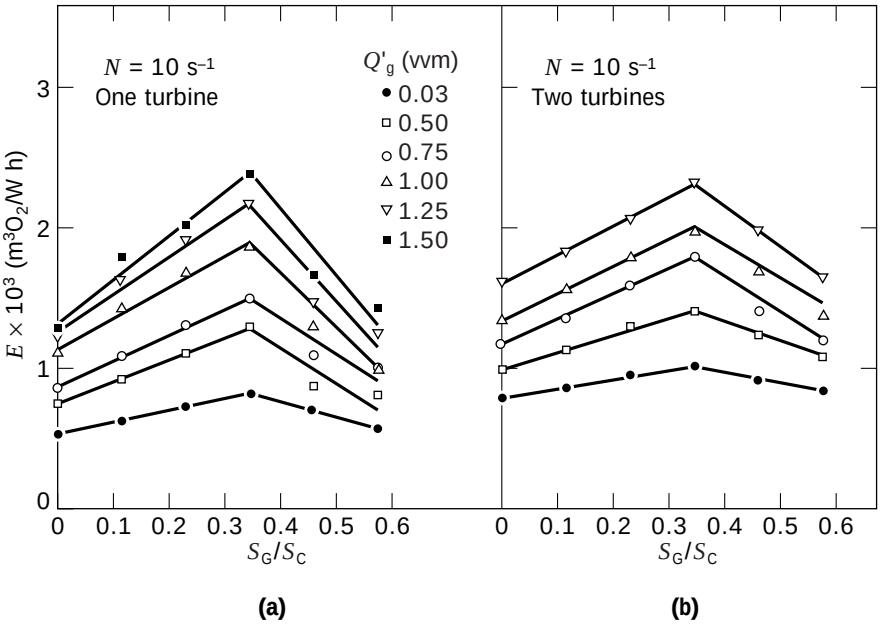

Figure 13. Variation of the oxygen transfer efficiency (E) depending on the surface fraction of the perforation at various values of the aeration rate: (**a**) single turbine; (**b**) double turbines. (*Source*: From Ref. 33, with permission.)

ology of the broth is affected by the composition of the original medium and its modification by the growing culture, the concentration and morphology of the biomass, and the concentration of microbial products. Complex interaction between transport phenomena and reaction kinetics characterizes bioreactors and determines their performance. The modified turbine TP3 with the surface fraction S_G/S_C of perforations equal to 0.353, considered an optimum in dispersion of the gas and solids in liquid, was investigated in antibiotic biosynthesis liquids in semiindustrial and industrial bioreactors.

Biosynthesis of Antibiotics in Semiindustrial-Scale Bioreactors

The experiments were carried out in two 20-m^3 stainless steel stirred tank bioreactors, equipped with three modified Rushton turbines (TP3) (blade width × blade length = 0.306 × 0.225 m), and three witness Rushton turbines (TR) (blade width × blade length = 0.225 × 0.225 m), respectively, having the same diameter and rotating with the same agitator speed (38). The experimental data in the biological systems were obtained using four different microorganisms: *Streptomyces erithreus*, *S. griseus*, *S. noursei*, and *Nocardia mediterranei*, producing erythromycin, streptomycin, nystatin, and rifamycin, respectively. During the four parallel fermentations, the specific power consumption, the volumetric oxygen mass transfer coefficient, the oxygen transfer efficiency, and the antibiotic concentrations were investigated. For each fermentation type, the power consumption for the TP3 agitator is diminished by a factor of 1.18 (streptomycin) to 1.6 (erythromycin) compared to that for the TR agitator (Fig. 16). Therefore, in the viscous mycelial fermentation, the TP3 agitator minimizes the drag forces associated with the motion of the blades, confirming the observations presented for a nonbiological system.

The Kla values, as measured by the dynamic method, decrease during the fermentation processes, depending on the microorganism growing in the liquid (Fig. 17). The fermentation media for *S. erithreus* and *S. noursei*, producing erythromycin and nystatin, respectively, contain starch as a degradable component (22,39), which confers a high viscosity on the initial medium; thus, Kla is smaller at the beginning of biosynthesis, compared to the initial medium for *S. noursei* and *N. mediterranei* without this component. The Kla values obtained under mixing conditions with the TP3 agitator are 25% (streptomycin) to 50% (nystatin) higher than those obtained by using the TR agitator. This effect can be explained by the improvement of the dispersion of the gas bubbles as a result of the impact of the jets that come through the perforations in the TP3 blades onto the relatively surface in the back of large cavities.

Because the TP3 blades are higher by 36% in comparison with the witness blades, the size of the well-mixed, low-viscosity, and high-Kla region is effectively increased. In the micromixing region, excellent bubble breakup and shear thinning of the viscous medium occurs, which results in oxygen transfer improving in accordance with the concepts of Bajpai and Reuss (40). Also, the macromixing region, away from the impeller where the oxygen transfer is relatively poor, is much smaller.

In the investigated biological systems, for 1 W h of energy consumption (for agitation and air compression), the oxygen volume transferred into the liquid phase is approximately 30% higher in the bioreactor equipped with a TP3 agitator (Fig. 18). The oxygen transferred into the medium is consumed mainly in the combustion reaction that takes place within the biomass, on which the antibiotic production depends. The relative antibiotic concentrations measured over the entire course of the fermentations are plotted in Figure 19.

The efficiency of the TP3 agitator was confirmed in that antibiotic production increased up to 35% in nystatin biosynthesis, as much as 9% in rifamycin biosynthesis, and up to 20% in streptomycin biosynthesis as well. No difference in erythromycin production was observed between

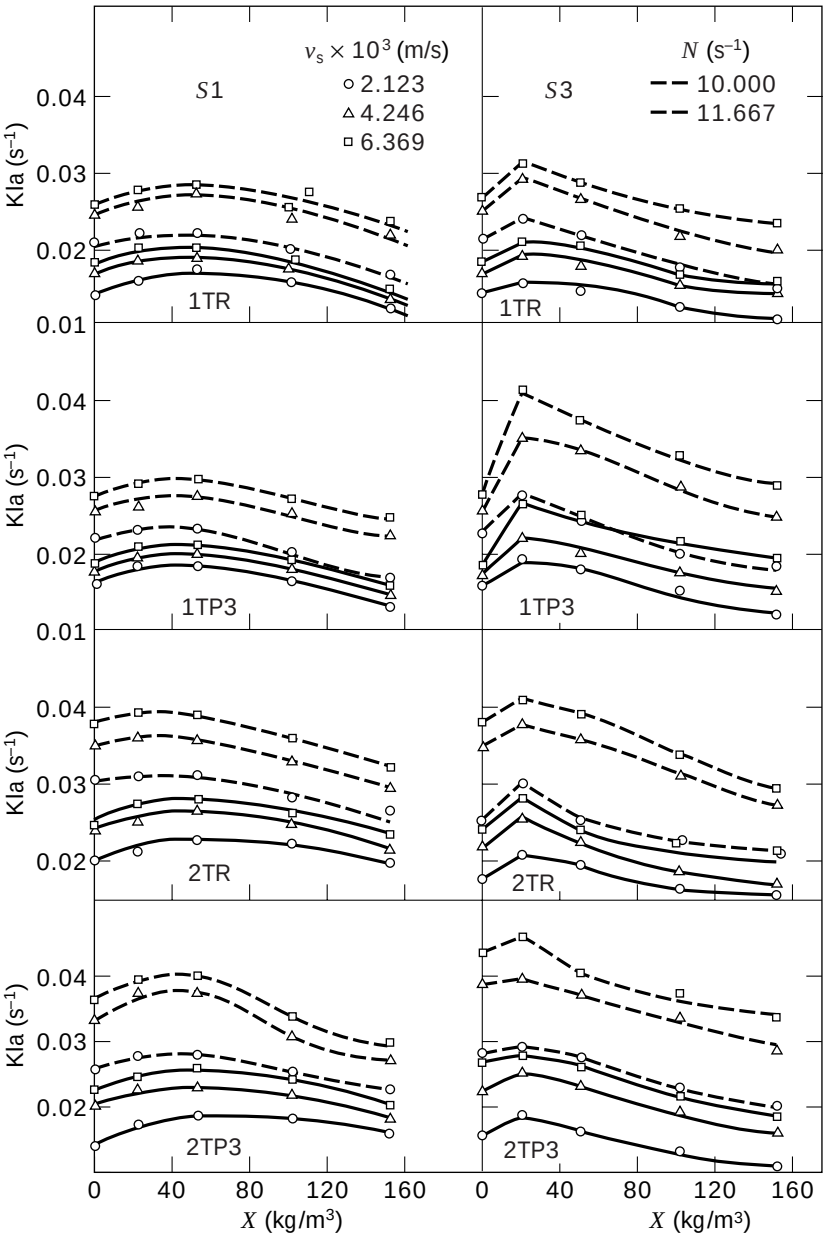

Figure 14. Effect of solid concentration on volumetric mass transfer coefficient for standard and modified Rushton turbine, positioned singly or doubly on the same shaft. (*Source*: From Ref. 35, with permission.)

the two parallel fermentations, but efficiency occurs from the energy savings. Therefore, using the TP3 agitator in the biosynthesis of antibiotics, it is possible to minimize the power consumption and to increase the antibiotic production for the same operating conditions as well as the TR agitator.

Biosynthesis of Antibiotics in Industrial-Scale Bioreactors

In the biosynthesis of antibiotics in semiindustrial-scale bioreactors, it was demonstrated that when the modified agitator has the same diameter and rotates with the same agitator speed as the standard agitator, the power consumption is reduced by a factor of 1.18 to 1.6 (38). Therefore, the use of a modified agitator in biosynthesis of the antibiotics may improve the productivity for a given power input by increasing the TP3 impeller diameter and keeping the agitator speed as high as for the TR agitator, and by increasing the TP3 agitator speed and keeping the impeller diameter as large as for the TR agitator.

The improved agitation performance by modified Rushton turbine agitators corresponding to the two aforementioned cases (if the specific power consumption is constant) was verified experimentally in industrial-scale bioreactors, as follows (41):

- In parallel fermentations of *S. aureofaciens* and *S. rimosus*, producing tetracycline and oxytetracycline, respectively, in two 100-m^3 stainless steel stirred tank bioreactors equipped with four modified impellers (TP3) and four standard impellers (TR), respectively (first case)
- In parallel fermentations of *Penicillium chrysogenum* producing penicillin, in two 63-m^3 stainless steel

stirred tank bioreactors equipped with three modified impellers (TP3) and three standard impellers (TR), respectively (second case)

The morphology of molds is a function of shear stresses in the bioreactor. The growth rate and partial pressure of oxygen, and the following elements, play a role: the growth of hyphae, the branching of hyphae, the dispersion (breakup) of hyphae caused by the shear stress in the vessel, and the tensile strength of hyphae. The breakup frequency (λ/k_o) is proportional to the frequency that a particle will have in the so-called dispersion zone (V_{disp}), that is, the volume at which the turbulent shear forces are greater than the forces necessary to break the hyphal cell wall (42). The λ/k_o and V_{disp} values for the agitators investigated are presented in Table 3.

Therefore, by using the TP3 agitators, the size of the well-mixed region is effectively increased up to 27% and the breakup frequency of the mycelial hyphae is increased up to 75%. The relative antibiotic production and variation

of the specific antibiotic production rate, Q_p, during the cultivation time, are plotted in Figures 20 and 21, respectively. The improvement in antibiotic production by more than 30% by using modified agitators can be explained by creating a better hydrodynamic microclimate, and effectively increasing the well-mixed region, oxygen mass transfer, discharge efficiency, and the breakup frequency of mycelial hyphae.

Table 3. Breakup Frequency of the Mycelial Hyphae and the Dispersion Zone of TP3 and TR Agitators

Product	Agitator	V_{disp} (m^3)	$\lambda/k_0 10^2$ (s^{-1})
Tetracycline and oxytetracycline	TR	1.846	1.688
	TP3	3.522	4.808
Penicillin	TR	1.948	2.255
	TF3	2.474	3.937

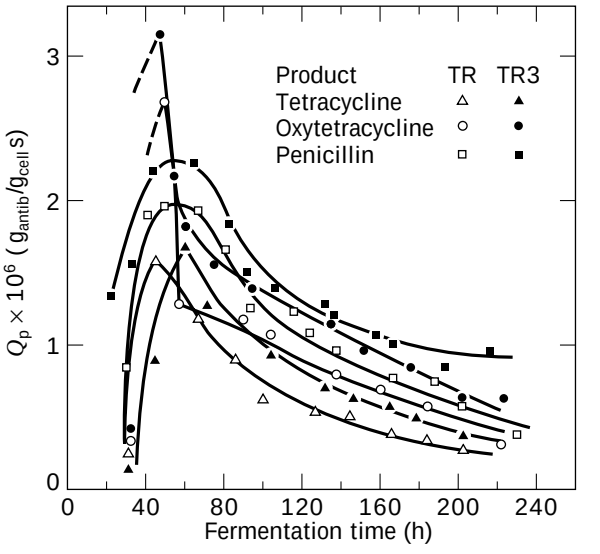

Figure 21. Specific antibiotic production rate profiles during the biosynthesis process using TP3 and TR agitators. (*Source*: From Ref. 41, with permission.)

The Q_p values reach a maximum in the early exponential phase of batch growth, although the cell mass concentration is small. The maximum values of the specific antibiotic production rate and the fermentation time at which these maximum points are reached depend on the type of producing microorganism and the type of agitator. Therefore, the standard and modified agitators create various types of environmental conditions under which the cells appear to adapt by structural and functional changes.

OUTLINE

INTRODUCTION

Transglutaminase (glutaminyl-peptide γ-glutamyltransferase/R-glutaminyl-peptide: amine γ-glutamyl transferase, EC 2.3.2.13) is an enzyme that catalyzes the acyl-transfer reaction between the γ-carboxyamide group of peptide- and/or protein-bound glutamine as the acyl donor and a variety of primary amines as the acyl acceptors (Fig. 1a) (1). If the side chain of protein-bound lysine acts as the acceptor, transglutaminase cross-links protein molecule(s) inter- and/or intramolecularly through the formation of ϵ-(γ-glutamyl)lysine isopeptide bonds between the γ-carboxyamide groups of glutamine and ϵ-amino groups of lysine in the protein molecule(s) (Fig. 1b). If no amines are present in the reaction system, the water molecule acts the acceptor, and the reaction results in deamidation of the γ-carboxyamide groups of glutamine in the proteins (Fig. 1c). Transglutaminase therefore is responsible for the post-translational modification of proteins as a biocatalyst.

In 1950, Borsook et al. observed the incorporation of radioactive lysine into protein components in the crude extract of guinea pig liver (2). Since then, research on the enzyme has continuously progressed. At present, the activity of most transglutaminases known so far is expressed in a calcium-concentration-dependent manner (3–8). Under physiological conditions in which the calcium catch-release mechanism is well regulated, most transglutaminases are controlled by such a mechanism. Transglutaminase is thus said to be calcium dependent. A typical example of transglutaminase-catalyzed protein cross-linking is readily observed in the final stabilization step of the blood coagulation or wound-healing process in warm-blooded species. In this case, plasma, platelet, and/or placental factor XIIIa (the activated form of blood transglutaminase) plays an important role in fibrin cross-linking, when the thrombin-mediated proteolytic cascade reaction along with elevation of endogenous calcium ion levels is induced by injury. The resulting cross-links are covalent, stable, and resistant to proteolysis, thereby increasing the resistance of fibrin clots to chemical, enzymatic, and physical degradation. The transglutaminase reaction with polyamines results in protein modifications, possibly affecting the biological activity or turnover of the target protein, but not polymer formation. Transglutaminase has a broad specificity for the acyl acceptor substrates (a variety of primary amines, peptide-bound lysine, or polyamines), but a relatively narrow specificity for the acyl donors (peptide-bound glutamine residues) is confirmed (amino acid sequence around the susceptible glutamine residue influences the specificity). Denaturation or proteolysis of a nonreactive protein can convert it to a transglutaminase substrate.

Transglutaminase thus can be used for intentional alteration of food protein functionalities (9). The starting point for the present industrial production of transglutaminase is the discovery of Ando et al. (10); calcium-independent transglutaminase is obtained by fermentation of a nonpathogenic and nontoxicogenic variant of *Streptoverticillium mobaraense.*

DISTRIBUTION OF TRANSGLUTAMINASE IN NATURE

Distribution of transglutaminases is ubiquitous in nature. Most mammalian organs, epidermis, plasma, and extracellular fluids contain transglutaminases in multiformity (6–8). Mammalian transglutaminase exists in five types: keratinocyte transglutaminase (TG_K, or type I), tissue transglutaminase (TG_C, or type II), epidermal transglutaminase (TG_E, or type III), prostate transglutaminase (TG_P, or type IV), and plasma and platelet transglutaminases (factor XIIIa) (Table 1). Each enzyme may have distinct physiological functions in the body; that is, the well-known blood transglutaminase, referred to as factor XIIIa, stabilizes fibrin entanglement by cross-linking; the guinea pig liver transglutaminase is classified as TG_C. Although this guinea pig liver transglutaminase was the first enzyme to be found and has been well characterized, its physiological role was the last to be solved.

Transglutaminases are found in not only in mammals, but also in fish, shellfish, crustaceans, amphibians, plants, and microorganisms. For instance, white croaker, carp, sardine, Alaska pollock, chum salmon, rainbow trout (11), horse mackerel (12), hoki (13), *Crassostrea gigas* (oyster) (14), *Tachypleus tridentatus* (horseshoe crab) (15), tadpoles of *Rana catesbeiana* (bullfrog) (16), *Beta vulgaris* L. (Silver beet), broccoli, spinach, (17), *Medicago sativa* L. (alfalfa) (18), *Helianthus tuberosus* (19), *Pisum sativum* seed (20), *Physarium* (21), *Bacillus* (22), and *Streptoverticillium* (10,23) have been reported to contain transglutaminase ac-

Table 1. Physicochemical Properties of Mammalian Transglutaminases

Type	Molecular weight	Subunit structure		Protease activation[a]	GTP effect[b]
Type I, TGK	≈90,000	Monomer	+ fatty acylation	No	None
Type II, TGC	≈8,000	Monomer	+ none	No	Inhibitory
Type III, TGE	≈80,000	Monomer	+ none	Yes[c]	?
Type IV, TGP	≈150,000 (≈71,000 × 2)	Homodimer	+ ?	?	None
Factor XIII					
Plasma	≈350,000	a2b2	+ none	Yes (thrombin)	None
Platelet	≈160,000	a2	+ none	Yes (thrombin)	None

[a]Protease responsible for in vivo activation of transglutaminase is indicated in parentheses.
[b]Effect of guanosine triphophate on transglutaminase activity.
[c]Proteases physiologically involved have not been specified.

tivity, for example, in organs, muscles, or tissue matrices. Although the classification of many enzymes is left undetermined, it is obvious that the enzymatic activity of all the transglutaminases, except microbial enzymes, is expressed only in the presence of calcium ions. The activity of transglutaminases from some microorganisms, such as *Bacillus* and *Streptoverticillium*, is expressed in both the absence and presence of calcium ions. This calcium independence is advantageous for food protein modification because many food proteins are affected by calcium ions. Further, recent investigations revealed that the activity of transglutaminases from oyster and scallop was quite interestingly regulated by both calcium and sodium ions.

ASSAYS FOR TRANSGLUTAMINASE ACTIVITY

There are both quantitative and qualitative assay methods for transglutaminase activity. Quantitative determination can be accomplished by (*1*) measuring the incorporation of any of several radioisotopically labeled primary amines (e.g., [^{14}C]- or [^{15}N]-labeled putrescence, cadaverine, methylamine, and glycine ethyl ester) into caseins, dimethylated caseins, the acetylated B-chain of oxidized insulin, or the glutaminyl peptide derivative, carbobenzoxy(*Z*)-glutaminylglycine; (*2*) measuring the incorporation of fluorescently-labeled primary amines (in most cases, dansylcadaverine) into caseins, dimethylated caseins, the acetylated B-chain of oxidized insulin, or *Z*-glutaminylglycine; (*3*) colorimetric measurement of an enzymatically produced colored γ-glutamylhydroxamate, between hydroxylamine and *Z*-glutaminylglycine, with acidic conditions (Fig. 2); or (*4*) measuring the ammonium released in the acyl transfer reaction (24).

For qualitative determination of the transglutaminases, the detection of either cross-linked proteins by

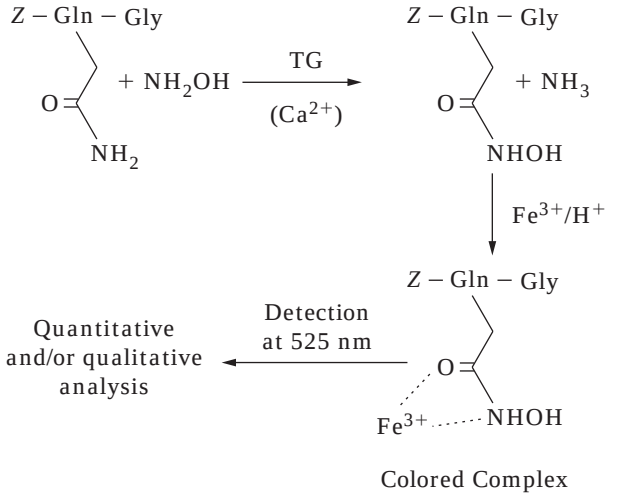

Figure 2. Reaction scheme of hydroxamate assay. Carbobenzoxy(*Z*)-glutaminylglycine and hydroxylamine act as the acyl donor and acceptor substrates. On the addition of ferric chloride/trichloroacetic solution in the acidic pH, the γ-glutamylhydroxamate derivative of *Z*-glutaminylglycine gives a red-colored complex.

(*1*) sodium dodecysulfate polyacrylamide gel electrophoresis (SDS-PAGE) with a reducing agent (e.g., 2-mercaptoethanol or dithiothreitol), or (*2*) test-tube inversion is effective. However, concentrated protein solution (a protein concentration of more than 50 to 100 mg/mL) must be used in the test-tube inversion assay because transglutaminase cross-links the protein substrate in both dilute and concentrate solutions, but a gel that remains at the bottom of the tube can be visually detected only in the concentrated protein solution. The detection of the ϵ-(γ-glutamyl)lysine bond, the enzymatic product, also indicates the presence of transglutaminase (25,26). Further, enzyme-linked immunosorbent assay (ELISA) using either a monoclonal or polyclonal antibody specifical to certain transglutaminases (27) indicates the presence of the enzyme both qualitatively and quantitatively, depending on the conditions of the assay. This method is effective for the detection of denatured transglutaminases in transglutaminase-utilized products.

To detect transglutaminase activity, appropriate assay methods should be carefully chosen. For instance, the sensitivity of the method, the quantity, and the specific activity of transglutaminase may alter the result. Also, substrate specificity, as well as the availability of the detective apparatus and appropriate facilities should be considered. It is known that transglutaminase from the hair follicles of guinea pigs did not recognize hydroxylamine and/or *Z*-glutaminylglycine as a substrate (28). Therefore, this method is not applied for the detection of hair follicle transglutaminases, although the hydroxamate method (hydroxylamine and *Z*-glutaminylglycine) is the most convenient for quantitative and qualitative detection of most transglutaminases.

In the all assays except that for ϵ-(γ-glutamyl)lysine detection, one has to bear in the mind that false results are always a possibility. For instance, some amidases and peptidoglutaminase (EC 3.5.1.43; an enzyme that catalyzes the incorporation of primary amines into the γ-carboxyamide group of glutamines in only short peptides, not in proteins [29]) give a positive result in the hydroxamate assay. Further, various amine oxidases, including lysyl oxidase and peroxidase, may introduce various primary amines in the protein substrates, or cross-link the protein substrates through Schiff base formation by oxidation of amines or the ϵ-amino group of lysine residues (6). Therefore, for final confirmation that the enzyme is truly a transglutaminase, one should check the presence or increment of the ϵ-(γ-glutamyl)lysine bond.

MAMMALIAN TRANSGLUTAMINASE

Transglutaminases in mammalian organs and tissues exit in multiformity depending on their physiological functions and significance. Ordinarily, for all the transglutaminases, including the well-characterized guinea pig liver enzyme and plasma factor XIIIa, the calcium ion requirement for expression of enzymatic activity is absolute (3–8). The primary structure of the five mammalian transglutaminases, namely, keratinocyte transglutaminase (TG_K, or type I), epidermal transglutaminase (TG_E, or type III), tissue transglutaminase (TG_C or type II), and prostate transglutaminase (TG_P or type IV), including plasma and platelet transglutaminase (factor XIIIa), have been established by either cDNA cloning or protein sequencing.

A major physiological role of all the distinct transglutaminases, except tissue transglutaminase, is to cross-link certain protein substrates in accordance with their existence in the organs, plasma, and extracellular fluids. Distinct transglutaminases may recognize the same protein as substrate, but different glutamine residues within the protein act as the acyl donors with different affinity and/or specificity. Their possible physiological functions are reviewed in detail elsewhere (6–8).

Physicochemical Properties

Transglutaminases can be purified by a set of various modes of chromatography (i.e., anion and cation exchange, heparin, blue Sepharose, or antibody-conjugated affinity, hydrophobic, and size-exclusion chromatography). The properties of the purified transglutaminases are summarized in Table 1. The monomeric forms of the four typical mammalian transglutaminases quite resemble one another, and their primary structures differ only slightly, thereby resulting in slightly different molecular weights (Table 1). The primary structures as revealed by cDNA cloning and/or protein sequencing have approximately 670–820 amino acid residues, and approximate molecular weights of the monomeric form of the four transglutaminases stay within the range of 71–92 kDa. TG_K has extra N- and C-terminal regions (about 60 amino acid residues) and fatty acylation through thioester-linked palmitic and myristic acid; hence, TG_K has the largest molecular weight. Other transglutaminases, such as TG_C and TG_E, have a few possible N-linked glycosylation sites and more

than 10 cysteine residues, but no glycosylation and disulfide bonding have been observed.

The structural similarity, as expressed by degrees of sequence identity among the four transglutaminases, is 92% between human and rat TG_K's, 80% between human and guinea pig TG_C's, and 75% between human and mouse TG_E's. On the other hand, the structural similarity between each of the four typical transglutaminases ranges from 31% to 37%. This indicates that the degree of sequence identity between species is rather more conserved than that between the types, thereby suggesting that the ancestral genes for each transglutaminase are limited to a few types (8).

Plasma and platelet factor XIII molecules have molecular weights of approximately 360,000 and 150,000, respectively (3,4,30). They are the zymogen of factor XIIIa, an activated form. Plasma factor XIII exists as a tetramer comprising two noncovalently associated a-subunits and two filamentous b-subunits, whereas platelet factor XIII exits as a dimer comprising two noncovalently associated a-subunits. Both plasma and platelet factor XIII are activated by α-thrombin cleavage of the a-subunit into factor XIIIa. In plasma factor XIIIa, b-subunits dissociate from a-thrombin-treated plasma factor XIII (or factor XIIIa) in the presence of calcium ions. In the continued presence of calcium ions, both plasma and platelet factor XIIIa become catalytically active. The a-subunit resembles four typical transglutaminases, with a sequence identity of 43% with TG_K, 36% with TG_C, 34% with TG_E, and 27% with TG_P. The three-dimensional structure of an activated form of factor XIII has been determined (29). Thorough observation of the structure revealed that the catalytic triad residues (cysteine-314, histidine-373, and aspartate-396) are essential for the expression of transglutaminase activity. Such structural information is critical not only for protein chemistry, but also for protein engineering and genetic engineering. The differences therefore are seen mainly in the physicochemical properties of the six transglutaminases from various sources and origins; amino acid sequences around the active site (an important region for expression of the catalytic activity) are highly conserved among all six transglutaminases (Fig. 3).

Figure 3. Sequence alignment of the active site region of six types of human transglutaminase. TG_K, keratinocyte enzyme; TG_C, tissue enzyme; TG_E, epidermal enzyme, TG_P, prostate enzyme; XIII, factor XIIIa subunit; MTG, microbial enzyme from *Streptoverticillium mobaraense* var. Underlines indicate residues conserved through all the transglutaminases, except MTG.

Enzymatic Properties

Enzymatic properties, such as optimum pH and temperature for the enzymatic activity of the guinea pig liver transglutaminase (TG_C) and factor XIII, have been extensively characterized and reviewed (3–5), whereas those of the remaining transglutaminases have been summarized briefly (7,8). For instance, TG_C can bind guanosine triphosphate (GTP) (32). At the same time, TG_C hydrolyzes GTP, and the TG_C activity is inhibited by GTP. In this context, the possible physiological function of TG_C has been postulated as a G-protein (Gh) in receptor-mediated signal transduction (33), and such a property is unique among the six transglutaminases.

MICROBIAL TRANSGLUTAMINASE

To achieve commercialization of transglutaminase, a constant mass supply is an absolute prerequisite. Among microbial transglutaminases from three microorganisms, *Bacillus*, *Physarium*, and *Streptoverticillium*, transglutaminase from *Physarium* has a molecular weight of 70,000 (21) (the largest of the three), whereas very few characteristics have been determined for *Bacillus* transglutaminase (22). On the other hand, transglutaminases from *Streptoverticillium mobaraense* var. (MTG) have been well characterized (10,23,34), and their industrial production has been established (see later). MTG is secreted into the culture broth so that cell disruption is unnecessary, and subsequently, easy purification has accelerated commercialization. *Streptoverticillium* transglutaminase was first named "bacterial transglutaminase" (BTG, or BTGase), however, the final taxonomical classification into *S. mobaraense* var. (23) urged the renaming of the enzyme as "microbial" transglutaminase (MTG, or MTGase).

Manufacturing Process

MTG is produced through the fermentation process using *S. mobaraense* var. (Fig. 4). The inoculum for industrial fermenters is built up in three stages: started in a shake flask, then moved via aseptic transfer to a large fermenter, and finally to a larger fermenter. Food-grade raw materials are sterilized and are either batched or continuously

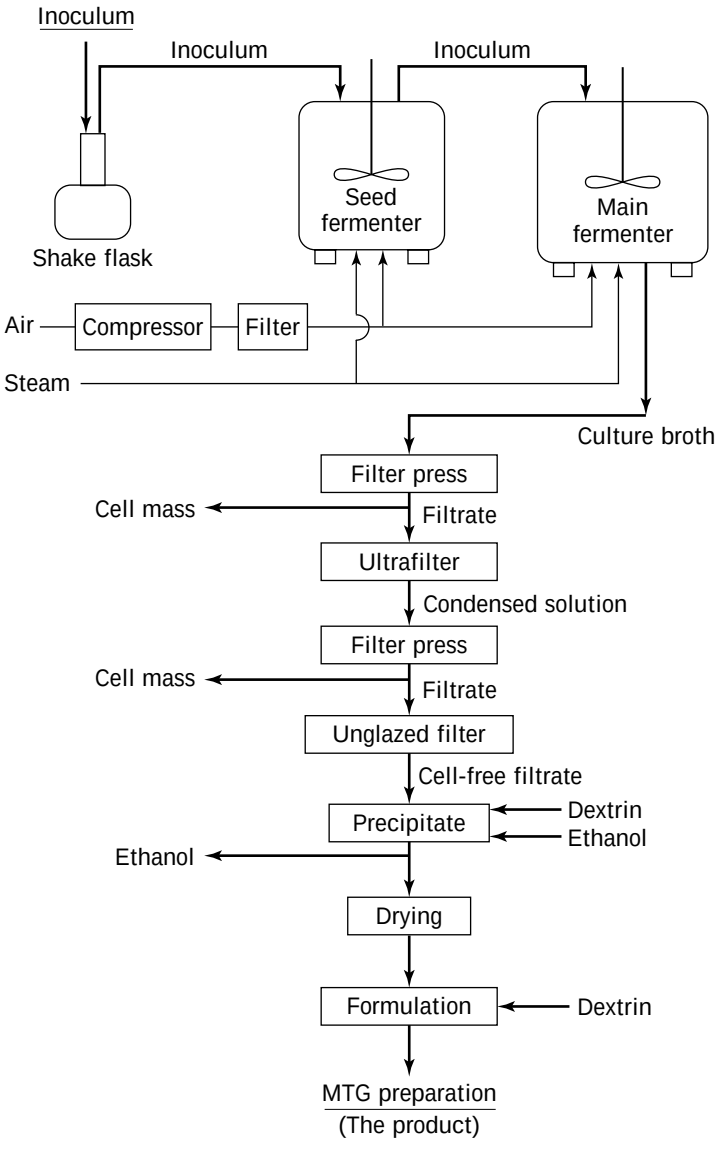

Figure 4. Manufacturing flow of transglutaminase from *Streptoverticillium mobaraense* var.

pumped to the fermenters. The build-up of the inoculum is started when the media are properly prepared and adjusted to suitable growth conditions, and a small inoculum of the pure culture is added. When proper growth is confirmed, the broth is pumped to the next phase. After these serial transfers, the inoculum is then transferred to the main fermenter. Under aseptic conditions, with pH, temperature, aeration and nutrients controlled, the organism begins to produce and excrete the enzyme. When MTG is accumulated to the proper level, the aerobic process is stopped. Thereafter, the whole broth is considered suitably treated, and the fermentation phase is considered completed. Next come the recovery and purification processes. The recovery of MTG from the cultural broth is initiated by the process that removes the organism and spent media. The liquid (broth) that contains the enzyme is subjected to ethanol precipitation, and the fraction containing the enzyme is concentrated by drying in vacuo before it is formulated for the product. All substances added during the recovery and formulating processes are of food grade. The product is then set aside until quality control can assure that it passes all the specifications.

There are various industrial technologies for enzyme recovery, most of which are currently employed. These technologies include the salting-out method, column chromatography, liquid–liquid extraction, ultrafiltration, diafiltration, and so forth. The processes employed in the recovery of MTG are ultrafiltration and solvent precipitation. Following fermentation of the producing organism, the organism is eliminated from the broth by a filter press and then a fine filter apparatus (made of unglazed filter tube). Food-grade dextrin is added to the concentrated enzyme solution for protection of the enzyme, and the enzyme is precipitated by ethanol. Then, the ethanol is removed by centrifugation, and the enzyme is dried in vacuo. The dried enzyme is formulated into the product, whose enzymatic activity is adjusted to 1,000 to 1,150 U/g. The product is kept until the quality control studies are completed.

Fermentation Flow. The pure culture of *S. mobaraense* var is lyophilized; the medium for storage consists of 10% skim milk and 1% monosodium L-glutamate. A lyophilized culture in an ampoule is thawed and suspended in sterile water. After suitable dilution with sterile water, a 0.15-mL portion of the suspension is aseptically inoculated in Venette agar medium containing glucose, peptone, meat extract, yeast extract, and agar. The inoculated media are incubated at 30 ± 1 °C for 10 days. After confirming sufficient mycelium growth and spore formation, the test tubes are examined macroscopically and microscopically. The strain is checked for the standard requirement of MTG activity (hydroxamate assay), protease activity, and pH value. The best strain selected by the above purity test is stored as stock spores at 5 ± 1 °C.

The preculture medium has the following ingredients, in decreasing order of predominance: starch, glycerol, meat extract, yeast extract, potassium dihydrogen phosphate, magnesium sulfate, and antifoam agent. These ingredients are dissolved in water, and the solution is neutralized with sodium hydroxide solution and sterilized at 121 °C for 20 min. Five 2-L shake flasks containing 500 mL of sterile preculture medium are inoculated with a loopful of the spores. The flasks are incubated on a reciprocal shaker at 30 ± 1 °C for 48 h. All of them are inoculated to seed fermenters including sterile preculture medium. The seed fermenter is aerobically incubated at 30 ± 1 °C for about 26 h under a pressure of 0.5 kg/cm^2 with agitation. The whole seed culture broth is transferred to the main fermenter containing a medium described later. The fermenter is conducted aerobically at 30 ± 1 °C for 85–90 h under a pressure of 0.5 kg/cm^2 with agitation. During the fermentation, the pH of broth and the amount of CO_2 in the waste gas are continuously measured; the mycelial growth is also checked. A microscope check for foreign microorganisms is done at 24-h intervals; if any are found, the entire batch is discarded.

The main culture medium has the following ingredients, in decreasing order of predominance: starch, peptone, meat extract, yeast extract, corn steep liquor, potassium dihydrogen phosphate, dipotassium phosphate, magnesium sulfate, and antifoam agent. These ingredients are dissolved in water, and the solution is neutralized with sodium hydroxide solution and sterilized at 121 °C for 30 min.

Purification Flow. The culture broth is passed through a filter press using diatomaceous earth to remove viable cells of *S. mobaraense* var. The obtained filtrate is concentrated to approximately 1/12 volume of the original culture broth and desalted by ultrafiltration. The concentration is filtered using a filter press and a fine-filter apparatus, which is made of an unglazed filter tube. The cell-free filtrate is mixed with ethanol after addition of food-grade dextrin, then stood at 10 ± 2 °C. Ethanol is removed with decantation. The precipitate is washed with ethanol twice. The precipitates are recovered by centrifugation, and the cake is dried in vacuo at 39 ± 1 °C for 22–24 h. The dry powder is ground out and passed through a 60-mesh screen. If necessary, the TG activity can be adjusted to an appropriate uniformity by mixing with a diluent such as dextrin.

Physicochemical Properties

MTG has a molecular weight of approximately 38,000 as determined by SDS-PAGE and gel-permeation chromatography (10). Mass spectrometric analysis indicates that MTG has a molecular weight of 37,869.2 ± 8.8. Amino acid (34) and cDNA (23) sequences reveal that MTG comprises 331 amino acid residues and has a single cysteine residue as a potential active site (Fig. 5). Although two potential glycosylation sites (-Thr-Xxx-Asn-) exist in the primary structure, MTG is a monomeric and simple protein (not a glycoprotein or lipoprotein, etc.). The cDNA structure reveals that MTG has a signal peptide of 18 amino acid residues in its N-terminal in the precursor. In fact, MTG is secreted into the cultural broth during the fermentation. A high isoelectric point (pI 8.9) suggests that MTG is a basic protein.

Enzymatic Properties

MTG has a wide optimum pH (from 5 to 8) for activity. Even at pH 4 or 9, MTG still shows some enzymatic activity. MTG is also stable at wide pH ranges. An optimum temperature for MTG activity was 45–55 °C, and MTG fully sustained its enzymatic activity even after heating at 50 °C for 10 min, both in the presence and absence of reducing agents (Fig. 6). On the other hand, MTG losses its activity within a few minutes on heating to 70°C. MTG expresses its activity even at 10 °C, and it exerts some activity even at near freezing (0 °C).

Expression of enzymatic activity for MTG is totally independent of calcium ions, and in this aspect MTG is unique as compared with other mammalian enzymes. Such calcium independence is useful for the modification of the functional properties of food proteins. Many food proteins, (e.g., caseins, soybean globulins, and myofibrillar proteins) are susceptible to calcium ions and, subsequently, are precipitated easily by calcium ions. The sensitivity toward other cations has also been investigated, and copper, zinc, and lead ions notably inhibited MTG. The results are reasonable because these heavy metals bind to and block the thiol group of the single cysteine residue; meanwhile, MTG was inhibited by thiol-modifying agents (10). For substrate specificity of MTG, to date, most food proteins, such as legume globulins, wheat glutens, egg yolk and white proteins, ovalbumin, actins, myosins, fibrins, milk caseins, α-lactalbumin, and β-lactoglobulin, as well as many other albumins, are cross-linked (35–42).

ALTERATION OF FUNCTIONALITIES OF FOOD PROTEINS BY TRANSGLUTAMINASE

In the formation and maintenance of tertiary and quaternary structures of protein molecules, hydrogen bonds, disulfide bonds, and electrostatic and van der Waal's hydrophobic interactions are essential. Especially in food, not only these bonds, but also other bonds and interactions, particularly those found in connective tissues, are very

important in the expression of textures or mouth-feel. Among them, covalent ϵ-(γ-glutamyl)lysine cross-linking is considered noteworthy. An example of such a cross-linking formation is found in the setting phenomenon or "suwari" of salted, ground fish protein pastes in Japanese kamaboko manufacturing. Contribution of such endogenous transglutaminase activity of fish in the suwari process has been well documented (43–45). As demonstrated in the these cases, transglutaminase has been believed to modify functional properties of protein substrates (9). In an attempt to develop new foods with unique protein utilization and processing methodology, we have been interested in the modification of the functional properties of food proteins through formation of ϵ-(γ-glutamyl)lysine bonds by transglutaminase.

Feasibility Study on Protein Modification by Transglutaminases

In the early 1980s, the possibility of modification of functional properties in milk caseins, soybean globulins, whey proteins, and beef, pork, chicken, and fish actomyosins was demonstrated using transglutaminase derived from guinea pig liver (46–59) or bovine plasma factor XIIIa (60,61). When protein solutions are cast on a flat surface, a transparent, water-resistant, and slowly digestible protein film can be prepared. A protein emulsion of the oil-in-water type can also serve as the substrate, and it is gelled by transglutaminase. In these studies, cross-linking between various proteins of different origins, gelation of various proteins by the transglutaminase reaction, as well as incorporation of amino acids or peptides to improve nutritive deficiency was shown. These results indicate that transglutaminase was potentially useful in creating proteins with new, unique functional properties, as previously postulated (9). However, limited supply and the unfamiliarity of guinea pig liver transglutaminase for food use hindered its commercialization.

Protein Cross-Linking

Discovery of MTG drastically accelerated its applicative studies on the alteration of food protein functionalities. MTG gels concentrate solutions of such proteins as soybean protein, milk proteins, gelatin, and beef, pork, chicken, and fish myosins, as does the guinea pig liver enzyme. Subsequently, improvement in solubility, water-holding capacity, and thermal stability was demonstrated. The gelled soybean globulin further hardened by heating at 100 °C, for 15 min, resulting in a protein with new gel properties. Caseins, non-heat-setting proteins, are also gelled by MTG without heating. Gelatin, a cold-setting protein, is also gelled, and in this case, the gelled gelatin no longer melts on heating at 100 °C. In practical application, soybean curd can be prepared by the ordinary process with the aid of MTG. This MTG-treated soybean curd becomes retort resistant in a way that the soybean curd retains its shape and is nonporous even after the retort treatment(s). More than two different proteins can be covalently conjugated by MTG to produce new proteins with novel functionalities, as with guinea pig transglutaminase. For instance, conjugation of caseins or soybean globulins with ovomucin, one of the egg white glycoproteins, improved emulsifying activity (44). Also conjugation of casein and gelatin by transglutaminase yielded novel proteins that were highly soluble in acidic pH regions (41). Practical applications of transglutaminases, including MTG, in food processing and manufacturing are summarized in Fig. 7, and detailed explanations of transglutaminase applications have been given in elsewhere (62–64).

Amino Acids and/or Peptides Incorporation into Proteins

Amino acids and/or peptides can be covalently introduced into substrate proteins by MTG. This improves nutritive values of caseins, soybean proteins, wheat gluten, and so on, whose methionine and lysine, are limiting amino acids. For practical application of amino acid incorporation, all the amino acids, except lysine, must have their α-carboxyl group amidated, esterified, or decarboxylated in order to be substrates of the transglutaminases. On the other hand, lysine with an ϵ-amino group on the side chain is a good substrate for transglutaminase. In the case of peptides, most should contain at least one lysine residue to be a suitable substrate. For instance, lysylmethionine or methionyllysine can be incorporated into caseins to improve the methionine deficiency. Likewise, lysylarginine or arginyllysine can be incorporated into caseins to improve the arginine deficiency in infant prawns. On the other hand, carnosine and β-alanylhistidine can serve as the substrate (65). Carnosine and anserine, a 1-methylated histidine derivative of carnosine, are thus used as inhibitors of protein cross-linking, because both peptides competitively act as the substrates in the transglutaminase cross-linking reaction.

BIOAVAILABILITY OF CROSS-LINKED PROTEINS

Although the scope of application of MTG-catalyzed modification of food proteins is vast, here attention is focused on the nutritional efficiency of the cross-linked proteins. MTG-modified proteins differ from native proteins only in the quantity of the ϵ-(γ-glutamyl)lysine cross-links, all else is the same. However, the digestibility or bioavailability of the ϵ-(γ-glutamyl)lysine moiety in the cross-linked proteins has been intensively investigated.

Distribution of Naturally Occurring ϵ-(γ-Glutamyl)lysine

Distribution of naturally occurring ϵ-(γ-glutamyl)lysine cross-links in raw materials such as animal organs and tissues and in commonly consumed processed foods have been determined by measuring the ϵ-(γ-glutamyl)lysine dipeptide after exhaustive digestion by proteases and peptidases (25,26). Raw food materials, e.g., meats, fish, shellfish, and most processed foods (e.g., kamaboko, ham, stewed beef, fried chicken, grilled pork, and hamburger) contained more or less certain amounts of ϵ-(γ-glutamyl)lysine cross-links (Table 2). However, dairy products (e.g., cheese, milk, and yogurt) scarcely contained these cross-links. The level of ϵ-(γ-glutamyl)lysine cross-links was higher in processed, especially cooked, foods than in raw materials. The ϵ-(γ-glutamyl)lysine cross-link

	Yogurt	nd

[a]Micromoles of ϵ-(γ-Glutamyl)lysine in 100 g protein of each item.

occurs naturally in eggs of red salmon, lumpfish, herring, sardine, and Alaska pollock (66), all of which have been popularly consumed as caviar in both Western and Eastern countries.

Mechanism of ϵ-(γ-Glutamyl)lysine Formation

It is highly likely that endogenous transglutaminases are responsible in the formation of ϵ-(γ-glutamyl)lysine cross-links in protein during the cooking process, because a variety of living organisms contain intrinsic, endogenous transglutaminase in their tissues and organs. During cooking, the temperature elevation in food materials is in fact very slow, such that the endogenous transglutaminases have some time to exert their enzymatic activity before heat inactivation takes place. Thus cooked or processed foods may contain larger amounts of ϵ-(γ-glutamyl)lysine cross-links than raw materials due to transglutaminase activity. That dairy products contained no ϵ-(γ-glutamyl)lysine cross-links may support an idea that milk itself does not contain any endogenous transglutaminase activities.

Besides the catalysis of the transglutaminases, heating has been reported to induce the formation of ϵ-(γ-glutamyl)lysine cross-links in chemical dehydration between the γ-carboxyl group of glutamate and ϵ-amino group of lysine (67–69). In this respect, humans have been ingesting the ϵ-(γ-glutamyl)lysine moiety since the discovery of cooking. Consequently, the safety of the ϵ-(γ-glutamyl)lysine moiety has been unintentionally and automatically demonstrated.

Degradation In Vitro of ϵ-(γ-Glutamyl)lysine

Ordinarily mammalian gastrointestinal digestive enzymes cleave proteins into amino acids, but leave the ϵ-(γ-glutamyl)lysine cross-link uncleaved after ingestion of cross-linked proteins. The uncleaved ϵ-(γ-glutamyl)lysine dipeptide may be absorbed through intestinal brush-border membranes to the kidney. As a factor responsible for the degradation of the ϵ-(γ-glutamyl)lysine cross-link, a kidney enzyme, γ-glutamylamine cyclotransferase, has been reported to cleave the ϵ-(γ-glutamyl)lysine dipeptide

form. This reaction yields a free lysine and 5-*oxo*-proline (synonym: pyroglutamate) from the dipeptide (70). Because lysine is an essential amino acid for humans and other mammals, the presence of such a pathway would help satisfy nutritional requirements. On the other hand, 5-*oxo*-proline should be converted to glutamate by an ATP-dependent enzyme, 5-*oxo*-prolinase. If a large amount of the cross-linked protein was ingested, a large amount of ATP would be consumed in the kidney. Such a large ATP consumption might overload kidney function, however, recently, γ-glutamyltransferase (γ-glutamyltranspeptidase; EC 2.3.2.2, (71)), present mainly in the intestinal brush-border membranes, kidney, and blood, has been found to cleave the ϵ-(γ-glutamyl)lysine dipeptide into a lysine and glutamate (72). This reaction uses no ATP to generate glutamate. Thus, the ϵ-(γ-glutamyl)lysine moiety, could be effectively metabolized into lysine by the two enzymes.

Degradation In Vivo of ϵ-(γ-Glutamyl)lysine

Many researchers have demonstrated that the ϵ-(γ-glutamyl)lysine dipeptide could be metabolized in rats, and that lysine was integrated in rat tissues (73–76). On the other hand, the bioavailability of the ϵ-(γ-glutamyl)lysine cross-linked moiety in the cross-linked proteins has not yet been experimentally demonstrated. This is because it would be unrealistic and impractical to prepare large-scale cross-linked proteins for animal feeding by using the guinea pig liver transglutaminase. With abundantly available MTG, cross-linked caseins in kilogram scale were fed to rats to evaluate the nutritive value of lysine in the ϵ-(γ-glutamyl)lysine moiety. Lysine generated in the rats has been proved to be nutritionally beneficial in the rats using MTG-catalyzed cross-linked wheat glutens (77). It is thus suggested that the ϵ-(γ-glutamyl)lysine moiety in the cross-linked caseins is cleaved, and the lysine in the moiety metabolically utilized in the body.

CONCLUSION

As stated earlier (9), transglutaminases have been found to drastically alter protein functionalities through the formation of ϵ-(γ-glutamyl)lysine cross-links in many food proteins. Vast application of the transglutaminase modification on food proteins can bring forth such promising results as novel foods and innovative processing techniques. Further, the discovery of transglutaminase from *S. mobaraense* var. (MTG) has accelerated applicative studies, and

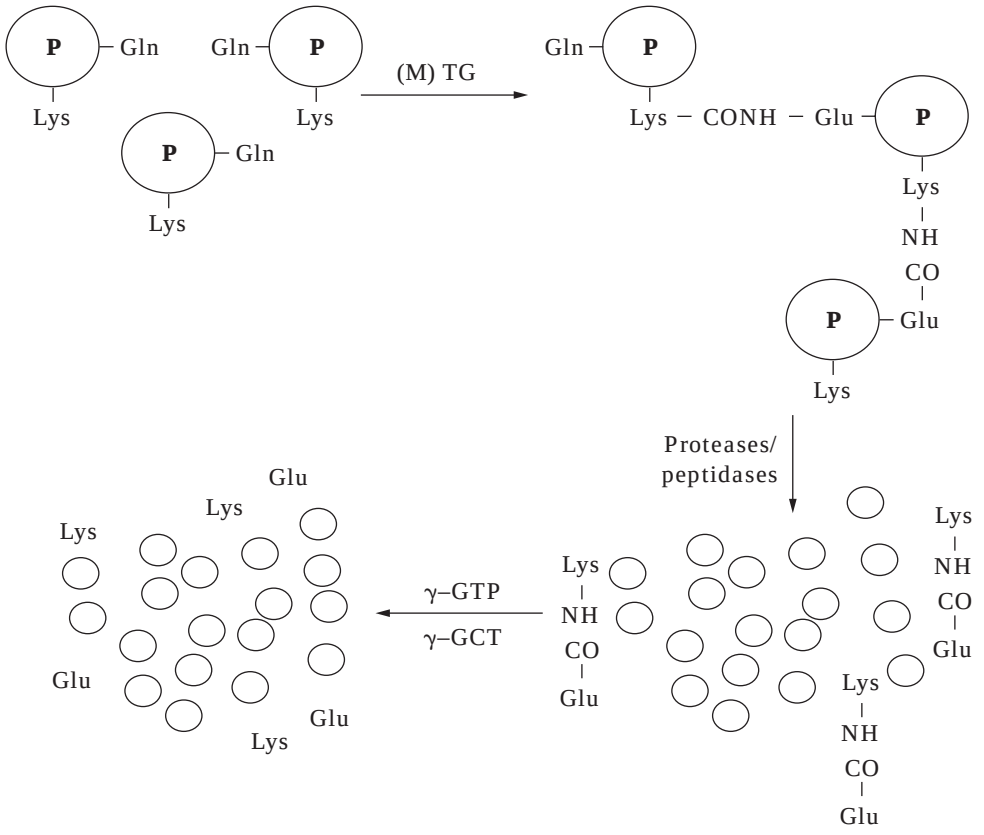

Figure 8. Reaction scheme of the digestion of transglutaminase-catalyzed cross-linked proteins. A large circle with *P* represents a protein or peptide; a small circle represents a single amino acid produced by digestion of proteases and/or peptidases; Glu-CONH-Lys, ϵ-(γ-glutamyl)lysine dipeptide; (M)TG, (microbial) transglutaminase; γ-GTP, γ-glutamyltransferase; γ-GCT, γ-glutamylamine cyclotransferase.

consequently, MTG can be used in surimi and sausage manufacturing in Japan.

With respect to the bioavailability of the ϵ-(γ-glutamyl)lysine moiety in the cross-linked proteins, many studies have been done, and it has been demonstrated that the ϵ-(γ-glutamyl)lysine dipeptide that usually can be produced from the cross-linked protein after exhaustive digestion by gastrointestinal digestive proteases and peptidases can be cleaved by both γ-glutamylamine cyclotransferase and γ-glutamyltransferase, yielding a free lysine. The lysine in the cross-linked proteins has been shown to be metabolizable in the body. The nutritive value of the lysine of the cross-linked protein has been proven using wheat gluten as a lysine-deficient model protein in rats (Fig. 8). Finally, with the evidence that the safety of ϵ-(γ-glutamyl)lysine moiety has been proved by long-established, habitual intakes of cooked foods by humans, the overall effectiveness and safety of protein modification by transglutaminase have been shown.

OUTLINE

OVERVIEW

Historically, the search for new genes and new gene functions has been the major driving force for the development of several powerful transient expression systems such as direct DNA transfection into mammalian cells, recombinant virus infection, injection of *Xenopus* oocytes with mRNA, or complete in vitro–coupled transcription–translation. In particular, functional expression of large cDNA libraries has allowed the cloning of many new genes. The analysis of the gene products, however, has lagged behind because of the lack of efficient, quick, and easy ways of producing sufficient amounts of the gene product to be studied. On another front, methods for stable expression of genes in mammalian cells have been available for many years and presently form the basis for the development of biopharmaceutical production in cell culture. One of the major drawbacks of stable expression lies in the time required for the construction of an optimal, stable recombinant cell line. Transient expression of human or mammalian genes has received considerable interest in recent years for its use in producing recombinant proteins, mainly for research but potentially also for clinical purposes. The ability to rapidly and reproducibly express one or several recombinant genes in a eucaryotic cell environment and to produce large amounts of the gene product now complements the conventional set of biotechnological tools. This article reviews the transient expression methods that can be used on a large scale for the production of recombinant proteins of pharmaceutical interest for in vitro biological, biochemical, animal, and human studies. The various methods presently available can be classified according to the vector used: plasmid DNA, insect viruses, or mammalian viruses. Several of the vectors used in transient expression are also used in gene therapy applications, but we will restrict the scope of this review to the production of recombinant proteins in cell cultures.

There are several key features of transient expression systems:

- Simplicity, in particular in the construction of the expression vector
- Intrinsic genetic stability, because the gene is constantly maintained in the expression host
- Speed, that is, the time required to obtain the first quantities of the gene product
- Application to a wide range of host cells (except in the case of the baculovirus system)
- Suitability to parallel processing, that is, the ability to study several genes or mutants at the same time

All of the transient expression methods have historically been designed for small-scale operations (Petri dish or tissue culture flasks). However, the emphasis of recent developments has been on the scale-up and application of these laboratory methods to large-scale production systems, and all methods can now be operated at pilot bioreactor scale.

DIRECT DNA TRANSFECTION

Introduction

Direct DNA transfection is a widely used system to efficiently produce a desired gene product at levels of 1–3 mg/L within a few weeks. Both genomic DNA and cDNA can be expressed using the classical COS host cell line. This allows the generation of large amounts of protein material with mammalian posttranslational modifications (glycosylation, disulfide bridges, carboxylation, amidation). The material produced can then be utilized for studying the structure and function of the gene product. In parallel, COS cells are routinely used for studying gene expression regulation and for expression cloning. The cells are readily available from public collections (ATCC, ECACC) and are efficiently transfected. Cultivation of these adherent cells does not pose any major problem, even for large-scale cultures. These properties have contributed to the wide popularity of this expression system.

COS cells are derived from green monkey kidney cells (CV-1) transformed with an origin-defective SV40 virus. Historically, the cell line was developed by Yakov-Gluzman (1) to allow the generation of SV40 virus mutants. He developed three cell lines: COS-1, COS-3, COS-7. The cells express high levels of the wild-type SV40 large tumor (T) antigen, an early gene product of 100 bp, which binds to the vector DNA at the origin of replication and allows the host-cell polymerase to run repetitive cycles of DNA replication. As a consequence, plasmids carrying the SV40 origin are maintained in the cell at high copy number (10^4–10^5 copies per cell), giving rise to abundant mRNA yielding high-level recombinant gene expression. COS cells are known to express for up to 1 week posttransfection, with peak protein production between 48 and 72 h posttransfection.

Lusky and Botchan in 1981 (2) were the first to use the large T antigen expressing COS in combination with an SV40 origin–containing plasmid for the identification of DNA transcription sequences. In 1982, the COS cell expression system was used for the first time by Rose and Bergmann to express cell surface and secreted proteins such as vesicular stomatitis virus glycoprotein (3). Subsequent applications by numerous other investigators demonstrated that the COS cell expression system generally yields biologically active proteins. The main factors influencing the expression level in this system are the expression plasmid construct and the transfection efficiency.

Today, many SV40 T antigen–dependent vectors (e.g., ATCC 37192, 37193, 53100) are available for gene expression with COS cells. Typical plasmids for COS transient expression carry the following major components (Fig. 1):

1. The SV40 origin for plasmid replication
2. Appropriate promoter, enhancer, and polyadenylation sequences
3. A prokaryotic origin of replication
4. A prokaryotic selectable marker
5. Unique restriction sites for target gene subcloning

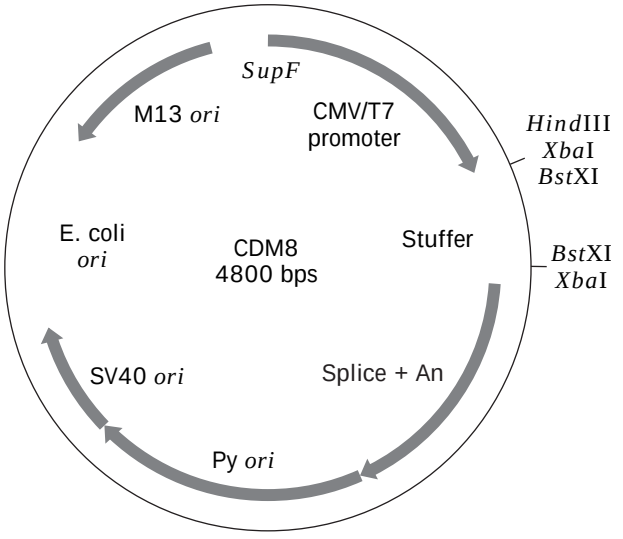

Figure 1. Typical COS expression vector. CDM8, a typical plasmid for transient expression in COS cells. The plasmid consists of CMV/T7 RNA polymerase promoter for high-level gene expression; (SV40 *ori*) SV40 and (Py) polyoma origin of replication; M13 origin of replication; a stuffer with unique restriction sites for subcloning; *E. coli* origin of replication; prokaryotic genetic marker (*SupF*); and splice and An, eukaryotic transcription regulatory elements. *Source*: Reprinted from Ref. 4, with permission of *Nature*.

The Epstein–Barr virus (EBV) also gave rise to a popular expression system based on vectors carrying the replication origin region (OriP) from EBV. EBV–transformed cell lines expressing the EBV nuclear antigen 1 (EBNA-1) replicate transfected plasmids and express the subcloned gene in a similar way to the COS cell–based system. Both genomic and cDNA sequences can be expressed in this system. EBV vectors replicate episomally in the nucleus and, under certain conditions, can be maintained by the cells upon prolonged passage, thus providing a way of obtaining either transient or stable expression of the recombinant protein. In addition, incorporation of the coding sequence for EBNA-1 on the expression vector yields a self-replicating expression plasmid that is autonomously maintained under selection pressure.

By maintaining transfected cells under selective pressure with hygromycin, 293 cells expressing EBNA-1 can be passaged for up to six months while still expressing recombinant proteins at a high level. For example, human placental alkaline phosphatase, tissue plasminogen activator, vascular endothelial cell growth factor, hepatocyte growth factor, prolactin, neurotrophins, and soluble tumor necrosis factor receptors were obtained at levels of 0.2–10 μg/mL (5).

Basic Principles and Protocols

COS Cells and Transfection. COS cell lines are available from the ATCC (COS-1:ATCC CRL 1650, and COS-7: ATCC CRL 1651). They are normally grown adherent onto tissue culture treated matrices in DMEM with 10% FCS and are split by trypsinization before reaching confluence to avoid aggregate formation. ATCC recommends handling the cells in accordance with Biosafety Level 2. Various transfection methods are available to introduce plasmids into mammalian cells. Calcium phosphate precipitation, DEAE dextran, lipofection, and electroporation are commonly used transfection procedures that are well established in cell culture laboratories. In addition, other methods have been described, such as receptor-mediated endocytosis, protoplast fusion, polylysine, and polybrene-mediated transfection. Direct DNA injection into cells with the gene gun (bombardment with DNA-coated gold particles) is used in special applications where cells are difficult to transfect or for certain electrophysiology studies.

Calcium Phosphate. DNA uptake by mammalian cells can be achieved by exposing cells to a calcium phosphate–DNA coprecipitate. The precipitate is formed within 20–30 min by diluting a $CaCl_2$/DNA mix into 2$\times$ HBS. It is then added to the cells in culture, and some protocols describe replacing the medium after about 10 min with fresh medium. In all cases, the transfection mixture is removed from the culture within 1 day after precipitate addition and replaced by fresh culture medium, allowing 2–3 days for gene expression.

Calcium phosphate transfection is also applicable to cells grown in suspension. After a wash with PBS, the cells are resuspended and incubated in a solution containing the calcium phosphate–DNA coprecipitate. After fresh medium top-up and a 1-day incubation, the cells are then pelleted and transferred into fresh medium. Several parameters for transfection with calcium phosphate are critical, including the time allowed for formation of the calcium phosphate–DNA coprecipitate and the pH at which this operation is performed. Scaling-up this method requires that the standard protocols be adapted to reduce or avoid the incubation, washing, and separation steps, because these steps are not compatible with large volumes.

Lipofection. DNA can be delivered to cells by liposome-mediated transfection. Positively charged liposomes are formed with various cationic lipids, such as for *N*-[1(2,3-diolexyloxy)propyl]-*N*,*N*,*N*-trimethylammonium chloride (DOTMA), and interact with DNA to produce DNA–liposome complexes. These complexes are adsorbed to and subsequently fuse with the lipid bilayer of cell membranes, delivering DNA into the cytoplasm.

The experimental protocols are relatively simple: plasmid DNA is diluted into serum free medium and mixed with preformed cationic liposomes. For the actual transfection, cells are overlaid with this mixture for several hours. Finally, fresh medium is added, and the culture is continued for a few days during which expression of the target gene is normally observed. No developments in large-scale transfections have been reported to date, probably because of the high costs of the liposome starting material required for lipofection. However, lipofection has been successfully carried out in spinner systems (Blasey et al., unpublished observation), which indicates the potential for scale-up.

DEAE-Dextran. One of the most widely utilized methods for the transfection of COS cells is the DEAE-dextran

transfection method. The method is based on the formation of a complex between DNA and high molecular weight DEAE-dextran, followed by the natural uptake of this complex by the cells.

COS cells are first grown up to 50–70% confluence, and medium is exchanged for the transfection medium, which is based on DMEM medium supplemented with 10% NuSerum (Collaborative Research, USA). Normal serum is substituted by NuSerum because of the formation of toxic precipitates. The transfection medium also contains DNA at about 2 μg/mL, DEAE-dextran and chloroquine. Chloroquine is believed to prevent DNA degradation induced by the acidic pH of the endosomes during transport. A DMSO shock is also normally applied to the cells to increase the transfection efficiency. Cells are finally plated out and 24 h after transfection are subjected to either a medium exchange, or a split. The cells or the secreted product are then harvested 24–96 h posttransfection. The major drawback of this method with respect to scale-up consists of the repeated medium changes and washing steps. In addition, the exact timing for the DMSO shock needs to be empirically determined for each transfection.

Electroporation. Transfecting cells by electroporation is achieved by imposing a short, powerful electrical field, (i.e., a pulse) onto the cells. The pulse is generated by discharging a capacitor, and as a consequence, small pores are created into the cell membrane, allowing DNA to enter the cell by diffusion.

Practically, cells are grown to submaximal density, pelleted by centrifugation, and suspended into a conductive medium (e.g., normal culture medium or PBS) together with the plasmid DNA. The mixture is transferred to a sterile electroporation cuvette built with two electrodes embedded in two opposing vertical walls. The electrical pulse is applied, and the cells are then diluted back into fresh medium. Following are the parameters that determine the transfection efficiency:

- The field strength (V/cm), defined by the voltage applied and the distance between the cuvette electrodes
- The pulse shape, which can be square or with a logarithmic decay
- The time constant, which is directly related to the type of the electroporation cuvette
- The type of conductive medium and the cell density
- The concentration of DNA
- The number of electrical pulses applied

The optimal settings of these parameters (Table 1) vary between different cell types and other factors such as the pre- and posttransfection incubation times with the DNA, the temperature at which the electroporation is performed, and the physiological state of the cells. Electroporation has been used to transfect COS cells at the liter scale, however, the process was carried out in batch mode (i.e., by electroporating a large number of cuvettes), and this operation mode clearly limits further scale-up. Commercially available continuous electroporation systems are available, but results using these systems have not been reported.

Results

Transient Expression Scale-Up with COS Cells. Large-scale transient expression with plasmids carrying the SV40 origin includes several steps, shown in Figure 2: production of large DNA quantities, scale-up of cell growth, transfection, and protein production.

Production of Large Quantities of DNA. After transformation of competent *Escherichia coli* cells, colony expansion, and propagation in fermentors, the required gram amounts of plasmid DNA can be obtained. Plasmid DNA is first extracted by conventional alkaline lysis and then purified by selective DNA adsorption onto commercial resins (Qiagen, Germany). One of the main goals of plasmid purification is to achieve a low final endotoxin level, which is essential for a high transfection efficiency.

Culture Scale-Up. COS cells, can be grown up to large quantities by any of several appropriate methods, such as tissue culture flasks, roller bottles, microcarrier cultures, or Cellcube, but clearly, only the last two provide an efficient means of large-scale cell production.

Large-Scale Transfection. COS cells are collected, suspended at high density (10^8 cells/mL) in 0.5 mL of electroporation buffer (see earlier) containing 80 μg plasmid DNA/mL, transferred into electroporation cuvettes (interplate distance of 4 mm), and electroporated (Biorad Gene Pulser) with 2 pulses at 260 V, 960 μF, and infinite resistance.

Protein Production. The transfected culture is allowed to recover for 1 day in FCS-containing medium, which is then exchanged for low-protein, serum-free medium for the protein production phase. Daily medium exchanges allow one to continue the culture for up to 10 days posttransfection. A typical run yields several milligrams of pure protein (6).

Alternatively, COS cells can be grown up in rollerbottles, and the culture is overlaid with a DEAE transfection mix. After applying a DMSO shock, medium is added, and the production is carried out for several days. This method was reported for producing, at 800-mL scale, 1–2 mg/L of the scFv::IgC-kappa fusion protein (7).

Scale-Up of the Calcium Phosphate Transfection with HEK Cells. HEK cells grown in stirred systems can be transfected by the calcium phosphate method. HEK cells previously adapted to suspension growth are propagated in a stirred bioreactor. Once the cell density reaches 3×10^5 cells/mL, the calcium concentration in the medium is elevated to 10 mM. After 30 min transfection is initiated by addition of 20 mL/L of the calcium phosphate/DNA precipitate (at 500 μg DNA/L); 4 h later, calcium phosphate is diluted by simple addition of fresh culture medium, thus avoiding a separation step. In a typical example, 0.5 mg/L recombinant tPA was produced during a 5-day production period (8).

BACULOVIRUS–INSECT CELL EXPRESSION SYSTEM

Introduction

Baculovirus: Overview. The baculovirus–insect cell expression system is based on the infection of insect cell lines

Table 1. Typical Electroporation Conditions (used in our laboratory)

Cell line	CHO Ta	HEK293EBNA	COS M6
Voltage (V)	230	230	260
Capacitance (μF)	960	960	960
Volume (mL)	0.25	0.25	0.5
Resistance (ω)	∞	∞	∞
Cuvette: plate distance (mm)	4	4	4
Plasmid (μg/cuvette)	40	40	30
Electroporation buffer	Basal medium with 10% FCS	Basal medium with 10% FCS	Hanks buffered salt solution
Number of pulses	2	1	1–2
Typical results (% positive)	35–40%	35–40%	40–70%

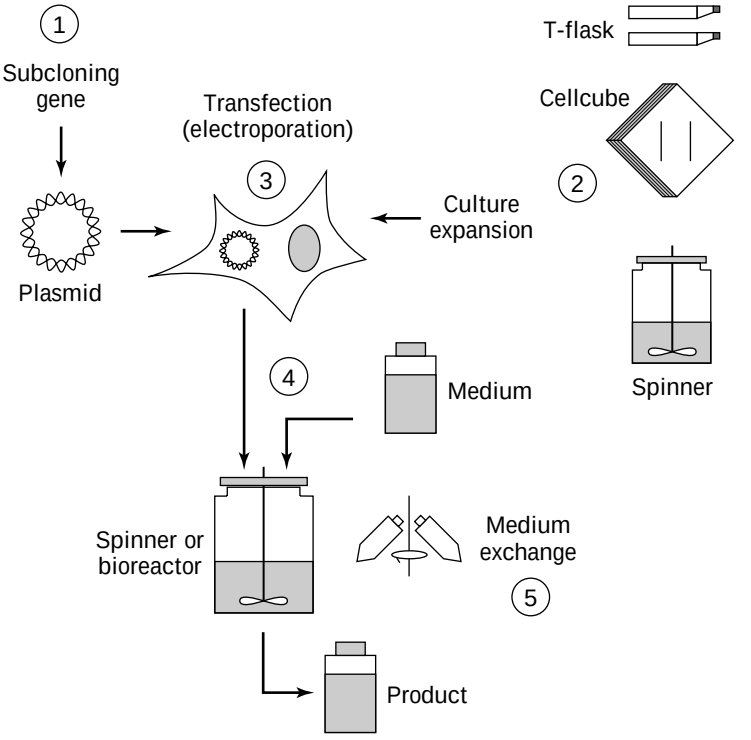

Figure 2. Large-scale COS expression. (1) The gene to be expressed is inserted into the multiple cloning site of the vector. COS cells are grown up in large amounts (2) and then transfected with the plasmid (3) by electroporation. After transfer into a spinner or bioreactor (4) the transfected culture resumes growth and produces the recombinant protein (4). Medium changes (5) extend culture life and allow long-term production (up to 10 days).

with a eucaryotic DNA virus: *Autographa californica* nuclear polyhedrosis virus (AcNPV). A powerful expression vector was originally derived from AcNPV by Summers (9) and Miller (10). It is helper independent and leads to very high expression of heterologous proteins. The expression system exploits strong viral promoters of nonessential genes such as the polyhedrin gene. It is also particularly well suited for coexpression of multisubunit proteins or complex, multicomponent assemblies such as viral capsids. The system is extremely safe because the virus does not replicate in mammalian cells and, in its nonoccluded form, cannot survive in the environment.

Virus Structure and Natural Life Cycle. AcNPV, a member of the Baculoviridae family is a large virus that infects mostly insects. The capsids are 40–50 nm in diameter and 200–300 nm in length. This large size explains in part why large insertions can be made into the viral DNA, a double-stranded circle of approximately 130 kb. The natural life cycle starts from polyhedra or occlusion bodies where virion particles are embedded into a crystalline protein matrix of polyhedrin (29 kDa). These polyhedra are ingested as part of their normal diet by insect larvae. The alkaline pH of the larva's mid-gut dissolves the polyhedrin matrix, releasing up to 100 virion particles per occlusion body. These particles fuse with the mid-gut epithelial cell plasma membranes, migrate to the nucleus where they replicate, and generate nonoccluded (NOV) or budded virus (BV). These budded virus particles are transported by the larva hemolymph to other tissues where they initiate secondary infection sites. In the secondary infection, virus penetrates the cells by receptor-mediated adsorptive endocytosis, a process that is also used during in vitro infection of cells in culture. The virus then infects other susceptible cells, is transported to the nucleus, and enters into a second round of replication that produces NOV again but also, later, occlusion bodies (OB), which close the cycle (Fig. 3). The polyhedrin present in the occlusion bodies can represent up to 50% of the total cellular protein at the peak of production.

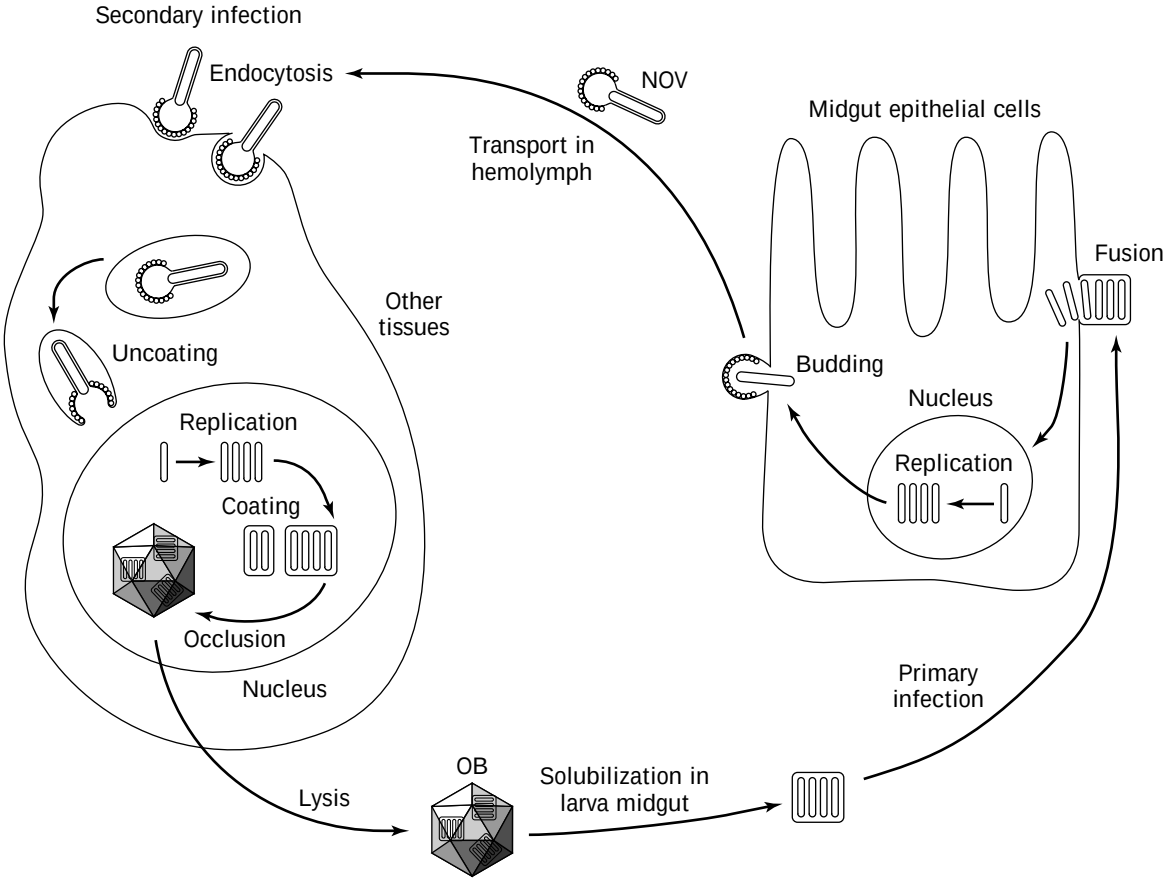

Figure 3. Baculovirus life cycle. The natural life cycle begins with primary infection: the insect larva ingests polyhedra or occlusion body (OB) particles as part of its normal diet. The alkaline pH of the larva's midgut dissolves the polyhedrin matrix. The released virion particles fuse with the midgut epithelial cell plasma membranes, migrate to the nucleus where they start replicating, and generate budded or nonoccluded (NOV) virus particles. NOVs are transported by the larva hemolymph to other tissues where they initiate secondary infection sites. In the secondary infection, virus penetrates the cells by endocytosis, uncoats, is transported to the nucleus, and enters into a second round of replication, which again produces OBs and closes the cycle.

Basic Principles and Protocols

Cell Lines and Media. Several lepidopteran cell lines are highly susceptible to AcNPV, but, two are most commonly used. One is derived from the fall armyworm, *Spodoptera frugiperda* (Sf9 clone), and is available from ATCC (CRL1711), the other is isolated from the cabbage looper, *Trichoplusia ni*, and commonly designated Tn5 (available as High Five cells from Invitrogen Corp.) (11). There are in fact, almost as many variants of these cell lines as laboratories working with them, and extreme caution should be taken when reporting or comparing results without a detailed knowledge of the particular cell line employed. All cell lines have very limited requirements for growth in tissue culture flasks (27 °C, no CO_2, adaptable to serum-free media), and most of them can be readily adapted to suspension culture.

Both cell lines can be used for the expression and production of recombinant proteins, but Sf9 is better suited for generating virus stocks and performing plaque assays because of its natural ability to stick to plastic, its higher susceptibility to the virus, and its ability to produce more virus particles per cell (Fig. 4).

Several media have been developed extensively for efficient growth and expression with the two cell lines described. Serum-containing media such as TNM-FH, IPL-41, and TC-100 are presently used less and less at the production stage, whereas serum-free and even protein-free media are available from commercial sources (JRH Biosciences, Gibco-BRL, Bio-Whittaker). Serum-free media offer clear advantages for large-scale manufacturing, particularly in the case of secreted proteins. When using serum-free media, cells should not be passaged for long periods of time (not more than 40–50 passages) to avoid gradual loss of susceptibility to the virus. Frozen stocks should thus be established to allow rapid and frequent expansion.

Transfer Vectors and Recombinant Virus Construction. In order to produce a recombinant baculovirus, and because the baculovirus genome is too large to be manipulated di-

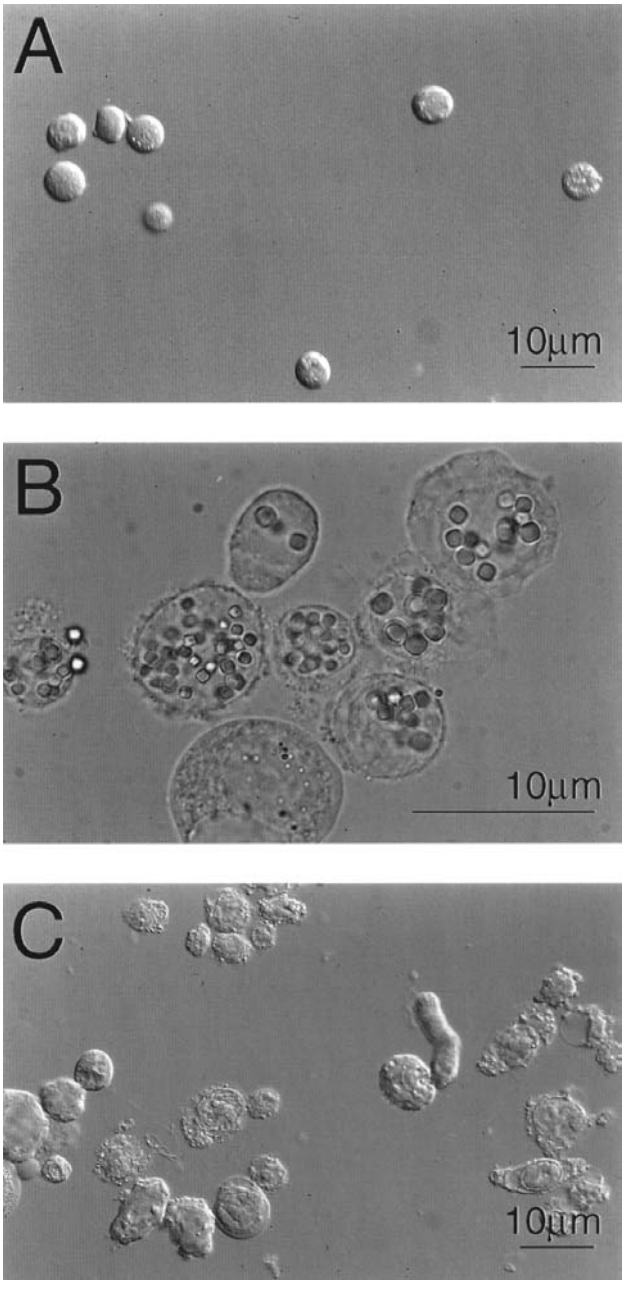

Figure 4. Noninfected Sf9 cells (**a**) and Sf9 cells infected with either WT (**b**) or with a recombinant virus (**c**). Noninfected cells appear round with smooth membranes; WT virus–infected cells contain many occlusion bodies in the nucleus, and recombinant (polyhedrin negative) virus–infected cells display an irregular, sometimes "sausage" shape with rough membranes.

rectly by restriction enzymes, the gene of interest needs to be inserted into a transfer vector (Figs. 5 and 6). Two different types of transfer vector are routinely used, depending on the recombination mechanism chosen:

Transfer Vectors for Recombination in Cells. Once assembled, the transfer vector generally contains one of the strong viral promoters, such as polyhedrin or p10, followed by the recombinant gene coding sequence and transcription termination signals and is flanked on both sides by AcNPV DNA sequences. These sequences allow homologous recombination with wild-type, linearized DNA. A wide variety of transfer vectors of this type have been constructed over recent years (12,13) and offer the possibilities of varying promoters, of multiple gene inserts, and of insertion of tags, fusion, partners, secretion signals, and other helpful features aimed at facilitating detection, expression, and purification.

The transfer vector and wild-type baculovirus DNA are then cotransfected into cells, and the foreign gene coding cassette is inserted into the viral DNA by homologous recombination. Because homologous recombination occurs at a low frequency (1–5%), the virus preparation needs to be purified by plaque assay in order to isolate a pure recombinant virus. It is possible to dramatically increase the proportion of recombinant over wild-type viruses (up to 90%) by using linearized and partially deleted viral DNA, as in the BaculoGold™ system (Pharmingen) (13), or in the MaxBac™ kit (Invitrogen Corp.), but this approach still does not eliminate the requirement for virus plaque purification.

Transfer Vectors for Recombination in E. coli. A newly developed system, BAC-TO-BAC, permits the rapid engineering of the recombinant virus in *E. coli* (14). It is based on site-specific transposition of the DNA cassette into the full viral DNA maintained in *E. coli* as a baculovirus shuttle vector (bacmid). This bacmid contains replication and kanamycin resistance functions and behaves like any common small plasmid in *E. coli*. In addition, a *lacZ*α region with a target site for transposition (mini *att*Tn7) was inserted into the bacmid, which allows transposition of the recombinant cassette from the transfer vector. The transposition machinery is provided in trans by a helper plasmid (tet resistant). This strategy allows fast, easy, and reliable selection of recombinant bacmid colonies on chromogenic substrate–containing plates. Most importantly, it eliminates the need for plaque purification of the recombinant virus. The recombinant bacmid DNA is prepared from the positive *E. coli* colonies and used to infect insect cells in culture in order to regenerate a pure recombinant virus stock.

Amplification and Titration. Titration of the virus is commonly performed by a standard plaque assay technique with Sf9 cell monolayers in presence of serum-containing media. This technique is laborious but gives the most accurate estimate of the number of infectious particles per unit volume (or plaque forming units) in the virus stock.

Table 2. Insect Cell Growth Parameters

Cell line	Medium	Td (h^{-1})	Max density (cells/mL)	Ref
Sf9	IPL41 + FCS	0.02	$5\ 10^6$	8
Sf9	SF900II	0.035	$1.5\ 10^7$	19
Sf9	TNMFH + FCS	0.032	$4.7\ 10^6$	1
Sf9	Excell 400	0.034	$2.9\ 10^6$	2
Tn5	Excel 401	0.030	$4\ 10^6$	3
Tn5	Excel 405	0.038	$6\ 10^6$	20
Tn5	SF-1	0.035	$5\ 10^6$	5

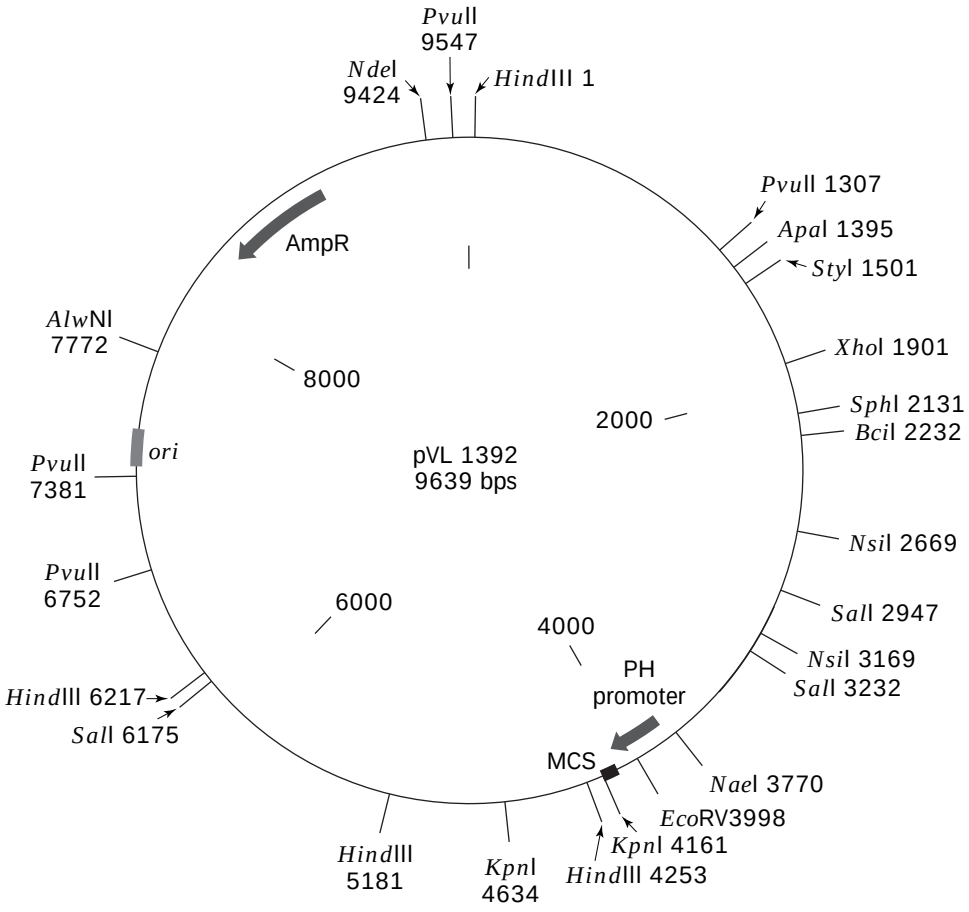

Figure 5. pVL1392 transfer vector. The pVL1392 baculovirus transfer vector was built from pUC8 with its origin of replication (*ori*) and ampicillin resistance gene (Amp^r). It contains the complete polyhedrin gene promoter sequence (PH promoter) but lacks part of the polyhedrin coding sequence. A multiple cloning site (MCS) region has been inserted 37 nucleotides downstream of the ATH polyhedrin start codon, which has been changed into an ATT. In a variant of this vector, pVL1393, the MCS contains the same restriction sites in the opposite orientation. *Source*: Reprinted from Ref. 12, with permission of Pharmingen, San Diego.

Once obtained in a pure form, the virus isolate must be expanded to larger volumes if required for manufacturing on a large scale. This can be accomplished by infection of a culture at a low multiplicity of infection (MOI = 0.01–0.1) so as to reduce the risk of producing defective interfering particles (DIPs) (15,16) and by harvesting the supernatant of the culture at the end of the infection phase (4 days). Titers between 10^7 and 10^8 PFU/mL are commonly obtained at this stage. Virus stocks can be stored at 4 °C, in the dark, for several months, although titers may be significantly reduced upon prolonged storage. A small aliquot can also be kept frozen at −70 °C for long-term storage.

Growth and Infection. Small-scale growth of the host insect cells and infection are easily obtained in stationary tissue culture flask cultures at 27 °C (15,17). Large-scale cultures can be performed with cells in suspension in spinner flasks or in bioreactors equipped with appropriate controls for temperature, dissolved oxygen, agitation, and a pH around 6.2 (18). Growth and product yields are fairly insensitive to bioreactor design but highly sensitive to reactor operation mode and other process parameters such as dissolved oxygen, cell density, and viability at onset of infection, MOI, and nutrient concentrations.

Insect cells have been known for a long time to be particularly sensitive to mechanical stress, in particular at the gas–liquid interface formed during the bubble-bursting process. This explains many of the initial failures in trying to grow insect cells in airlift bioreactors. This problem can be alleviated by supplementing the growth medium with appropriate surfactants such as Pluronic F-68 at a concentration of 0.02%, which prevents cells from being adsorbed on air bubbles.

Normally growth occurs with a doubling time of less than 24 h, and cell density reaches a plateau at 10^7 cells/mL in conventional media (Table 2). Infection is started by simple addition of a virus stock to the culture in full exponential growth ($1–2 \times 10^6$ cells/mL) and at high viability as determined by the Trypan blue exclusion method. A

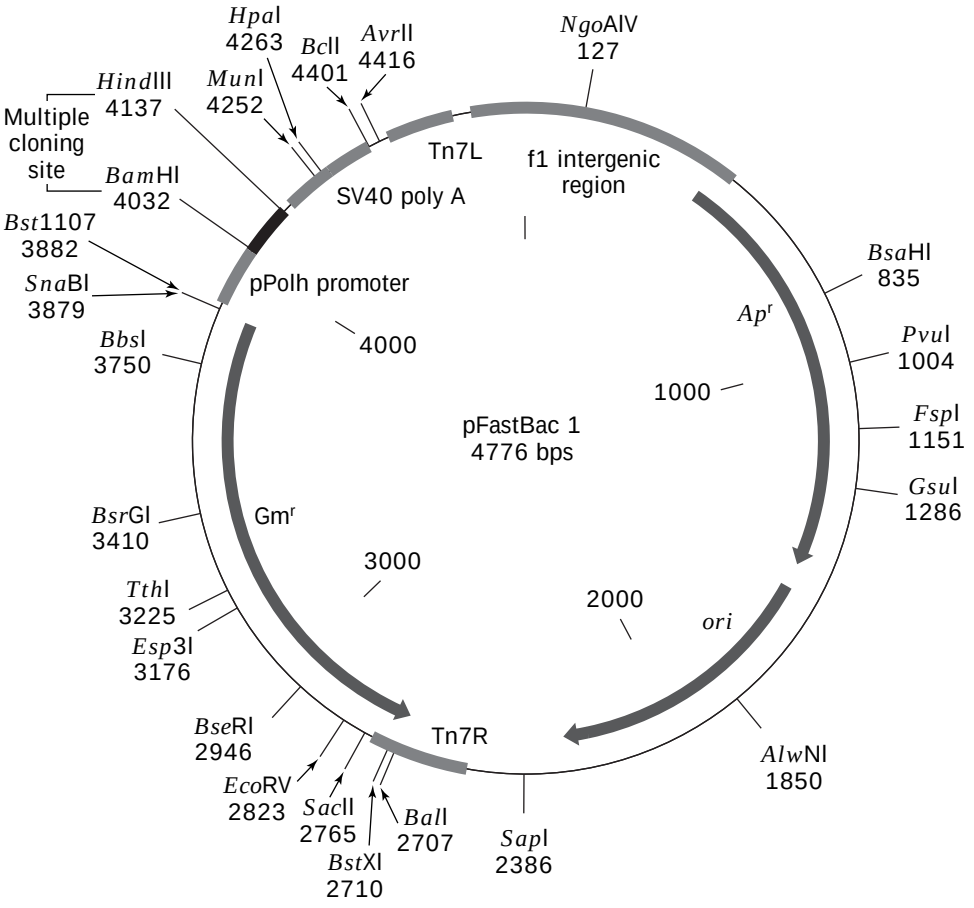

Figure 6. pFast-Bac1 transfer vector. The pFastBac1 vector contains the pUC origin of replication (*ori*), the ampicillin resistance gene (Ap^r), and transposon sequences (Tn7L, Tn7R) to produce recombinant bacmid DNA in *E. coli*. For selection and expression in insect cells, a gentamicin resistance gene (Gm^r), the polyhedrin promoter, SV40 polyadenylation signal, and a multiple cloning site are present. *Source*: reproduced from the GIBCO-BRL 1997–1998 product catalog, with permission from Life Technologies, Inc.

high MOI (5–10) guarantees a fast and uniform infection of all cells and maximizes the final product yield, but the amount of virus should not exceed 10% of the culture volume to reduce the addition of cell debris and spent medium. (Fig. 5).

The level of nutrients present in the medium at the time of infection is probably one of the most important parameters of the process. The nutritional state of the cells conditions the success of the infection and the final product yield, and the lack of a proper control of this parameter explains most observations relating the final expression level to the cell density. It has been clearly demonstrated by several groups that infection could actually be carried out at high cell densities (above 10^7 cells/mL), provided that the nutrient level was kept stable by either one or a combination of strategies, such as medium replacement, concentrated nutrient addition, and perfusion. (Fig. 6).

Another key element in large-scale insect cell processes is oxygen transfer, due to the high natural specific consumption rate (around 5×10^{-17} M/cell/s) by the insect cells. In the early infection process oxygen transfer becomes even more problematic because the cell's requirement can double in the first 24 h of infection. Thus, sparging pure oxygen, increasing agitation rates, and gas flow rates are the most efficient means of maintaining a stable dissolved oxygen concentration (set point between 20 and 50% of air saturation) throughout the whole process.

Results

Timing of Expression. The timing of expression is directly related to the promoter used in the construction of the recombinant virus. The kinetics of accumulation of the recombinant protein in the culture is a result of two inverse phenomena: translation of the recombinant gene from the viral DNA inside the infected cells, and progressive cell death due to viral induced cell lysis. Peak expression is usually observed between 48 and 72 h postinfection when the target gene is under control of very late promoters such as polyhedrin or p10. It may be advantageous, however, to drive expression from earlier promoters, such as the basic protein or *pcor* promoters, which leads to max-

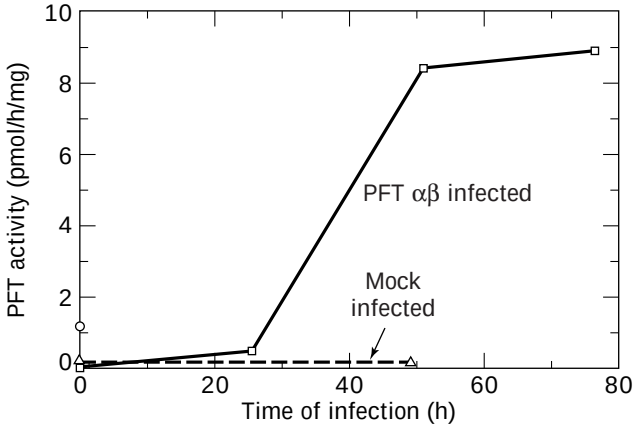

Figure 7. Time course of PFT production by baculovirus–infected Sf9 cells. Multiple cultures of Sf9 cells (4×10^6) were either infected with no virus (i.e., mock infected) (○), infected with wild-type virus (□), or infected with recombinant baculovirus containing the coding regions for both the a- and b-subunits of the rat brain PFT (△). Following infection, cells were incubated for the indicated times, whereupon they were harvested by centrifugation and soluble extracts prepared. The extracts were assayed for PFT activity as previously described (21). *Source*: Reprinted from Ref. 21, with permission of *Journal of Biological Chemistry*.

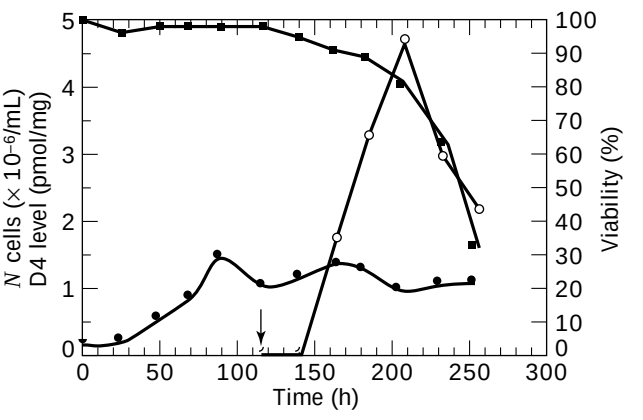

Figure 9. Expression of human dopamine D4 receptors in Sf9 cells. Sf9 cells were propagated in 15-L bioreactors at 27 °C, in TC100 medium (Gibco-BRL) supplemented with 10% FCS and 0.1% Pluronic F68 (BASF, Germany). Dissolved oxygen was controlled at 50% air saturation by pure oxygen sparging on demand. Once the culture reached a cell density of 1.5×10^6/mL (•) with a viability above 95% (■), fresh medium was added together with an aliquot of the virus stock so as to obtain a cell density of 1.0×10^6/mL and an MOI of 10 (arrow). Every 24 h postinfection, a sample was withdrawn for receptor binding activity measurements (○) with [^{3}H] spiperone, as previously described (24).

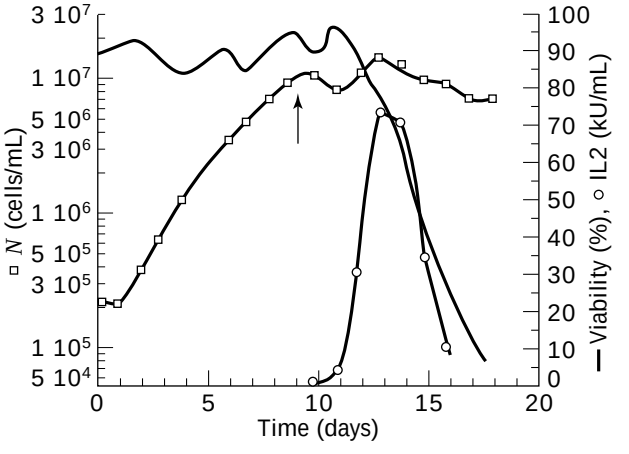

Figure 8. High-density perfusion culture of Sf-21 cells in serum-free Ex-Cell 401 medium. After 9 days, cells were infected with 1.8×10^8 AcNPV/pVL30 corresponding to a MOI of 0.015 (arrow). Maximum productivity was reached 4 days postinfection at a viability of 80%. *Source*: Adapted from Ref. 50, with permission.

imal expression earlier when cell viability is still above 80%.

Expression Level. A high expression level of recombinant proteins is commonly achieved with the baculovirus system; however, it is heavily dependent upon the nature and specific characteristics of each protein and each construct. Clearly, the expression level is also affected by the type of promoter used to drive expression of the foreign gene. The highest levels reported are in the range of several hundred micrograms of active protein per milliliter of culture, as in the case of expression of *β*-galactosidase in monolayer cultures (10). Some cytoplasmic or secreted proteins can also be produced in the 100-mg/L range in large-scale cultures (21,22) (Figs. 7 and 8), but more complex proteins such as multisubunit complexes and single or multiple transmembrane proteins are usually produced at lower levels, typically 0.1–5 mg/L (Fig. 9) (24).

Posttranslational Events. One of the strong arguments for the baculovirus is the ability of insect cells to process nascent polypeptides in a way that is similar to that mammalian cells, and most mammalian proteins produced by this system are virtually identical to their native equivalent in terms of their biochemical or biological activity. It is well established, however, that N-glycosylation performed by the most commonly used cell lines, Sf9 or Tn5, is significantly different from mammalian N-glycosylation, with most proteins being processed to the high-mannose structure steps. However, glycosylation by other specialized insect cell lines such as *Estigmene acrea* (25) appears to be more closely related to that of mammalian cell lines. This area is of course of considerable interest and is still the subject of intensive research.

Due to the availability of several promoters, and because large sequences of DNA can be inserted in the viral genome, the baculovirus is particularly well suited to the production of multisubunit complexes. Mammalian viral capsids or viruslike particles can also be reconstituted inside the cell, and this property is being exploited for the development of novel cattle and human vaccines.

Conclusion and Perspectives

The baculovirus system has shown to be a very useful tool for the production of numerous recombinant mammalian

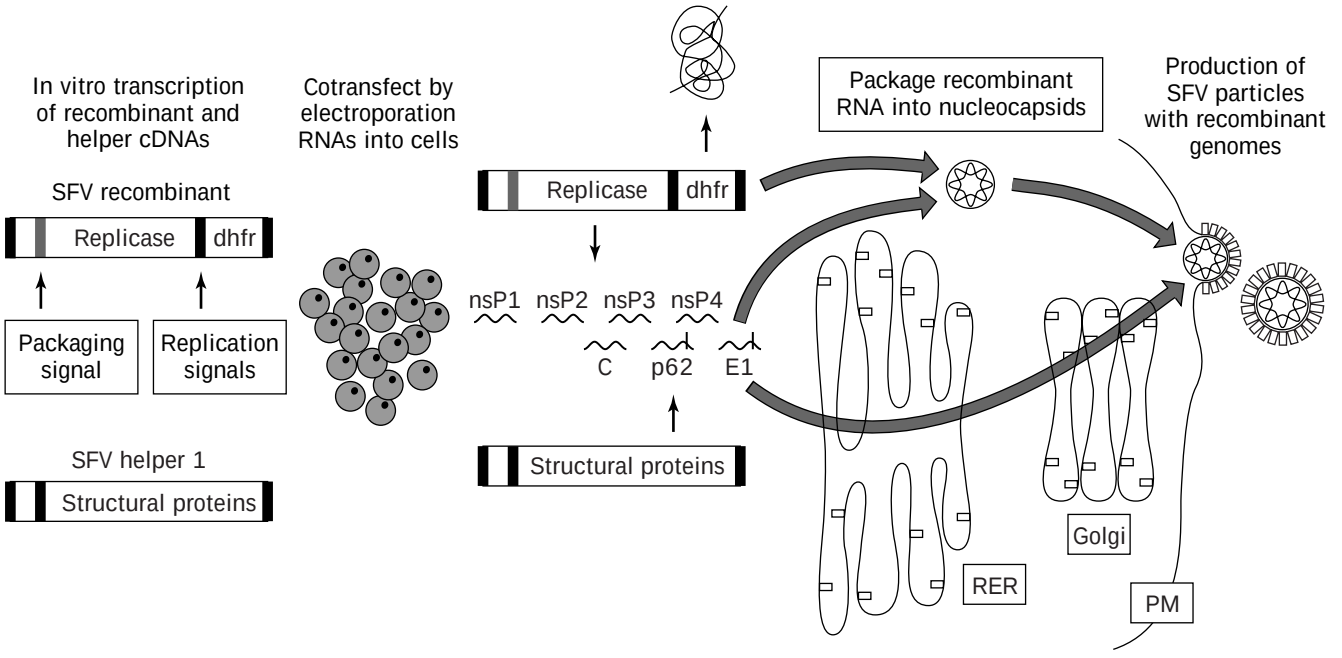

Figure 10. In vivo packaging of recombinant SFV RNA transcripts into infectious particles. After cotransfection of RNA transcripts from the expression and the helper vector, the replicase, coded on the recombinant vector, drives RNA replication and transcription for both plasmids. Structural genes from the helper are translated into proteins. While the capsid protein stays cytosolic and binds RNA to form the nucleocapsid, the membrane proteins undergo posttranslational modifications. E1 and p62 are dimerized in the endoplasmic reticulum and are transported to the plasma membrane where virus budding occurs. Because the viral packaging signal is found only on the recombinant RNA, selective packaging of the pSFVdhfr occurs and as a result yields nonreplicative infectious SFV particles. *Source*: Reprinted from Ref. 26, with permission of Nature-Biotechnology, N.Y.

proteins for research, animal vaccination, and clinical applications. Several biological products produced with this system are being tested in therapies or preventive vaccination, and it seems likely that at least some of them will soon obtain approval for marketing. The major advantages of the system are high-level expression, safety, speed, coexpression of several proteins, easy scale-up, and low cost, which explain its widespread use in particular for the production of research material. Future work is needed to improve control over posttranslational events, which is the only area of difference with more conventional mammalian cell–based expression systems.

SEMLIKI FOREST VIRUS

Introduction: Alpha Virus–Based Expression Systems

Alphaviruses such as the Sindbis virus (SIN) or the Semliki Forest virus (SFV) are very small enveloped viruses containing single-stranded RNA of positive polarity. The 12-kb RNA is capped at the 5′ terminus and polyadenylated at the 3′ terminus. SIN and SFV are the most-studied alphaviruses, and both have been used for the expression of various heterologous genes. Upon infection, the 5′ two-thirds of the RNA is translated into polypeptides, which are processed into four nonstructural proteins (nsP1–nsP4). The nonstructural proteins include transcriptase, which produces a negative-strand copy of the RNA genome, serving as a template for the generation of positive-strand RNA copies. The 3′ third of the genome codes for the structural proteins (i.e., for the capsid C and two membrane proteins, p62 and E1). After translation, the capsid protein C binds to genomic RNA within the cytoplasm. The membrane proteins are translocated into the endoplasmic reticulum, where they form heterodimers and allow virus budding from the cell surface. The released virus can then be taken up by receptor-mediated endocytosis and infect a wide range of mammalian cells.

Semliki Forest Virus Expression System

The broad host range of the SFV expression system has made it a particularly attractive system for functional studies and investigation of the biological role of proteins. It was originally developed by Liljeström and Garoff (26), who split the SFV genome into two plasmids: the cloning vector, pSFV1, which carries the replicase genes; and the pSFV-helper, which encodes the structural proteins of the virus (Figs. 10 and 11). In order to increase the level of biological safety, they later also introduced a mutation into the spike protein–encoding gene, generating pSFV-helper II (27). The mutation prevents the natural proteolytic processing of the spike protein into an active protein, which

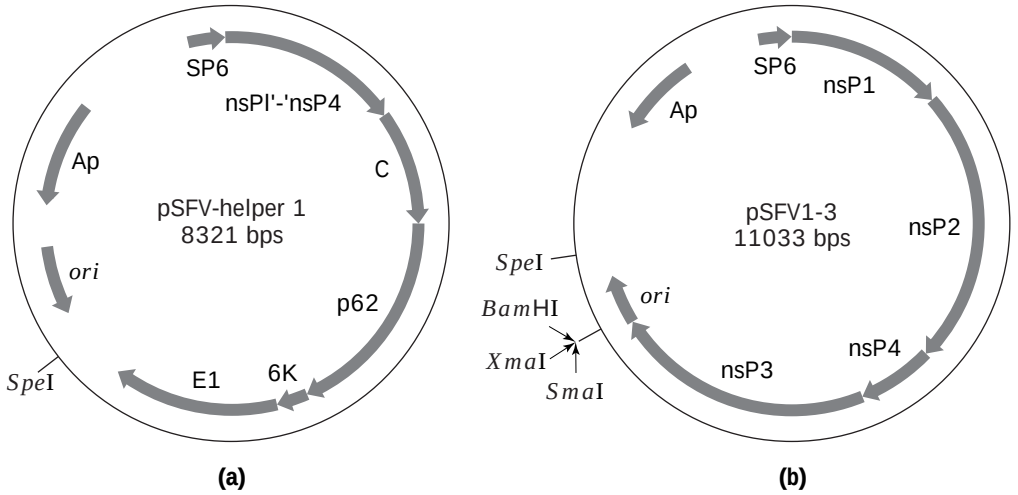

Figure 11. pSFV Helper1 (**a**) and pSFV1-3 plasmids (**b**). Construction of the SFV expression plasmids was done by deleting most of the coding region for the structural proteins (C, p62, 6K, E1) from the cDNA clone, which spans the complete SFV genome. The vectors retain the promoter region of the 26S subgenomic RNA (at the end of the nsP4 region) and the last 49 amino acids of the E1 protein as well as the complete noncoding 3′ end of the SFV genome. Downstream of the 26S promoter, a polylinker (*Bam*III, *Xma*I, *Sma*I) was introduced. The SP6 promoter, which is followed by the replicase (nsP1-nsP4), allows in vitro generation of full-length SFV RNA transcripts. The eukaryotic origin of replication (*ori*) and antibiotic resistance (Ap) allow for plasmid production in *E. coli*. A unique *Spe*I restriction site was inserted for plasmid linearization. The pSFV-helper1 represents the SFV genome cDNA being deleted of most of the nonstructural region but carrying all the structural genes (C, p62, 6K, E1). The pSFV-helper2 codes for a cleavage-deficient variant of the spike protein. *Source*: Reprinted from Ref. 26, with permission of Nature-Biotechnology, N.Y.

mediates entry into the cell. However, the processing can be obtained by chymotrypsin cleavage, thus restoring full infectivity of the virus stock (27). High expression levels are obtained due to the extremely efficient SFV 26S promoter used and also to the high number of copies of RNA (200,000) present in each infected cell. For example, levels up to 25% of total cell protein have been reported for β-galactosidase (26), and several million neurokinin 1 receptors per cell (28). Because the virus can be used to infect almost any mammalian cell, recombinant proteins can be produced with posttranslational modifications based on the specific processing capacities of the host cell selected (Table 3).

Infection and protein expression properties. SFV can infect a broad range of host cells; however, the level of expression differs between cell lines: BHK, CHO, and COS cells yield higher levels of expression than other cells such as NSO, RPMI 8226, and HeLa. This was clearly demonstrated for different types of proteins: a multitransmembrane receptor (neurokinin 2 receptor), a secreted protein (soluble placental alkaline phosphatase), and a cytosolic protein (β-gal).

At least in BHK cells it is known that the optimal pH is different for SFV infection (pH 6.9) and protein production (pH 7.3). The MOI also clearly modulates the expression level (30): a higher MOI results in elevated expression levels.

Transfecting cells with RNA generated in vitro from the cloning vector also leads to RNA replication and subsequent expression of the subcloned gene, a method that should be applicable to the expression of oncogenes and other hazardous genes. However, infection with recombinant packaged SFV particles is still a more efficient way to deliver recombinant RNA inside the cells.

Basic Principles and Protocols

Virus Generation. After subcloning the gene of interest into the multiple cloning site of pSFV, the plasmid is linearized to prepare for in vitro transcription and RNA production. BHK cells are then cotransfected with the recombinant and helper RNAs (Fig. 12), which initiates the in vivo packaging process. It is important to note that the packaging signal is present only on pSFV-1 and is absent from the pSFV-helper vector. As a consequence, infectious but nonreplicative recombinant virus particles are produced, and a high titer (approximately 10^9 virus particles/mL) is harvested 24 h after transfection.

Protein Expression. As a first step, BHK cells are grown to confluence in T-flasks. The virus is activated by incubation with chymotrypsin, which is inactivated after 20 min by addition of aprotinin. Virus is transferred into the culture to give a MOI of 30 for infection. Product can be detected by pulse labeling after 4–6 h postinfection while the host cell protein synthesis is dramatically reduced or shut down and cell growth is arrested. Maximum product concentration is usually reached 1 day postinfection but

may vary depending on the proteins expressed. The culture is harvested by centrifuging the cells after detachment.

Semliki Forest Virus Scale-Up Results

BHK cells are grown in single cell suspension to 10^6 cells/mL using a stirred-tank reactor equipped with a Vibromix stirring system and oxygenation by silicone tube gassing (Chemap/MBR, Switzerland). This agitation method proves to be optimal for minimizing cell aggregate formation, and the oxygenation method is preferred over direct gas sparging into the bulk of the liquid so as to eliminate any aerosol formation.

Before infection, 90% of the medium is exchanged by external cross-flow filtration. The virus is activated separately and the culture infected by addition of the activated virus stock. At 16 h postinfection the culture is harvested by centrifugation and the recombinant protein purified.

Recent results of large-scale protein production with SFV have recently been described:

- Cyclooxygenase-2: 16 mg microsomal protein per 10^9 cells, activity: 3,942 pg PGE_2/μg microsomal protein (30)
- 5HT3 receptor: 1–2 mg 5HT3 receptor protein per liter culture, or 25–50 pmol binding sites per cell (19)

Commentary

The SFV expression system has quickly found wide acceptance due to the high level of expression achievable combined with the short time scale for production. It is preferentially used to express receptors and intracellular products.

Virus generation for large-scale infection is still laborious, in particular the RNA generation and transfection of cells with the two RNAs. This constitutes the main difference with other viral-mediated expression systems.

Biological safety of the SFV expression system has been given significant attention. The virus is nonreplicative and only conditionally infective. However, because the culture

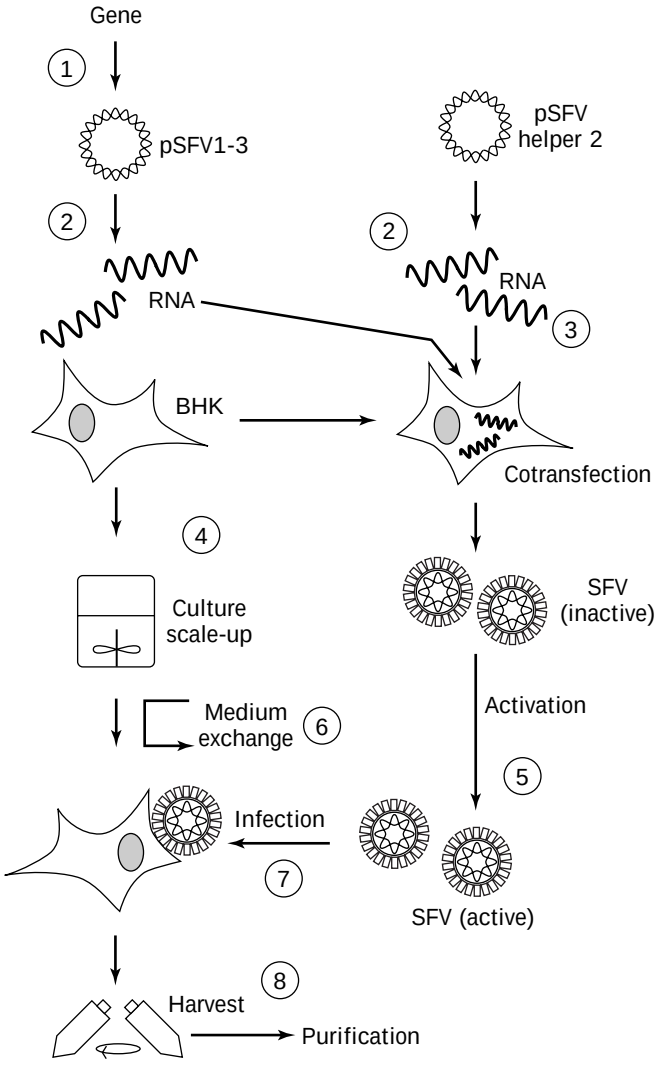

Figure 12. SFV infection process. Large-scale recombinant protein production with the Semliki Forest virus system. The gene to be expressed is subcloned (1) into the recombinant vector pSFV1-3. In vitro transcribed RNA (2) from the recombinant plasmid pSFV1-3 and the pSFV-helper-2 are cotransfected (3) into BHK cells; virus is harvested 24 h later. BHK cells are grown up to 10^6 cell/mL as suspension culture in a mechanically stirred reactor (4). Virus is activated (5), the culture medium is exchanged (6), and the culture infected (7). Cells are harvested (8) 1 day after infection by centrifugation, and the protein is purified.

at the time of harvest potentially contains active virus, it is recommended that this expression system and the handling of products obtained by this technology be operated under safety category two or higher.

OTHER VIRAL-MEDIATED EXPRESSION SYSTEMS

Adenovirus

Introduction. Isolated in the early 1950s, adenoviruses have recently received a renewed interest for their use as vectors for DNA delivery to cells in vivo in gene therapy applications, as potential vaccine vectors, or as expression vectors for heterologous genes in vitro. In this section, the latter application of adenoviruses is reviewed.

Adenovirus Life Cycle. The adenovirus life cycle starts with an early phase in which regions E1–E4 and L1 of the linear double-stranded DNA (36 kb total length) are actively transcribed from the early (E) and major late promoters (MLP), respectively (61). Viral replication begins 8 h after infection, and host transcription as well as protein synthesis are gradually shut off as the cycle enters the late phase of infection. In this phase, late transcripts from the MLP, L2–L5 appear together with structural proteins. The MLP promoter drives high levels of expression of these late proteins, which can account for up to 50% cellular protein. The cycle also leads to cell death and to the release of high virus titers (10^8–10^9 PFU/mL).

Expression Vectors. The extensive knowledge accumulated over the years on adenovirus transcription regulation allowed the engineering of adenovirus vectors (Ad) modified for the expression of heterologous genes (61). The first modification consists in deleting the early regions E1 and E3. Whereas E3 is not essential to viral replication in cell cultures, E1 deletion renders the virus replication incompetent, and this function must then be provided in trans by the host cell, as is the case for 293 cells, which constitutively express the E1 protein. The second modification consists in introducing an expression cassette in place of the deleted E1 region. In the cassette, the recombinant gene is placed under control of an additional (or ectopic) MLP and follows the tripartite leader and splicing signal sequences, thus taking advantage of the strong natural positive regulation of the promoter. Alternatively, the recombinant can be placed under control of an exogenous promoter such as CMV (62) or the natural MLP, but in this latter case, the recombinant virus must then be treated as a helper-dependent virus. Very recently, a new series of vectors, pAdBM5, was constructed (63) with significant improvements in the ectopic MLP region by insertion of enhancer sequences that stimulate the promoter's transcriptional activity. The fact that the virus can be propagated in suspension cell cultures is also of considerable advantage over other similar processes.

Results. Several heterologous proteins have been expressed from Ad vectors at high levels in 293 cells. Most constructions have been done in the Ad5 serotype background, and with a few exceptions, such as DHFR, CAT, factor IX or the vitamin D3 receptor, all were made for expressing viral proteins. SV40 large T antigen was expressed at high levels and could be purified to homogeneity, Herpes simplex virus type 2 ribonucleotide reductase subunit R2 was expressed in 293 cells at 4–5% of cellular proteins, and the polyomavirus middle T antigen and the hepatitis B surface antigen were also expressed at high levels in the same cells. The pAdBM5 vector has been reported to yield even higher levels of expression (10–20% of cellular

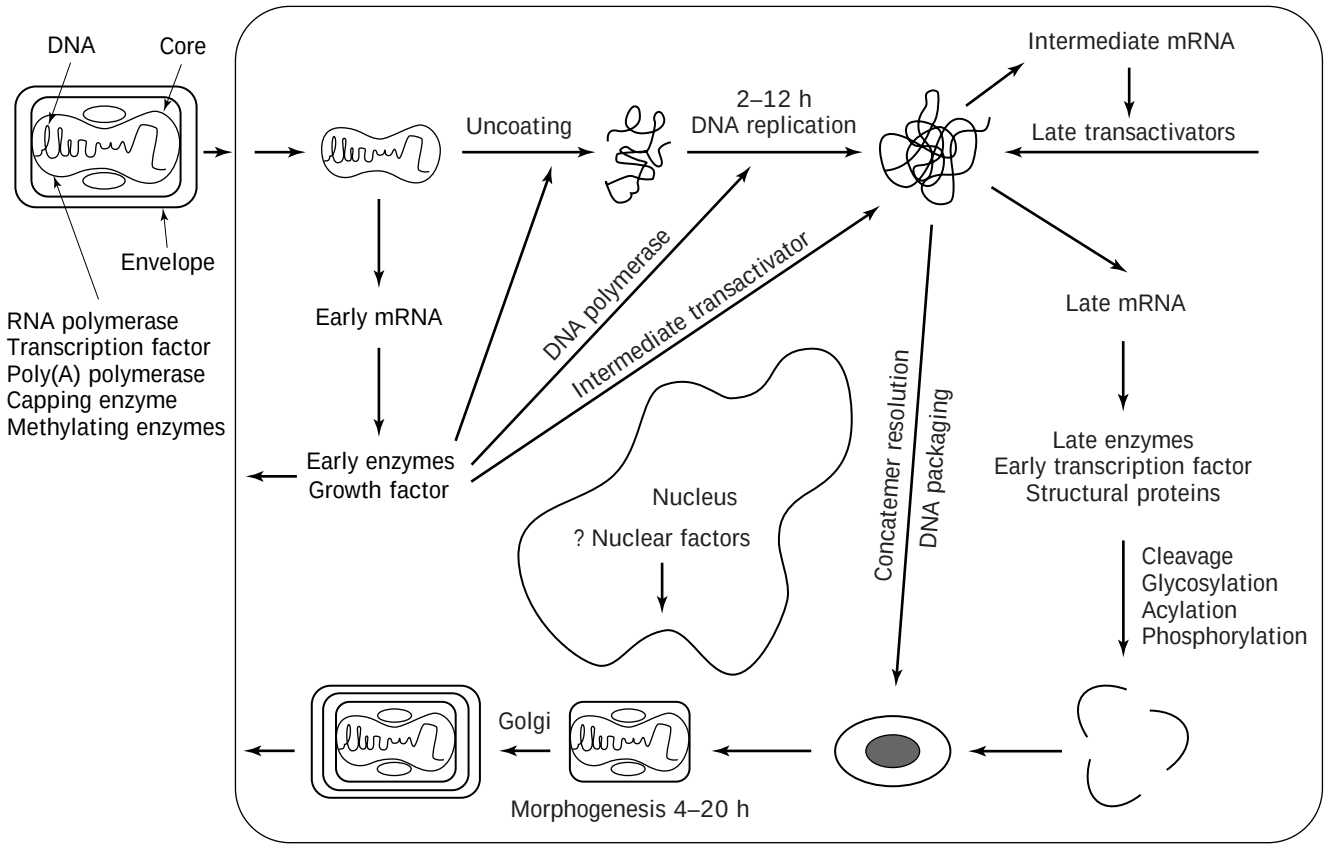

Figure 13. Replication cycle of vaccinia virus. After entry of vaccinia virus into cells, early genes are expressed, leading to secretion of several proteins (including a growth factor), uncoating of the virus core, and synthesis of DNA polymerase (and other replication proteins), RNA polymerase subunits, and transcriptional transactivators of the intermediate class of genes. After DNA replication, intermediate mRNAs are made, some of which encode late transcriptional transactivators, leading to expression of late genes. The latter encode structural proteins, enzymes, and early transcription factors, which are packaged in the assembling virus particles. Some of the mature virions are wrapped in Golgi-derived membranes and are released from the cell. The bold arrows indicate the products that exit the cell. *Source*: Reprinted from Ref. 66, with permission of Raven Press, N.Y.

Table 4. Vaccinia Large-Scale Production

Product	System	Cells	Company	Ref.
HIV-1 rgp160	150-L microcarrier	BHK	Pasteur Merieux	67

proteins), with a tyrosine phosphatase (PTP1C) used as a model in bioreactor-scale cultures of 293 cells (64,65).

As is normally expected, posttranslational processing of Ad-derived recombinant proteins has been shown to be identical to the native protein.

Vaccinia Virus

Vaccinia Virus Characteristics. The vaccinia virus, an *Orthopoxivirus*, belongs to the family of Poxviridae. It has a double-stranded DNA of nearly 200,000 bp and replicates in the cytoplasm of the host cell (Fig. 13). The lipoprotein envelope contains the core structure, including an RNA polymerase, a transcription factor, capping and methylating enzymes, and a poly(A) polymerase.

Infection of cells with the vaccinia virus leads to the suppression of host cell protein synthesis, and cytopathic effects occur. Up to 5,000 virus particles are produced per cell, which, depending on the virus strain, will stay cell associated or can be found in the culture medium.

Table 5. Transient Expression Systems

	Time scale	Advantages	Disadvantages	Applications	Yields
			DNA vectors		
Large T–expressing cell lines (e.g., COS)	3–4 weeks	Established technology Simple to execute Scale up to liter scale demonstrated	Large DNA and cell quantities required for transfection Large-scale transfection Short expression time after transfection (1–2 weeks), overgrowth by non producers Safety category 2–3	Functional and structural studies	0.1–3 mg/L Up to 10 mg protein
HEK293 EBNA	4–8 weeks	Simple to execute Culture scale-up under selective pressure Transfection requires only small quantities of DNA and cells Stable under selection Potential selection of clones Establishing seed: bank possible	Safety category 2	Functional and structural studies, target validation, preclinical studies	0.1–10 mg/L 100 mg protein
			Viral vectors		
Baculovirus	6–8 weeks	Established technology Easy scale-up Safe viral system	Lytic system Nonmammalian glycosylation	Functional and structural studies, target validation, preclinical studies	0.5–30 mg/L gram quantities
Semliki Forest virus	2–6 weeks	Exceptionally short time from gene to product High yields Very broad host range	Safety category 2 for activated virus Limited virus scale-up Lytic system	Functional and structural studies, target validation	Up to 8×10^6 cell Up to 100 mg
Vaccinia	2–8 weeks	Easy scale-up to very large scale Virus simple to scale-up Broad viral host range	Pathogenic: safety category 2 Lytic system	Functional and structural studies, target validation, preclinical studies; vaccines	Around 0.1–5 mg Gram quantities

Vaccinia Virus for Heterologous Expression. For recombinant protein expression, the gene of interest is placed under the control of a vaccinia promoter. Late promoters are preferred for yielding high-level protein expression. Integration of the foreign gene can be accomplished by one of three methods: homologous recombination, direct cloning, or construction of a hybrid of vaccinia with the bacteriophage T7 RNA polymerase.

Homologous recombination is performed by (*1*) subcloning cDNA into a plasmid next to a vaccinia promoter, flanked by nonessential vaccinia gene sequences; (*2*) recombining into the vaccinia genome (cell infection with wild-type vaccinia virus and transfection of recombinant plasmid); and (*3*) screening for recombinant virus.

Direct cloning is performed by inserting the cDNA into a unique restriction site of the vaccinia virus genome, which is packaged after transfecting helper cells (fowlpox virus–infected cells). High-level expression can also be achieved with the vaccinia virus–T7 RNA polymerase hybrid system. This system relies on the cytoplasmic expression of the bacteriophage T7 RNA polymerase (e.g., by a stable transfected cell line). The recombinant gene is inserted into a vaccinia virus under the control of the T7 RNA polymerase promoter. To provide the T7 polymerase, either constitutively expressing cells are infected or cells are cotranfected with a polymerase expressing vaccinia virus.

Advantages of the vaccinia virus system are (*1*) the wide host range of mammalian cells that can be infected, (*2*) the mammalian posttranslational modification machinery, (*3*) the high expression levels, and (*4*) easy production of the virus. A disadvantage of the system is the safety level required when working with vaccinia.

The vaccinia system has been successfully scaled up to very large scale (Table 4).

CONCLUSION

Transient expression technologies have been available for many years and have been applied to many different objectives. Recent novel applications cover the use of these technologies for producing recombinant proteins in amounts sufficient for biochemical and biological studies (100–1,000 mg). Table 5 summarizes the essential features of each technology. A first step common to all technologies presented here is the large-scale preparation of the expression vector (plasmid DNA, mammalian or insect recombinant virus). Speed is the principal motivation (starting from cDNA, the protein is produced within 10–15 days) in contrast to more classical technologies such as stable cell lines, which require selection and amplification of the recombinant gene. In addition, novel routes to pharmaceutical discovery such as human genome sequencing create a serious need for high throughput, medium-scale (10–100 mg of protein) expression systems in order to quickly characterize and evaluate the function of novel gene products. The eukaryotic environment in which most of these transient expression systems operate ensures that elaborate posttranslational modifications are properly carried out and that the protein product obtained provides an authentic representation of its native human counterpart.

OUTLINE

INTRODUCTION

This article covers transport processes in microorganism of industrial importance. General aspects of transport and uptake of solutes are considered, but as far as possible, examples involving industrial organisms are presented. Figure 1 presents a summary diagram reviewing the major types of transport systems in bacterial cells. Recent reviews from a less applied perspective are cited in the bibliography.

Cell Structure and Solute Movements

Solute transport across membranes plays major roles in the physiology of industrial organisms and may determine which solutes are transformed into products or if the organisms can function under the rigors of industrial process environments. Gram-positive bacteria generally have a single cytoplasmic or protoplast membrane surrounded by a thick cell wall with an elastic peptidoglycan network containing various other polymers and forming a heteroporous molecular sieve that restricts entry of large molecules into the cell. Fungal and plant cells also have thick, heteroporous walls but do not contain the peptidoglycans that are peculiar to eubacteria. The wall is a coarse sieve, whereas the membrane is a finer sieve. In fact, generally only very small solutes pass through the cytoplasmic membrane unless the membrane has specific transport proteins that catalyze movements into or out of the cell. Walled cells generally have what is called osmotrophic nutrition and only small nutrients, for which there are transport systems in the cytoplasmic membrane, can be transformed through the actions of cytoplasmic enzymes. However, bacteria and fungi are noted for secreting hydrolytic enzymes that catalyze breakdown of polymers in the environment. The released fragments then pass through the cell wall to be transported across the cytoplasmic membrane into the cell. Many of these exoenzymes are of major industrial importance, although their primary function for the producing cell is to provide nutrients.

Gram-negative eubacteria generally have two membranes, an inner or cytoplasmic membrane bounding the protoplast, and an outer, cell wall membrane. Both membranes are barriers to solute uptake. The outer membrane is a less-restrictive barrier but does largely prevent movement of larger molecules into the cell unless there are specific receptors for the molecules. Movement even of smaller molecules commonly involves protein porins, which form channels across the membranes. The inner membrane is the equivalent of the cytoplasmic membrane of Gram-positive bacteria and contains transport catalysts for movement of solutes into and out of the cytoplasm. The space between the two membranes contains a thin layer of peptidoglycan, lipoprotein molecules that bridge the peptidoglycan layer and the outer membrane and a variety of enzymes and binding proteins, some of which are involved in solute transport. Small hydrophilic solutes may pass through porins in the outer membrane and be bound by specific binding proteins in the periplasm between the membranes. Binding protein–solute complexes may then interact with specific transport proteins in the cytoplasmic membrane to catalyze transport of the solute into the cell and release of the binding proteins back into the periplasm.

Archeae, which are becoming more and more prominent in biotechnology, have cytoplasmic membranes with ether-linked lipids rather than the ester-linked lipids of other organisms and contain phytanols rather than the more usual types of fatty acids of eubacterial and eukaryotic cells. Various protective envelope structures external to the membrane have been described, but none contains the peptidoglycans characteristic of most eubacterial cells. The membrane transport systems of the *Archeae* are generally similar to systems in eubacterials cells but with differences in the molecular details of the components. Since many *Archeae* are adapted to function in what are considered to be extreme environments, their transport systems are also adapted to function at, for example, high temperatures,

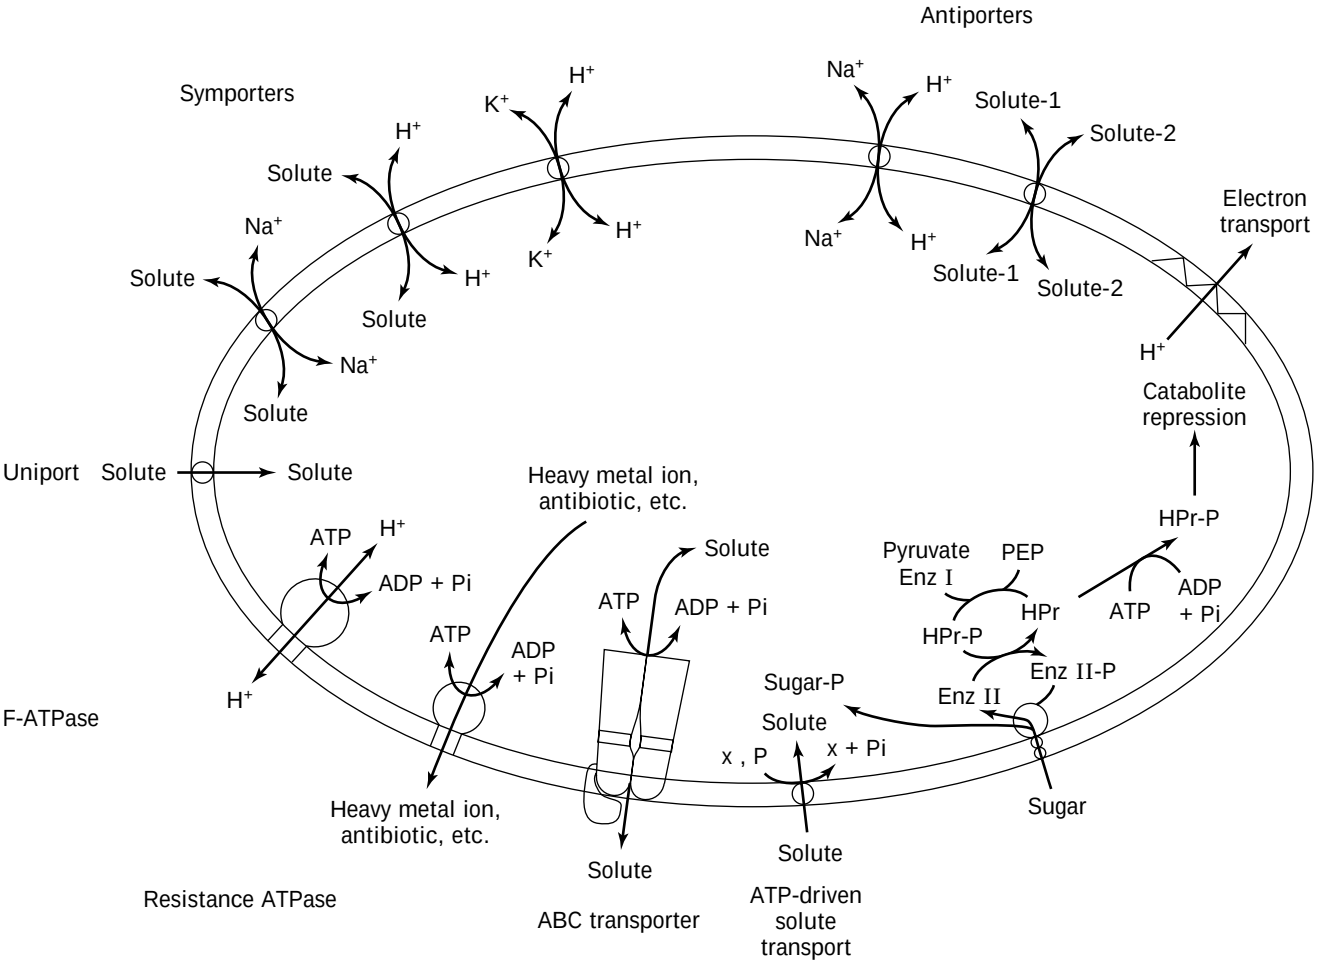

Figure 1. Solute transport systems.

low pH values, very high salt concentrations or low oxidation-reduction potentials.

Eukaryotic organisms used in industrial microbiology include yeasts and other fungi, but also animal cells used, say, for production of monoclonal antibodies, and increasingly, plant cells. Most eukaryotes have multiple membranes that regulate solute transport into and out of the cells and also into and out of the various organelles within in the cells. Indeed, these organisms nearly all have a mix of prokaryotic and eukaryotic characteristics. For example, their major energy-transferring organelles, mitochondria and chloroplasts, are derived from prokaryotic endosymbionts and so have modified prokaryotic membranes and transport systems.

Transport in Biofilms

Special problems of solute transport may be encountered in biofilms, which are important in many biotechnological applications ranging from food fermentations to sewage treatment. Entry of solutes into and out of these consortia of organisms associated with a surface is generally controlled by diffusion across the surface of the biofilm. The situation is often one in which there is flow of a fluid over the biofilm and passage of solues from the fluid across the surface of the film into the polysaccharide matrix and thence into the cells. The passage of solute generally follows the Fick diffusion equation, $dS/dt = PA(\Delta C)$, where dS/dt is the change in the amount of solute in the biofilm per unit of time, P is the permeability coefficient (which has units of distance divided by time), A is the surface area for diffusion, and ΔC is the difference in solute concentration between the interior and exterior of the biofilm surface. Theoretical aspects of antibiotic diffusion into biofilms have been reviewed by Stewart (1), and his analyses can be applied to other solutes.

The biofilm may be mainly exposed to air or other gases. However, the film is still covered by a liquid, and passage, say of O_2, is from the gas phase into the liquid phase and thence into the biofilm. O_2 movement into the film is limited, and biofilms generally contain a diversity of aerobic, facultative, and anaerobic organisms with stratification of the anaerobes away from the surface. Many or most biofilms are penetrated by aqueous channels that may help to deliver solutes to lower parts of the consortium. Nutrients may be leached from solid substrata by biofilms, but again, the limitation on leaching is commonly surface-limited diffusion.

Biofilms have long played key roles in industrial processes ranging from vinegar production to sewage treatment. Our appreciation of them is growing, and they are likely to play even more prominent roles in the future. As mentioned, they allow for wide biodiversity in populations, and this diversity is key in many types of biocatalysis involving cometabolism. They also allow for coexistence of genetically engineered organisms that otherwise would not be competitive. They serve also to mute adverse environmental influences so that members of the community have time to undergo phenotypic or even genotypic adaptations in response to environmental stresses. Certainly, it is well know that cells in biofilms are far more resistant to biocides than are cells in open cultures. However, biofilms do present special challenges in terms of supply of O_2 and other solutes and diffusion of products away from the consortium.

PRIMARY TRANSPORT SYSTEMS

In cells, the primary mechanisms for energy transfer from fuel to function include substrate-level phosphorylations, such as those of glycolysis and other fermentative pathways, and so-called chemiosmotic processes first elucidated by Peter Mitchell. The hypothesis of chemiosmotic energy coupling was based on two fundamental insights. The first involved realization that biological membranes allow for charge separation across a hydrophobic barrier and a conversion of chemical bond energy to electrical energy. During respiration or photosynthesis, protons are moved out of the cell or organelle, such as a mitocondrion or chloroplast, to create a gradient of pH and charge across the membrane. The potential energy of the charge separation was defined by Mitchell in terms of the protonmotive force (Δp) expressed in volts or millivolts

$$\Delta p = \Delta\psi + z\Delta\text{pH}$$

where $\Delta\psi$ is the electrical potential across the membrane (measured experimentally or calculated by use of the Nernst equation), ΔpH is the pH difference across the membrane, and z is equal to 2.3 RT/F with R being the gas constant, T the Kelvin temperature, F the Faraday constant, and the multiplier 2.3 is for conversion of natural log to base 10 log.

The Δp potential energy can then be transferred to synthesis of ATP, to solute movements across the membrane, or to other endergonic processes such as motility. Mitchell's other major insight was that there was associated with the membrane an ATPase that could catabolize synthesis of ATP from ADP and inorganic phosphate in association with proton movements back into the cell. Thus, the electrical energy associated with charge separation across the membrane could be converted back to chemical bond energy. These enzymes are generally called F-ATPases and have the peculiarities that they can operate reversibly and do not become phosphorylated during their catalytic cycles. They are the major agents for chemiosmotic ATP synthesis in respiring and photosynthetic organisms. For example, in the average human, they catalyze synthesis of some 70 kg of ATP per day. The equivalent enzymes of *Archeae* are generally called A-ATPases, and they are able to couple charge separation across the cell membrane to ATP synthesis.

F-ATPases serve major functions even in nonrespiring, fermentative organisms. For example, fermentation commonly results in acid production, and the F-ATPases act to move protons from dissociated acids out of the cytoplasm to develop ΔpH across the cell membrane with the interior alkaline relative to the exterior.

It is now apparent that chemiosmotic energy transfer can involve sodium ions (ΔpNa) and sodium-transporting ATP synthases (2). The ATPases responsible for this type of transfer are distinct from the enzymes responsible for proton-based energy transfer. Proton-based systems are more common than Na^+-based systems, but the latter are widely distributed among prokaryotes.

SECONDARY TRANSPORT SYSTEMS

ATP-Dependent Transport

F-ATPases play a key role in acid-base physiology by transporting protons out of the cytoplasm to reduce internal acidification. This role is clearly important in many industrial fermentations in which acid is produced (e.g., in vinegar production) or in which there is an acidification phase before production of another metabolite (such as in the butanol fermentation by *Clostridium acetobutylicum*). For the bacteria involved in a wide range of processes from yogurt production to acid leaching of copper ores, F-ATPases are needed for the organisms to operate under acidic conditions. Brewing or wine making also are examples in which acidification precedes ethanol production. Yeasts are eukaryotes, and their plasma membrane ATPases, which are not of the reversible F-type, are important for moving protons out of the cell. Also, the vacuole-ATPase (V-ATPase) of the organism appears to be important for acid tolerance. The V-ATPases are multisubunit enzymes with hydrophilic and hydrophobic membrane-embedded components involved in proton pumping or other ion movements. The actions of V-ATPases are not reversible, and so they do not serve for chemiosmotic ATP synthesis. The yeast must then depend on glycolysis for ATP under anaerobic conditions of ethanol production or on the F-ATPases of their mitochondria under aerobic growth conditions.

In bacteria, ATPases other than F-ATPases also are involved in ion movements across the cell membrane. These ATPases are often what are called P-ATPases because they become phosphorylated during their catalytic cycles. Among the best known are heavy-metal-transporting ATPases (3) that play major roles in the resistances of many bacteria to heavy metals such as cadmium. Bacteria also have multisubunit ATPases for the transport of mineral ions such as K^+, Na^+, and CA^{2+}.

ATP can also serve as the energy source for transport of macromolecules across cell membranes, either into the cell or out of the cell, as reviewed by Palmen et al. (4). An example in the dairy industry concerns metabolism of proteins such as casein in manufacture of cheese and related

products. As described by Poolman et al. (5) for *Lactococcus lactis*, the proteolytic pathway involves initial cleavage of proteins by proteinases outside of the cell membrane, in this case mainly the so-called Prt-P proteinase. The cleavage may release free amino acids, which are then transported into the cell by standard amino acid transport systems, mainly energized by Δp or by antiport systems. The products of Prt-P hydrolysis are a wide variety of peptides. Di- and tripeptides can be transported into the cell by means of specific transport systems with relatively broad specificities energized by Δp (Dtp-P transport system) or by ATP (Dtp-T system). The peptides are then broken down in the cytoplasm to amino acids. Oligopeptides can be transported into the cell by the oligopeptide transport system, which is an example of ATP binding cassette (ABC) system consisting of two membrane-spanning proteins, two ATP-hydrolyzing subunits, and a binding subunit associated with the outer face of the cytoplasmic membrane. Oligopeptides are then hydrolyzed in the cytoplasm to amino acids by a variety of peptidases. Oligopeptides are the major source of nitrogen for the organism when it is growing in milk. ABC transporters commonly work in the opposite direction to catalyze movement of polymers out of the cell and so are important for many industrial processes such as production of polysaccharides or enzymes and various other proteins.

Phosphoenolpyruvate-Dependent Transport

The phosphotransferase system (PTS), or as it is now more commonly called, the phosphoenolpyruvate:sugar phosphotransferase system, plays major roles in sugar transport in facultative bacteria. However, it appears that the system may be more widespread among organisms and may play major regulatory roles, especially in catabolite repression (6). The biochemistry of catabolite repression has been elucidated for Gram-positive bacteria such as *Bacillus subtilis*. Repression involves an HPr(Ser)-kinase, which can be activated by fructose-1,6-bisphosphate or gluconate 6-phosphate. The kinase can phosphorylate the HPr protein of the PTS at serine-46. The HPr-P can then combine with CcpA (the repressor-activator protein mediating catabolite repression and glucose activation) and fructose-1,6-bisphosphate to form a complex that binds to the cis-acting DNA sequence called the catabolite repression element (CRE) to inhibit transcription. Thus, many Gram-positive bacteria are able to regulate metabolism in response to rises and falls in cytoplasmic levels of glycolytic intermediates. In Gram-negative organisms, catabolite repression involves cyclic AMP and cyclic-AMP-receptor protein, as described in standard textbooks. Catabolite repression is important in many industrial microbiology processes and allows for sequential utilization of mixed substrates, often to allow mainly growth initially and product formation subsequently, for example, in many antibiotic fermentations.

A major function of the PTS is uptake of sugars. The system has common elements, specifically HPr protein and enzyme I, which catalyze transfer of phosphate from phosphoenolpyruvate to a histidine moiety on HPr. The PTS has elements designed for specific sugars, notably IIC proteins or peptides, which are the actual permeases embedded in the cytoplasmic membrane for catalysis of sugar transport across the cell membrane and phosphoryl transfer from enzyme IIB to the incoming sugar. For many of the industrial lactic acid bacteria, the PTS is the major agent for sugar uptake, although nearly all PTS-positive bacteria also have alternative systems for sugar uptake, especially if sugar fermentation plays a major role in their physiology. Thus, for example, dairy lactic acid bacteria may take up milk sugar lactose by a PTS or by transport systems energized either by Δp or ATP.

Proton-Motive Force–Dependent Transport

Coupling of Δp to transport is a very direct means for energy transfer. This coupling is dependent on what is often referred to as *the energized membrane*. The advantage to the organism in direct coupling is obvious, and direct coupling occurs not only for solute transport but also for functions such as motility. However, there can also be disadvantages because the energized state of the membrane is very sensitive to environmental changes. Energizers such as ATP or PEP generally are not released from cells unless there is major damage to membranes. However, Δp can be discharged by a variety of mild insults including exposure to weak acids, which can enter the cell in the protonated state and dissociate within the cytoplasm to diminish the ΔpH component of Δp. This sort of discharge can occur to a degree when weak acids such as formate, acetate, or lactate are produced metabolically. The discharge then puts additional energy demands on the organism, requiring additional catabolism for growth and maintenance of cell functions. The uncoupling may actually be an advantage in many fermentation processes, permitting high production of metabolic products with less production of cells. The discharge of ΔpH can also be of advantage in applications such as the use of fluoride to inhibit acid production by the plaque bacteria that cause dental caries. Fluoride acts in the protonated form, HF, to bring extruded protons back into the cell and thereby to reduce acid tolerance and the capacities of cariogenic bacteria to produce acid at low pH values (7).

Δp-dependent systems occur widely for uptake of small solutes. For example, uptake of many sugars is coupled to proton reentry. Thus entry of galactose, lactose, rhamnose, fucose, and so forth can be coupled through symport proteins to proton movements back into the cell. Many organisms also have PTS systems for the same sugars. We have found for oral streptococci that use of a system for galactose uptake coupled to proton movements, rather than the PTS, actually reduces acid tolerance of the organisms (8).

Δp-coupled uptake and excretion of a wide variety of organic solutes is known to involve proton symport or antiport. For example, lysine is taken up by *L. lactis* through a proton symport mechanism. In the same organism, the transport systems for Leu/Ile/Val, Ala/Gly and Ser/Thr are also dependent on Δp (9). Citrate uptake is commonly coupled to movements of protons back into the cell. Antibiotic

resistance in many organisms may have its base in transport systems that move antibiotics out of the cell. Perhaps the best example is that of tetracycline efflux systems in a number of organisms involving antiport of tetracycline out and protons or K^+ in. Multidrug efflux pumps occur also in a variety of organisms and have recently been reviewed by Nikaido (10).

Now that the specifics of Na^+-based energetics are well established (2), it is clear that organisms such as *Propionigenium modestum* depend on ΔpNa, rather than ΔpH, for coupling transport of various solutes to movements of Na^+. In any organism, there can be a mix of Δp and ΔpNa coupling, but in general in the biological world, Δp coupling is predominant.

In general, the biopolymers within cells have a net negative charge and a need for cations to neutralize the excess charge. The potential across the cell membrane ($\Delta\psi$) reflects a nonequilibrium state in metabolizing cells. However, it is a component of Δp that can serve to energize transport. Generally, it is considered that $\Delta\psi$ can be converted readily to ΔpH, and so it is often difficult to separate $\Delta\psi$-driven processes from ΔpH-driven processes. It should be appreciated that a large fraction of the cations within cells, predominantly K^+, are retained simply for charge neutralization. If the cell membrane is damaged in a walled organism, such as a eubacterial cell, there is an efflux of solutes, but there is also a retention of cations as counterion for polymers that cannot exit readily through the porous wall. Of course, when the membrane is damaged, the major agent for selectivity of solute entry is damaged, and cation exchange can occur readily. Movements of mineral ions across membranes by symport and antiport play major roles in cell physiology. A good example is in the capacities of many organisms, predominantly bacteria, to function at alkaline pH values. The most common basis for this ability is H^+/Na^+ antiporters that move protons into the cell to reduce the cytoplasmic pH value in association with movement of Na^+ out.

Energy Recycling Systems

Microorganisms often are able to use transport systems for energy conservation. One of the early proposals for this sort of conservation involved glycolysis by dairy streptococci (11). Glucose is catabolized by these organisms to yield lactate. At higher pH values, lactate excretion is electrogenic because more than one proton is excreted per lactate anion. This excretion then results in Δp across the cell membrane, which can be converted chemiosmotically to chemical energy in the form of ATP through the action of F-ATPases.

Another example pertinent to industrial fermentations is that of the malolactic fermentation carried out by *Oenococcus oenos* and related organisms and important in production of wine, cider, and a variety of fermented beverages. Malate is transported into the cell where it is decarboxylated by the malolactate enzyme to yield CO_2 and lactate, which are then moved out across the membrane in association with protons to create Δp (12). The use of the conserved energy in the Δp can then allow for some 25 to 50% increase in growth yields of the organisms.

Symporters and Antiporters Not Coupled to Δp or ΔpNa

As already reviewed, the energetic coupling of Δp or ΔpNa to solute movements into and out of cells commonly involves mechanisms of symport and antiport. Thus, the potential energy of a gradient of protons or of sodium ions is translated into kinetic energy of movement of other solutes, or the electrical potential across the cell membrane may be the basis for movement of counterions into the cell to reduce the potential. Other types of symporters and antiporters may not be so directly coupled to the energized state of the membrane. A good example is the ornithine/arginine antiport system of many organisms that use the arginine deiminase system (ADS) for ATP synthesis or for neutralization of cytoplasmic protons through production of ammonia (13). The ADS involves three enzymes, arginine deiminase, ornithine carbamyl transferase, and carbamate kinase, plus an antiporter. ATP is synthesized in association with the carbamate kinase–catalyzed reaction. Ornithine is produced in the reaction catalyzed by ornithine carbamyl transferase. It exchanges with arginine so that substrate is brought into the cell, and product is excreted without the need to make use of the ATP produced by the system. This exchange allows for operation with a net gain in ATP, and many organisms can grow with arginine as fuel without need for respiration. In fact, oxygen often is repressive for the ADS. CO_2 is produced by the system, and it can diffuse out of the cell. The other main product, NH_3, reacts with protons within the cytoplasm and serves to maintain acid-base balance in many organisms.

TRANSPORT ASSAYS

Various methods used to assay transport of molecules into cells have been reviewed recently (14), with distinction made between assays primarily for determining permeability of a cell or cell component to a particular compound, and those for assessing the activities of transport systems for active movement of solutes across the cell membrane. Also, methods are reviewed for assessing Δp from its two components, ΔpH and $\Delta\psi$, and for assessing osmotic responses of cells.

In practical situations, cell permeability often is key for entry of solutes into cells. For example, gases are hydrophobic and generally pass readily through hydrophobic membranes. In industrial fermentation in which O_2 must be supplied to aerobic or facultative organisms, the major barrier to be overcome in supplying the gas is at the boundary between the gas phase and the liquid phase. O_2 is relatively insoluble in aqueous solution, and so a high concentration cannot be built up in the aqueous phase of a culture. For a rapidly respiring microbial population, supplying sufficient O_2 can be nearly impossible. Efforts are made then to increase the surface area for diffusion of O_2 into the culture by sparging. Also, pure oxygen may be used to increase supplies. Still, it is common for the cells to be starved for O_2, which passes readily from the medium into the cell as it becomes available. Metabolically produced gases, such as CO_2 and H_2, also pass readily across the cell membrane so that cells do not build up stores of

the gases. In fact, gas bubbles generally do not form within cells unless special structures are produced by the cell, such as the gas vesicles used for flotation by certain aquatic microorganisms (15).

Perhaps the most important solute that enters cells without specific transport mechanisms is water. All cells are highly permeable to water, even bacterial spores; and when cells are mixed with water labeled with tritium or deuterium, equilibration of the labeled water generally occurs in seconds. Indeed, osmotic equilibration of water can occur in milliseconds. Other small solutes may also penetrate rapidly. In fact, labeled urea or glycerol is commonly used to assess the total water space of cells because of their ready movement into the total water volume of cells. Recently, the roles of ubiquitous major intrinsic proteins (MIP) in movements of water and neutral solutes across membranes have been studied (16). Hydrophobic solutes may also readily enter biological membranes, especially if they are of low molecular weight. Higher molecular weight hydrophobic solutes also may enter the membrane readily but may remain there and cause membrane dysfunction (17). Mention was made earlier of the effects of organic weak acids on membranes related to movements of the protonated forms into and through membranes (18).

For measurements of passive permeability of cells to solutes, thick suspensions of cells can be used, and the disappearance of solute from the suspending medium assayed. The uptake process is generally not saturable at high solute concentrations, although cells may passively concentrate solutes, especially at low concentration, because of passive binding, for example, binding of cations to negatively charged polymers in the cell wall, membrane, or cytoplasm. For assays of active transport, much less dense suspensions of cells are generally used. Cells and suspending medium may then be separated by centrifugation or by membrane filtration. In some cases, there is no need to make the separation. For example, in assays of proton movements into cells, the pH electrode detects protons outside the cell but not those within the insulating membrane. Thus, as protons move into the cell, the pH value measured by the electrode rises. From the level of pH rise and knowledge of the volumes of cells and suspending medium, the flow of protons across cell membranes can be calculated. When transport depends on metabolism, provision must be made for such metabolism, which may supply ATP, serve to energize the membrane, or produce solutes that may exchange with other solutes in the medium, for example, in arginine/ornithine antiport. In many cases, it is difficult to allow for adequate metabolism, and for example, measurements of movements of protons or other solutes into cells may be affected very much by the experimental conditions. Maintenance of Δp is particularly sensitive to changes in experimental conditions. The cell membrane is at least moderately permeable to protons, and cells must work to maintain ΔpH. If the proton-extruding functions of the F-ATPase are upset, or if proton permeability of the membrane is increased, say, by weak acids, then ΔpH declines and the energized state of the membrane declines. Similarly, $\Delta\psi$ may also be affected adversely, say, by agents such as gramicidin or lantibiotics that enhance membrane permeability to ions.

REGULATION OF TRANSPORT

Transport systems may be regulated in association with the catabolic systems they serve. The best-known example is that of the *lac* operon. The operon contains the gene *lacY* for lactose permease. The operon in *Escherichia coli* is derepressible by β-galactosides and also controlled by catabolite repression involving cyclic AMP and cyclic-AMP-receptor protein. Thus, the permease system is synthesized only when needed for transport of β-galactosides into the cell and maintained at a very low level when β-galactosides are not present. However, genes for transport proteins need not be in the same operon, or even the same regulon, as the genes for metabolism of the transported substrates. An example pertinent to industrial microbiology involves the inducible transport systems for citrate in organisms such as *Lactobacillus rhamnosus* (19). This organism and related organisms are important for flavor development in fermented products through production of diacetyl and acetoin. These products are produced in association with increased consumption of citrate or pyruvate from the environment. The transport system for citrate is repressed in the presence of glucose but becomes derepressed when glucose is exhausted. Thus, flavor enhancement follows derepression of citrate transport after the main phases of growth and acid production.

As might be expected, key enzymes such as the F-ATPases, are mainly constitutive. There is adaptive regulation of F-ATPase synthesis, but the excursion from minimum to maximum levels is small. Thus, for example, for *Streptococcus mutans* and *Enterococcus hirae*, the range is only three to four times the minimal level (20). These organisms depend on their F-ATPases for maintaining acid-base balance, and so appear not to be able to tolerate repression of synthesis of the enzymes to low values. However, upregulation of synthesis of the enzymes does result in increased acid tolerance, and this sort of adaptive tolerance occurs widely among bacteria. It is of importance in many industrial processes in allowing a variety of organisms to operate under adverse conditions.

One of the best examples pertinent to a wide variety of industrial organisms involves the adapation to adverse osmotic conditions of reduced water activity. Adaptation involves pooling of compatible solutes such as K^+, glycine betaine, proline, or polyols and generally involves upregulation of transport systems and enhanced synthetic capacities (21).

INDUSTRIAL EXAMPLES AND APPLICATIONS

Current knowledge of the molecular details of many of the transport systems of industrially important microorganisms is sufficiently advanced to allow for genetic engineering of improved strains, although to date the major work has been on engineering organisms so that they have systems for export of proteins coded by transferred genes. The range of possibilities for advantageous manipulation of

transport systems is wide. It is generally considered that organisms that are adapted to oligotrophic environments have transport systems geared for obtaining nutrients from very dilute solutions. Part of their strategy for survival involves formation of biofilms to take advantage of the associations of molecules with interfaces. However, they also need to have transport systems with low K_m (Michaelis–Menten coefficient) values. Thus, they are a source for genes for high-affinity transport systems. The possibilities for developing improved strains include extending the range of substrates that can be used by any one organism. For example, most strains of *Saccharomyces* yeasts used for ethanol production are not very versatile in the range of sugars they can utilize. *Kluyveromyces fragilis* is able to metabolize the sugar lactose, and so there is a possibility of developing hybrids that will allow *Saccharomyces* organisms to use milk sugar for alcohol production. The need to extend the metabolic range of an organism is evident also in development of organisms to transform various xenobiotics. Generally, the xenobiotic must be transported before it can be metabolized. Fortunately, many organisms have two separate transport systems for, say, an amino acid: one highly specific and one with lower specificity. Often xenobiotics can be taken up by the system with lower specificity. However, there are still possibilities for engineering high-affinity systems to the level that they favor the xenobiotic over a related natural compound.

Other examples include work on a variety of organisms for antibiotic production. Generally, producing organisms need to be resistant to the antibiotics they produce, and for example, resistance to tetracyclines can depend on efflux systems. Resistance to heavy metals also commonly depends on efflux systems, often involving efflux ATPases. Mention has already been made of bacterial adaptation to acid conditions and the role of proton-transport systems in the adaptation. However, adaptation to alkali environments in certain foods or in industrial processing also depends very much on transport systems, often K^+/proton antiport or Na^+/proton antiport (22).

Another area in which there has been a great deal of activity concerns excretion of proteins by various genetically engineered organisms. Often simply transferring the genes for synthesis of a particular protein from one organism to another does not result in a useful producing strain. In fact, the transfer can be lethal if the protein cannot be excreted.

OUTLINE

INTRODUCTION

Tyrosine phenol lyase (TPL) is a pyridoxal 5′-phosphate (PLP)–dependent multifunctional enzyme catalyzing a degradation reaction of L-tyrosine into phenol, pyruvate, and ammonia. TPL is produced by enterobacteria grown in the medium containing L-tyrosine as an inducer. A crystalline preparation of the enzyme was obtained from two bacterial strains, *Escherichia intermedia* and *Erwinia herbicola*, and their properties were elucidated. The genes of TPL (*tpl*) were cloned, and their nucleotide sequences were determined. The molecule of TPL consists of four identical subunits, each with a molecular mass about 50 kDa, and binds four molecules of PLP per tetramer. The three-dimensional structure of apoenzyme form of TPL (apo TPL) has been refined at 2.3-Å resolution. TPL biosynthesis is regulated transcriptionally, and the DNA binding regulator proteins, TyrR and CRP, are working in this regulation system.

The enzyme catalyzes the synthesis reaction of 3,4-dihydroxyphenyl-L-alanine (L-DOPA) from pyruvate, ammonia, and pyrocatechol in a one-step reaction. L-DOPA is an effective agent in the treatment of Parkinson's disease.

Kakihara and Ichihara (1) reported that phenol is produced from L-tyrosine by an intestinal bacteria, not through stepwise degradation, but through primary fission of the side chain. The tyrosine-inducible enzyme responsible for this conversion was named *β*-tyrosinase and elucidated to be PLP dependent. The recommended name of this enzyme is tyrosine phenol lyase (deaminating) (EC 4.1.99.2).

Apparently homogeneous preparations of TPL were prepared from cells of *Escherichia intermedia* and *Erwinia herbicola* grown on media supplemented with L-tyrosine. The crystalline preparations of the enzyme catalyze a series of *α,β*-elimination (equations 1 and 2), *β*-replacement (equations 3–5), and racemization (equation 6) reactions. The reverse of the *α,β*-elimination reaction to synthesize L-tyrosine or L-DOPA (equations 7 and 8) was also found to be catalyzed by the crystalline preparations of the enzyme (2).

$$\text{L-Tyrosine} + H_2O \rightarrow \text{pyruvic acid} + NH_3 + \text{phenol} \quad (1)$$

$$\text{L-Serine} \rightarrow \text{pyruvic acid} + NH_3 \quad (2)$$

$$\text{L-Tyrosine} + \text{pyrocatechol} \rightarrow \text{L-DOPA} + \text{phenol} \quad (3)$$

$$\text{L-Serine} + \text{phenol} \rightarrow \text{L-tyrosine} + H_2O \quad (4)$$

$$\text{L-Serine} + \text{pyrocatechol} \rightarrow \text{L-DOPA} + H_2O \quad (5)$$

$$\text{L-Alanine} \rightarrow \text{DL-alanine} \quad (6)$$

$$\text{Pyruvic acid} + NH_3 + \text{phenol} \rightarrow \text{L-tyrosine} + H_2O \quad (7)$$

$$\text{Pyruvic acid} + NH_3 + \text{pyrocatechol} \rightarrow \text{L-DOPA} + H_2O \quad (8)$$

The bacterial cells containing this enzyme catalyze the synthesis of L-DOPA from pyruvic acid, ammonia, and pyrocatechol in significantly high yields, and this reaction is used in industrial production of L-DOPA (3).

PROPERTIES OF TPL

TPLs have been purified and crystallized in the laboratory (4,5,6) from cells of *Escherichia intermedia* and *Erwinia herbicola* grown in a medium supplemented with L-tyrosine by a procedure including cell disruption by ultrasonic oscillation, ammonium sulfate fractionation, protamine sulfate treatment, DEAE-Sephadex column chromatography, hydroxyapatite column chromatography, Sephadex G-150 gel filtration, and crystallization. Photomicrographs of the crystalline holoenzyme prepared from *Erwinia herbicola* are shown in Figure 1.

Crude and partially purified preparations of the TPL were preserved at 5 °C in 0.01 M potassium phosphate buffer, pH 6.0, containing 5 mM mercaptoethanol. Variations in pH in the range of pH 6.0 to 7.0 had little effect on enzyme stability. Outside this range, however, the rate of inactivation increased rapidly. Solutions of highly purified enzyme were less stable than those of partially purified preparations. For example, a sample of the enzyme from *Escherichia intermedia*, with a specific activity of 1.94, lost to 6 to 10% of its initial activity after standing for 2 days at 5 °C in 0.01 M potassium phosphate buffer, pH 6.0, containing 5 mM mercaptoethanol.

The crystalline enzyme preparations could be stored at 0 to 5 °C as suspensions in 10 mM potassium phosphate buffer, pH 6.0, containing 5 mM mercaptoethanol and 60% saturated ammonium sulfate. The specific and total activity of the enzyme remained constant for periods of more than 1 month. Preservation in this fashion constituted the best storage procedure.

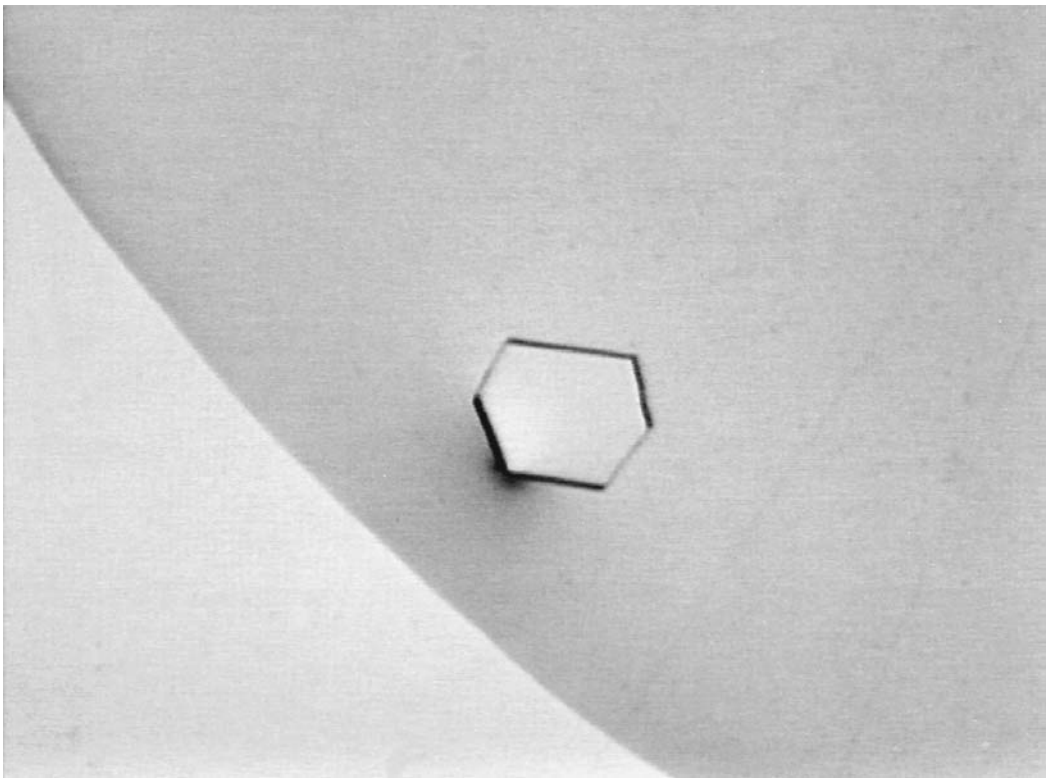

Figure 1. A photomicrograph of the crystalline holo TPL prepared from *Erwinia herbicola*.

On heating, the crystalline enzyme was rather stable up to 40 °C, but above 50 °C, it was rapidly inactivated.

Recrystallized enzyme preparations gave a single band on acrylamide gel electrophoresis. The molecular weight of the enzymes was estimated about 200,000, and that of the subunit is about 50,000. The gene cloning and subsequent nucleotide sequencing gave the molecular mass of the subunit 51,439 Da for *Escherichia intermedia* TPL and 51,364 Da for *Erwinia herbicola* TPL (7,8). These data indicate that TPL has homotetramer structure.

The enzyme has been shown to have cofactor requirements (5). Crystalline TPLs prepared by the above procedure showed negligible activity when assayed in the absence of PLP; they are purified as the apoenzyme. Half the maximum enzymic activity was obtained at the respective PLP concentrations of 1.3×10^{-6} M and 1.5×10^{-6} M for the enzymes from *Escherichia intermedia* and *Erwinia herbicola*. On association with PLP, pronounced absorption maxima appeared at 340 and 430 nm. Absorption in the 410 to 440 nm region is characteristic of many PLP enzymes and has been attributed to a hydrogen bound azomethine of PLP. The absorption maxima of holo TPLs were not appreciably shifted by variations in pH between 6.0 and 9.0.

The crystalline enzymes from *Escherichia intermedia* and *Erwinia herbicola* showed a similar requirement for K^+ and NH_4^+ for their maximum activities. However, Na^+ was inactive.

The amount of PLP bound by the apoenzyme was determined by chemical and spectrophotometric titration methods. The results obtained from these two procedures indicated that there are two PLP binding sites per molecule of enzyme. The crystallographic studies showed the existence of sulfate residue at the binding site of phosphate residue of PLP, suggesting the prevention of PLP binding to the binding site. The proper number of PLP molecules bound is estimated to be four per tetramer.

The catalytic properties of the enzyme have been determined with the crystalline TPL from *Escherichia intermedia*. The enzyme catalyzed a series of α,β-elimination, β-replacement, recemization, and reverse reaction of α,β-elimination (equations 1 to 8).

α,β-Elimination Reaction

TPLs catalyze the conversion of L-tyrosine into phenol, pyruvate, and ammonia in the presence of PLP (3,4). Pyruvate formation was also observed with β-chloro-L-alanine, *S*-methyl-L-cysteine, L- and D-serine, and L- and D-cysteine.

L-Alanine competitively inhibits pyruvate formation from L-tyrosine, *S*-methyl-L-cysteine, and L-serine. Phenol, pyrocatechol, and resorcinol also inhibit pyruvate formation, but the inhibition was a mixed type. The α,β-elimination reactions proceed optimally around pH 8.2.

β-Replacement Reaction

TPL catalyzed the synthesis of L-tyrosine from L- or D-serine and phenol in the presence of PLP. β-Chloro-L-alanine, *S*-methyl-L-cysteine, and L-cysteine replaced L- or

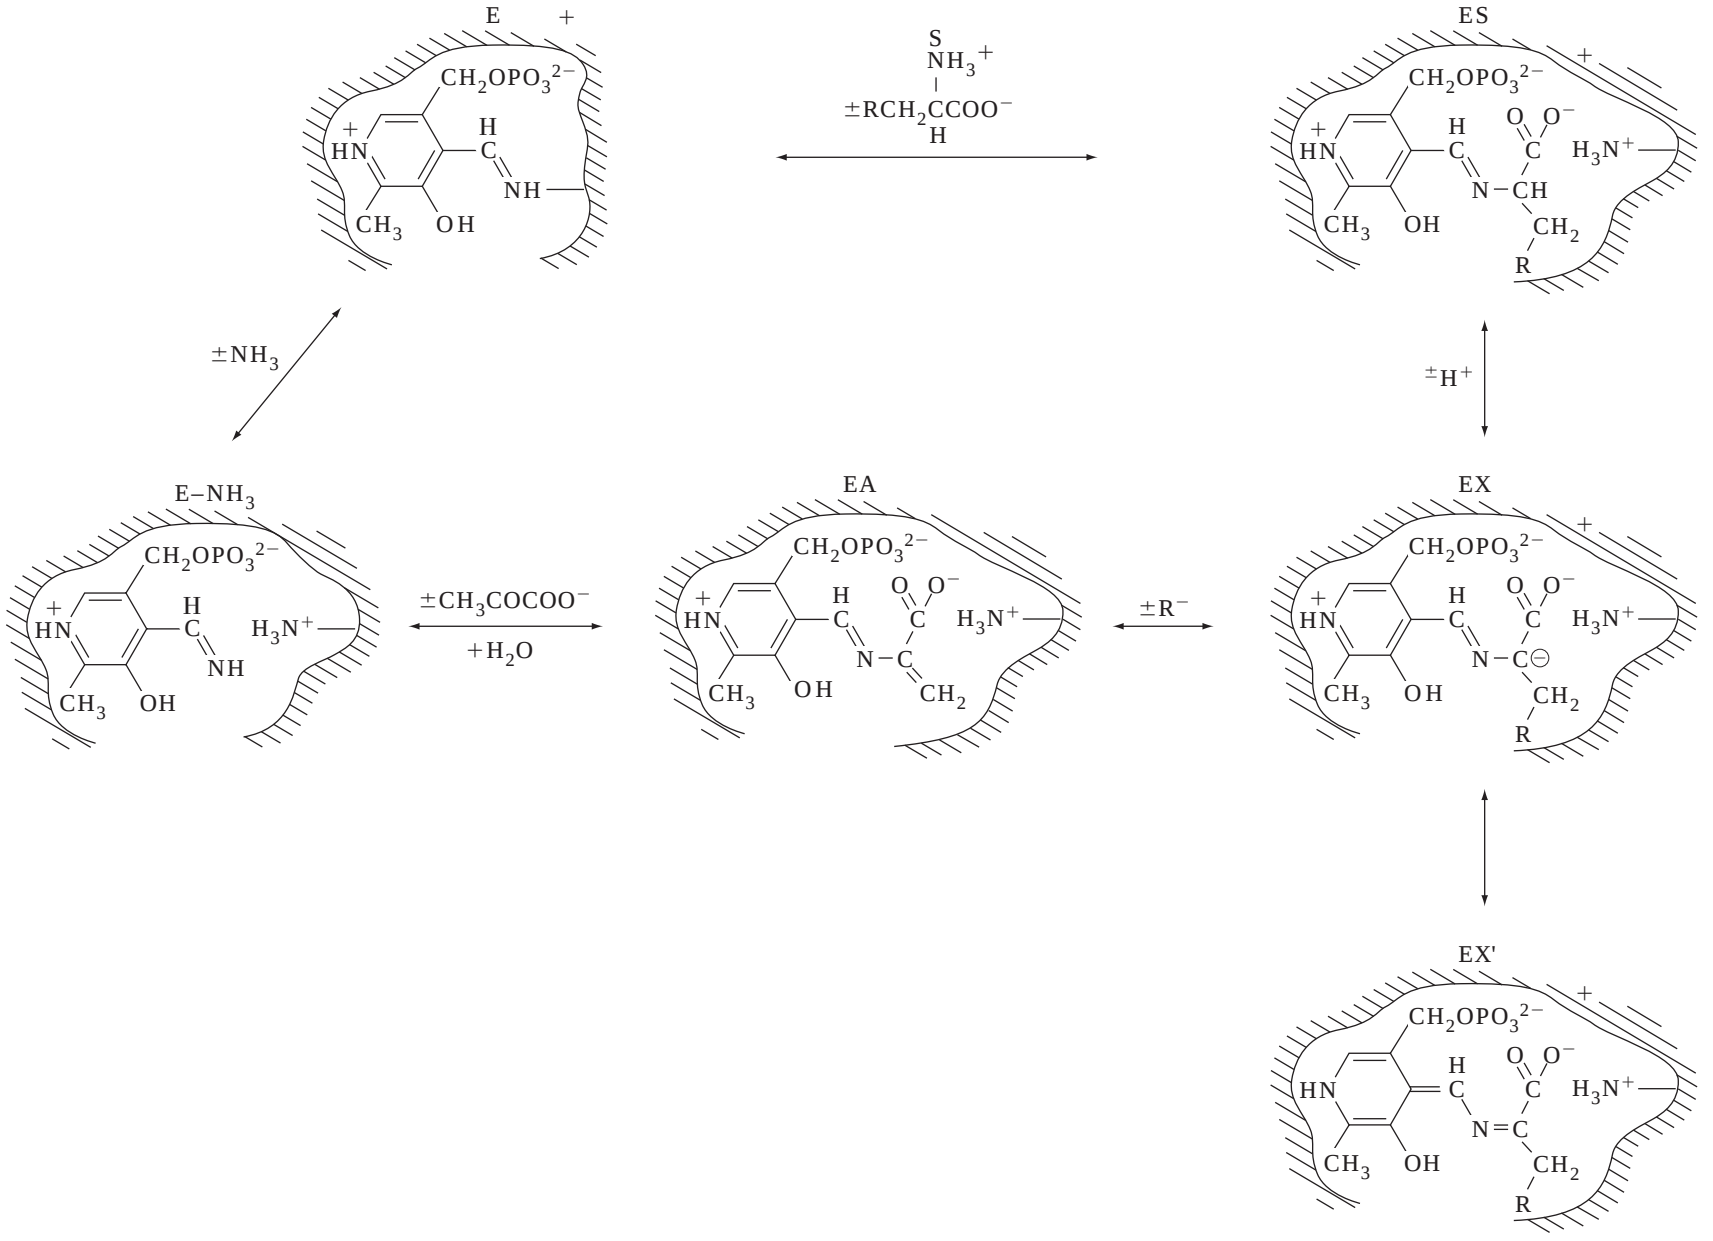

Figure 2. Schematic representation of the mechanism for the reactions catalyzed by TPL. Different species of the enzyme and enzyme-substrate complexes are represented.

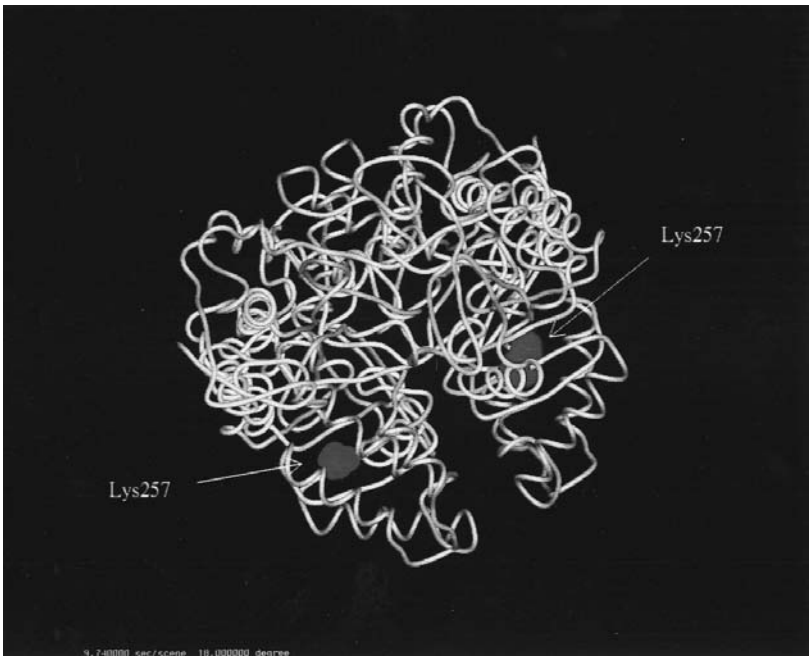

Figure 3. Three-dimensional structure of TPL from *Erwinia herbicola* estimated by computer modeling. TPL has a homotetramer structure, and only dimer structure is shown in this figure. Lysine 257 residues where coenzyme PLP bind are shown by arrows.

D-serine in the synthesis of L-tyrosine (3). When pyrocatechol, resorcinol, pyrogallol, and hydroxyhydroquinone were added to the reaction mixture in place of phenol, L-DOPA, 2,4-dihydroxyphenyl-L-alanine (2,4-L-DOPA), 2,3,4-trihydroxyphenyl-L-alanine (2,3,4-L-TOPA), and 2,4,5-trihydroxyphenyl-L-alanine (2,3,5-L-TOPA) were, respectively, synthesized. These β-replacement reactions proceed optimally at pH 8.0 to 8.5.

Racemization Reaction

The conversion of D- or L-alanine into the racemate is catalyzed by TPL in the presence of PLP (3). The K_m value for L-alanine was 2.6 mM and the maximum velocity of the racemization reaction was 0.05 μmol/min per milligram of protein. The optimum pH for this racemization reaction is between 7.2 and 7.5.

Synthetic Reaction

The synthesis of L-tyrosine from phenol, pyruvate, and ammonia is catalyzed by TPL in the presence of PLP (2,3). This synthesis proceeds as a function of the concentration of phenol, pyruvate, and ammonia. *K* values were obtained by using three substrate kinetics (3). The K_m values for phenol, pyruvate, and ammonia calculated were 1.1 mM, 12 mM, and 20 mM, respectively, and the maximum velocity was 3.3 μmol/min per mg of protein, which is about 1.5 times higher than that of L-tyrosine degradation by the reaction of equation 1.

When pyrocatechol and resorcinol were, respectively, added to the reaction mixture in place of phenol, L-DOPA and 2,4-L-DOPA were synthesized. Cresols (*m*- and *O*-) and chlorophenols (*m*- and *O*-) also replaced phenol to synthesize, respectively, methyl-L-tyrosine (2- and 3-) and chloro-L-tyrosine (2- and 3-) (3).

REACTION MECHANISM

The crystalline preparations of TPL from *Escherichia intermedia* and *Erwinia herbicola* catalyze a variety of α,β-elimination, β-replacement, racemization, and synthetic reactions (3). These reactions are partially explained by adopting the general mechanism for pyridoxal-dependent reactions proposed by Braunstein and Shemyakin (9) and by Metzler et al. (10). This mechanism is shown in Figure 2, with a modification in which PLP in the enzyme is shown as an internal azomethine. The enzyme-bound α-aminoacrylate (EA) is the key intermediate in this proposed mechanism. The α,β-elimination reaction is considered to proceed via steps

$$E + S \rightarrow ES \xrightarrow{-H^+} EX \xrightarrow{-R^-} EA \xrightarrow{+H_2O} E + \text{pyruvate} + NH_3$$

The β-replacement reaction proceeds via steps

$$E + S \rightarrow ES \xrightarrow{-H^+} EX \xrightarrow{-R^-} EA \xrightarrow{+R'^-} EX' \xrightarrow{+H^+} ES' \rightarrow E + S'$$

and the racemization reaction proceeds via steps

$$E + L - S \rightarrow E \cdot L - S \xrightarrow{-H^+} EX \xrightarrow{+H^+} E \cdot DL - S \rightarrow E + DL - S$$

The synthetic reaction of L-tyrosine seems to proceed via the reversal steps of α,β-elimination. The stereochemistry and reaction mechanism of TPL were investigated and reported (11).

GENE CLONING AND STRUCTURE ANALYSIS

TPL genes from *Escherichia intermedia* (12), *Cirobacter (Escherichia) freundii* (7), and *Erwinia herbicola* (8,13) were cloned and their nucleotide sequences were deter-

mined. The amino acid sequences deduced from the nucleotide sequences showed the following homology: 100% identical between *Citrobacter freundii* and *Escherichia intermedia*; 90.6% between *Escherichia intermedia* and *Erwinia herbicola*. The PLP binding site of TPL is determined as Lys 257 (8). The three-dimensional structure of apo TPL of *Escherichia intermedia* was analyzed by X-ray crystallography at 2.3 Å resolution and reported after refinement with primary amino acid sequence of the *tpl* from *C. freundii*. The three-dimensional structure of apo TPL was estimated from that of *Escherichia intermedia* by computer analysis (Fig. 3).

REGULATION OF TPL BIOSYNTHESIS

Induction and repression of TPL of *Erwinia herbicola* were regulated on the transcriptional level; mRNA of TPL was increased by the addition of tyrosine and decreased by the addition of glucose in the medium. The 5′ flanking region of its gene, *tpl*, was analyzed and its transcriptional start point was determined. TyrR box and operator-like region were also found in this region (14). TyrR box is a typical binding site of DNA where a regulator protein TyrR binds and regulates transcription of structure genes of enzymes or transporters responsible for aromatic amino acid biosynthesis or transportation.

OUTLINE

INTRODUCTION

Disease Applications for Vaccines

Vaccines are suspensions of live, killed, or attenuated microorganisms such as bacteria or viruses or components of them. They are designed for human or veterinary use to prime the immune system to produce antibodies or cellular responses that ward off future challenge by pathogenic organisms or their toxins (1–4). *Antibodies* are a group of related proteins that bind specifically to the molecules that induce their formation, *antigens*, and in doing so help facilitate their destruction and clearance from the body. Some molecules, such as carbohydrates, lipids, and small molecules, are themselves poorly immunogenic and must be coupled to proteins to more effectively stimulate an immune response. Although numerous examples exist of vaccines against diseases of bacterial origin (*Haemophilus influenzae, Corynebacteria diphtheria, Streptococcus pneumoniae*, etc.), they are particularly useful prophylactic treatments for viral pathogens, against which antibiotics are ineffective (measles, mumps, rubella, hepatitis B, hepatitis A, etc.). In addition, vaccines have been produced to effectively counteract bacterial toxins such as diphtheria (*Corynebacterium diptheria*) (3) and tetanus (*Clostridium tetanii*) (3) by producing a benign form of the toxin, referred to as a toxoid, by heat or chemical treatment (phenol, formaldehyde, etc.). Vaccines may also offer protection against certain cancers. Hepatocellular carcinoma resulting from chronic hepatitis B infection can be effectively eliminated by preventing the initial infection through vaccination (5–8). Likewise, evidence suggests that certain stomach cancers may be preventable through vaccination with *Helicobacter pylori* preparations (9), or some cervical cancers by vaccination with human papillomavirus vaccines (10,11).

Overview of Preparation

The success of vaccines is most significantly influenced by five factors: (*1*) the nature and dose of the immunogen, (*2*) the adjuvant or excipients used in the formulation, (*3*) the immunization schedule, (*4*) the route of administration, and (*5*) the immune status of the person being vaccinated, influenced by age and disease (2). The vaccine preparations themselves may consist of killed whole bacterial cells or live attenuated or inactivated viral preparations. Alternatively, subunit vaccines are those that rely on recognition of specific components of pathogens by the immune system, instead of the whole microorganism, to elicit a response. These components may include capsular polysaccharides (e.g., vaccines against *Haemophilus influenzae* type b or *Streptococcus pneumoniae*) (12–14), viral coat proteins (15), or other structural components of the organism that can be recognized and responded to by the immune system. Also, recombinant DNA technology provides a means to express subunits of pathogenic bacteria or viruses. For example, a highly effective vaccine against hepatitis B infection has been made by expressing the hepatitis B viral coat protein surface antigen in yeast (15), thereby eliminating the need to the handle infectious blood from which the vaccine was originally isolated. Modern techniques for cell culture, fermentation, isolation, and formulation allow the manufacturer of vaccines of unparalleled purity, specificity, and safety. The high levels of purity offer the advantage of low reactigenicity, with reduced pain, swelling, redness at the site of injection, or systemic effects such as fever. Higher purity presents new challenges, however, in that the highly pure components are typically poorer immunogens than their whole cell counterparts (16–19), driving active research into other agents that can be coadministered (adjuvants) to boost their effectiveness.

Routes of Administration

Vaccines are typically administered intramuscularly or subcutaneously but may be designed, as appropriate, for administration by other routes (e.g., oral polio vaccine). Active research programs exist to study alternate methods for vaccine administration, because most infections are acquired naturally by mucosal routes, either orally, nasally, or genitally, and parenteral vaccines are often poor inducers of mucosal immunity (2). Mucosal vaccines, however, must be designed to overcome the normal rapid clearance, and oral vaccine candidates must be designed to survive the enzymes and pH extremes associated with the gastrointestinal tract (2).

Immunization Strategies

Vaccination strategies include inoculation of individuals who are, because of lifestyle or circumstance, susceptible to a particular pathogen. Alternatively, widespread immunization of a demographic group may be desirable to protect entire populations. This is accomplished in the United States and many other countries through compulsory vaccination of schoolchildren, health care workers, and those serving in the armed forces. This approach has been particularly effective in eliminating the threat of endemic disease in children, such as polio and measles (20,21).

Schedules for vaccine administration vary from product to product and often from one country to the next (4,22). For full and lasting immunity to be achieved, repeated exposure to an antigen may be required (23–25). Therefore, most vaccines are administered through regimens of two to four doses. Even after serum antibody titers drop below detectable levels, immune memory results in a rapid and substantial *anamnestic* response, whereby antibody titers rise rapidly upon revaccination or subsequent challenge with the targeted disease entity (23,25). Table 1 lists a number of currently available vaccines and their administration schedules (2).

It is now widely accepted that the prophylactic prevention of disease through vaccination is an effective and cost-effective means to disease management (4). Smallpox has been eradicated through rigorous worldwide public vaccine programs, and many other diseases have been brought under control, fueling tremendous public optimism in our ability to alleviate morbidity and mortality associated with the many bacterial, viral, and parasitic infections that continue to plague us (20,21). Further applications toward the prevention of reproductive fertility and cancer treatment are also being explored. It is critical at this juncture that continued research into vaccine development and production provide the means to further reduce vaccine costs and make compliance to vaccine schedules easier through the advent of combination vaccines (to reduce required injections) or alternate delivery systems.

EARLY VACCINE HISTORY

Vaccine technology enjoys a rich history with brilliant contributors (26). The first successful vaccine was demonstrated by Jenner in the late 1700s. Jenner had observed that milk maids, who often harbored lesions from benign cowpox infections, were immune to smallpox. He found that a person inoculated with the fluid from a cowpox lesion would be protected from disease if later challenged with fluid from a person with smallpox. The word vaccine is derived from the Latin word *vaccinus*, which means "of or pertaining to cows."

Koch was responsible for advancing the concept that each infectious disease is caused by a single, unique pathogenic species, and whose work with anthrax, cholera, and tuberculosis shook the medical community of his time. Likewise, Pasteur's flamboyant style and flare for publicity popularized the notion, through work with cholera, anthrax, and rabies, that many diseases of animals and people could be prevented or cured. And so early successes with smallpox, cholera, anthrax, and rabies fueled an enthusiastic search for cures and preventative measures for such scourges as diphtheria, tetanus, and polio. Early vaccines for the first time offered hope that the infectious diseases responsible for widespread morbidity and mortality could be prevented.

METHODS FOR VACCINE MANUFACTURE

The earliest vaccine preparations were isolated from tissue fluids obtained from infected people or animals, beginning with Jenner's cowpox vaccine against human smallpox. Through the middle of the 20th century all viral vaccines originated from live or killed whole virus, derived from infected organs or tissues of animals or embryonated hens' eggs (15). Modern methods required for the preparation of vaccines are as varied as the vaccines themselves, tailored to the unique chemical and physical properties of the antigen being cultured or isolated (27–29). Because the course of vaccine treatment is confined to just a few highly potent doses, administered in low volumes (typically a milliliter or less), manufacturing scales for vaccines are small relative to many therapeutic products requiring higher doses or longer courses of treatment.

Propagation of Live, Attenuated Viral Vaccines

The basis for live, attenuated viral vaccines is that by repeatedly subculturing the virus through appropriate host cell lines (e.g., chicken embryo or monkey kidney cell), its virulence can be sufficiently attenuated to avoid a fulminant infection upon inoculation, while still preserving the antigens required to elicit protective immunity. Because viruses are obligate intracellular parasites, they require viable eukaryotic cells for propagation (30–32). The following paragraphs will provide further details on cell culture lines and cell culture techniques that are used in the preparation of vaccines.

Primary Cell Lines. Vaccines have been manufactured by culturing viruses in a variety of animal organs or tissues in vivo or primary cells in vitro. These include embryonated chicken or duck eggs and primary cells obtained from a variety of different animals. Primary cells refer to cells obtained directly from tissue sources and transferred

Table 1. Pharmacokinetic Parameters of Vaccines

Vaccine	Recommended age for first vaccination[a]	Interval for vaccination schedule (mo)	Route	Onset (wk)	Duration (y)	FDA-defined risk factors in pregnancy[b]
			Short-acting vaccines (<2 y)			
Cholera	5 y	0–0.5; every 6 mo	SC or IM (PO) available	2	0.5	C
Influenza	6 mo	Annually	SC	2	1	C
Japanese encephalitis	3 y	0–0.25–0.5; 4 y interval	SC	8	0.5–1	C
Pertussis, accellular[c]	6 wk	0–1–2	IM	4	>1.5	ND
			Moderately short-acting vaccines (2–5 y)			
Haemophillus influenzae b	6 wk	0–2–4–10	IM	16[d]	>4	C
Meningococcus	2–6 y	Single dose	SC	2	3	C
Polio, inactivated	6 wk	0–1–6	SC	6–24	5	C
Typhoid	3 y	4 doses over 1 wk	PO, fasting	1	5	C
			Moderately long-acting vaccines (5–10)			
Diphtheria	6 wk	0–1–2–8; 6 y	Deep SC or IM	8	>10	C
Hepatitis A	2 y	0–1–7	IM	3	5–10	ND
Hepatitis B	2 mo	0–1–6	IM	4–8	5–7	C
Pneumococcus	2 y	Single dose	SC or IM	2–3	5–8	C/X
Varicella	12 mo	0–1	SC	6	5–10	C (D in first trimester)
			Long-acting vaccines (>10 y)			
Measles	9 mo	Single dose; 6 y interval	SC	ND	>21	X
Mumps	15 mo	Single dose; 6 y interval	SC	4	15	X
Polio, live	2 mo	0–2–16	PO	1	>12	C/X
Rubella	12 mo	Single dose	SC	2–4	Lifelong	X
Smallpox	12 mo	Single dose	ID with bifurcated needle	ND	30	X
Tetanus	6 wk	0–1–2–8; 6 y interval	SC or IM	4	12	C
Yellow fever	9 mo	10 y interval	SC	2	30–35	D
			Duration not clear			
Rabies	12 mo	0–0.25–1	ID or IM; postexposure IM	1–2	ND	C
Tuberculosis (BCG)	3 mo	Single dose	ID	2–3	ND	C

Note: BCG = bacille Calmette-Guerin; FDA = U.S. Food and Drug Administration; ID = intradermal; IM = intramuscular; mo = month(s); ND = no data available; PO = oral; SC = subcutaneous; wk = week(s); y = year(s).
[a]Younger children may receive some of the vaccines.
[b]C = animal studies have revealed adverse effects on the fetus (use only if potential benefit justifies the potential risk to the fetus); D = positive evidence of human fetal risk; X = human beings have demonstrated fetal abnormalities or evidence of fetal risk, based on human experience.
[c]Duration is still under investigation.
[d]Also dependent on age.

for the first time into an in vitro growth environment (32). Examples include chick fibroblasts cultured from chicken embryos for the production of measles and mumps vaccines. Cell lines for viral propagation grow either as attachment-dependent or, occasionally, suspension cultures (32).

To produce measles and mumps vaccines, those viruses are grown and attenuated by passage through cultures of chicken embryo cells. Chicken embryos are harvested from eggs, obtained from special isolated flocks, and then minced and treated with disaggregating enzymes such as trypsin, collagenase, hyaluronidase, and pronase. The chick fibroblast cells released by this process are attachment dependent, requiring solid surfaces for growth. The successful commercial manufacture of viral vaccines in attachment-dependent cell systems rely on the establishment and maintenance of healthy cell monolayers. Selection of the appropriate growth and maintenance media are critical, as are careful attention to nutrient depletion, waste accumulation, and changes in pH over time (33).

Diploid and Continuous Cell Lines. Serially passaged diploid strains of cultured human cells were first described in the 1960s by researchers at the Wistar Institute (34). The concept of using human diploid cell lines for vaccine preparation was hotly debated in the 1960s, for fear that

cancer-causing DNA or human viral agents might be unknowingly coadministered with the vaccine. Extensive karyological (i.e., chromosomal) characterization and thorough searches for viral contaminants were necessary to ensure that cultures were free of exogenous infectious agents before the first diploid cell product, poliomyelitis vaccine, was licensed in the United States (11). Human diploid cell lines (WI-38 or MRC-5) have since been used to produce a number of licensed vaccine products against poliovirus, adenovirus types 4 and 7, rubella (German measles) virus, rubeola (measles) virus, rabies, hepatitis A, and varicella virus (chickenpox) (30–32). A distinguishing feature of the human diploid cells such as WI-38 or MRC-5 is that they have a finite life span, reaching senescence after 40 to 60 population doublings (32). In contrast, continuous cell lines exhibit no such constraints and divide indefinitely. An example of a nonhuman continuous cell line that has been used successfully for the manufacturing of vaccines such as polio, rabies, and influenza is Vero (32,35). Vero cells are a continuous monkey kidney cell line (35).

Serially cultured or continuous cell lines are advantageous in that each new production batch is derived from a uniform master cell bank, characterized to be free of contaminating infectious agents, contaminating proteins, or nucleic acids. Proper maintenance of a master cell bank is critically important for the consistency of cell culture products. They are usually stored as small aliquots in liquid nitrogen and tested at intervals for chromosomal (karyology) and cell integrity to establish long-term stability (32).

Cell Culture Reactors. Cylindrically shaped roller bottles have been used successfully to establish monolayers of chick fibroblasts on their inner surfaces, which can be monitored microscopically through the clear plastic. The cell sheets are continuously bathed by a growth medium contained within the bottle during slow axial rotation on special roller racks. After the cell sheets are established, they are infected by introduction of the specific virus. After incubation, the cells and virus may be harvested (e.g., varicella). In the case of rubella, viral fluids may be harvested at approximately 2- to 3-day intervals, through 10 to 12 harvest cycles. Although millions of doses have been successfully manufactured using roller bottles, capacity is limited by the space that a large number of roller bottles requires and by the time-consuming and often labor-intensive manipulations for harvesting and pooling the viral fluids from them. Robotics may reduce the labor burden associated with the latter and have been successfully used by Merck for the manufacture of their chickenpox vaccine, Varivax, in roller bottles (33).

Multidisk reactors offer an alternative to roller bottles for attachment-dependent cell lines (36). They consist of 10-L stainless steel reaction vessels containing approximately 100 parallel titanium disks that slowly rotate through growth media and provide solid surfaces for cell attachment and monolayer formation. In addition to their improved capacity, the stainless steel reactors are jacketed for temperature control. Monolayers cannot be microscopically monitored, however. Another alternative for cultivating attachment-dependent cells was described in 1979 (37) and consists of stacked polystyrene unit trays (NUNC single-tray unit). Again, cell monolayers can be established, infected, and harvested more efficiently than with roller bottles (33). Other solid supports for attachment-dependent cell lines include ceramic or membrane (hollow fiber) solid supports, and microcarriers. Microcarriers may be composed of a variety of materials such as gelatin, polystyrene, cellulose, polyacrylamide, dextran, or glass, but usually are approximately 200 μm in diameter. They offer advantages of improved process control and scaleability because, like suspension cultures, they can be cultured in large-scale bioreactors. They are, however, susceptible to shear stress and physical deterioration and so must be suspended with low-shear agitators (38). For further reading on cell culture techniques for attachment-dependent cell lines and suspension cultures, please refer to *Large-Scale Mammalian Cell Culture Technology* (39,40).

Purified and Killed Whole Viral Vaccines

Examples of purified whole viral vaccines includes those to protect against polio, influenza, and hepatitis A viruses.

For the large-scale preparation of a killed polio vaccine, viral infected Vero cells have been grown on microcarriers in fermenters (35). Purification of the whole virus vaccine is as follows (36). The crude virus suspension is clarified by filtration, then concentrated 250-fold by hollow-fiber ultrafiltration (100,000 Da MW cutoff), which retains >99% of the virus. The virus is further purified by DEAE-Sephadex chromatography and then sterile filtered through a 0.22-μm filter before formaldehyde inactivation.

Traditionally, methods for influenza vaccine manufacture have always involved growth of the virus in embryonated chicken eggs. Recently, a manufacturing process for a formaldehyde-inactivated whole virus vaccine against influenza virus was developed using Vero cells in a microcarrier-based fermentation system (35). Supernatants from microcarrier cultures are clarified before benzonase treatment to digest Vero cell DNA. After formaldehyde inactivation, the product is concentrated by ultrafiltration (200,000 Da MW cutoff) and further clarified by protamine sulphate precipitation. Further purification is accomplished by continuous-flow zonal centrifugation of a 0 to 50% sucrose gradient, followed by ultrafiltration and sterile filtration.

Development of the hepatitis A vaccine began with demonstration that formaldehyde-inactivated virus extracted from the livers of infected marmosets would induce protective antibodies in susceptible marmosets (41). During the years that followed, various cell culture and purification schemes were developed for hepatitis A vaccine preparations (42,43). VAQTA® is one example (44,45), and is a highly purified, formaldehyde-inactivated hepatitis A viral vaccine. The virus is harvested from MRC-5 cells grown in Costar Cubes (46,47) after lysis with Triton X-100, followed by nuclease treatment of the lysate to digest nucleic acids. Concentration of the product is accomplished by adsorption on an anion exchange column and then PEG precipitation. Solvent extraction of the resuspended PEG pellet contributed significantly to the purification, as did the anion exchange and SEC steps that followed. The product is

subsequently formaldehyde inactivated and adsorbed onto aluminum hydroxide.

Purified Subunit Vaccines

The high levels of purity achieved by subunit vaccines have the potential to increase the specificity and significantly reduce the number or degree of adverse reactions associated with less-pure preparations. Their goal is to present the patients' immune systems with the specific feature, be it capsular polysaccharide in the case of *Haemophilus influenzae* or *Streptococcus pneumonia*, or viral coat proteins in the case of hepatitis B vaccines, conserved in all variants of a given species such that specific antibodies produced against it will neutralize the whole organism upon subsequent invasion. These components may be isolated from the organism itself, or expressed by a suitable host through recombinant DNA technology.

Manufacturing processes for subunit vaccines typically have six steps in common (1,48,49), which include (*1*) cell multiplication, either through fermentation or cell culture; (*2*) phase separation to remove cells, if the product is extracellular, or to harvest and wash cells if the product is intracellular; (*3*) product recovery; (*4*) purification; (*5*) polishing; and (*6*) adjuvanting and filling.

Cell Multiplication. The source culture for a subunit vaccine varies, depending on the nature of the product. Examples where components of the pathogens themselves are purified to produce vaccines include *Streptococcus pneumoniae, Haemophilus influenzae* type b, *Neisseria meningitidis, Clostridium tetanii, Corynebacteria diptheria*, or *Bordatella pertussis*. These bacteria are usually grown in batch culture on complex nutrients, such as yeast extract and soy peptone, with addition of specific growth factor supplements, such as hemin, that may be required for growth (50). As a general rule, defined or minimally complex media are sought to minimize purification demands. The antigens of interest, from the above examples, may be capsular polysaccharides (*Streptococcus pneumonia, Haemophilus influenzae*), or protein toxins that are chemically or thermally inactivated (tetanus, diphtheria, or pertussis). Capsular polysaccharide vaccines are sometimes adjuvanted by chemically conjugating them with protein components of other bacteria. Examples are Hib conjugate vaccines in which the capsular polysaccharide of *Haemophilus influenzae* type b is chemically coupled to the outer membrane protein complex of *Neisseria meningitidis*, diptheria toxoid, or tetanus toxoid (12,14). And although the current pneumococcal vaccine is formulated using 23 types of *Streptococcus pneumoniae* (1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19F, 19A, 20, 22F, 23F, and 33F), new pneumococcal polysaccharide–protein conjugate vaccines are being developed to improve T-cell-dependent antibody responses, improve long-term immunologic memory, and otherwise enhance immune responses in young children, the elderly, and other groups at risk for pneumococcal infection (13).

Alternatively, proteins representing key antigenic determinants from a target pathogenic microorganism can be recombinantly expressed in bacterial, yeast, or mammalian cell cultures. Important factors influencing the choice of a host expression system are freedom from adventitious agents (51,52), the scientific and organizational experience with a given system, efficiency of product expression, the need for specific glycosylation patterns for full efficacy, or the desirable purification characteristics. Proteins expressed in *Escherichia coli* are not glycosylated and accumulate intracellularly in inclusion bodies that require denaturation, then refolding to return the protein to its native conformation. Proteins expressed in yeast may be either excreted or accumulated intracellularly as viruslike particles, depending on the construct. Mammalian host systems express proteins extracellularly (17). Yeast and mammalian cell host systems, because they are eukaryotic, are often considered when consistent patterns of glycosylation are important (53). Expression systems are also chosen for their scaleability, so that conditions studied in the laboratory can be more easily applied to full-scale manufacturing. Growth media vary depending on the specific host system and on the recombinant expression system. For example, stable maintenance of a plasmid-encoded protein in yeast or bacteria may depend on a culture medium deficient in a particular amino acid, where the plasmid compensates or a specific host auxotrophy (54,55). Alternatively, the coding region for a particular protein product may be regulated by an inducible promoter, such that product expression is triggered by addition of the appropriate chemical or nutritional component (54,55).

Frozen master cell banks (-70 °C), consisting of clonal isolates tested to ensure purity and stability of expression, are subpassaged to generate a working cell bank. In this way, batch-to-batch consistency and purity can be ensured.

Stirred tank reactors, in volumes of hundreds to thousands of liters, are commonly used to cultivate bacterial or recombinant cultures. The bioreactors are jacketed for control of temperature and sparged to provide appropriate levels of oxygenation. Monitoring may be on-line or off-line, by periodic sampling and analysis, for such parameters as biomass, carbon-source (e.g., glucose) consumption, pH, temperature, dissolved oxygen, etc. Valuable information can also be attained on culture physiology by monitoring head space gases for carbon dioxide evolution or oxygen consumption or volatile organic by-products (e.g., ethanol, in the case of yeast cultures). In addition to proper maintenance of master and working cell banks, equipment maintenance and careful attention to fermentation raw materials are essential to ensure reproducible fermentation results (50,56).

Phase Separation. After the final production phase of cell culture, it is usually necessary to separate cells from the remainder of the fermentation broth. This may be accomplished either by continuous centrifugation or microfiltration. If the product is intracellular, the removal of residual culture media components or antifoaming agents from the whole cells is a useful method to reduce the number of contaminants that must be removed by subsequent downstream steps. Regardless of whether products are intracellular or extracellular, care must be taken to avoid cell disruption by excessive shear or osmotic stress to prevent

cells from spilling their contents. In the case of intracellular product, this would result in yield losses, and for extracellular products, it would result in the cells' intracellular contents adding to the total number of impurities that must be removed by subsequent downstream steps.

Product Recovery. Figure 1 depicts the typical flow of downstream processing from recovery through purification. Intracellular products are liberated by cell disruption, which is typically accomplished using either bead mills or continuous homogenizers. Bead mills rely on mechanical shear, whereas continuous homogenizers create fluid shear by forcing the cell slurry through a small opening at high pressure (50). Bacterial inclusion bodies require solubilization with chaotropes such as urea or guanidine HCl, followed by renaturation in appropriate buffers (1,27). Virus-like particles in yeast may be tightly associated with intracellular membranes, such as endoplasmic reticulum, requiring detergents for liberation (54). Removal of cell debris is often accomplished by filtration or centrifugation. Where concentration of the desired product is necessary, membrane ultrafiltration is common.

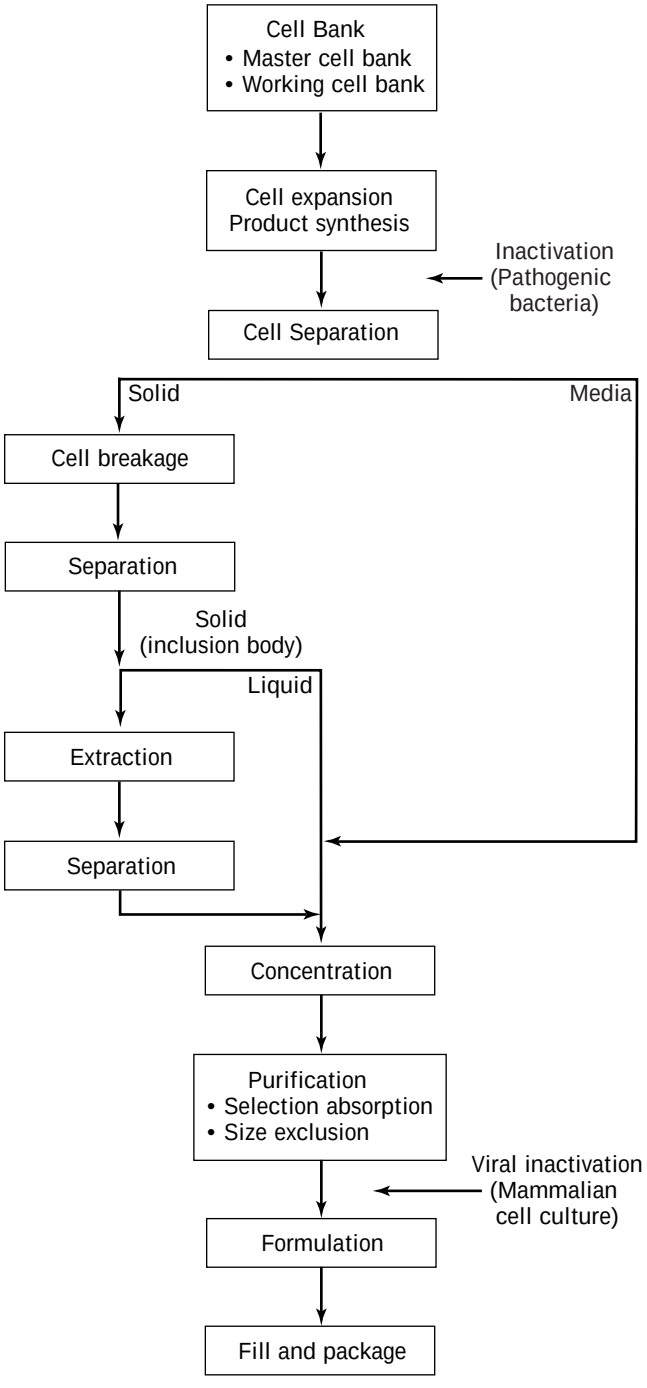

Figure 1. Generic process flow: microbial fermentation or cell culture products.

Purification. Numerous choices exist to accomplish purification, and selection of the most appropriate technologies must be grounded in an understanding of the physical, chemical, and biochemical properties of the starting material and key impurities (1,48,49). Some of the options are outlined in Table 2 (27–29,57). Because yield losses occur at each purification step, the number of steps should be kept to a minimum. This will improve overall recoveries and reduce costs by keeping resource requirements, including raw materials, testing costs, and labor, to a minimum (27–29,48,49,58).

Manufacture of Hepatitis B (Subunit) Vaccines: The original hepatitis B vaccine (HEPTAVAX B®), licensed in 1981, was a subunit vaccine isolated from the blood of hepatitis B infected donors (15). Although derived from infected blood, the final product consisted of a highly purified preparation of 22-nm particles containing HBV surface antigen, subunits of the HBV virus. These particles are expressed in copious amounts by patients suffering from acute infection or in hepatitis B carriers. Although these

Table 2. Downstream Operations for Large-Scale Recovery and Purification of Vaccines

Operation	Physicochemical Property
Cell breakage	
Bead Milling	Liquid/solid shear
Homogenization	Pressure gradient
Cell separation and product recovery

Reverse-phase liquid chromatography	Hydrophobic and hydrophilic interactions

subunits themselves are noninfectious, they are effective in stimulating a strong immune response and provide lasting protection against hepatitis B infection.

The isolation process consisted of (*1*) defibrination of the plasma with calcium; (*2*) ammonium sulfate precipitation, rate zonal centrifugation (sucrose gradient), and isopycnic banding (sodium bromide); (*3*) pepsin digestion; (*4*) urea denaturation/renaturation; (*5*) SEC; and (*6*) formaldehyde treatment. The process not only resulted in greater than 99% purity, but also ensured safety from extraneous infectious viruses through the sequence of viral inactivation steps—pepsin digestion, urea denaturation, and formaldehyde treatment (15).

Problems associated with the manufacture of plasma-derived hepatitis B vaccines included limitations in the supply of source plasma and a manufacturing process that was state-of-the-art at that time, but still laborious and requiring a year or more to complete each batch. In addition, although HEPTAVAX B® had an excellent safety and efficacy profile in millions of people around the world (59), it was not quickly accepted because of growing concerns over AIDS that might be present in the same infectious plasma that served as the source for the vaccine (59). These concerns led to strong public and government pressure to develop a recombinant hepatitis B vaccine for human use, of which RECOMBIVAX HB® was the first. This recombinant hepatitis B vaccine is prepared for human use by expression of the hepatitis B surface antigen (HBsAg) in a recombinant yeast strain that is batch cultured in stirred-tank fermenters. Cells are separated from the fermentation broth, concentrated, and washed with buffer (to remove media components and antifoam) by microfiltration. Cells are lysed to release the HBsAg, which is accumulated intracellularly by the yeast cells, by passage through a high-pressure homogenizer. Phenylmethylsulfonyl fluoride, a protease inhibitor, is added immediately before lysis to prevent proteolytic degradation. Triton X-100 detergent is added to liberate the HBsAg from tightly associated membrane components, and the product is recovered using a microfiltration system. Cell debris and unbroken cells are retained by the filter and eventually discarded, and the HBsAg is recovered in the filtrate. The product stream is ultrafiltered against a 100-kDa molecular weight hollow-fiber filter cartridge to clear small molecular weight contaminants and concentrate the product. Residual detergent is removed by recirculation through polystyrene beads (XAD-4) followed by adsorption of the antigen on colloidal silica (Aerosil). The HBsAg is eluted with warm borate buffer, which interacts with the silica surface to facilitate its release. Final polishing is accomplished by hydrophobic interaction chromatography, using butyl agarose, followed by treatment with thiocyanate to promote disulfide cross-linking of the protein components of the HBsAg particle. Afterward, the product is sterile filtered through a 0.22-mm membrane. The product is adjuvanted by coprecipitation with aluminum hydroxide (60).

Process Ruggedness. Once promising vaccine candidates are identified through research, and their safety and efficacy is proved through clinical studies, strong medical and financial drivers motivate a rapid introduction of the product into manufacturing. Once the manufacturing facility is constructed and qualified, and the final process is established, a consistency series of three to five lots serves to confirm that product profiles are unchanged through the final process and facility scale-up. Data from these full-scale runs support product licensure. Therefore, at the time of licensure, a considerable body of information will have been amassed at laboratory and pilot scale, but full-scale manufacturing data are limited. Because of the speed through which final process scale-up and manufacturing introduction are accomplished, abundant opportunities generally exist to improve manufacturing efficiencies and overall productivity after product introduction. Such changes must be approved by regulatory agencies before incorporation, supported by data confirming that the product's safety, purity, or potency are not diminished.

It is important to be aware of common pitfalls in new process introductions that might later interfere with a consistent product output. Process ruggedness is a key consideration. For example, a single lot of a key reagent, such as a fermentation raw material or chromatographic resin, may suffice to prepare numerous test lots at laboratory scale, and there may be a strong temptation to show process consistency by using a single lot of a key reagent during the manufacturing demonstration. It is absolutely crucial, however, to identify those critical raw materials early in process development and challenge the process with different vendor lots and from multiple vendors, if possible, to better understand the impact that those changes will have later on in manufacturing when much larger quantities will be consumed and when lot-to-lot variations will stress process consistency. Critical process parameters must also be identified early and the process challenged around them to better understand failure limits. In that way, unplanned process deviations associated with equipment failures or operator error can be more easily addressed, and rapid decisions can be made on the quality of a particular lot. Also, the more thorough the understanding of which steps are truly critical to achieving product quality goals, the less likely that a deviation at a noncritical step will result in product discard (52,61,62).

ADJUVANTS

The term *adjuvant* is derived from the Latin word *adjuvare,* which means to help. Adjuvants are used in conjunction with vaccines to aid in eliciting a rapid, high-level, and long lasting humoral or cellular immune response to the target antigen. Their significance is increasing because of the development of more highly purified subunit and synthetic vaccines that are more specific but inherently are less immunogenic. In addition, such vaccines tend to be very expensive to produce, so an effective adjuvant should also allow for the use of less antigen to stimulate the desired level of immunity. Ideally, an adjuvant should (*1*) enhance the ability of an antigen to stimulate a strong and persistent immune response in all age groups targeted for vaccination, whether newborns or older adults; (*2*) allow lower or fewer doses of antigen to be used; (*3*) be biode-

gradable; (*4*) not itself be immunogenic; (*5*) not interact with the antigen to cause its deterioration; and (*6*) be nontoxic and without side effects (63). An important issue for the development of vaccines today for human use is striking a balance between stimulation of a strong immune response and toxicity or other undesirable side effects. Those side effects may be localized or systemic. Local reactions, such as pain, swelling, and redness, can be a result of depot formation (localization of an antigen), which is also a primary mechanism of action of some adjuvants, such as mineral compounds, oil–water emulsions, liposomes, or biodegradable polymeric microspheres. These geltype or emulsion-based-adjuvants increase the half-life of the antigens associated with them, which might otherwise be cleared too rapidly from the body for an effective immune response to be mounted. Alternatively, systemic reactions may develop, depending on the type and amount of cytokines that might be elicited after stimulation of the immune system.

Adjuvant History

In 1916, LeMoignic and Pinoy first described the use of mineral oil and lanolin as an adjuvant emulsion in a killed *Salmonella* vaccine (64). In the 1920s, Ramon showed that immune responses to tetanus and diphtheria toxoids were enhanced when used in conjunction with other compounds such as agar, tapioca, lecithin, starch oil, saponin, or even breadcrumbs (65,66). Later, in 1926, Glenny described the use of aluminum compounds as adjuvants (19,67). In the early 1930s and 1940s, Freund developed his water-in-oil emulsion containing killed mycobacteria that became known as Freund's complete adjuvant. The reactigenicity was reduced significantly by elimination of the mycobacterial component. This modified formulation became known as Freund's incomplete adjuvant and was successfully used in several vaccine formulations (19). In 1956, Johnson et al. reported that lipolysaccharide endotoxins (LPS) from Gram-negative bacteria had adjuvant activity (19,68). This work provided the foundation for further studies into the use of detoxified LPS, or subcomponents such as lipid A (19,69). In 1974, Lederer et al. identified muramyl dipeptide (MDP) as the smallest adjuvant-active component of mycobacteria (19,70). Since then, more than 300 compounds have been investigated in search of those retaining the potent adjuvant activity but without unwanted side effects such as pain, redness, swelling, or fever.

Types of Adjuvants and Mechanisms of Action

Adjuvants are a chemically diverse group of substances that can be categorized based on chemical properties and physical or chemical properties (19). Adjuvants have also been characterized by mechanism of action (19,63,71), including (*1*) causing depot formation at the site of injection (e.g., mineral compounds, oil-based adjuvants, liposomes [72], oil adjuvants, biodegradable polymeric microspheres of >10 mm, etc.); (*2*) delivery vehicles for antigens to target specific immune-competent cells such as macrophages or dendritic cells (e.g., liposomes, oil adjuvants, biodegradable polymer microspheres <10 mm, nonionic block polymer surfactants); or (*3*) acting as immunostimulators (e.g., Freund's complete adjuvant, muramyl depeptide, lipopolysaccharide, lipid A, monophosphoryl lipid A, pertussis toxin, etc.) to facilitate production of relevant lymphokines. Antigens can also be modified to enhance immunogenicity (adjuvant effect) through (*1*) polymerization of the protein constituents using aldehydes (tetanus and diphtheria toxoids); (*2*) cationization of proteins (diphtheria toxoid); or (*3*) chemical conjugation of polysaccharide antigens to carrier proteins (e.g., *Haemophilus influenzae* vaccines), which may provide T-cell epitopes to the coupled antigen or simply increase its effective molecular weight.

The only adjuvants used routinely in human vaccines are aluminum salts (16,19), either aluminum hydroxide or aluminum phosphate (19). These have a long history of safety and efficacy, since it was discovered in the 1930s that suspensions of alum-precipitated tetanus and diphtheria toxoids had a much higher immunogenicity than the soluble toxoids, and their use became common with diphtheria-tetanus-pertussis (DTP) vaccines. Billions of doses have been safely administered. Despite their reputation for safety, alum adjuvants do have some drawbacks. They have occasionally been associated with subcutaneous nodules or allergic reactions. They cannot be frozen or lyophilized without collapse of the gel structure. Aluminum-based adjuvants are primarily effective in eliciting a humoral as opposed to cell-mediated response (16). This is a significant limitation when considering their use with vaccines targeting a T-cell response, such as against intracellular viral or parasitic agents such as AIDS or malaria, respectively (19,63,71).

Alum has several forms, including aluminum hydroxide and oxyhydroxides, aluminum phosphate gels (73–76) and precipitated alum [$KAl(SO_4)_2 . 12H_2O$]. Preparation of vaccines or toxoids with aluminum adjuvants is either by coprecipitation of the antigen with the aluminum-based compound ($KAI(SO_4)_2 . 12H_2O$ added to the product (76) or adsorption onto preformed aluminum compounds. Currently, most vaccines are manufactured by the adsorption methods. Their mechanism of adjuvant activity includes (*1*) depot formation at the site of injection, from which antigen is slowly released; (*2*) stimulation of immune-competent cells through complement activation and induction of eosinophils and macrophages; and (*3*) efficient uptake of aluminum-adsorbed antigens due to their particulate nature and optimal size (<10 mm) (21).

Research continues to contribute to a better understanding of adjuvant molecular mechanisms, the biochemistry of the immune response to various diseases, and how to selectively invoke classes of cytokines or immune-competent cells to best suit an antigen's specific purpose (i.e., humoral or cellular response) (19,71). In addition, controlled release of vaccines through the use of biodegradable microspheres may provide a mechanism for single-dose vaccines by either slow or intermittent antigen release. This is particularly important in some developing countries where contact between health care workers and the vaccine recipients for booster doses may be difficult to achieve (77,78).

REGULATORY CONSIDERATIONS FOR VACCINES

Published Federal Guidelines

Vaccine manufacture in the United States is regulated by the arm of the Food and Drug Administration (FDA) known as the Center for Biologics Evaluation and Research (CBER). In addition, the FDA's *Code of Federal Regulations* is a codification of the general and permanant rules published in the *Federal Register* by the executive departments and agencies of the federal government. Title 21, parts 600 to 699, was written with certain vaccines in mind (pertussis, typhoid, anthrax, cholera, polio, measles, mumps, and rubella), but it has evolved to include guidance for the manufacture and testing of all vaccines and many other biological products. Included are sections on personnel responsibilities and training, facilities, equipment, and animal care, record maintenance and retention, labeling, packaging, and shipping.

Parts 210 and 211 of Title 21 provide manufacturers of human drugs, veterinary drugs, and medical devices with guidance regarding current good manufacturing practices (cGMPs). The cGMPs are comprehensive and encompass manufacturing methods, facilities, controls, packaging, storage, and installations for drug operations. Currently, licensure of a vaccine product entails licensure of both the product and procedures by which it was made and tested, packaged, labeled, and distributed (product license) as well as the facility and equipment in which it was made (establishment license). The latter includes air handling systems; water and air supply and testing; personnel, product, and equipment flows; materials of construction for equipment; interior and exterior materials of construction; and cleaning and decontamination procedures. Government inspections are held before product approval and at a minimum of every 2 years thereafter to ensure compliance with existing regulations. Minor adverse inspection observations are presented by the inspectors, at the conclusion of an inspection, to the responsible head of the facility, on form 483. Other mechanisms exist for the FDA to prevent continued distribution or manufacture of products if more severe compliance violations are observed. In any event, the observations from FDA inspections are published and provide manufacturers with information on emerging trends within the FDA (79,80).

Process Validation

Regulations governing vaccine manufacture have evolved and continue to do so. In recent years, that evolution has led to an ever-increasing emphasis on validation, which is a formal method to demonstrate that a given process can accomplish its intended goals consistently and reproducibility. The need for validation of sterilization and cleaning procedures has gained widespread acceptance to ensure that equipment in direct contact with manufactured products is free from extraneous chemical or microbial contamination and from product-to-product or batch-to-batch carryover. In addition, testing procedures used to assess potency, and purity must also be validated.

Increasing emphasis is being placed by the FDA on process validation (81). The goals of process validation are to ensure the consistency of consecutive batches of vaccine using a particular process (82). Each process consists of a series of steps, referred to as unit operations, executed in sequence by a prescribed "recipe." Each of those operations has a specific goal. In the case of fermentation or cell culture, the goal is to increase cell density and expression of the particular antigen of interest. Downstream steps may include release of intracellular antigens through cell disruption, filtration or centrifugation steps, salt or alcohol precipitations, filtration steps to remove small molecular weight contaminants or exchange buffers, or chromatographies to remove contaminants such as unwanted proteins or nucleic acids. Additionally, chemical steps may be required achieve an optimal conformation for enhanced immunogenicity or adjuvant binding. Regardless of the steps, each serves a particular purpose to improve the purity or maintain or enhance the potency of the particular antigen of interest.

To accomplish process validation, a formal document or protocol is prepared delineating those steps critical to the overall success of the process, the intended goals of each of those steps, and the analytical methods required to monitor the consistency of the process to achieve its intended goal. Expectations are established early through laboratory- and pilot-scale runs, and then confirmed upon scale-up to the final manufacturing scale. Those equipment settings necessary to achieve a consistent outcome are referred to as critical process parameters. Analytical measurements of process performance are referred to as critical quality attributes. Prerequisites to process validation include appropriate controls over raw materials; qualification and maintenance of utilities and equipment; calibration and preventative maintenance of scales, gauges, and other mechanical and electronic monitoring devices; comprehensive quality control programs for analytical testing and established procedures for batch review and release; unambiguous manufacturing instructions approved by manufacturing and quality control personnel; and programs for comprehensive training. In addition, validation of equipment cleaning and sterilization are necessary.

Filter validation is another emerging arm of process validation. Goals include insurance that filter membranes, housings, and support components do not leach objectionable chemicals into the product stream during manufacturing and that the filters are sufficiently rugged to stand up to process conditions without integrity failure. Critical process filters are tested before and after use for integrity to provide greater assurance that they performed properly toward their intended goal.

Included among the overall benefits of process validation are the greater understanding of process variables, allowing the manufacturer to more reliably supply customers with the highest quality product with fewer discarded batches.

FUTURE DIRECTIONS FOR VACCINE TECHNOLOGY

Research into vaccine technology continues on many fronts to provide safe, efficacious, and affordable vaccine prod-

ucts. Many at-risk individuals living in Third World and endemic areas do not have ready access to health care, so compliance to the multidose regimens required to achieve full protection may be difficult. Also, cold chains may not exist for those vaccine preparations that must be kept refrigerated to maintain proper levels of potency. Improvements in the thermal stability of vaccine preparations is advantageous (83).

One approach to improve coverage that is being adopted by many vaccine manufacturers is to combine antigens into single preparation so that immunity to two or more diseases can be achieved with a single injection (84). Time-release polymeric preparations are also being explored even for monovalent preparations to achieve repeated antigenic stimulation of the immune system without the need for multiple injections. Other research initiatives seek to eliminate the need for needles for delivery of vaccines through the use of oral vaccines (85,86), aerosolizers for inhalation (87), or needleless devices that use compressed gases at high pressure to deliver transdermal doses of vaccine preparations (88).

A fairly recent development in vaccine technology may offer several advantages over more conventional preparations in terms of manufacturing ease, potency, and flexibility in terms of delivery systems and disease targets. Observations in the early 1990s that plasmid DNA-encoding antigenic proteins can elicit an immune response when injected directly into animals has sparked intensive research and tremendous excitement as well as concern over long-term safety (89). With DNA vaccines, the coding region for a specific antigenic protein is incorporated into plasmids that are amplified in a host bacterial strain, such as *Escherichia coli*, then purified. The bacterial hosts for the coding plasmids are easily scaleable, and generic purification schemes may be possible because the product would always be plasmid DNA. After injection, the naked plasmid DNA yields protein expression in its native conformation, to which both humoral and cell-mediated antibody responses are mounted (90). The DNA constructs can be customized to coexpress both the coding region for the antigen as well as an immune modulator to enhance the immune response or increase its specificity (91,92). The tremendous amount of research in the past few years has led to progress in the development of vaccines against disease targets associated with bacterial, viral, and parasitic infections and provides hope for combating autoimmune and inflammatory diseases (93) as well as cancer.

OUTLINE

INTRODUCTION

The monitoring of exhaust gas is an ideal universal method for fermentation characterization because most biological processes involve exchange or consumption of gases and volatile compounds. Its noninvasive application does not compromise the sterility of the fermentor, providing a clear advantage over in situ probes, which contact the broth. The monitoring of gas concentrations, such as carbon dioxide and oxygen, in the entry inlet and outlet gas streams and incorporated into liquid and gas balances makes it possible to quantify rates of gas utilization on production and respiratory quotient. The use of these data in conjunction with the fast response of the analyzers allows on-line real-time monitoring of the physiological state of the fermentation, including growth kinetics, and substrate consumption and product formation information. This utilization has made the technology invaluable in research and manufacturing for applications such as fermentation optimization, batch-to-batch reproducibility, on-line troubleshooting, process decision making, and inoculation criteria (1,2). The aqueous concentration of organic volatile compounds, such as ethanol, butanol, and methanol, can also be determined from vent gas analysis and have been used to optimize productivity in industrial processes (3,4).

METHODS OF VENT GAS ANALYSIS

A variety of methods are available for monitoring gases. However, only the methods most applicable for monitoring gases of interest to bioprocesses are described here.

Thermal Conductivity

The sensor for thermal conductivity is typically a resistance temperature detector whereby gas is passed over a heated filament and the magnitude of cooling is measured by the change of resistance of the filament as measured by a Wheatstone bridge (5). For a single flowthrough unit, the gas flow rate must be kept constant. Units with a bypass have two flows; one path houses the sensor with two heated coils. The heated gas is transported from upstream to downstream coils, changing their resistance. The bridge circuit with constant current input gives an output voltage in direct proportion to the difference in resistance, with heat input and specific heat assumed constant. For detectors used in gas chromatography, the heat transfer of the sample gas is compared with the transfer of the carrier gas. The rate of transfer depends on the thermal conductivity

of the gas, which is proportional to the square root of molecular weight.

The Wheatstone bridge balances the current through the sample element to restore its temperature to that of the reference. Tungsten resistance wires are used for ambient and low temperature; metallic oxides are used for high temperature (5). The reference and sample detectors are housed in a single metal block with a high heat capacity to minimize errors from transient heating and cooling (6). Instruments are calibrated for the gas to be used and can have a fast response time of 1 s, detection threshold of 30 ppm, and accuracy of 2%. Carbon dioxide is often measured with this technique as the thermal conductivity of CO_2 is about two-thirds that of oxygen and nitrogen. The bypass units where the bulk of the flow bypasses the sensor are less sensitive to gas flow rate fluctuations but have larger response times, 20 s compared with 1 s. Although this technology has been used for many years it does not provide accuracy or long-term reproducibility. It is sensitive to gas flow rate, temperature, and mechanical vibration. Contamination of the sample cell can lead to drift, and frequent calibration is required of these inexpensive devices. Sample pretreatment is often required to remove contaminants by condensation and drying.

Flame Ionization

In this method the sample gas is burned in a hydrogen/air-induced flame. An electrical voltage is applied across two electrodes to remove the resulting ions from the flame. The current created across the two electrodes is a measure of the ion concentration (5). The detector has high linearity and sensitivity (ppb) with a short response time. It is efficient for a variety of organic components, but no response occurs for O_2, N_2, H_2, CO_2, Ar, H_2O, NH_3, or simple organics such as formic acid and formaldehyde. This characteristic makes the method universal for organic analysis by gas chromatography, especially because contaminants, water, air, and ammonia are not detected. However, its application for vent gas analysis is thus limited to ethanol and organic volatiles.

Gas Chromatography

Gas chromatography is the phase separation of gas component by adsorption equilibrium differences between stationary and mobile phases (6). The stationary phase is coated on small solid particles (typically silica or polystyrene) that are packed or coated onto the walls of highly efficient fused silica columns (several meters in length). The particles have an affinity for the chosen gas analysis to achieve separation of gas components based on equilibrium differences. The system requires a carrier gas to transport the gas sample through the stationary phase (typically oxygen-free dry helium), a sample injection system, column temperature controller, and a detector. Thermal conductivity and flame ionization detectors are most commonly used, as previously described. An analysis time of about 5–30 min is typical for each sample, which is much longer than other simpler, faster, and less expensive methods. However, gas chromatography has been used to determine H_2, CO_2, O_2, N_2, and organic volatiles.

Electrochemical Sensors

Amperometric methods can measure oxygen concentration in the vent gas using technology similar to the probes used for dissolved oxygen tension. The Clark principle incorporates the separation of electrodes from the broth using a semipermeable membrane (silicone or polytetrafluroethylene, PTFE) (7,8). A polarization voltage (600–800 mV) reduces oxygen at the cathode (Pt or Au) to peroxide and hydroxyl ions. The resulting current between cathode and anode (Ag/AgCl) is proportional to the oxygen partial pressure. Cl ions are consumed and supplied by the electrolyte (KCl). The probe relies on diffusion between gas, membrane, and electrolyte, which results in a slow response time delay, usually about 10–100 s to reach 63% of total change in dissolved oxygen level. The oxygen diffusion across the membrane results in a temperature-sensitive process. Equally, electrolyte depletion and water loss into the gas stream and membrane fouling make the system prone to drift. Thus, the technology is rarely used for vent gas monitoring.

Zirconia ceramic sensors have been developed for oxygen detection. Thimble-shaped, nonporous, oxygen ion-conducting electrolyte (yttrium-stabilized zirconia) separates two platinum electrodes and the reference from the measurement gas (9,10). The sample gas passes through the center of the sensor tube, contacting the anode platinum electrode, while the reference gas passes between the cathode electrode and the cylinder outer wall. The electrolyte, which separates the two gas phases, is a good conductor of oxygen ions because the ceramic lattice has vacancies for oxygen from the substitution of tetravalent zirconia ions by trivalent yttrium ions. When the oxygen sensor is exposed to a gas mixture, oxygen molecules absorb onto the electrode surface. This changes the molecule concentration on sensor electrode, which in turn changes the charged oxygen vacancy concentrations inside the solid zirconia electrolyte. An electrostatic field is generated from the differences in charge density between the charged oxygen vacancies inside the zirconia electrolyte and electrons in the electrode. The electromotive force (emf) generated across the electrochemical zirconia cell is proportional to the concentration of the adsorbed oxygen. The electrochemical reaction is temperature sensitive and takes place between 600 and 800 °C, requiring good temperature control. Temperature elevation can catalyze a reaction between platinum anode and combustible gases in the sample, resulting in measurement of net oxygen concentration rather than total oxygen concentration (6). For cost-effectiveness as opposed to accuracy, this sensor may be applicable as it is inexpensive, robust, and simple to operate, with accuracy about 1%, suitable for fermentation monitoring (11).

Alternative sensors have been developed for volatile organic species based on solid-state technology. The technology is mostly proprietary, but the sensors are often tin (IV) oxide (SnO_2) and have been demonstrated for ethanol monitoring of fermentation vent gas (12). The gas of interest is detected using two chemically inert electrical conductors of the same composition interfacing with a solid electrolyte. The gas diffuses into the electrolyte and alters

its impedance by a change in the charge density. These inexpensive sensors offer good sensitivity but have slow response times.

Infrared Absorption

The bonds of nonsymmetrical molecules vibrate and stretch from bombardment with infrared radiation, resulting in energy absorption. The specific vibration or rotation of a particular bond only takes place at a given frequency. For infrared adsorption, the molecule must be exposed to radiation of the precise frequency at which the molecular motion occurs. Thus, the fundamental frequencies of vibration and rotation for a particular compound can be used to identify it from a mixture. For fermentation analysis, carbon dioxide is the only gas of interest that can be detected by infrared (IR) because oxygen and nitrogen contain only one element. Most commonly used analyzers are nondispersive, which excludes most wavelengths apart from a few narrow bands of radiation. They are less selective than dispersive analyzers but more sensitive, simple, and reliable (13). Sources of radiation include quartz iodide lamps, tungsten filaments, and nichrome wires (6). A specific interference filter assembly, a monochromator, is chosen to filter out all wavelengths except for a desired wavelength band. The resulting radiation is a narrow band based around the mean of the desired wavelength (4,200–4,400 nm for CO_2). Alternatively, a cell containing the gas of interest is used to isolate the desired wavelength source.

In a typical optical arrangement, such as the Luft analyzer, an optical beam splitter is used to split the single radiation source to two beams, that pass into two separate chambers (Fig. 1). One chamber houses the sample cell and the other the reference cell. Both chambers contain a gas that absorbs at the desired wavelength, and the detector gas is usually the same as the desired gas for analysis. The sample cell is a flowthrough device with inlet–outlet ports designed to have zero dead legs. Its material depends on the corrosivity of the sample, usually stainless steel or Teflon, and the sample window is usually quartz or sapphire (6). Differences of IR absorption occur between the two chambers, reference and sample, generating pressure imbalances. This imbalance distorts a diaphragm that separates two chambers in the detector and forms part of a condenser microphone. A chopper wheel, a perforated or segmented disk, is used to block the radiation from one chamber and to allow radiation to reach the detector through the other chamber. The alternate blocking of the reference and sample chambers allows each radiation to be sampled at the appropriate side of the detector. The alternating flow of radiation produces an oscillating effect on the diaphragm. The amplitude of the oscillations is measured by the capacitance of the condenser microphone, which is correlated to the concentration of absorbed gas. A variation of this analyzer is to use a microflow sensor to replace the capacitance detector. Fluctuating radiation flow, generated by the chopper, is detected by a flow cell. The cell measures the temperature difference between two heated elements in the flow path. The temperature difference produces a corresponding difference of electrical resistance using a Wheatstone bridge that is correlated to the sample gas concentration.

Other alternative detectors include a thermocouple detector made of blackened gold foil to which two wire leads made of dissimilar metals are attached (6). The metals are selected to provide large thermoelectric emf. As the gold foil absorbs radiation, an emf forms between the gold foil and the metal. The strength of the emf is a function of the radiant power absorbed. The entire device is enclosed to minimize heat loss. Pyroelectric detectors absorb IR radiation, which raises the temperature of the ferroelectric crystal sensing element, typically Pd-$LiTaO_3$ (14), or $Pb(Zr_{52}Ti_{48})O_3$ (15,16). Spacing between the crystalline lattice changes as heat is absorbed, which affects the electric polarization of the element (14). Two electrodes are used, one of which is transparent to radiation, and the crystal is mounted between the electrodes. The sample gas concentration is correlated from the voltage required to balance the polarization charge of the crystal.

IR analyzers have been used to monitor CO_2 and organic volatiles such as ethanol for vent gas analysis (17), but they are sensitive to interference from other components of the gas such as water. The accuracy of IR analyzers is reasonable for fermentation processes, typically about 1% of the range, but are prone to drift (as much as 1% full scale per day for both the zero and span). The cal-

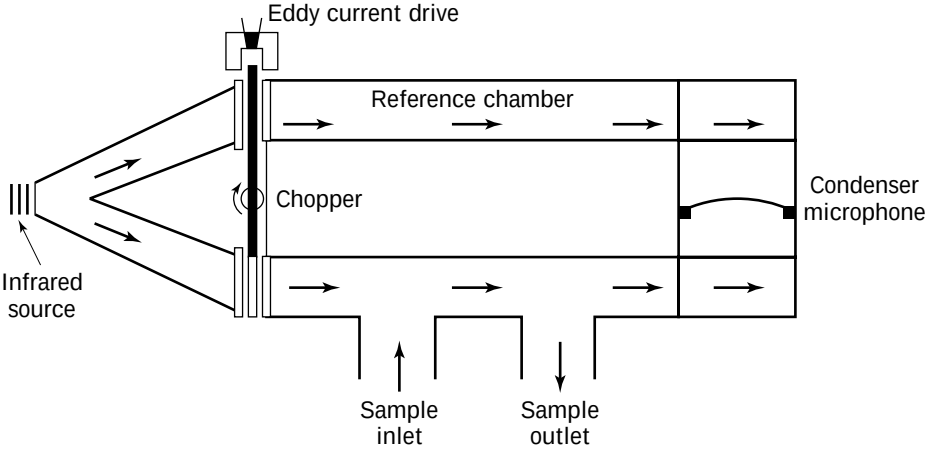

Figure 1. Luft nondispersive infrared analyzer with microphone sensor.

ibration curve is typically nonlinear, which gives added difficulty to frequent recalibration required to counteract drift. However, the 0–90% response time of 0.5–5 s is reasonably fast compared with other technologies already discussed.

Paramagnetism

Gases with unpaired electrons, such as oxygen, generally have high magnetic susceptibility. The unpaired electrons spin around the nuclei in a unbalanced manner. When a magnetic field is applied, the atoms orientate themselves in the orientation of the direction of the field, which has enabled specific instruments to be made for oxygen analysis. The principal instrument, a thermomagnetic analyzer, uses the principle that the magnetic susceptibility is proportional to the difference between sample temperature and the Curie point of 80 °C for oxygen (6). In a typical analyzer, gas flows through a heated magnetic field so that the oxygen becomes less magnetic. Cooler oxygen, which is more magnetic, pushes the hot oxygen, creating a magnetic wind. The magnitude of the flow determines the temperature of the coils, which changes the coil resistance as measured by a Wheatstone bridge. These instruments are sensitive to temperature variations and the thermal properties of the sample gas. Severe calibration shift and slow response times have also been reported (18).

An alternative analyzer is the magnetodynamic analyzer, which measures the mechanical deflection of a rigid test body (dumbbell) caused by the paramagnetic properties of oxygen. The dumbbell consists of two diamagnetic fused quartz spheres (2 mm in diameter) filled with nitrogen and mounted on a rod that is suspended by stiff quartz or platinum–iridium fiber in the cell chamber. A nonuniform magnetic field is applied to the gas sample in the chamber. The oxygen of the sample is attracted toward the most intense magnetic field, and the spheres are displaced until the force is balanced by the torque on the suspended fiber. The resulting torque is proportional to the difference of magnetic susceptibility between test body and surrounding gas. A light ray reflected by a mirror, mounted on the test body, transmits the angular deflection, which is directly proportional to the oxygen concentration in the chamber. Some instruments employ a feedback winding on the dumbbell with an electromagnet to maintain zero deflection, and the oxygen concentration is calculated from the current required. Unlike the thermomagnetic unit, the magnetic analyzer is not affected by temperature or thermal conductivity of the sample. However, care must be taken in orientation of the unit as it is sensitive to vibration. The unit is also sensitive to pressure as the amount of O_2 present in the sensing chamber, rather than the oxygen concentration, determines the balance of magnetic forces (6).

Another type of instrument is the Quincke-type analyzer, which measures the pressure difference when two gases with different oxygen concentrations come together in the magnetic field. The reference gas (N_2, O_2, air) flows through two restrictions so the gas entering either side of the sample chamber has equal flows (Fig. 2). One section of the reference gas is subjected to a pulsating magnetic field, and if oxygen is present then a pressure difference is created between the two reference flows. The Luft capacitance sensor has been used as a detector. Alternatively, Siemens AG developed an analyzer with a microflow detector in a connecting channel that detects the pulsing flow, producing a current proportional to the oxygen concentration (Fig. 2). The separation of the sample from the detector reduces the possibilities of drift and instrument failure from contamination or corrosion of parts.

These paramagnetic analyzers have found to be susceptible to vibration, pressure, and sample conditions with respect to moisture content and flow rate, resulting in frequent calibration to compensate for drift (2). Nevertheless, Quincke-type analyzers have been found to be more robust and have been widely used, including at the Merck & Co., Inc., production facilities. The units are priced similarly to IR analyzers but are more expensive than zirconia sensors. However, they provide only single-component analysis, with susceptibility to moisture and high sample flow requirement, and have poor accuracy (1–2% of range), with slow response times (5–100 s) (19). The units require calibration from drift, the frequency of which depends on care on calibration, maintenance of the machine, and sample treatment (20).

Mass Spectrometry

Mass spectrometry allows simultaneous measurement of both air gases (Ar, O_2, N_2, and CO_2) and volatile substances (including ethanol, acetone, and acetic acid) (21,22) present in the fermentor headspace. A mass spectrometer with multipoint analysis and fast response times (seconds) allows many fermentors and different processes to be monitored on the same instrument. The analysis involves admitting a gas stream to an ion source and then ionizing the molecules by electron bombardment under a high vacuum. The ions produced are subsequently separated, according to their mass-to-charge ratio, by either a magnetic sector or a quadrupole mass filter and detected sequentially. The systems are expensive but offer long-term accuracy and precision, with flexible analysis type and with sub-ppm detection limits and minimum operator intervention.

Vacuum System

The analyzer chamber of a vacuum system is kept under high vacuum (between 10^{-6} and 10^{-8} mmHg) to minimize collisions between particles. At this pressure, the mean free path of particles will be long enough, 50 m as opposed to <0.01 m at atmospheric pressure, and the number of collisions small enough for good analysis (6). Particle collision reduces instrument resolution and sensitivity by increasing kinetic energy distribution of the ions, inducing fragmentation or preventing ions from reaching the detector (23). The vacuum is created in two stages: a roughing pump, which reduces the vacuum to 10^{-3} mmHg, then a diffusion or turbomolecular pump, to obtain pressure as low as 10^{-9} mmHg. The roughing pump is usually a reciprocating mechanical pump lubricated with low vapor pressure oil to prevent oil contamination of the mass spectrometer (6). The diffusion pump uses an oil, often polyphenol

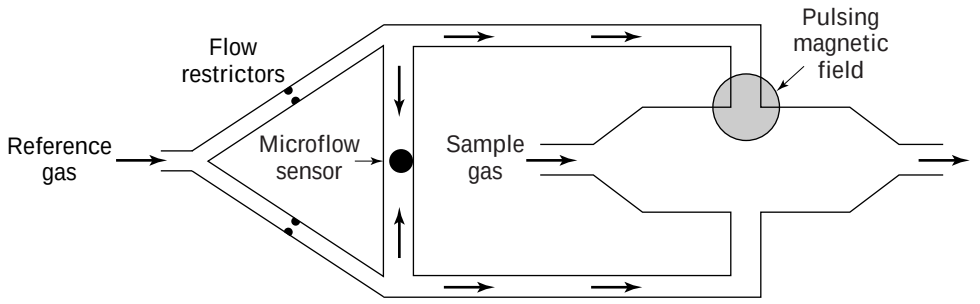

Figure 2. Quincke-type oxygen analyzer with capacitance sensor developed by Siemens AG.

ether, to force molecules out of the vacuum chamber. Oil is heated at the bottom of the pump, causing it to vaporize, and water-cooled coils at the top of pump then allow the oil to cool and condense. Large oil molecules force the smaller molecules down into the pump via momentum exchange, and smaller gaseous molecules exit through the mechanical pump at about 200 L/s. The disadvantage is that diffusion pumps are selective because noble gases are pumped at reduced rates (24). Turbomolecular pumping is mechanical; molecules are forced into the fins of the turbomolecular pump by momentum exchange. Fins revolve at about 10,000 rpm and produce an effective pumping capacity of about 400 L/s. Turbomolecular pumps are often preferred to diffusion types because they cause very low contamination by hydrocarbons and high vacuum is obtained very quickly on start-up. However, turbomolecular pumps are noisy, although they can be muffled to some degree, and highly mechanical, requiring regular servicing.

Sample Inlet

The capillary inlet design is most often used for mass spectrometer sampling, although some systems use a membrane inlet. The membrane material is typically silicone rubber or Teflon, which protects the vacuum integrity of the instrument and separates the analyzer from the atmosphere and contaminates such as foam or water. The membrane inlet has mostly been used for on-line in situ liquid analysis of organic volatiles in the fermentor (21,24–26) and has limited use for vent analysis because the membrane increases the response time to about 30 s. The most popular design is the capillary inlet on which a small representative sample flows from the main sample gas stream, which is continually venting, and "leaked" into the instrument, typically at 20 mL/min (18,27). The constant flow of gas stream from sample line to vent and to the leak of the analyzer means that line flushing can be ignored. The capillary is heated at 80–120 °C to preserve the vapor state of the sample. The rotary pump draws the sample by creating a pressure drop through the capillary. At the outlet, before the ionization chamber, the molecules cross a fritted glass or metal filter to further reduce pressure (13). The response times of such an inlet system can be about 0.5 s, achieved by low dead volumes and maintaining the whole system at 80 °C (28). Volatile components in the gas stream can contaminate the stainless steel capillary by adsorption and desorption, causing larger response times and memory effects from long transition times through the capillary (19,29). These factors can be reduced by using a capillary (diameter, 3 mm; length, 1–3 cm) lined with borosilicate glass that is heated resistively through a stainless steel outer sheath to 150 °C.

Ionization

The most widely used technique is electron impact ionization, where gas passes into an electron beam, resulting in electron ejection and a degree of fragmentation (2). Electrons ejected from a heated tungsten filament are accelerated through an electric field at 70 V to form an electron beam. The vacuum system draws molecules through the sample leak into the ionization chamber. Neutral molecules pass freely through the negatively charged ion repeller in front of the leak and are thermally desorbed into the electron beam, transferring kinetic energy to the sample molecule. The ionization (electron ejection) results in parent ions with the same mass to charge to MW with 6 eV of excess energy (Fig. 3). The excess energy in the molecule leads to some degree of fragmentation to molecular ions, fragment ions, and neutral fragments. A negative ionization step (electron capture) also occurs but is 100 times less efficient than electron ejection. Electron bombardment is most stable and reliable but is complicated by excessive fragmentation. Other soft ionization techniques have been developed: fast atom or ion bombardment, matrix-assisted laser desorption–ionization, and electrospray ionization, which produce only a few fragments. These methods give greater sensitivity and mass range but have primarily been developed for large molecules and solids analysis (23).

Ion Separation

Several methods are available to separate the ions after bombardment: quadrupole filter, magnetic analyzer, time-of-flight detectors, and Fourier transform detectors. The aim is to separate the ions of mass m from the ions of m', which is most commonly done by quadrupole filter or magnetic analyzer because these are easy to operate and compact (30).

The quadrupole filter is a set of four cylindrical rods, typically 125–300 mm long and 6–16 mm in diameter, held in a square array to which an RF and DC potential are applied (24,31). Two rods are connected and two are kept

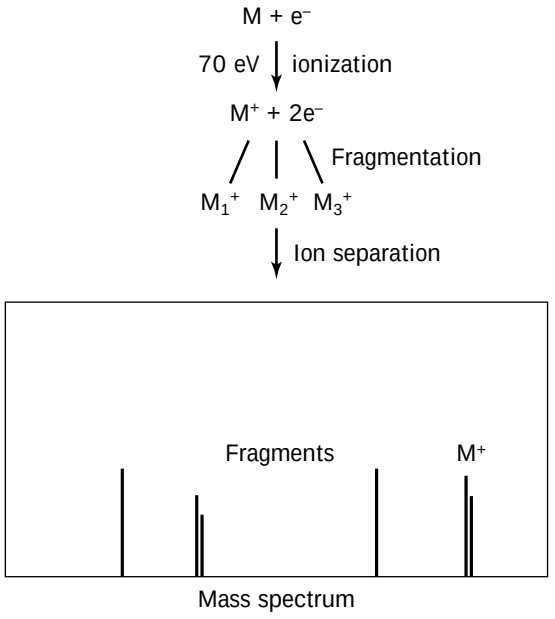

Figure 3. Ionization of molecules (M) producing fragment ions (M_1^+, M_2^+, and M_3^+).

180 degrees out of phase (Fig. 4). This forms crossed, oscillating electric fields perpendicular to the line of travel of the ions between the source and the detector. If the oscillating motion of the ion is out of resonance, the ions strike the walls and are not detected. Applying a certain voltage and RF can control the trajectory of a known mass-to-charge ratio to selectively strike the detector (30). Scanning RF and DC voltages from zero allows ions to be transmitted through the quad filter sequentially in order of their m/z values with constant resolution allowing multiple ion analysis. Resolution attained is determined by the accuracy of control of the parameters U, V, f, and ω radius within the quad rods (30).

The magnetic analyzer uses a magnetic field to separate the different ions. A moving charge passing through a magnetic field will experience a force and travel in a circular motion with a radius of curvature depending on the m/z of the ion. A magnetic analyzer separates ions according to their radii of curvature, and therefore only ions of given m/z will be able to reach a point detector at any given magnetic field (Fig. 5) (30). In a single detector system, an electromagnet is used to adjust the magnetic field to detect any m/z peak of interest (2). Alternatively, a multicollector system is set up whereby each ion fragment is measured by a small number of Faraday bucket collector assemblies, located along the focal plane according to which particular signals are of interest. Single detector systems are more common because they allow the combined use of the secondary electron multiplier that is too large to be used in conjunction with multiple detector systems.

Quadrupole systems are known to be faster, less expensive, and smaller than magnetic sector instruments. Yet the resolution is lower, easily contaminated, and less stable over time, making the magnetic sector a superior choice for industrial on-line monitoring (19,30). The response times of both systems are comparable because the magnetic hysteresis associated with magnetic sectors has been eliminated using laminated magnets. The precision from magnetic sectors comes from the flat-topped peak profiles of ion current versus magnetic field strength that they exhibit (Fig. 5). Thus, peak center and peak height can be precisely determined. Any minor drifting that may occur from temperature fluctuations has no effect, which results in high stability, accurate peak jumping, and long periods between recalibration (up to several weeks for fermentation application). Absolute accuracy is less than 0.05% for O_2 and less than 0.1 for N_2. Quadrupole filters exhibit a Gaussian-type peak profile and are more susceptible to drift (see Fig. 4) and temperature variation. Reduced accuracy and precision result in more frequent calibration. Insufficient resolution leads to an abundance sensitivity problem whereby peak discrimination is difficult at low concentrations with adjacent peaks. Experience with mass spectrometers at Merck during the past two decades favors the magnetic sector as opposed to quadrupoles. VG Gas Analysis Systems manufacture both quadrupoles and magnetic sectors and have shown improved accuracy and drift by a factor of 2 for magnetic sectors over quadrupole systems (27,29). Nevertheless, a considerable number of useful applications for fermentation vent gas analysis have been demonstrated using quadrupole systems (32,33).

Ion separation is still the limiting factor for mass spectrometry, however, because soft ionization produces larger molecular weight ions. Quads with electron ionization have been used since the 1950s but have found new utility when coupled with electron spray systems for solution analysis; however, this method has not been applied to vent gas analysis (23).

Detectors

Faraday cup and secondary electron multiplier are the two common detectors used for mass spectrometry. In the Faraday cup, ions pass the beam-defining slit of the cup and strike a metal dynode plate of a secondary emitting material, such as BeO, GaP, or CsSb, that induces several secondary electrons to be ejected and temporarily displaced. This temporary emission of electrons induces a current in the cup and provides a small amplification of the signal when an ion strikes the cup (23). The signal is measured by a electrometer and is directly proportional to the ion concentration. For the single-collector system, with a single amplifier and auto gain switching, high precision can be maintained over the widest range. In this arrangement any such drift is equal for all components and can therefore be compensated for by using any internal standard (2). The secondary electron multiplier (SEM) is a series of dynodes (about 10) maintained at ever-increasing potentials. Ions strike the dynode surface, resulting in emission of secondary electrons that are attracted to the next dynode where again secondary electrons are generated. A cascade of electrons is produced, transferring from plate to plate in a cycloidal flow path between two glass plates.

The signal amplification or current gain of an electron multiplier is 10^6 with a lifetime of 1–2 years, limited by

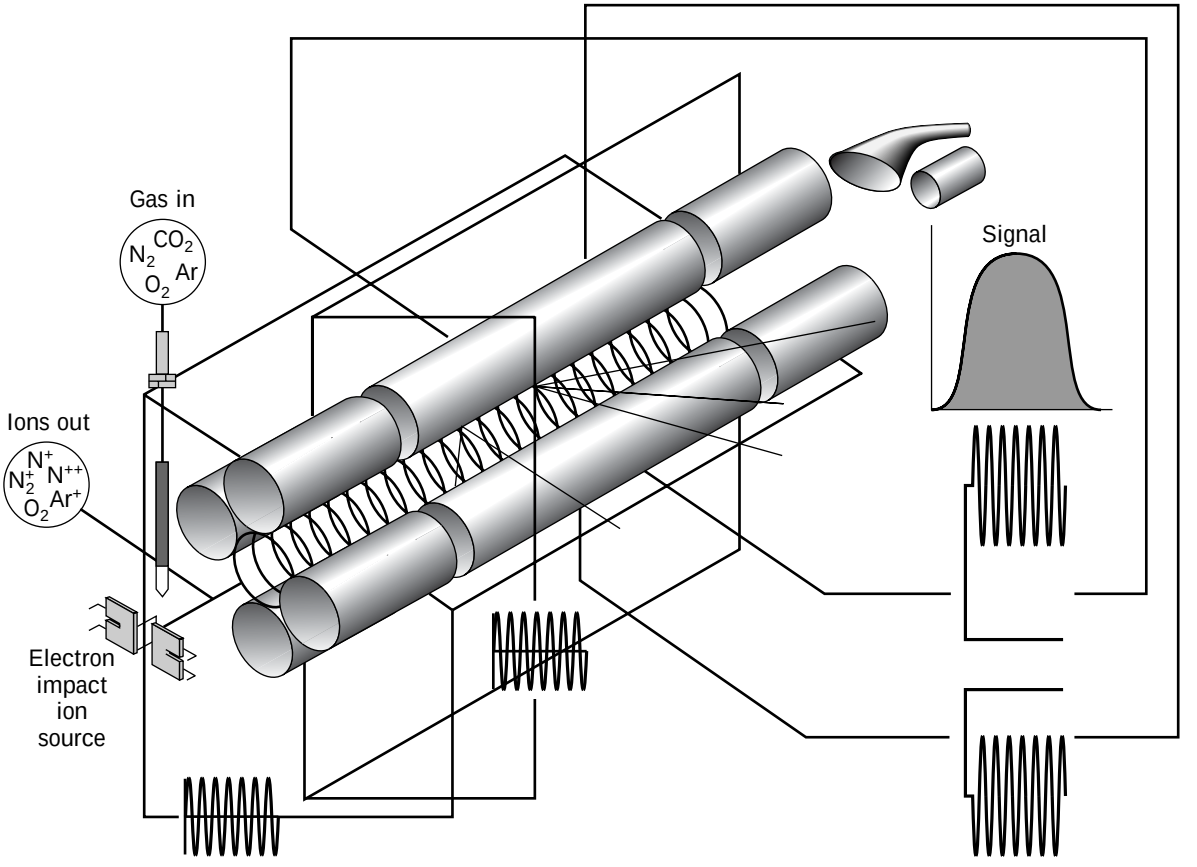

Figure 4. Quadrupole mass filter configuration and Gaussian-type profile curve for the signal, ion current versus electric field strength (VG Gas Analysis Systems Ltd.).

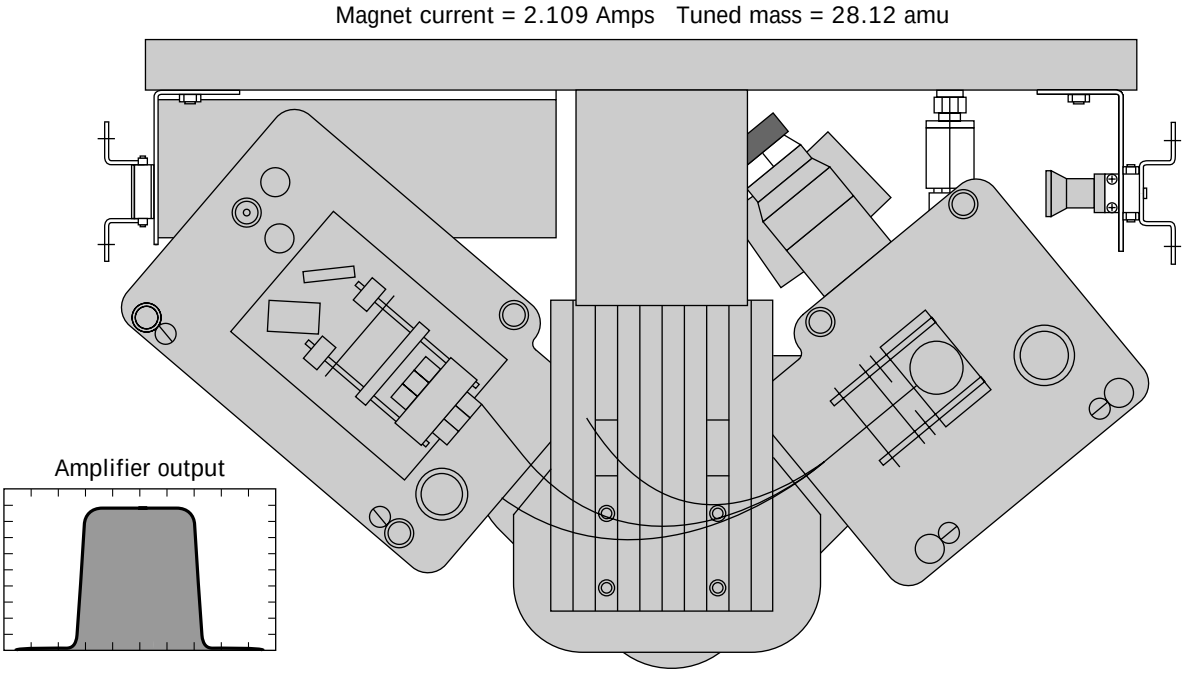

Figure 5. Magnetic sector mass spectrometer showing ion trajectory through magnetic field and the flat-top type profile of the ion current versus magnetic field strength (VG Gas Analysis Systems Ltd.).

surface contamination from incident ions or poor vacuum (19). The Faraday cup is considered rugged, reliable, and typically capable of measurements to 1–10 ppm concentration levels (28). The SEM detector offers greater sensitivity (sub-ppm) with a faster response but has poorer long term stability and is generally less accurate (2). SEM can be sensitive to repeated air exposure; background noise increases when the gain decreases, and it is far less rugged than the Faraday cup (13). In a single-collector arrangement with either a magnetic sector or quadrupole system, it is common to have remotely switchable Faraday cup–SEM assemblies. The appropriate detector is selected by the software, allowing all species to be monitored from 100% to parts per million (24). For example, a Faraday cup is used for air components and a secondary system for volatiles such as ethanol, acetone, or butandiol (22).

Spectral Analysis

To analyze a mixture of ion fragment intensities, with n components, a system of linear equations must be solved to calculate individual component concentrations $c_1, c_2 \ldots c_n$. The ion current signals, S_1, for each mass/charge is considered to be the sum of the contributions of all components, which are proportional to the concentration of each component:

$$\begin{aligned} s_1 &= c_1 m_{11} + c_2 m_{12} + \ \ldots \ + c_q m_{1q} \\ &\cdot \quad\ \cdot \quad\ \cdot \quad\ \cdot \\ &\cdot \quad\ \cdot \quad\ \cdot \quad\ \cdot \\ &\cdot \quad\ \cdot \quad\ \cdot \quad\ \cdot \\ s_p &= c_1 m_{p1} + c_2 m_{p2} + \ \ldots \ + c_q m_{pq} \end{aligned}$$

or

$$\vec{s} = \mathbf{M}\vec{c}$$

where s is the signal, M is the fragmentation pattern or sensitivity factor matrix determined by calibration with individual pure components, and c is the desired concentration (28). Most species produce several peaks due to fragmentation or double ionization. For instance, nitrogen has peaks at nominal m/z values 28, 14, 29, and 15. Thus, a set of linear equations is overdetermined and solved using an iterative route of multidimensional least squares technique (34). The best fit is then made between the observed spectrum and that which can be synthesized following small adjustments of the species concentration. These adjustments use the known fragmentation patterns of various species. Therefore, all the mass spectral information is made available by the single detector instrument, which is most effectively used in achieving the concentration analysis.

Suitability of Mass Spectrometry

A typical magnetic sector mass spectrometer instrument has excellent repeatability of $\pm 0.1\%$ of range at calibration, zero and gain drift less than 1% of range per month, and a response time of 1 s (1,19,28). The limiting step of the response time becomes the passage through the sampling system rather than the mass spectrometer itself. The fast analysis times (seconds) mean that many fermentors and indeed several different processes can be monitored simultaneously. This method provides a cost-effective device for multifermentor sampling despite the high purchase cost of an individual unit. Maintenance is usually associated with contamination of the inlet device and filament and ion pump replacement. However, this is offset by the rapid analysis for polar organic species, excellent long-term accuracy and precision, plus flexibility of analysis. These features make mass spectrometry the most flexible and versatile instrument for vent gas analysis.

INSTALLATION AND OPERATION

Careful consideration must be made in designing a sampling system for a vent gas system, which usually involves the multiplexing of one analyzer to a variety of fermentors. A sample handling system incorporates gas transport from the fermentor, followed by pretreatment before passing through the multipoint sampling manifold into the analyzer. The design of such a system must minimize the response time of sample analysis. The gas must take the shortest route from the fermentor to the pretreatment steps through to the analyzer. The amount of sample pretreatment required can be process specific. Most applications require removal of moisture and contaminating species from the vent gas, which involves steps such as filtering and heating before the analyzer. The materials of construction for transport lines, line purging, sample flow rate, and minimizing tubing lengths must all be considered.

Fermentor Sampling Location

The position of a gas sampling point from the fermentor requires care and to some degree depends on the species for analysis. If fermentor overpressure is to be used for gas transport to the mass spectrometer, then it is pertinent to have the sample port between the headplate and the control valve. The vent lines of fermentors often contain a condenser, double-piped steam heater, or vent filters that are steam dried from a jacket. These techniques can remove volatile compounds from the exhaust gas, so the sampling point should be upstream of these devices if organic volatile analysis is desired. The removal of water via the condenser may also affect carbon dioxide because the solubility of this species is high. Nevertheless, moisture must be removed before the analyzer, so sampling after the condenser may be advantageous.

If fermentor operation requires the use of a vent filter for containment, then sampling must be completed after the filter unless a separate vent gas filter is installed. Foaming and liquid entrainment can occur in the vent line. Some prevention of entrainment into the sampling system can be made by facing the sample port downstream of the gas flow (34). Gas has to make a 180-degree turn to the sample port, while tending to exclude liquid as its inertia prevents it from turning. Foam detection systems can also prevent sample line contamination. The foam sensor, using capacitance or conductivity between two elements, usually probe and tank wall or two elements in the probe, can be

mounted on the fermentor headplate; this can be part of an automatic defoamer addition system on foam detection. A second probe can be mounted in the vent gas line to close the off-gas sample valve on foam detection.

Sample Delivery and Pretreatment

Commonly, the fermentor headplate overpressure is used to transport gas to the analyzer. However, for laboratory-scale vessels a gas membrane or piston pump may be required. A 0.1-bar pressure is sufficient for a 100-m length of standard 6-mm nylon tubing (or ¼-in tubing) (28). The tube can be stainless steel, nylon, or preferably PTFE for volatile samples. The tubing is heated to between 60 and 160 °C to ensure compounds in the vapor phase, which avoids removal via condensation; this can be done electrically, by steam, or by jacketed hot water (29). For volatile analysis, heating the tube to about 150 °C and the use of Teflon are essential for fast responses times (35). Adsorption–desorption effects of volatile components with stainless steel tubing walls can hinder response times (>5 min) and cause memory effects.

The vent gas is often passed through a (0.2-μm) hydrophobic filter (PTFE) as a final particulate protector before the analyzer. For unheated lines, moisture is removed by condensation. Knockout pots are used in combination with a coalescing filter whereby large drops form and settle by gravity (34). A graded porosity hydrophilic matrix is used with a drain layer to direct coalescing liquids into a sump at the base of the housing. Automatic draining of the pot is ideal via solenoid actuation periodically or on liquid detection. If further moisture removal is required, various technologies are available, including small concentric tubes or coils in shell heat exchangers with refrigerated coolant. Other systems include the Peltier effect cylindrical gas cooler with a sealed tube containing a pure fluid. A wick lines the inner walls, which ensures fluid return by capillary action. One end of the tube is heated, liquid evaporates, and the gas flow displaces the steam toward the end of the tube. The steam expands and condenses back to the heated end (13). Desiccants such as anhydrous calcium chloride, alumina, or silica gel can be used for further sample drying, but this is rarely necessary.

Sample-Handling Manifolds

Most industrial applications utilize one mass spectrometer for vent gas analysis of an array of fermentors (>10). This requires a fast manifold system free of cross-contamination and leaks to automatically switch between fermentor samples and calibration gases. A typical system has the sampling streams from all tanks under permanent flow to guarantee instant sampling availability and avoid line purging (Fig. 6). Three-way valves can eliminate dead legs, and use of two valves per sample stream allows gas to flow to drain rather than contaminate other streams if both valves fail. Solenoid valves are often used as they are inexpensive and compact compared to air-actuated ball valves. Rotameters can be used to verify flow at the vent side of the three-way valve. The manifold is mounted in a cabinet with heat control to a temperature above the process temperature or to 110 °C required for organic volatiles. Multistream rotary valves have been designed that are actuated by an electric stepper motor for cross-contamination sampling (27,28). The unit (designed by VG Gas Analysis Systems Ltd.) can be configured for 16, 32, 48, or 64 sample streams, connected to the periphery of a circular flat distribution plate, that vent into a cylindrical housing with a common exhaust (Fig. 7). The electric stepper motor drives the rotary arm to position at a sample stream, and sample flows directly into the sample transfer tube. Cross-contamination of other gases is inhibited by a spring-loaded face sealing sleeve (2).

The response time of the manifold system can be reduced by minimizing tubing lengths. The time required to flush the lines should be four times the gas residence time (2). This is estimated using plug flow, but experimental measurements are preferred because of backmixing through valves and regulators.

Sample Flow Control

The signal from a gas analyzer is proportional to the volumetric concentration of the component of interest so that sample pressure will directly influence the results. This can be remedied by measuring internal standards (typically N_2, or Ar), or by measuring the concentrations of all other components, and converting to mole fractions. Alternatively the pressure can be measured and the data corrected using the ideal gas law or by controlling the pressure at the fixed value (34). Pressure control can be overcome by simply venting the instrument outlet to atmosphere. An upstream needle valve can be used to reduce the pressure and to control sample flow rate through instrument. Locating the valve as far upstream as possible reduces the lag time, as the gas velocity is increased after the pressure reduction. However, this leaves a 2–3% variation from atmospheric pressure. If this is an unacceptable error, then an absolute backpressure regulator must be employed on the outlet (34). Temperature is controlled within the analyzer but it is useful to control temperature of the manifold cabinet by an electric heater. A temperature greater than 60 °C will prevent condensation, unless moisture has been removed, and minimize adsorption of compounds.

System Monitoring

Water can be detected in a manifold system by a U-shaped liquid trap with a sensor to detect water in the sample lines. The low electrical conductivity of water in the sample means that the sensor must monitor either the dielectric constant or refractive index of the stream or even thermal dissipation from a self-heated thermistor or electric coil. The sample flow rate (>1 mL/s) can be controlled by a simple needle valve and rotameter. A thermal sensor and auto control valve will ensure sample flow rate is adequate and stable. Leak testing by pressuring the system from instrument air and closing the valves. Alternatively, the pressure can be monitored while the sample system is evacuated if this step is part of the sampling sequence. Diagnostic packages supplied with most analyzers will alarm for problems associated with the capillary, filament, vacuum, and power supply.

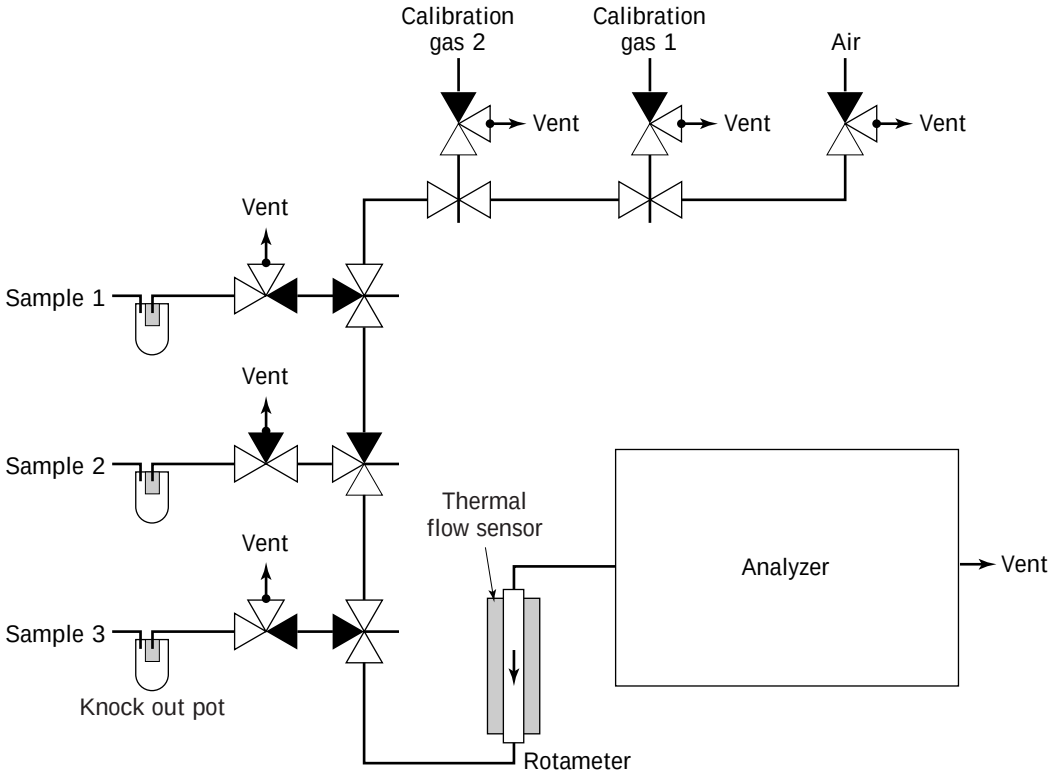

Figure 6. Multistream sample switching system. Solid segments indicate valve-closed position.

Process Measurements Required for Variable Calculation. Measurements of pressure, volume, air flow, and dissolved oxygen are required. To calculate the vent gas variables that are useful to fermentation (oxygen uptake rate [OUR], carbon evolution rate [CER], and respiratory quotient [RQ]). Broth volume can be determined by load cell or differential pressure transducers, air flow rate by a mass flow meter, and dissolved oxygen concentration by a polarographic probe whose response should be checked systematically by varying the headspace pressure or degassing with N_2. Strain gauge, piezoresistive, capacitance, or resonant wire transducer can be used for pressure measurement.

Data Acquisition. For a number of fermentors connected to a multistream manifold, such as a RMS, fast turnover of samples is required although measurements must be accurate. Therefore data acquisition must occur after a suitable line purge time. Multiple measurements can subsequently be made and filtered or smoothed to reduce noise (2). A typical approach is to use an algorithm to produce a stable reading (34). A linear exponential filter is used where each successive measured value c_t is used to update a smoothed estimate as $\hat{c}_t = \kappa c_t + (1 - \kappa)\hat{c}_{t-1}$ where k is a filtering parameter. The trend in the smoothed data is estimated as $\hat{S}_t = \lambda(\hat{c}_t - \hat{c}_{t-1}) + (1 - \lambda)\hat{S}_{t-1}$, where λ is another parameter. A typical algorithm acquires at least $1/\kappa$ values and continues until the absolute value of the trend $\hat{S}_t$ is less than a target tolerance, δ, indicating that a stable result has been obtained. The values of κ, λ, and δ depend on the rate of data acquisition and on instrument performance (34).

Vent gas analysis processes gases on a dry gas basis whereas the actual gases from the fermenter are saturated with water vapor. Standard handbooks can be used to correct these data (36). Most vent gas analysis is expressed as a mole fraction basis. If this is not the case, then data should be adjusted using the ideal gas law to standard conditions of temperature and pressure to allow mass balances to be performed.

Good precision is achieved if signals are noise free with no drift. However, the combination of vent gas data with online data such as air flow rate and dissolved oxygen for mass balancing introduces noise. These errors of measurement can dramatically enlarge errors in the data. Low-pass filters can be used to smooth the data, and many acquisition systems have built-in analog filters for this purpose.

PARAMETER CALCULATION

Vent gas analysis data are only useful when configured to quantify consumption rates and metabolic factors, which requires equation balances for the gas and liquid phases. When completed, the vent gas variables enable characterization of the microbial physiology of the fermentation broth.

Well-Mixed Liquid- and Gas-Phase State

The following balance equations for species i in the gas and liquid phases are written assuming well-mixed phases in

Figure 7. Magnetic sector mass spectrometer unit from VG Gas Analysis Systems Ltd. fitted with the rotary motor sample device.

the fermentor; this assumes that concentrations are uniform throughout the liquid phase, and that mole fractions are uniform throughout the gas phase. The assumption is accepted for small-scale stirred reactors but is less valid at large scale, >100 L. Axial volumetric concentration gradients of species in the gas phase as a consequence of the hydrostatic pressure gradient have been observed at large scale, which leads to alternatives for large-scale vessels, discussed in the next section. For low pressure and dilute concentrations of interest, the ideal gas law and the simplest form of Henry's law (relating equilibrium gas and liquid-phase concentrations through a simple proportionality constant) can be used. The equations have been given by Heinzle and Dunn (2) and modified by Salmon and Buckland (34). It is assumed that the fermentor is isothermal and has a uniform cross-sectional area.

$$\frac{dV_G C_{G_{e,i}}}{dt} = G_o C_{G_{o,i}} - G_e C_{G_{e,i}} - k_{L_i} a V_L (C^*_{L_{e,i}} - C_{L_{e,i}}) \quad (1)$$

$$\frac{dV_L C_{L_{e,i}}}{dt} = L_o C_{L_{o,i}} - L_e C_{L_{e,i}} + k_{L_i} a V_L (C^*_{L_{e,i}} - C_{L_{e,i}}) - V_L \Sigma r_i \quad (2)$$

where $C_{G_{o,i}}$, $C_{G_{e,i}}$, $C_{L_{o,i}}$ and $C_{L_{e,i}}$ are the gas- and liquid-phase concentrations, subscripts *o* and *e* refer to the influent and effluent, and subscripts *G* and *L* refer to the gas and liquid phases, respectively, V_G and V_L are the gas- and liquid-phase volumes, G_o, G_e, L_o, and L_e are the influent and effluent gas and liquid flow rates, $k_{L_i}a$ is a mass transfer coefficient, $C^*_{L_{e,i}}$ is the liquid-phase concentration that would be in equilibrium with $C_{G_{e,i}}$, and Σr_i is the total consumption rate of species *i* in the liquid phase. Standard conditions of pressure and temperature (typically $P_{ref} = 1$ atmosphere, $T_{ref} = 25$ °C) have been used for gas-phase concentrations, volumes, and flow rates.

An expression can be written for $C^*_{L_{e,i}}$, liquid-phase concentration, using Henry's law and integrating over the fermentation broth volume (34):

$$C^*_{L_{e,i}} = (RT_{ref}/H_i P_{ref})(P_h + V_L \rho_L g/2A) C_{G_{e,i}} \quad (3)$$

where H_i is the Henry coefficient, P_h is the headspace pressure, ρ_L is the liquid-phase density, and A is the cross-sectional area of the fermentor. It is usual to assume that the liquid-phase supply, removal, and accumulation terms in equation 1 are negligible for gases such as oxygen that have low aqueous solubility. The gas-phase accumulation term in equation 1 is also ignored because gas holdup is small and changes in oxygen utilization occur slowly. However, this simplification may not be valid for rapidly growing cultures (37) or when sudden metabolic changes occur (38), in which case the calculated results will lag actual events in the fermentor. Using the discussed assumptions, equations 1 and 2 can be added and rearranged to obtain an expression for $OUR = r_{O_2}$, the net oxygen utilization rate:

$$OUR = G_o(C_{G_{o,O_2}} - G_e/G_o C_{G_{e,O_2}})/V_L \quad (4)$$

An expression for the mass transfer coefficient, in a dimensionless form, can also be made from equation 1:

$$\alpha_{O_2} = \frac{k_{L_{O_2}} a V_L}{G_o} = \frac{C_{G_{o,O_2}} - G_e/G_o C_{G_{e,O_2}}}{\beta_{O_2}(1 + \gamma/2) C_{G_{e,O_2}} - C_{L_{e,O_2}}} \quad (5)$$

where $\beta_{O_2} = R\ T_{ref} P_h / H_{O_2} P_{ref}$, and $\gamma = V_L \rho_L\ g/AP_h$. Values of the Henry coefficient, H_{O_2}, can be obtained from the literature (39). The aqueous oxygen concentration, $C_{L_{e,O_2}}$, found in equation 5, can be measured on line using a polarographic probe calibrated to read $\beta_{O_2}(1 + \gamma/2) C_{G_{o,O_2}}$ before inoculation. The constant, 1, assumes that the difference of oxygen solubility in the fermentation medium compared to water is negligible. This assumption is reasonable as the constant can be estimated for most fermentation broths (39,40) and a value of 0.945 is achieved for a typical broth containing, salts, yeast extract, and glucose.

Inert gas species (such as Ar or N_2) are monitored to compensate for gas flow changes caused by the presence of moisture and volatiles in the exhaust gas. The net utilization for the inert gas is zero and consequently $G_e/G_o = C_{G_{o,inert}}/C_{G_{e,inert}}$ by using the simplifications for oxygen.

For carbon dioxide the situation is more complex because its high solubility (H_{CO_2} of 34 L bar/mol compared with H_{O_2} of 856.9 L bar/mol) means the liquid-phase accumulation cannot be ignored. Also, carbon dioxide reacts with water to give biocarbonate at pH > 6.5.

$$CO_2 + H_2O \underset{k_b}{\overset{k_f}{\rightleftarrows}} H_2CO_3 \overset{K_a}{\leftrightarrow} H^+ + HCO_3^- \leftrightarrow 2H^+ + CO_3^{2-} \quad (6)$$

The hydration of CO_2 to H_2CO_3 is a slow rate constant; however, its concentration is low (<0.3% of CO_2 present) (41) because it is almost instantaneously dissociated to HCO_3^-. At the pH range 4–8 for fermentation processes, the concentration of carbonate ions is negligible, complexing of CO_2 with amine groups can be ignored, and the reaction of dissolved CO_2 with OH^- is negligible (42). Bicarbonate accumulation increases with pH, and at pH 6.3 the concentration can be equal to the dissolved CO_2. Thus, the basic liquid-phase equation 2 must be modified to include accumulation of bicarbonate:

$$\frac{dV_L C_{L_{e,CO_2}}}{dt} = L_o C_{L_{e,CO_2}} - L_e C_{L_{e,CO_2}} + k_{L_{CO_2}} a V_L (C^*_{L_{e,CO_2}} - C_{L_{e,CO_2}}) + V_L(CER - r_{HCO_3^-}) \quad (7)$$

$$\frac{dV_L C_{L_{e,HCO_3^-}}}{dt} = L_o C_{L_{o,HCO_3^-}} - L_e C_{L_{e,HCO_3^-}} + V_L r_{HCO_3^-} \quad (8)$$

where $CER = -r_{CO_2}$ is the net carbon dioxide evolution rate from the biomass and $r_{HCO^-}3$ is the net rate of bicarbonate formation given by

$$r_{HCO_3^-} = k_f C_{L_{e,CO_2}} - k_b/K_a \, C_{L_{e,H^+}} \, C_{L_{e,HCO_3^-}} \quad (9)$$

Values for the constants k_f, k_b, and k_a can be obtained from the literature (43). Rearrangement of equation 1 gas-phase balance, and neglecting accumulation terms as before can produce the following balance:

$$k_{L_{CO_2}} a V_L (C^*_{L_{e,CO_2}} - C_{L_{e,CO_2}}) = G_o C_{G_{o,CO_2}} - G_e C_{G_{e,CO_2}} \quad (10)$$

and solved for the liquid-phase CO_2 concentration,

$$C_{L_{e,CO_2}} = \left\{\frac{1}{\alpha_{CO_2}} \frac{G_e}{G_o} + \beta_{CO_2}(1 + \gamma/2)\right\} C_{G_{e,CO_2}} - \frac{1}{\alpha_{CO_2}} C_{G_{o,CO_2}} \quad (11)$$

where $\alpha_{CO_2} = k_{L_{CO_2}} a V_L / G_0$, and $\beta_{CO_2} = RT_{ref} P_h / H_{CO_2} P_{ref}$. Henry coefficient H_{CO_2} estimates are found in the literature (39). Combining and rearranging equations 7, 8, and 10 gives

$$CER = \frac{1}{V_L}\left\{\frac{dV_L(C_{L_{e,CO_3}} + C_{L_{e,HCO_3^-}})}{dt} - L_o(C_{L_{e,CO_2}} + C_{L_{e,HCO_3^-}}) + L_e(C_{L_{e,CO_2}} + C_{L_{e,HCO_3^-}}) - G_o(C_{G_{o,CO_2}} - G_e/G_o C_{G_{e,CO_2}})\right\} \quad (12)$$

The evaluation of $C_{L_{e,HCO_3^-}}$ can be considered in three algorithms of complexity (34). Equations 8 and 12 can be solved progressively as the fermentation proceeds using current and past data. This practice enables monitoring of CO_2 evolution under dynamic conditions, so long as the rate of data acquisition by the analyzer is sufficiently rapid. This may be a problem when acid is introduced intermittently for pH control because the CO_2 concentration in the vent gas will increase for a short period after each addition (44). A second approach can be applied if the time constant for process changes is greater than 5 min. In this case, the hydration reaction can be assumed to be at equilibrium, yielding $C_{L_{e,HCO_3^-}} \approx (k_f/k_b) K_a 10_{pH} C_{L_{e,CO_2}}$. Substituting this expression into equation 12 allows the value of CER to be calculated directly if the rate of change of the dissolved CO_2 concentration is estimated using current and past data (34). Finally, it is common practice to ignore the transient terms so long as changes of pH and CER are slow. Heinzle et al. (45) demonstrated that including dynamic changes of CO_2 and HCO_3^- in a simulation only produced relative errors <2% in the CER.

Large-Scale Mixing Models

The assumption of ideal mixed gas and liquid phases is reasonable for tanks less than 100 L. However, upon scale up to production scale (100– 100,00 L), axial gradients and large mixing times are observed and so previous equations for oxygen transfer rate, OTR, and OUR based on the well-mixed system may not be valid. Hydrostatic pressure gradients in tall fermentors will cause large differences in oxygen solubility C_L from liquid surface to tank bottom. The dissolved oxygen concentration in a stirred tank can vary linearly from 5.4 mg/L at the surface to 12.1 mg/L at a depth of 10 m. At the bottom of the tank the oxygen solubility for a given gas composition is twice as a consequence of the doubled hydrostatic pressure, as shown by Henry's law. This change will double the maximum oxygen transfer rate, and, hence, dissolved oxygen concentration, oxygen solubility, gas holdup, and transfer parameters may vary with depth in a tall reactor.

Limited experimental and theoretical data are available on concentration in homogeneities or gradients within large fermentors, but radial and axial gradients of pH, conductivity, and dissolved oxygen have been observed (46,47). Residence time distribution data using liquid and gas transfers have characterized the mixing to produce a variety of models (48–51). Various models have been determined for large-scale mixing, where axial backmixing has been described by dispersion theory or a tank in series with recirculation based on the measurement of residence time distribution. Other models include compartmentalization of the reactor into zones, such as two well-mixed impeller compartments and the remainder for the rest of the tank, with transport between compartments based on the pumping power of impellers (46).

The model behavior is described through simulations of the coupled material balance equations for oxygen transfer rate, mixing, and kinetics. The importance of backmixing and hydrostatic pressure on scale-up was demonstrated by using a three-phase multimixed compartment model (50). The flow conditions of these models fall between extremes of well-mixed and plug flow. Simplification for large-scale reactors is to assume that the liquid phase is well mixed but that the gas phase moves in plug flow (no backmixing) from inlet to outlet (51). The gas-phase concentration of species *i* was described by Salmon and Buckland (34) using this equation:

$$\frac{dC_{G_i}}{dx} - \alpha_i\{\beta_i[1 + \gamma(1 - x)]C_{G_i} - C_{L_{e,i}}\} = 0 \qquad (13)$$

where α_i, β_i, and γ are defined in the previous section. For the gas-phase concentration of species *i*, a closed-form solution to this equation was used to calculate $C_{G_{e,i}} = C_{G_i}(1)$ from the inlet condition of $C_{G_i}(0) = C_{G_{o,i}}$. Salmon and Buckland (34) used this solution to produce a comparison between the estimates of equilibrium between liquid and gas phases at two scales, 0.15 and 60 m^3 (where differences are solely due to hydrostatic pressure), and between the two models of well-mixed phases and a gas phase with plug flow. For a given mass transfer coefficient, the predicted liquid-phase concentrations were closer to equilibrium with the effluent gas for the plug flow model than with the well-mixed system. This difference was accentuated with the large-scale tank (where hydrostatic pressure is significant). This conclusion seems reasonable because the mass transfer coefficient required to achieve a desired liquid-phase concentration is lower for a production vessel than for a small laboratory fermentor. Thus, for a given mass transfer coefficient the gas-phase and liquid-phase concentrations in a large vessel will be closer to equilibrium than those in a small vessel. This agrees with the observation that the dissolved carbon dioxide in a large tank can be calculated by presuming equilibrium with the vent gas, whereas this assumption is not appropriate for small fermentors.

Aqueous Concentration Estimation for Volatile Organic Compounds

The liquid-phase concentration for an organic species can be calculated as for $C_{L_{e,CO_2}}$ (equation 11) assuming that the system is well mixed with respect to the gas and liquid phases and that the inlet gas-phase concentration is zero (34):

$$C_{L_{e,i}} = \beta_i\left[\frac{1}{\alpha_i\beta_i}\frac{G_e}{G_o} + (1 + \gamma/2)\right]C_{G_{e,i}} \qquad (14)$$

As $\alpha_i\beta_i \to \infty$, the liquid-phase concentration approaches $\beta_i(1 + \gamma/2)\, C_{G_{e,i}}$, which is the concentration in equilibrium with the gas phase at the average fermentor pressure. Equilibrium constants can be attained for any volatile compound under most conditions (22) because most compounds have a high affinity for the liquid phase and hence a low Henry's coefficient (ethanol 10^{-2} bar/L/mol) compared to gas. Camelbeeck et al. (29) have experimentally confirmed this conclusion by demonstrating that changes in the rates of agitation and aeration have no influence on the vent gas measurements.

The ability to monitor a specific organic compound depends on concentration and volatility and analyzer sensitivity. Oeggerli and Heinzle (22) compared partial pressures above an aqueous solution at a concentration of 0.1 g/L at 30 °C. Compounds were considered analyzable if the partial pressure was greater than 1 μbar; hence, ethanol at 22.24 μbar and acetone at 181 μbar could be monitored (oxygen, $>10^6$ μbar). However 2,3-mesobutanediol was considered undetectable as the partial pressure was 0.0174 μbar, and its limit of detection was found to be 5 g/L with a quadrupole mass spectrometer.

Calibration is usually achieved by adding a known amount of compound to the fermentor before inoculation and measuring concentrations from liquid samples off line by HPLC or GC. Most volatiles require a SEM for accurate detection as volatiles are in the ppm level in the headspace (22,29).

Growth Kinetics

Growth rate kinetics including yield of biomass from oxygen consumed, Y_{x/O_2}, from carbon dioxide evolution, Y_{x/CO_2}, and the specific growth rate (52,53) can be simply determined using vent gas analysis:

$$Y_{x/O_2} = \frac{d(\mathrm{TOC})/dt}{dx/dt} \qquad (15)$$

$$X = Y_{x/O_2}(\mathrm{TOC}) \qquad (16)$$

where TOC is the total oxygen consumed estimated from the summation of the OUR versus time and X is the biomass concentration from oxygen. Linear regression from a curve of biomass concentration (determined off line) versus TOC and total carbon dioxide evolved (TCE) can then lead to the respective yields factors for biomass from oxygen and carbon dioxide. The specific growth rate, μ, can be determined by

$$\mu = \frac{d(\mathrm{TOC})/dt}{\mathrm{TOC}} = \frac{\mathrm{OUR}}{\mathrm{TOC}} \qquad (17)$$

where the Y_{x/O_2} is assumed to be constant. Good agreement can be made between specific growth rates as calculated on line using TOC data and off-line data from experimental dry cell weight (53). This calculation provides a useful on-line tool for analyzing growth rate during process and development. This analysis is especially important for secondary metabolites in which the understanding of growth and production rates are critical to process optimization, often involving substrate feeding. For example, the control of specific growth is very important for the synthesis of avermectin by *Streptomyces avermitilis* (53). The impact of decrease of temperature by a few degrees at 12 h into the fermentation clearly showed a dramatic decrease in specific growth rate compared to the control, as measured by the on-line method (Fig. 8).

Mass Balancing and RQ

Vent gas analysis data can be used to describe the substrate utilization and production kinetics of a fermentation via mass balancing (2,34). A typical fermentation could involve $CH_{h_S}N_{n_S}O_{o_S} + aNH_3 + bO_2 \rightarrow Y_{X/S}CH_{h_X}N_{n_X}O_{o_X} + Y_{P/S}CH_{h_P}N_{n_P}O_{o_P} + cCO_2 + dH_2O$, where biomass $CH_{h_X}N_{n_X}O_{o_X}$ and product $CH_{h_P}N_{n_P}O_{o_P}$ are formed from substrate $CH_{h_S}N_{n_S}O_{o_S}$. The coefficients a, b, c, and d can be solved from elemental balances for carbon, hydrogen, nitrogen, and oxygen. Coefficients for oxygen and carbon dioxide are $b = (\gamma'_s - Y_{X/S}\gamma'_x - Y_{P/S}\gamma'_p)/4$ and $c = 1 - Y_{X/S} - Y_{P/S}$, where $\gamma'_i = 4 + h_i - 3n_i - 2o_i$ is the so-called generalized degree of reduction for compound

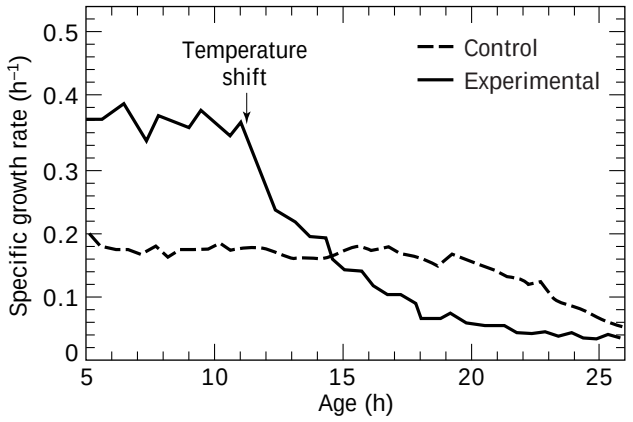

Figure 8. Impact of temperature shift on estimated specific growth rate (on line) of *Streptomyces avermitilis* at 800 L (53).

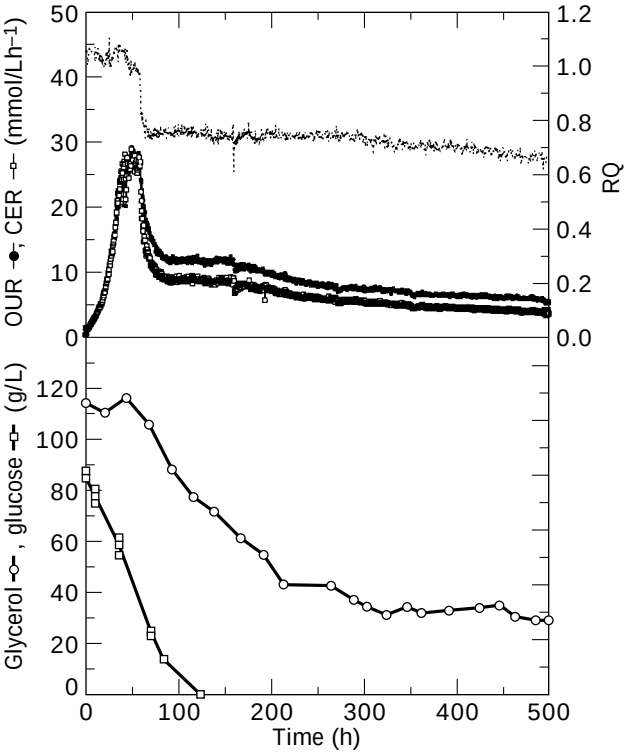

Figure 9. Comparison of vent gas analysis to off-line substrate data for a fungal fermentation at 1,600 L.

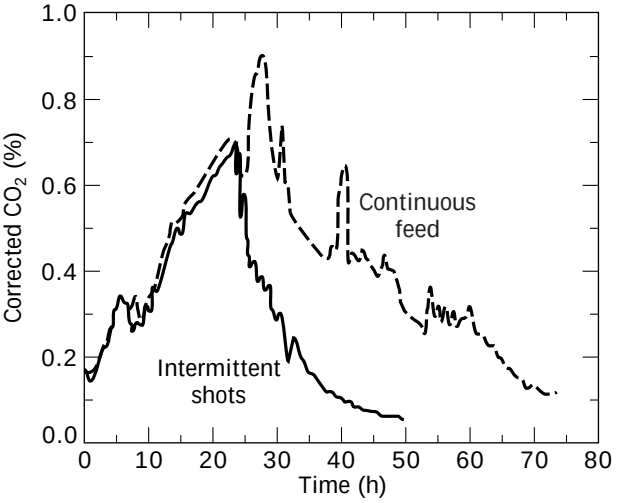

Figure 11. Comparison of the vent gas CO_2 concentration for *Nocardia* sp. between continuous and intermittent shot process for addition (54).

$CH_{h_i}N_{n_i}O_{o_i}$. The value of μ' for biomass is consistently about 4.2, and the values for some common substrates and products can be found in the literature (8). An expression can then be made for the respiratory quotient, RQ, the ratio between the rates of CO_2 evolution and oxygen utilization, as $RQ = 4(1 - Y_{X/S} - Y_{P/S})/(\gamma's - Y_{X/S}\,\gamma'_p)$. Thus, for a given fermentation the RQ, defined from vent gas analysis, CER/OUR, can be used with off-line analysis of biomass, carbon, nitrogen, and production concentrations to define the yield coefficients for substrate and production (32). Elemental balancing requires high-precision gas analysis with 0.01% accuracy because a 1% error relative offset calibration error for oxygen can result in an error for product estimation >50% (2).

For industrial applications, the unusual mutant strains have complex metabolism, of which little is understood. It is thus difficult to define stoichiometric equations for a process, limiting the use of elemental analysis. Nevertheless, vent gas analysis is a valuable tool for studying process kinetics and metabolism. For example, during a fungal fermentation the RQ was found to switch from unity to 0.7, indicating the change in metabolism from glucose to glycerol (Fig. 9). The reduction of growth rate, as shown by the OUR profile, and commencement of glycerol utilization indicated the start of secondary metabolite production. In

another fungal fermentation, the depletion of D-mannitol and subsequent reduction in volumetric productivity corresponded with the RQ reduction from 1 to 0.8 (Fig. 10). Shot additions of D-mannitol were made in response to the change in RQ, which prolonged the fermentation and increased production.

During the microbial hydroxylation of simvastatin (a cholesterol-lowering drug) by a *Nocardia* species, high concentrations of the substrate inhibit production (54). Maintaining a low concentration of the substrate using a controlled continuous feed strategy as opposed to a shot process enabled yield improvements of the biotransformation. The carbon dioxide profile was used to monitor process performance (Fig. 11) where the continuous substrate feed prolonged the decrease of carbon dioxide after 30 h compared to the rapid decrease observed with the shot processes. Therefore, combining vent gas data, including RQ, with off-line analysis of substrate utilization and productivity rates, along with an understanding of biochemical pathways, can enable process monitoring and feedback control.

Vinegar production

OUTLINE

INTRODUCTION

Worldwide, acetic acid is called vinegar, if obtained by oxidative fermentation of ethanol-containing solutions by acetic acid bacteria. Although vinegar does not entirely exclude diluted chemically produced acetic acid in every country of the world, this term is used here to define acetic acid that is produced from ethanol by a primary microbial metabolism, the so-called acetic acid fermentation or vinegar fermentation.

BASES OF ACETIC ACID FERMENTATION

Acetic acid fermentation (acetous fermentation) is an oxidative fermentation by which solutions of ethanol are oxidized to acetic acid and water by acetic acid bacteria using atmospheric oxygen. The oxidation proceeds according to the basic equation

$$C_2H_5OH + O_2 \rightarrow CH_3COOH + H_2O$$
$$G^\circ = -455 \text{ kJ mol}^{-1}$$

The alcohol-containing solution is called mash. Its alcohol concentration is given in percent by volume. Usually it also contains some acetic acid expressed in grams of acetic acid per 100 mL (% w/v). The sum of ethanol (vol%) and acetic acid (g 100 mL^{-1}) is called total concentration because the sum of these rather incommensurable values gives the maximal concentration of acetic acid that can be obtained by complete fermentation (1). The quotient of the total vinegar concentration produced over the total mash concentration indicates the concentration yield.

RAW MATERIALS FOR ACETIC ACID FERMENTATION

All mashes must contain ethanol and water and provide the acetic acid bacteria with nutrients.

Alcohol

By far the largest percentage of vinegar is alcohol vinegar, which is produced from diluted purified ethanol. Other common names for the same product are white vinegar or spirit vinegar. It is customary in almost all countries to denature the ethanol serving as raw material for the vinegar industry. In the United States, this is mostly done with ethyl acetate, and in most European Countries, with alcohol vinegar.

Mashes obtained by alcoholic fermentation of natural-sugar-containing liquids also serve as raw materials. The designation of vinegar is according to the particular raw material used: wine vinegar is produced by acetic acid fermentation of grape wine; cider vinegar is produced from fermented apple juice; malt vinegar is the undistilled product of alcoholic and subsequent acetous fermentation of an infusion of barley or other cereals, the starch of which was converted by malting; rice vinegar is made from saccharified rice starch, followed by alcoholic and acetous fermentation.

Water for Processing

The water used for the preparation of mashes must be clear, colorless, odorless, bacteriologically safe, and without sediments or suspended particles. It must also be free of chlorine, ozone, other chemical compounds, and damaging bacteria.

Nutrients

Most natural raw materials do not require the addition of extra nutrients. However, apple cider is usually low in nitrogenous compounds, but this can be corrected by the addition of ammonium phosphate. Some grape wines also require the addition of ammonium phosphate for an optimal fermentation. In rare cases, all nutrients discussed next must be added for the production of wine vinegar.

For the production of alcohol vinegar, a mixture of the required nutrients was developed. When producing vinegar with up to 15% acetic acid, the acetic acid bacteria definitely require glucose and potassium, sodium, magnesium, calcium, ammonium as ammonium phosphate, sulfate, and chloride. The following trace minerals are needed: iron, manganese, cobalt, copper, molybdenum, vanadium, and zinc. These additions are sufficient for an optimal acetic acid fermentation.

Commercially available mixtures contain supplements such as dried yeast extract in order to restart a fermentation more quickly if stopped by a disturbance such as a power failure. Principally, nutrients should be added sparingly in order to exert a selection pressure directing to a low requirement for nutrients.

PRODUCTION BY ACETIC ACID FERMENTATION

Microorganisms

Overview and Basic Problems of Classification. The microorganisms oxidizing ethanol to acetic acid are commonly called acetic acid bacteria. This special primary microbial metabolism at low pH of the surrounding medium differentiates them from all other bacteria. Acetic acid bacteria are polymorphous. Cells are Gram-negative, ellipsoidal to rod shaped, straight or slightly curved, 0.6 to 0.8 μm long, occurring singly, in pairs or in chains. There are nonmotile and motile forms with polar or peritrichous flagella. They are obligately aerobic. Some produce pigments, some cellulose.

Numerous attempts to classify acetic acid bacteria were carried out as summarized in the work by Ebner and Follman (1). A major contribution to the exact taxonomy of acetic acid bacteria were the DNA-rRNA hybridization studies of Gillis and De Ley (2). A first conclusion from this work was that the two groups *Gluconobacter* and *Acetobacter*, as classified earlier, were closely related groups, justifying their union in the family *Acetobacteraceae*. Although in 1984 a set of 32 features was given to differentiate the genera *Gluconobacter*, *Acetobacter*, and *Frateuria* (3), not all of them are necessary for a satisfactory identification.

The feature of acetate overoxidation identifies the strains used in high-acid fermentations as members of the genus *Acetobacter*, and thus separates them from the genera *Gluconobacter* and *Frateuria*.

Required Properties of Industrially Used Strains. Considering the interest of many microbiologists in acetic acid bacteria, it is surprising that the available information about these bacteria has had so little effect on vinegar production. Working strains were isolated, but lost again, demonstrating the difficulties to isolate and grow *Acetobacter* strains from industrial vinegar fermentations on solid media. Considerable progress was achieved by propagating bacteria from fermenters in Japan on a special double-layer agar. The bacteria isolated on this medium have been described as *Acetobacter polyoxogenes* (4). However, *A. polyoxogenes* was not available from the Japan Collection of Microorganisms because of problems of propagation and preservation.

A new species in the genus *Acetobacter*, for which the name *Acetobacter europaeus* was proposed (5), has been isolated and characterized in pure culture from vinegar fermentations at high acidity in Germany and Switzerland. All investigated strains isolated from submerged fermenters and trickle generators had very low (0 to 22%) DNA–DNA similarities with the traditional strains of *Acetobacter* and *Gluconobacter*. The phenotypical differentiation on the species level of the genus *Acetobacter* is rather difficult, because different strains of a single species do not necessarily utilize the same carbon source. A useful and significant criterion for the distinction of *Acetobacter europaeus* from the other *Acetobacter* species is the strong tolerance to acetic acid of 4 to 8% in AE-Agar and the absolute requirement of acetic acid for growth.

Independent of all these problems and difficulties, the first and foremost interest of the vinegar industry is to use a strain of acetic acid bacteria that tolerates high concentrations of acetic acid and total concentration, requires small amounts of nutrients, does not overoxidize the acetic acid formed, and yields high production rates. At present, it also seems to be necessary to make this strain phage resistant (6).

Industrially Used Strains. The vinegar industry has always worked with acetic acid bacteria that, in most cases, were not derived from pure cultures. The striking fact that common microorganisms used on a large scale for industrial vinegar production were not properly described and characterized in taxonomic terms is caused by the difficulty to cultivate them on semisolid media.

Industrial submerged vinegar fermentations are started by inoculation with inoculation vinegar, microbiologically undefined remains from previous fermentations. Acetic acid fermentation can be carried out for years without interruption or decrease in efficiency or yield, if suitable conditions are chosen to allow a permanent selection of strains tolerating high acidity at a minimum of nutrient concentration. Such cultures are delivered to vinegar factories in all parts of the world by Heinrich Frings GmbH & Co KG, Bonn, Germany.

Plasmid Profile Analysis for Characterization of Acetobacter Strains. Plasmids are circular, extrachromosomal DNA molecules that can be extracted from bacteria by a sophis-

ticated technique. The plasmid profile of a strain is very specific. Plasmids can determine certain properties of bacteria, such as phage resistance or citrate metabolism. The potential of this technique for vinegar fermentations was investigated (7–9). The majority of the acetic acid bacteria contain 1 to 8 plasmids from 1 to more than 17 MDa. Plasmid profile analysis has been applied to characterize the *Acetobacter europaeus* strains and the microflora of industrial vinegar production plants (10). It was shown that the microflora in submerged fermentations consists of one predominant strain, whereas in trickling generators the microflora is quite heterogenous, containing a mixture of several *Acetobacter europaeus* strains with quite different plasmid profiles. This is probably the reason for the susceptability of submerged fermentations to bacteriophage attack. In conclusion, the determination of plasmid profiles from submerged vinegar fermenters represents a new and powerful technique to characterize the microflora of such fermentations and to answer questions that could not have been approached until now, such as the stability, origin, and identity of the prevailing microflora.

Recent investigations have shown that the plasmid profiles of these strains are able to rest stable over a period of at least 5 years and are not changing their phenotypic features during this time. Complete sequencing of the 16S rDNA genes have shown the phylogenetic position of *Acetobacter europaeus* to be close to *Acetobacter xylinum* and well separated from seven other *Acetobacter* species. Acetic acid bacteria together with *Acidiphilium* species and *Rodopila globiformis* represent a distinct acidophilic branch in the α-subclass of *Proteobacteria*.

Electrophoretic protein patterns correlated with the percentage of DNA similarity of DNA–DNA hybridization proved to be very useful for the delineation of the strains from industrial vinegar fermentations at the species/subspecies level (11,12).

Genetic Improvement of *Acetobacter* strains. To improve strains of *Acetobacter* and *Gluconobacter* genetically, recombinant DNA techniques are considered to be useful. Host–vector systems and an efficient transformation method have been developed. The preparation of spheroplasts and the development of a spheroplast fusion method have been described (13). A strain growing at 37 °C and 4% acetic acid and a strain unable to grow at 35 °C and 5% acetic acid were spheroplasted and fused. Fusion products were received growing at 37 °C on agar plates containing 5% acetic acid, on which both parent strains were unable to grow. Some more genetic transformation systems have been described (14–16).

When summarizing the present technique, Fukaya (17) states that recombinant DNA technology can contribute to advances in the basic knowledge of acetic acid bacteria and additionally provide new tools for improving them. But to apply recombinant DNA technology to improving acetic acid bacteria even more, basic research concerning gene expression, protein engineering, and other fundamental studies are required.

Bacteriophages. *Acetobacter*-specific bacteriophages demonstrated by electron microscopy in submerged and trickling fermenters are said to be responsible for fermentation problems in industrial vinegar fermenters (18–21). In trickling generators, fermentation is sometimes slowed down, but hardly stops completely. In submerged fermentations, complete loss of productivity has been observed. Only three morphologically different *Acetobacter* phage types were described until 1992, when a great variety in phage types, regarding the dimensions of the phage heads and tails was reported (20). All phages isolated from vinegar fermentations in Germany, Austria, and Denmark showed long contractile tails and isometric heads belonging to Bradley's group A (22) and the family of *Myoviridae* (23), respectively. Although not all phages described have actually been shown to be infective for defined *Acetobacter* strains because of a lack of a suitable technique, their occurrence in high numbers (10^6 to 10^9 mL^{-1}) in disturbed fermentations suggests that bacteriophages may actually be the source of fermentation problems.

Biochemistry

During acetic acid fermentation, ethanol is almost quantitatively oxidized to acetic acid. Concentration yields between 95 and 98% are common, and the remainder is mainly lost in the effluent gas. At the same time, a suitable C_6-carbon source (preferably glucose) is oxidized. End products of this oxidation are CO_2 and H_2O.

Ethanol. Ethanol oxidation is performed by two sequential reactions catalyzed by alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH), located at the outer surface of the cytoplasmic membrane. Their function is linked to the respiratory chain of the organism (24,25).

Alcohol dehydrogenase has been purified from several acetic acid bacteria and shown to contain pyrroloquinoline quinone (PQQ) and heme C as prosthetic groups (26–28). Extensive purification and characterization of the enzymes involved in ethanol oxidation of *Acetobacter aceti*, *A. rancens*, and *G. suboxydans* have been reported (26–32). It has been shown that ADH of acetic acid bacteria donates electrons directly to ubichinone in the cytoplasmic membranes. Thus, the ethanol oxidase respiratory chain of acetic acid bacteria is made of only three membranous respiratory components, alcohol dehydrogenase, ubichinone, and terminal oxidase (33).

It has been confirmed that ADH and ALDH of acetic acid bacteria had the same prosthetic group, PQQ, as their glucose dehydrogenase (30). These quinoproteins, glucose, ADH, and ALDH are involved in sugar oxidation that links them to an electron transport system in the membrane of oxidative bacteria. ADH and ALDH from *A. polyoxogenes* sp. nov. have been purified (34,35). This strain originated from a vinegar factory showing higher acid productivity and higher tolerance to acetic acid than strains isolated from natural sources. In contrast to the ADH and ALDH obtained from *A. aceti* and *G. suboxydans*, the enzymes of *A. polyoxogenes* were quite stable, and this high stability seems at least to be partially involved in the ability of *A. polyoxogenes* to produce high concentrations of acetic acid.

Sugar. For the breakdown of sugars, *Acetobacter* is equipped with the hexose monophosphate (HMP) pathway

and the TCA cycle (36), whereas glycolysis is either absent or very weak. The enzymes of the Entner-Doudoroff pathway are present in *Gluconobacter* and in *Acetobacter xylinum*. *Gluconobacter* and *Acetobacter* are known for their direct oxidative capacity on sugars, alcohols, and steroids (37). For further details see the work by Ebner and Follman (1). The biochemistry of the ketogenic activities of acetic acid bacteria have been reviewed (38).

Acetate. Strains of *Acetobacter* are able to oxidize acetate as well as lactate either in the presence or in the absence of ethanol by using enzymes of the tricarboxylic cycle.

Carbon Dioxide. *Acetobacter* needs CO_2 for growth (39). CO_2 is incorporated into cell substances, where approximately 0.1% of the cell carbon is derived from CO_2. A very small but measurable portion of acetic acid too is derived from CO_2 (40).

Nitrogen. If an organic carbon source is present, a number of acetic acid bacteria can use ammonium as sole nitrogen source. Some strains need the presence of amino acids; others need cofactors such as vitamins or purines (41). No essential amino acids are known.

Growth Factors. Growth factor requirement depends on the carbon source supplied (42). Some strains require *p*-aminobenzoic acid, niacin, thiamin, or pantothenic acid as growth factors (43). Some *Acetobacter* strains do not need vitamins in the presence of glucose (44). But the combined addition of glutathione with Na glutamate has a cumulative effect on the growth of *A. aceti* (45).

PQQ, the novel prosthetic group in acetic acid bacteria, also shows an interesting growth-stimulating effect for various microorganisms (45–47). One of two PQQ effects was the stimulation of both the growth rate and the total cell yield with only a trace amount of PQQ as an essential growth factor. The second effect of PQQ observed universally was a marked reduction of the lag phase in microbial growth, but no increase of the growth rate in the subsequent exponential phase or in the total cell yield at the stationary phase.

Physiology

Oxygen Demand and Total Concentration. During commercial use of many aerobic microorganisms it is common practice to permit the inoculum to remain in a fermenter for some time up to several days without aeration before inoculation into the main fermenter. However, application of this procedure is impossible in the case of acetic acid fermentation.

Extensive tests have been conducted (48,49) concerning the damage to acetic acid bacteria caused by an interruption of aeration as a function of total concentration, acetic acid concentration, rate of fermentation, and length of interruption of aeration. The longer the interruption of aeration and the higher the total concentration of the mash, the more marked is the effect. At a total concentration of 5%, an interruption of aeration for 2 to 8 min leads to the same damage as an interruption for 15 to 60 s at total concentrations of 11 to 12%. At constant total concentrations, damage increases with increasing concentration of acetic acid and with increasing fermentation rate. The specific production of cell material is extremely low (1).

Experiments conducted later (50) confirmed these results. It was found that there was a sharp drop in the oxidation rate of ethanol as well as in the activity of enzymes involved (ADH and ALDH) after an interruption of oxygen supply, with an acetic acid concentration of 6%. ADH activity in the membrane fraction was highly stable in the culture broth containing 4% or less acetic acid. But the purified enzyme was very unstable even in the culture broth of 2% total concentration. It was suggested from this fact that the ADH has a membrane component contributing to its own stability at acetic acid concentrations of less than 4%, which becomes gradually liable to damage with further increasing acidity. But, the relationship between the ADH system and oxygen has not been elucidated at all.

Under conditions of industrial acetic acid production, the microorganisms undergo considerable stress caused by a high concentration of acetic acid and limited oxygen supply. A high utilization of oxygen up to 70% can be achieved in industrial production. A sparing use of air is very important because of the volatility of ethanol and acetic acid. However, the use of pure oxygen or highly oxygen-enriched air may easily damage the bacteria (48).

In 1985, it was found that at a total concentration of 13%, the ATP pool and the growth rate show a reverse behavior (51). The energy charge (average value of intracellular ATP, ADP, and AMP) showed a rather high value of 0.84 at the beginning of the fermentation. During fermentation, although the acetic acid concentration increased from 9 to 12%, the energy charge decreased to 0.7. After interruption of aeration for 45 s, the energy charge dropped to 0.58, and after several weeks of storage the charge of the inoculum was only 0.50.

Lack of Ethanol. Acetic acid bacteria are also damaged if a vinegar fermentation is carried out to the point where all the ethanol has been oxidized and the addition of fresh ethanol-containing mash is delayed. This is analogous to the damage resulting from an interruption of oxygen supply and also depends primarily on the total concentration and the duration of ethanol lack.

Specific Growth Rate. In 1953, the specific growth rate of acetic acid bacteria was calculated for the first time (52). In semicontinuous fermentations there was no decrease of the specific growth rate at increasing acetic acid concentrations, but at increasing total concentrations the specific growth rate decreased from 0.49 h^{-1} at 5% to 0.16 h^{-1} at 11%.

In continuous culture at a total concentration of 12%, the specific growth rate decreased from 0.027 h^{-1} at 4.5% ethanol to 0.006 h^{-1} at 1% ethanol. It should be mentioned that the specific growth rate obtained in continuous fermentations with constant concentrations of acetic acid and ethanol are less favorable than those obtained under semicontinuous conditions. Batch fermentations carried out with *Acetobacter suboxydans* (53) showed at a total con-

centration of 7.5% a specific growth rate of 0.30 h^{-1}, a result that is in good agreement with other studies (51).

Specific Product Formation. In 1949, a specific product formation was found of 21 g of acetic acid per gram of bacterial dry substance per hour in semicontinuous tests at a total concentration of 10% (54). This very high value was independent of the acetic acid concentration of 4.5 to 7.2%. In 1972, a strong dependence between specific product formation and acetic acid concentration in continuous fermentations at a total concentration of 7% was found (55). The maximum specific product formation was 15 $g\,g^{-1}\,h^{-1}$. The specific product formation follows a growth-associated mechanism as long as the acetic acid concentration is below 3%. At higher acetic acid concentrations up to 7%, an additional nongrowth-associated term must be considered. The highest value obtained with cell recycle in continuous culture of *A. suboxydans* was 11.5 $g\,g^{-1}\,h^{-1}$ (53).

Changes in Concentration and Temperature. Charging of a fermentation must be done with mash at the same total concentration and under rapid mixing because a locally formed strong concentration gradient damages the bacteria. The next cycle starts without any lag phase. At the same time, temperature has to be kept constant because a repeated change in temperature causes a similar result (1).

Overoxidation. Overoxidation is the undesirable oxidation of acetic acid to CO_2 and H_2O that has to be prevented by avoiding lack of ethanol and keeping the total concentration at a high level. In trickle fermenters, this is much more difficult than in submerged fermenters (1).

Industrial Processes

Submerged Vinegar Fermentation ***Semicontinuous and Continuous Fermentations.*** For the production of vinegar with more than 12% and up to 15% acetic acid (56), the process has to be carried out in a semicontinuous manner; each fermentation cycle taking about the same time as the preceding and following cycles. The starting concentration of each cycle is 7 to 10% acetic acid and about 5% ethanol. When an alcohol concentration between 0.05 and 0.3% has been achieved in the fermentation liquid, a quantity of vinegar is discharged from the fermenter. Refilling with new mash of 0 to 2% acetic acid and 12 to 15% alcohol leads to the starting concentrations for the new cycle mentioned earlier. Discharging must be carried out quickly in order to avoid complete alcohol depletion. Charging must be done slowly under constant fermentation temperature and rapid mixing.

Since the middle of 1994, it has been possible to produce vinegar of up to 19% acetic acid in a modified single-stage process. Starting with similar concentrations as mentioned earlier, alcohol is slowly added at a constant alcohol level of 2 to 3% in the fermentation liquid, creating a corresponding increase of the total concentration. Addition of alcohol is stopped when the desired total concentration has been reached. When alcohol approaches zero, a part of the fermentation liquid is discharged and replaced by mash with lower total concentration to bring the acetic acid concentration and total concentration back to starting conditions, thereby enabling the bacteria to multiply faster. Later, total concentration is increased again by adding alcohol.

Continuous fermentation is only possible up to a maximum of 9 to 10% acetic acid because the specific growth rate of the bacteria decreases with decreasing ethanol concentration. To obtain high yields, the fermentation must be carried out at a low alcohol concentration.

Two-stage Processes. In the canning industry, vinegar with a very high percentage of acetic acid is in demand. The vinegar industry is interested in producing vinegar of high acidity in order to save storage and transport costs. Therefore, a two-stage process for the production of vinegar with more than 15% acetic acid was developed (57). During a submerged fermentation with a total concentration below 15% in a first fermenter, alcohol is added slowly to increase the total concentration up to about 18.5%. After the acetic acid concentration has reached 15%, about 30% of the fermenting liquid is transferred into a second fermenter. The first fermenter is resupplied with new mash of lower total concentration. In the second fermenter, the fermentation continues until the alcohol is almost depleted. The whole quantity of the finished vinegar is discharged. The fermentation liquid in the first fermenter is supplied with alcohol at the appropriate time and later divided again.

Since the end of 1993, vinegar of more than 20% acetic acid has been produced using this process. An automatic control for this process has been described (58).

In 1981, a similar two-stage process for the production of vinegar with more than 20% acetic acid was described (59,60). The second fermentation stage is carried out at a reduced temperature of only 18 to 24 °C, whereas in the first fermentation stage, the normal temperature range of 27 to 32 °C is used.

In 1984, another two-stage process was claimed (61) with semicontinuous fermentation in at least two fermenters, membrane filtration of the mash from the semicontinuous stage, using lower temperatures at higher acetic acid concentrations, and with the membrane-filtered vinegar to be used as a second end product.

The Frings Acetator®. Frings Acetator® is the most common equipment for the production of all kinds of vinegar. At the end of 1996, 642 Acetators, continuously improved, enlarged and automated, were in operation all over the world with a total production of $1{,}524 \times 10^6$ L/year of vinegar with 10% acetic acid. Energy consumption is about 400 W L^{-1} of fermented ethanol with decreasing tendency; yield is up to 98%.

Commercial sizes of Acetators are for the fermentation of up to 3,600 L of pure ethanol in 24 h.

The different processes demand excellent performance of the fermenter, especially of its aeration system. The Frings aerator (62), as shown in Figure 1, is self-aspirating; no compressed air is needed. The hollow rotor is installed on the shaft of a motor mounted under the fermenter, connected to an air suction pipe and surrounded by a stator. It pumps liquid that enters the rotor from above outward through the channels of the stator that are formed by the wedges, thereby sucking air through the

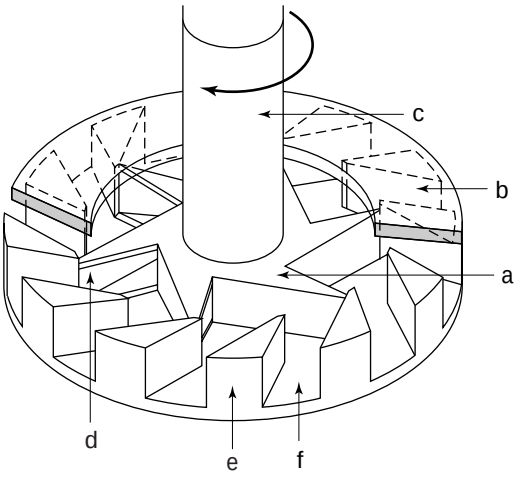

Figure 1. The Frings Aerator. a = hollow rotor; b = stator; c = air suction pipe; d = openings for air exit; e = wedges to form the channels; f = channels to form the beams of air–liquid emulsion.

openings of the rotor and creating an air–liquid emulsion that is ejected outward at a given speed. This speed must be chosen adequately so that the turbulence of the stream causes a uniform distribution of the air over the whole cross-*section of the fermenter.

Figure 2 shows this situation in a fermenter containing for demonstration a small amount of water immediately after the start of the aeration. Air is aspirated through the air suction pipe from the top, and the formed emulsion is spread out in beams at the bottom of the fermenter where they reach the wall of the fermenter somewhat outside of the cooling coils. Seconds later, the uniform aeration of the liquid takes place.

Because foam formation cannot always be avoided, the Acetator is equipped with a mechanical defoamer. From 1966 to 1991, the following equipment (63) was used. The rotor, turning in a spiral housing, separates liquid and gas and returns the liquid into the lower part of the fermenter. Only during discharging of the finished vinegar a part of this returned liquid is pumped out of the fermenter. Because this liquid causes foam formation, the defoamer must operate most of the time of a fermentation cycle. In an improved version (64), the separated liquid portion is not pumped back into the fermenter, but into a small collection vessel to be mixed with the vinegar end product later. Lysis of harmed vinegar bacteria releases foam-causing surface-active substances. By means of the total elimination of the separated liquid, further foam formation is avoided. Minimized foam formation with a shorter operating time of the defoamer and consequently a lower power uptake and a negligibly small volume of the separated liquid are the result.

The Frings Alkograph® (65), an automatic instrument for measuring the amount of ethanol in the fermenting liquid, has been in use since 1965. Small amounts of liquid flow through the analyzer continuously, at first through a heating vessel and then through three boiling vessels. The boiling temperature of the incoming liquid is measured in the first boiling vessel. While alcohol is distilled off continuously from the second and the third boiling vessel, the higher boiling point of the liquid from which ethanol has been removed is measured in the third boiling vessel. The difference in temperature corresponds to the ethanol content and is recorded automatically. Because the flow through the vessels takes some time, there is a delay of about 15 min between the beginning of the inflow of a sample and the appearance of the correct value on the recorder. Because alcohol concentration is decreasing slowly during fermentation, this delay has no disadvantage on fermentation control.

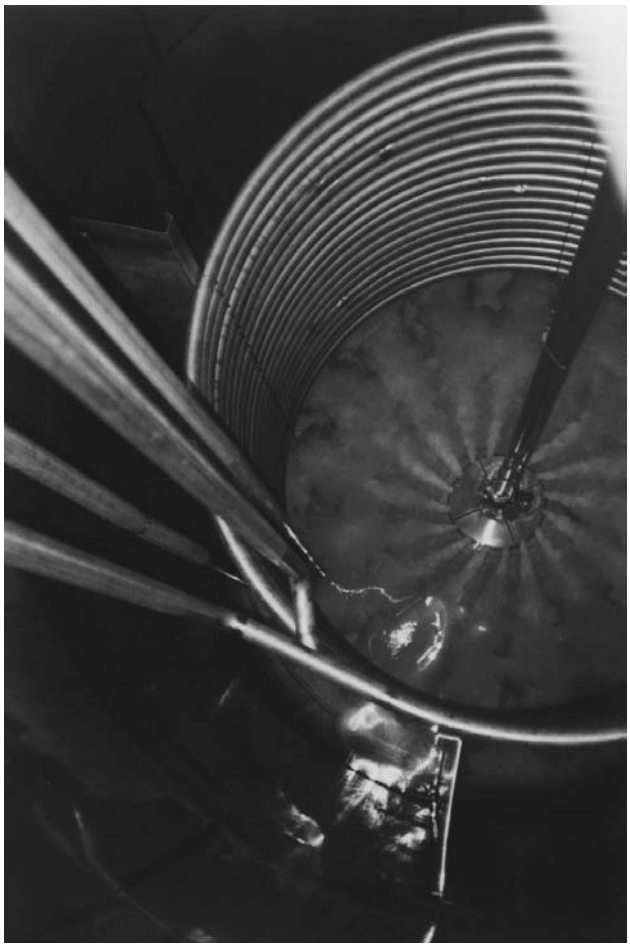

Figure 2. How the Frings Aeration System works. Acetator filled for demonstration with a small amount of water immediately after the start of the aeration. Air is aspirated through the suction pipe from the top and the formed emulsion is spread out in beams at the bottom of the fermenter, reaching the wall of the fermenter somewhat outside of the cooling coil.

To carry out the single-stage semicontinuous process at a defined alcohol content, a contact in the Alkograph activates the vinegar discharge pump. As soon as a preset level has been reached, the mash pump starts adding fresh mash. This pump is controlled by the fermentation temperature in order to refill under constant temperature. The pump is stopped when the desired level is reached and an automatic cooling system is activated. A fermentation cycle takes 24 to 48 h.

The Frings Alkograph® has worked with high reliability for about 30 years in 231 Acetators around the world. New biosensors together with modern membranes permitted the development of a device to measure alcohol without any time delay; the Frings Alkosens®. A device for measuring volatile constituents of the fermentation medium was described (66). A membrane serves to filter these volatile constituents from the fermentation liquid into a carrier medium, and they are recorded by an electronic sensor. Because the measurement relies on diffusion, ambient temperature has to be kept always at the same level. Thus, the alcohol probe is situated in the fermentation broth. The alcohol value displayed at the analyzer is influenced by the concentration of acetic acid, and, therefore, new calibrations are needed at different total concentration levels. This disadvantage has been overcome recently by a new system, which incorporates a multilayer membrane. New sensor technologies and more sophisticated computer equipment permit a fully automated process control of continuous, semicontinuous as well as single-stage or two-stage high-strength fermentations—preparation of mash included.

Further Trends in Submerged Processes. A computerized experimental laboratory system was applied 1992 (67) to submerged acetic acid fermentation with industrial *Acetobacter* strains at about 10% of final acidity using automated semicontinuous cycles during a period of one year. Based on these data, a mathematical model was developed to predict the time course of a cycle, even in the case when at the beginning of the cycle a lag phase occurred because of a lack of substrate at the end of the foregoing cycle. The parameters substrate, product, and biomass, however, were not sufficient to characterize the physiological status of the culture, since the behavior of the microorganisms also depends on their past. RNA concentration per unit of cell mass was found to be an internal key parameter that showed a reasonable agreement of the experimental data and the mathematical model.

In 1989, the possibilities of on-line measurement of alcohol concentration in vinegar production were summarized (68). In addition to the Frings Alkograph® the Alcolyzer®, a Japanese instrument based on the same principle, immobilized microbial sensors, and semiconductor alcohol sensors were described.

Experiments for the continuous production of acetic acid by submerged fermentation with continuous removal of acetic acid by electrodialysis, continuous supply of ethanol and concentrated nutrient solution, and control of ethanol and pH were reported (69–71). The reason for the continuous removal of acetic acid from the reaction mixture was to alleviate the inhibitory effect of the produced acetic acid. Ethanol concentration was kept constant at 1%, acetic acid concentration at approximately 2%. Without dialysis and pH control, acetic acid production already stopped after 2 days at approximately 4%, whereas with dialysis it lasted 30 days.

Other Submerged Fermentation Processes. Other processes of little practical significance and abandoned processes have been described (1).

Continuous Culture and Cell Recycle. Much work was invested (53,72) to increase the productivity of the acetic acid fermentation by continuous culture and cell recycle.

It must indeed be admitted that at first sight the productivity in an Acetator does not seem to be very high. The Acetator 3600® produces during 24 h 4,000 kg acetic acid with a concentration of up to 15% in a fermenting volume of 100 m^3, that is, 1.6 g L^{-1} h^{-1} acetic acid in average or about 2.4 g L^{-1} h^{-1} at the maximum fermentation rate. The aeration rate is 0.1 vvm only; the nutrient consumption is the same as described in Physiology.

Kinetic studies (72) clarified the dependence of the bacterial growth rate on ethanol concentration, on acetic acid concentration, and on concentration of dissolved oxygen. The optimum ethanol concentration is 23 g L^{-1}, the optimum acetic acid concentration is 36 g L^{-1}, and the optimum oxygen concentration is 2.5 − 3 mg L^{-1}. The productivity of acetic acid formation mainly depends on the growth rate but also on the cell concentration. Therefore, the maximum productivity of 6 to 6.6 g L^{-1} h^{-1} acetic acid can be obtained at 32 g L^{-1} ethanol, and 60 to 66 g L^{-1} acetic acid.

The synergistic effects of acetic acid and ethanol on the growth of *Acetobacter* sp. at low concentrations showed similar results (73).

At first sight, the potential productivity is about 4 times higher than presently achievable and could even be further increased by recycling of the bacteria. However, this high degree of productivity can only be achieved at a narrow concentration range. A slight change of ethanol, acetic acid, or oxygen concentration results in an immediate return to lower values.

For technical applications, a second fermenter in series to the fermenter, operating at optimal fermentation conditions, would be necessary to complete the fermentation. To keep a high oxygen concentration in the fermenting liquid at the higher fermentation rate, a high aeration rate would be necessary with recovery of ethanol and acetic acid from the exhaust gas to obtain high yields, and probably addition of oxygen would be necessary. Higher nutrient consumption as well as increasing foam formation would result. The cell recycle system would need a continuous microfiltration avoiding a lack of oxygen and require an automatic control of cell concentration. But all the expenditure in process control only allows the production of the same amount of vinegar, containing not more than 10% acetic acid, in a smaller fermenter. Apparently, the demand for high productivity does not necessarily indicate the optimal developments for future production.

An attempt was made to enhance continuous acetic acid production in a laboratory fermenter equipped with a hollow fiber filter module by increasing the concentration of dissolved oxygen (74,75). The maximum acetic acid concentration achieved was 5%. The highest productivity obtained with yeast extract as nutrient was 107 g L^{-1} h^{-1}. The concentration of dissolved oxygen was already lower than the critical concentration of 1 ppm, although pure oxygen was supplied at an aeration rate of 1 vvm. Furthermore, it was difficult to maintain a high concentration of viable cells in the cell recycle culture, because the cells were inactivated by the lethal conditions of acetic acid concentration, oxygen deficiency, and nutritional limitation.

The effect of dissolved oxygen and acetic acid concentration on acetic acid production in continuous culture has

extensively been investigated (75). The optimum concentration of dissolved oxygen was found to be about 2 ppm for acetic acid production at low acidity. The specific acetic acid production rate, however, was diminished to complete inhibition when the dissolved oxygen concentration was higher than 2 ppm at an acetic acid concentration of more than 4.5%. This is in good agreement with older findings (48), stating that the use of pure oxygen during fermentation can completely inhibit the acetic acid formation.

Because viability of the bacteria is important for high productivity, the factors affecting viability have been investigated (76). To study the effect of cell bleeding (withdrawing at constant flow rate), serial experiments were performed in a bioreactor with cell recycle and were supported by mathematical analysis. Acetic acid concentrations were up to 5.6%. The maximum value of productivity was 123 g L^{-1} h^{-1}. The bleed ratio and dilution rate at which concentration of acetic acid and viable cells are relatively high can be predicted now.

The authors expect these results to be useful for designing a two-stage culture for acetic acid production using the active cells in the bleed from the first stage in a second-stage vessel beyond a lethal acetic acid concentration.

How far these certainly interesting results will influence the construction of industrial equipment in Japan remains to be seen. The costs of such complicated fermenters may slow down or even prevent a fast conversion to industrial scale, although in Japan the demand for vinegar with 5% acetic acid is relatively high. However, these results will certainly have no influence on the production of vinegar with more than 10% acetic acid. A review of the Japanese development work (77) states that the problem of scale-up remains for further investigation.

Semicontinuous Culture with Cell Recycle. During investigation of semicontinuous cultures with cell recycle, an increase was found in the productivity compared to semicontinuous culture without cell recycle at an acidity of up to 6% (78). Although the concentration of total cells increased in every cycle, the viable cells reached a much lower quasi steady-state value, which was explained by product inhibition. The productivity was 2.9 g L^{-1} h^{-1} without and 5.0 g L^{-1} h^{-1} with cell recycle at 6% final acetic acid concentration, but 14 g L^{-1} h^{-1} at 3% final acetic acid concentration.

In another study (79), semicontinuous fermentations were reported in which the ethanol concentration was kept for a certain time between 20 and 30 g L^{-1} by adding ethanol-enriched medium. At the end of the cycle, ethanol-poor medium was added. Cells were recycled by membrane filtration. The goal was to obtain high concentrations of acetic acid; the highest amount reached was 9%. It was found that the *Acetobacter* cells lost their viability at about 6% acetic acid, but these nonviable cells were still effective for ethanol oxidation. This interesting feature of *Acetobacter* cells had already been reported much earlier (80).

Surface Fermentation. ***Old Surface Fermentation Processes.*** Detailed descriptions of the history of vinegar fermentation were published in 1976 (81). Today, the equipment used in the famous Orleans process for the production of wine vinegar can only be seen in museums.

New Experiments with Surface Fermentation. A new approach to surface fermentation has been tried (82). The authors used a bioreactor with a shallow, horizontal flow of the medium under a bacterial film with a surface of a few hundred cm^2. Liquid depth was up to 10 mm, and the acetic acid concentration of the effluent was 5.76%. The oxygen absorption rate through the microbial film was found to be very high; a kinetic study of acetic acid production was published (83).

A surface fermentation process in a system of serial intercommunicating fermentation vessels, with flow-regulating devices that enforce the flow to approach plug flow, was described (84). The liquid depth under the layer of acetic acid bacteria was about 50 mm. The inflowing liquid had 2% acidity and contained 3.5% alcohol. The acidity of the effluent stabilized at 5% acetic acid. The residence time was about 21 h.

Investigations on continuous surface fermentations in a single vessel with a working volume of 16 L were reported (84). Under optimum conditions with a liquid depth of 100 mm, 2 to 3% acidity and 20 to 30 g L^{-1} h^{-1} alcohol concentration of the inflowing liquid, vinegar with 4.5% acetic acid was produced during 80 days. The flavor of this vinegar was claimed to be better than that of vinegar produced by other processes.

As a consequence of the efforts to produce rice vinegar at low acidity with better quality, surface fermentation is developing in Japan into an automatic fermentation process at lower costs.

Trickling Processes. The old semicontinuous generator process used beech wood shavings, birch twigs, or corn cobs as carrier material for the vinegar bacteria. Large wooden tanks with up to 100 m^3 shavings are still in use. For more details refer to the work by Ebner and Follman (1). Despite the disadvantages of the trickling process, the use of a silicate carrier material with a large specific inner surface and an open pore structure was proposed recently (86).

Experiments with Immobilized Acetic Acid Bacteria. Many Japanese scientists investigated the fermentation of rice or fruit vinegar with the usual concentration of about 5% acetic acid in continuous fermentation of high productivity with immobilized acetic acid bacteria.

A 460-day run in an airlift bioreactor with acetic acid bacteria immobilized on κ-carrageenan gel beads, where living cells were newly released into the reactor, was reported (68). These newly released bacteria showed extremely high growth rates and respiratory activity that they retained for a few generations after leakage.

Polypropylene fibers as carrier material for *Acetobacter* producing rice vinegar of 3% acetic acid were proposed (87,88). With ceramic honeycomb-monolith as carrier in a fixed-bed reactor a maximum of 4% acetic acid was achieved (89). Calcium alginate beads in a fluidized bed reactor were investigated and 3.5% acetic acid obtained (90). The same author (91,92) used this reactor in combination with an ethanol fermenter to produce rice vinegar of up to 6.5% acetic acid from a saccharified rice medium.

A two-column bioreactor of porous ceramics was tested to produce vinegar of an orange wine with up to 8.4% acetic

acid (93). If the cells were fixed on woven cotton fabric, vinegar of kiwi fruit and persimmon of 4.5% acetic acid could be produced (94). A new ceramic carrier called Aphrocell with a continuous pore structure was tried (95), but the oxygen supply to this structure was difficult. None of the tested carriers proved to be ideal.

Experimental and theoretical studies on the continuous acetic acid production by immobilized cells in a three-phase fluidized-bed bioreactor at very low acetic acid concentrations were carried out (96). The influence of gel-entrapped and suspended cells, gel size, $k_L a$, and solid hold-up on productivity was studied by theoretical calculations and experiments.

Mori et al (97–99) reported that immobilized acetic acid bacteria are highly oxygen dependent. Therefore, it is advantageous to supply oxygen to a closed and pressurized culture. Because acetic acid inhibits the bacteria, it is considered that multiple reactors in series would be the best solution to obtain an increasing acidity, thereby keeping the dilution rate higher and creating the prolonged residence time necessary. An output acidity of 5.5% was obtained in two fluidized-bed type tabletop reactors in series. In scaling up to a pilot reactor, however, the microbial layer peeled off from the carrier too easily independent of its material. More operational know-how is needed for the practical application of this technology.

Environmental Protection. Today it is possible to produce vinegar without any environmental pollution. The exhaust gas contains alcohol, acetic acid, and ethyl acetate according to their vapor tension at a fermentation temperature of about 30 °C. To obtain high yields, the aeration rate is chosen as low as possible. It is furthermore common practice today to cool the exhaust gas down with cooling water as far as possible, and in order to absorb the rest of the volatiles it can be scrubbed with water that is recycled and used for mash preparation later.

The raw vinegar contains bacteria that have to be filtered off. Today, most modern factories use cross-flow filtration without adding any filter aid. The very small quantity of remaining solids of about 100 g $\times$ 1,000 L^{-1} of vinegar formed by acetic acid bacteria are degraded during wastewater treatment.

Production Volumes

United States. The U.S. vinegar industry ceased years ago to control and to publish vinegar production figures. Therefore, older figures must be quoted here. Production volumes in 1987 were 581 $\times$ 10^6 L of distilled vinegar, 54 $\times$ 10^6 L of cider vinegar and 126 $\times$ 10^6 L of other types of vinegar, all of different strength.

European Union. In 1995, the European Union produced 349 $\times$ 10^6 L alcohol vinegar, 160 $\times$ 10^6 L wine vinegar and 57 $\times$ 10^6 L other kinds of vinegar (all of 10% acetic acid), together 566 $\times$ 10^6 L.

Japan. In 1994, Japan produced 56 $\times$ 10^6 L of rice vinegar, 146 $\times$ 10^6 L of other grain vinegar, 22 $\times$ 10^6 L of fruit vinegar, and 166 $\times$ 10^6 L of other brewed vinegar, all together 390 $\times$ 10^6 L at a concentration of 4 to 5% acetic acid.

Worldwide. The world production (excluding the USSR and China) of vinegar of 10% acetic acid is assumed to be around 2,000 $\times$ 10^6 L per year, or 200, 000 tons of pure acetic acid.

OUTLINE

INTRODUCTION

Waste air or waste gases of industrial processes may contain volatile organic or inorganic odorous or toxic compounds. These gases are not to be released to the environment, according to national or European legislation, which defines the allowances of the individual compound to be released. Environmental biotechnology including waste gas treatment was first developed in countries using the German language and in The Netherlands. In these countries, waste gas treatment was applied by the industry for elimination of odor emitted from wastewater treatment plants, slaughterhouses, and such facilities. For more than two decades, plants have been operated with increasing efficiency, and their application has been extended to the chemical, pharmaceutical, and food industries. Initially, most information has evolved from these European countries; experience has been compiled and merged into guidelines for design and application of industrial biofilters, trickle-bed reactors, and bioscrubbers. The principles of these plants are shown in Figure 1. These guidelines have been published by the Verein Deutscher Ingenieure (VDI, Association of German Engineers) in German and in English (1,2). The developing technology was subsequently recognized on other continents. Previous articles on biological waste gas cleaning have covered different processes, mass transfer, biological, chemical, and olfactory aspects, and costs, and the reader is referred to comprehensive reviews (3–5) with detailed references therein.

High concentrations of organic or inorganic pollutants are currently eliminated from waste gases by sorptive processes or thermal of catalytic oxidation. Low pollutant concentrations and odorous compounds are also being traditionally eliminated by biological processes. Plant investment and operating costs of biological waste gas cleaning processes are significantly less than alternative physicochemical processes (6). This fact is the major driving force for academic and industrial research to develop biological processes and to extend these for elimination of high concentrations of pollutants from waste gases.

Presently, the three types of plants mentioned (Fig. 1) are currently used for biological treatment of different qualities of waste gases, which later are treated in detail. Biofilters require a substantial area and are filled to a low height with organic matter such as compost or chopped wood, which serves in part as a source for minerals for the attached microorganisms. Biofilters are suited for cleaning low concentrations of pollutants. Trickle-bed reactors require less area, are operated as towers, and are filled with incompressible porous minerals as air–liquid contactor and as support for microbial growth. Bioscrubbers are generally composed of two units—one for scrubbing the pollutants from the gas phase and the other as fermentor for microbial degradation of the pollutants comparable to activated sludge.

Microorganisms, bacteria or fungi, use the organic or inorganic compounds for energy transformation and for biomass formation. Biological waste gas cleaning is an aerobic process and is brought about by aerobic microorganisms either suspended in water or attached to some support material as a biofilm. Process development is required to establish and to maintain optimum conditions for these microorganisms to achieve an optimal elimination of pollutants from air. Microorganisms require different elements to build up biomass, which is composed of proteins, sugar polymers, fatty acids, nucleic acids, and so forth. The

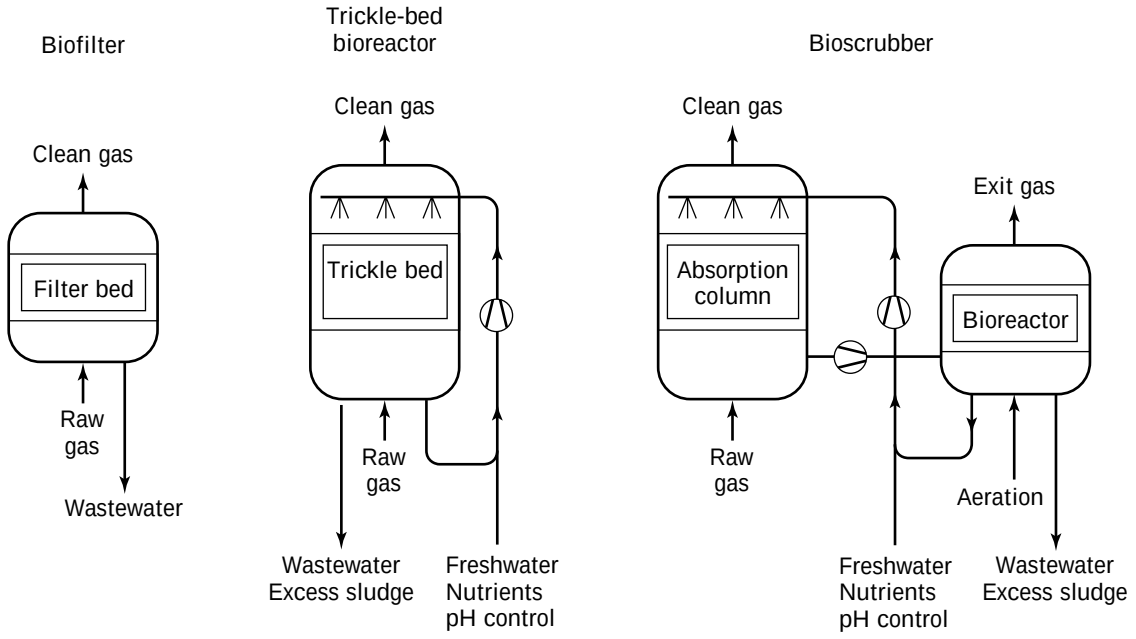

Figure 1. Schematic representation of different types of plants currently used for waste gas treatment.

energy to build up the respective monomers and to polymerize these is derived from the biochemical oxidation of volatile organic matter to carbon dioxide or from gaseous inorganic reduced compounds. Because the microorganisms are present in the aqueous phase, the organic or inorganic substrates must be transported from the gas to the liquid phase. Because biological waste gas cleaning is also an aerobic process, oxygen has to be transported to the liquid film and products have to be transported either to the gas or to the liquid phase.

The degree of elimination of a pollutant and the selection of the process is determined by different factors (Fig. 2): (*1*) the quality of the waste gas determined by the chemical nature of the pollutant, composition of different pollutants, pollutant concentrations, pollutant metabolic accessibility, and the volume of the gas emitted per unit of time; (*2*) the biomass and its physiological state determined by the rate of conversion of the substrates; (*3*) the availability of the substrates determined by the mass transfer of the pollutants and of oxygen from the gas phase to the biofilm and the export of degradation products therefrom (mass transfer depends on the process selected [e.g., biofilter, trickle-bed reactor, or bioscrubber] and on the physicochemical nature of the pollutants to be eliminated); and (*4*) costs of investment and of operation for waste gas cleaning determine the selection of each of these factors by the impact on overall productivity, reliability, and thus profitability.

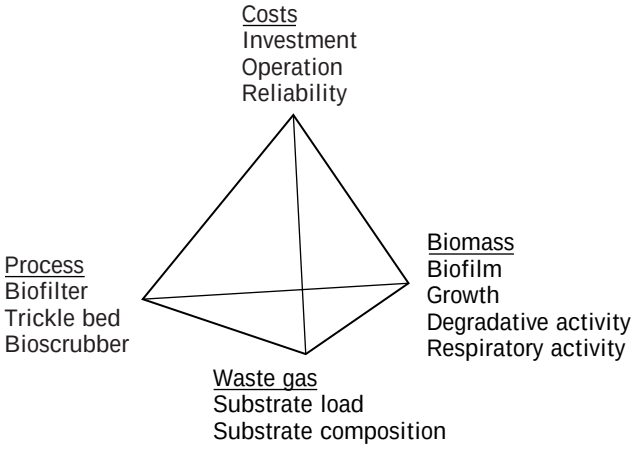

Figure 2. Interrelationships of different parameters crucial for costs and efficiency of waste gas treatment plants.

MICROORGANISMS AND THE BIOFILM

Industrial waste gas cleaning systems are currently operated under nonaxenic conditions and, as a result, contain different populations of bacteria, fungi, and protozoa. Such populations may establish randomly by means of the content of bacteria and bacterial and fungal spores in the surrounding air. To rapidly establish a microbial population in the reactors, these are often inoculated with suspensions of wastewater treatment plants. Because the composition of the waste gas determines the development of microorganisms best fitted to respective conditions, initial efficiency of a plant may be suboptimal. Also, because microorganisms are the crucial phase in biological treatment, they are emitted by the stream of the clean gas that is the subject of hygienic concern.

Establishment of the Microbial Population

Initial colonization of the microbes is the result of adsorption onto the surface of the support material, which occurs

almost instantly. Secondary colonization is characterized by the formation of filaments and of extracellular polysaccharides, which together form the biofilm. The kinetics of biofilm formation, its composition, changes, properties, and impact on biocorrosion have been reviewed previously (7). The composition of the species changes with duration of operation. Moreover, under steady-state conditions of the plant, the biofilm represents an ecosystem with grazing protozoa digesting free-living bacteria. Protozoan predation has resulted in a low and constant level of of bacteria, which, however, may not be detrimental to the efficiency of a plant but increase stability of trickle-bed reactors, for example. Enhancement of carbon mineralization up to 22 to 80% and decrease in pressure drop by preventing the extent of clogging have been reported from laboratory waste gas treatment systems. Moreover, most protozoa are not attached to surfaces and could be purged out by flushing the different systems (summarized in Ref. 8).

The use of pure bacterial cultures with defined catabolic properties with the ability to degrade xenobiotic or toxic compounds at known rates has been suggested to be advantageous with respect to waste gas cleaning. Several bacterial species specialized to degrade different solvents have been adsorbed on activated carbon. With suitable bacterial strains, 90% of the solvents could be eliminated from the gas phase, and mass transfer to the biofilm appeared to be limiting the efficiency of the laboratory trickle-bed reactor (9). No reports are presently available for industrial application of monocultures.

Health Considerations

Health hazards for personnel or the surrounding population emerging from waste gas treatment plants have not been reported. However, different bacterial species so far identified from various waste gas treatment plants have been mainly related to the degradative capability of the respective facility. Among these, species of the genus *Pseudomonas* have been identified that are highly versatile in utilizing aromatics and other volatiles. One concern is the release of potentially pathogenic microbes to the environment with the exit gas stream. Some studies have been devoted to this fact. The transport of microbial germs, mainly bacteria and to a smaller extent spores of molds, in the outlet gas of the different full-scale biofilters varied between 10^3 and 10^4 cells/m^3, which is of the same order of magnitude as indoor air (10). Search for fungal spores, the potential causative agent of mycogenic allergies, revealed a minor reduction of spores emitted from clean gas as compared to raw gas from moist biofilters, whereas emission from a dry biofilter temporarily exceeded that determined from raw gas by more than three orders of magnitude (11).

Identification of microorganisms is laborious, time consuming, and costly, and most reports consider the absorption of pollutants rather than the emission of microbes. The technology to detect and to identify specific bacteria within multispecies biofilms, however, is presently available and is used to describe microbial ecosystems. Nucleic acid hybridization techniques and comparative sequence analyses are increasingly being applied to environmental microbiology. More recently, fluorescent dye-labeled oligonucleotide probes have been used for identification of single cells (12).

MICROBIAL GROWTH AND DEGRADATIVE ACTIVITY

Organic or inorganic pollutants of waste gases are substrates for microorganisms. Organic carbon sources have a dual function as substrate for the living cell. Dissimilation of the carbon source characterizes its quality as an energy source to donate electrons for aerobic respiration, which yields the energy required for growth and maintenance of the cell. Carbon is also assimilated by the cell for growth to build up cell constituents. Carbon dioxide and water are the products of the dissimilatory aerobic respiration, and biomass is the product of the resulting assimilation. The quality of a given carbon source as an energy source depends on its degree of reduction and on the type of metabolism, as is shown for dissimilation of one-carbon compounds such as methane, methanol, and formaldehyde (Table 1).

These compounds are oxidized to carbon dioxide, water, and the reductant. Moreover, substitutions of hydrogen by halogens such as methylenechloride cause the release of hydrochloric acid. Degradation of methylmercaptane results in the release of hydrogen sulfide and that of methylamine results in the release of ammonia. The by-product hydrogen sulfide is subsequently oxidized by thiobacteria to sulfuric acid, and ammonia is oxidized by nitrifying bacteria to nitric acid, both resulting in acidification of the environment (Table 1). Therefore, the nature of the pollutant to be mineralized by the microorganisms has a significant impact on the pH of the microenvironment within the plant and on pH-dependent microbial degradative activity.

Table 1. Respiration and Mineralization of Differently Reduced and Substituted One-Carbon Compounds, Nitrification, and Sulfur Oxidation

Respiration

$$4[H]^a + O_2 \rightarrow H_2O$$

Mineralization

$$CH_4 + O_2 \rightarrow CO_2 + 4[H]$$
$$CH_3\text{-}OH + H_2O \rightarrow CO_2 + 6[H]$$
$$CH_3\text{-}NH_2 + 2H_2O \rightarrow CO_2 + NH_3 + 6[H]$$
$$CH_3\text{-}SH + 2H_2O \rightarrow CO_2 + H_2S + 6[H]$$
$$CH_2\text{-}Cl_2 + 2H_2O \rightarrow CO_2 + 2HCl + 4[H]$$
$$CH_2O + H_2O \rightarrow CO_2 + 4[H]$$

Nitrification

$$NH_3 + 2H_2O \rightarrow HNO_2 + 6[H]$$
$$HNO_2 + H_2O \rightarrow HNO_3 + 2[H]$$

Sulfur oxidation

$$H_2S + 4H_2O \rightarrow H_2SO_4 + 8[H]$$

[a][H] is equivalent to ($H^+ + e^-$) and represents the reductant hydrogen carrying one electron.

Acidification as a result of the elemental composition of the pollutants as well as the composition and distribution of the different microbial species may require mixing, washing, and pH control of the biofilm attached to the support material or being suspended in the aqueous phase. The different principles of waste gas treatment processes such as biofilter, trickle-bed reactor, or bioscrubber differ in efficiency in mass transfer, capacity to harbor biomass, and costs. Thus, knowledge of the quality of the waste gas with respect to its composition or load is essential for selection of the process.

One crucial criterion in microbial transformations is the overall rate of degradation. The mean residence time of a gas passing certain industrial waste gas treatment plants is occasionally less than a second (2). In this period of time, mass transfer and degradation of the pollutant must occur—and it does.

CELLULAR YIELDS AND MAINTENANCE REQUIREMENTS

The composition of the waste gas usually contains few elements—carbon, hydrogen, or oxygen as in the case of acetone—and other elements (N, P, S, Mg, K, Fe, etc.) are also required to build up biomass. Formation of biomass with constant elemental composition is a function of the organic substrate when each element required for growth is supplied by the environment and expressed as the cellular yield ($Y_{X/S}$) (gram dry cell weight per gram of substrate). In biofilters, some minerals may originate from the support material such as wood, heather, or compost, whereas in other waste gas cleaning plants minerals may be supplied from the added water. Mostly, there will be a severe imbalance in supply with elements required for microbial growth, whether the major pollutant was a hydrocarbon, solvent, hydrogen sulfide, ammonia, or methylenchloride. Imbalance in nutrient supply may originate from the surplus of the carbon source or from the limited supply of minerals, both resulting in two different consequences. First, imbalance of the elemental composition of the biomass may result from storage of different compounds. Excess phosphate supply to certain bacteria results in accumulation of intracellular polyphosphate; excess carbon and energy source may result in either intracellular accumulation of polyhydroxy fatty acids or the formation of extracellular polysaccharides and biofilms. Second, the growth rate may be affected and the requirements for maintenance energy may increase significantly. Maintenance energy is defined as the amount of substrate required by the cell to maintain vital cell functions without growth (equation 1). The concept of maintenance requirements was first described by Pirt (13) and was later extended by Neijssel and Tempest with the definition of overflow metabolism (14).

$$1/Y = m/\mu + 1/Y_{max} \quad (1)$$

where Y is the cellular yield, Y_{max} the maximum cellular yield, μ the specific growth rate (1/h), and m the maintenance coefficient (g substrate/g dry cell weight h^{-1}).

Overflow metabolism may result in two different phenomena: *(1)* the uncoupling of energy transformation of respiration leading to a low cellular yield and higher rate of oxidation of the substrate to carbon dioxide and *(2)* the formation of polymeric or monomeric by-products. The applicability of these academic findings to waste gas cleaning systems has been subsequently proven successful in laboratory plants (15). However, defined conditions of specific nutrient limitations are susceptible to changing concentrations of volatile organic carbon in the raw gas, which changes the balance in nutrient supply, and thus conditions for optimal mineralization to carbon dioxide and water are difficult to maintain.

ORIGIN, COMPOSITION, AND SENSING OF WASTE GAS COMPONENTS

Waste gas originates from very different industries, from air exchange of buildings, and from various processes. More than 500 biofilters and more than 200 bioscrubbers are currently operated in Germany and in The Netherlands, although outside Europe this technology is less often used. Different industries that apply biological waste gas cleaning as an air pollution control technology are listed in Table 2. The efficiencies of some of these to remove volatile organic carbon or odor are compiled in Table 3. A more comprehensive compilation is given elsewhere (1,2). Most of these facilities emit gases at high flow rates of 1,000 to 120,000 m^3/h but with low concentrations of volatile organic and inorganic compounds. Odor removal is quantified by olfactometry, which is costly and requires reliable calibration as evident from an interlaboratory comparison of odor measurements of *n*-butanol (25). Recent developments aim at on-line sensors for the quantification of odors. Odor threshold concentrations to be recognized by humans depend on the respective compound and composition of the volatiles. Some threshold concentrations for sensing the odor of chemicals such as dimethylethylamine, phenol, or volatiles of defined composition have been correlated to total organic carbon determined by flame

Table 2. Compilation of Some Industries Applying Biological Waste Gas Cleaning

Biofilter	Trickle-bed reactor	Bioscrubber
Animal rendering	Chemical industry	Aluminum foundry
Bone processing	Concrete slap production	Animal rendering
Chemical industry	Fibrous skin production	Blood processing
Coal mine exit gas	Grease melting plant	Chipboard production
Dump gas	Plastic production	Egg farms
Feces drying	Rayon production	Grease melting plant
Fish smoking	Sewage treatment plants	Grinding wheel production
Fish processing		Printing plant
Foundries		Tobacco industry
Fragrance production		Polyester production
Food production		
Pig farms		
Slaughterhouse		
Tobacco processing		
Varnish production		

Table 3. Compilation of Selected Efficiencies of Different Industrial Waste Gas Cleaning Facilities

Waste gas cleaning plant	Type of reactor	Eliminated pollutant	Total gas flow rate	Raw gas concentration	Clean gas concentration	Refs.
Rendering plant	Tree bark biofilter	Odor/VOC	160 $m^3\ m^{-3}\ h^{-1}$	256 mg organic C/m^3	38 mg organic C/m^3	
				1,700 OU	160 OU	1
Domestic refuse compost	Compost biofilter	Odor/VOC	60 $m^3\ m^{-3}\ h^{-1}$	230 mg organic C/m^3	8–9 mg organic C/m^3	1
Piggery	Peat/twigs biofilter	Odor	141 $m^3\ m^{-3}\ h^{-1}$	50–200 OU	Not detectable	1
Leather processing facility	Compost/chaff biofilter	Solvents	128 $m^3\ m^{-3}\ h^{-1}$	61 g $m^{-3}\ h^{-1}$	41 g $m^{-3}\ h^{-1}$	16
Canning industry	Compost biofilter	Solvents	40 $m^3\ m^{-3}\ h^{-1}$	470 mg organic C/m^3	55 mg organic C/m^3	23
Lacquerworks	Pilot biofilter	Solvents	30–71 $m^3\ m^{-3}\ h^{-1}$	642–1,415 mg/m^3	60–79 mg/m^3	17
Cacao roast house	Biofilter	VOC	75,000 m^3/h	7–615 mg organic C/m^3	1–6 mg organic C/m^3	18
		Odor		49,927–446,000 OU	35–773 OU	18
Printer's color production	Trickle-bed reactor	Toluene/ ethanol	214 $m^3\ m^{-3}\ h^{-1}$	450 mg organic C/m^3	<70 mg organic C/m^3	19
Resin-laden waste gas	Pilot trickle-bed reactor	Formaldehyde	760 $m^3\ m^{-2}\ h^{-1}$	10–30 mg/m^3	0.9–2.7 mg/m^3	20
		Phenol		10–30 mg/m^3	0.1–0.3 mg/m^3	20
		Ammonia		20–90 mg m^3	1.6–7.2 mg/m^3	20
Plastic production	Trickle-bed reactor	Styrene	51,000 m^3/h	0.6 g/m^3	Data not given	21
Lacquer production	Bioscrubber/ biofilter	Solvents	16,000 m^3/h	≤800 mg/m^3	50 mg/m^3	21
Car tunnel exit gas	Pilot trickle-bed reactor	Carbon monoxide	8–23 m^3/h	10–30 ppm	0.8–2.4 ppm	22
		NO_x		0.5 ppm	0.1 ppm	22
		C_xH_y		2 ppm	0.8 ppm	22
Wastewater treatment	Bioscrubber	Hydrogen sulfide	6.000 m^3/h	20 ppm	0.2 ppm	23
Rendering plant	Bioscrubber	Odor	40.000 m^3/h	10,000–70,000 OU	<100 OU	2
Plastic production facility	Bioscrubber	Hydrophobic VOC	10.000 m^3/h	≤200 mg organic C/m^3	10–40 mg organic C/m^3	24

Note: VOC, volatile organic compounds; OU, olfactometric units (cannot be compared from different references).

ionization detection, which is a reliable and available technology for continuous exit gas analysis. Threshold concentrations for odor sensing vary from 0.1 to 4.9 mg organic carbon/m^3 for defined chemicals and from 0.1 to 0.5 mg organic carbon/m^3 for waste gas from food processing and other industries. Usually, the degree of reduction of odor intensity is more effective than the elimination of volatile organic carbon.

Flame ionization detection of volatiles allows quantification of organic carbon but does not differentiate between different components of the waste gas. Thus, the degree of elimination of individual compounds cannot be differentiated. To follow the elimination of different components, identification by gas chromatography is required. This analysis has been used to follow degradation of different solvents in waste gases.

Corrosion of the detecting devices may be observed on on-line quantification of haloorganic compounds such as chloromethanes, chlorobenzenes, chloroethanes, or fluorinated or bromated compounds by flame ionization detection because of formation of the respective hydrohalic acids. Therefore, sampling, gas chromatography, and different detection systems may be advisable.

MASS TRANSFER IN WASTE GAS TREATMENT PLANTS

The principles of mass transfer were first elaborated to understand and to design chemical reaction processes and have been described elsewhere (26,27). However, these principles can be transduced also to biochemical and biological reactions where substrates must be delivered to the microbial cell and metabolic products have to be removed therefrom (3,28,29). This is especially important when a substrate is supplied from the gas phase to the aqueous phase, which is the environment for microbial life and activity.

The principles of mass transfer are applicable to the different processes treated here. However, the differences in design of these plants are based on different principles of gas–liquid contactors for transfer of volatile chemicals of different properties such as hydrophilic or hydrophobic and soluble or insoluble compounds. Therefore, the principles of the transfer of substrates of different physicochemical properties from the gas phase to the biofilm are discussed first, and subsequently mass transfer in biofilters, trickle-bed reactors, and bioscrubbers.

Mass Transfer from the Gas Phase to the Biofilm

Total mass transfer rate (J) from the gas to the liquid phase is driven by the difference in concentration of a given component in equilibrium with the gas phase (c_G) and the actual concentration in liquid phase or the biofilm (c_B), the specific interfacial area (a), and a correlation factor designated mass transfer coefficient (β) as described by equation 2:

$$J = \beta a(c_G - c_B) \quad (2)$$

The specific interfacial area is generally defined as the quotient of the total area for mass transfer and the total reactor volume.

The mass transfer coefficient is influenced by the different steps for mass transfer from the gas phase to the liquid phase and to the biofilm. These steps are the superpositions of convection and diffusion in both fluid phases and the absorptive transition of the component to the liquid phase and to the biomass, as shown schematically in Figure 3a. The equilibrium in absorption at the transition phase is expressed by Henry's law, equation 3:

$$c_G = Hc_F \quad (3)$$

where c_G is the partial pressure of the component in the gas and c_F of that in the fluid. A similar correlation holds for the phase-interface liquid or biofilm.

During steady-state operation of a plant, mass transfer rate (J) is in equilibrium with the substrate consumption rate (J_R) of the biomass as expressed in equation 4:

$$J = J_R = K_R a c_B^r \quad (4)$$

where K_R is the reaction rate of the biomass, a the specific area, c_B the concentration of the component in the biofilm, and r the order of the reaction. Mostly, biological reactions are of zero order when these are independent of the substrate concentration and of first order when the substrate concentration determines the reaction rate. The overall reaction rate is determined by the different steps just mentioned. However, in special cases one step may dominate the process, for example, when the rate of absorption of a pollutant is low as given for chemicals with Henry coefficients >1 MPa or low biological degradation rates. Parameters affecting the capacity of waste gas cleaning facilities are discussed next.

Limitations of Reaction Rates

Several examples have been described that demonstrate the significance of single steps on the overall process (27,28,30). The degradative activity of a given biofilm may be limited by suboptimal physiological conditions, which are discussed here, and the mass transfer rates. These conditions apply to the organic or inorganic electron donor for energy transformation, in our case the volatile pollutants, mass transfer rate of the electron acceptor oxygen, the low rate of pollutant degradation by the biofilm, or a combination of these caused by local differences within the reactor.

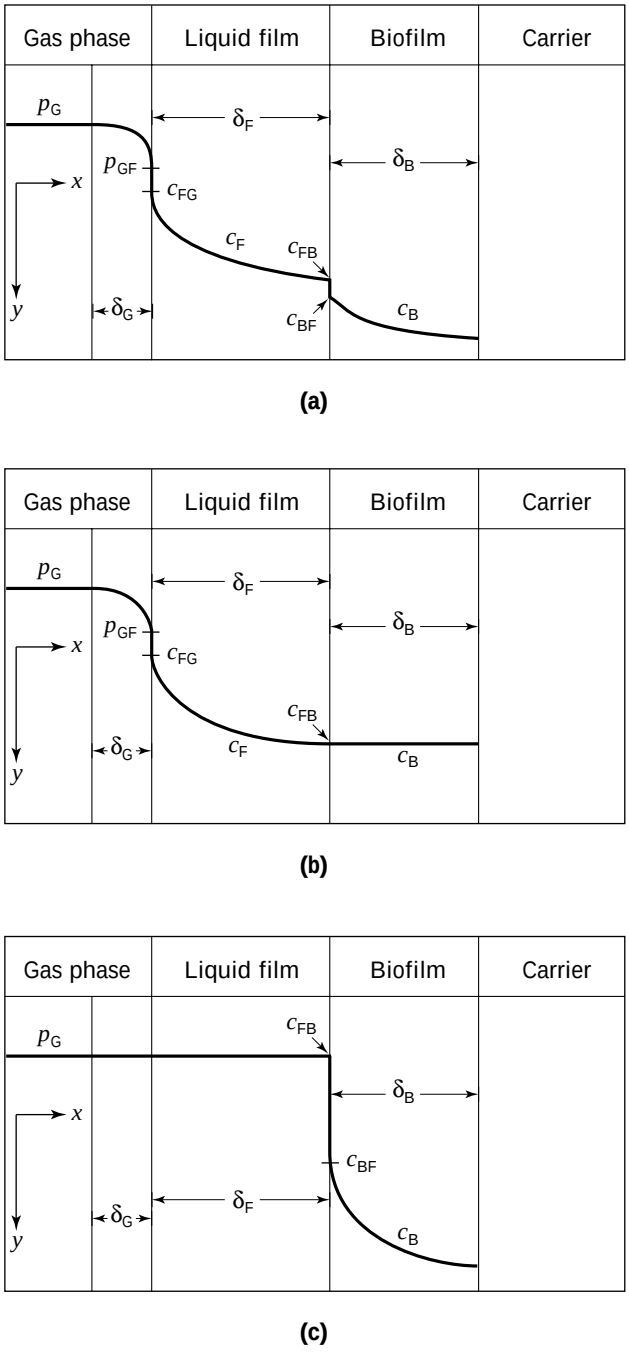

Figure 3. Substrate concentration profiles within the gas phase, the liquid phase, and the biofilm. (**a**) Decrease in concentration caused by biofilm degradative activity and substrate transport by diffusion and convection; (**b**) limitation by mass transfer from the gas phase to the liquid film; (**c**) limitation by degradative activity of the biofilm. p_G, p_{GF}, pollutant partial pressure in the gas phase and at the phase-interface gas–fluid; c_{FG}, c_F, c_{FB}, pollutant concentration at the phase-interface fluid–gas, fluid, and phase-interface fluid–biofilm, respectively; c_{BF}, c_B, pollutant concentration at the phase-interface biofilm–fluid and in the biofilm; δ_G, δ_F, δ_B, boundary layer thickness of the gas phase, fluid, and biofilm, respectively.

- Limitation by mass transfer of oxygen from the gas to the liquid phase may be given for a pollutant highly soluble in water, easily transferred from the gas into the biofilm, and rapidly degraded therein (Fig. 3a). Although the oxygen partial pressure of air is 21 kPa, it is barely soluble in water (7.5 mg of oxygen/L at 30 °C), and thus its mass transfer rate competes with that of low concentrations of the pollutants.
- Limitation by mass transfer of the pollutant from the gas to the liquid phase may result from rapid degradation of a pollutant by the biomass. In this case, mass transfer can be enhanced by increase in superficial gas velocity or by reduction of the irrigation rate. Both operations decrease the thickness of the boundary layers δ_G and δ_F (Fig. 3b).
- Limitation by microbial degradation may result either from low degradative activity or from low biomass. Both affect the efficiency of waste gas cleaning similarly. Low degradative activity is given for toxic or xenobiotic pollutants and other persistent chemicals not accessible to the common microbial metabolism (Fig. 3c). Low biomass may result from insufficient supply of mineral nutrients, nonphysiological pH, and support material inadequate to allow sufficient biomass attachment.
- Different limitations, as have been described, may be present in one system at different locations. In a system with a high load of a pollutant, insufficient degradation may take place at the entrance of the reactor where the mass transfer rate is higher than the degradation rate. As the pollutant is removed from the gas stream while passing through the reactor, the concentration in the gas phase decreases. Finally, a limiting mass transfer rate may result as compared to the potential microbial degradation rate.

The efficiency of elimination of a pollutant is clearly dependent on its solubility and mass transfer characteristics. Consequently elimination of a pollutant from the gas phase is linked to the Henry coefficient of the respective compound whether it is eliminated by physicochemical processes or microbial degradation. Such a link is evident for the theoretical and actual efficiency of elimination of different pollutants shown in Figure 4.

The differences in the processes of waste gas cleaning beneficial or deterious to the aspects as stated are discussed in the respective sections.

PARAMETERS FOR PLANT DESIGN

For a given waste gas to be treated, the appropriate type of plant has to be selected, and its size has to be estimated. Therefore, basic characteristics are crucial for plant design. Available area and costs are criteria for choosing between biofilter and trickle-bed reactor, while the hydropathic nature of a pollutant is crucial to decide for or against a bioscrubber. For elimination of pollutants with Henry coefficients >1 MPa, bioscrubbers are usually not chosen.

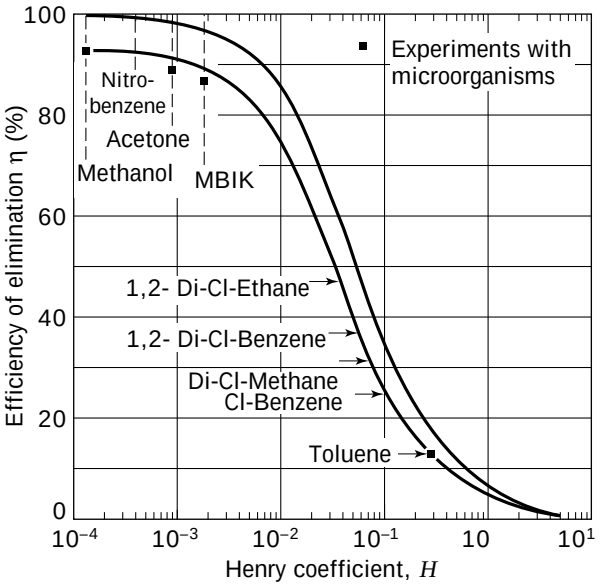

Figure 4. Dependency of the efficiency of elimination of various components on their Henry coefficients. The data are based on a single plate bioscrubber. The upper line represents theoretical efficiency; the lower line gives data of a single-plate bioscrubber. Liquid height on plate = 70 cm, T = 20 °C, u_0 = 0.55 m/s. The dimension of H (MPa) is equivalent to 135.4 ($kg/m^3_G/kg/m^3_L$). *Source*: Redrawn from Ref. 33, with permission.

In general, the mean residence time of the gas and the fluid is crucial for the three types of plants. The residence time is a measure to define the time given for contact of the gas, the liquid, and the biomass to allow mass transfer. The mean residence time (t_m) of a gas or fluid in a reactor with a given volume (V_R) at a given flow rate (V^*) is expressed in equation 5:

$$t_m = V_R/V^* \quad (5)$$

The inverse relation of this mean residence time of the gas defines the volumetric flow rate (τ_V), as expressed in equation 6:

$$\tau_V = V^*/V_R \quad (6)$$

The relation of the flow rate of a gas or fluid to the area of the cross section of the plant (A_R) is defined as area load (τ_A) as expressed in equation 7:

$$\tau_A = V^*/A_R = u_0 \quad (7)$$

where u_0 is the superficial velocity of a gas or fluid, which is the velocity with which they pass the free cross section of the reactor.

In waste gas cleaning, two criteria are important with respect to a pollutant: its concentration and its amount. The amount of a pollutant fed to a plant of a defined volume per unit of time is given by its concentration per volume of gas (c_{in}) and by the gas flow rate, and is expressed as volumetric load (V_L) as shown in equation 8:

$$V_L = (V^*/V_R)c_{in} \quad (8)$$

The pollutant is metabolized in the plant by the biomass and eliminated from the gas phase. Generally, the elimination is equivalent to the degradation of the pollutant, and this term is subsequently used. The overall degradation is defined as volumetric degradation rate (V_D), as expressed in equation 9:

$$V_D = (V^*/V_R)(c_{in} - c_{ex}) \quad (9)$$

The difference in concentration of a pollutant in the feed and the exit gas (c_{ex}) related to the feed concentration characterizes the efficiency of a plant, as expressed in equation 10:

$$\eta = (c_{in} - c_{ex})/c_{in} \quad (10)$$

The efficiency of a plant is determined by various parameters such as the chemical nature of the pollutant, biomass degradative activity, and gas or fluid flow rate. The latter is determined by the resistances within biofilters or trickle-bed reactors given by the type of filling, its density, porosity, and height of the package resulting in pressure loss (26), and may be a significant cost factor for operation. The power (P) required to achieve a certain gas flow rate (V^*) will compensate for the overall pressure loss (Δp) across the reaction zone of a plant, as expressed in equation 11:

$$P = \Delta p V^* \quad (11)$$

Other pressure losses resulting from such components as pipings, nozzles, and orifices are not specific to waste gas cleaning facilities and are not treated here.

The porosity (ε) is a crucial parameter of pressure loss for biofilters or trickle-bed reactors, and is defined by the interstitial volume of a rector. This factor is given by the difference in volume of the empty reactor (V_R) and the volume of the particles (V_P) related to the total reactor volume, as expressed in equation 12:

$$\varepsilon = (V_R - V_P)/V_R \quad (12)$$

TYPES OF WASTE GAS TREATMENT PLANTS

As mentioned, three types of plants are currently used for treatment of industrial waste gases of different origin and composition: biofilter, trickle-bed reactor, and bioscrubber (Fig. 1). Their principles, industrial sizes, capacities, and advantages or disadvantages are outlined next. Certain characteristics increase with the plant used. The applied volumetric flow rate (see equation 6) increases roughly 10-fold as the order of biofilters, trickle-bed reactors, and bioscrubbers. This order reflects not only an inverse relationship of efficiency and size of the plants but also their increasing complexities.

Biofilters

Different designs are currently applied for the construction of biofilters: single bed, multiple bed, and closed bed, either requiring land or installed on top of a roof. Biofilters require an area of 10 to more than 1,000 m^2 filled to a height of 0.5–1.6 m with different materials as support for microbes and for fine distribution of the gas. The filters are operated at rates of 100–120,000 m^3/h. The gas flow rate related to the filter volume (see equation 6) varies from 10 to 580 $m^3\ m^{-3}\ h^{-1}$. The superficial gas velocity of biofilters varies from 0.1 to 8 cm/s. The mean residence time within a filter bed of 1-m height is rather long and amounts to about 10 to 700 s (1). The filling material may be compost, peat, heather, chopped wood, bark, or disrupted root wood to which microorganisms are attached. Biofilters are suited to eliminate odors and volatile organic or inorganic compounds at rather low concentration, as detailed next. The area of the biofilter contains a wall of wood or concrete and a system for distribution of the main stream of the gas. It is practical for the biofilter to be vented from the bottom, that the orifices or slits allow constant gas flow rates over the filter area, and—for larger plants—to allow machines to enter the filter for exchange of the filling.

A waste gas may contain dust particles that are removed by a deduster before feeding into the biofilter. The gas passed through the biofilter should either be humidified to about 95% or the filter should be irrigated to ensure a moist environment as required for microbial activity. The concentration or the composition of the pollutants may vary with the operation of the emitting source, resulting in changes of load. Moderately higher concentrations can be temporarily reduced and a portion of the compounds stored in the filling material according to its adsorptive properties. The compounds are subsequently released therefrom for mineralization by the biomass. Thus, the efficiency of the biofilter can be maintained.

The filling material supplies the attached microorganisms with the minerals necessary for growth. The degradative capacity of the biofilters is limited by the low supply of minerals, which in turn causes a low amount of active biomass present on the support material, its limited buffering capacity for protons or volatiles, and the lack of control of the microbial environment with respect to pH. The filling material is of natural organic matter and subject to microbial degradation at different rates according to the structure, surface, and density. Moreover, environmental conditions may add to the rate of decomposition and loss of mechanical properties of the filling material. Such conditions may be acidification by organic or mineral acids as detailed in Table 1. Decomposition of the filling material results in settling, reduction in pore size, and increase in pressure loss and consequently in increased energy requirements for air compression. Moreover, settling of the filling may result in channeling wherein the gas stream circumvents but does not penetrate portions of lower porosity within the filter bed. This in turn causes reduction of the residence time of the gas and reduction in efficiency of pollutant elimination. Reduction in efficiency of the plant requires exchange of the decomposed filling material, which usually occurs after 1–3 years of continuous operation depending on filling texture, mechanical properties, and degradability and the load of the waste gas to be treated.

Trickle-Bed Reactor

Pollutants with low solubility in water may be eliminated from waste gases by trickle-bed reactors. The advantage of operation of a trickle-bed reactor over biofilters is not only in the increased mass transfer but also in the ease of controlling physiological conditions such as pH and the addition of minerals in the trickling fluid in the bottom of the column. Moreover, trickle-bed reactors require less land than biofilters and are operated in single or multiple stages. They are built as columns filled with incompressible and mostly inert support material for gas–liquid contact and attachment of biomass. The bed heights vary from 1 to 3 m, the reactor volumes from 2 to 160 m^3, and the flow rates from about 3,000 to 85,000 m^3/h. The mean residence time of the gas within the columns is generally less than 4 s, which is considerably shorter than reported for biofilters (see Table 3), and the superficial gas velocities vary from 0.1 to 1.6 m/s. The volumetric gas flow rates are rather divergent and vary from 250 to 4,700 $m^3\ m^{-3}\ h^{-1}$ (2).

The inert support material may be slag, natural porous stones, coke, charcoal, granular clay, ceramics, sintered glass, or plastics and other material proven to be suitable in absorption technology. The filling is trickled from top, and the surface area of the filling provides a major basis for mass transfer from the gas to the fluid phase. Sufficient empirical data are available for choosing geometry, size, and filling for various industrial applications. Moreover, based on the geometry of the fillings, the total surface area of the trickle bed can be calculated. The thickness of the fluid film is proportional to the irrigation rate and inversely related to the total surface area. This in turn allows calculating the mass transfer rate for a given pollutant (27). Also, total biomass can be deduced from the mean thickness of the biofilm. Trickle-bed reactors may be seeded with microorganisms by spraying activated sludge from wastewater treatment plants. The microbes will be selected and the population of the biofilm will be established according to the given pollutants.

A major resistance for mass transfer from the gas phase to the biofilm is the thickness of the fluid film, determined by the rate of irrigation and rate and direction of the gas flow. Therefore, the irrigation rate should be reduced to generate thin films. Depending on the waste gas to be treated, the rates vary from 0.04 to 50 $m^3\ m^{-2}\ h^{-1}$ as reported from laboratory and industrial reactors. However, industrial plants are preferentially operated at <0.5 $m^3\ m^{-2}\ h^{-1}$ (2). To enhance mass transfer and to reduce diffusional resistance by the liquid film, intermittent irrigation has been applied for elimination of pollutants by a laboratory trickle-bed reactor, which still ensured sufficient moisture for the biofilm (31–33).

Mass transfer may also be increased by increasing the surface area as given with support material of high specific surface. Application of such material results in lower interstitial volume, lower bed volume, and a smaller plant size. However, the thickness of the biofilm will increase with time of operation of the trickle-bed reactor, decreasing or abolishing the small interstitial volumes, which results in increase in pressure loss, clogging, and channel formation. The mean residence time is reduced and the efficiency of the plant declines in eliminating pollutants from the gas stream. The otherwise favorable characteristics of trickle-bed reactors with respect to mass transfer and control of circulation have led to the concept of removing excess biomass by various means: increased irrigation rate to wash off the biofilm (2), periodic pulses of air pressure after flooding, and movement of the trickle bed itself to shear off the biofilm (32). In laboratory systems this procedure of biomass removal has led to continuous operation for more than 2 years with constant degrees of elimination of pollutants. Research data now suggest that the degradative capacities of trickle-bed reactors can be better described mathematically than biofilters and allow conclusions for growth of biomass and of operation of trickle-bed reactors in industrial scale (31,32). Reduction of biomass as a result of a biological equilibrium of biomass formation and biomass degradation has been reported from a pilot trickle-bed reactor after long operation. In this system, elimination of the acidogenic pollutant dichloromethane was reported, involving conversion into biomass, whereas clogging as a result of biomass degradation was not observed (34). Dichloromethane is a substrate with low yield in energy transformation (Table 1) and maintenance requirements (see earlier discussion).

Bioscrubbers

The decision to select bioscrubbers for waste gas cleaning is based on the physicochemical properties of the pollutants and the availability of space for placing the plant. Bioscrubbers are usually smaller than biofilters and consist mostly, but not exclusively, of two units, one for absorption of the pollutant from the gas phase and the other as a fermentor for their mineralization and growth of microorganisms. Bioscrubbers are usually inoculated with activated sludge, and the microbial population will develop according to the volatiles supplied with the gas stream. Waste gas is passed through a spray tower, bubble column, absorber column, or other gas–liquid contactors for absorption of the pollutants. Industrial bioscrubbers presently treat 9,000 to 150,000 m^3 waste gas per hour. Scrubber units are built in heights of 2–4 m and volumes of 10–100 m^3 and exhibit volumetric gas flow rates of 1,000–3,600 $m^3\ m^{-3}\ h^{-1}$. Bioscrubbers are usually operated with superficial gas velocities of 0.8–2.0 m/s and with mean residence times of <3 s. The specific flow rate of the liquid phase to be circulated per area of the absorber unit ranges from 12 to 40 $m^3\ m^{-2}\ h^{-1}$. Some data of industrial plants are compiled in Table 3, and more have been given elsewhere (2). Elimination of hydrophobic pollutants from the gas phase in single-unit bioscrubbers is usually not advisable because of the high volumes of water to be moved. However, single-unit bioscrubbers have been successfully applied to clean industrial volatile pollutants with Henry coefficients of more than 1 MPa (24). Moreover, new developments in part operating in an industrial scale have been reported for application of bioscrubbers that combine both units in one apparatus. These systems consist of special devices for gas or liquid dispersion, special orifices at the bottom of bubble columns that contain the dispersed

microorganisms (33), or gassed closed-loop air-lift reactors (35), which, however, await industrial application.

The physiological conditions for the microorganisms such as pH, salinity, and oxygen partial pressure can be well controlled in bioscrubbers, as similarly described for trickle-bed reactors. Also, mineral salts nutrients can be added to the medium to allow microbial biomass to grow. The advantage of bioscrubbers over trickle-bed reactors is in the ease of controlling the environment for microorganisms and mechanically improving mass transfer rates by movement of the liquid according to the need to absorb pollutants from the gas phase. On the other hand, elimination of hydrophobic compounds with low solubilities in water requires movement and dispersion of large volumes of liquids. Bioscrubbers are an interesting alternative to other technologies that have been outlined with respect to the ease of operation, environmental control, and adjustment to changing conditions in the quality of the feed waste gas. Thus, bioscrubbers can be applied for elimination of hydrophobic pollutants (24). A variation of the process uses silicon oil for absorption of hydrophobic volatiles. Problems, however, may arise from disposal of silicon oil–containing sludge (2).

COSTS

Application of biological treatment has been proven useful to economically clean waste gases of different sources. Presently, waste gases with concentrations of less than 1 g of organic carbon/m^3 or of inorganic compounds are treated by biological processes. At these concentrations, biological processes are economically advantageous over alternative processes such as condensation, thermal or catalytic oxidation, or adsorptive and desorptive technologies. These processes are economically feasible at higher concentrations, as detailed in Table 4. Separation of organics from the gas phase by membrane technologies listed in Table 4 is just in its infancy (6,37). Performance of membrane bioreactors for waste gas treatment is presently being examined at a laboratory scale. Reactor performance, however, is hampered by unstable biofilms or by clogging of the liquid channels from excess biomass formation. On solution of these problems, membrane bioreactors are expected to be useful tools for treatment of poorly water-soluble pollutants such as highly chlorinated hydrocarbons (reviewed in Ref. 21).

In a comparative study, costs for investment and for operation were related to treatment by biofilters. Costs of investment include those for the plant and for measuring and controlling devices. Costs of operation include consumables, energy requirements, and costs for personnel (6) (Table 5). From this study it is evident that bioscrubbing is more costly with respect to investment and operation. At present, data on the economy of trickle-bed reactors are not available. However, biofiltration and bioscrubbing are significantly less costly than catalytic oxidation or adsorption (Table 5).

Adsorptive processes aim at the recovery of solvents, for example, whereas thermal or catalytic oxidation aims at the elimination of the pollutants. To make use of the low costs of biological processes for elimination of a pollutant, it is anticipated to extend this technology to waste gases with organic loads significantly larger than 1 g organic carbon/m^3. Two alternatives are presently considered. First, classical engineering processes as specified are applied to eliminate high concentrations or peak concentrations toxic to microorganisms and to combine these with conventional biological processes. This concept was successfully applied recently for elimination of solvents from waste gas of the lacquer industry (38). Second, the inexpensive biological processes are to be extended to treat waste gases with high organic load. The conversion of this concept requires addition of mineral nutrients, which results in formation of high amounts of biomass. Removal of the excess biomass is required to prevent undesired consequences such as clogging in trickle-bed reactors or increase in salt concentration in bioscrubbers or both. However, at laboratory scale high concentrations of biomass allowed the complete (100%) elimination of as much as 4.2 g toluene/m^3 or 8.7 g *n*-butanol/m^3 from the gas stream (39).

GENERAL CONSIDERATIONS

Biological waste gas treatment is less costly and requires less maintenance than conventional physicochemical, thermal, or catalytic processes. However, problems may arise from the chemical nature of the compounds to be

Table 4. Processes and Ranges of Concentrations Commonly Used to Eliminate Hydrocarbons from Waste Gases

Process	Concentration (g organic carbon/m^3 waste gas)

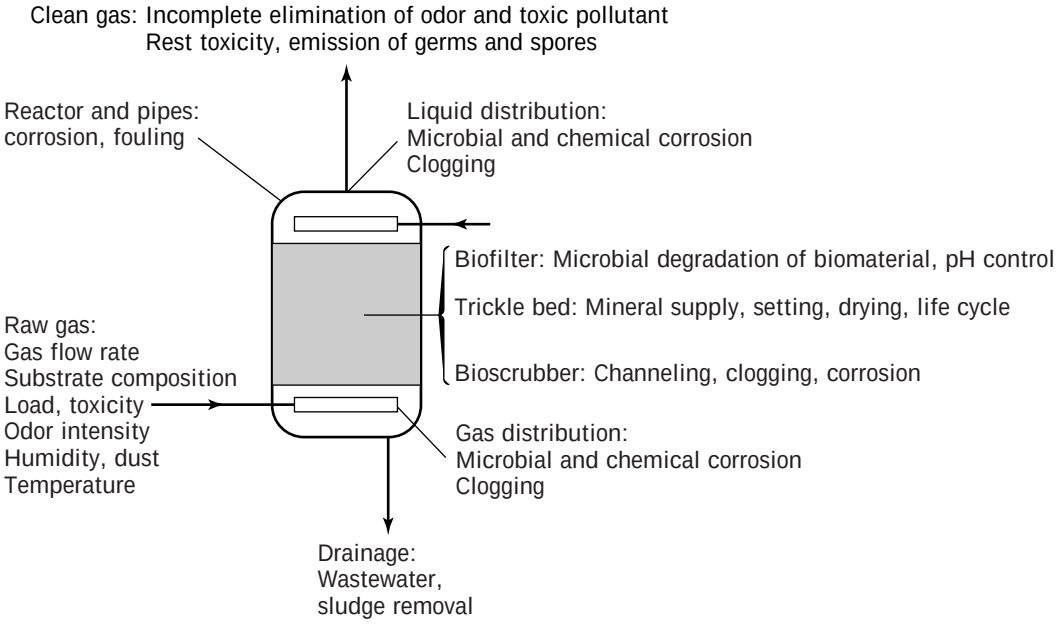

Figure 5. Summary of general problems of biological waste gas treatment plants.

eliminated from waste gases and from the material of which parts of the plant are constructed, such as the walls of the reactor and such parts as piping, orifices, and nozzles (Fig. 5). The waste gases to be treated may contain compounds that are hardly or very slowly biodegradable, such as benzene and xenobiotics, and other compounds toxic to different cell functions, such as solvents, cyanic acid, and hydrogen sulfide. However, successful operation of laboratory-scale waste gas treatment plants to eliminate such compounds point to the applicability of biological treatment to this category of pollutant also.

Different compounds may be converted to organic acids by incomplete oxidation when the mass transfer of oxygen is insufficient. Inorganic acids may be released on microbial degradation of acidogenic compounds, as detailed in Table 1. Acidification, however, not only results in decrease of pH and an unfavorable change of the physiological conditions for the microorganisms but also in corrosion of the material of the plant. The waste gas of rendering plants contains volatile organic sulfur compounds converted to sulfuric acid; this causes severe corrosion of concrete supports of the gas distribution devices of the filter bed. Therefore, such devices have to be exchanged for such components as wooden beams. The same applies for other acidogenic compounds of waste gases. Therefore, the appropriate material for piping and such should be selected according to the expected composition of the waste gas for the three types of plants.

Trickle-bed reactors may especially suffer from clogging and channeling by excess formation of biomass or slime with high loads of the waste gas or extended operation, as was outlined. Therefore, altered processes are presently being examined to extend the application of biological treatment of waste gases loaded with compounds that are slowly degraded or that contain high loads of organic and inorganic pollutants. This application in turn will require devices for the control of the environment for the microorganisms and the removal of excess biomass, and recent developments have been devoted to this need.

OUTLINE

TREATMENT PLANT PROCESSES

The treatment of municipal and some industrial wastewater generally uses a combination of primary, secondary, and tertiary treatment. Primary treatment simply screens and settles large particulates and skims off floating greases and oils. Secondary treatment biologically removes organic carbon, and in newer plants, soluble nitrogen or phosphates. Tertiary treatment attempts to limit the microorganisms and other pathogens in the treated water by membrane filtration or deep-bed filters and some form of disinfection using chlorine, ozone, or ultraviolet light.

The secondary or biological treatment of wastewater uses a number of key processes, unit operations in the process engineering terminology. These include primarily processes for biological reactions and processes for settling and clarification. Chemical precipitation to remove phosphorous is sometimes used just before the settling and clarification. There are many flowsheet configurations, often of a proprietary nature, that attempt to obtain the optimal combination of anaerobic, anoxic, and aerobic con-

ditions for the microorganisms. Commonly used flowsheets are shown in Figure 1. A detailed account of instrumentation, control and automation in wastewater treatment plants has been made in the textbook by Olsson and Newell (1).

GOALS AND INCENTIVES FOR CONTROL

The goal of the operation of a wastewater treatment plant is to satisfy the effluent requirements at all times at minimum cost. The effluent quality and a good performance has to be guaranteed *consistently*, which will have a great impact on instrumentation, control, and automation. Effluent requirements are usually formulated in terms of daily, weekly, or annual averages of suspended solids, biological oxygen demand (BOD), total nitrogen, and total phosphorus. To comply with the limits of the effluent concentrations, certain safety margins are required. The goal of automatic control is to keep the effluent quality consistently good, despite disturbances. This allows the margins to be smaller, thus saving costs.

Criteria

The capital costs are usually the dominant part of the total cost. Traditionally, many plants have been designed with large tank volumes to meet the varying loads to the system. The total cost can be decreased, if the balance between design and operational costs is systematically considered. There are many components of the operational costs, such as consumption of electric energy (for pumping, aeration, etc.), chemicals for phosphorus removal, or polymers for sludge. Obviously, labor costs are important. The balancing of costs is, of course, an important reason for control. Considering the increasing demand of consistent operation and effluent water quality around the clock, however, will probably be the main driving force for plant control and automation.

Driving forces for instrumentation, control, and automation (ICA) in a large number of countries were discussed at an IAWQ symposium in 1993 (2). The major incentives were categorized as

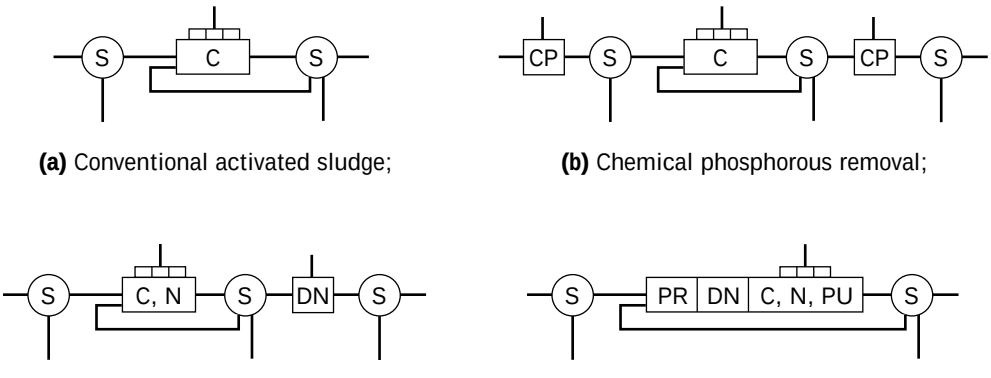
- Effluent quality standards
- Economy
- Increasing plant complexity
- Available tools (sensors, computers, models)

In some countries, there is a water shortage, which in itself is a driving force for improved wastewater treatment, such as for recycling.

In many industrial countries there is today an elaborate requirement for nutrient removal. This has led to the need for quality control based on advanced on-line instrumentation. With more complex processes, the needs for energy conservation and consistent operation are apparent. Ammonium and nitrate on-line instrumentation in the activated sludge was developed and documented in the late 1970s. At that period, the on-line measurements were still limiting the applicability. Very large efforts have been spent on the development of N and P analysers, and there has been a lot of progress in the instrumentation technology. In 1990s, the control is extended to include biological P removal in many plants. Today, commercial applications of nutrient removal control based on advanced instrumentation are common (3). A typical representative layout of nutrient removal plants is the University of Cape Town (UCT) activated sludge plant (Fig. 2).

Disturbances

The essence of the control problem in wastewater treatment is related to disturbances. They are critical to the approach to control and have some specific features:



(a) Conventional activated sludge; **(b)** Chemical phosphorous removal; **(c)** Postdenitrification process; **(d)** Typical BNR process.

C carbon removal, N nitrification, D denitrification, CP chemical precipitation, PR phosphorous release, PU phosphorous uptake, S setting and clarification

Figure 1. Typical wastewater treatment process flowsheets. (**a**) Conventional activated sludge; (**b**) Chemical phosphorous removal; (**c**) Postdenitrification process; (**d**) Typical BNR process. C = carbon removal; N = nitrification; D = denitrification; CP = chemical precipitation; PR = phosphorous release; PU = phosphorous uptake; S = settling and clarification.

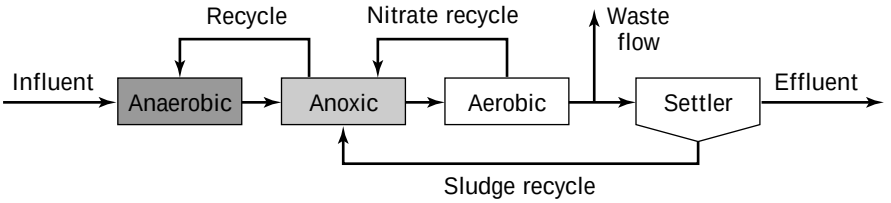


Figure 2. The UCT process, designed to remove organic material, ammonium nitrogen, and phosphorus.

- The daily volume of wastewater treated can be huge.
- The disturbances in the influent are enormous compared to most industries.
- The influent must be accepted and treated; no returning it to the supplier.

Because the disturbances to a wastewater treatment system are significant, the plant is for all practical reasons never in steady state. The disturbances are related to flow rate changes as well as concentration and composition variations. Figure 3 illustrates a typical influent situation in two municipal treatment plants.

The disturbances are not only related to the influent flow characteristics, but may be generated internally in the plant because of operational procedures. For example, poor pumping operations contribute to hydraulic disturbances (4). Clarifier upsets are often caused by inadequate pump control. A sudden flow increase caused by a pump start will influence the flow propagation along the plant within a fraction of an hour. A proper settler operation requires that the influent pumping has to be smooth. Variable speed pumping is a proved technology today and is a crucial component to create a smooth hydraulic operation of the plant. If primary pumps or other recycle pumps are operated on/off in too-large steps, the resulting solids–liquid separation will suffer, as will the effluent water quality.

Concentration disturbances are also generated within the plant itself. For example, sludge thickener overflow is usually returned to the plant inlet. This overflow is usually operated with on/off pumping without considering the influent load. Because the recirculated flow may have a large concentration, it will make a significant contribution to the overall load, both in terms of hydraulics and substrate loading.

It is usually impossible to remove the source of the disturbance, even if this is an important option, especially for industrial effluents, where production control in the industry may be improved. Sometimes the magnitude of the disturbance can be reduced *before* it reaches the plant. An integrated sewer-treatment plant control can attenuate hydraulic disturbances, and some waters can be pretreated in order to avoid harmful effects on the plant, such as neutralization of wastes with high or low pH. The control can also compensate for effects *within* the process. A common example is dissolved oxygen control.

All these disturbances will more or less influence the effluent water quality. An ultimate operational goal is to minimize the influence of disturbances and to maintain consistently a high effluent quality.

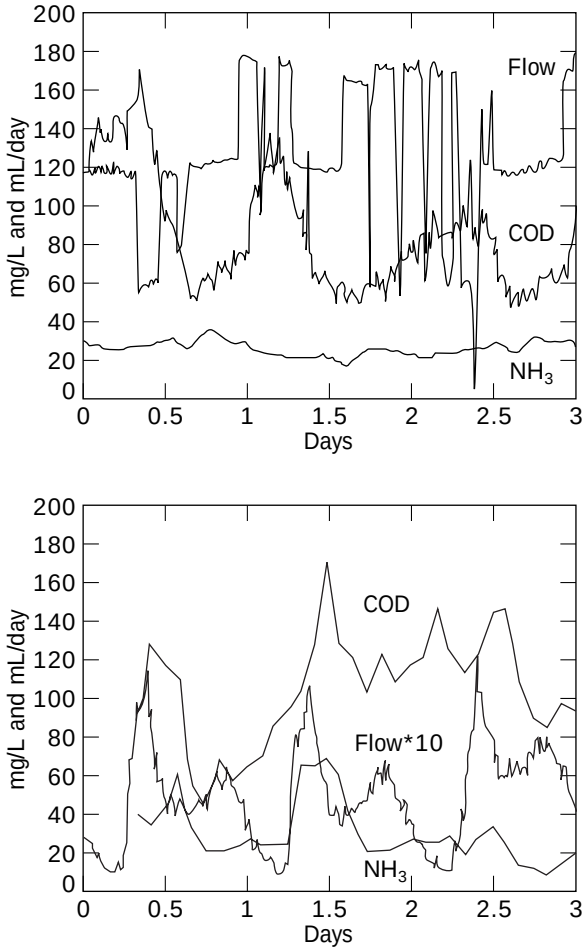

Figure 3. Typical influent disturbances from a large plant in Sweden (**a**) and a small plant in Australia (**b**). The flow rate as well as influent concentrations of chemical oxygen demand (COD) (related to organic content) and total nitrogen have significant variations.

CONTROL AND OPERATIONAL GOALS

It is far from straightforward to implement control in an activated sludge system; some of the reasons are listed here:

- The process has significant nonlinearities limiting the usefulness of simple controllers.
- There is a very wide range of response times, both a problem and a blessing.
- There are many interactions within the process with major recycles.

- There are many external couplings from the sewer to the receiving waters.
- Designers often leave too few manipulated variables and too little control authority.
- The concentrations of nutrients (pollutants) are very small, even challenging sensors.
- Sensors do not exist for many states and are expensive for others.
- The value of the product in the marketplace is remarkably low.

Other attributes why control is far from straightforward include:

- The microorganisms change their behavior and their population distributions.
- The separation of the effluent from the biomass is challenging and easily disturbed.
- Future effluent standards will be tight and based on spot checks.

Disturbance rejection is a major goal of activated sludge control. Large disturbances must be attenuated, and we must do it as early in the process as we can. This will ease the task of controllers later in the process.

The formulation of the goal of a wastewater treatment operation is much more demanding than to define the effluent standards. When a goal or a performance criterion is defined, then the necessary control actions can be analyzed. There are several goals of wastewater treatment, and one has to recognize the different levels and interest groups. The specific goals are set so that they contribute to meeting the more general corporate and community goals. They include at least

- To meet effluent discharge requirements.
- To achieve good disturbance rejection.
- To optimize operation to minimize the operating cost.

The first goal of course includes keeping the plant running. This is the major task for many operations, at least in terms of manpower. It is not a trivial task to maintain advanced instrumentation and equipment, to make sure it runs smoothly, and to detect any faults in its operation. Much of this is traditional automation and process control and is not specific to running wastewater treatment systems (5,6). The environment may be very specific and harsh for much equipment, but that is also the case in other industries as well, so from a strict control point of view the problems are traditional.

However, keeping the plant running and simply recording effluent quality is too often taken as the only goal. This has been and is still largely because of the lack of process knowledge on the part of plant operators. Too many operators of plants rely on the consultant for expertise in both design and operation. To satisfy the effluent quality requirements, it is crucial to ask: is this task solved primarily by design or do instrumentation, control, and automation play significant roles in this part? The traditional answer among designers used to be *no*. When only carbonaceous removal was considered, the plant was considered self-regulating and could take care of load disturbances and still produce a satisfactory effluent. The traditional method was large volumes, excess aeration, and chemical dosage. Consequently, a lot of plants have been oversized. No incentive was given for improved operation, because operational costs were not compared with investment costs. Often they were met from different financial sources.

Because of the significant load variations and disturbances typical for wastewater treatment systems, the plant is hardly ever in steady state. Despite the wide swings of load, the plant still has to *consistently* produce a satisfactory effluent. If the volumes of the tanks are not oversized, this means that some control system has to minimize the influence of disturbances and ensure that the operation is satisfactory. Pressures to fully utilize volumes and the complexities of nutrient removal are making process control essential. This of course includes disturbance attenuation.

Minimizing the operating cost and maximizing the use of available capacity is becoming necessary. Here, control and optimization are the key tools. Costs to be minimized include electrical energy to produce air, chemicals, pumping, and carbon addition.

MANIPULATED VARIABLES

There are quite a few variables to manipulate in an activated sludge process. Still, the possibilities to control the plant in a flexible way are quite limited. In many plants, however, there may be a potential to make a better use of the manipulated variables that are available. We categorize them in the following groups:

- Hydraulic, including sludge inventory variables and recirculations.
- Additions of chemicals or carbon sources.
- Air or oxygen supply.
- Pretreatment of influent wastewater.

There are several other manipulated variables in a plant that are related to the equipment and to basic control loops in the process, such as local flow controllers, level controllers, and so on. They are not included in this discussion. Further details are found in the work by Olsson and Jeppsson (7).

A majority of the manipulated variables are meant to change the hydraulic pattern in the plant. The different flow rates will influence the retention times in the different units. Moreover, the clarification and thickening processes are particularly sensitive to the *rate* of change. The hydraulic flows also determine the interaction between different unit processes. We classify the hydraulic manipulated variables into four major groups:

- Variables controlling the influent flow rate.
- Variables controlling the sludge inventory and its distribution, including return sludge flow rate, waste sludge flow rate and step feed control.
- Internal recirculations within the activated sludge system.

- External recycle streams, influencing the interactions between sludge and liquid processes.

Sequential batch reactors (SBR) offer other control possibilities because of the flexibility associated with working in time rather than in space. Some of the features of SBRs are described in some detail in the work by Irvine-Ketchum (8). The Danish Bio-Denitro and Bio-Denipho processes are not the traditional fill-and-draw process but are alternating processes with continuous discharge (9,10).

Some of the control variables are sometimes called *selection mechanisms* for the viable bacteria in the system (11). They are classified in the groups:

- Electron acceptors (e.g. oxygen or nitrate).
- Substrate.
- Thickening or clarification properties.
- Temperature.
- Growth rate.
- Free swimming organisms.

Not all of these can be manipulated. Only the electron acceptors (mostly oxygen) and (to some extent) the thickening and clarification properties can be controlled (by chemical precipitation). Moreover, substrate can be added (e.g. carbon sources).

IMPORTANT CONTROL LOOPS

Out of the many manipulated variables, we will consider a few. Probably the most important is the control of dissolved oxygen (DO) by using the air supply. Other important measures are the sludge inventory, controlled by the return sludge flow rate, and the waste sludge flow rate.

DO Control

The DO supply is a key control variable for the aerator system, both for carbonaceous and nitrogenous organisms. It influences the operating costs significantly, so there is an incentive to minimize the air consumption. From a microbiology point of view the choice of a proper DO set point is crucial, and too little DO will limit the growth of organisms.

From a process control point of view, DO control is known and proved technology. As long as the air supply is variable, the control of DO is quite straightforward. The tuning of the controller has to be different at different loads because of the inherent nonlinearities, and this can be compensated for by self-tuning regulators, prove in full scale for a long time (12). Another way is demonstrated in pilot scale, where a nonlinear controller can be used to operated over a wide range of loads (13).

The oxygen transfer rate determines how fast gaseous oxygen is transferred into DO. This in turn decides that the DO concentration can be manipulated by air flow changes within fractions of an hour. Changes in the oxygen demand, however, may influence the DO concentration within minutes. Not only the total amount of oxygen but its distribution in space and time are essential for the operation. Some of the considerations are:

- *Total air supply*. The total demand of air is basically determined by the total mass of viable organisms in the system multiplied with the biodegradable substrate concentration. The air supply control has an essential impact on the energy cost for the plant.
- *DO set points*. It is important to be able to select the DO set point. However, little is known about the proper choice of it. Generally, under closed loop DO control, it is made constant. There is, however, some evidence that a time variable set point may be advantageous (12).
- *DO spatial distribution (profile)*. It is a great advantage to be able to individually change the air flow rates along the aerator. This makes it possible to obtain an accurate air flow spatial distribution.
- *Pure oxygen addition*. Some aeration systems are supplied with pure oxygen instead of air. Pure oxygen is now and then used in conventional air systems to add extra DO to the system under extreme load situations.
- *Anoxic/aerobic zones*. Because loading conditions may change significantly on a weekly or longer basis, it is of interest to vary the size of the anoxic reactor volume and change the relative retention times between nitrification and denitrification. Such a control is, of course, easy to realize in SBR systems.

Given an adequate controller, it is straightforward to change the DO set point. However, to know which set point is the best from a microbiological point of view is a much more intricate question, and much remains to be studied before the ideal DO control system has been found. Consider an example of a compromise between competing goals within the same plant. The anoxic unit in the activated sludge system, Figure 2, is used to denitrify the nitrate, that is, to reduce the nitrate to free nitrogen by the oxidation of organic carbon. The dominating organisms in the process are the heterotrophs, a proportion of which reduce nitrate in an (ideally) oxygen-free environment. Therefore, the DO level has to be kept at a minimum. If not, the organisms will use oxygen instead of nitrate as the electron acceptor, and the zone will work at least partly like an aerobic reactor.

There are several disturbances that may violate the anoxic condition. The nitrate recycle stream may have a high DO concentration that will rapidly influence the DO concentration of the anoxic zone, thus the denitrification (DN) rate. It is apparent that from a DN point of view that the DO concentration at the outlet of the aerator has to be kept as low as possible, so that no more oxygen than necessary is recirculated. However, for the nitrification taking place in the aerator, a high DO concentration is required. Consequently, the DO concentration at the aerator outlet has to be a compromise between the needs of nitrification and denitrification.

Sludge Inventory Control

The sludge inventory can be controlled primarily by three manipulated variables: the waste-sludge flow rate, the

return-sludge flow rate, and the step-feed flow rates. Manipulation of the waste-sludge flow rate is used to control the total inventory of sludge in the process. Because the total inventory is a function of the total growth rate of organisms, it is used to control the sludge retention time, or the sludge age. It will influence the system in a time scale of several days or weeks.

Manipulation of the return-sludge flow rate is used to distribute the sludge between the aeration basins and the settler units or between the acidogenic and methanogenic reactors in two-stage anaerobic systems. Recycle from the settling stage is an important variable for obtaining the right operating point in the reactors, but seldom useful for the control on an hour-to-hour basis (14). Some systems are supplied with several feeding points for the return sludge. This has a potential for sludge redistribution for certain loads, such as toxic loading.

A *combination* of different recycle may be important. In systems with chemical precipitation, sludge from the secondary settler may be combined with chemical sludge from a postprecipitation settler unit. In that way, the flocculant properties may be influenced, and the chemicals better utilized for phosphorus removal.

By controlling the step feed in an activated sludge plant, the sludge within the aeration basin can be redistributed, given the proper amount of time (15). As a special case of step-feed control, one will obtain a *contact stabilization* structure.

MEASUREMENT AND DIAGNOSIS

Measurement technology is crucial for adequate operation. In particular, on-line analysis is of key interest to control the effluent water quality. It is of great importance to extract maximum information from available instrumentation. Therefore, detection and diagnosis, based on combination of measurements, are models that make up a basis for successful plant operation.

Sensor Technology

Sensor technology is crucial for the success of control and operation, and great progress has been made over the last few years (3). Measurement for control is not necessarily the same as measurements for quality check or for regulatory agencies. The sampling rates have to be consistent with the plant dynamics, and the location of some of the sensors has to be chosen with care, for example, DO probes. Important types of measurements include:

- Flow rates in different plant units.
- Air flow rates and air pressure.
- Sludge flow rates.
- Temperature in water basins and in digesters.
- Gas (e.g., methane) flow rates and temperatures.
- Alkalinity.
- pH.
- DO in different locations.
- Sludge levels.
- Suspended solids in different places.
- BOD, COD, TOC.
- Phosphorus fractions.
- Nitrogen fractions.
- Respiration rate.

There are many instruments that satisfactorily measure flows, levels, pressures, dissolved oxygen in liquids and suspended solids, and dry solids concentrations in sludge. Even if an instrument is deemed to be reliable, proper maintenance is still required. Maintenance requirements will vary greatly between different applications. The development of respirometry has been significant. Within IAWO, task group prepared a scientific and technical report during 1997 (16). Also, advanced N and P analyzers are becoming common in the advanced operation and control of nutrient removal plants (3).

Diagnosis and Estimation

It is clear that more information than the primary sensor signals is required in order to get good operation. The idea of estimation is to mix sensor information with mathematical models. In this way, variables that are not measurable may be reconstructed by combining a mathematical model with sensor information about some other variable. Consider the respiration rate (or the oxygen uptake rate) in an aerator. It can be measured by using respirometers. Alternatively, it can be obtained from measuring the DO concentration and calculation of the DO mass balance. Consider the DO mass balance in a complete mix aerator:

$$\frac{dc}{dt} = d_i \cdot c_i - d \cdot c + k_L a \cdot (c^s - c) - R \qquad (1)$$

where c is the DO concentration; c_i the influent and c^s the saturation DO concentrations, respectively; $k_L a$ the oxygen transfer rate, and R the oxygen uptake rate. The parameters d and d_i are dilution terms. If the oxygen transfer rate $k_L a$ is known, then R can be easily calculated from the DO measurements and the mass balance (equation 1). Usually, however, $k_L a$ must be determined, because it varies slowly with time. Therefore, both the oxygen transfer rate and the respiration rate R to be determined simultaneously from measurements of the DO, preferably under closed loop DO control. This is not trivial, because there is an identifiability problem. A positive change in R can be explained by a similar positive change in $k_L a$ and no unique solution is found (17). However, certain measures can be taken in order to find the parameters uniquely, so that the respiration is found under DO control (13,18,19).

INTEGRATED OPERATION

Because of the combined development of instrumentation, computer technology, operating technology, and the understanding of plant dynamics, the goal is today a plant-wide control. Recognizing the interaction between various unit processes, the overall control of a plant tries to make maximum use of volumes, energy, and other resources.

Because biological nutrient removal (BNR) will become more common, plant complexity will grow. This may be a major driving force for more instrumentation, control, and automation. In a BNR process, there is a delicate balance between carbon, nitrogen, and phosphorus removal. Some important couplings (see Fig. 2) are:

- The phosphorus release has to take place in an anaerobic environment—no oxygen or nitrate can be present. If oxygen-rich water is recirculated, it may impede the P release. If nitrate is allowed to enter the anaerobic zone, the bio-P process is also inhibited.
- Denitrification takes place in an anoxic environment. The various couplings to other unit processes were discussed earlier.
- Both the phosphorus release and the denitrification require a certain carbon concentration. At low loads this may not be sufficient, and an extra carbon source has to be added.

It will become more and more important to understand the impact of load variations. Furthermore, the increased quantities of sludge makes it necessary to develop better control methods for sludge treatment and disposal processes. The drive for a sustainable environment is an incentive to make better use of automation in order to reach such goals.

An efficient operation of a plant has to consider not only the couplings between various unit processes within the plant, but couplings to external processes. Realizing that sewer operation must be coordinated with plant control, there has been a strong development of combined sewer and plant control (20). Disturbances can be detected and controlled as early as possible.

OUTLINE

INTRODUCTION

Activated sludge for biological wastewater treatment has been broadly available for a long time. But, water pollution and eutrophication in rivers lakes, and inland seas have resulted from insufficiently treated water. To protect and control these occurrences, it is critical to consider biological oxygen demand (BOD) and nitrogen-phosphorus (N-P) removal in the development of anaerobic–aerobic wastewater treatment systems.

Increasing volumes of wastewater, combined with limited space availability and progressively tightening standards and quality control, require the development of new intensive biotechnologies for wastewater treatment. Recently, there has been a significant increase in the use of immobilization processes for municipal and industrial wastewater treatment. Immobilization processes offer several advantages because of higher volumetric load, increased process stability, compactness, and so on, as shown in Table 1.

The successful application of an immobilized system as biocatalyst relies on the proper choice of the immobilizing materials and reactor type. The most important requirements for wastewater treatment are as follows:

1. High cell mass loading capacity.
2. Simple nontoxic immobilization procedure.
3. High surface-area-to-volume ratio.
4. Mechanical stability.
5. Chemical stability.
6. Reusability.
7. Suitable for conventional reactor systems.
8. Economic feasibility.

An ideal system that possesses all these optimal properties does not exist, and a suitable compromise has to be found.

For wastewater treatment, bioreactors with immobilized microbes have been examined as a combination of activated sludge process for BOD and nitrogen removal and as an anaerobic process for methane production. But, the attempted immobilization to an anaerobic process is scarcely used in a practical scale because the handling of microbes is difficult at the immobilization and the effects of immobilization are not clear (1). The immobilized microbe treatment process clearly is an effective method of aerobic wastewater treatment.

On a laboratory scale, the immobilization of microorganisms has also been applied to the removal of specific compounds such as phenol and its derivatives (2–5), coloring matter (6), and other inorganic compounds such as cadmium (7,8), uranium (9), and hydrogen sulfide (10). Consequently, they can maintain higher biomass concentrations, and a high degree of organic carbon or nitrogen removal, or both, is achieved by these compact systems. Moreover, minimized production of excess sludge is expected by maintaining a low food-to-microorganism ratio.

CLASSIFICATION OF IMMOBILIZATION TECHNIQUES

Whole-cell immobilization is always used in wastewater treatment and may be defined as the physical confinement or localization of intact cells to a certain defined region of space with the preservation of some decomposition activity (11–13). Accordingly, the immobilization technique using biocatalysts is developed to reuse the catalytic activity and for continuous operation in a bioreactor.

The immobilization of microbes for wastewater treatment is broadly classified into four major categories: adsorption of attachment to a surface, entrapment within a porous matrix, containment behind a barrier (semipermeable membrane and microcapsule), and self-aggregation. These techniques can be applied to all wastewater treatments that use a viable cell system.

Cells Attached to a Surface

Attaching cells to a surface is a very popular immobilization technique because it is simple and fast. A suitable adsorbent for attachment should display a high affinity toward microbial cells and yet cause minimal denaturation. A surface-attached process is the immobilization method in which cells are bound to a surface, regardless of the type of binding. Microbial cell walls carry a charge that depends on the pH of wastewater and other environmental conditions. Biofilms resulting from the growth of cells on the surfaces of inorganics such sand or rock are present in conventional industrial processes (14–21), and the self-immobilization of cells (22,23) is a widespread process. But in recent years, intensive treating processes have indicated a need for the development of immobilization for a given process.

Table 1. Advantages and Disadvantages of Immobilized Living Cell Systems

Advantages	Disadvantages
1. Self-proliferation or self-regeneration of immobilized cell systems.	1. The mechanical and chemical stability of some supports materials limits its use (shear, dissolution, and attack by product).
2. Higher productivities because of higher biomass density.	2. Cell growth can destroy the matrix.
3. Tailoring to the most efficient reactor is possible.	3. Diffusion limitations may limit the biodegradation rates.
4. During continuous fermentations, washout can be avoided at high dilution rates.	4. Biocompatibility of immobilization matrices is not sufficient for cells.
5. Better protection from surroundings.	5. Immobilization techniques and materials can be too expensive be used in large-scale processing.

The strength with which the cells are bonded to the support varies, with cell type, support type (24,25), and the variation of operation condition. The industrial use of surface-attached cell systems (biofilm) has been extensively examined in the field of wastewater treatment (26). For strengthening the attachment, porous supports such as porous glass are used (27).

However, in the fluidized-bed type bioreactors for wastewater treatment, inorganic materials are generally not used because of the difficulty in controlling their specific gravity, brittleness, and shortcoming of abrasion-resistance.

Cells Entrapped in a Porous Matrix

The second immobilization technique is entrapment within a porous matrix that is synthesized in situ around the cells. This method is rapidly coming into widespread use (28). The cells are entrapped in a matrix that protects them from the shear field outside the particles. A high degree of cell viability is retained in most entrapment methods. These systems are therefore useful for a variety of growth-related processes. An advantage of the preformed support particles is that they are more resistant to the compression and disintegration in fluidized-bed bioreactors. Cell growth is controlled by the continuous flow of wastewater past the particles (29).

A variety of compounds can be used for cell entrapment, with minimal loss of viability (30). Natural polymers used for immobilization include polysaccharides, such as alginate (31), carrageenan (32), cellulose, and agar, and polypeptides, such as gelatin and collagen. These natural polymers are compatible with microorganisms, but they are not suitable for wastewater treatment because of their assimilation by microorganisms in activated sludge.

Accordingly, only synthetic polymers, such as polyacrylamide (33), poly(vinyl alcohol) (34,35), poly(ethylene glycol), and polypropylene, and hydrophilic photo-cross-linkable resin can be applied to the immobilization of biomass in terms of mechanical strength and durability that are required for industrial usage. For successful immobilization, the hydrogel must be effective in cell viability and function (biocompatible) (36). The method of entrapment can reduce the culture viability. The entrapment in a polyacrylamide gel destroys viability in 50 to 90% of the cells by the toxic acrylamide monomers (37).

Several reviews (28,38,39) offer a thorough treatment of methods and application in immobilized cells. Examples of the various types of polymers are shown in Table 2.

Cells Contained Behind a Barrier

The third major category of cell immobilization is containment behind a barrier. When cell separation from the effluent is required, these systems are highly useful (56).

The barrier that immobilizes cells can be as simple as the liquid–liquid phase interface between two miscible fluids. Mohan and Li (57) immobilized the denitrifying bacteria, *Micrococcus denitrificans*, by emulsifying the cell suspension with surfactant into a hydrocarbon solvent. Cells in the surfactant-enclosed aqueous droplets did not leak from aqueous phase through the organic phase to the cell-free aqueous phase surrounding the droplets. Because the cells are retained behind a semipermeable wall or membrane, this type of system is very similar to microcapsulation in an engineering sense. Nutrients (mainly BOD components) are supplied to, and products are removed from, the cell mass by diffusion. In wastewater treatment, the barrier loses its separation activity during long operations.

Self-Aggregating Cells

Cells naturally aggregate or flocculate and produce extracellular polysaccharides. The large size of the aggregates makes their use possible in reactors designed for immobilized cells, such as packed-bed or fluidized-bed reactors. Artificial flocculating agents or cross-linking agents may be added to enhance the process of aggregation for cells that do not naturally flocculate. Similar mechanisms govern both artificially and naturally induced flocculation (58). The durability of the aggregate will depend on its hydrodynamic interactions with the environment. Many cells produce extracellular polysaccharides, some of which can act to promote the cohesion of a biofilm. These substances might be important determinants of the diffusive resistance in these films.

INDUSTRIAL APPLICATIONS OF IMMOBILIZED CELLS

Much research has focused on industrial applications using immobilized cell technology for wastewater treatment. In an industry setting, entrapment and adsorption are the predominant techniques used for wastewater treatment. The nitrifying process is described in this section, examples include entrapment using PBG gels and adsorption using photo-cross-linked resins.

Gel Entrapment of Microbial Cells

The entrapment of microbes is the most popular immobilization technique for living cells in wastewater treatment. The BOD sensor was developed to abbreviate the long measurement time by entrapping the activated sludge (59,60). In wastewater treatment, immobilization processes should be mild to minimize the damage to the living cells. Entrapping materials must also have proper permeability to allow sufficient diffusion and transport of oxygen and essential nutrients, metabolic waste, and secretory products across the hydrogel network at supplemental culture.

Considering the use of synthetic polymers serving as the synthetic extracellular matrixes for cells, it is important to understand the transport properties through these gels to predict whether nutrients can diffuse into the matrix. Supplemented culture media provide the cells with essential nutrients for growth and development as well as a means of oxygen and metabolic product transport while in vitro (61,62). Traditionally, mass transfer behavior in the gel matrix has often been recognized as a rate-limiting factor in an entrapping cell system. Some of the immobilizing matrixes are highly hydrated, allowing almost unhindered diffusion for products and substrates with molec-

Table 2. Environmental Application of Gel-Entrapped Microorganisms

Substrate	Microorganism	Entrapment method	Reference
Ammonia	*Nitrosomonas europaea*	Ca-alginate	40
		κ-carrageenan	41
	Nitrosomonas europaea	Polyelectrolyte	42

ular weights less than 10,000 Da (36). The effective diffusivity of oxygen, glucose, and various ions in gel has been studied by several groups (63–65).

For industrial applications, microbes must be cultivated for entrapment and storage to keep the activity of immobilized microbes after immobilization.

Entrapping Materials. Mass transport through gels is governed by the size and shape of the pores and solute molecules as well as by the nature of the interaction between solute molecule and gel material. The value of the equilibrium coefficient reflects the relative affinity of the solute for the gel relative to its affinity for the surrounding medium. The species concentration in the gel at equilibrium is obtained by mass balance using the known values for the reservoir and gel volumes. The value of K, the partition coefficient, is calculated by the following equation:

$$K = C^{\text{gel}}/C^{\text{bath}} \quad (1)$$

The average pore diameters of gels were estimated from the diffusion of solutes and the hydrodynamic diameter of solute (60).

Biomass decay is an important parameter in the dynamics of the immobilized microbe system. *Nitrosomonas europaea* cells entrapped in a gel can lose their viability during cultivation; they die first in the center of a gel bead but also will die in the outer layers at low substrate loadings. If the substrate concentration is raised, the number of viable microbes near the surface of the gel increases again. The fluorescein diacetate and lissamine-green staining techniques were useful in distinguishing between viable and dead cells in gel beads (66).

Successive nitrification and denitrification are effective biological processes for the removal of nitrogen in the form of ammonia, nitrite, and nitrate from aqueous waste. In this biological nitrogen-removal system, nitrification is generally the rate-limiting step because of the extremely low growth rate of obligate autotrophic nitrifying bacteria. The use of immobilized cells in nitrification overcomes this disadvantage and shortens greatly the hydraulic retention time (HRT) in continuous nitrification.

In a synthetic resin gel such as polyacrylamide, the gel strength decreased about 50 to 60% in the presence of microbes. But the density of microbes in the gel did not influence its strength (67). The immobilization of nitrifying bacteria by using urethane prepolymers of the hydrophilic type exhibited a drastic improvement in the activity yield (68). These immobilized cells were prepared by entrapment using alginate (69–71), polyelectrolite complex (72), polyethyleneimine (73), photo-cross-linkable resin (74), poly(vinyl alcohol) (75), polyethylene (76), and poly(ethylene glycol) (PEG) (77).

Characteristics of Microbes Entrapped in Polyethyleneglycol. The PEG gel was prepared by radical reaction under existing microbes to exhibit about 3 kg/cm^2 of gel strength (78). These gels are nontoxic for microbial cells and show viability. Furthermore, this method is easy industrialized for a large-scale production.

Microorganisms such as nitrifying bacteria grow near the surface of gels (about 60-μm depth). After about a month's cultivation, they have constant activity. The rate of oxygen consumption the parameter of activity, is 60 mg O_2/L gel/h at initially and 800 mg O_2/L gel/h at the end of precultivation. At the steady state, the concentration of microbes in the gel carrier is increased to contain about 10^{10} cells per milliliter of carrier. On the other hand, the concentration of nitrifying microbes in the activated sludge is usually 10^3 to 10^5 cells/mL. Figure 1 depicts nitrifying pellets (about 3 mm^3) and a cross-section of pellets and bacteria in colony.

Nitrification and denitrification of entrapped microbes were scarcely influenced by the operation temperature, and the activity of nitrification was about three times higher than that of the activated sludge, as shown in Figure 2. In Figure 2, the reaction rates are exhibited on the basis of suspended solid for comparing the activity of im-

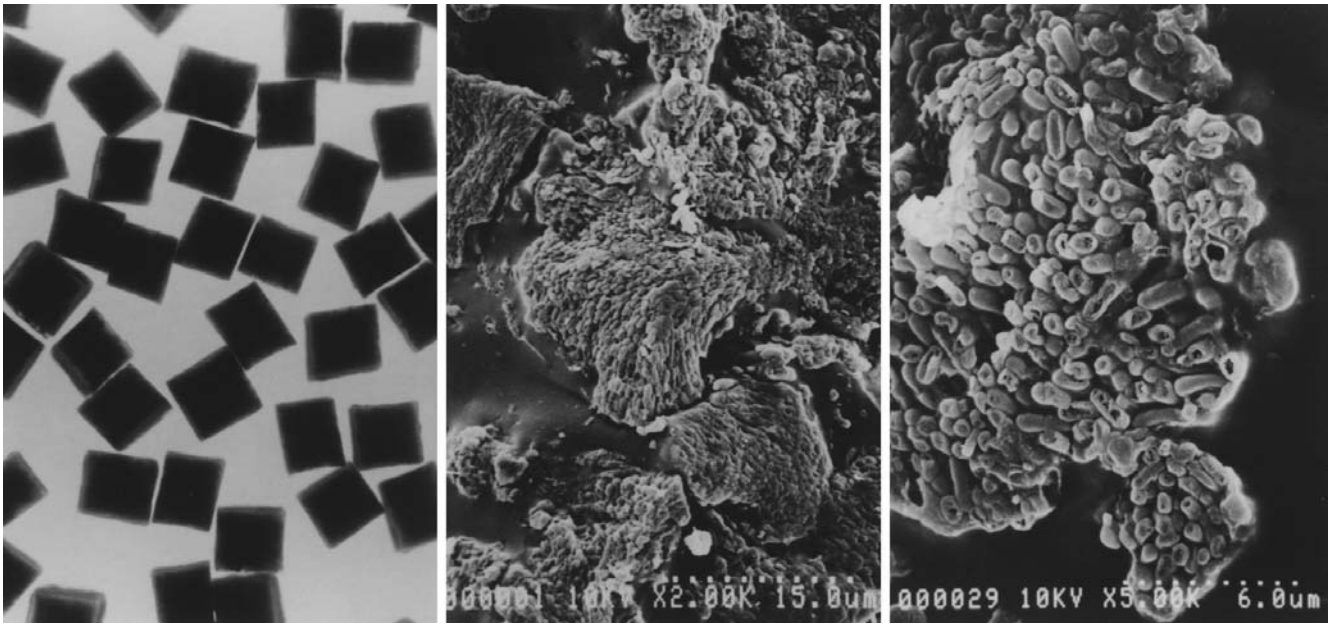

Figure 1. Photographs of nitrifying pellets. Cross-section of pellets and bacteria in colony. (a) Nitrifying pellets of 3-mm cubic gel; (b) Cross-section of pellet by electron scanning micrograph; (c) Bacteria in colony under electron scanning micrograph.

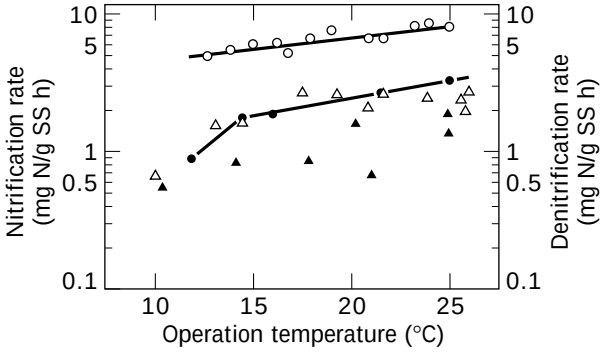

Figure 2. Effect of operation temperature on nitrification rate and denitrification rate of entrapping method against the activated sludge method. Nitrification: ○ = immobilized: △ = activated sludge. Denitrification: ● = immobilized: ▲ = activated sludge. Range of BOD loading: immobilized = 0.1–0.15 (kg/kg SS day). Activated sludge = 0.02–0.08.

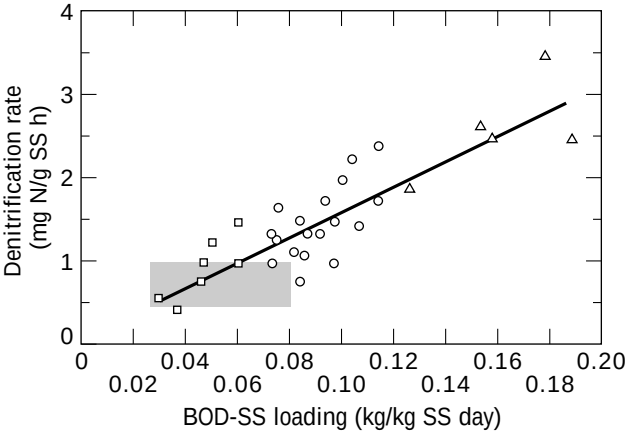

Figure 3. Relationship between denitrification rate and BOD-SS loading in the entrapping method. BOD loading (kg/kg SS day) at 15 °C: □ = 0.02–0.07; ○ = 0.07–0.12; △ = 0.12–0.19. Shaded part indicates the range of the activated sludge method.

mobilization with that of activated sludge. The nitrification rate of precultured immobilized gels was about 100 mg N/L gel/h at 13 °C. Accordingly, the system using entrapped microbes showed a high denitrification rate owing to high BOD loading resulting from short retention time in the nitrification tank (Fig. 3).

Continuous Wastewater Treatment by Entrapped Microbes (79). Figure 4 shows a schematic diagram of a pilot plant using PEG-entrapped gels. It is composed of an initial and final sedimentation tank, a denitrification tank, and a nitrification tank. The volume ratio of denitrification to nitrification is 1.5/1.0, and the gel separator (the net of 1.5-mm mesh) in the nitrification tank is installed for preventing gel bead washout. The mesh size of the gel separator should be half the gel diameter for sufficient separation. Wastewater treatment was recycled between the denitrification tank and the nitrification tank. Retention times are 4.8 and 3.2 h for denitrification and nitrification, respectively. The average total nitrogen removal is represented as

$$\text{Total N removal (\%)} = R/(R + 1) \times 100 \qquad (2)$$

with R as the recycling ratio (−). The total N removal is

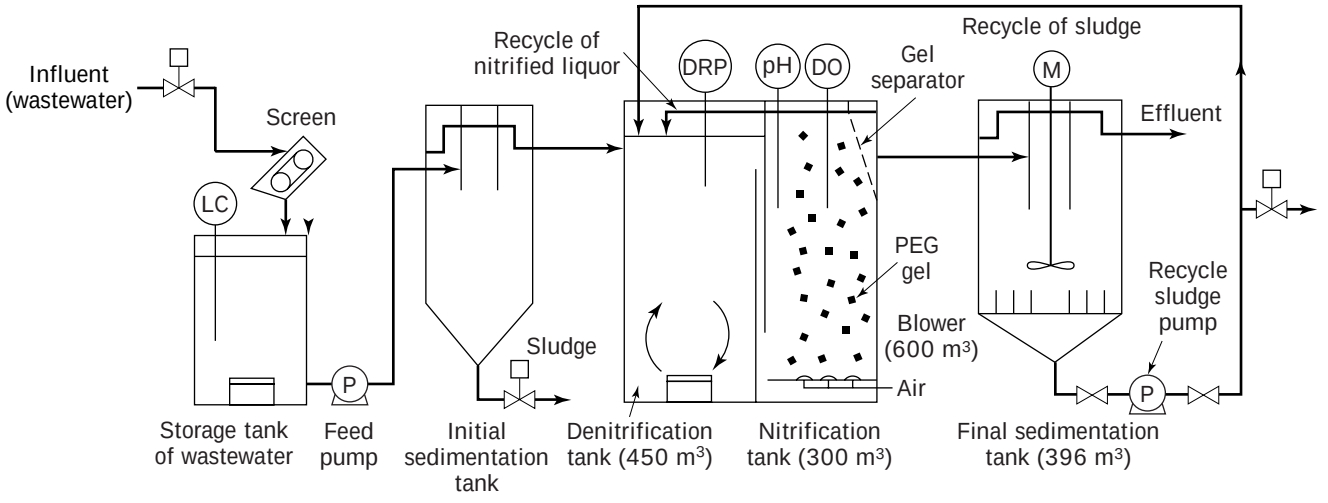

Figure 4. Schematic diagram of wastewater treatment plant with a capacity of 2,250 m^3/day (max, 3,000 m^3/day). DO = dissolved oxygen electrode; ORP = oxidation–reduction potential; pH = pH electrode; LC = level control; P = pump; M = mixer.

increased according to the enlargement of the recycling ratio, but the dissolved oxygen in the denitrification tank is also increased. Consequently, recycling is generally operated at a 1:2 recycling ratio to maintain the anaerobic condition of denitrification and compensate for the increased power cost in nitrification. Gel beads are fluidized by the air blowing at the bottom of nitrification tank.

The packing ratio of entrapped gels in the reactor is usually 5:15 volumetric percent depending on the treatment. In the entrapment method, gels are added at 7.5 volumetric percent to the nitrification tank. The floating carriers are distributed homogeneously. In the entrapment method, specialized equipment and sufficient time are needed to prepare an adequate number of gels for large-scale wastewater treatment.

The result of continuous wastewater treatment in the PEG entrapping method is shown in Figure 5, and the operation conditions of the plant are shown in Table 3. Even in winter nitrification was thoroughly carried out, and BOD as well as suspended solids in the effluent were lower than 10 mg/L. This method needs about 8 h of retention time to eliminate 70% of nitrogen in wastewater. After continuous operation for 2 y, it was concluded that gel beads must have above 1.5 kg/cm^2 compressive strength; therefore, the initial compressive strength of gel absent from microbial cells needs to be over 2.7 kg/cm^2.

For the nitrification, photo-cross-linkable resin was used to obtain an activity of 1.5 kg of N/m^3 gel/day for continuous wastewater treatment (80). On the other hand, the drop in denitrifying activity at the immobilization was restored in the medium containing nitrite or nitrate with sodium acetate as a hydrogen donor.

Industrial Application of Adsorption Method

Systems in which cells are immobilized by adsorption are popular because of the ease of this type of immobilization. The strength with which the cells are bonded to the support varies with cell type and support type (81,82).

The adsorption method differs from the entrapment method, advantages include easy gel formation (no consideration of microbes at cross-linking reaction), mass transfer of gel barrier, good storage stability before usage, and low transportation cost of gels at the industrial scale. A disadvantage is the long induction period for steady wastewater treatment.

The growth rate of nitrifying bacteria is about 10 times less than that of general microbes. The attachment of biomass on the gel surface occurs during the start-up phase. After this phase, the reactor is operated continuously at different hydraulic and surface loading rates. Accordingly, the gels must have high strength and good cell attachment on their surfaces.

A positively charged macroporous cellulose carrier is used for immobilization of nitrifying bacteria by the adsorption method (83). This carrier promotes stable adhesion of bacteria onto the carrier walls and allows transfer of nutrients into the carrier. A porous cellulose carrier was produced from cellulose with a polyethyleneimine coating to form a stable cross-linked structure. Similarly, polyurethane foam (84) and other carriers (85,86) have been used for wastewater treatment.

Advantages of Adsorption Using Photo-Cross-Linked Gels. To use immobilized microbes in wastewater treatment, the preparative method, especially the support material used for the preparation, must be selected from the standpoint of its economy and feasibility on a large-scale operation. For these reasons, photo-cross-linkable resins are promising support materials for the immobilization of microbes.

Although this immobilization process may have various conceivable features, its features are summarized as follows (87):

1. The immobilization procedure (gel formation) is simple because of ultraviolet irradiation.

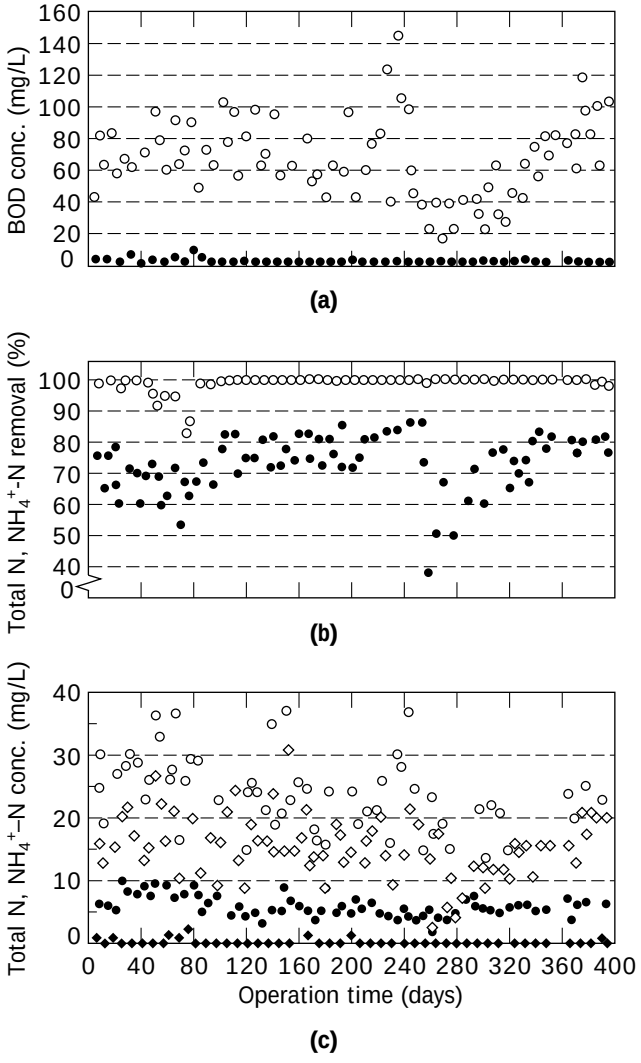

Figure 5. Continuous wastewater treatment using entrapped microbes. (**a**) Influent (mg/L): ○ = BOD; effluent (mg/L) ● = BOD. (**b**) Removal (%): ● = total N removal (%): ○ = NH_4^+-N. (**c**) Influent (mg/L): ˆ = total N, ◇ = NH_4^+-N; effluent (mg/L): ● = total N, ◆ = NH_4^+-N.

2. The gel materials have great mechanical strength.
3. The surface of gel beads can be regulated by the properties of photo-cross-linkable resin.
4. The manufacture of photo-cross-linkable resins and the process of gel formation can be easily industrialized.

The photo-cross-linkable resins usually have a main chain of PEG, a mixture of PEG and poly(propylene glycol) (PPG), or poly(vinyl alcohol) (PVA) with photo-cross-linkable ethylenic double bonds. By irradiation of ethylenic double bonds with UV eight, polymerization is induced, forming three-dimensionally-cross-linked gels.

Surface Structure of Gels for Good Cell Adsorption. The sludge used is taken from the recycle line of an activated sludge treatment plant treating wastewater, because organic nitrogen and ammonia nitrogen are present in wastewater. Acclimatization of the sludge is carried out in a batch reactor. The carrier elements are made of hydrophilic photo-cross-linkable resin with a 4-mm bead diameter.

Because the nitrifying bacteria do not flocculate differently from the activated sludge, it is difficult to attach the nitrifying bacteria on the surface of the carrier. The adsorption rate of nitrifying bacteria is maximum at pH 4.8, and nonbiological factors are important at the initial stage of attachment (88). Fluorescence studies of the adsorbing surface clarified that the affinity to water and ζ potentials of the surfaces are important factors for adsorption (89). Among the synthetic polymers, photo-cross-linkable resin has largely resolved the problems with inorganic carriers described in the Introduction. Its surface structure may be suitable for attachment of microbes, controlling the properties of photo-cross-linkable resins.

Several factors affect cell affinity and behavior on hydrogel: the general chemistry of the monomers and the cross-links, hydrophilic and hydrophobic properties, and surface properties involving charged functional chemical groups. Physical properties of the hydrogel also govern the adhesion affinity; therefore, altering pore size and network structure can convert cell adhesion as well as morphology and function.

The attachment of biomass on the charged gel surface occurs during the start-up phase. Designing gel carriers using photo-cross-linkable resin has resulted in good cell growth on their surface with good mechanical strength (90). The surface of PEG-PPG-type hydrophilic resin is most hydrophobic and has an excellent affinity to microbes. This phenomenon is practically confirmed in continuous denitrification, as shown in Table 4.

When observing the surface of PEG-PPG-type photo-cross-linked resin and the results of contact angle, the phase separation of the gel in which hydrophobic domains of about 1-μm diameter separated on the hydrophilic phase of PEG was seen on SEM of the surface (Fig. 6) and with the optical microscope. From these results, the surface of hydrophobic domains formed on hydrophilic phase, the so-called macrophase separation of hydrophilic gel, may be best for the attachment and growth of nitrifying microbes.

The structure of the gel bead is controlled with a combination of PEG and PPG, PVA type, and PEG type. Beads with a diameter of about 4 mm and compressive strength of more than 20 kg/cm^2 can be produced by immobilization (91).

Continuous Wastewater Treatment. Continuous wastewater treatment can be carried out by a process using gel for microbial adsorption, as shown in Table 5 (92–94). Removal performance of the pilot plant with a retention time of 8 to 9 h in the bioreactor is obtained as follows. The average total N of the influent is 31.8 mg/L, and that of the effluent total N is 8.3 mg/L. The average P of the influent is 2.57 mg/L, and that of the effluent total P is 0.60 mg/L.

The nitrification rate of immobilized gels is of zero-order

Table 3. Operation Condition of Plant

Item	Run 1	Run 2	Run 3
Operation period	18	11	18
Infuluent (m^3/day)	2,720	2,280	1,350–3,150
Retention time (h)	6.6	7.9	5.7–13.3
Aeration (Nm^3/h)	610	670	800
Recycling ratio (−)	2.8	2.7	2.0–7.0
MLSS (mg/L)	2,800	1,840	1,880
BOD-SS loading (kg/kg day)	0.070	0.149	0.0965–0.302
BOD loading (kg/m^3 day)	0.196	0.275	0.182–0.570
Total N and SS loading (kg/kg day)	0.0285	0.0535	0.0226–0.0772
Total N loading (kg/m^3 day)	0.0793	0.0980	0.0426–0.146
Recycling ratio of sludge (%)	64	64	47–109
Temp. of water (°C)	23.5	14.0	14.2
Total SRT (day)	14.6	9.0	8.8
Aerobic SRT (day)	5.8	3.6	3.5

Notes: Run 3 = Variation test of loading. MLSS = Mixed liquor suspended solid; BOD = Biological oxygen demand; SS = suspended solid; SRT = sludge retention time.

reaction in which the produced NO_z-N increases directly with the reaction time, and the nitrification rate is about 2.5 kg NO_k/m^2 gel/day, as calculated in Figure 7. In the relationship between the dissolved oxygen (DO) and the nitrification rate coefficient (K_M) of gels, K_M largely depended on the DO. It is considered that the oxygen diffusion through the biofilm on the surface is the rate-determining step for nitrification. The phosphorus uptake increased in proportion to the denitrified nitrogen, and the weight ratio of phosphorus to nitrogen is about 0.75. From these facts, nitrifying microbes are suggested to be phosphorus-accumulating microorganisms (95,96).

Water qualities and flow diagram for metal-finishing wastewater are shown in Table 5 and Figure 8, respectively. Since 1997, a denitrification plant using these gels (nitrifying tank volume, 10,000 m^2) has been operating in Tokyo (Fig. 9).

EVALUATION OF IMMOBILIZATION

The development of processes using immobilized microorganisms has made it possible to eliminate BOD and nitrogen in half the time (6 to 8 h), compared with conventional activated sludge. In addition, these processes maintained constantly high activity during winter. The treatment cost containing the depreciation is 80 to 90% of the activated sludge.

Table 4. Comparison of PEG-PPG/PVA Type Gels and PVA Type Gels

Species of gels	PEG-PPG/PVA type	PVA type
DO (mg/L)	2.8	6.0
NH_3-N value added (kg/m^3 day)	0.29	0.21
Nitrification velocity (kg/m^3 day)	0.21	0.15
Cells attached (mg/L)	6,920	1,620

To gain the advantages of immobilization, reductions are needed in the immobilized gel costs, particularly for large-scale operations, which include raw materials costs, immobilization facility, transportation cost, storage cost, and so on.

cells are still under development and will be further improved in the future. Particularly, it is expected that carrier gels will regulate their structure and form a particular reaction site in gels or on the surface of gels independent of the surroundings.

OUTLINE

INTRODUCTION

During the past 20 years there have been considerable developments in winemaking techniques, with the introduction of processes and machinery borrowed from other sectors of the food industry. These developments have affected all phases of wine production, wine being the end product of a technological chain that includes the preparation and treatment of the must, fermentation, aging, and bottling. Thus, technological progress has improved the quality of the wine produced. Wine quality is measured by finesse, intensity, and originality in taste and smell and by microbiological and physicochemical stability (1–4).

The main phases of production of white and red wines are illustrated schematically in Figures 1 and 2. Figure 3 shows those technological innovations that may be of practical use. Among these, during the past few years particular attention has been paid to enzyme treatments and to the use of selected fermentation starters (both free and immobilized). Some of these processes have already been applied to production, and others are still in the experimental stage.

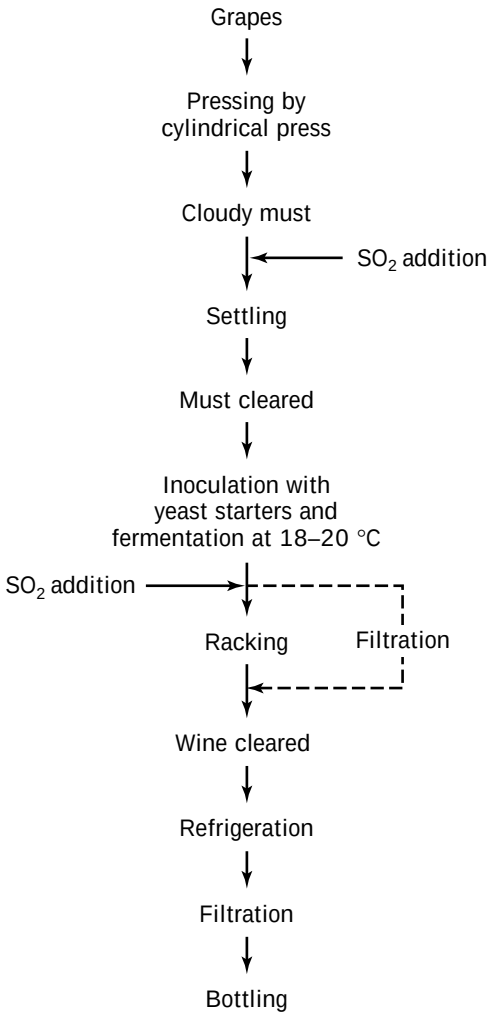

Figure 1. Scheme of a process for white wine preparation (fermentation with skins off). Terms are defined as follows. Pressing by cylindrical press: The operation of applying pressure to grapes to extract the liquid, which allows the juice to separate from the solids (skins, seeds, and stems). Settling: The operation of clarifying must at T = 5 to 10 °C (must can also be clarified by centrifugation or filtration). Refrigeration: The operation of cooling to 0 °C or below, used to hasten the precipitation of potassium bitartrate and to improve the stability of the wine.

ENZYME TREATMENTS

Winemaking is a biotechnological process in which enzymes play a fundamental role and in which the use of exogenous enzyme preparations makes it possible to overcome the problem of insufficient activity of endogenous enzymes in the grapes. The enzymic treatments have a multiple purpose in that the changes made to the grapes, the

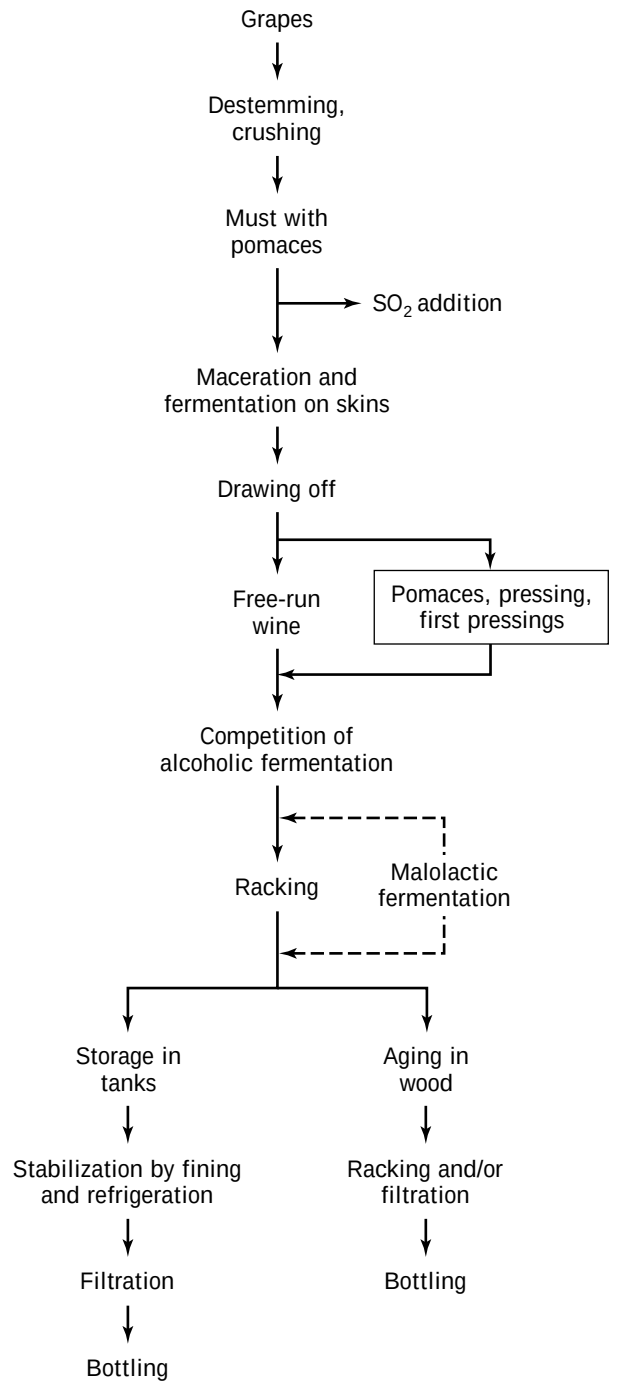

Figure 2. Scheme of a process for red wine preparation (fermentation with skins on). Terms are defined as follows. Destemming-crushing: The operation that mechanically removes the stems from the grapes and liberates the juice. Maceration: Contact of the must with the solid parts (skins and seeds) of the berries to enrich the juice with skin constituents. The maceration conditions (temperature, duration, pumping oversystem) change in relation to the grape variety and to the organoleptic characteristics of the wine produced. Alcoholic fermentation: With natural or selected yeasts. Malolactic fermentation: The biological decomposition of malic acid can be carried out soon after alcoholic fermentation or during storage (aging).

must, and the wine have an influence on the processes of clarification and filtration, the processes of extraction of color and aroma, and the stability of the wine (6–10). It must, however, be remembered that the use of enzymes in the wine industry, apart from pectolytic enzymes, remains extremely limited for a series of reasons that can be summarized as follows:

- The traditionalism of the wine industry, which is still anchored to classical methods
- Limitations of enzymic activity connected with the composition of the must and the wine (low pH, ethanol concentration, presence of tannins, and a fairly low working temperature compared to the optimum for enzyme preparations)
- Legal restrictions

However, during the past few years, research has suggested the use of enzymes that catalyze the transformation of glucan (glucanase), proteins (peptidase), and polyphenols (laccase, peroxidase, phenolase, and tannase), all of which are compounds that condition the stability and organoleptic characteristics of wines. Particular attention has been paid to glycosidases that are able to free odorous compounds by hydrolyzing terpene glycosides.

Pectolytic Enzymes

Pectolytic enzymes have been widely used for many years, because they act on the pectins. Pectins are complexes of acids (homogalacturonan and rhamnogalacturonan) and neutral polysaccharides (arabinan, galactan, and arabinogalactan) that are found in the must in colloid form. They act as protective colloids, causing problems in the clarification and stabilization (11–13).

Enzymes that can act on the pectic substances are usually classified into two groups, as shown in Figure 4 (14,15): de-esterifiers (pectinmethylesterase) and depolymerases that catalyze both hydrolysis (polygalacturonase) and β-elimination reactions (pectin lyase and pectate lyase). Purified enzymic preparations from cultures of microorganisms normally contain polygalacturonase and lyases associated with hemicellulase and cellulase. However, the presence of pectin methylesterase must not be too great in order to limit the liberation of methanol, which is found esterified with the carboxylic groups of the galacturonic acid in the pectic molecule (16). Pectolytic enzymes are used at vintage time in the preparation of both white and red wines. Italian law permits the use of pectolytic enzymes in the processing of pressed grapes, the must to be used for producing white wine, musts and wines obtained using the thermovinification system, and wines after they have been separated from the pomaces (Ministerial Decree of 8 September 1976, G.U.I.). In the context of numerous experiments that have been carried out during the past few years as well as the development of new commercial products, various authors have evaluated the influence of the use of these enzymes on the extraction of juice, color, and aroma and on the clarification and filtration processes. Ough and Crowell (17) investigated the effect of the use of some exogenous pectolytic enzymes at pressing on the must yields, turbidity, and solids, using different varieties of grapes. The enzyme-treated samples gave better juice yields than the untreated samples. The amount of sediment after overnight settling was less for the controls. After racking and centrifuging, the enzyme-treated juice samples were clearer and contained fewer insoluble solids.

The addition of pectolytic enzymes has a favorable influence on the clarification of musts and, consequently, also has a positive effect on such parameters as viscosity and filterability (18,19). The treatment of crushed grapes with pectolytic enzymes in the production of red wine leads to a more rapid and complete breakdown of the cell wall of the skin. This leads to greater extraction of anthocyanins and, thus, to an increase in color, although the results may vary according the cultivar of grapes used (20).

Rational use of pectolytic enzymes, especially in the case of grapes particularly rich in pectic substances (e.g., muscat) makes it possible to improve the economics of the process (e.g., through reduction in time required, better use of equipment, and reduction in loss of must and wine) without negatively altering or modifying the quality characteristics of the final product (21,22).

β-Glucanase

Glucan is a polysaccharide with a high molecular weight (M_r 10^5 – 10^6), consisting entirely of glucose subunits. It is a (1–3:1–6)-β-D-glucan. It is found in must and wines from grapes infected by *Botrytis cinerea* (23). In these wines, the glucan is of great technological importance because it tends to clog the filters if a quantity is present by forming a glutinous layer on them. This causes considerable problems in clarification and filtration. In order to solve this problem of clogging, an enzyme treatment was set up in the 1980s, based on β-glucanase, which hydrolyzes the glucan excreted by the *Botrytis cinerea* (25).

Experiments carried out by Villettaz (9,26,27) and Wucherpfenning and Dietrich (28) to evaluate the efficacy of β-glucanase have demonstrated the technological and economic importance of this enzyme in improving the filterability of wines produced from grapes affected by *Botrytis*.

β-glucanase has been included in the practices and treatments permitted by the EEC, although the conditions for use have yet to be defined (29,30).

Proteolytic enzymes

In winemaking, treatments are carried out to lower the protein content, because in must and wine, proteins are found in colloidal dispersion, which can become insoluble, forming haze and precipitates (31,32). When this occurs during processing it causes delays, but if it occurs when the wine is already on sale it causes economic loss. This phenomenon occurs predominantly in white wines and only very rarely in red wines. Red wines contain tannins, which are believed to react with the proteins to form insoluble tannoprotein compounds. During fermentation and aging, this leads to a drastic reduction in the protein levels (33). Although the proteins responsible for the instability have not yet been well characterized, it seems that the protein fractions of lower MW (12,600 and 20,000 to 30,000) and lower P_i (4.1 to 5.8) and glycoproteins are the major and most important fractions contributing to protein instability in wines (34). Treatments with proteolytic enzymes have been tried as an alternative to using traditional finings such as bentonite. These enzymes cause hydrolysis of the proteins into amino acids or short-chain peptides that are completely soluble in the wine (35–37); however, intervention with exogenous enzymes is not free from problems. Many of the traditional proteases (papain, pepsin, and trypsin) are not suitable for use in wine; they require high temperatures that are deleterious to wine quality, and they do not have their optimal pH in the range of 3 to 4, which is ideal for wines. For these reasons, studies have mostly been directed toward the use of acid proteases of fungal origin in free and immobilized forms; however, so far the results have not always been positive. Modra and coworkers (38) assessed the action of commercial peptidases on proteins isolated from muscat grapes. This treatment modified the HPLC elution profile of a high relative molecular weight fraction containing protein. The most generally discernible change was a decrease in the M_r 23.000 peak, with a concomitant increase in the 10.000 M_r peak, and a loss of resolution in both. The change in protein profile varied among the peptidases, but none of the enzymes gave complete proteolysis after 7 days. The tests carried out on muscat must confirmed that the peptidases modified the proteins; however, their efficacy was not sufficient to make the wine stable, and treatment with bentonite was required.

Woiwodow et al. (37) tested the action of an acid protease from *Aspergillus niger* immobilized on Sylochrom C-80 on the proteins of white table wines. Experiments were carried out with different quantities of enzyme (2 to

10 g/L) and with different times of contact (2 to 48 h) at a temperature of 23 to 25°C. Complete stability of the wine was reached after prolonged treatment (48 h) with very high quantities of immobilized enzyme (10 g/L). In other tests, electrophoresis of the proteins isolated from the wine before and after treatment showed a diminution in both number and intensity of protein fractions, but the wine was not completely stable. Bakalinsky and Boulton (35) studied the use of food-grade acid protease (from *A. niger*) covalently linked to agarose spheres of 100 μm. Four types of wine were treated at temperatures of 30 and 37 °C in a recirculating flow packed-bed reactor containing 226 mg of dry weight conjugate. At the end of the treatment, the wines were subjected to heat-stability testing. The results showed that the enzyme, although active in all of the wines tested, achieved protein stability only in Riesling wine. The Riesling was the only wine whose pH was adjusted to 3.0 for treatment, whereas the other wines were treated at their natural pH levels (Sauvignon blanc, 3.65; chardonnay, 3.57; Gewürztraminer 3.59). The pH adjustment may have been the cause of the successful stabilization.

That immobilized protease was active in the wine but failed to have any significant effect on the protein stability may indicate that the proteases do not hydrolyze the protein fractions responsible for the instability or that the hydrolysis occurs along with the formation of products that are still unstable. If the potentially unstable wine proteins were complexed with polyphenolic compounds, one would expect them to be more resistant to enzymic hydrolysis. Currently, the use of free or immobilized proteases to stabilize wine requires more information on the nature of the proteins, their interactions with the other components of wine, and the conditions that cause them to become insoluble. Furthermore, sensory evaluation of the treated wine is recommended to assess possible detrimental alterations in flavor caused by the probable increase in peptide content. Small hydrophobic peptides, in particular, are recognized as having a bitter flavor (39).

Enzymes with Specific Action for Polyphenols

Phenols in wine predominantly arise from the grapes and are primarily flavonoid. They are crucial components in wines because of their basic importance to the color and flavor. Flavonoids (catechins, proanthocyanidins) are also responsible for discoloration, turbidity, and flavor changes in wines. Review of the importance of phenolic compounds in grapes and wine has recently been published (40,41). Chemical and enzymic oxidation of phenolic compounds leads to the formation of highly reactive intermediates (quinones) that interact with amino acids to reduce sugars and alcohol and give rise to chromophores and volatile substances (40,42,43). This results in a loss of freshness, anywhere from yellowing to browning of the wine, and turbidity (42,44). A summary of these reactions can be found in Figure 5.

The removal of polyphenols is a common practice in winemaking processes to prevent discoloration and to obtain stabilization against oxidation, especially in white and rose wines (45). Wine technology tends toward the adoption of systems for extraction of the must that limit the solubilization of oxidizable substances (46) and toward the use of finings (gelatin and casein), adsorbants (active carbon), and polyvinylpolypyrrolidone (PVPP) (47,48). The use of these additives in wine production is aimed at reduction of the level of polyphenols and compounds that catalyze their transformation, particularly enzymes and heavy metals. To limit the amount of treatment with chemical-physical agents, it has been suggested that enzymes active against polyphenols (oxydases, hydrolases, and transferases) be used in the prefermentative phase. The aim of this is to set off a process of enzymic oxidation of polyphenols in the must under controlled conditions, so as to destabilize them and accelerate the process of polymerization and flocculation. Enzymes and reactions are shown in Table 1. The possibility of eliminating or achieving reactivity loss of the polyphenols responsible for wine instability has been tested on the bench and on a pilot scale using enzymic preparations containing, respectively, tannase (from *Aspergillus* sp.), phenolase (prepared as an extract or acetoin powder from *Agaricus campestris*), and laccase (from *Polyporus versicolor* in a liquid culture, partially purified) (47,49).

These different enzyme treatments were compared with each other, and some were then compared with conventional systems of stabilization. The polyphenol concentration in wines prepared from the same, but differently processed, pinot grapes showed that laccase was more effective than the other enzymes tested and produced a wine with a more stable color (Table 2). The possibility of using laccase was checked on a pilot scale with the must from Trebbiano grapes. Laccase treatment was compared with clarification carried out with casein, active carbon, and bentonite, with or without sulphur dioxide. The use of the enzyme was shown to be highly effective, preferable or practically identical to the results from traditional processing. The wines treated with laccase had different and better organoleptic maderization-resistant features (47). In the case of muscat and Riesling, the action of laccase (8,300 units/L) was compared with that of fining agents (gelatin/SiO_2) (50). The results obtained with muscat must without SO_2 and Riesling must with SO_2 (150 ppm) (Table 3) shows that the enzymic treatment is highly effective, preferable, or practically identical to traditional processing, especially when using must without sulphur dioxide (Table 3).

These interesting results allow us to conclude that laccase prefermentative treatments make it possible to eliminate instability in white wines caused by oxidizable polyphenols. Obviously, the process of winemaking must include physical (e.g., ultrafiltration) or chemical (e.g., addition of sulphur dioxide, deproteinization) systems that make it possible to eliminate the enzyme. The enzymic treatment coupled with a filtration system (filtration by diatomaceous earth, PVPP, or silica of ultrafiltration) is probably a technique that gives sufficient stability for white wines.

Glycosidases Acting on Precursors of the Aroma

The aroma of grapes includes volatile free odorous substances, especially terpenes (linalool, geraniol, nerol, citro-

nellol, α-terpineol, linalool oxide) that play a fundamental role in giving character to certain cultivars, for example, muscat (51–53). In addition, grapes also include compounds called aroma precursors, which are glycosides mainly of linalool, nerol, and geraniol (for example 6-*O*-α-L-arabinofuranosyl-β-D-glucopyranosides, 6-*O*-α-L-rhamnopyranosyl-β-D-glucopyranosides and β-D-apiofuranosyl-β-D-glucopyranosides (54–57). The ratio between bound and free monoterpenols ranges from 1 to 5 in juice grape cultivars of muscat and Riesling and can be as high as 15 in the Gewürztraminer variety (58,59). From a technological point of view, the existence of such bound forms is interesting because these glycosides, nonvolatile precursors, can give flavoring aglycones when hydrolytic reactions take place. High-temperature acid hydrolysis can be used, but it may lead to extensive rearrangements of the terpenols. A study of the transformations of the terpenic compounds has in fact shown that, as the pH of the aqueous medium diminishes, the hydration and cyclization of linalool increase (60).

Enzymic methods are attractive for increasing the concentration of free flavorants with minimal changes in the natural monoterpene composition. Recent studies have shown that enzymic hydrolysis occurs in two stages, following a sequential mechanism illustrated in Figure 6. In the first stage, the intersugar linkage is cleaved by arabinofuranosidase, rhamnopyranosidase, or apiofuranosidase (depending on the structure of aglycon moiety), and the corresponding monoterpenyl-β-D-glucosides are released. In the second stage, the liberation of monoterpenols takes place after action of a β-glucosidase on the previous monoterpenyl β-D-glucosides (62,63).

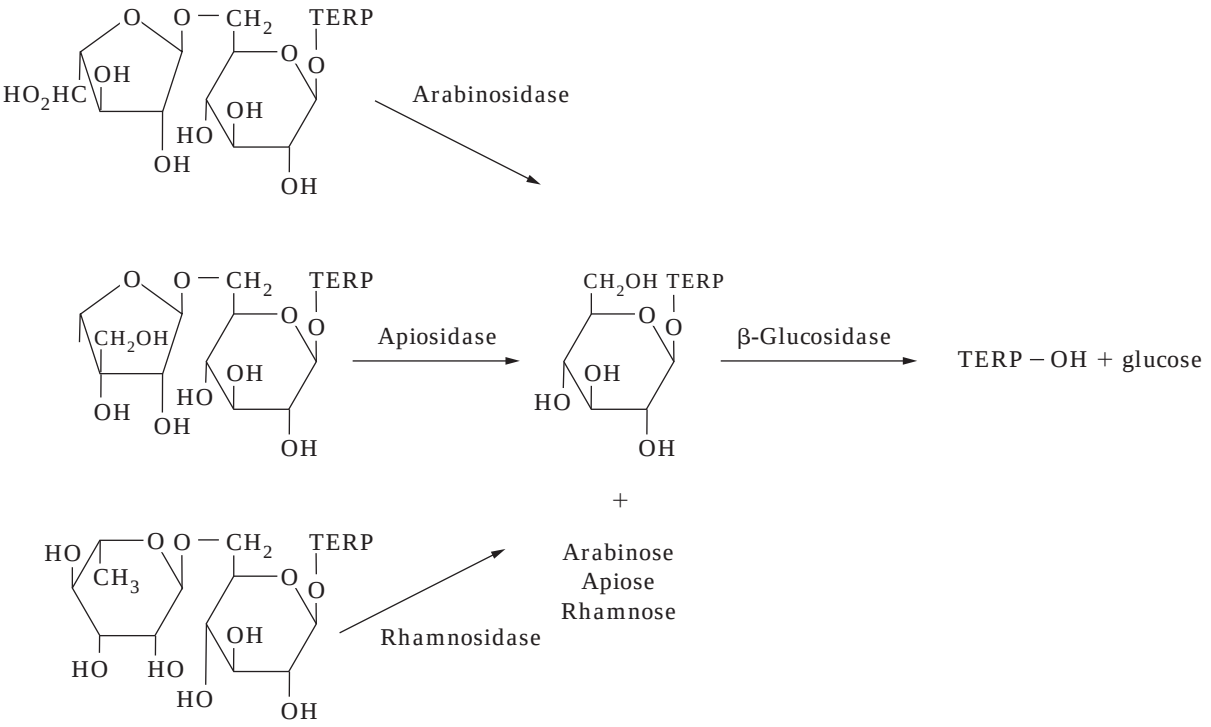

Figure 6. Sequential mechanism of terpene glycosides enzymic hydrolysis (61).

In the search for an enzymatic compound suitable for the hydrolysis of these precursors, different commercial products (pectinase, cellulase, hemicellulase, lypase, and protease) have been tested. Some of the preparations tested have contemporaneously good α-arabinofuranosidase, α-rhamnopyranosidase, and β-glucosidase action, but their efficacy in the must and wine is a function of numerous factors (64). The efficiency of hydrolysis of monoterpenyl β-D-glucosides by β-glucosidases was found to be dependent on the structure of the aglycon and the origin of the enzyme. Moreover, the efficiency of β-glucosidase is influenced by the concentration of glucose and gluconolactone, and in sweet wines, the hydrolysis is interrupted at the stage of the monoglucoside without freeing the odorous monomers. In the case of dry wines, on the other hand, there is a considerable increase of most of the free terpenes (65). Considering that the glycosidases used so far have not given the results hoped for, and that this is principally because of the properties of β-glucosidase, the hydrolytic activities of various plant and fungal β ;-glucosidases toward terpene glycosides are being studied. The goal of these studies is to find an enzyme with large aglycon specificity and good stability to low pH as well as tolerance to glucose and ethanol.

USE OF SELECTED CULTURES AND INNOVATION IN THE FERMENTATION PROCESS

Of the two fermentation processes, alcoholic fermentation causes the transformation of sugars into ethyl alcohol and CO_2, whereas malolactic fermentation causes the transformation of malic acid into lactic acid and CO_2. However, both processes produce compounds (organic acid, alcohols, ester, and carbonilic compounds) that influence or determine the organoleptic characteristics of wines and so play a fundamental role in fixing wine quality (3,66–68). For this reason, the microorganisms responsible for these transformations, yeast and bacteria, have for some time been the object of great interest. The work of Pasteur (1886) was followed by numerous studies of the microflora of grapes and of the factors that regulate the equilibria between the various species and their metabolism. In fact, a great variety of microorganisms are present in grapes and musts, and the yeasts responsible for alcoholic fermentation are but a small part of them (69–71). The fermentative yeasts (particularly *Saccharomyces cerevisiae* and related species) generally predominate because the chemical composition of the must is more favorable for their development than for that of other eumycetes and schizomycetes (72,73). However, it is difficult to control alcoholic fermentation that develops naturally, because certain parameters (such as temperature, degree of oxygenation, degree of clarity of the must, and phenomena of microbial antagonism) can modify the natural selection and therefore condition the development and completion of the process. This alters the ratio between the principal (ethanol and CO_2) and secondary (acetic acid, succinic acid, acetoin, 2,3-butanediol, acetaldehyde, glycerol) products.

Because it is impossible to cover in this review even all the main aspects of microbial biochemistry involved in winemaking and the influence of certain environmental conditions on grape must fermentation, textbooks or re-

views should be consulted for more detailed information on these topics (66,72,74–80).

Selected *Saccharomyces cerevisiae*

To overcome the problems mentioned earlier, for many years it has been standard practice, especially in the production of white wine, to use dry pure cultures of enologically suitable species (in particular *Saccharomyces cerevisiae* and all its physiological variants) with known properties. This ensures a quicker start to alcoholic fermentation (thanks to the massive addition of yeast), prevents the development of atypical microflora, and therefore eliminates the uncertainty and variation that occur in spontaneous alcoholic fermentation (50,66,76). Selected culture has therefore been the subject of many investigations that have considered the desirable characteristics of wine yeasts and their influence on the composition of wine and its organoleptic characteristics. Numerous properties of yeasts have been studied: some are always desirable, and others are always undesirable (Table 4) (81).

During the past few years, the wine industry has looked with interest at yeast genetics and strain development programs in order to obtain modified yeasts suitable for winemaking technologies that do not impair the flavor and bouquet of the final product. Yeast geneticists have carried out programs of genetic improvement to obtain new yeast strains that possess a high fermentation rate and high ethanol production as well as other relevant winemaking characteristics (82,83). This program has used both classical genetics (e.g., hybridization through conjugation between spores or aploid cells) and more recent biotechnological methods, such as somatic hybridization through fusion of protoplasts induced chemically or physically and transformation through the introduction of fragment of extraneous DNA using molecular vectors. Some reviews on this topic have recently been published by Falcone and Frontali (84) and by Pretorius and van der Westhuizen (85).

Thus far, it has been possible to eliminate foaming capacity of strains thought to be highly suitable for inducing alcoholic fermentation (86,87). Certain wine yeast strains produce proteins that are responsible for the foaming associated with fermentation. Excessive foaming during wine fermentation is an undesirable characteristic of wine yeast strains. The formation of a froth head can result in the loss of grape juice or reduce the capacity of plant equipment, because part of the fermentation vessel may have to be reserved to prevent the froth from spilling over. Foaminess also detracts from the visual appeal of the product (88).

Furthermore, it has been possible to effect genetic marking (89) to differentiate the selected strains from those of the indigenous microflora (always present in musts) and to give the killer phenotype to a strain (90–92) to increase its competitiveness with indigenous flora. The killer phenomenon is related to the ability of some yeasts to secrete toxic proteins that are lethal for so-called sensitive strains (93).

Particular attention is being given to the following possibilities: (*1*) introduction of the flocculent characteristic into yeast strains to facilitate the separation of cells from wine at the end of fermentation (94–97); (*2*) introducing malolactic enzymic activity into yeasts with the object of effecting alcoholic fermentation and malolactic fermentation with a single microorganism (yeast), a modification that would yield obvious technological advantages (98); (*3*) obtaining modified strains for the production of the aroma components (esters, fatty acids, and alcohols) (99); and (*4*) obtaining strains that do not produce H_2S, a component responsible for organoleptic alterations in the wine (100).

Achievements are still modest in the field of genetic improvement of enogical strains because of various factors: (*1*) the complex genetic background of industrial strains (ploidy, homothallism, poor sporulation, etc.) (101–104); (*2*) the impossibility of describing the genetic basis of most enological characteristics and, thus, of elaborating simple screening tests for them (85,105); and (*3*) the presence of indigenous microflora in the must that, unlike other substrata, cannot be subjected to sterilization without altering the wine characteristics.

Table 4. Some Characteristics of *Sacchromyces cerevisiae* Affecting the Winemaking Process

Desirable
Rapid initiation of fermentation
Efficient conversion of grape sugar to alcohol
Ability to conduct even fermentation
Ethanol tolerance
Ability to settle rapidly at the end of fermentation to aid clarification
Fermentation at low temperatures such as 10–14°C
Retention of viability during storage
Sulfur dioxide resistance (sulfur dioxide is normally used in winemaking)
Production of desirable fermentation bouquet and reproducible production of the correct levels of flavor and aroma compounds
Killer factor or resistance to killer toxins
Film-forming capacity
Undesirable
Production of sulfite, hydrogen sulfide, or mercaptan
High production of acetaldehyde, acetic acid (volatile acidity), ethyl acetate, and higher alcohols
foaming capacity
Production of urea, which can result in the formation of ethyl carbamate

Process Innovation in Alcoholic Fermentation

Another line of research that has developed in the field of enology is the search for and optimization of new processes that are able to meet the technological and organizational needs of the industry (greater productivity, reduction in the time needed for the process, reduction in capital and running costs). In this field, we can mention the use of yeasts immobilized in natural nontoxic polymers or contained in a microporous membrane and of the cell-recycle batch fermentation process (CRBF) for the preparation of

white wines and sparkling wines. The advantages that are sought are summarized in this section.

Bottle-Fermented Sparkling Wines (Champenois Method). It would be desirable to eliminate the phase of remuage, with a considerable savings in labor and time, thanks to instant sedimentation of the immobilized yeasts by gravity. Sparkling wine produced by the champenois method is characterized by fermentation of wine in the bottle, to which sugars, yeasts and other fermenting agents have been added (Fig. 7). The bottles thus prepared are stacked horizontally in thermoregulated environment (12 to 18 °C) where the secondary fermentation is carried out. Once fermentation has terminated and the wine has been in contact with the yeast for at least a year, the bottles are turned frequently and inclined (an operation referred to as remuage), so that the yeast sediment slides toward the bottle neck and settles on the stopper. The sediment is then eliminated by degorgement. Remuage is both long and arduous in that it requires a large amount of labor over a long period of time (1 to 4 months) and the occupation of large wine cellars. By using immobilized yeasts, it is possible to move directly from the stacks to degorgement with a saving in production costs of about 80% when compared with the traditional method (106).

Production of Sparkling Wine in Tanks (Charmat Process). The possibility of using a high cellular concentration and

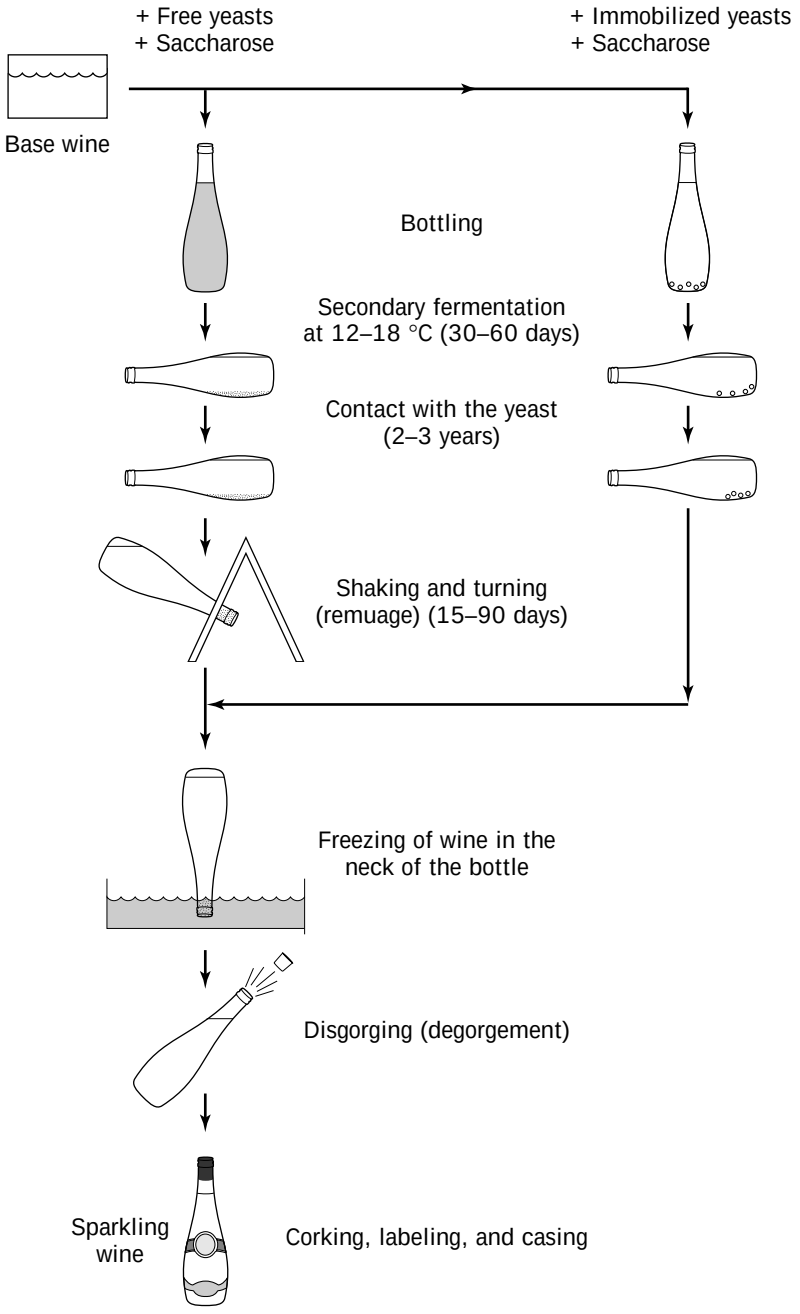

Figure 7. Scheme of the process for bottled sparkling wine preparation with traditional methods and with immobilized yeast.

thus of obtaining a very high rate of reaction so as to achieve a continuous process (107) is another desiderable innovation. This would allow a reduction in the dimension and number of pressure tanks, with a diminution in the costs of running and equipment. In the bulk process for sparkling wine production, the Charmat method (Fig. 8), sugars, other nutrients, and yeasts are added to the base wine, and the second fermentation occurs in large stainless steel sealed tanks. The sparkling wine is then filtered, fined, and bottled. This process is the cheapest for producing sparkling wines, but it still requires a considerable number of expensive tanks.

Use of Yeast Entrapped in Wine Production. The possibility of improving the rate and efficiency of transformation by increasing the concentration of yeast would be an advantage in general wine production. In this way, a linear development of the fermentative process is achieved, excluding the yeast induction phase and exponential growth. This reduces the time required by the fermentative process and the final level of the secondary products of fermentation (acetaldehyde, acetic acid, products of catabolism of the amino acids, etc.) that accumulate in the first phase of fermentation when the biomass is formed (50).

The use of yeasts entrapped in calcium alginate and in other materials has been investigated by Cantarelli (50); Duteurtre et al. (108); Lemonnier and Duteurtre (109); Loureiro (110); Zamorani et al. (111); and researchers at our Institute (106,112–115). This research has made it possible to observe the following:

- Of the various compounds used for entrapment—agar, agarose, calcium alginate, barium alginate, κ-carrageenan, gelatin, pumice stone, porous porcelain, controlled porous glass, and dyalysis membranes—agar and calcium alginate gel are the most suitable for fermentation (110).
- The retention power of the immobilizing matrix is inversely linked to the fermentative capacity of the yeast and to the alginate/yeast ratio (112).
- The presence of structural constituents of alginate (uronic acids) in the wine may be ignored up to bead content equal to 14 g/bottle (106).
- The phosphate and tartaric, malic, and citric acids present in wine do not have a disintegrating effect on the structure of the alginate (106).
- The enrichment of cells that proliferate in nucleic acids, reserve polysaccharides (trehalose and glycogen), and structural polysaccharides (mannan and glucan) is not reflected in a variation in the content of the wine (106).

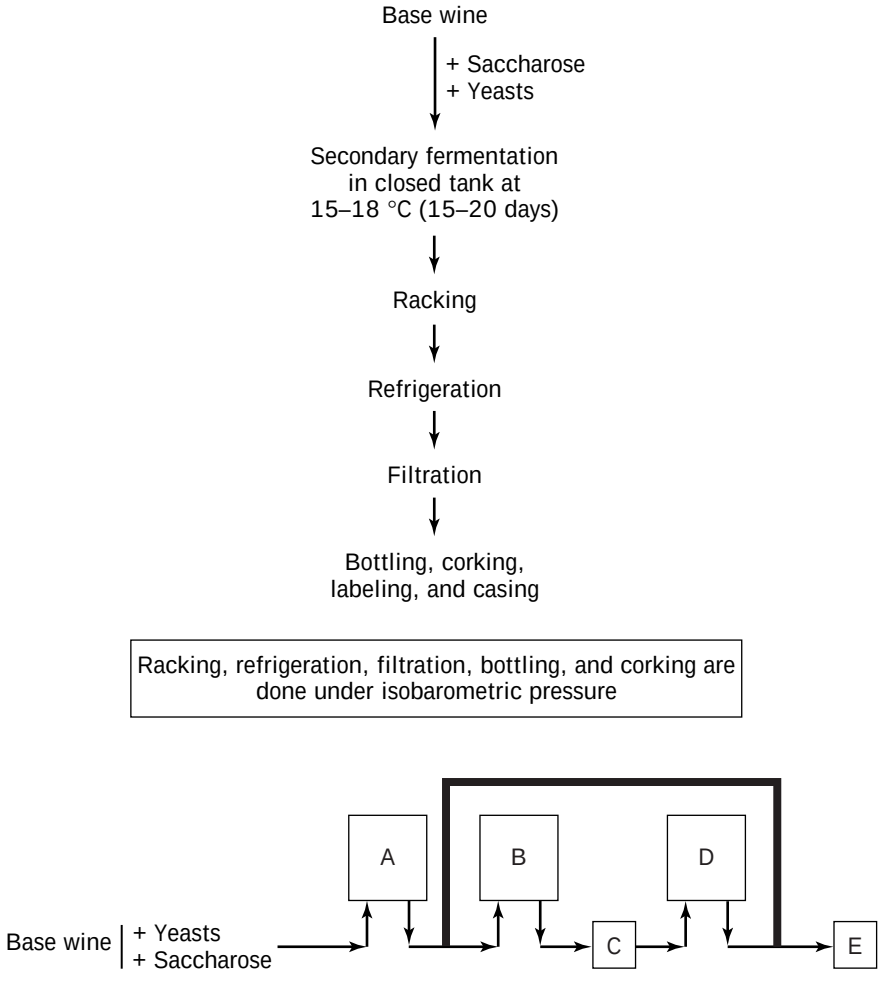

Figure 8. Scheme of a process for sparkling wine preparation by the close tank or Charmat methods. A, closed tank for secondary fermentation; B, tank for refrigeration; C, fieter; D, tank for ready to be bottled; E, isobarometric bottling.

- When the concentrations of alginate and cells in beads are equal, then the smaller the inoculum at draught, the greater the cellular release; however, this release can be avoided by using nonproliferating yeasts (106).

As for the evaluation of the influence of the alginate immobilization technique on the fermentative process, the composition, and the organoleptic characteristics of the bottled sparkling wine, Fumi et al. (114) observed that the use of immobilized cells does not cause any significant change in the second fermentation process. The main components (ethanol, organic acids, total nitrogen, and higher alcohols) are not appreciably different in sparkling wines obtained by immobilized yeast when compared with traditional sparkling wines (Table 5), but some differences are found as regards certain amino acids and some aroma components (Table 6). As shown by tasting, however, these differences do not affect the organoleptic characteristics. Sensory evaluation of sparkling wines obtained with immobilized yeasts versus a control was performed using a duo-trio test and black glasses.

Divies (116) and Duteurtre (108) conducted comparative tests with free and calcium alginate immobilized yeasts for bottled sparkling wine production, and they also noted that there are no variations in the principal chemical or physical characteristics.

Experiments to avoid cell release were performed by coating alginate/yeast beads with a protective cell-free alginate gel layer. These studies were carried out by Duteurtre (108), Fumi et al., (106), and Loureiro (110) for bottled sparkling wine production. A complete bottle fermentation was achieved without cell release, independent of the different conditions adopted—concentration of the alginate, time of gelification, and $CaCl_2$ concentration. However, Ors et al. (117) noted that the double layer must have a minimum critical thickness, equal to 0.2 mm, in order to avoid cellular release.

In an assay where agar cylinders covered with a protective layer of agar without cells were used, equally satisfactory results were not achieved (110).

Although the problem of cell release from the immobilization matrix during fermentation may be solved, there

are other difficulties to overcome for the industrial application of calcium alginate immobilization. The possibility of supplying wineries with ready-to-use immobilized cells would be a significant step for the implementation of this technique. For this, Loureiro (110) has performed freeze-drying experiments of cells immobilized by gel occlusion. These tests with different polysaccharide gels showed that it was possible to freeze-dry without changing bead shape using either κ-carrageenan or κ-carrageenan plus calcium alginate. However, cell release always occurred, and further studies will be necessary to optimize the thickness and rigidity of the protective bead layer for controlling cell release.

Lemmonier and Duteurtre (109) developed a device consisting of a small cartridge containing two microporous membranes, one hydrophilic and the other hydrophobic, which is filled with yeast and placed in the neck of the bottle. The two membranes hold the yeasts captive, enabling a free and total exchange between the yeasts and the wine. When the cap is opened, the cartridge is automatically ejected. The first results showed that production of sparkling wine with immobilized yeasts occurs in a manner similar to that using traditional methods with free cells. Some differences have been noted regarding protein and polysaccharides (118).

The use of a continuous fermentative system with a calcium alginate immobilized yeast bioreactor was tested by Fumi et al. (115) for the production of sparkling wines in tanks. The experimental system is shown in Figure 9. The general idea was to run the second fermentation outside the principal stainless steel tank using equipment that could easily be moved from one tank to another. The tests were carried out by placing 2 L of 1.5% alginate and 8% yeast beads (yeast inoculum was 250 g dry weight) or 3 L of 1.5% alginate and 10% yeast (yeast inoculum was 500 g dry weight) distributed or not on five distanced supports of pierced stainless steel, in a 10-L bioreactor. The base wine (9.95% v/v ethanol, 5.61 g/L titratable acidity, pH 3.04) was continuously supplied at a rate of 5 L/h and sucrose syrup at 0.14 L/h. The results showed that a high concentration of immobilized yeasts and a distribution of immobilized yeast mass in the bioreactor greatly affect the fermentation rate, making the process faster than the traditional one (78 h, as compared to 10 to 15 days needed for the traditional process). The sparkling wines have a composition (Table 7) comparable to that of traditional sparkling wines, and sensory evaluation (expert panel of eight tasters) of immobilized test versus control did not show significant differences at a level of $p < 0.05$.

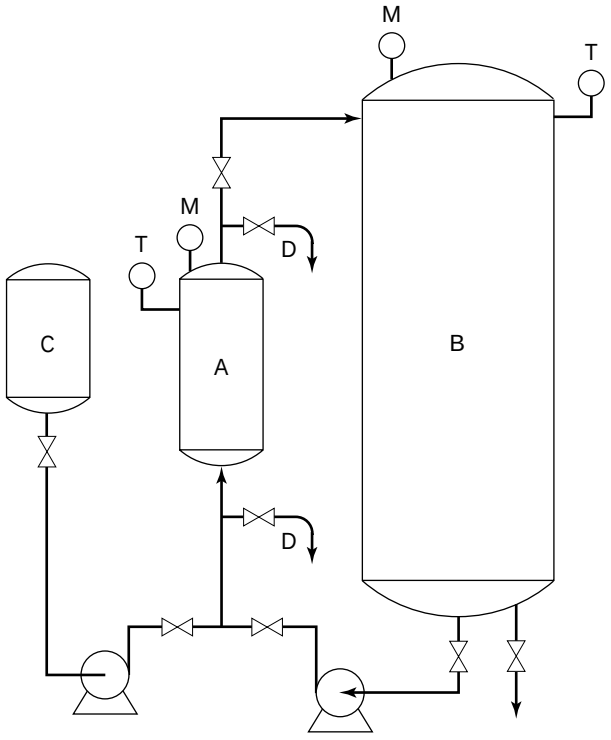

Figure 9. Scheme of the system used in the production of sparkling wine in tanks with immobilized yeast (117); A, bioreactor with immobilized yeast; B, sealed tank; C, syrup tank; D, sampling taps; M, manometers; T, thermometers.

The influence of cell-recycle batch fermentation process on sparkling wines produced in pressure tanks was studied by Ciani et al. (119). They noted a reduction in the time of fermentation as well as an improvement in ethanol productivity and yield. This was linked to the increased inoculum and also to the disappearance of the lag phase, which lasted approximately 150 h in batch. The increase in ethanol yield is probably correlated with a resting cell state highlighted by a lower percentage of new cells produced in steady-state conditions (120). The analytical characteristics of the sparkling wine obtained were not significantly different from those of sparkling wine produced by traditional batch fermentation.

As far as the fermentative process of must is concerned, Cantarelli (50) conducted comparative tests with free and calcium alginate immobilized yeasts. A fluidized or

packed-bed reactor consisting of a 200-L tubular fermenter with immobilized yeast beads at various concentrations (maximum 8 g/L) was used for wine production. The results showed that immobilized yeast, compared with free yeast, had almost linear fermentation kinetics without a lag or exponential phase. In addition, organoleptic and chemiometric evaluation of analytical data both showed that there were no significant differences in by-products. Therefore, the final by-product content of wine produced by a fluid-bed fermenter was lower than by a packed one.

Batch fermentation tests on Riesling grape juice were carried out by Fumi et al. (113) using two 50-L working volume fermenters with calcium alginate immobilized biocatalysts (beads with alginate/yeast ratio of 1.5 wt/dry wt, reintroduced into 1% alginate and supported by stainless steel pierced plates vertically disposed) with surface area to volume ratios 1.33 and 0.66, respectively. The immobilized-system kinetic parameters had similar values, and they were not influenced by the different surface area to volume ratios of the biocatalysts. Analytical data showed no detectable differences between the wines obtained by the immobilized system and wines produced traditionally. During the first phases of fermentation with immobilized cells, the must was kept perfectly clean in both bioreactors. Nevertheless, at the end of the fermentation process, a free-cell deposit, caused by yeast leakage from the beads, was found in the bioreactors.

Selected Lactic Acid Bacteria and Innovation in Malolactic Fermentation

Malolactic fermentation is an important factor for many red wines or at least for those high acid wines produced from grapes grown in cool climate (121,122).

This process is effected by a strain of lactic bacteria of the genera *Leuconostoc*, *Lactobacillus*, and *Pediococcus* (67,122,123) and essentially consists of the degradation of malic acid into lactic acid and carbon dioxide, the consequence of which is a reduction in total acidity (deacidification). In addition, the transformation of malic acid is always accompanied by the fermentation of sugars, which although on a modest scale has the result of increasing aroma components such as acetaldehyde, acetic acid, acetoin, diacetyl, 2,3-butandiol, ethyl lactate, and high alcohols (67,68,122). As a whole, the wine gains in mellowness, roundness, and fullness and becomes more pleasing to the palate (68,123).

The difficulties that hinder growth of lactic bacteria in wine have causes known only in part (pH, ethanol concentration, SO_2 concentration, fermentation temperature, competition between lactic bacteria and other microorganisms, lack of nutrients). Thus, spontaneous biological deacidification of wines is not always possible. To help in the deacidification of wines, it is a common practice to make use of an inoculum of active indigenous bacteria effected through the addition of wines where malolactic fermentation is in process or has just finished. However, this system does not always give good results and is unsuitable for those wines that must maintain their peculiar characteristics unaltered (122).

For quite some time, attempts have been made to induce malolactic fermentation by inoculating the wine with selected lactic acid bacteria (121). For this purpose, lactic bacteria have been isolated from musts and wines and have been selected for their tolerance of ethanol (13 to 14 vol.%) and sulphur dioxide, their capacity to develop in the pH of wine, their capacity to produce small quantities of acetic acid, and their capacity to not alter organoleptic characteristics (121,124,125). Dried or frozen cultures of selected bacteria suitable for malolactic fermentation have been on the market for some years. Research carried out thus far on the efficacy of these preparations has shown that malic acid is broken down completely if the strain is previously reactivated in suitable substrata (67,126–130). Lonvaud-Funel (128) observed that complete breakdown of malic acid is achieved by using an inoculum containing up to 10^7 cells/mL that has been allowed to develop previously for 24 h in either a synthetic substrate (40 g/L glucose, 3 g/L malic acid, 5 g/L of neopeptone, 50 mg/L of Mg^{2+}, 20 mg/L of Mn^{2+}, 50 g/L of yeast extract, pH 4.5) or in a grape juice base substrate.

Some investigators (131–136) have suggested the use of immobilized lactic bacteria or enzymes to convert malic acid into lactic acid.

Spettoli et al. (136) immobilized *Leuconostoc oenos* ML34 in 1.67% calcium alginate gels and tested their ability to convert L-malic acid into L-lactic in a red wine having 10.20% v/v alcohol; 7.90 g/L of titratable acidity; pH 3.15; 21 mg/L of total SO_2, and 1.50 g/L of L-malic acid. The cells, in batch reaction, maintained 56% conversion of L-malic acid after 16 h.

Cuenat and Villettaz (132) immobilized a strain of *Leuconostoc oenos* on alginate (1 vol of 15% dry weight cells in 5 to 12 vol of alginate, 5% (w/v)). A complete degradation of malic acid (from 6.1 to 0.07 g/L) was obtained in a continuous system where 25 L of wines (pH 3.3; 11.3% (v/v) ethanol, 139 mg/L total SO_2) was passed through the columns in 5.5 h.

Naouri et al. (134) compared the malic-acid-degrading ability of a strain of *Leuconostoc oenos* with that of a strain of *Lactobacillus* sp. immobilized in alginate in a high compacting multiphase reactor (HCMR) containing 170 g of alginate beads and 1.41 L of red wines. After bioconversion in the reactor, malic acid was almost completely (82%) degraded by the immobilized *Leuconostoc* strain, whereas incomplete (45%) degradation was obtained with the *Lactobacillus* strain.

Crapisi et al. (131) reported on the efficiency of a continuous-flow bioreactor filled with *Lactobacillus brevis* immobilized on four types of alginate and κ-carrageenan for the control of malolactic fermentation in wine. Bioreactor efficiency seems to be dependent on gel properties ranging from 34 to 45%, depending on the immobilization matrix used.

Attempts to deacidify wine using malolactic enzyme immobilized on gels have not been successful (137) probably because of the inactivity of the enzyme at wine pH and because the required cofactor, NAD, is particularly unstable in wine.

CONCLUSION

Factors limiting the application of standardized biotechnological processes to wine production include the following:

- The seasonality and high variability in grape composition
- The limited annual season of vintage
- The length of the winemaking process for some wines, which delays experimental results
- The variations in the amount of wine production (ranging from a few hundred hectolitres to more than 200.000)

In fact, under the generic term wine there is a diversity and hierarchy of quality that is quite unique among the products of the soil and that is connected to the cultivar, the area of cultivation, and the transformation technologies applied to the grapes. The latter includes the transformation of the must by yeast fermentation, which is certainly the oldest of biotechnologies. The principles of winemaking have been established empirically over the course of several centuries of rigorous and methodical observation. The production of quality wines came before all scientific knowledge.

However, although its origins were empirical, the production of quality wine has, in the last quarter of a century, benefited most from research developments. In this area, biotechnological knowledge may well become more and more important, not only as regards the microorganisms involved in the fermentation process but also because of the use of enzymes in pressing grapes, prefermentation treatments, and refinement of the wines.

Since the development of the use of pectolytic enzymes, the tendency has been to search for enzymic preparations that have precise effects and that allow us to reduce the use of chemical additives. In this field, studies have made it possible to show that there are numerous limitations to the use of enzymes in the field of enology. For example, experiments with enzymes to improve the stabilization of white wines and to increase the aroma of some wines have demonstrated that the composition of the medium and the working conditions are not very favorable to the action of enzymes such as proteases and glycosidases. At present, the use of extracellular yeast enzymes, such as proteases, able to act on the constituents of the must are being studied (138,139). This is obviously of technological interest, because it would make it possible to take advantage of the enzyme activity of the yeast, not only for fermentation but also for stabilization of wines. In addition, the energy liberated during the fermentation process would give temperatures better suited to the activity of the enzymes.

These days a selected yeast is required not only to ensure that undesirable characteristics do not arise but also in order to have a positive effect on the characteristics of the wine. Methods of genetic improvement offer a means of programming and constructing new strains of yeasts. However, certain problems remain when one attempts genetic improvement of the strains, not the last among which is the lack of objective methods of evaluation of the quality of the yeast. The contribution of yeast to the quality of wine is complex because it is the result of interactions between grapes, yeast strains, and technology. In spite of this, the application of recombinant DNA technologies to the improvement of wine strains has undergone rapid development, and although practical applications have not yet been achieved, the basis for future advances has been established.

In the field of bottled sparkling wine production, studies have led to the creation of technologies that permit the use of alginate-immobilized yeasts at a semi-industrial level (108). However, the technology of entrapped yeast for must fermentation requires further optimization of immobilized systems, in the areas of mass transfer, reactor design, and yeast physiology. The most logical strategy for providing the means of increasing productivity without changing the flavor characteristics of fermented products must be found.

Reactors with immobilized lactic acid bacteria have also been shown to be potentially very interesting, but putting them into operation on an industrial scale still requires critical evaluation, not only of the efficiency of the breakdown of malic acid but also of the results on the organoleptic characteristics of the wines.

Every biotechnological advance that is to be accepted in winemaking must allow one to maintain the quality of the product, must take into account the hygienic and legal aspects as well, and must not impair the flavor and bouquet of the final product.

OUTLINE

INTRODUCTION

A variety of polysaccharides are generated by microorganisms. Examples include alginate, curdlane, dextran, gellan, glucan, pullulan, and xanthan. Also cellulose can be produced by microbes. Among the microbial polysaccharides, xanthan plays a dominant role due to the relative easiness to produce it and as a result of its outstanding properties. Indeed, it has found widespread applications ranging from food and cosmetics additives to enhanced oil recovery. This polymer represents the fastest growing segment of the polysaccharide industry (Table 1). The largest growth is expected to be in food applications (8.3%/year), where demand for natural gums is decreasing. Xanthan gum is an exoheteropolysaccharide produced by the bacterium *Xanthomonas campestris*.

Structure and Properties

The xanthan polymer consists of repeated units of five sugars, namely, two D-glucose, two D-mannose, and one D-glucoronate, and varying amounts of acetate and pyruvate. Its primary structure is shown in Figure 1, based on the results of Jannson et al. (5) and Melton et al. (6), revised according to Hassler and Doherty (7), and confirmed by McIntyre et al. (8).

The polysaccharide backbone, made up of β-[1–4]-linked D-glucose units, is identical to that of cellulose. To alternate D-glucose units at the O-3 position, a trisaccharide side chain containing a D-glucoronosyl unit between two D-mannosyl units is attached. The terminal β-D-mannosyl unit is glycosidically linked to the O-4 position of the β-D-glucoronosyl unit, which in turn is glycosidically linked to the O-2 position of an α-D-mannosyl unit. The terminal D-mannosyl unit of the side chain contains a pyruvic acid moiety as a 4,6-cyclic acetal in variable degree. Finally, the nonterminal D-mannosyl unit is stoichiometrically substituted at O-6 with an acetyl group. Xanthan gum also contains monovalent cations, which can be Na, K, or ½ Ca.

The secondary structure is known to undergo an order–disorder conformational transition at particular salinity

Table 1. Annual Average Growth Rates of the Main Commercial Polysaccharides: Market Analysis and Forecast for the United States

	Annual average growth rate (%)		
Polysaccharide	Food	Petroleum	Cosmetics and toiletries
Starches	2.5	1.5	–
Natural gums			
Guar	2.1	–	–
Algins	2.7	–	3.7
Arabic	2.6	–	3.7
Carrageenan	4.5	–	3.7
Locust bean	1.9	–	3.1
Cellulosics			
CMC	3.5	0.5	3.0
HPG	–	1.5	–
HEC	–	0.5	–
MC	3.5	–	3.7
Xanthan	8.3	2.0	5.9
Pectin	5.2	–	–

Note: CMC, carboxymethylcellulose; HPG, hydroxypropyl guar; HEC, hydroxyethylcellulose; MC, methylcellulose.

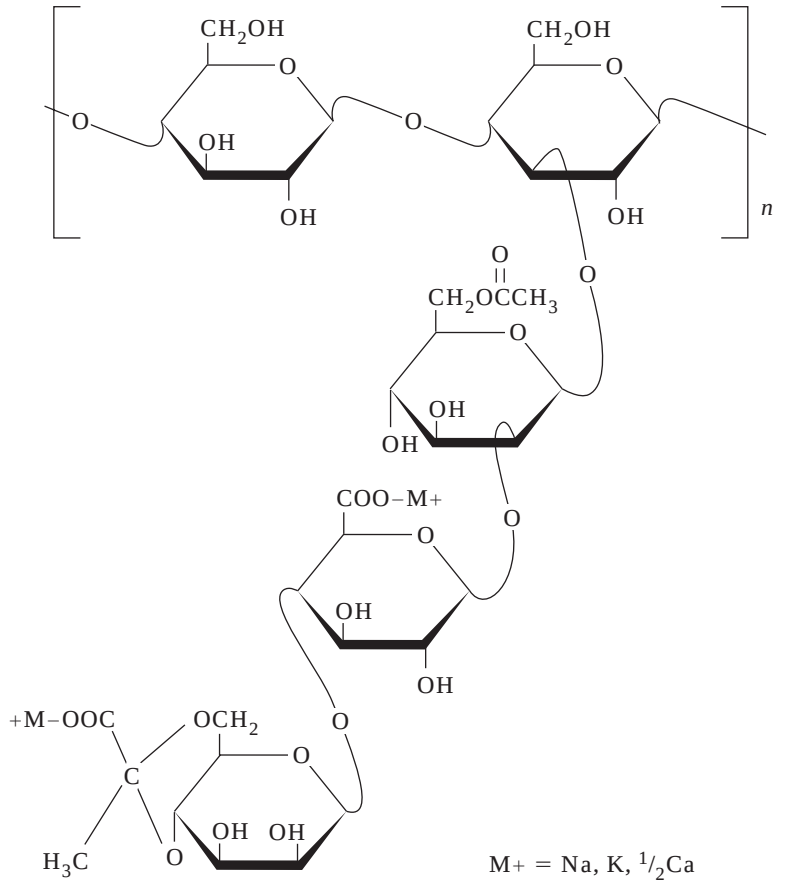

Figure 1. Chemical structure of the xanthan repeating unit.

and temperature levels, depending on the extent of pyruvate substitution (9,10). Most authors explain the stabilization of the ordered form by a noncovalent packing of the side chains along the backbone by H-bonding. X-ray fiber studies have indicated that the polymer adopts a right-handed helical conformation with fivefold symmetry and a helix pitch of 4.7 nm^3 (11). However, the question of whether this polymer dissolves in water as a single (11,12) or a double strand (13,14) has been a matter of controversial discussion. It now seems to be anticipated that xanthan may effectively be a single or a double strand, depending on the fermentation process, the acyl content, the thermal history, and the downstream process (12,15,16).

The most important property of xanthan is its ability to form solutions of high viscosity at rest or at low shear forces, which are highly pseudoplastic, and may display also a viscosity yield value. The viscosity of xanthan solutions is stable over a wide range of salt concentrations (up to 150 g/L NaCl), temperature (up to 90 °C) and pH (2–11). These solution characteristics of xanthan give rise to the functional properties such as thickening and stabilizing ability, which are used in a diverse range of applications. In addition, xanthan shows a synergistic interaction with various galactomannans (17,18), chitosan (19), and β-lactoglobulin (20), which results in enhanced solution viscosity or formation of gels, depending upon the type of mixture.

The rheological behavior of xanthan solution is most conveniently described by the two-parameter model of Ostwald and de Waele (power law)

$$\tau = k\dot{\gamma}^n \tag{1}$$

where τ is the shear stress and $\dot{\gamma}$ the shear rate. From equation 1, the effective viscosity, μ_{eff}, follows as

$$\mu_{\text{eff}} = k\dot{\gamma}^{n-1} \tag{2}$$

The fluid consistency factor, k, and the flow behavior index, n ($\leq$1 in case of the pseudoplastic xanthan solutions), are dependent on xanthan concentration and quality. Xanthan quality is predominantly determined by its molecular mass, but the pyruvate content has also a significant effect, though the influence of the pyruvate content on the viscosity yield is not yet clearly recognized. Flores-Candia (21) observed a sharp increase in viscosity (about a hundredfold) when the pyruvate content increased above ca. 3% wt. This is in accordance with Cadmus et al. (22) who stated that many industrial applications require a xanthan with a pyruvate content above 3.3% wt. The effect of xanthan molecular mass (pyruvate content $\geq$3.5 wt) on viscosity was studied by Herbst et al. (23) and Peters et al. (24). Figure 2 demonstrates the strong dependency of the vis-

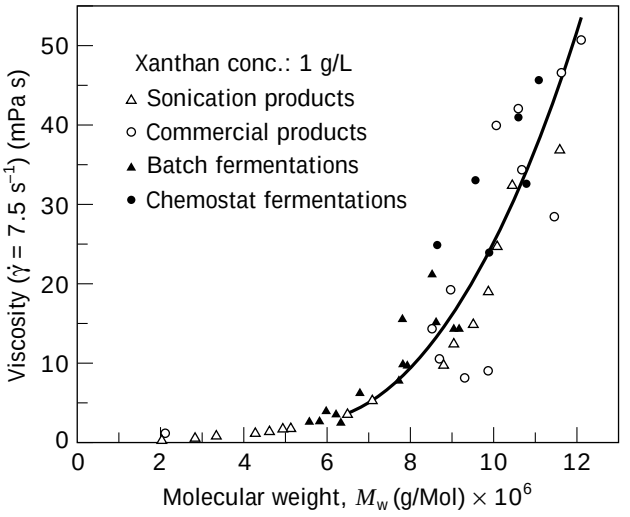

Figure 2. Effect of average molar mass on solution viscosity at a shear rate of 7.5 s^{-1} and a xanthan concentration of 0.1 % wt. *Source*: From Ref. 23.

cosity on the molecular mass of xanthan products of different origin.

Peters et al. (24) developed the following correlations for predicting the rheological parameters of equation 1 from the molar mass, M, (kg $kmol^{-1}$) and polymer concentration, c_p (kg m^{-3})

$$k = 10^{-3} + 2.58 \cdot 10^{-6}\left(\frac{M}{10^6}\right)^{3.69} c_p^{2.72} \quad (3)$$

$$\frac{1 - n}{n - 0.071} = 0.0227\left(\frac{M}{10^6}\right)^{2.08} (k - 10^{-3})^{0.47} \quad (4)$$

The thickening ability is related to the viscosity of a gum solution and can be defined as the resistance to flow of a liquid. Because of its high solution viscosity at low concentration and shear thinning behavior, xanthan is a particularly useful thickener. Xanthan is also used for the stabilization of suspensions, emulsions, and foams. This functional property is enhanced by a high solution viscosity and the existence of a viscosity yield value. Thus, if the suspended particles exert a force less than the yield value, they will be dispersed effectively (25). Again, the shear thinning behavior of xanthan is important because some stabilized products require a low viscosity during their application. Although xanthan does not possess the functional property of gelation, it will form thermoreversible gels with certain galactomannans. Gelation arises from intermolecular associations to form a three-dimensional continuous network that traps and immobilizes the water within it to form a rigid structure that shows resistance to flow under pressure.

BIOSYNTHESIS

Xanthan is produced by the bacterium *Xanthomonas campestris*, isolated originally from cabbage in which it causes black rot disease (26). *Xanthomonas* species are Gram-negative bacteria taxonomically placed in the Pseudomonadaceae family (27). According to the genetic basis of the classification, the average genome size of *Xanthomonas* is 2.5×10^9 Da. The percent G + C (guanine + cytosine) content of the DNA ranges from 63 to 71% (28). The cells have a rodlike form, slightly curved with rounded ends, measuring 0.2–0.6 by 0.8–2.9 μm. They occur mostly alone or in pairs, but chains and filaments are also observed. *X. campestris* forms smooth yellow mucoid colonies on solid media, and cells are surrounded by xanthan gum (extracellular polysaccharide). The chemical structure of the yellow pigment was determined to be mono- or dibromoaryl polyene and is probably bound to the cellular membrane. Genetic instabilities that affect quality and yield of xanthan have been observed in *Xanthomonas* cultivation (29). Genetic mutations are associated with the formation of L (large) and S (small) colony types. Whereas L-type colonies produce high xanthan yields with the desired rheological characteristics, the S-type colonies give low product yields with poor quality.

The natural function of xanthan is not fully recognized, but there is strong evidence indicating that the polysaccharide layer, surrounding the microbial cell, protects the microorganisms from various environmental factors. The water-retaining capacity of xanthan, for example, provides the microorganism with a protective layer under dry environmental conditions, thus providing some degree of desiccation resistance (30). Furthermore, recent reports of xanthan yield improvements in the presence of detergents (31) and bacterial-toxic acids (32) reveal that xanthan biosynthesis is induced under stress conditions.

In *X. campestris*, the Entner–Doudoroff pathway in conjunction with the tricarboxylic acid cycle pathway is the predominant mechanism for glucose catabolism (28,33,34). A small portion of glucose is routed via the pentose phosphate pathway (28,35). For glucose uptake, two discrete systems seem to exist (35). The biosynthesis of xanthan, as in most polysaccharide-producing bacteria, utilizes various activated carbohydrate donors to form the polymer on an acceptor molecule. The oligosaccharide repeated units of xanthan are constructed by the sequential addition of monosaccharides from sugar nucleotide diphosphates to an isoprenoid lipid acceptor molecule.

At the same time, acyl substitutes are added from appropriate activated donors. As shown in Figure 3, the xanthan backbone is formed by the successive addition of D-glucose-1-phosphate and D-glucose from two moles of UDP-D-glucose. Thereafter, D-mannose and D-glucoronic acid are added from GDP-mannose and UDP-glucoronic acid, respectively. O-Acetyl groups are transferred from acetyl-CoA to the internal mannose residue, and pyruvate from phosphoenolpyruvate is added to the terminal mannose. This pattern of reactions was elegantly demonstrated by Ielpi and his colleagues (36,37) using permeabilized cells and radioactively labeled precursors. Further, it was also shown that each of these steps, as just described, requires specific substrates and a specific enzyme for completion. If either the substrate or the enzyme is absent, the step is blocked (39–41).

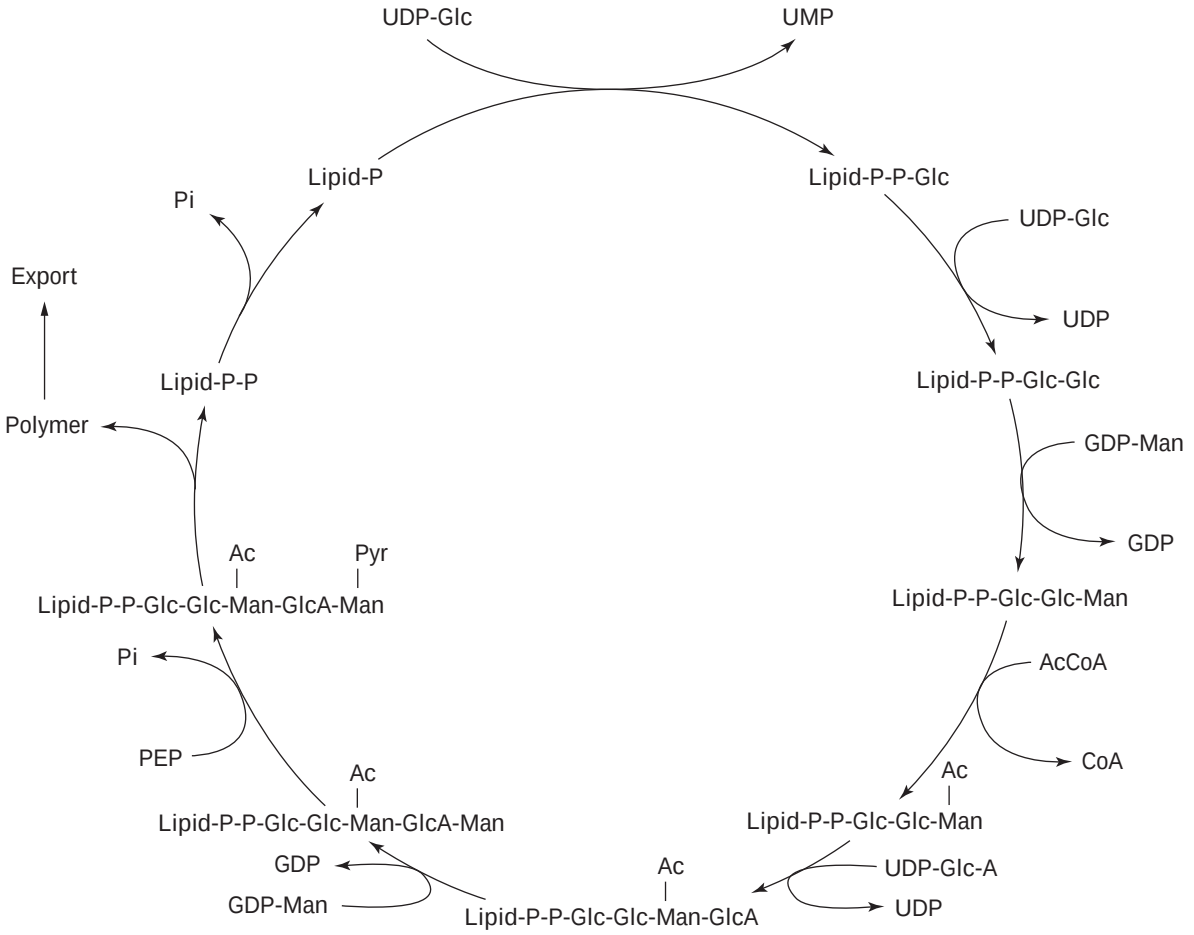

Figure 3. Biosynthesis of xanthan gum from activated precursors of carbohydrates and acyl groups. *Source*: From Refs. 36–38.

It has been suggested that the construction of the exopolysaccharide follows a "tail-to-head" polymerization (36–38,41). After the pentasaccharide repeated unit is formed, oligomers are formed by transfer to other lipid intermediates, gradually increasing the size of the carbohydrate chain. As noticed by Sutherland (38), oligomer construction normally involves the addition of the longer oligosaccharide sequence to the nonreducing terminus of a single repeat unit attached to the isoprenoid lipid diphosphate. The inactive lipid carrier is dephosphorylated to yield isoprenyl phosphate, which can then reenter the biosynthetic sequence.

Although the structure of the repeating units is determined by the sequential transfer of the different monosaccharides and acyl groups from their respective donors by highly specific sugar transferases, the polymerase enzyme responsible for polymerization of the pentasaccharides into a macromolecule of $M > 10^6$ has been shown to be less specific (38). The final stages of exopolysaccharide secretion from the cytoplasmic membrane, passing across the periplasm and outer membrane and finally excreted into the extracellular environment, are much less well specified than the previous biosynthetic events. This mechanism must exist in all polysaccharide-producing bacteria for releasing polymer from the isoprenoid lipid prior to transport to its final destination. The process obviously requires an energy source and may be analogous to the export of lipopolysaccharide to the outer membrane (42), in which ATP is the energy supplier.

Significant advances have been made in genetic research on *X. campestris*. Using transposon mutagenesis, Harding et al. (43) found a cluster of linked genes that encode enzymes for the assembly of the pentasaccharide. This same cluster was also isolated and analyzed by Thorne et al. (44). Vanderslice et al. (45) sequenced the DNA in this region and showed that it contains 12 genes (Fig. 4), which included seven gene products needed for monosaccharide transfer and for acylated repeating units. The genes responsible for xanthan acylation were further corroborated by Marzocca et al. (46). In addition, a recent analysis of the transcriptional organization of the gene cluster indicated that the gum region was mainly expressed as an operon from a promoter located upstream of the first gene, *gumB* (47). Another important contribution to the genetics of *Xanthomonas* is the identification of *xanA* and *xanB* genes (48). These genes were reported to be involved in UDP-glucose and GDP-mannose biosynthesis. Recently, it was also demonstrated that the gene encoding

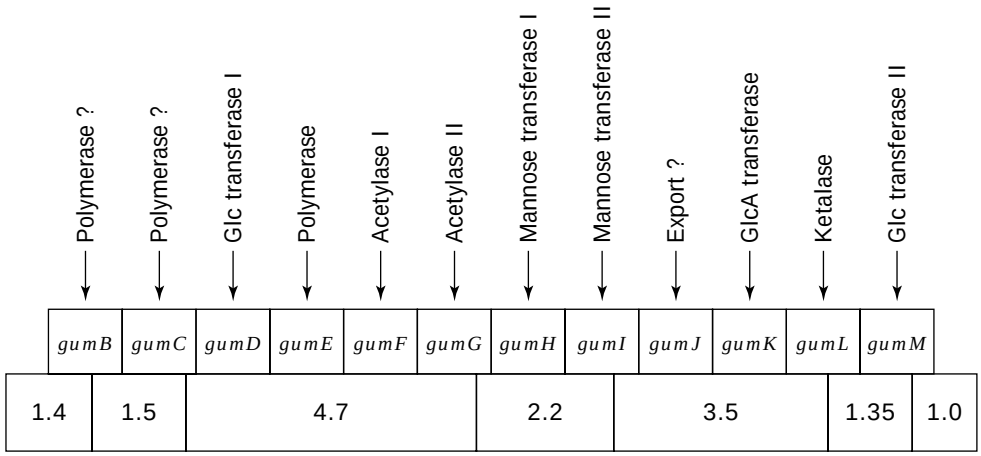

Figure 4. Genetic map of the genome segment of *X. campestris* involved in xanthan production. The *Bam*HI restriction map (bottom) indicates the order and the approximate size in kilobases (kb) of the fragments that comprise the xanthan gene cluster. This cluster has a total DNA length of 16 kb. The genetic map (center) indicates the 12 separate xanthan genes, designated *gumB* to *gumM*. The biochemical functions (top) indicate the enzymatic activity identified for each gene; (?) refers to possible involvement with polymerization or export as indicated; Glc, glucose, GlcA, glucoronic acid. *Source*: Adapted from Vanderslice et al. (45) and Sutherland (38).

UDP-glucose pyrophosphorylase is essential for xanthan synthesis (49). In fact, over 20 relevant genes seem to be identified by genetic analysis and DNA sequencing (50).

BIOPROCESS TECHNOLOGY

Raw Materials

The most efficient xanthan gum producer is *X. campestris*, however other species such as *Xanthomonas phaseolis, Xanthomonas malvacearum, Xanthomonas carotae, Xanthomonas manihotis, and Xanthomonas jugandlis* are known to be able to produce the exopolysaccharide as well. The nutritional versatility of *X. campestris* allows the use of industrial, complex, and synthetic media formulations. In industrial processes, commercial-grade glucose or hydrolized starch is used as the carbon substrate. Sucrose and acid whey are also used. Glucose concentrations up to 5% have been found to give the best product yield; at higher glucose concentrations, xanthan yields decrease. In fact, the maximum level of glucose is limited by the rheology of the fermentation broth. Nitrogen sources, such as corn steep liquor, casein hydrolysates, distiller's dried solubles, yeast, and soybean extracts, can be used, but because of their relatively undefined and variable composition they have been replaced by ammonium salts. Xanthan can indeed be produced in good yield when *X. campestris* is grown in a simple synthetic medium composed of ammonium chloride, glucose, and salts (51). The benefits of using synthetic media are twofold: control of genetic instabilities and improvement of product quality (52). Although the structure of xanthan synthesis is essentially independent of media formulation, there are some differences in acyl substituents and the rheological properties of the polysaccharide, as well as in the product yields (21).

Basic Structure of the Production Process

The design of a xanthan production process depends on the economic requirements to achieve optimum performance with regard to productivity, product concentration, and yield and, at the same time, to fulfill the desired product quality and application specifications. However, this is not a straightforward task because, during the production process, viscosity increases drastically. Therefore, product concentration are usually low and product quality also varies. A compromise between the commercial targets and the limitations inherent to the process must be reached at the industrial level by establishing the relationships between the bacteria's performance, environmental conditions, and equipment design and operation.

Xanthan is produced commercially in a conventional batch process using mechanically agitated vessels (Fig. 5) and a culture of *X. campestris* in a suitable fermentation medium. It is an aerobic process that runs for about 100 h under the following operating conditions: 28–30 °C, pH ~ 7, aeration rate higher than 0.3 vvm, and specific power input for agitation higher than 1 kW/m^3. A product yield approaching 50% is typical in the standard process. The inoculum preparation includes several stages requiring different set of reactors ranging from 10 L for the initial seed culture up to 100 m^3 for production purposes, the need volume being usually enlarged by a factor of 10.

Typical profiles of batch culture of *X. campestris* using synthetic media similar to that used by Davison (53) and the operating conditions mentioned above are shown in Figure 6. The data are plotted as the time courses for cell dried mass (CDM), xanthan, glucose, the rheological parameters k (consistency factor) and n (flow index), the oxygen transfer rate (OTR), and the oxygen partial pressure (pO_2). As the fermentation evolves, cells grow exponentially, resulting in a rapid consumption of the nitrogen

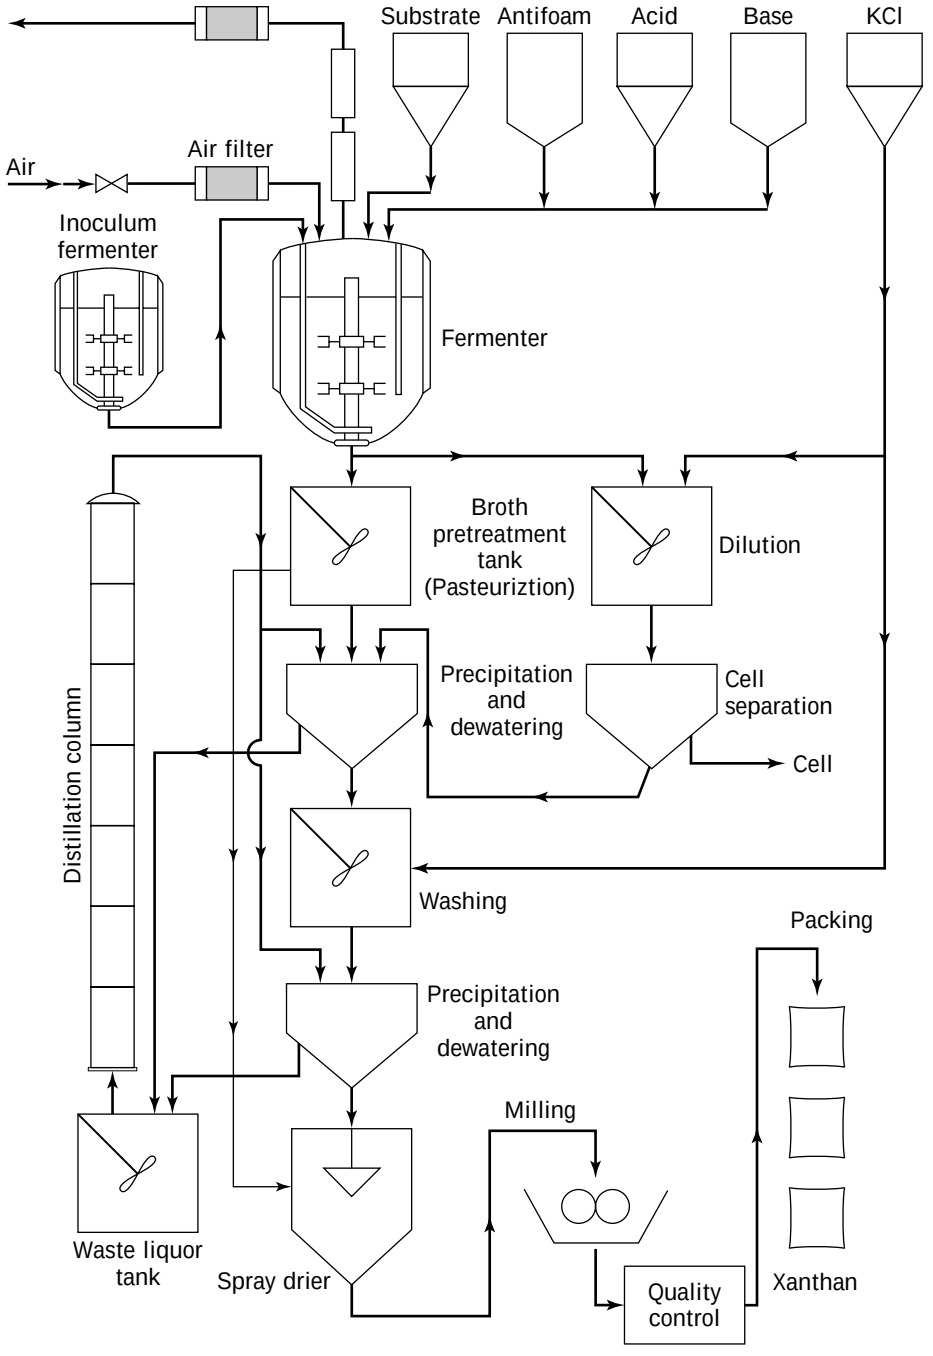

Figure 5. Flowsheet for production of xanthan.

source (not shown). Under N-limitation, cells enter the stationary phase. Xanthan is synthetized in both the growth and the stationary phases, reaching a final concentration of about 20 g L^{-1}. Xanthan biosynthesis ceases as glucose is completely consumed. The consistency factor (k) as a parameter of the rheological properties of xanthan increases from ~15 mPa sn to 30,000 mPa sn. The pO_2 dropped over the initial periods to a minimum value corresponding in time to peak oxygen uptakes rates during the growth phase. Thereafter, both OTR and pO_2 decrease continuously toward the end of the fermentation, reflecting the effect of increasing broth viscosity on the oxygen transfer rate.

After the fermentation stage, xanthan is recovered through a multistep downstream process (Fig. 5). The characteristics of this process are defined by the end product application and the difficulty of removing bacterial cells from viscous culture broths. As pointed out by Smith and Pace (54), the objectives of the recovering process are (*1*) concentration of the fermentation broth to a solid form, which has to be microbiologically stable and easy to handle, transport, and store; (*2*) purification to reduce the degree of nonpolymer solids, such as cells and/or salts, in order to improve the functional performance (odor, color, and taste) of the product; (*3*) deactivation of undesirable contaminating enzymes, such as pectinases and cellulases;

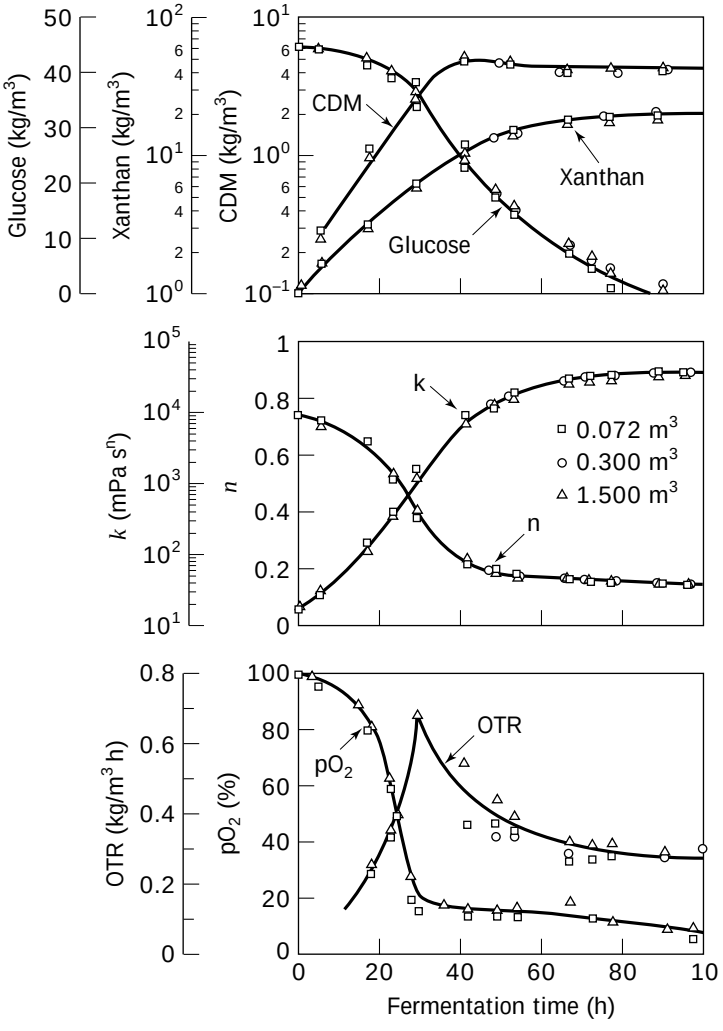

Figure 6. Time profiles of xanthan fermentation in reactors of 72 L, 0.3, and 1.5 m^3 applying the same power input (3.3 kW/m^3) and gas flow rate (7.2 mm s^{-1}). *Source*: Adapted from Herbst et al. (23).

and (*4*) modification of the chemical properties of the product to alter either the application performance or the dispersion and solution rate characteristics of the polymer.

When industrial grade Xanthan is required, the postfermentation process starts with the pasteurization of the fermentation broth to kill the bacterial cells (Fig. 5). Because *Xanthomonas* are sensitive to temperature and are nonspore formers, complete pasteurization can be readily accomplished. However, caution has to be taken with the temperature of the transition midpoint (T_m) for xanthan in order to avoid thermal degradation of the polymer. The T_m for xanthan is about 100 °C but varies with the total ionic strength and the ratio of the contents of pyruvate and acetate groups (55–57). For xanthan applications where maximum cell removal is required (such as in the food, pharmaceutical, and cosmetics industries), cell separation by centrifugation is facilitated by dilution of the fermentation broth to reduce viscosity. Alternatively, the bacterial cells can also be subjected to chemical or enzymatic digestion (58,59); however, the resultant product may contain cell fragments, and solutions are optically not clear. Such a product may be restricted to applications in the petroleum industry.

After the prerecovery treatment just mentioned, the isolation of xanthan is accomplished by lowering its solubility in order to obtain either a precipitate or a polymer-concentrated phase by either the addition of lower alcohols, or salt or acid, respectively. The more favored method is the addition of ethanol or isopropanol. The added alcohol is subsequently recovered from the spent liquor by distillation (Fig. 5). The addition of salts improves the precipitation by creating a charge reversal effect in which all the available anionic groups are bound with cations of the added salt. The addition of KCl to assist precipitation reduces, for example, the amount of isopropanol required by about 30% (60). Consequently, increasing both the product concentration and the ionic strength prior to precipitation will decrease the amount of alcohol required per mass of product. This has a positive inpact on the economics of the process because the cost of alcohol recovery and the inevitable losses of alcohol during xanthan precipitation represent an important portion of the production cost.

Once the polymer is obtained in a wet solid form, its final purity (quality) and the economics of the next operation units can be determined by dewatering and washing. The xanthan precipitate may be centrifuged or pressed in

order to remove free liquid, thereby improving the purity of the product and reducing drying costs. At this stage, the additional washing (Fig. 5) may be carried out to improve the quality of the product by removing as much as possible the particulate matter (cell debris, microgels, organics residues, and pigments). To this end the concentrated form of xanthan is redissolved, washed with water/KCl, precipitated, and dewatered again.

The precipitated cake is then dried in batch or continuous driers under vacuum or with forced air, or with inert gas if the solids contain inflammable solvents. To avoid undesirable effects, such as polymer deterioration, discoloration, and impairment of solubility, the drying temperature must be carefully controlled.

The dried xanthan is then milled to the desired mesh size to control dispersability and dissolution rate as well as to make solids handling easier. The mesh size can range from 40 to 200; the most common mesh sizes are 80 (177 μm) and 200 (74 μm). A range of products with these particle sizes is marketed.

Because an important part of the production costs represents the recovery and purification of xanthan, preparations that have been concentrated directly from the fermentation broth are also commercially available at lower prices. These xanthan concentrates, prepared by tangential flow filtration, contain between 8 and 12% dry polysaccharide to which antibacterial agents are added to prevent deterioration. This form of xanthan, which is specially useful in drilling operations in the oil industry, is available in different industrial grades and can be readily diluted to the required concentrations.

Reactor Designs and Operation Modes

During xanthan fermentation the hydrodynamic behavior of the broth changes substantially as the polymer is produced. The rheology exhibited by the xanthan fermentation culture is complex and includes pseudoplastic flow behavior, yield stress, and viscoelasticity. The effective viscosity increases by about three powers of 10. Under such conditions adequate aeration and mixing have to be provided if high specific xanthan productivity is to be maintained and stagnant zones and hence oxygen limitation avoided. Fermenter and impeller design, therefore, plays a critical role in ensuring good mass transfer and homogeneity and, hence, good product quality. Because the turbulence and shear rate in stirred tank-reactors (STRs) is higher near the impeller than in bulk mixing, optimal design requires the provision of high turbulence to give good gas dispersion and bulk mixing. The conventional Rushton turbine (the most widely used impeller in the fermentation industry) has shown to be disadvantageous because of its high unaerated power number (61) and compartimentalization effects (62). At high xanthan concentration the sorption efficiency (mass of oxygen absorbed at maximum driving force per energy supplied) of an STR with a Rushton turbine drops significantly below that of other reactors (Fig. 7). Consequently, alternative impeller types such as the Intermig, Prochem Maxflo T, and Scaba 6SRGT have been tested (23,64). Among these, the Intermig has shown a four times higher sorption efficiency at high xanthan concentrations, compared with Rushton turbines (23).

Reactor design has also been targeted as a means of improving xanthan production and quality. The plunging jet reactor (65), airlift reactor (66), centrifugal fibrous-bed bioreactor (67), STR with draft tube (68), and bubble column (66), have all been tested for that purpose. In spite of the lower energy requirements and higher oxygen sorption efficiency, the poor mixing in the wall region of the plunging jet reactor is a problem that needs to be solved. The limitation of oxygen supply in the downcomer of airlift reactors has negative effects on the xanthan production rate and product yield (66). Although the design is novel, the recently proposed centrifugal fibrous-bed bioreactor (67) does not show obvious advantages. An STR with a draft tube shows good performance as evaluated by its sorption efficiency (Fig. 7) (68). At low xanthan concentration the bubble column has significantly higher efficiency than the other reactors (Fig. 7). Even at high xanthan concentrations the bubble column exhibited excellent mixing performance; slug flow prevails and inhomogeneities (stagnant zones) are avoided (34,66).

The possibility of running a xanthan bioprocess continuously has been also examined at laboratory scale (69–71). The main features of this mode of operation are (*1*) higher specific productivity, (*2*) no definite limit (in theory) to the length of run because bacterial degeneration could be avoided using synthetic media with reduced levels of sulfur, (*3*) avoidance of time losses in restarting batch runs, and (*4*) near maximum process productivity and a constant product quality, owing to steady-state conditions. One of the most interesting applications of continuous mode operation may be found in the oil industry, where in situ production plants may provide xanthan in different industrial grades that can readily be diluted to the required solution concentration. However, a serious weakness of the process is the low product accumulation, which is around 5–7 g/L at the conditions where maximum productivity and high product quality are favored (dilution rate $\sim$0.075 h^{-1}). This constraint and limitations in avoiding culture contamination are important reasons why industry has not yet adopted this cultivation method.

Unfortunately, fed-batch strategies with glucose feeding (70,72–77) have not brought significant improvement to the process; some resulted in a performance that was even worse than that of batch culture. A common characteristic of these processes is that an important portion of the glucose supplied (up to 60%) remains in the reactor without being utilized. These limitations in fed-batch culture make this process strategy not economically attractive.

Recently, a new fed-batch operation mode was proposed, based on the observation that the N-source inhibits growth of *X. campestris* (21). Therefore, the novel feature of this process is the use of ammonia feeding to control growth. This allows major product accumulation with higher molecular weight during the growth phase (21). The benefits to be expected are as follows: (*1*) larger product yield, (*2*) higher volumetric productivity, (*3*) improvement of product quality and uniformity, (*4*) reduction in capital investment and unit production costs, and (*5*) increase in plant production capacity as compared with the standard batch process (Table 2). The application of this process at the production level may require combined strategies in-

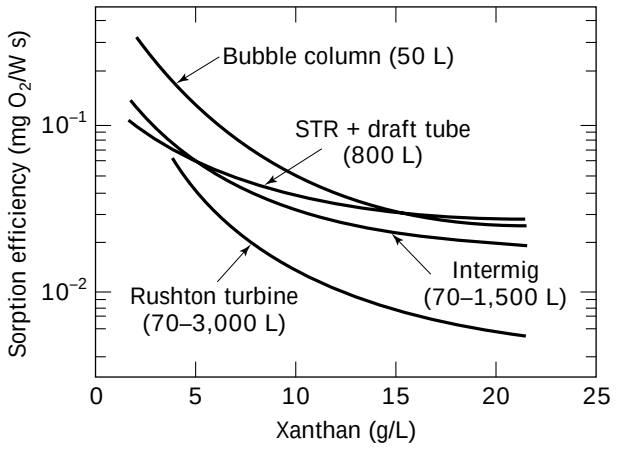

Figure 7. Comparison of the energetic efficiencies of oxygen transfer during xanthan production in various bioreactors and different impeller design. *Source*: From Herbst (63).

Table 2. Comparison of Performance and Costs of Xanthan Cultivation in Batch and Fed-Batch Operation Mode

Parameter	Standard batch	Fed-batch
X_O (g L^{-1})	0.2	0.5
X_f (g L^{-1})	4	5.2
$Product_{(harvest)}$ (g L^{-1})	25.38	30.8
Run time (h)	84	49
Productivity (g L^{-1} h^{-1})	0.3	0.63
$Y_{P/S}$	0.507	0.65
Capital investment cost ($ $\times$ 10^3)[a]	5,493	2,930
Production cost per kg ($)[a]	7.28	5.38

Cost analysis has been made taking a production plant capacity of 1,500 tons/year (21).

cluding the use of the Intermig impeller in STRs with a multiple feeding device, or the use of a bubble-column reactor.

Oxygen Transfer and Scale-Up

Transport processes are dependent on scale because the time constants for transport processes increase with scale. Scale-up problems are pronounced in xanthan fermentation because of the highly viscous pseudoplastic flow behavior of the culture broth, which deteriorates the mass transfer, mixing, and heat transfer capabilities of the fermenter. The actual oxygen concentration and the kinetic behavior of the bacteria are dependent on scale owing to the fact that oxygen and other nutrients involved in the bacterial metabolic activity are consumed and have to be supplied by transport processes. Sufficient oxygen supply to the obligately aerobic bacterium is of particular importance. If dissolved oxygen becomes depleted in the culture medium, the specific xanthan productivity of the cells decreases linearly with the specific oxygen uptake rate (78) (Fig. 8). Furthermore, and as shown in Figure 9, a lower molar mass product is formed under oxygen limitation (79). The information in Figures 8 and 9 shows that, among other scale-up criteria, scale-up at constant specific oxygen transfer rate is the most appropriate choice to achieve constant productivity and high product quality. Maintaining

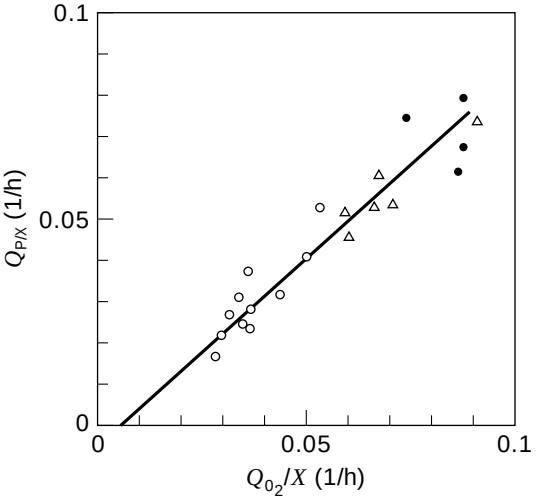

Figure 8. Dependence of the specific xanthan production rate on the specific oxygen uptake rate. Circles refer to runs in an STR at 15 L and 1,500 L, triangle correspond to bubble-column reactor; filled symbols denote no oxygen limitation.

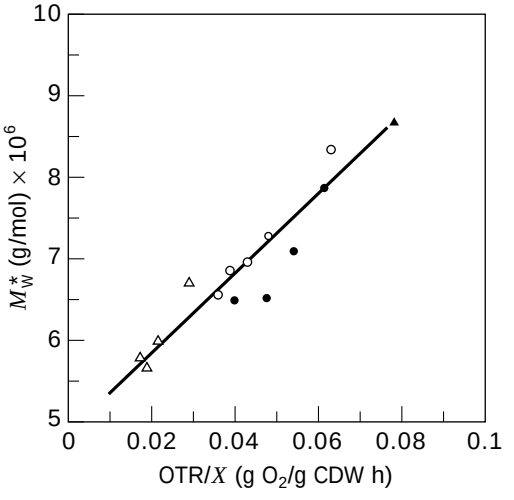

Figure 9. Influence of the specific oxygen transfer rate on the weight-mean molar mass of the xanthan produced.

a constant volumetric mass transfer coefficient (k_La) in process scale-up is approximately the appropriate condition to guarantee the same oxygen supply rate to satisfy the oxygen demand of the cell population.

Aiming at high product concentration for economic downstream processing, oxygen transfer limitation is likely to occur at the final stage of the fermentation. This applies particularly to industrial fermentations where the specific power input is bound to be low. Any error at the design stage when estimating the oxygen transfer capacity of the fermenter results in a proportional error in the maximum xanthan production rate. Consequently, the volumetric mass transfer coefficient, k_La, must be accurately estimated.

Various approaches toward the estimation of k_La in stirred-tank reactors with viscous pseudoplastic liquid have been proposed in the literature. The flow behavior is commonly described according to the Ostwald-de Waele relationship (equation 1). Because the shear rate in the STR is locally nonuniform, the effective mean shear rate, $\dot{\gamma}_{eff}$, caused by the impeller is described, for example, in terms used by Metzner & Otto (80):

$$\dot{\gamma}_{eff} = AN \tag{5}$$

where A is a constant characteristic of the impeller and N is the sirrer speed. Various expressions for $\dot{\gamma}_{eff}$ in the STR, employed to calculate the effective viscosity, η_{eff}, from equation 2, are listed in Table 3. Equation 6 of Table 3 allows one to predict shear rates at turbine impeller blades, whereas equation 7 applies in the "stirrer zone." Equation 8, is a modification of the Metzner–Otto relationship including a function of the flow behavior index (n) and differs only marginally from the original one (23). Herbst et al. (23) showed that the predicted $\dot{\gamma}_{eff}$, using Calderbank and Moo-young's relationship, is almost two orders of magnitude lower than the shear rate at the stirrer tip proposed by Henzler & Kauling (84). The last predicts a different trend because increasing viscosity is assumed to lower the shear rate. It is obvious that any correlation of the volumetric mass transfer coefficient will be affected by the choice of relationship for the effective shear rate $\dot{\gamma}_{eff}$.

A number of mass transfer correlations exist in the literature, some of them are given in Table 4. The relationships in Table 4 may be divided into those that reflect the effect of the stirring speed directly (equations 10, 11, and 13) and those that take into account the resultant power input (equation 12). The predictive capability of these equations, however, differs significantly (Fig. 10). Based on the results shown in Figure 10, it can be concluded that, the dimensional relationship of Kawase and Moo-Young (87), equation 12, gives the best representation of the experimental data. Herbst et al. (23), working with reactor volumes ranging from 0.015 to 1.5 m^3, demonstrated further that the power input required to achieve a desired mass transfer rate calculated from equation 12 was reduced considerably when Intermig impellers are applied. Figure 11 shows that the experimental data are well described by the relationship of Kawase and Moo-Young (equation 12) when the power input (P/V) was modified by a factor of three (23).

The scale-up criteria of a constant specific oxygen transfer rate was experimentally confirmed to be valid in xanthan bioprocesses by Herbst et al. (23). In order to keep the volume-specific oxygen transfer rate constant, equal power input ($\sim$3.3 kW/m^3) and superficial gas velocity (7.2 mm s^{-1}) in reactors ranging from 0.072 to 1.5 m^3 were employed. Under these operating conditions all the main fermentation performance parameters show an excellent reproducibility independent of the scale. This can be recognized in the results in Figure 6 where all concentrations, the rheological properties (K, n), and the oxygen transfer rate and the dissolved oxygen concentration are reproducible. Moreover, the product quality as evaluated by its molecular weight, the polydispersity index, and the pyruvat content were constant irrespective of the fermenter scale. These results highlight that constant specific oxygen transfer rate is the suitable scale-up criterion for constant xanthan productivity and product quality.

Effects of the Process Design on Product Quality

The high viscosity yield of xanthan at low shear rates and its shear thinning behavior are particularly important during and after processing of many industrial products. Thus, a highly pseudoplastic xanthan is required. This means that, according to the rheology (equation 2) for a determined shear rate, $\dot{\gamma}$, high values of the rheological parameters k and n are desired to achieve a maximum effective viscosity (η_{eff}). However, in real terms, there is no way to vary k and n independently because both appear to be interdependent (see equation 4). The solution of equation 4 is given by equation 14, which exhibits an inverse functional relationship between the flow index, n, and both the xanthan molar mass, M, and the consistency factor, k.

Table 3. Selection of Relationships for the Effective Shear Rate in Stirred Tanks

Reference	Approach	Correlation	Eq.

$$n = \frac{1 + 0.071 \cdot B}{1 + B}, \text{ with}$$
$$B = 0.0227\left(\frac{M}{10^6}\right)^{2.08}(k - 10^{-3})^{0.47} \qquad (14)$$

As observed in the results in Figure 6, k rises by three orders of magnitude toward the end of the fermentation, while n declines by less than one order of magnitude. This indicates that the consistency factor, k, is a predominant factor in determining the rheological properties of xanthan. The functional dependence of the parameter k on xanthan molar mass and product concentration is well established (see equation 3). Therefore, to achieve high values of k for a given product concentration, conditions of high xanthan molar mass have to be achieved. To this end the empirical correlation of Peters et al. (24) may be considered (equation 15):

$$M = 4.9 \cdot 10^6 + 3.8 \cdot 10^6 \cdot \mathrm{OTR}/Q^*_{O_2} + 2.6 \cdot 10^7 \mu \qquad (15)$$

Equation 15 implies that conditions of no oxygen limitation and high growth rates have to be ensured when xanthan of high viscosity yield to be produced. This rationale was proven to be right by the scale-up results of Herbst et al. (23) mentioned earlier. Furthermore, the media formulation has shown to affect indirectly the mean molar mass of xanthan (21,66). On one hand, when complex media are

used, oxygen limitation is encountered at an early stage of the fermentation run, and hence, the mean molar mass of xanthan is impaired (66). On the other hand, high levels of the N-source in synthetic media formulations inhibit the bacterial growth, with the consequent result of low molar mass xanthan synthesis (21). It was further found that the N-source level also affects the pyruvate content of xanthan (21). The same author demonstrated further that the rheological properties of xanthan improve as the degree of pyruvate substitution increases (Fig. 12). This is in accordance with the initial observations of Sandford (86) and Cadmus et al. (52). Thus, the pyruvate content of the polymer should be regarded as an important parameter in order to design, predict, and control the rheological behavior of the fermentation broth, and as regards the product application.

COMMERCIAL APPLICATIONS

5.1 Food uses

Several applications that illustrate xanthan use in the food industry are given in Table 5. First of all xanthan gum is incorporated into foods to control the rheology of the final product. In performing this functional task, the polymer has a major effect on various sensory properties such as texture, flavor release, and appearance, which contribute to the acceptability of the product for consumer use. Because of its solution properties, xanthan can be used to provide a desired functionality at a lower concentration than most gums and, therefore, may be more cost-effective. Additionally, because of its pseudoplastic properties in solution, xanthan has a less "gummy" mouth-feel than gums that exhibit Newtonian behavior. An additional advantage in food formulations is the antioxidative action of xanthan as compared with other polysaccharides and additives (93).

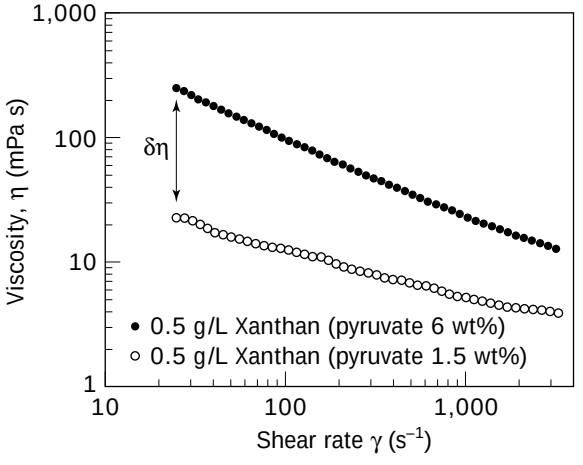

Figure 12. Comparative viscosity curves of 0.5 g/L xanthan in 0.12 M KCl with varying degree of pyruvate substitution. Filled symbols correspond to xanthan with about 6 wt% pyruvate content and M_w of 7×10^6 g/mol; open symbols relate to xanthan with about 1.5 wt% pyruvilation degree and M_w of 6.5×10^6 g/mol (run F7). *Source*: Results from Flores-Candia (21).

Table 5. Main Practical Uses of Xanthan for the Food Industry

Function	Application
Adhesive	Icings and glazes
Binding agent	Pet foods
Coating	Confectionery
Emulsifying agent	Salad dressing
Encapsulation	Powdered flavors
Film formation	Protective coatings, sausage casings
Foam stabilizer	Beer
Gluten substitution and dough processing	Baked goods, pasta
Stabilizer	Ice cream, salad dressings, juice drinks, margarine
Swelling agent	Processed meat products
Syneresis inhibitor, freeze–thaw stability	Cheese, frozen foods
Thickening agent	Jams, sauces, syrups, and pie fillings
Pumping and filling improvement	Processing of canned products

Source: From Refs. 87–92.

Xanthan is also being used in the formulation of reduced-calorie products, representing the second and third generation of fat replacers and stabilizers (87).

Cosmetics and Pharmaceutical Uses

Xanthan gum is used in cosmetics and toiletries as a bodying agent and emulsifier. Personal care products such as shampoos, creams, lotions, make-up, hair care products, and toothpastes can be formulated with xanthan (88,94,95). Additionally, xanthan provides creams and lotions with a good "skin-feel" during and subsequent to application (88). Recently, a new xanthan formulation (Ticaxan) was introduced into the market for that purpose (96).

In the pharmaceutical industry, xanthan is used to suspend pharmaceuticals such as antibiotics and to provide formulations of uniform dosage (88). It can also be used to stabilize emulsified cream formulations containing pharmaceuticals. Presently, xanthan is being evaluated in controlled-release applications, such as in gastrointestinal pharmaceutical applications, as rate limiting membranes for sustained delivery of oral formulations (97,98) and as dissolution and binding agents in tablets and rectal preparations (99,100).

Agricultural and Other Industrial Applications

Xanthan is used in a diverse range of industrial applications, particularly as a suspending or thickening agent. The polymer improves the flowability of fungicides, herbicides, and insecticides by uniformly suspending the solid components of the formulation in an aqueous system or by stabilizing emulsions and multiphase liquid systems (88). The unique rheological properties of xanthan solutions also improve sprayability, reduce drift, and increase pesticide cling and permanence (89,101,102). Recently, various "tolerance exemptions" were issued by the U.S. Envi-

ronmental Protection Agency for the use of xanthan as a surfactant in pesticide formulations (103). Because of its ability to disperse and hydrate rapidly, xanthan is used in jet injection printing. It is nonpolluting and gives a good color yield. It is also used in several mining processes for removing dissolved metals in a highly efficient process (104). Lately, in the formulation of a new generation of thermoset coatings, xanthan was introduced by Monsanto with the aim of addressing customers' environmental challenges (105).

Petroleum Industry

In the petroleum industry, xanthan gum finds a wide range of applications. Among these are oil drilling, fracturing, pipeline cleaning, workover, and completion. Xanthan's unique solution rheology, its excellent compatibility with salts, and its resistance to thermal degradation have made it useful as an additive to drilling fluids (88,106). The pseudoplasticity of its solutions provides low viscosity at the drill bit, where shear is high, and high viscosity in the annulus, where shear is low. Therefore, xanthan serves a dual purpose in allowing faster penetration at the bit because of the low solution viscosity in that area and, at the same time, suspending cuttings in the annulus because of the high solution viscosity in that area. Hydraulic fracturing is used to effect deep-penetrating reservoir fractures that improve productivity of the well. Xanthan's high solution viscosity at low shear is important for proppant suspension in this operation (107). The pseudoplastic rheology, shear stability, and friction reduction impaired by xanthan provide for maximum delivery of pressure to the formation and minimal friction loss in the tubing and reservoir. A workover and completion fluid is essential for achieving and maintaining maximum well productivity. Xanthan contributes to excellent hole cleaning, suspension, friction reduction, and stability to shear and high temperatures. An important speciality application employs a xanthan gel to remove rust, welding rods, wet slag, and other debris from gas pipelines. This pipeline cleaning method is considered safe, environmentally acceptable for open sea disposal, and cost-effective (88).

Enhanced Oil Recovery

For every barrel of oil actually produced, about another two remain in the ground (108). Therefore, enhanced oil recovery (EOR) may become important in the next decades to meet the increasing energy demand of the future. Xanthan gum can be used in two types of enhanced recovery systems. The principal use is for an improved form of water flooding in secondary oil recovery, a phase in which polymers are used to increase the efficiency of water contact and to displace reservoir oil. The second application is in micellar-polymer flooding as a tertiary oil recovery operation. Polymer-thickened brine is used to drive a slug of surfactant through the porous reservoir rock to mobilize residual oil; the polymer prevents fingering of the drive water through the surfactant ban and ensures good area sweep. In both applications, the function of the polymer is to reduce the mobility of injected water by increasing its viscosity. Evaluation of hundreds of biopolymers has found xanthan to be one of the best candidates for use in EOR operations. The reasons for this are its (*1*) non-Newtonian behavior, (*2*) high viscosity yield even at low concentrations (600–2,000 ppm), (*3*) low sensitivity of viscosity to salinity changes (unlike the polyacrylamides), (*4*) resistance to mechanical degradation, (*5*) stability with respect to higher temperature (up to almost 90 °C).

One of the major limiting factors in the application of xanthan in EOR is that, by the nature of its production method, it is expensive, and the current general market price is in excess of $11/kg (109). In addition, some drawbacks during field operation are associated with poor injectability behavior, adsorption into the rock strata, and plugging problems (110,111). These problems have been attributed to the quality and composition of the polymer (110,112), to water quality (111), and to well configuration (113,114).

MARKET SIZE AND FUTURE DEVELOPMENT

Xanthan gum currently dominates the microbial gum market, which is growing at between 6 and 7% per year (115). It has been suggested that global production exceeds 50,000 tons per year (116). The worldwide xanthan market is valued between $600 and $800 million per year (109,116,117). The European Union market accounted for about $158 million in 1994, and the U.S. market was reported to be about $120 million in 1995. Table 6 shows the U.S. market size and forecast of xanthan consumption by major end uses. Food accounts for about 70% of total consumption; the remainder is spread among petroleum production, cosmetics, and other uses. Overall growth is forecasted at about 7.0% yearly, with food applications providing most of the impetus at 8.3% annually (1). Consumption of xanthan in petroleum is forecasted at a very modest rate (2%), which is due mainly to recovery operations rather than oil well drilling (2). Because of its unique properties, the application of xanthan in cosmetics has been growing successfully at 5.9% per year (82). It should be noted that use in textile production is very nominal because the textile industry in the United States is conservative and only growing with the national economy (3).

An analysis of Table 6 shows that xanthan is positioned well in U.S. markets. Further analysis reveals that xan-

Table 6. Market Analysis and Forecast: Xanthan Consumption in The United States

End use	1993 ($ M)	1995 ($ M)	1998 ($ M)	AAGR (%) 1993–1998
Food	74.4	89.5	111.0	8.3
Petroleum	16.5	17.1	18.2	2.0
Cosmetics and toiletries	9.0	10.2	12.0	5.9
Textiles	1.4	1.4	1.4	0
Other	1.1	1.1	1.7	8.5
Total	102.4	119.1	144.3	7.1

Source: Business Communications Company (1–4,94).
Note: Major xanthan demand according to end use is listed in millions of dollars (M); AAGR, annual average growth rate.

than gum represents the fastest growing segment of the polysaccharide industry (1–4). Most growth is in foods, where demand for natural gums is falling as a result of market share erosion by xanthan (118).

The high growth rate of the xanthan market may explain not only why the major producers have all expanded in recent years (119) but also why Archer Daniels Midland Co. has decided to enter the xanthan market with an estimated 10,000 tons of annual capacity (119,120). Between 1992 and 1994, the global xanthan production capacity doubled in size (119,121). Recently, Nutrasweet Kelco Co., the world's leading producer of xanthan, has announced further expansion (122). In fact, an overcapacity has been created in the xanthan market, which may have two important consequences: (*1*) an accelerated penetration of xanthan into new markets, and (*2*) stiff competition for new polysaccharides. Success may be limited only to those polymers that have a clear advantage in performance or customer perception. Less-expensive polymers that do not perform better may be disadvantaged due to the high costs of incorporating new gum into the end product. An estimate from 1982 suggests that the testing required by the U.S. Food and Drug Administration to gain food clearance approval for a new additive can cost about $2 million and may take up to 8 years (123).

According to a market forecast, the two main factors shaping the xanthan market in the next century are growing xanthan demand in developing countries and worldwide energy demand, which will stimulate EOR operations as reserves decline (124,125). Indeed, the large strategic value of xanthan still remains in EOR operations, whose worldwide production at the beginning of 1996 was estimated to be around 2.2 million barrels/day (126).

The large economic value of xanthan in the EOR market can be assessed, as suggested by Moses (127), by looking at the amount of oil that remains in the earth's crust (Table 7). Thus, it becomes clear that the EOR markets are very large indeed. They are, however, low-price markets that could be developed only through the use of much improved technologies with low production costs. To improve the competitive advantage of xanthan in EOR, more efficient fermentation processes and better control of the polymer quality are required.

Table 7. Approximate Value of Oil Not Economically Recoverable by Present Technology

Source region	Estimated value of oil unrecoverable by present technologies ($ × 10^{12})
Asia-Pacific	0.6
Western Europe	0.8
Middle East	12.4
Africa	1.9
Western Hemisphere	4.1
Former East-Block states	2.9
Total for the whole world	22.7

Source: From Ref. 25.
Note: The estimate was based on the following assumptions: (*1*) a crude oil price of $18.00 per barrel, (*2*) that proven reserves (i.e., reserves regarded as presently recoverable) represent 35% of the original oil-in-place.

Relatively high xanthan costs, some technical drawbacks and the (relatively) low oil price have prevented market entry in recent years. Xanthan usage in EOR is typically 0.4% w/w (about 0.5 kg per barrel of oil), which represents about 25% of the estimated equilibrium oil price ($20 per barrel)—a value that is evidently too high for the oil industry.

A recent survey of EOR shows that polymer flooding is achieving commercial success (126). In this operation, up to 35% of original oil in place has been recovered in the Junggar basin (China). Polymer flooding is being used in several projects in France, Germany, China, India, and Romania. For example, polymer flooding accounts for about 50% of the total EOR operations in China. Even when it is not exactly clear what percentage xanthan is responsible for, the fact that the largest xanthan gum production plant has been brought onstream for oil applications is an indication that xanthan use in EOR is not far away. Analysts in marketing research are convinced that the use of xanthan as well as other microbial gums in EOR will become more prevalent as increasing worldwide energy demand results in rising oil prices.

NOMENCLATURE

a (m^{-1})	Interfacial area per unit volume of liquid
A	Impeller-related factor
b (m)	Height of stirrer blade
C_P ($kg\ m^{-3}$)	Product concentration
d (m)	Stirrer diameter
D (m)	Reactor diameter
g ($m\ s^{-2}$)	Gravitational acceleration
k (mPa sn)	Consistency index
k_L ($m\ s^{-1}$)	Liquid-side mass transfer coefficient
M ($kg\ kmol^{-1}$)	Weight-mean molecular weight
N (s^{-1})	Stirring speed
n	Flow behavior index
OTR ($g\ L^{-1}\ h^{-1}$)	Oxygen transfer rate
P (W)	Total power input
pO_2 (%)	Partial oxygen pressure
Q_{O_2} ($g\ L^{-1}\ h^{-1}$)	Microbial oxygen demand
u_b ($m\ s^{-1}$)	Bubble rise velocity
u_G ($m\ s^{-1}$)	Volumetric gas flow rate
V (m^3)	Dispersion volume
V_G ($k\ mol^{-1}$)	Mole volume of ideal gas
x	Molar fraction

Greek Symbols

$\gamma\cdot$ (s^{-1})	Shear rate
η (mPa s)	Viscosity
τ (Pa)	Shear stress
ρ ($kg\ m^3$)	Density
λ (s)	Relaxation time
σ ($N\ m^{-1}$)	Surface tension

Subscripts or Superscripts

L	Liquid phase
eff	Effective
w	Water

OUTLINE

INTRODUCTION

Baker's yeast consists of microorganisms selected for the production of bread. The history of the baker's yeast industry for breadmaking was briefly described in *Encyclopedia of Food Science and Technology* (1). In the modern baker's yeast industry, specially selected strains of *Saccharomyces cerevisiae* are used. Baker's yeast is able to metabolize the commonly available sugars, such as D-glucose, D-mannose, sucrose, and maltose, very readily under both aerobic and anaerobic conditions.

In 1874, the reducing action of fermenting *Saccharomyces cerevisiae* was observed in which hydrogen sulfide was liberated on addition of finely powdered sulfur to a suspension of fresh baker's yeast in sugar solution. The reduction of furfural to furfuryl alcohol, the first transformation of an organic molecule, was then reported. Since the beginning of the 20th century, numerous biotransformations, biodegradations, and fermentations using other microorganisms (or microbial enzymes) in addition to baker's yeast have been studied by biotechnologists and organic chemists (2–6). Organic synthetic chemists have applied the microbial (or enzymatic) transformation to the synthesis of chiral molecules in enantiomerically pure form, and they have used baker's yeast among microorganisms and lipases among enzymes by preference. The reasons for these choices are that baker's yeast is versatile and inexpensive, and its growth does not require the assistance of a microbiologist. In addition, hydrolytic enzymes do not require cofactor regeneration and are easy to use. Thus, a large number of references to scientific studies in this area have been reported to date.

Microbial transformation of unnatural molecules has been used in industry to prepare optically pure compounds. For example, optical resolution by enantioselective hydrolysis with lipase is used in the synthetic process of a medicine such as diltiazem hydrochloride. Conversely, the baker's yeast-mediated transformation is not industrially applied. However, metabolisms including cofactor regeneration in baker's yeast have been thoroughly investigated in the 1990s. Therefore, the baker's yeast-mediated reduction now has the potential for industrial use.

TYPE OF TRANSFORMATIONS

The scientific studies devoted to baker's yeast-mediated transformation have gradually grown since the 1950s. The transformations of various classes of synthetic organic molecules were examined using baker's yeast as a reagent in organic synthesis, and the number of the papers is now more than 500. Those transformations were reviewed from the viewpoint of chemical reaction in three excellent articles published in 1990, 1991, and 1992, respectively (7–9). In these reviews, the uses of baker's yeast in synthetic organic chemistry are fully covered.

The baker's yeast-mediated transformations are mainly classified into four types as follows.

1. Carbon–carbon bond formation
2. Reduction of ketones and carbon–carbon double bonds
3. Oxidation
4. Hydrolysis of esters

The general goal of these transformations mediated by baker's yeast is considered to be the preparation of chiral molecules in enantiomerically pure form, because the catalytic synthesis of optically pure compounds is one of the most exciting chapters in organic chemistry.

Among the reports on baker's yeast-mediated transformations, more than half of the studies are devoted to the asymmetric reduction of prochiral carbonyl compounds, such as cycloalkanones, aliphatic alkanones, sulfur-containing alkanones, cyclic diketones, acyclic diketones, keto esters, and so on. Chiral alcohols are easily obtained using baker's yeast under mild conditions on a laboratory scale. Asymmetric C–C bond-forming reactions have been investigated by many chemists because of their importance as a fundamental reaction and as an attractive method from a synthetic point in organic chemistry.

Organic chemists sometimes use active dry yeast (certain strains of *S. cerevisiae* having higher resistance to drying with good baking activity [10]) instead of baker's yeast (compressed). Biotransformation mediated by active dry yeast also proceeds in the same manner as that by baker's yeast (compressed); therefore, both biocatalysts are not distinguished in this article.

C–C BOND FORMATION

In 1921, the process for the stereospecific preparation of D-ephedrine was developed using baker's yeast (11). This was the first example of the successful combination of chemical and enzymatic reactions. The key intermediate, L-1-hydroxy-1-phenyl-2-propanone, was produced by treating benzaldehyde under fermenting conditions of baker's yeast in the presence of glucose (Fig. 1). In this reaction, benzaldehyde is stereospecifically condensed with a CH_3CO unit to give the α-hydroxy ketone. The unit comes from decarboxylation of pyruvate through the EMP pathway of glucose and reacts with aldehyde. Hitherto, this is only the industrial use of the baker's yeast-mediated transformation in synthetic organic chemistry.

This acyloin-type condensation with baker's yeast has been applied to other aldehydes and α,β-unsaturated aldehydes. Furthermore, unnatural α-keto acids instead of pyruvic acid were used in this condensation reaction with aldehyde. The α-hydroxy ketones obtained in these reactions were further reduced to afford the *erythro*-diols in more than 95% enantiomeric excess (ee).

Another C–C bond formation mediated by baker's yeast is a Michael-type addition. The reaction of α,β-unsaturated ketones with 2,2,2-trifluoroethanol under fermentative conditions afforded the corresponding trifluoromethyl methyl carbinols with more than 90% ee.

ASYMMETRIC REDUCTION OF PROCHIRAL KETONES

The baker's yeast-mediated reduction of prochiral ketones with varying substituents (Me, Et, *n*-Pr, *n*-Bu, Bz) was systematically investigated in the 1960s. The prochiral ketone, with R_L representing a large substituent and R_S a small substituent adjacent to the carbonyl group, was transformed to the secondary alcohol with an *S* configuration. Therefore, it was judged that a hydrogen transfer to the *re*-face would preferably occur in the baker's yeast cells (Fig. 2). However, it was pointed out that this rule, the Prelog rule (12), should be cautiously applied to baker's yeast-mediated reduction, because exceptions to this rule were found.

In asymmetric reduction, its stereoselectivity is practically most important. Unsatisfactory stereoselectivity would be the consequence of two situations (7). The first case is that a single enzyme, catalyzing the reduction of each substrate, cannot recognize its structural features. The second case is that two or more oxidoreductases for each substrate act simultaneously with opposite stereochemical preferences. Although each of the oxidoreductases catalyzes the enantioselective reduction with high enantioselectivity, stereoselectivity of the transformation and the optical purity of the product are the consequence of the activities of those enzymes. This second case was recently found in baker's yeast-mediated reduction. By characterizing oxidoreductases in baker's yeast followed by modifying the structures or procedures, improvement in the enantiomeric excess of the product was accomplished in some reactions. In this article, the successful result for production of (*S*)-ethyl 3-hydroxybutanoate with high ee is described.

Method

Compared with the chemistry of the baker's yeast-mediated reduction, the method, especially for large-scale production, has hardly been investigated. In the 1990s, regeneration systems for nicotinamide coenzymes in the baker's yeast-mediated reduction were extensively investigated, and consequently, an effective method for large-scale production has been developed (13).

The details of the use of baker's yeast in an asymmetric reduction of prochiral ketones were described on a laboratory scale in *Organic Syntheses*. Reductions of acetol (AC) to (*R*)-propylene glycol (PG) (14), of ethyl acetoacetate (EA) to (*S*)-ethyl 3-hydroxybutanoate (E3-HB) (15), and of 2,2-dimethylcyclohexanone-1,3-dione to (*S*)-3-hydroxy-2,2-dimethylcyclohexanone (16) were fully reported (Fig. 3). Thus, asymmetric reduction mediated by baker's yeast was recognized as a useful technique by synthetic chemists.

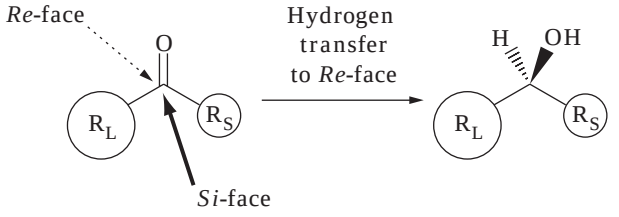

Figure 2. Asymmetric reduction of a prochiral ketone by hydrogen transfer to the *Re*-face.

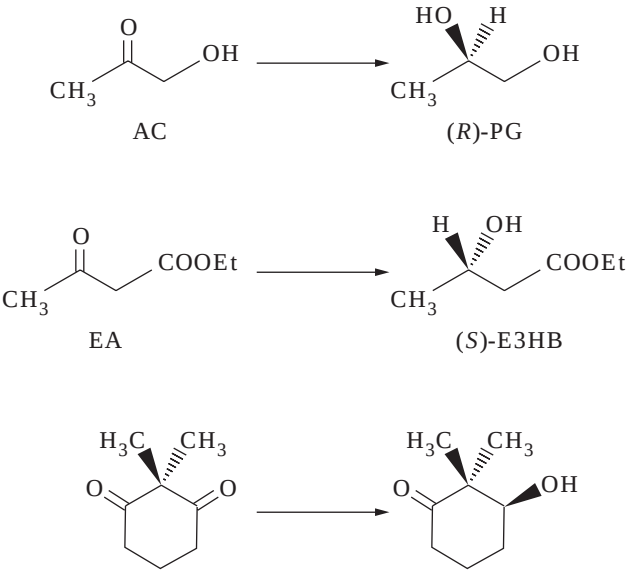

Figure 3. Baker's yeast-mediated reduction fully described in *Organic Syntheses*.

These three bioreductions, and other many similar ones, were done in an aqueous solution containing carbohydrate with stirring, as chemical reactions. Under these conditions, reductions successively proceed consuming carbohydrate, the energy source for coenzyme regeneration. Reduction by carbonyl reductases is coupled with regeneration systems of the reduced form of nicotinamide coenzymes NADPH from the oxidized form $NADP^+$ through glucose oxidation, as shown in Figure 4. However, the use of carbohydrate as the energy source for NADPH regeneration was thought to be inadequate, because the amount of carbohydrate is quite excessive compared with that of the substrate, and the metabolism of the carbohydrate is accompanied by the production of a vigorous foam of carbon dioxide, ethanol, and smelly by-products.

Recently, an efficient method for a baker's yeast-mediated reduction was developed (13). It uses ethanol and oxygen instead of carbohydrate as the energy source for NADPH regeneration. NADPH is regenerated from $NADP^+$ through ethanol oxidation to carbon dioxide, as shown in Figure 5. The asymmetric reduction of several carbonyl compounds by this new method afforded similar results in the chemical yield and optical purity of the product. The method, operating in about 100 mM EtOH under aerobic conditions, is clean and efficient, because no by-product except carbon dioxide was detected, and the energy source can be efficiently used for coenzyme regeneration.

NADPH Regeneration System

In the baker's yeast-mediated reduction, NADPH, which is the hydrogen donor in the reduction, must be successively regenerated from the corresponding oxidized form in the cells. The system responsible for the coenzyme regeneration must be then coupled with reduction of a substrate. Recently, Yamada et al. characterized the enzymes responsible for the NADPH regeneration system using carbohydrate as the energy source with some microorganisms (17). With *S. cerevisiae*, the enzymes were shown to be D-

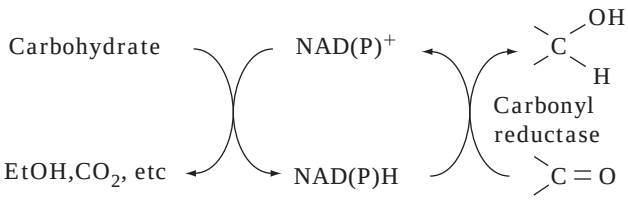

Figure 4. Outline of the reaction mechanism using carbohydrate as the energy source.

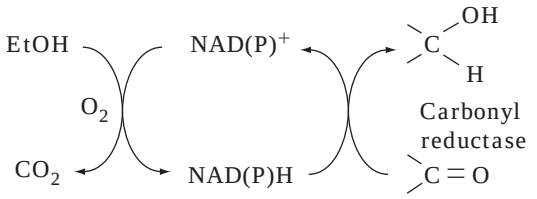

Figure 5. Outline of the reaction mechanism using EtOH as the energy source.

glucose-6-phosphate dehydrogenase and 6-phospho-D-gluconate dehydrogenase in the hexose monophosphate pathway.

In the method using ethanol as the energy source, NADPH is regenerated from $NADP^+$ through the oxidative pathway of ethanol to carbon dioxide, and the system is also efficiently coupled with reduction of a ketone. The enzyme system responsible for NADPH regeneration was investigated by studying the reduction of AC and EA, catalyzed by NADH- and NADPH-dependent carbonyl reductases, respectively. NAD^+ formed during the reduction of AC is reduced to NADH through the oxidative pathway of ethanol to acetate, catalyzed by alcohol dehydrogenase and aldehyde dehydrogenase. On the other hand, $NADP^+$ formed in the reduction of EA is reduced to NADPH through the oxidative pathway of acetate to carbon dioxide. The enzyme responsible for NADPH regeneration must be malate dehydrogenation (decarboxylating) in leaving the TCA cycle into pyruvate.

Asymmetric Reduction of Ethyl Acetoacetate

Reduction of EA by baker's yeast is the most extensively studied transformation, leading to an important chiral building block, (*S*)-ethyl 3-hydroxybutanoate (E3-HB), for the syntheses of the carbapenem thienamycin, (*S*)-(+)-sulcatol, nystatin, and so on. However, the methods described in the literature have been considered to be unacceptable for large-scale production of (*S*)-E3-HB. The reasons are as follows: (*1*) a relatively low concentration, (*2*) tedious isolation and purification processes, and (*3*) a relatively low optical purity. Fortunately, these disadvantages have recently been overcome in developing an efficient system for the baker's yeast-mediated reduction of EA suitable for actual large-scale production.

The first and second disadvantages were simply solved by applying a method using ethanol as the energy source for NADPH regeneration. Because the amount of byproducts inactivating baker's yeast cells was considerably diminished as described, they were active longer and, as a result, the product could accumulate in high concentration.

Regarding the third disadvantage, the reported ee values of the product vary from 70 to more than 95%. To realize those results and improve the ee values, purification and characterization of EA reductases in the baker's yeast cells were very helpful. In 1988, two NADPH-dependent oxidoreductases responsible for the reduction of EA in bakers' yeast were purified and characterized (18). One enzyme, with a K_m value for EA of 0.9 mM, catalyzes the reduction to give (*S*)-E3-HB, and the other, with a K_m value for EA of 17.0 mM, to give (*R*)-E3-HB. Therefore, it was supposed that the ee values might easily vary because of the condition of the initial concentration of EA. The former enzyme would mainly participate in the reduction at a low EA concentration, affording high optical purity. Actually, the optical purity was dramatically improved by applying a fed-batch operation of EA to afford more than 99% ee (*S*)-E3-HB (13).

Bubble-Column Reactor

The baker's yeast-mediated reduction of EA and AC were effectively achieved on a large scale using a bubble-column reactor, which had advantages such as decreasing the operating costs due to low energy requirements. Because the aeration rate is the most important factor in this reactor, its effect on the reduction rate was examined. In the case of EA, the specific reduction rate increased according to the increase in the aeration rate, then became constant. Conversely, the specific reduction rate of AC was almost constant regardless of the aeration rate. These results were consistent with coenzyme requirements and their described regeneration mechanisms.

The large-scale production of (*S*)-E-3HB and (*R*)-PG was performed by applying the fed-batch operation for the addition of the substrates and ethanol in a bubble-column reactor containing 10 L of medium (Table 1) (13). Compared with the results by the conventional procedure described in *Organic Syntheses*, the yield and the optical purity were markedly improved, and the procedure could be applied on an industrial scale (14,15). (*R*)-PG is actually used as a chiral building block for preparation of (*S*)-ofloxacin, although it is now industrially produced by catalytic hydrogenation using a chiral *Ru* complex.

Diltiazem Synthesis

Diltiazem hydrochloride, (2*S*,3*S*)-3-acetoxy-5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-1,5-benzothiazepin-4(5*H*)-one hydrochloride, is a representative calcium channel blocker that has been clinically used as an antianginal and antihypertensive agent in more than 100 countries. In the synthetic process, the key step is the

Table 1. Comparison between EtOH Procedure and the Conventional Procedure Described in *Organic Synethese*

	EtOH procedure (EA reduction)	Conventional (Acetol reductin)
Water	1,000 mL	1,000 mL
Baker's yeast	112 g (77 g)	112 g (100 g)
Energy source	104 g of EtOH (192 g of sucrose)	18 g of EtOH (100 g of sucrose)
Substrate	60 g (15.3 g)	40 g (10 g)
Air	25 L/min	3 L/min
Reaction time	62 h (74 h)	38 h (72 h)
Temperature	30 ° (r.t.)	30 °C (32 °C)
Recovery	40.5 g (10.6 g)	22 g (5.5 g)
Optical rotation	+44.3° (+37.2°)	−17.3° (−15.0°)
ee	99.3% (85%)	98.2% (90%)

introduction of two chiral centers. Optical resolution of a racemic intermediate, lipase-catalyzed enantioselective hydrolysis of methyl 3-phenylglycidate, is now industrially used. Recently, a new efficient synthetic process involving asymmetric reduction by baker's yeast as a key step was reported. The transformation of a racemic ketone, (*RS*)-2-(4-methoxyphenyl)-1,5-benzothiazepin-3,4(2H,5H)-dione afforded only the desired (2*S*,3*S*)-2,3-dihydro-3-hydroxy-2-(4-methoxyphenyl)-1,5-benzothiazepin-4(5*H*)-one (Fig. 6). The difficulty in the industrial application because of its low productivity, caused by low solubility of the substrate in water, was also overcome by changing its physical property. The crystalline substrate was first converted to an amorphous-like solid aggregate by pouring a DMF solution of the substrate into water. After separation, the aggregate was used for the reduction under the usual conditions. Thus, 100 g of the substrate in 1 L of a reaction medium was reduced to produce the chiral intermediate with more than 99% ee in 80% yield (19).

ENANTIOSELECTIVE OXIDATION

Baker's yeast is widely used as a reducing agent in organic synthesis for preparing enantiomerically pure chiral alcohols. One enantiomer can be conveniently prepared by this method, but the other is essentially impossible to prepare with the same system. Several methods for controlling the enantioselectivity of the baker's yeast-mediated reduction have been reported; modifying the structure of the substrate, the reaction conditions, and adding a third reagent. These methods are very interesting but not convenient for large-scale production. Therefore, baker's yeast-mediated oxidation was developed to prepare the antipode of the reduction product on a large scale.

(*R*)-1,2-Alkanediols were found to be easily oxidized to 1-hydroxy-2-alkanones with baker's yeast under aerobic conditions, and (*S*)-1,2-alkanediols, conversely, could not be oxidized under the same conditions. Thus, treatment of racemic 1,2-alkanediols with baker's yeast to oxidize (*R*)-1,2-alkanediols to 1-hydroxy-2-alkanones followed by separation of the 1-hydroxy-2-alkanones afforded the (*S*)-1,2-alkanediols (Fig. 7) (13).

NAD^+ Regeneration

In this biooxidation, NADH-dependent oxidoreductases participating in the asymmetric reduction of 1-hydroxy-2-alkanone catalyze the contrary enantioselective oxidation, and NAD^+ is regenerated from NADH in the yeast cells for the successive oxidation. A preliminary experiment showed that the oxidation did not proceed under anaerobic conditions. Thus, an outline of the oxidation, especially in relation to the condition of oxygen supply, was examined by analyzing the transformation of (*R*)-PG to AC (13). The amounts of oxygen consumed and AC produced increased with increasing $k_L a$, and the ratio was about 1.7 (AC mmol/O_2 mmol). Because 2 mol (*R*)-PG would be theoretically oxidized using 1 mol of oxygen, as shown in Figure 8, this result suggests that oxygen is effectively used during the biooxidation (85% efficiency).

Optical Resolution of 1,2-Alkanediols

Treatment of racemic 1,2-alkanediols with baker's yeast affords (*S*)-1,2-alkanediols and 1-hydroxy-2-alkanones that are easily separated because of a considerable difference in their volatilities. The asymmetric reduction of 1-hydroxy-2-alkanones with baker's yeast affords (*R*)-1,2-alkanediols (13). Thus, the optical resolution of racemic 1,2-alkanediols was conveniently accomplished using only baker's yeast, as summarized in Figure 9.

The oxidative resolution and the asymmetric reduction have been achieved using the bubble-column reactor on a large scale. The specific oxidation rate is sufficiently fast and reaches equilibrium within 24 h, affording the (*S*)-1,2-alkanediols with 79% ee. The aqueous layers after removal of (*S*)-1,2-alkanediols are directly used for baker's yeast-mediated reduction, affording the (*R*)-1,2-alkanediols with over 98% ee.

CHARACTERIZATION OF OXIDOREDUCTASES

There have been several reports on purification and characterization of enzymes from baker's yeast that catalyze the reductions of unnatural substrates. The purposes are to understand the mechanism of the stereochemistry of baker's yeast-mediated transformation and, as a result, to improve the ee of the reduction product by some modifications. Furthermore, some purified reductases would be useful for synthetic purposes.

First, Sih et al. isolated three oxidoreductases that catalyze the reduction of alkyl 4-chloroacetoacetate (20). They reported that stereochemical control by modification of the substrate stems from the difference in relative activities of the D- and L-enzymes depending on the length of the carbon chain in the substrate. Furuichi et al. purified 2-

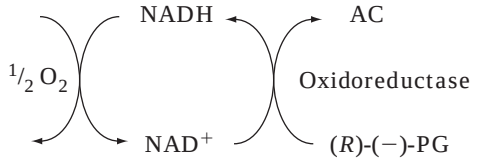

Figure 8. Outline of the reaction mechanism of the yeast-mediated oxidation.

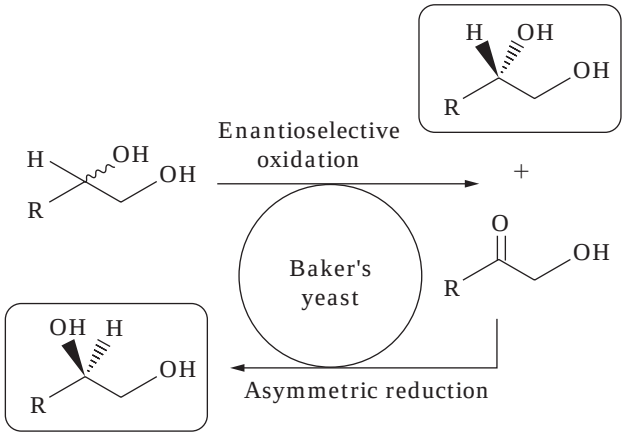

Figure 9. Oxidative resolution of racemic, 1,2-alkanediols with baker's yeast.

methyl-3-oxobutanoate reductase (21) and Heidlas et al. purified two oxidoreductases that catalyze β-, γ-, and δ-keto esters (18). The latter report was very useful for improvement of the ee of the product by baker's yeast-mediated reduction of EA as described. Nakamura et al. isolated four enzymes that catalyze β-keto- and α-alkyl-β-ketoesters and three α-ketoester reductases (22).

IMMOBILIZATION

Immobilized baker's yeast, using polyurethane, calcium alginate, or κ-carrageenan, has been applied to change the reaction conditions (8). Some marked differences have been reported in the stereochemistry, mostly due to a change in the concentration of the substrates. In some cases, immobilization of baker's yeast improved the ee of the products. The immobilized baker's yeast was shown to be active for several weeks, longer than free baker's yeast. However, reductions using immobilized baker's yeast gave lower yields as compared with the analogous reduction with free baker's yeast. Thus, the immobilization did not improve the efficiency of the baker's yeast-mediated transformation for large-scale production.

CONVERSION FACTORS, ABBREVIATIONS, AND UNIT SYMBOLS

SI UNITS (Adopted 1960)

The International System of Units (abbreviated SI), is being implemented throughout the world. This measurement system is a modernized version of the MKSA (meter, kilogram, second, ampere) system, and its details are published and controlled by an international treaty organization (The International Bureau of Weights and Measures).

SI units are divided into three classes:

BASE UNITS		SUPPLEMENTARY UNITS	
length	meter† (m)	plane angle	radian (rad)
mass	solid angle	steradian (sr)	kilogram (kg)
time	second (s)		
electric current	ampere (A)		
thermodynamic temperature‡	kelvin (K)		
amount of substance	mole (mol)		
luminous intensity	candela (cd)		

Quantity	Unit	Symbol	Acceptable equivalent
volume	cubic meter	m^3	
	cubic diameter	dm^3	L (liter) (5)
	cubic centimeter	cm^3	mL
wave number	1 per meter	m^{-1}	
	1 per centimeter	cm^{-1}	

In addition, there are 16 prefixes used to indicate order of magnitude, as follows:

Multiplication factor	Prefix	Symbol
10^{18}	exa	E
10^{15}	peta	P
10^{12}	tera	T
10^{9}	giga	G
10^{6}	mega	M
10^{3}	kilo	k
10^{2}	hecto	h[a]
10	deka	da[a]
10^{-1}	deci	d[a]
10^{-2}	centi	c[a]
10^{-3}	milli	m
10^{-6}	micro	€
10^{-9}	nano	n
10^{-12}	pico	p
10^{-15}	femto	f
10^{-18}	atto	a

[a]Although hecto, deka, deci, and centi are SI prefixes, their use should be avoided except for SI unit-multiples for area and volume and nontechnical use of centimeter, as for body and clothing measurement.

For a complete description of SI and its use the reader is referred to ASTM E380.

A representative list of conversion factors from non-SI to SI units is presented herewith. Factors are given to four significant figures. Exact relationships are followed by a dagger. A more complete list is given in the latest editions of ASTM E380 and ANSI Z210.1.

†The spellings "metre" and "litre" are preferred by ASTM; however, "-er" is used in the *Encyclopedia*.

‡Wide use is made of Celsius temperature (t) defined by

$$t = T - T_0$$

where T is the thermodynamic temperature, expressed in kelvin, and $T_0 = 273.15$ K by definition. A temperature interval may be expressed in degrees Celsius as well as in kelvin.

CONVERSION FACTORS TO SI UNITS

To convert from	To	Multiply by
acre	square meter (m^2)	4.047×10^{3}
angstrom	meter (m)	1.0×10^{-10}†
are	square meter (m^2)	1.0×10^{2}†
astronomical unit	meter (m)	1.496×10^{11}
atmosphere, standard	pascal (Pa)	1.013×10^{5}
bar	pascal (Pa)	1.0×10^{5}†
barn	square meter (m^2)	1.0×10^{-28}†
barrel (42 U.S. liquid gallons)	cubic meter (m^3)	0.1590
Bohr magneton ($€_B$)	J/T	9.274×10^{-24}
Btu (International Table)	joule (J)	1.055×10^{3}
Btu (mean)	joule (J)	1.056×10^{3}
Btu (thermochemical)	joule (J)	1.054×10^{3}
bushel	cubic meter (m^3)	3.524×10^{-2}
calorie (International Table)	joule (J)	4.187
calorie (mean)	joule (J)	4.190
calorie (thermochemical)	joule (J)	4.184†
centipoise	pascal second (Pa s)	1.0×10^{-3}†
centistokes	square millimeter per second (mm^2/s)	1.0†
cfm (cubic foot per minute)	cubic meter per second (m^3/s)	4.72×10^{-4}
cubic inch	cubic meter (m^3)	1.639×10^{-5}
cubic foot	cubic meter (m^3)	2.832×10^{-2}
cubic yard	cubic meter (m^3)	0.7646
curie	becquerel (Bq)	3.70×10^{10}†
debye	coulomb meter (C m)	3.336×10^{-30}
degree (angle)	radian (rad)	1.745×10^{-2}
denier (international)	kilogram per meter (kg/m)	1.111×10^{-7}
	tex‡	0.1111
dram (apothecaries')	kilogram (kg)	3.888×10^{-3}
dram (avoirdupois)	kilogram (kg)	1.772×10^{-3}
dram (U.S. fluid)	cubic meter (m^3)	3.697×10^{-6}
dyne	newton (N)	1.0×10^{-5}†
dyne/cm	newton per meter (N/m)	1.0×10^{-3}†
electronvolt	joule (J)	1.602×10^{-19}
erg	joule (J)	1.0×10^{-7}†
fathom	meter (m)	1.829
fluid ounce (U.S.)	cubic meter (m^3)	2.957×10^{-5}
foot	meter (m)	0.3048†
footcandle	lux (lx)	10.76
furlong	meter (m)	2.012×10^{-2}
gal	meter per second squared (m/s^2)	1.0×10^{-2}†
gallon (U.S. dry)	cubic meter (m^3)	4.405×10^{-3}
gallon (U.S. liquid)	cubic meter (m^3)	3.785×10^{-3}
gallon per minute (gpm)	cubic meter per second (m^3/s)	6.309×10^{-5}
	cubic meter per hour (m^3/h)	0.2271
gauss	tesla (T)	1.0×10^{-4}
gilbert	ampere (A)	0.7958
gill (U.S.)	cubic meter (m^3)	1.183×10^{-4}
grade	radian	1.571×10^{-2}
grain	kilogram (kg)	6.480×10^{-5}
gram force per denier	newton per tex (N/tex)	8.826×10^{-2}
hectare	square meter (m^2)	1.0×10^{4}†
horsepower (550 ft · lbf/s)	watt (W)	7.457×10^{2}
horsepower (boiler)	watt (W)	9.810×10^{3}
horsepower (electric)	watt (W)	7.46×10^{2}†
hundredweight (long)	kilogram (kg)	50.80
hundredweight (short)	kilogram (kg)	45.36
inch	meter (m)	2.54×10^{-2}†
inch of mercury (32°F)	pascal (Pa)	3.386×10^{3}
inch of water (39.2°F)	pascal (Pa)	2.491×10^{2}
