Validation is subdivided into prospective, concurrent, and retrospective according to the timing relationship between the validation work and production (1). Prospective validation studies "are conducted prior to the [commercial] distribution of a new product, or product made under a revised manufacturing process, where the revisions may affect the product's characteristics" (1). Concurrent validation studies employ data derived from production runs for product in distribution. How prospective and concurrent validations are conducted is often defined in preapproved validation protocols. Retrospective validation studies demonstrate, "in some measure, the adequacy of the process by examination of accumulated test data on the product and records of the manufacturing procedures used. Retrospective validation can also be useful to augment initial premarket prospective validation for new products or changed processes" (1). Retrospective validation is generally not conducted according to a preapproved validation protocol, but this practice may change in the future.

In reality, most comprehensive process validation programs involve all three types of validation throughout the lifetime of a product. Consistency validations are most often run prospectively in full-scale production equipment for clinical supplies or commercial purposes. Concurrent and retrospective validations can be used to set new operating ranges not covered by previous validation work or to modify (usually narrow) operating ranges based on manufacturing experience using statistical process control, control charting, or related techniques. A final precaution should be taken regarding recent regulatory concerns on retrospective validation. Retrospective validations are acceptable as an adjunct to a well-defined and comprehensive prospective validation program, but they cannot substitute for it.

Another technical consideration to be defined is the scale at which process validation studies are to be conducted. One could assume that the most authoritative results would be obtained by conducting validation experiments at the scale intended for commercial manufacturing. This assumption normally leads manufacturers to validate process consistency using the equipment to be licensed. It is not unusual, however, to identify 50 operating parameters for which low and high operating range limits are sought. This could involve 100 experiments (if interactions among parameters were disregarded) and up to 1×10^{15} experiments (if interactions are included), which is clearly not feasible in full-scale equipment. The infectivity and limited quantity of viral reagents used in clearance validations prevent these studies from being executed at full scale or in a GMP facility. GMP prohibits the intentional introduction of infectious agents into processing areas (21). In other clearance validations, limitations on the quantity of reagents used for spiking (e.g., host cell proteins, host cell DNA, and affinity ligands) prevent these studies from being conducted in full-scale equipment.

One approach to these problems is to scale down processing steps. Scale-down factors from 10- to 10,000-fold have been employed in industry. In some cases, validation experiments can be run in parallel using multiple identical scaled-down units (e.g., fermentors), which enable statistical design of experimental techniques and a significant shortening in the overall time expended for validation experiments. In other cases a hybrid approach can be taken in which samples of in-process streams taken from the full-scale process are used as feed streams to scaled-down unit operations to assess performance. Virus clearance studies that employ live viruses and retroviruses are conducted in this manner. The use of scaled-down systems for virus clearance validations also facilitates adequate biological containment.

If scaled-down models are to be employed, then it is necessary to establish that the models are predictive of full-scale performance. A useful scaled-down model may be developed by attending to three considerations: performance, design, and quality (PDQ). The performance of the scaled-down model should be identical to or at least predictive of the full-scale process. Typical performance characteristics are titer, cell density, viability, processing rates, and step yields. In cases where there is a performance difference between the scales, it should be quantified and the basis for the difference should be understood from technical and

scientific principles whenever possible. The degree of variation in the model should not be greater than variation at full scale to ensure that process changes are distinguishable from natural variation in the model. During the design of the scaled-down model, it is important to observe the same technical principles used to scale up a unit operation. Typical examples are maintaining constant culture split ratios in cell culture and to preserve chromatography bed heights and linear flow velocities in purification (22,23) during scale-up or scale-down. The quality of the intermediate produced by each scaled-down unit operation should be identical or similar to its full-scale counterpart in its analytical attributes. Finally, it is important to document the qualification of scaled-down models used for process validation.

As the definition of *process validation* states, documentation of validation work is essential. The validation master plan defines the overall validation philosophy, the systems to be validated, the general testing scheme to be employed, the responsibilities of various groups, and the approval mechanisms of the program. It may also define the evolution of validation throughout the life cycle of the process, from its origins in process development through validation maintenance during commercial manufacturing. Another class of document is the validation protocol, which prospectively defines the details for testing of each validation stage. The validation protocol is defined by the FDA as "a written plan stating how validation will be conducted, including test parameters, product characteristics, product equipment, and decision points on what constitutes acceptable test results" (1). The final document is the process validation report, which includes the validation protocol, deviations from the protocol, the results from the validation experiment, and the conclusion regarding the validation status for the processing stage. An important phrase in the definition of process validation is establishing documented evidence. Validation experiments must be documented in reports to be acceptable to regulatory agencies. Copies of the most critical validation reports and summaries of the others are included as part of the license application (20). All other process validation reports must be available to the regulators for inspections as part of the licensing process or during routine postlicense inspections. Failure to submit essential process validation reports can lead to a refusal to file determination by the FDA in the United States. A failure to produce appropriate validation reports during regulatory inspections can lead to a rejected license application or other regulatory actions such as the issuance of an FDA 483 form.

CLEARANCE VALIDATIONS

Clearance validations are generally concerned with the capacity of the recovery and purification process to remove process contaminants. Of particular concern are contaminants with toxic, pharmacological, or infectious potential in humans; studies of these risks are thus among the first to be undertaken in a validation program. The overall approach to this form of validation can be illustrated using the clearance of DNA.

DNA contaminants could contain genes that encode harmful proteins (e.g., toxins and oncogene products), viruses, or retroviruses endogenous to the host. If these gene contaminants could transfect patient cells (resulting in retention and duplication of the gene), then expression of the gene product is a theoretical possibility. The World Health Organization (WHO) has established a 100 pg/dose limit to DNA contaminants in biopharmaceutical products. Proposals are under consideration to increase this limit to 10 ng/dose. One approach to validating adequate clearance of DNA by the process is to measure the DNA level in the BBS over the full range of process operating conditions. If these measurements fall below the 100 pg/dose limit, then the process is validated for this clearance capability. This approach is taken for contaminants whose assays are sufficiently sensitive to quantify levels in the BBS.

Often the assays for DNA and many other process contaminants are not sufficiently sensitive (24) to quantify the contaminant in the bulk product, and an alternate validation approach must be used. Clearance factors are established for upstream unit operations for which DNA levels can be measured in the in-process streams. For downstream steps for which DNA levels are immeasurable, host cell DNA is added (spiked) to the feed stream for each unit operation at a level sufficient to detect it in the output stream. Clearance factors for the downstream steps can then be calculated. The clearance factors are then summed together to give a total clearance factor for the process. This total may be adjusted downward to eliminate double counting steps that have similar mechanisms of clearance. If, for example, a process includes two anion exchange steps, only one would be included in the analysis of clearance. This is based on the notion that virus particles capable of being removed by this mechanism (i.e., anion exchange) would only be removed by the first step. No further clearance could be expected in the second or additional anion exchange steps. The total clearance factor is then applied to the range of DNA levels present in unprocessed bulk harvests. If the calculated DNA level in the BBS is below the 100 pg/dose level, then the process is validated with respect to DNA clearance.

Spiking studies frequently use a hybrid of the full-scale process and scaled-down process models during validation. During full-scale operation, samples of in-process streams are collected and stored. Portions of these samples are spiked with the appropriate contaminant(s) and are then processed over a scaled-down model. In some cases, the spiked species may be labeled with a radioactive label to facilitate quantitative detection in in-process streams. This approach is often used for measuring DNA clearance.

When animal cells are employed during production, clearance of putative viruses constitutes the largest group of clearance validations. The general approach is similar to that described for DNA clearance (25). The product safety concern is to minimize the risk of viruses or retroviruses contaminating the product. The viruses can originate as active or latent viruses associated with the host cells (i.e., endogenous viruses) or can be introduced with raw materials (i.e., adventitious viruses), particularly those derived from animals. In most cases, if viruses exist at all, they are present at levels below detection in in-

process streams, making spiking–clearance studies necessary for all steps in purification. For infectious contaminants such as viruses, there are two modes of clearance. The first involves removal by each purification step, similar to the manner in which DNA is removed. The second involves inactivation, where additives or conditions are used to disable the virus without removing it.

The determination of the viral load to the process depends on the specifics of the host cell system. For Chinese hamster ovary (CHO) cells, the load can be estimated by measuring the level of retrovirus-like particles (RVLPs) present in the unprocessed bulk harvest. CHO cells are known to produce RVLPs, which resemble intracytoplasmic type A retroviruses and cell membrane budding type C retroviruses (26). Even though these particles are defective in their ability to infect other cells, they nevertheless provide a basis for estimating a retroviral load in the process. Levels of 10^5 to 10^7 RVLPs per milliliter of unprocessed bulk are typical. The level of viral clearance to target depends on the perceived risk to the patient. One target for retroviral clearance in processes involving CHO cells is to allow no more than 1 RVLP per million doses of final product (4). The total process retroviral clearance and the level of RVLPs in the unprocessed bulk are used to calculate an estimate of the RVLPs in the final product. The process is considered to be validated for retroviral clearance when the estimated level of RVLPs in the final product is less than or equal to the target. Process clearance factors of 15–20 logs are typical for murine retroviruses. The FDA has suggested that a minimum of 3 logs of clearance is necessary based on the initial level of contamination entering the purification process (16).

For most viruses other than endogenous retroviruses, the validation exercise becomes more academic; there is no reasonable basis for establishing the virus load in the process because there should not be any present. In these cases, measured clearance factors are reported to provide some assurance that if these types of viruses were inadvertently introduced into the process, there would be a defined capacity to clear them.

The spiking studies use model viruses that are representative of the most likely contaminants and when grouped together cover a broad spectrum of virus characteristics. Clearance studies are often performed for a number of viruses to test the ability of the process to clear viruses in general. The choices of model viruses depend on the cell line employed and the viruses could contain. For CHO cells, typical model viruses include a small, nonenveloped virus (e.g., simian virus [SV40], human polio virus 1, animal parvovirus), a medium-to-large enveloped RNA virus (parainfluenza virus, influenza virus, Sinbis virus), a medium-to-large DNA virus (e.g., herpes simplex virus 1 and pseudorabies virus), and a murine retrovirus (e.g., murine leukemia virus) (6). The first three viruses are chosen because they cover a range of virus characteristics, and the murine retrovirus is chosen to model one that could infect the CHO host cell line.

OPERATING RANGES

The purpose of validating process operating ranges is to demonstrate the robustness of the process to excursions in operating parameters that are likely to be encountered in a practical manufacturing environment. The process can be subdivided into a series of validation stages or modules. In some cases, a stage corresponds to a specific processing step (e.g., production fermentation or a chromatography step). In other cases, a stage may be a series of steps (e.g., media preparation or seed expansion). The choice of defining validation stages depends on the specifics of the process and the manner in which the process is controlled. One validation staging strategy for a typical biopharmaceutical process is shown in Figure 1.

Once the stages are identified, inputs and outputs to each stage are defined. Typical inputs include the operating parameters, properties and storage duration of the feedstock derived from the previous upstream step, and quality attributes of critical raw materials used in the step. Typical outputs include the performance attributes for the stage (e.g., titer and yield) and the properties of the product stream (product homogeneity, purity, contaminant levels, and chromatogram shape). For chromatographic steps, the shape of the chromatogram has been used to indicate step performance. Suggested quantitative measures of chromatogram shape have been proposed, such as SPEW, for the retention times (or chromatogram distance) when

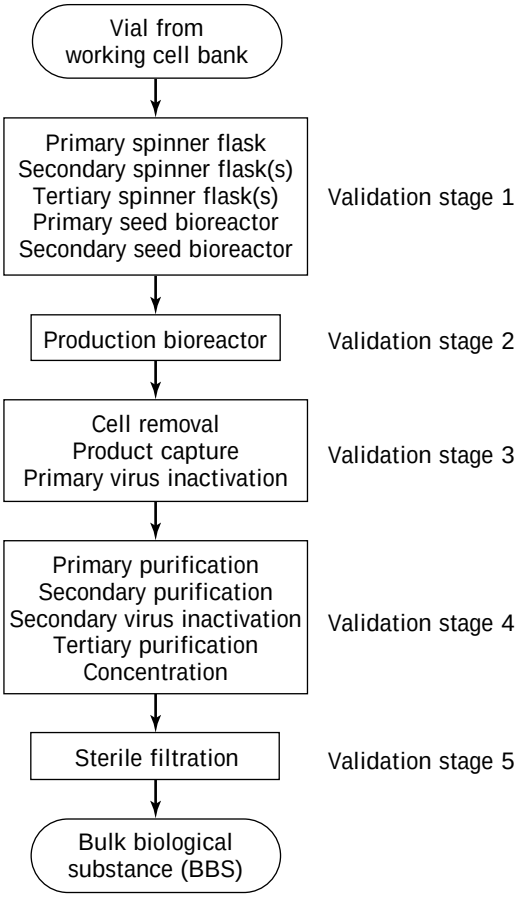

Figure 1. Validation of a process can be simplified by dividing the process into a sequence of validation stages, some of which include multiple processing steps.

the product collection starts, peaks, and ends and the width of the elution peak (27). In general, all in-process controls must be included within the list of process step outputs. Representative inputs and outputs for a fermentation stage and a purification stage are illustrated in Figure 2.

It is usual to prioritize the inputs to be validated based on the *(1)* sensitivity of process outputs to variations in each input, *(2)* proximity of the validation stage to the final product, and *(3)* technical difficulty in controlling an input to within a specified range. Assessment may be based on an analysis of all data that are available and documented, including process development, monitoring of clinical manufacturing, and any experiments specifically designed to gauge the sensitivity of the process to variations. The most important stage inputs must be included in the operating range validation program.

Having identified the parameters to be validated, the next step is to define the criteria on the outputs that will be used to determine whether a validation experiment is successful. These criteria are typically a mixture of process performance results (e.g., titer, yield, and concentration) and quality of the product intermediate (e.g., protein purity, product homogeneity, and contaminant levels). The need for both types of criteria is based on the assumption that no amount of testing of the end product can ensure consistency without also showing the process to be controlled. These criteria are based on a variety of considerations and experience with the process. In some cases, these criteria are based on the output range results from operational history of the process during development or clinical supply production. In other cases, they may be based on equipment limitations. For example, a minimum titer from the production fermentation tank may be established by the resin bed size and lower capacity limit for the first chromatography step in a process. In still other cases, output criteria may be derived from product specifications. If, for example, product purity is primarily determined by the performance of the first purification step of a five-step process producing a monoclonal antibody, then the product purity specification can be used to define a purity output criterion for the first step.

It is then necessary to define an overall experimental paradigm. Usually, the experimental program begins with a set of proposed operating ranges for the inputs to be evaluated for each validation stage. These ranges may be based on equipment capability, theoretical considerations, process development data, operating history, the need for flexibility in manufacturing, or other considerations. Each validation stage is then run using inputs at the limits of the proposed operating ranges. These experiments can be run to investigate one input at a time or in parallel using statistical design of experiment (DOE) techniques. The outputs from these experiments are obtained, and the proposed operating ranges become proven acceptable ranges (PARs) (9) if the output criteria are met. If the output cri-

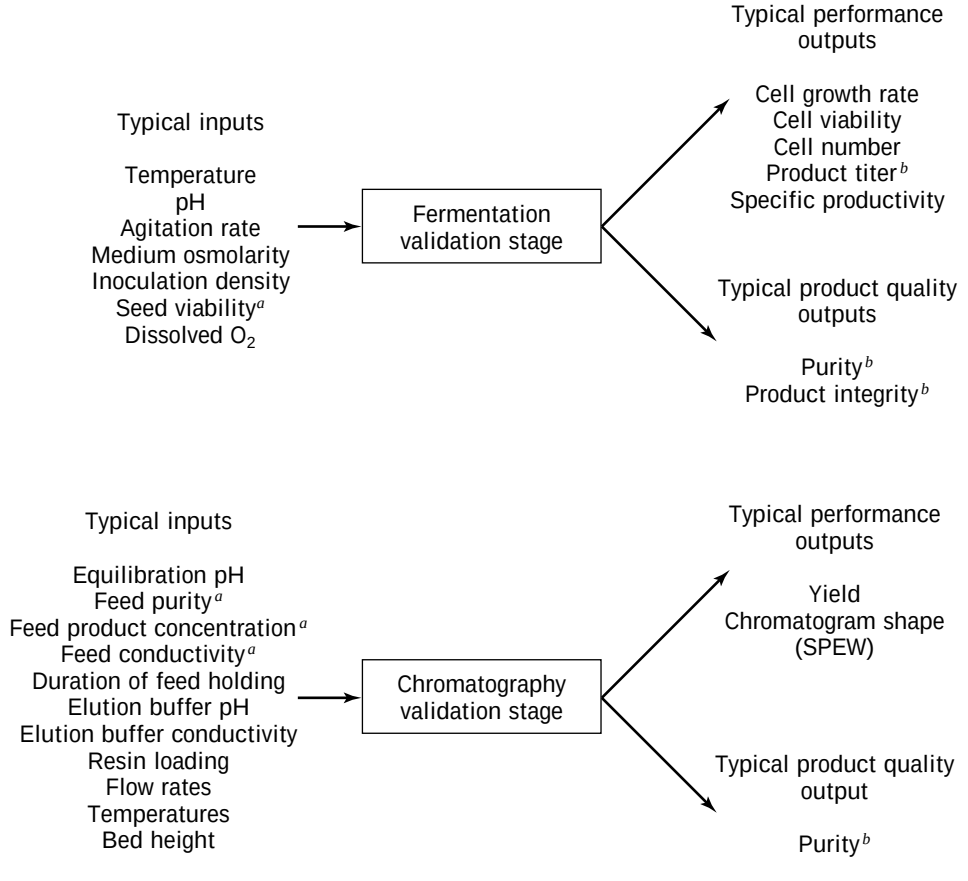

Figure 2. Each validation stage is driven by a set of inputs and produces a set of outputs. The outputs may be related to process stage performance or product quality. The general goal is to validate that the outputs are maintained within satisfactory ranges when the inputs are permitted to vary within defined ranges. [a]Forward linkage input–output from previous stage; [b]forward linkage output–input to next stage.

teria are not met, then the input ranges are narrowed and the experiments are repeated until the criteria are met.

This approach is taken for each validation stage. However, it may be necessary to explore interactions among the validation stages. For example, the performance of a purification step or the quality of the product it produces often depends on the quality of the input feed stream. Because the input feed stream is an output from the previous purification step, one way to handle these interactions is to include the input stream properties as other inputs to the validation stage. Input streams of high and low quality are then required. One approach to obtain these streams is to operate the upstream purification step under best- and worst-case conditions. Alternatively, by knowing the function of the purification step to be validated (e.g., endotoxin removal, host cell protein removal, DNA removal, or removal of product isoforms), one can prepare input streams of high and low quality by spiking in the appropriate species to be removed. The pair-wise validation of processing steps has been referred to as forward linkage validation. *Worst case* and *most appropriate challenge* are terms that describe the validation of a process run with its critical operating parameters set at the limits of their operating ranges (11).

PARs are generally used to establish maximum operating ranges (MORs) bounded by action limits for the important process variables. When a process variable exceeds the outer limits of an MOR, then the impact on the process and the product may be unknown. This event often requires corrective action to be taken by operations staff and various QA systems. Depending on the importance of the variable, the duration and extent of the excursion beyond the MOR, and other operating data from process operations, a variety of follow-up actions may be appropriate. These actions can include relatively minor responses such as requiring a more detailed batch record review or more analytical testing than is normally required for product release when appropriate analytical systems and databases are available. Other QA responses include launching an investigation to look for the cause of the problem, requiring the demonstration of lot stability before release, requiring reprocessing of the lot, or rejecting the lot.

VALIDATION OF PROCESS CONSISTENCY

From the standpoint of process control, it is necessary to determine the extent to which the process and product vary naturally under normal operating conditions. This knowledge is important in defining the normal operating range (NOR) bounded by alert limits for each important process variable. When a NOR is exceeded, operations staff may have to take corrective action. NORs must fall within the MORs established in most cases by the PAR studies. When NORs exceed MORs, the process is not sufficiently controlled to provide "a high degree of assurance that a specific process will consistently produce a product meeting its pre-determined specifications and quality attributes" (1). NORs are typically calculated from replicate runs of the process that produces product that meets specifications. The calculation of a 99% or 95% confidence interval is a typical means of establishing NORs.

The relationship among ranges for any process variable is shown in Figure 3. Process development or optimization often establishes a desired value known as a target or setpoint (e.g., 37 °C) for a process variable. Under normal operating conditions, however, a process variable varies within an NOR (e.g., 37 ± 0.5 °C). Validation studies can determine a PAR (e.g., 37 ± 2.0 °C), which can be used to set the MOR (e.g., 37 ± 2.0 °C). The MOR falls within a broader range bounded by the edge of failure (e.g., 32–40 °C). A process variable that exceeds the edges of failure will cause the process or product to fail, but the edges of failure are not typically determined during process development or validation except by accident. The ranges over which the variable can be controlled (e.g., 20–80 °C) and for which it can exist (e.g., ≥ −273 °C) are still broader (9).

POSTLAUNCH PROCESS VALIDATION

Process validation is a requirement for product licensing. However, it continues throughout the lifetime of the product. Experience with a process in the commercial manufacturing facility is often very limited when the facility files license applications. Experience may mean production of as few as three or five lots to meet the qualification lot requirements for filing in the United States or Europe, respectively. These numbers of lots are insufficient to generate meaningful process or product specifications. As a consequence, initial process validation data are generally derived from pilot plant experiences obtained during the production of supplies for clinical trials or the development of the process. Regulatory authorities accept this information as sufficient for licensing, but many of the MORs, NORs, and product specifications may be refined during actual commercial production experience. In most cases, changes to these ranges are reported to regulatory authorities in annual updates, particularly when the change re-

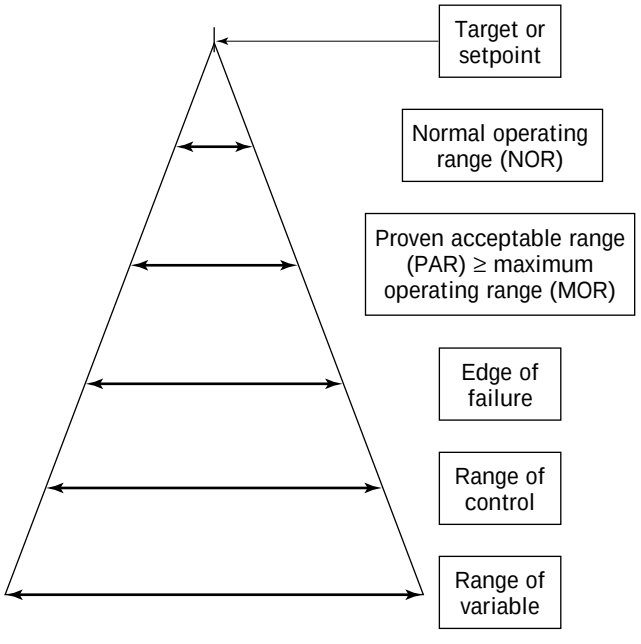

Figure 3. Relationships among ranges for process variables.

sults in a narrowing of a control range or an improvement in product quality. In other cases, however, the change may need to be proposed to the FDA and regulatory approval gained before implementation.

FUTURE PROSPECTS

The significance of process validation has grown from its origins in the mid 1970s to the present time. Of major importance to the biopharmaceutical industry has been the total absence of medical incidents traceable to process control problems, largely because of the application of validation principles. More recently, regulatory authorities have reconsidered their former positions that most changes to the manufacturing process, including relatively minor ones, led to a product that might be different. In the past, clinical studies were required to establish the safety and efficacy of the new product. Today, many changes can be justified using analytical data and process validation studies without the need to undertake a clinical trial. More recently, the FDA has dropped the requirement for filing an establishment license application (ELA) for "therapeutic recombinant DNA-derived products and/or monoclonal antibodies" (20). The FDA has also dropped the requirement for the FDA Center for Biologics Evaluation and Review (CBER) to release test each lot of product with this classification. These changes are due largely to the increase in powerful analytical methods that are available to test these types of products and the greater sophistication of validation to characterize the process.

Because of the growing importance of process validation and the absence of all but the most general guidance from regulatory agencies, it is likely that process validation will become the subject of future regulatory focus by the FDA and the European Union. Most cGMP regulatory requirements are specified for final product, and efforts in the United States to define cGMPs specifically for the production of bulk pharmaceutical chemicals (also known as APIs) are in progress (19). It is in these guidelines that we can expect more practical directives on process validation to be detailed. Given the expense of process validation work, guidance that leads to improved definition of requirements and elimination of process validation studies of marginal significance will be welcome. A reexamination of the balance among prospective, concurrent, and retrospective validation approaches will also be useful. Industry will need to contribute to these debates to ensure that validation costs and their impact on the overall health care system cost are directed toward areas with the greatest impact on the safety and efficacy of biopharmaceutical products.

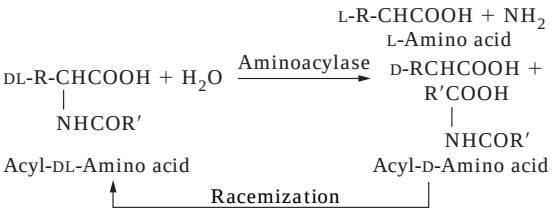
OUTLINE

Bibliography

At present, fermentative and chemical synthetic methods are used for the industrial production of L-amino acids instead of conventional isolation from protein hydrolysates. However, chemically synthesized amino acids are optically inactive racemic mixtures of L- and D-isomers. The L form is the physiologically active natural form and is therefore the required form for medicine and food. To obtain L-amino acid from the chemically synthesized DL form, optical resolution is necessary.

Generally, optical resolution of racemic amino acids can be carried out by physicochemical, chemical, enzymatic, and biological methods. Among these methods, an enzymatic method developed by Chibata et al. (1) using mold aminoacylase is one of the most advantageous procedures, yielding optically pure L-amino acids. The reaction catalyzed by the enzyme is as follows.



Chemically synthesized acyl-DL-amino acid is asymmetrically hydrolyzed by aminoacylase to give L-amino acid and the unhydrolyzed acyl D-amino acid. After concentration, both materials are easily separated on the basis of the difference in their solubilities. Acyl-D-amino acid is racemized and reused for the resolution procedure.

Chibata et al. (1) studied enzymes catalyzing the reaction and found that aminoacylase produced by *Aspergillus oryzae* has high activity and broad substrate specificity, that is, it can asymmetrically hydrolyze many kinds of acyl-DL-amino acids.

From 1953 to 1969, this mold aminoacylase was used for the industrial production of several L-amino acids. This method was one of the most advantageous procedures for the industrial production of L-amino acids. However, because the enzyme reaction was carried out batchwise by incubating a mixture containing the substrate and soluble enzyme, the procedure had some disadvantages for industrial purposes. For instance, to isolate L-amino acid from the enzyme reaction mixture, it was necessary to remove enzyme protein by pH and/or heat treatment. Thus, even if enzyme activity remained in the reaction mixture, the enzyme had to be discarded because there was no suitable procedure for isolating the active enzyme from the mixture. In addition, a complicated purification procedure was necessary for the removal of proteins and coloring materials contaminating the crude enzyme preparations usually used for industrial purposes.

To overcome these disadvantages and to improve this enzymatic method, we extensively studied the continuous optical resolution of DL-amino acids using a column packed with immobilized aminoacylase (2). An efficient and automatically controlled enzyme reactor system was achieved, and since 1969, we have been industrially operating a series of these reactors in our plants.

Various immobilization methods were investigated, and relatively active and stable immobilized aminoacylases were obtained by ionic binding to DEAE-Sephadex (3), covalent binding to iodoacetylcellulose (4), and entrapping into polyacrylamide gel (5). However, for the industrial operation of a continuous enzyme reaction using an immobilized enzyme, it was necessary to satisfy many conditions. Thus, the characteristics of these three immobilized aminoacylases were compared, and aminoacylase bound to DEAE-Sephadex was chosen as the most advantageous enzyme preparation for the industrial production of L-amino acids, because (*1*) preparation is easy, (*2*) the activity is high, (*3*) the stability is high, and (*4*) regeneration of deteriorated immobilized enzyme is possible.

To design the most efficient enzyme column, the following are important factors: (*1*) the effect of flow rate of substrate on the reaction rate, (*2*) the flow of the substrate solution, (*3*) the effect of column dimension on the reaction rate, and (*4*) the pressure drop in the column.

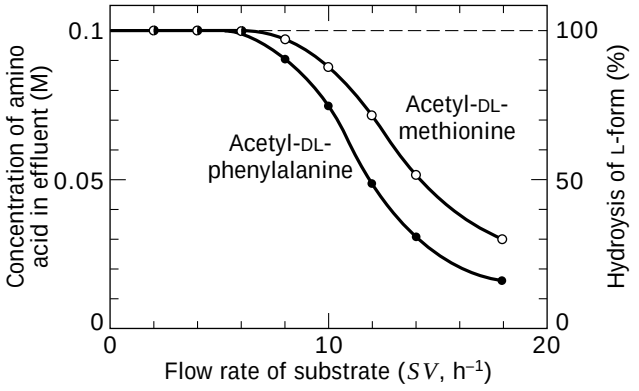


Figure 1. Continuous hydrolysis of acetyl-DL-amino acids by an immobilized aminoacylase column. Relationship between flow rate of substrate and extent of hydrolysis. Aminoacylase was immobilized by ionic binding to DEAE-Sephadex. Concentration of substrate, 0.2 M (containing 5×10^{-4} M Co^{2+}); reaction temperature, 50 °C.

Because it is one of the factors considered in the design of an enzyme reactor, the relationship between the flow rate of a substrate solution passing through the enzyme column and the extent of the reaction must be investigated in advance. We investigated the relationship between the flow rate of a solution of acetyl-DL-methionine or acetyl-DL-phenylalanine and the extent of the reaction, and the results are shown in Figure 1 (2). An aqueous solution of acetyl-DL-amino acid (0.2M, pH 7.0 to 7.5, containing 5×10^{-4} M Co^{2+}) was passed through a DEAE-Sephadex-aminoacylase column at various flow rates at 50 °C. In Figure 1, flow rate is expressed in terms of space velocity. The space velocity is the volume of liquid passing through a given volume of immobilized enzyme in 1 h divided by the latter volume. If the space velocity is reduced, that is, the flow rate is slowed, the reaction proceeds more effectively and the relationship between the flow rate and the extent of the reaction is sigmoidal. As shown in Figure 1, when the concentration of L-amino acid in the effluent reached 0.1 M, the reaction stopped. This result indicates that the L-form of 0.2 M acetyl-DL-amino acid was completely hydrolyzed and its D-form was not hydrolyzed, that is, asymmetric hydrolysis occurred.

The pressure drop of the enzyme column is also important factor in the design of an enzyme reactor. Thus, the relationship between the flow rate of substrate solution and the pressure drop of the column was investigated using columns of various lengths. The pressure drop of the DEAE-Sephadex-aminoacylase column was found to be proportional to the flow rate of substrate solution and the column length.

Table 1. Production of L-Amino Acids on 1,000-L DEAE-Sephadex Aminoacylase Column

		Yield (theory) of L-amino acids per	
L-Amino acid	Space velocity	24 h (kg)	20 days (kg)
L-Alanine	1.0	214	6,420
L-Methionine	2.0	715	21,450
L-Phenylalanine	1.5	594	17,820
L-Tryptophan	0.9	441	13,230
L-Valine	1.8	505	15,150

In addition, by considering some other properties of the immobilized enzyme, such as optimum pH, the effect of temperatures on the reaction rate and stability, and so on, we designed an enzyme reactor system for continuous production of L-amino acids, as shown in Figure 2. In this system, the flow rate and pH of substrate solution and the operating temperature can be automatically controlled and recorded.

Since 1969, continuous optical resolution of acetyl-DL-amino acids has been carried out using this system, and several kinds of optically active amino acids such as methionine, phenylalanine, valine, and others have been industrially produced at Tanabe Seiyaku Company, Japan. Several examples of the production of L-amino acids are summarized in Table 1, which shows the space velocity and the theoretical yield for each amino acid produced in a 1,000-L aminoacylase column. That was the first industrial application of immobilized enzymes.

The immobilized aminoacylase was very stable, as shown in Figure 3, and maintained 60 to 70% of its initial activity after continuous operation for 30 days at 50 °C. The enzyme column can be completely regenerated after prolonged operation by the addition of an amount of aminoacylase corresponding to the lost activity. The carrier, DEAE-Sephadex, is also very stable and has been used for more than 5 years in our column process without any change in adsorption capacity for the enzyme, shape, or pressure drop. A continuous enzyme reaction using such a stable immobilized enzyme gives not only high productivity per enzyme unit, but also high product yield, because contamination of the effluent by such impurities as proteins and coloring substances does not occur, so the product can be obtained by simple purification and the amount of substrate required is reduced. Further, automatic operation reduces labor costs, and a significant reduction in production cost can be expected in comparison with the conventional batch process using soluble enzyme. A comparison of the production costs of L-amino acids by the conventional batch process using soluble enzyme and by the continuous process using immobilized enzyme in our plant is shown in Figure 4. In the immobilized enzyme process, the overall production cost is more than 40% lower than that of the conventional batch process using soluble enzyme. Savings of enzyme and labor costs are the main contributors, as are the increase in product yield from the easy isolation of L-amino acids from the reaction mixture. Although DEAE-Sephadex is a relatively expensive carrier, production costs are not greatly affected by the cost of the carrier, because it can be used for a very long period, as mentioned.

Besides immobilization by ionic binding, mold aminoacylase from *Aspergillus* sp. was also immobilized by covalent binding to alkylaminosilanized porous glass with glutaraldehyde or to the diazonium derivative of acylaminosilanized porous glass, and these immobilized aminoacylases were used for continuous preparation of L-amino acids from acetyl-DL-amino acids (6).

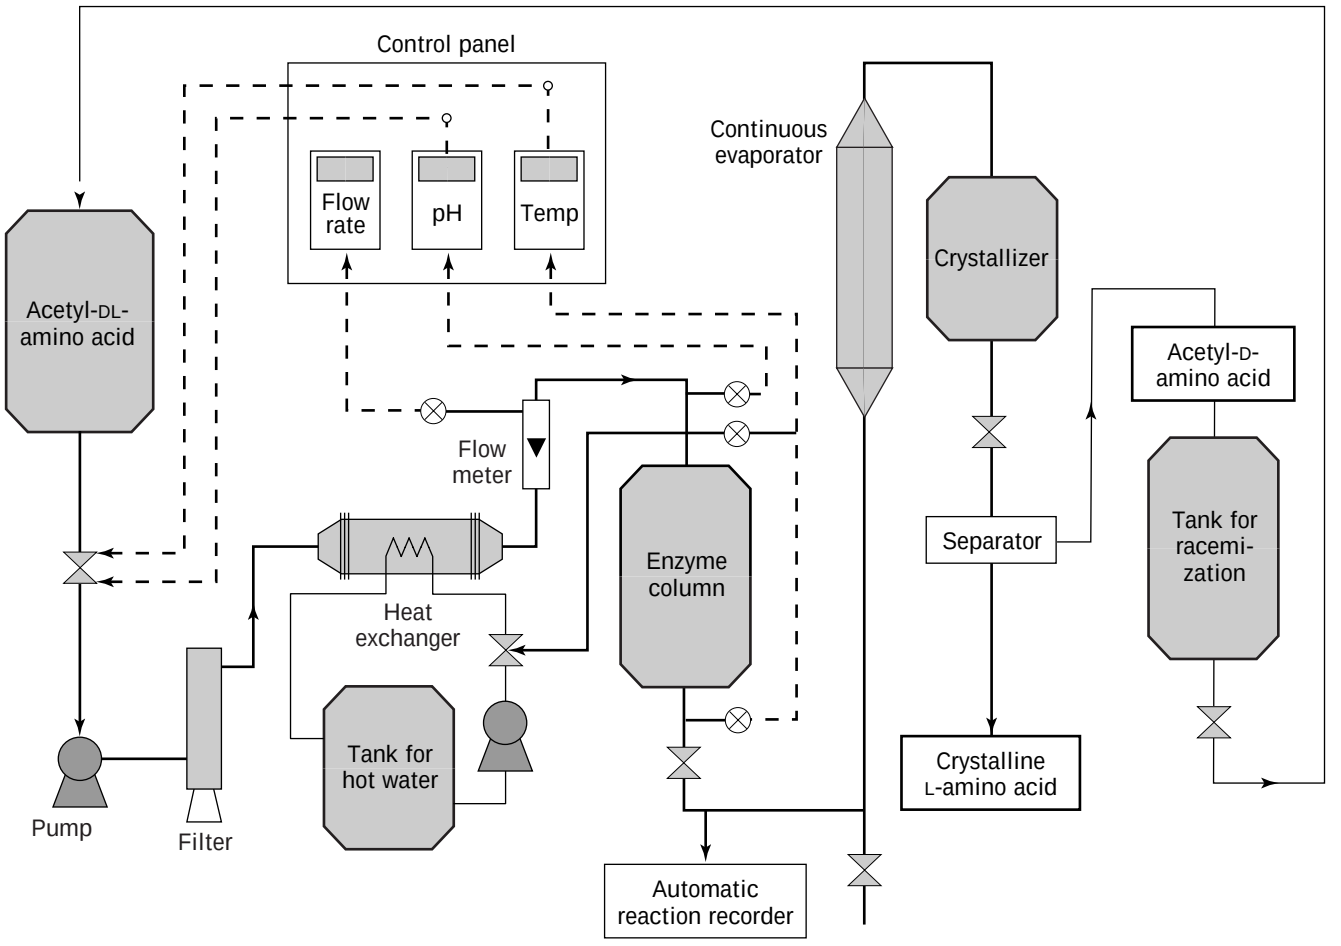

Figure 2. Flow diagram for the continuous production of L-amino acids by immobilized aminoacylase.

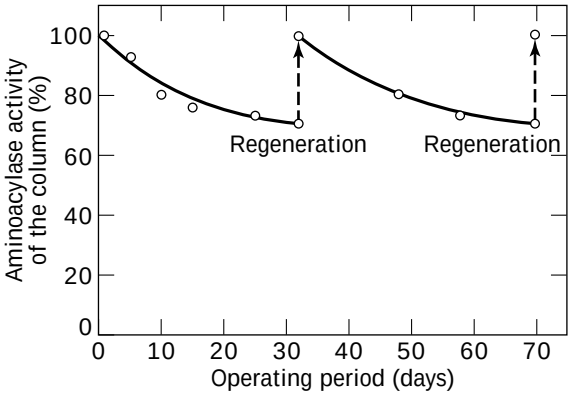

Figure 3. Stability and regeneration of an immobilized aminoacylase column. Aminoacylase was immobilized by ionic binding to DEAE-Sephadex, and 0.2 M acetyl-DL-methionine (containing 5×10^{-4} M Co^{2+}) was continuously passed through a column packed with the immobilized aminoacylase at a flow rate of SV = 2 at 50 °C.

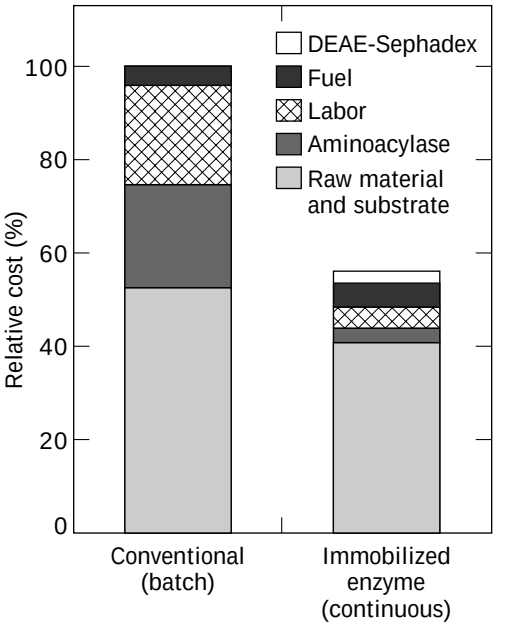

Figure 4. Comparison of production costs of L-amino acids by batch and continuous processes.

Bacterial and animal aminoacylases have been also immobilized. Bacterial aminoacylase has been covalently bound to diazotized polyaminostyrene (7,8). The aminoacylase from pig kidney was immobilized by ionic binding to DEAE-cellulose (9) and by covalent binding to the azide derivative of Enzacryl AH (10) or diazotized Enzacryl AA (11). However, these preparations were used batchwise and on only a laboratory scale for the preparation of L-amino acids from acyl-DL-amino acids.

OUTLINE

INTRODUCTION

L-Glutamic acid monosodium salt was first discovered by Dr. Kikunae Ikeda as a taste component of *konbu*, a sea tangle, which is a food taste-enhancing material traditionally used in Japan. Based on this discovery, L-glutamic acid monosodium salt was industrially produced from wheat gluten by hydrolysis with hydrochloric acid (1). Later, the raw material was replaced by soybean protein, and a synthetic method was studied and finally industrialized. In addition attempts were made to produce α-ketoglutaric acid, which is a precursor of L-glutamic acid, by organic acid fermentation. These attempts were aimed at producing L-glutamic acid by transamination from the resulting α-ketoglutaric acid.

In 1957, Kinoshita et al. succeeded in establishing a process to produce L-glutamic acid by direct fermentation from a carbohydrate and ammonia using a microorganism, *Corynebacterium glutamicum*, which they had isolated from nature (2). Compared to the then conventional hydrolytic process comprising the hydrolysis of natural protein, this direct fermentation process made it easy to secure the production raw material, and at the same time facilitated a drastic reduction of cost.

With establishment of the fermentative process, the monosodium glutamate production industry showed rapid growth. In recent years, the production worldwide has been estimated to reach to about 600,000 tons per year as L-glutamic acid (Table 1). As the production cost was cut

Table 1. Production of Monosodium Glutamate

Years	Production of MSG (t/year)
1954	7,652
1960	22,177
1970	92,935
1988	340,000
1994	592,000

Note: MSG, monosodium glutamate.

owing to improvement in production technologies, the production plants, initially operated only in Japan, have been extended worldwide, particularly to South East Asia where there are abundant supplies of raw materials and also consumption of the product (Table 2).

SYNTHETIC PATHWAY OF L-GLUTAMIC ACID

In the biosynthesis of L-glutamic acid (Fig. 1), a key step is a reductive ammonia-addition reaction of α-ketoglutaric acid, which constitutes the TCA cycle:

$$\alpha\text{-ketoglutaric acid} + \text{NADPH} + \text{H}^+ + \text{NH}_4 \xrightarrow[\text{glutamate dehydrogenase}]{} \text{L-glutamic acid} + \text{NADPH}^+ + \text{H}_2\text{O}$$

NADPH, the coenzyme of this reaction, is supplied through coupling in the reaction to form α-ketoglutaric acid:

$$\text{isocitric acid} + \text{NADPH}^+ \xrightarrow[\text{isocitrate dehydrogenase}]{} \alpha\text{-ketoglutaric acid} + \text{CO}_2 + \text{NADPH} + \text{H}^+$$

L-GLUTAMIC ACID FERMENTATION

Initially, a glutamic acid–producing bacterium was isolated as a biotin-requiring mutant of *C. glutamicum*, and a fermentative production process in which the strain is cultured in a medium containing a limited concentration of biotin was industrialized. Afterward, use of cheap cane molasses attracted attention as a raw material carbohydrate; however, cane molasses contains a large amount of biotin. To enable use of cane molasses, the penicillin shot method was developed, which made it possible to accumulate L-glutamic acid in the presence of excess biotin, and the industrial technology had been further advanced. Subsequently, techniques to use oleic acid–requiring strains or to add saturated higher fatty acid esters (or saturated higher fatty acid) such as polyoxyethyleneglycol parmityl ester were developed. Also, use of various carbon source materials other than carbohydrate was examined. L-Glutamic acid fermentation from *n*-paraffin (3,4) has been much studied, and the production process has become almost as well established as the use of carbohydrate. However, the production from *n*-paraffin has never been commercialized because of the high cost of the main raw material, as well as other reasons. Currently, the penicillin shot method using cane molasses, beet molasses, glucose, and so forth as raw materials is most frequently employed in industry because of cost, stable production, and other reasons.

METABOLIC MECHANISMS OF L-GLUTAMIC ACID PRODUCTION

Change of the Membrane-Permeation System

As already mentioned, the L-glutamic acid production process was initially established using a biotin-requiring bacterial strain and strict control of biotin concentration. It was later found that production could be accomplished even under excess biotin conditions by adding penicillin, using oleic acid-requiring microorganisms, and adding saturated higher fatty acid esters such as polyoxyethyleneglycol parmityl ester or fatty acid itself. It was also found that, under high oleic acid concentration, although L-glutamic acid was not produced by the addition of higher fatty acids or their esters, the penicillin shot method was still effective. Today, these phenomena are explained as attributable to dependency of L-glutamic acid accumulation on the changes of the membrane-permeation system (Fig. 2). More particularly, biotin plays a role in the biosynthesis of oleic acid by glutamic acid–producing bacteria, and under the biotin-controlled condition, oleic acid formation is repressed. This causes a change in fatty acid composition and phospholipids that constitute the cell membrane and, consequently, a change in permeability of L-glutamic acid through the membrane. Oleic acid–requiring mutants and the direct addition of saturated higher fatty acid bring about a similar change in composition whether or not biotin is present, and produce a similar effect. Hence these conditions do not give rise to L-glutamic acid accumulation at a high concentration of oleic acid. On the other hand, it is believed that the addition of penicillin inhibits synthesis of cell walls rather than changes in the composition of fatty acid that constitutes the membrane, thereby causing a difference in the osmotic pressure between the outside and the inside of the membrane. It is this pressure differential that causes the membrane to undergo a change that leads to L-glutamic acid accumulation.

When *n*-paraffin is used as a raw material, the mechanism of L-glutamic acid production is explained by a similar change of membrane permeability, although a threonine-requiring strain is used in place of the biotin-requiring strain used in carbohydrate fermentation; and the presence of a copper ion additionally affects L-glutamic acid formation (4).

Other Factors for Excess Formation of L-Glutamic Acid

There has been a report on the change in the activity of the L-glutamic acid–producing enzyme system in its L-glutamic acid formation phase (6). Furthermore, in some cases, L-glutamic acid–producing strains with an enhanced biosynthetic enzyme system have been obtained by recombinant technology. Thus, L-glutamic acid production may not be totally explained by "leakage" of the amino acid. This may be a problem to be studied in the future.

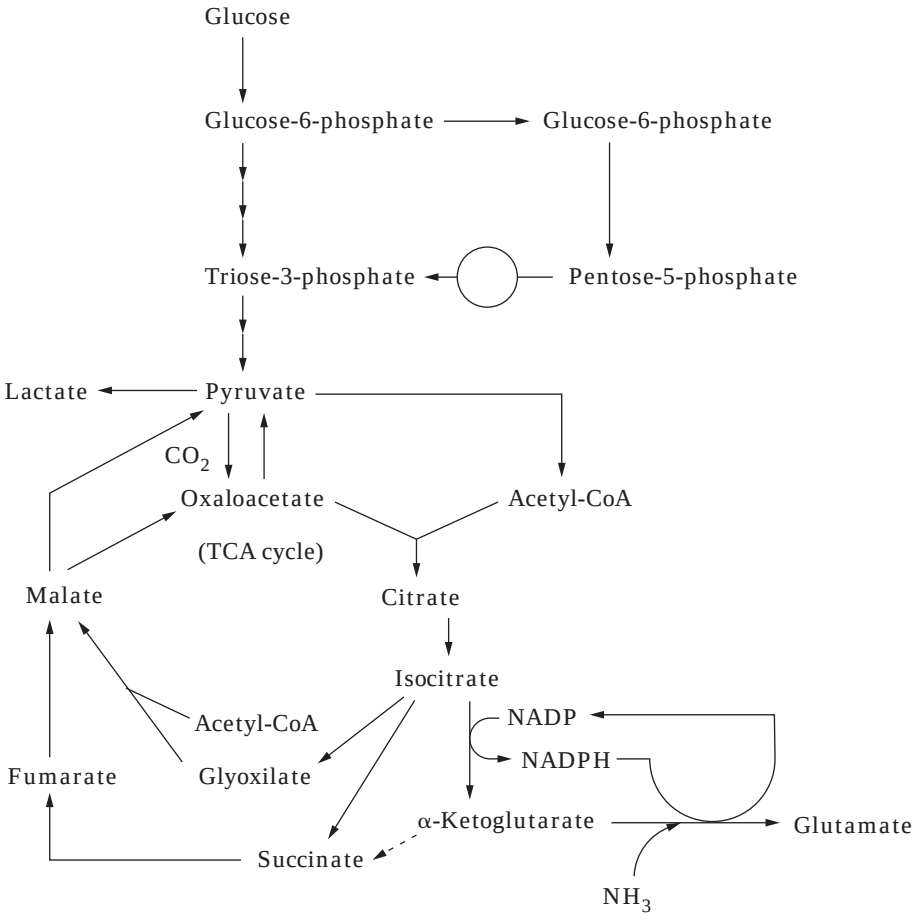

Figure 1. The biosynthetic pathway of glutamate.

In a recent report (7) a gene for detergent-sensitivity (*dtsR*) carried by a wild-type strain was identified using a polyoxyethylene sorbitan fatty acid ester–sensitive strain of *Brevibacterium lactofermentum*, and a mutant lacking this gene was found to accumulate L-glutamic acid in a medium containing excess biotin and in the presence of polyoxyethylene sorbitan oleate ester. Under these conditions the wild-type strain did not accumulate the amino acid. This strain had its specific activity of 2-oxoglutarate dehydrogenase complex (an enzyme involved in the TCA cycle that converts α-ketoglutaric acid to succinyl-CoA) reduced to one-third of that possessed by the wild-type strain. From these findings, Kimura et al. (8) proposed a mechanism of L-glutamic acid fermentation: "The target of controlling biotin concentration and addition of surfactants is biotin enzyme complex containing DtsR, and the reduction of the activity of this biotin enzyme complex may possibly cause glutamic acid formation." According to this report, the sensitive strain propagates in response to the concentrations of oleic acid and polyoxyethylene sorbitan oleate ester in the medium. Protein, a product of the DtsR gene, had homology with a biotin enzyme derived from other organisms and was involved in the biosynthesis of higher fatty acid. Furthermore, accumulation of L-glutamic acid has been reported by a mutant strain having membrane permeability to L-glutamic acid. The mutation was induced from a wild-type methanol-assimilating strain that does not accumulate L-glutamic acid in the medium (9).

These findings suggest some ideas for the improvement of techniques to construct L-glutamic acid–producing strains by the recombinant technology. In the future, more efficient fermentation production of L-glutamic acid may be possible through diverse analyses of production processes and mechanisms, and construction of mutant strains.

INDUSTRIAL PRODUCTION OF MONOSODIUM GLUTAMATE

Fermentation Processes

The typical L-glutamic acid–producing wild strain of *C. glutamicum* isolated from nature requires biotin for growth and accumulates L-glutamic acid in the medium when cultured under conditions that include sufficient ammonium ions and controlled biotin concentration. This glutamic acid–producing strain shows different forms of fermentation, depending upon fermentation conditions other than biotin concentration. Basic fermentation conditions and the forms of fermentation corresponding to them are shown in Table 3. Glutamic acid production requires sufficient oxygen, appropriate amounts of phosphoric acid, and a nitrogen source, as well as controlled biotin concentration. This strain grows vigorously in a medium containing excess biotin and does not accumulate L-glutamic acid. However, fermentation production under

Table 3. Coversion of Fermentation by Glutamic Acid–Producing Bacteria with Nutrient and Atmospheric Regulation

Regulatory factors	Coversion of fermentation
Oxygen	Lactate or succinate ↔ Glutamate (anaerobic) (aerobic)
NH_4^+	α-ketoglutarate ↔ Glutamate ↔ Glutamate (unsatisfy) (optimal) (oversatisfy)
pH	*N*-Acetylglutamine ↔ Glutaminate (or Glutamine) (acidic) (basic)
Phosphate	Valine ↔ Glutaminate (high)
Biotin	Lactate or succinate ↔ Glutamate (satisfy) (deficiency)

Source: From Ref. 10.

controlled biotin concentration involved two difficulties: *(1)* available raw materials were restricted (particularly, it was difficult to use cane molasses due to its high biotin content) and *(2)* fermentation production lacked stability because cell growth was not stable. Hence in order to solve this problem, various processes were attempted to accumulate L-glutamic acid under excess biotin conditions. Among these, there are two methods that have become employed as typical methods for industrial production. One is the penicillin shot method in which penicillin is added to cells cultured with sufficient biotin, and the other is the addition of saturated fatty acids or their esters to accumulate L-glutamic acid. The latter method was developed with the elucidation of the physiological effect of the penicillin shot. At present, the penicillin shot method is considered to be advantageous because it is stable in industrial operation. This method is discussed in detail later.

Raw Materials

From the viewpoints of stable supply and low cost, cane molasses (hereinafter referred to simply as "molasses"), beet molasses, and glucose are popular as the main raw material carbon sources. When molasses is used, it is necessary to employ a technique for excess biotin conditions described in the article GLUTAMIC ACID PRODUCING MICROORGANISMS because molasses contains excess biotin. On the other hand, when beet molasses and glucose are used, it is necessary to add biotin to the medium, whether using conditions of excess biotin or limited biotin. The following discusses the penicillin shot method using molasses.

When molasses is used as a main raw material, necessary components such as carbon, nitrogen, phosphoric acid, potassium, sodium, sulfuric acid radical, various metal ions, vitamins, and so on can be derived from this raw material. Any components revealed to be lacking by preliminary tests are supplemented to the medium.

In the following description of the penicillin shot method of L-glutamic acid fermentation, *C. glutamicum* and molasses are used, respectively, as the strain and the raw material, and culturing is carried out by a fed-batch system.

The fermentation tank is a basic aeration/agitation tank, shown in Figure 3. Generally, jacket-type (small fermenter) and coil-type (large fermenter) cooling devices are used for controlling the temperature, but cooling may also be effected by a system that cools the fermentation liquor with an external heat exchanger. In the L-glutamic acid fermentation from carbohydrate, optimization of oxygen supply is an essential condition, and equipment needs be selected to satisfy this condition. A seed medium prepared in a seed tank is transferred to a main fermenter containing a sterilized (using the equipment mentioned later) initial medium, and culturing is initiated after the culturing conditions are adjusted as predetermined by earlier tests. Penicillin G potassium salt is added (8–10 units/L) during the logarithmic growth phase. By adding penicillin, the strain undergoes changes, mainly in membrane permeability, to produce L-glutamic acid, and L-glutamic acid accumulates in the medium. Culturing is then carried out by continuously adding sterilized liquid molasses and controlling the pH around neutrality with ammonia. Liquid molasses is added until the strain no longer produces L-glutamic acid. As shown in Figure 4, which gives one example of a time course of fermentation, generally, the L-glutamic acid production phase continues only 30 or so hours after the addition of penicillin. L-Glutamic acid is finally produced in a concentration of 90–105 g/L. Unlike the culturing process with controlled biotin concentration, it is a characteristic feature of the penicillin shot method that culturing can be carried out under optimum conditions for microbial growth during the early phase of culturing. The advantages of this process are that culturing can be controlled easily, cell concentration is maintained almost at a constant level, and process control (i.e., the rate of molasses addition) is relatively easy. As shown in Table 3, glutamic acid fermentation undergoes different patterns as a result of certain factors. For example, an excessively high rate of carbohydrate addition leads to increased con-

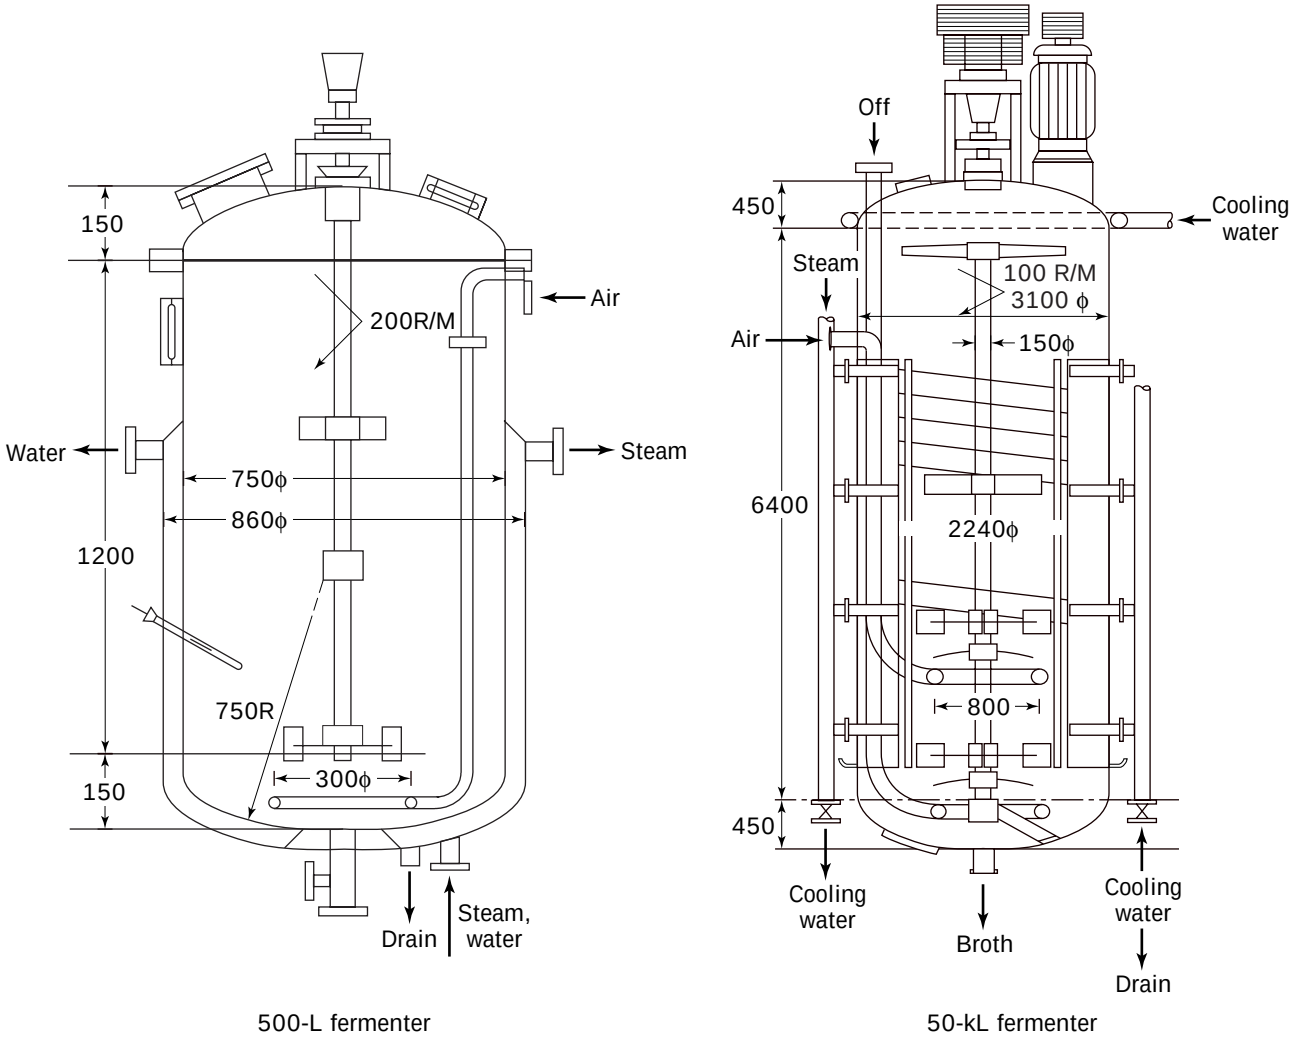

Figure 3. Example of a fermenter. *Source*: From Ref. 11.

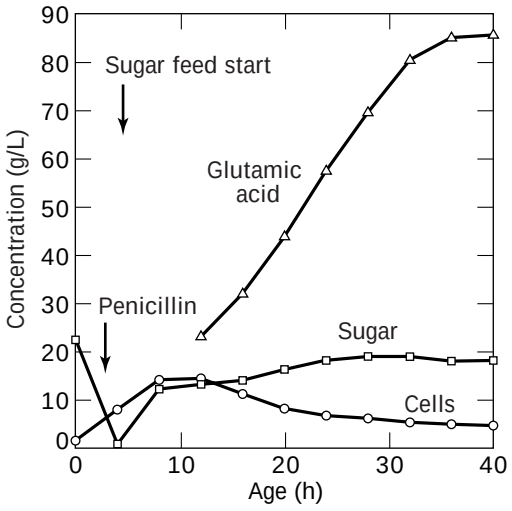

Figure 4. A fed-batch culture producing L-glutamate (*C. glutamicum*).

sumption of oxygen, resulting in oxygen shortage and, consequently, lactic acid and other organic acid formation. The control of cell growth is delicate when accomplished by the control of required substances, and the penicillin shot method is superior in ensuring stable productivity. Furthermore, the penicillin treatment concomitantly reduces the fraction of insoluble cells to a remarkable extent, which makes the recovery of L-glutamic acid from the fermentation broth much easier. This makes it possible to omit the mechanical separation of cells, resulting in simplification of the whole process.

It is, however, a problem that under the conditions currently used, the L-glutamic acid productivity lasts only about 30 h, as already mentioned. Generally, continuous processes are used because they improve productivity, but there is no continuous process that can practically operated due to the limited period of L-glutamic acid formation.

Purification: Direct Concentration and Crystallization

The outline of the purification step is shown in Figure 5. This step consists of two sub steps: recovering the slurry of L-glutamic acid from the fermentation broth (GA step), and producing the final product, monosodium L-glutamate, from L-glutamic acid (MSG step).

The GA step is directed to efficient recovery of high-purity GA crystals from the fermentation broth and the MSG-crystallized mother liquor resulting from the MSG step, and discharges the depleted GA-crystallized mother liquor out of the system. According to the penicillin shot method, in which most of the cells in the fermentation broth are lysed and solubilized, physical separation of the cells, such as with centrifugation, can be excluded, and the cell components are discharged into the GA-crystallized mother liquor. Precipitation is effected at the isoelectric point. GA crystals are known to take either the α- or the β-form. The α-crystal, which can be readily isolated, needs to be selectively precipitated because removal of impurities is accomplished by washing the crystals with water.

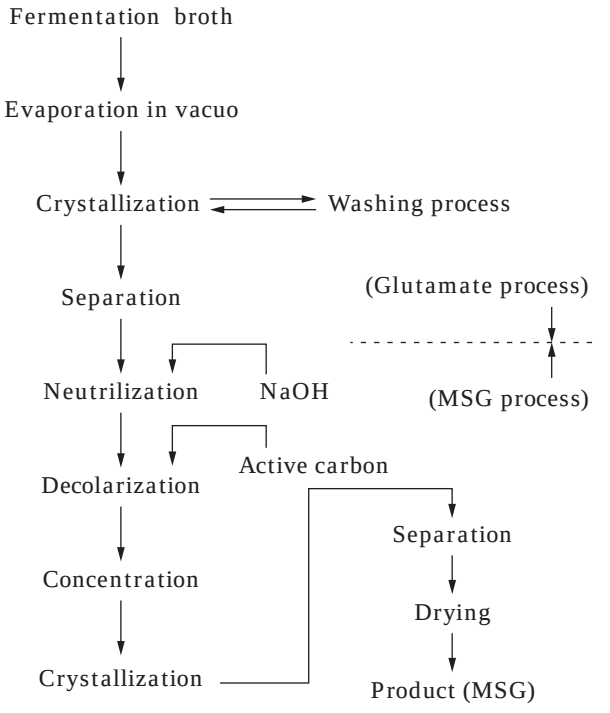

Figure 5. Process flow of purification of monosodium glutamate (MSG).

In the MSG step, ensuring high quality of the final product is essential, and improvement of the yield is required. To this end, both high purity of the GA crystals and efficient use of activated carbon must be attained. The resulting MSG-crystallized mother liquor, which still contains a high concentration of dissolved MSG, is sent back to the GA step to enhance the overall purification yield. In the whole process, from fermentation to final product, the GA-crystallized mother liquor and a decolorized cake of activated carbon are the main wastes discharged from the system. If the high quality of the product is to be ensured, it is apparent that the properties of the fermentation broth strongly affect the yield as a whole. Also, efficient use of the GA-crystallized mother liquor in view of utility and cost is an important factor in evaluating the process. Thus, in MSG production by the direct concentration and crystallization method, the process as a whole, from the selection of raw materials to the final product production, consists of linked steps that cannot be simply compared with other methods such as the resin methods. The purification yield of MSG from L-glutamic acid contained in the fermentation broth is estimated to be nearly 100% (78% in terms of ratio by weight and L-glutamic acid recovery). If the GA-crystallized mother liquor, which is rich in nutrient sources of plant origin and is used as an organic fertilizer, is efficiently used, this process as a whole constitutes an efficient, recycleable production system.

As is already mentioned, yield of L-glutamic acid is strongly affected by the ratio of this substance to the total solids in the fermentation broth. This ratio varies depending upon the sugar purity of the raw material used (ratio

of sugar to total solids) and the conversion to L-glutamic acid based on sugar. Because sugar purity varies greatly, depending on the different raw materials used, selection of appropriate raw materials is important.

FUTURE PROSPECTS OF COMMERCIAL MONOSODIUM L-GLUTAMATE PRODUCTION

Genetic Recombination Technology

There have been many reports concerning the application of current genetic recombination technology to the construction of amino acid–producing bacterial strains. Among them are studies on *Escherichia coli*, for which there has been advanced analysis on the genetic level, and those strains of coryneform bacteria that are most widely used for amino acid production. As shown in Figure 1, the biosynthetic pathway of L-glutamic acid is relatively simple compared with that of other amino acids and requires strong assimilability of ammonia, which indicates that coryneform bacteria are preferred producers of this substance. Figure 6 shows one example of improving L-glutamic acid productivity using recombinants of coryneform bacteria. In this example, productivity was improved by introducing a variant-type gene of L-glutamic acid biosynthetase into *C. glutamicum*. Although the productivity did not reach a practical level, this suggests the possibility of constructing an industrially feasible strain by making further improvements to both the donor gene and receptor microorganism. Currently, success in the application of recombinant technology to construction of amino acid–producing strains has been reported in connection with amino acids that have a relatively complicated mechanism of metabolic regulation, such as the aromatic amino acids histidine and threonine. With respect to amino acids that are produced in good yields as a result of conventional construction method, such as L-glutamic acid, so far there have been no reports published on remarkable productivity improvements achieved by recombinant technology. However, there is still high technical potential, and drastic improvement in production may be expected in the future using this technology.

Continuous Fermentation

The penicillin method batch-type L-glutamic acid fermentation gives only a short period of high L-glutamic acid productivity. Though continuous fermentation is desired to improve productivity, it is difficult to establish a continuous process with the currently available technologies. Studies on measures to stabilize the productivity, and establishment of the process with techniques other than the penicillin method are desired. Further improvement in productivity may be expected in combination with genetic recombination technology.

Replacement of Raw Materials: L-Glutamic Acid Fermentation with Petrochemicals

In the fermentation processes, the main raw materials are carbohydrate derived from molasses, corn, beet molasses, and so forth, with ammonia as a nitrogen source. Although industrial production has been carried out by fermentation with carbohydrate, the possibility of using petrochemicals including normal paraffin, ethanol, methanol, and acetic acid as fermentation raw material has been extensively studied (13–15). However, fermentation production using petrochemicals as a raw material has not been industrialized, except for partial use of acetic acid, because of the cost (16).

Acetic acid, derived from petrochemicals, may partially replace molasses. Glutamic acid–producing microorganisms from carbohydrate can easily utilize acetic acid if it is in low concentration, and acetic acid may be used in industrial processes if its concentration in the culture medium is kept at a low level. Acetic acid is supplied during the fermentation. With this method, although the cost of raw materials for culturing increases, the purification yield can be enhanced by increasing the ratio of L-glutamic acid to the total solid of fermentation broth. The feasibility must be evaluated with respect to the process as a whole.

Due to the rising cost of petroleum, L-glutamic acid production by fermentation from petrochemicals, particularly normal paraffin, is presently not practical, and the prospects for the future are not optimistic. However, this technology is discussed in this section because L-glutamic acid

fermentation (and, similarly, fermentation to produce other amino acids) from hydrocarbons may provide one option for replacing raw materials. Naturally isolated, hydrocarbon-assimilating L-glutamic acid–producing microorganisms did not show a requirement for biotin, unlike those producing L-glutamic acid from a carbohydrate such as molasses; but they did require other vitamins for growth. Typical L-glutamic acid producers of the genera *Corynebacterium* and *Arthrobacter* had a requirement for thiamin. As in the case with fermentation using carbohydrate, L-glutamic acid was accumulated in the medium under the controlled concentration of the required vitamin, and the membrane permeability underwent a change when the microorganism was in the L-glutamic acid production phase. Also, the addition of penicillin or saturated fatty acids or their esters to the cells growing in the presence of a sufficient concentration of the required substance converted the cell from the growing phase to the L-glutamic acid production phase. Whereas carbohydrates are metabolized through glycosylation, hydrocarbons are metabolized through β-oxidization. However, subsequently, L-glutamic acid formation undergoes similar metabolic regulation in both processes.

With respect to the reaction processes, carbohydrates are used basically as an aqueous solution, whereas hydrophobic hydrocarbons separate into a layer of oil on water. Furthermore, oxidization of hydrocarbons requires much more oxygen compared with the oxidation of carbohydrates, although an advantage of the hydrocarbon process is that continuous feeding of the raw material, as required with carbohydrates, is not necessary, and, therefore, high-concentration culturing is possible in a batch culturing manner. The equipment for glutamic acid production must provide efficient dispersion of the oil to enlarge the surface area of the oil layer and also must provide efficient aeration and agitation to supply the large volume of oxygen required. Under optimum conditions, glutamic acid production from hydrocarbons is very similar to production from carbohydrate. There is no major difference between the two processes in the purification step, except that fermentation from hydrocarbons does involve steps for removing trace residual oil and cells.

Environmental Problems

The main raw materials, molasses, beet molasses, and glucose, are agricultural products. It is necessary to establish a production process that takes into consideration the possibility of recycling the wastes produced. The current industrial process uses the remaining fractions to produce organic fertilizers, and the process as a whole is designed to be a closed system.

Memphis, Tennessee

OUTLINE

INTRODUCTION

The primary purpose of this article is to benefit the tens of thousands of individuals who either utilize biomolecular analyses and syntheses provided by resource laboratories or help to oversee, administer, and regulate the hundreds of biopolymer core laboratories that are dedicated to support research, quality control, and quality assurance programs. The core laboratories that provide these biopolymer analyses and syntheses are in turn supported by the Association of Biomolecular Resource Facilities (ABRF), an international, nonprofit organization of more than 300 core laboratories that is truly remarkable in terms of the ever-widening expanse of its research and outreach activities; the dedication, volunteerism, and extent of participation of its members; and the laudable goals to which it aspires. These are well summarized in its mission statement:

> A. To promote and support resource facilities, research laboratories, and individual researchers regarding operation, research, and development in the areas of methods, techniques, and instrumentation relevant to the analysis and synthesis of biomolecules.
> B. To provide mechanisms for the self-evaluation and improvement of procedural and operational accuracy, precision, and efficiency in resource facilities and research laboratories.
> C. To provide a mechanism for the education of resource facility and research laboratory staff, users, administrators, and interested members of the scientific community.

Following a brief history, which describes the genesis of bioanalytical core laboratories and the organization they engendered, the ABRF, are nine sections that chronicle the work of ABRF's research committees. These sections are followed by a section on the effective use of biomolecular resource facilities, and the article concludes with a prognostic look into the expanding role that core laboratories are likely to play in the postgenome era.

HISTORY AND ACTIVITIES OF THE ABRF

RONALD L. NIECE
University Of California–Irvine
Irvine, California

The formation of shared biotechnological instrumentation laboratories in the 1980s provided a major and highly efficient mechanism to bring state-of-the-art biomolecular syntheses, analyses, and advice to tens of thousands of investigators at minimal cost. Growth in the number of biotechnological core laboratories and the parallel growth in the diversity of services they offer reflect the increasing sophistication of the protocols and instrumentation needed to conduct research in the life sciences. The ever-increasing complexity of the equipment increases the cost of conducting research in multiple ways. In addition to higher capital costs, operating expenses are higher due to high-purity custom reagents and increased service contract and maintenance costs. Specialized parts and highly trained instrument service representatives contribute to the cost of high-performance instrumentation. Laboratory staff costs are higher because of the need for experts in operation of the instrumentation and interpretation of the resulting data. The establishment of biomolecular resource laboratories has provided expensive and sophisticated technology at minimal cost.

Core laboratories began to evolve in the early 1980s from individual research laboratories and programmatic centers that were often equipped with an automated amino acid analyzer and/or spinning cup protein/peptide sequencer and that provided analyses on an informal or collaborative basis. This evolution was spurred on by the introduction and commercialization of the gas phase protein/peptide sequencer (1) and automated oligonucleotide synthesizers (2) and by the inauguration of the Shared Instrumentation Grant Program of the National Institutes of Health in 1981.

An awareness that many laboratories were providing services for other researchers (i.e., they were carrying out noncollaborative analyses on samples not prepared in their own laboratories) emerged at the Symposium of American Protein Chemists in San Diego, California, in 1985. This led to the informal association of Research Resource Facilities (RRF) (3), which met annually to exchange views on sample handling in the core facility setting, improvements in protocols, and advances in technology. A significant innovation of RRF was the inauguration of research committees devoted to analyzing instrumentation capabilities and to providing a realistic definition of state of the art in terms of what could be accomplished by the majority of the practitioners of the art. The first "unknown" sample presented to affiliates was a peptide designed to assess the performance of automated protein sequencers and amino acid analyzers (4). In 1989 the informal RRF group incorporated as the Association of Biomolecular Resource Facilities (ABRF). ABRF research committees based on other themes including peptide synthesis, mass spectrometry, nucleic acids chemistry, DNA sequencing, laboratory quality and compliance, and carbohydrate analysis were established subsequently (see following sections).

As it has been from the beginning, a major focus of ABRF is to establish realistic expectations of what can be accomplished with currently available technology in resource and research laboratories. The laboratories using the technology provide the best definition of requirements for sample preparation or design, instrument performance, and personnel proficiency. Since 1988 ABRF research committees have designed experiments and distributed test samples and syntheses for membership participation (see later sections) following the model described (4) for the 1988 sequence and amino acid analysis sample. An "unknown" sample or synthetic project that reflects a typical task is distributed to members with the recommendation that it receive no more nor less care than would any other request made to the laboratory.

The research committees analyze the resulting data and synthesized products as described in the sections that follow. The results help establish a useful assessment of the range of performance and capabilities on instruments in member laboratories. Because the data and products are submitted anonymously, individual core facilities cannot be identified. The anonymity helps ensure that samples and data returned are in fact representative of what happens on a day-to-day basis and allows member laboratories to compare their performance relative to that of their peers and relative to the level appropriate to their constituency. Unless a laboratory knows that it is performing below the average level defined by peers using similar instruments, reagents, and protocols, there is little incentive to improve. The best analyses and highest-quality synthetic products highlight the level of performance possible under actual operating conditions and identify the conditions needed to attain this high level of performance. Surveys of the composition, capabilities, and performance of core laboratories provide a complementary means of defining realistic expectations (5–7). In addition, survey data on operations and financial support and expenses of core facilities is collected anonymously as with the "unknown" samples.

Comparison of performance in terms of sensitivity, throughput, turnaround time, and so forth with the average provides a performance baseline that can serve as an incentive for performing as effectively as one's peers. The detailed financial data provided by the surveys have documented the economics of core facilities. Although the centralized laboratory with shared instrumentation provides considerable economies of scale and pooled expertise, the survey data demonstrate that only a small percentage are able to recover 100% of operating expenses from user fee income.

Results of the research studies are distributed directly to the members who participated and are also published (3–50). Originally, the research results were presented at an annual satellite meeting held in conjunction with the Symposium of the Protein Society. Today symposia, workshops, and tutorials are presented by the ABRF. Symposia on leading-edge technologies presented at national and international scientific meetings introduce the scientific community to the range of capabilities available in core facilities while highlighting the constraints on sample preparation or design required for success. Because ABRF consists of the users of the technology, the workshops emphasize the practical tools needed for improved and high performance. The tutorials are popular and effective tools for helping core facility staff expand their repertoire of capabilities and increase their level of expertise.

The research undertaken by the ABRF has been funded by federal grants, corporate sponsors, institutional contributions, and membership dues. These funds are leveraged by voluntary contributions of individual research committee members, their laboratories, and their institutions. Research committees consist of volunteer ABRF members with a designated liaison from the executive board. ABRF is an incorporated, nonprofit organization led by an elected, volunteer executive board. Business activities are handled by the Federation of American Societies for Experimental Biology (FASEB) business office (ABRF, 9650 Rockville Pike, Bethesda, MD 20814-3998; 301-571-8300; FAX: 301-530-7049; E-mail: *abrf@faseb.org*). Official ABRF business is conducted at an annual business meeting.

The ABRF Corporate Sponsorship program provides a unique opportunity to enhance communication between the manufacturers and suppliers of biotechnological instrumentation and the laboratories that depend on this equipment. ABRF research activities help define how effective the instruments and protocols are in the field, the level of training required for their optimum use, and what happens to this performance as the instruments age. Identifying performance levels, new applications, and unforeseen problems that accompany the running of "real" samples that were not anticipated by manufacturers promotes improvements and corrective actions. ABRF surveys of satisfaction with instrument performance, service support, reagent and supply costs, and application support offer unbiased group feedback from the day-to-day users who best understand the instrumentation and protocols.

Since 1994 the ABRF has presented an annual award for outstanding contributions to the development of technologies used in core facilities. An independent, anonymous panel of respected scientists presents the ABRF executive board with candidates for this award. This ABRF award recognizes contributions to science through technological advances and is accompanied by $10,000 and an opportunity to address the ABRF members at their annual meeting. In 1994 and 1995 Beckman Instruments funded the awards; in 1996 Hewlett-Packard began sponsoring of the award. The first award was presented to Dr. Frederic Sanger, the winner of two Nobel prizes, for his development of methods for sequencing proteins (chemistry, 1958) and for sequencing DNA (chemistry, 1980). In 1995 Dr. Klaus Biemann was honored for his contributions in the development of mass spectrometry for analysis of biomolecular polymers and for his training of mass spectrometrists. Dr. David Lipman received the 1996 award for developments of computational methods for analysis of protein and DNA sequences. The 1997 award was presented to Dr. Lloyd Smith for his contributions to the advancement of automation in DNA sequencing. The 1998 award went to Nobel laureate (chemistry, 1984) Dr. Bruce Merrifield for developing the concept and strategies for solid-phase synthesis of peptides, which opened the way for peptide and other organic syntheses to become routine.

ABRF educational initiatives target member laboratories, the scientific community, which represents its user base, the manufacturers of instrumentation and reagents used in core facilities, and the administrators and decision makers who deal with science, scientists, and the delivery of research resources. To fulfill the educational needs, ABRF promotes several activities beyond conducting and publishing research reports. Since 1986 symposia have been organized in conjunction with the Protein Society and the International Congress of Biochemistry and Molecular Biology and joint symposia have been presented at the FASEB and American Society of Biochemistry and Molecular Biology (ASBMB) annual meeting. Workshops and symposia have been presented at meetings of the American Peptide Society, American Society of Cell Biology, American Society of Mass Spectrometry, European Protein Society, International Genome Sequencing and Analysis Conference, and the Methods in Protein Structure Analysis. From 1986 to 1998 the ABRF organized workshops and symposia at 32 different meetings and held three independent meetings, each of which were attended by 500 to 1,000 individuals.

Another significant medium for information exchange and education of members has been the newsletter, *ABRFnews*. The newsletter contains peer-reviewed articles including summaries of meetings, methods and review papers, and laboratory tips. A new dimension in publication of methods in biomolecular research began in 1997 with the launch of the electronic *Journal of Biomolecular Techniques: The Official Methods Journal of the ABRF (http://www.abrf.org/JBT/JBT.html)* edited by John Shively. Beginning in 1998, *ABRFnews* and the electronic journal were merged into one under the title *Journal of Biomolecular Techniques*, with Clayton Naeve as the editor in chief. To maintain the advantages of the electronic journal, accepted rapid communications are immediately posted on the Web site followed by reprinting in the next issue of the journal. Electronic communications using an E-mail bulletin board (*abrf@aecom.yu.edu*) connect more than 900 members around the world; the novice and expert can almost instantaneously assess instrument and reagent problems, discover if other laboratories have similar concerns, and help one another design experimental protocols. The ABRF Web site (*www.abrf.org*) contains written protocols distributed at workshops and tutorials, the results of many research studies, and comprehensive archives of the discussions on the E-mail bulletin board. The Web site averages more than 100 inquiries per hour to one or more documents.

The concept that developed into ABRF began with six scientists in 1986. In 1998 there were more than 900 members listed in the ABRF directory. Members reside in 26 different countries on six continents. Three-quarters (76%) are in the United States, from 40 different states, half (55%) are in academic institutions, 13% in research institutions, 28% in industry, and the balance in government laboratories. Although these numbers are illustrative, they fail to adequately convey the underlying reason for the success of ABRF: The ABRF is uncommon in terms of the unrelenting volunteer spirit and commitment of its members and its single-minded purpose of helping to bring state-of-the-art biotechnology to bear on the myriad array of biochemical and biomedical challenges that are its reason for being. It is unique in its multipronged, targeted research by its research committees, which study technical capabilities, current protocols, and emerging technologies.

AMINO ACID ANALYSIS

DANIEL J. STRYDOM
Bio Nebraska, Inc.
Lincoln, Nebraska
JOHN W. CRABB
Cleveland Clinic Foundation
Cleveland, Ohio

Amino acid analysis (AAA) is one of the major analytical techniques used in the biochemical and biotechnical environments. It is the method of choice for reliable quantification of peptides and proteins and also provides useful qualitative information in the evaluation of synthetic peptides and recombinant proteins, the identification of proteins based on composition, and the detection of unusual amino acids. AAA also has applications in protein sequence studies, such as in the design of fragmentation strategies, the identification of amino- and carboxy-peptidase reaction products, and the quantification of samples subjected to Edman degradation to detect those with blocked N-termini. In addition, AAA is used for the characterization of feed and food samples and physiological fluids.

Two basic approaches to quantitative AAA receive widespread use, namely (*1*) classical postcolumn derivatization followed by ion exchange chromatography and (*2*) precolumn derivatization followed by reverse-phase HPLC. Excellent instrumentation and more than one method is available for these basic approaches. Because AAA applications are of such varied character, no single methodology can be shown to be superior in all respects. The technology is deceptively simple but actually is one of the more complex and difficult in protein chemistry. The greatest benefit of AAA is its quantitative capability; however, measuring many different amino acids with quantitative accuracy is precisely what makes the analysis so difficult. AAA is a statistical type of measurement; amino acids vary widely in their stability/lability to acid hydrolysis, oxidation, and modification. Trp and Cys are destroyed by HCl hydrolysis, Ser and Thr are partially destroyed, Ile and Val are slow to cleave, Met is subject to oxidation, and Asn and Gln are completely deamidated. Variable, but ubiquitous, background (most frequently Gly, Ala, and Ser) plus variable instrument and analyst performance can confound the analysis, particularly at and below the low picomole level. As a consequence, realistic expectations concerning the accuracy and precision of AAA must be tempered with an appreciation for the difficulties of the technology.

The annual ABRF AAA studies between 1988 and 1997 provide a broad performance comparison of AAA methods and instruments (Table 1). In addition to the reports in Techniques in Protein Chemistry (Table 1), the ABRF AAA studies have been highlighted in the *ABRFnews* and reported elsewhere (12,13,49). The number of participating

Table 1. Summary of ABRF Amino Acid Analysis Studies, 1988–1996

Year	Sample description	Number of participants	Sample amount[a] (μg)	Average % error[b]	Study focus	Reference
1988	Synthetic peptide (STD-2)	45	5	19.3	Accuracy and sensitivity	4
1989	β-Lactoglobulin (89AAA)	17	0.2	25.3	Accuracy, precision, sensitivity	10
		26	5.0	13.9	Hydrolysis methods; and Cys quantification	
1990	Myoglobin control (90AAA1)	41	1.3	13.5	AAA in the presence of buffer salts and on PVDF membrane	15
	Myoglobin + salt (90AAA2)	35	1.3	19.7		
	Myoglobin on PVDF (90AAA3)	30	0.9	26.9		
1991	Bovine serum albumin (91AAA)	51	150	9.5	Accuracy with unlimited sample; Trp and Cys quantification	18
1992	Chymotrypsin (92AAA)	59	56	10.5	Trp and Cys quantification	21
1993	Synthetic peptide (93AAA)	50	23	12.5	Phosphoamino acids and hydroxyproline analyses	26
1994	RNase + angiotensin (94AAA1)	58	30	10.9	Hydrolysis and chromatography methods; cys and glucosamine analyses	30
	Prehydrolyzed 94AAA1 + glucosamine (94AAA2)	60	30	6.5		
1995	Myoglobin on PVDF (95AAA)	77	30	21.4	AAA on PVDF membrane	35
1996	Triose phosphate isomerase (96AAA)	71	10	11.9	Protein identification from AAA databases	48
1997	Bovine serum albumin, lysozyme on PVDF (97AAA)	40	1	30	AAA on electroblotted PVDF	49
			5	19	Protein identification from AAA	
			10	19		

[a]Sample amounts provided since 1991 were meant to be adequate for all methods and not to restrict performance.
[b]Average percentage compositional error for each study is shown for all methods combined without results for Cys, Trp, or unusual residues.

laboratories per year has varied from about 40 to 77 (Table 1); approximately 38% of the participants since 1989 have used postcolumn ninhydrin methodology, approximately 48% have used precolumn phenylthiocarbamyl (PTC) methods, and 14% have used other AAA methods. The ABRF AAA studies are crafted to examine some aspect of the AAA technology to help participating laboratories evaluate and improve their capabilities; participation is organized in an anonymous and noncompetitive manner. In general, these studies demonstrate that more than one AAA method works well and that the skill of the analyst is probably the most important determinant of success. More specifically, these collaborative trials have evaluated AAA performance with high and low amounts of sample, in the presence of salt, on PVDF membrane, with emphasis on difficult residues (e.g., cysteine/cystine, tryptophan, and phosphoamino acids), with special focus on hydrolysis and chromatography conditions, or with attention to protein identification methods based on amino acid composition data. Each year, these studies have published the average levels of AAA performance and also typically spotlighted the highest-quality analyses attained with different AAA methods.

The overall AAA accuracy in the past 10 years of ABRF studies has ranged from 6.5% to 30% average compositional error per study (Table 1). Accuracy is strongly dependent on the type and amount of sample provided, hydrolysis conditions, and level of background contamination during the analysis. The ninhydrin-based postcolumn analyses require more sample (typically 5–10 μg per analysis) than precolumn derivatization–based techniques (0.5–1 μg per analysis). Each year a broad range of accuracy is apparent, including some analyses that are grossly wrong and others that are exceptionally good (e.g., 3–5% average error). The studies indicate that knowledgeable and skillful analysts can expect high-quality results with approximately 10% average compositional error from more than one AAA method.

Instrument calibration and peptide/protein hydrolysis to individual amino acids are critically important for high-quality AAA. General parameters for sample hydrolysis have been considered frequently in the ABRF studies (e.g., vacuum, temperature, acid additives, liquid acid versus acid vapor), and two trials have specifically evaluated the hydrolysis process by providing both a hydrolyzed and an unhydrolyzed sample for analysis (10,30). Study results clearly demonstrate the variability of the hydrolysis process from laboratory to laboratory (30) and emphasize the importance of controlling this step. Vapor-phase acid hydrolysis has become the most popular methodology over the course of these trials. Instrument calibration has been examined also, and results demonstrate that replicate analysis of amino acid standards such as Pierce standard H provided superior results, whereas

hydrolyzing the standard appears to be disadvantageous (18).

Quantification of cysteine is difficult because hydrolysis in constant-boiling HCl destroys cysteine and partially destroys the disulfide-linked, dimeric form of the residue, cystine. Tryptophan is destroyed by routine HCl hydrolysis and is even more challenging to quantify than cysteine. Cys is best analyzed by various pretreatments of the sample, such as oxidation, reduction and alkylation, or perhaps optimally by adding disulfide exchange reagents during acid hydrolysis (21). Trp appears best analyzed by adding dodecanethiol to the hydrochloric acid used for hydrolysis (21).

Rare and modified residues are of continual interest to many investigators. Phosphoamino acids and hydroxylated and glycosylated residues have been examined in the ABRF collaborative trials; such analyses are not routine for most laboratories. No current AAA methodology allows quantitation of phosphoamino acids in a single analysis in conjunction with all the common amino acids (26). Optimal hydrolysis conditions must be determined for each sample; however, precolumn analyses such as the phenylthiocarbamyl (PTC) method were more effective in the chromatographic resolution of phosphoamino acids than the postcolumn ninhydrin method (26). In analyses of the 93AAA sample, 41% of the facilities detected an unknown amino acid and 75% of these correctly identified it as hydroxyproline. Glucosamine in the 94AAA2 sample was detected by only 13% of the participants, although all had been alerted to its possible presence.

Comparison of ninhydrin and PTC methodologies in the ABRF AAA studies reveals statistically significant differences. For example, the interlaboratory variability of Arg, His, Leu, Lys, Met, Pro, and Val is dramatic between these two techniques, perhaps due to chromatography issues and reagent-related peaks. Pro is the only of these amino acids that appears to be analyzed more consistently and accurately by PTC than by ninhydrin methods, primarily due to its low color yield with ninhydrin. Met is underestimated by ninhydrin sites, probably due to oxidation and to chromatographic disturbances, and it is overestimated by PTC sites. The latter can be due to overlap of the PTC Met peak with reagent-related peaks. The oxidation of Met leads to high Arg values in PTC analyses due to coelution of the oxidation product with Arg, whereas ninhydrin methods frequently underestimate Arg, most likely due to the very broad chromatography peak and consequent integration problems. Other residue-specific problems were addressed in the 1991 study (18), including low values for PTC Asp and PTC Glu caused by metal contamination from glass hydrolysis tubes that often can be remedied by drying the samples with EDTA prior to hydrolysis. Although more than one ABRF AAA study has shown precolumn derivatization techniques more sensitive than ninhydrin methods, the 1990 study demonstrated that postcolumn derivatization methods generally provided better AAA results in the presence of buffer salts.

Two ABRF studies have evaluated AAA on PVDF membranes (15,35), and both resulted in compromised accuracy (21–27% average error) relative to nonimmobilized samples. The 1995 study further demonstrated significantly high backgrounds on blank PVDF membranes (35), suggesting that perhaps the higher error from PVDF immobilized samples is due in part to background contamination that is difficult to extract from the membranes. The 1997 ABRF AAA study readdressed AAA on PVDF by probing whether PVDF electroblotted samples exhibit less background contamination. Results in 1997 indicated that the average error for samples blotted to PVDF was still about twofold higher than for solution samples (49).

The 1996 ABRF AAA study (48) demonstrated that 90% of participating laboratories could correctly identify an unknown sample protein (triose phosphate isomerase) from their AAA data (11.9% average compositional error) using the World Wide Web and either ExPASy *(http://expasy.hcuge.ch/ch2d/aacompi.html)* or PROPSEARCH *(http://www.EMBL-heidelberg.de/aaa.html)* database computer query programs. Results from the 1997 AAA study on PVDF membrane suggest that correct protein identifications can be made with AAA data containing up to 15% average error. In the years to come, AAA will likely become a more widely recognized and valuable tool for the identification of proteins.

PROTEIN SEQUENCING

JOSEPH FERNANDEZ
Rockefeller University
New York, New York

KATHRYN STONE
Yale University
New Haven, Connecticut

The ABRF Protein Sequence Research Committee focuses primarily on providing member laboratories with "unknown" protein/peptide samples that are representative of samples routinely submitted for protein sequence analysis. Participating laboratories characterize the primary structure of the protein/peptide, or the sequence, typically from the amino-terminal end of the sample utilizing automated Edman degradation chemistry.

Chemistry and Sample Preparation

The chemistry used during Edman degradation (51) consists of consecutive cycles; one cycle contains the following steps: (*1*) coupling of phenylisothiocyanate (PITC) with the α-amino group or amino-terminal amino acid of the protein/peptide at pH 9–10 to form a phenylthiocarbamyl (PTC) group, (*2*) removal of chemistry by-products using organic washes, (*3*) cleavage with anhydrous trifluoroacetic acid (TFA) to generate a protein/peptide minus the first amino acid (or N-1 protein/peptide, which contains a free α-amino group for a subsequent cycle of Edman sequencing), along with an anilinothiazolinone (ATZ) derivative of the released amino-terminal amino acid, (*4*) extraction of the ATZ derivative from the N-1 protein/peptide, and (*5*) conversion of the ATZ derivative to the more stable phenylthiohydantoin (PTH) form. The PTH amino acid derivative can then be identified by its retention time on reverse phase HPLC, during which amino ac-

ids, chemistry artifacts, and derivatized amino acids are resolved from each other. Figure 1 shows chromatograms distributed to ABRF members as a sequence assignment exercise (46) and represent an example of a PTH amino acid standard HPLC profile, along with Edman cycles showing residues 1–7 of the peptide. Cysteine is destroyed during the Edman chemistry and thus is usually reduced and alkylated before automated sequence analysis (52).

The performance and capabilities of automated Edman degradation chemistry are generally characterized by initial yields, repetitive yields, and lag (carryover). Initial yield refers to the recovery of the first amino acid, typically in picomoles, and is generally expressed as a percentage of the total picomole amount of protein/peptide analyzed (typically 50–80%). Repetitive yield provides a measure of the average amino acid recovery after each cycle. Although it usually ranges from 90 to 99%, repetitive yield also varies with sample and instrumentation. Lag or carryover means the yield, expressed as a percentage, of the amino acid that appears in the subsequent cycle ($n + 1$) relative to the actual cycle (n). Repetitive yield and lag indicate the degree of completion of the Edman chemistry and generally determine how far a protein can be sequenced before the signal becomes indistinguishable from the noise.

Edman degradation is only possible when the protein/peptide has a free amino (N) terminus. If a naturally occurring or other chemical group is present at the N-terminus, no data can be obtained and the sample is considered blocked. Some of the more common naturally occurring blocking groups are acetylated amino acids, formylated methionine, and pyroglutamic acid. Generally, the percentage of naturally blocked proteins isolated from an organism increases along with the complexity of the organism. Hence, while only a few bacterial proteins are blocked, approximately 80% of soluble proteins isolated from a mammalian tumor cell line appear to be blocked (53). Artificial blockages can occur during electrophoresis, but certain precautions, such as using high-purity reagents, can be taken to help decrease this type of blocking (54). A lack of sequence or PTH amino acid signal can also be due to an insufficient amount of protein/peptide used during sequencing. The reason for a lack of sequence (a blocked amino terminus or an insufficient amount of protein/peptide) can often be inferred by performing hydrolysis and an AAA (see previous section) of the sample and its sequencing support, after sequencing.

Samples for sequence analysis by Edman degradation are generally prepared in one of three forms: (*1*) in solutions that often contain nonvolatile buffers (phosphate, Tris, SDS, etc.), (*2*) in volatile buffers, such as the trifluoroacetic acid/acetonitrile solutions used to elute reverse-phase HPLC columns, and (*3*) noncovalently bound (via electrophoretic transfer) to PVDF membranes (55). All samples in these forms can be directly sequenced, although certain instruments are better designed for one sample form over another.

ABRF Protein Sequence Studies

Over the past 10 years, the ABRF Protein Sequence Research Committee has distributed annually an unknown amino acid sequencing sample, along with a survey, to member laboratories. The purpose of these studies is to provide participating laboratories with a mechanism for evaluating their own sequencing capabilities, particularly as new instruments and techniques are introduced. Because many laboratories are involved in these studies (the average number of participating laboratories is 69; see Table 2), they provide a reasonable approach to determine realistic expectations regarding the average amount of protein/peptide that can be routinely sequenced. In addition, the quality or accuracy of the resulting data can be determined because the identity of the sample was unknown to the participants. Each study has been designed with a particular emphasis: sensitivity of sequencing (STD-1, ABRF-93SEQ, and 97SEQ), posttranslational modification (ABRF-92SEQ), heterogeneity (ABRF-89SEQ, ABRF-95SEQ, ABRF-96SEQ, and ABRF-97SEQ), protein bound peptides (which mimic large proteins) on PVDF or in solution (ABRF-90SEQ and ABRF-91SEQ), identification of problematic residues such as cysteine and tryptophan (ABRF-94SEQ, ABRF-95SEQ, and ABRF-96SEQ), and distance sequenced (ABRF-95SEQ). In addition, emphasis is placed on positive correct calls or positive accuracy, which is defined as the number of correct positive calls per total number of positive calls. A summary of these studies is found in Table 2.

The amount of sample supplied in these studies has ranged from a high of 500 pmol (ABRF-92SEQ) to a low of 10 pmol (ABRF-97SEQ). In the first study (STD-1, 1988 [4]), 100 pmol of a unique 40-residue synthetic peptide was supplied. The positive accuracy for this study was quite good, with ~95% correct. Because real samples often contain some heterogeneity, the following study (ABRF-89SEQ [8]) contained a mixture of two unique synthetic peptides at a 5:1 molar ratio (248:48 pmol). The lengths of these peptides were similar to the STD-1 sample, and the positive sequence calling accuracy for the major sequence was again ~95%. This indicated that the participating laboratories were quite good at differentiating a major sequence from a minor sequence when the abundance of the minor sequence was ~20% of the major. Furthermore, it provided a guideline of about 80% for the minimal requirement of purity for samples destined for N-terminal sequencing. A sequence mixture was also provided as a sequence assignment exercise in the ABRF-96SEQB (46) study, where participating laboratories received the HPLC chromatograms of a sequence mixture in place of an actual sample. The positive accuracy for the major, 10-pmol, 22-mer sequence was still 95%. In this study, the accuracy for the minor 14-mer sequence, which was at the 2-pmol level, was also determined and found to be 85%. This lower sequence calling positive accuracy most likely resulted from either the very low amount of sample sequenced or the fact that it was a minor component.

The ABRF-93SEQ (25) sample had the same composition and length as the STD-1 sample. However, only 50 pmol of ABRF-93SEQ was supplied as compared with the 100 pmol of the STD-1 sample that was distributed for the 1988 study (Table 2). A comparison of several sequencing performance parameters (positive sequence calling accuracy, number of positive correct assignments, and average

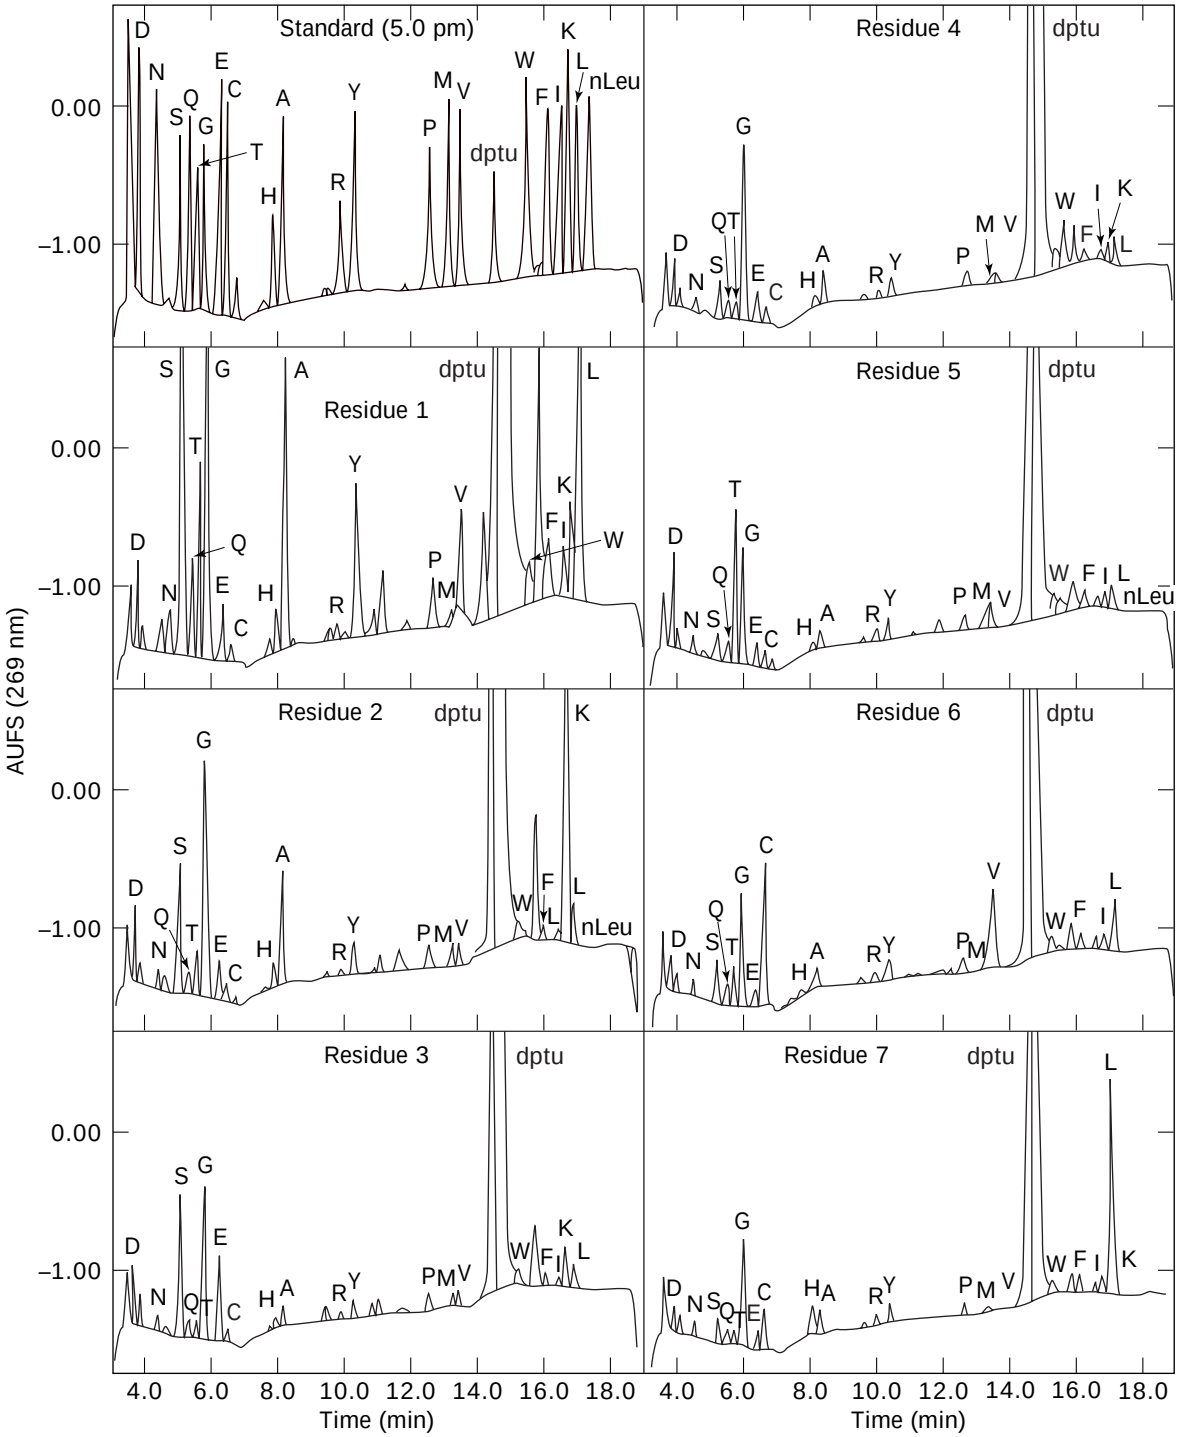

Figure 1. PTH chromatograms from ABRF-96SEQ Dataset B that was distributed as a sequence assignment exercise. Cysteine was present in both the standard and sample as the carboxamidomethylated derivative. The derivative nLeu represents PTH norleucine and is present only in the standard, and diphenylthourea (dptu) is an Edman chemistry by-product. The sequence of the major peptide indicated was leucine-lysine-serine-tryptophan-threonine-cysteine-leucine (LKSWTCL) and the minor was tyrosine-alanine-glutamic acid-glycine-aspartic acid-valine-histidine (YAEGDVH).

Table 2. Summary of ABRF Protein Sequencing Studies, 1988–1997

Sample	Sample description	Number mailed	Number responses[a]	Amount sent (pmol)	Positive accuracy (%)	Reference
STD-1	40-residue synthetic peptide	103	47 (47%)	100	~95	4
ABRF-89SEQ	40-residue synthetic peptide (major)	123	49 (40%)	240	~95	8
	43-residue synthetic peptide (minor)			48		
ABRF-90SEQ	29-residue synthetic peptide covalently attached to acetylated transferrin (90%) bound to PVDF	132	56 (42%)	30	83	14
ABRF-91SEQ	29-residue synthetic peptide dried with acetylated transferrin (90%)	198	90 (45%)	80	83	16
ABRF-92SEQ	37-residue synthetic peptide with two unusual amino acids	225	74 (32%)	500	94	22
ABRF-93SEQ	40-residue synthetic peptide with same composition as STD-1	274	80 (29%)	50	91	25
ABRF-94SEQ	Lactoferrin to assist sequencing labs in identification of cysteine and tryptophan	258	78 (30%)	50	95	31
ABRF-95SEQ	Recombinant protein to determine maximum length of sequences that can be obtained; sample also contained four heterogeneous positions	252[b]	71 (28%)	45	78	37
ABRF-96SEQA	Sequence calling exercise (single sequence)	210[b]	95 (45%)	40	99.8	46
ABRF-96SEQB	Sequence calling exercise (major)	210[b]	95 (45%)	10	96	46
	Sequence calling exercise (minor)			2	85	46
ABRF-97SEQ	21-residue synthetic peptide (major)	215	50 (23%)	10	92	
	14-residue synthetic peptide (minor)			2	72	

[a]Percentage based on number of responses divided by number mailed.
[b]Samples for ABRF-95SEQ, ABRF-96SEQ, and ABRF-97SEQ were mailed only to facilities that perform protein sequencing.

repetitive yield) between the STD-1 and ABRF-93SEQ studies indicated there was no significant improvement in sequencing performance over this 5-year period. Again, however, the amount of peptide provided in the ABRF-93SEQ study was half that provided in the STD-1 study.

To better study the factors that affect sequence calling accuracy, the ABRF-96SEQA and ABRF-96SEQB (46) studies were sequence calling exercises. In each case, the PTH chromatograms were supplied to participants rather than an actual sample to be sequenced. The ABRF-96SEQA sample was at a relatively high level (40 pmol) and had the highest degree of positive correct calls for any ABRF sequence study, with an accuracy of 99.8%. This study indicated that PTH chromatograms generated from straightforward, high-level samples with no heterogeneity can be used to assign a positively called sequence with a very high level of confidence. ABRF-96SEQB was a sequence mixture as described previously, and here the positive sequence calling accuracy was 96%. ABRF-97SEQ also contained a mixture of two peptides and was similar to ABRF-96SEQB in quantity (~10:2 pmol ratio) and peptide composition. The ABRF-97SEQ study, which involved member laboratories running the sample and interpreting the resulting data, was designed to be comparable with the ABRF-96SEQB sequence calling exercise. The positive sequence calling accuracy of ABRF-97SEQ major was 92%, which was slightly lower than the ABRF-96SEQB major (96%). However, a comparison of the positive sequence calling accuracy obtained from ABRF-97SEQ samples run by the committee using the same instrumentation as the ABRF-96SEQB analysis shows the same positive sequence calling accuracy (96%). Thus, the positive sequence calling accuracy appears to be more dependent on instrumentation (model and upkeep) and sample handling and loading than on data interpretation.

ABRF-90SEQ (14) differed from all of the other studies in that this sample was adsorbed to a PVDF membrane. A major advancement in Edman sequencing was realized when Matsudaira (55) discovered that proteins could be sequenced from sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS PAGE) after electroblotting to a PVDF membrane. Sequencing from PVDF membranes propelled SDS PAGE from an analytical tool to a preparative procedure; it is still the method of choice for the final purification of proteins destined for N-terminal and internal (see next section) sequencing. The goal of the ABRF-90SEQ sample was to mimic a large electroblotted protein. Hence, a 29-residue synthetic peptide was covalently attached to an acetylated transferrin, mixed with yeast glucose-6-phosphate isomerase, and adsorbed onto a PVDF membrane. The sequence identified for this sample achieved only an 83% accuracy with respect to positive calls. This decrease from ~95% positive accuracy for previous studies may have been due to the difficulty of the sequence, the PVDF support, or background from the acetylated protein.

Therefore, the following study, ABRF-91SEQ (16), used a sample similar to ABRF-90SEQ. In this study, the 29-residue synthetic peptide was not covalently attached to the transferrin, and the sample (also containing the glucose-6-phosphate isomerase) was supplied in a dried form, which was dissolved before loading onto the sequencer. The positive sequence calling accuracy was also 83% for this study, and thus the PVDF appeared to not

have influenced the ability to call this sequence. The lower sequence calling accuracy in these two studies was probably due to the sample itself, which demonstrates nicely the dependence of the quality of the sequence data on the sample. In this instance, the lower sequence calling accuracy for the ABRF-91SEQ (83%) as compared, for instance, with the STD-1 sample (95%) may well be attributed to the increasing background that would be expected to accompany sequencing of the relatively high molecular weight (~80,000) transferrin protein that was in the ABRF-91SEQ sample. That is, the small fraction of nonspecific cleavage that occurs during each cycle of Edman degradation becomes more significant as the size of the protein (and thus the probability that it will contain an increased number of acid labile peptide bonds) is increased.

Two other challenges faced in amino acid sequencing are identification of posttranslational modifications and identification of difficult residues. ABRF-92SEQ (22) contained two posttranslationally modified amino acids—hydroxyproline and phosphoserine. Hydroxyproline was identified by 45% of the study participants using Edman sequencing alone, whereas only 13.9% were able to identify phosphoserine. Participants were encouraged to use amino acid composition, mass spectrometry, capillary zone electrophoresis (CZE), or other techniques to properly identify these residues. However, very few participants used techniques other than Edman degradation for sequence identification.

ABRF-94SEQ (31) focused on tryptophan and cysteine identification, which tend to be problematic because PTH cysteine is destroyed during Edman chemistry, and PTH tryptophan, recovered in low yields, often elutes on or near an Edman chemistry by-product, diphenylurea. Tryptophan identification in this study was somewhat improved (86%) over several previous studies (~70%), possibly because of the addition of isopropanol to solvent B. The isopropanol helps to separate the diphenylurea from tryptophan. Because cysteine degrades during Edman sequencing to dehydroalanine, it is usually necessary to reduce and alkylate the cysteines in the sample before sequencing. The ABRF-94SEQ study provided participants with seven different techniques that could be used to modify cysteines, with the hope of improving cysteine (Cys) identification. These techniques included cysteine modification to carboxymethyl-Cys, carboxamidomethyl-Cys, pyridylethyl-Cys, Cys-S-propionamide, Cys-S-dimethylpropionamide, *N*-isopropylcarboxyamidomethyl-Cys, and aminopropyl-Cys. Cysteine identification improved from ~53% in the ABRF-93SEQ sample to 82% in the ABRF-94SEQ sample.

In the ABRF-96SEQB (46) study, the cysteines were carboxamidomethylated with iodoacetamide by the committee, the sample was sequenced by the committee, and the PTH HPLC chromatograms were sent out to participating laboratories. In this study, 99% of the cysteines were identified correctly. This suggested that some difficulty was being encountered by facilities in alkylating the sample, willingness to alkylate the sample, or separating the PTH cysteine derivative from the Edman chemistry by-products or other PTH amino acids.

The ABRF-97SEQ study attempted to address this issue by alkylating the cysteines to Cys-S-propionamide using acrylamide before distributing the sample. This test sample contained a 10:2 pmol mix of two synthetic peptides and was the lowest amount of sample provided thus far in these studies. Two controls were also included with the sample, a PTH-Cys-S-propionamide standard and an internal sequencing standard. The PTH-Cys-S-propionamide standard was included so that separation of this derivative could be obtained before sequencing the sample. The cysteine calling accuracy for the ABRF-97SEQ sample was 88% for the cysteine in cycle 4 and 97% for the cysteine in cycle 13. Thus, although the positive sequence calling accuracy for cysteine was not quite as high in the ABRF-97SEQ study (Cys-13 = 97%) as in the ABRF-96SEQ study (Cys-13 = 99%), there was definite improvement over the ABRF-95SEQ study (Cys-15 = 63%). The 17-residue internal sequencing standard peptide (56) was composed of norleucine in cycles 1, 6, 11, and 16 and succinylated lysine in the other positions. Because this peptide is composed of nonnaturally occurring amino acids, it can be mixed with "unknown" sequencing samples. This allows independent and continuous monitoring of the sequencer's performance during all sequencing runs and rapid detection of instrument problems. The low amount of the ABRF-97SEQ sample was expected to be a challenge for the participating laboratories. However, based on the positive sequence calling accuracy for the 50 participating laboratories, the accuracy (92%) was not significantly decreased even for this low amount of sample (see Table 2).

In the ABRF-95SEQ (37) study, the sample was a recombinant 20K protein that contained microheterogeneity (2:1 molar ratio) in positions 6–9. The purpose of this sample was to assess participating laboratories' abilities to recognize microheterogeneity and to determine the length of sequence assignment that is possible. The longest correct sequence observed was 62 residues, including 1 cysteine and 2 tryptophans. The best responses (based on number of residues sequenced and sequence calling accuracy) were obtained on new-generation sequencers, specifically the Hewlett Packard G1005A and Perkin Elmer/Applied Biosystems Division 494 sequencers. Hence, this study suggests that these new instruments may result in improved performance. The overall average positive sequence calling accuracy on this sample was only 78%, which increased to 80% if the four cycles of microheterogeneity were excluded. The majority of the errors occurred in the later cycles and could have been minimized by terminating the sequence earlier, which illustrates another common problem, overcalling of sequences. Basically, the confidence of sequence calling decreases as the sequencing run progresses due to both loss of signal and (especially with relatively high molecular weight proteins) increased background.

Instrument Technological Improvement/Design over the Course of ABRF Studies

The first automated protein sequencer, based on Edman degradation chemistry, was designed by Edman and Begg in 1967 (57) and was manufactured by Beckman. This instrument, a Series 890 Beckman Automated Protein/

Peptide Sequenator (a liquid-phase sequencer), used a spinning cup to perform the coupling and cleavage reactions and was a major step forward in protein sequencing. A solid-phase automated sequencer was developed by Laursen in 1971 (manufactured by Sequemat) in which a polypeptide was covalently attached to derivatized controlled-pore glass beads to minimize sample washout. The PTH conversion and PTH amino acid analysis for both the liquid-phase sequencer and the solid-phase sequencer were done off-line and required several nanomoles of starting material.

A major advance in instrumentation occurred in 1981 with the introduction of the gas-phase sequencer (1), which was made commercially available by Applied Biosystems, Inc. The commercial instrument performed the entire Edman chemistry (including conversion), delivered the coupling base and TFA as gases (greatly reducing background), miniaturized the chemistry plumbing, and, most importantly, increased sensitivity to ~500 pmol of starting material. Samples were analyzed by application to a glass fiber disk coated with a polymer support (polybrene), which helps retain the sample. Shortly after the introduction of the gas-phase sequencer, Applied Biosystems introduced an on-line HPLC to serve as a dedicated PTH analyzer. This change automated the sequencing process, increased the quality of the data, and decreased the amount of starting material required to ~100 pmol. Minor improvements were made by Applied Biosystems such as incorporation of computer control of the instrument, data collection, and the introduction of pulsed-liquid delivery of TFA, which increases repetitive yields. Another sequencer, manufactured by Porton, was one of the first instruments to run multiple consecutive samples in series on a single instrument.

The next major change in Edman chemistry involved the introduction of biphasic columns (half reverse-phase-type material and half hydrophilic-silica-type material) by Hewlett-Packard to analyze samples. This allows samples to remain in the sequencer without use of a polymer support and also allows loading of samples in various salt-containing solutions. In the past few years, Perkin Elmer/Applied Biosystems Division has further miniaturized the instrument design and incorporated in-line sensors to regulate exactly how much reagent is delivered, thus optimizing the chemistry. Perkin Elmer/Applied Biosystems Division recently introduced a sequencer that uses a capillary HPLC, which increases sensitivity to below 1 pmol of starting material, so that PTH amino acid signals of ~50 fmol can be identified. Hence, the overall amount of protein/peptide required for Edman sequencing has decreased over the years from nanomoles (Beckman spinning cup) to subpicomole amounts (Procise cLC) and represents a greater than 10,000-fold increase in sensitivity in 17 years.

Due to these developments, it is currently relatively routine for a laboratory that specializes in high-sensitivity sequencing to obtain sequence from ~5 pmol of sample and, if the sequencer and PTH analyzer are carefully optimized, from 1–1.5 pmol of sample. In this regard, it is important to note that although reverse-phase HPLC-purified peptides typically have initial sequencing yields of ~50%, initial yields for SDS-PAGE purified samples are often less than 25% if electroblotting is not optimized or artificial N-terminal blockage occurs. Assuming 50% electroblotting efficiency from an SDS polyacrylamide gel to a PVDF membrane and an initial sequencing yield of ~15% for a sample that has been subjected to SDS-PAGE, 700 femtomoles of protein would need to be subjected to SDS PAGE to provide the minimum PTH amino acid signal of ~50 fmol required for the cLC instrument. It is important to note that although such a sample might yield 5–10 residues of sequence, a 10-fold greater amount would almost certainly result in higher-quality data and more positively called residues. Thus, it is difficult to respond to the often asked question of how little material is required because the answer depends on the quality and quantity of the sequencing data, the extent of N-terminal blocking that may have occurred during sample preparation, the molecular weight of the protein, the sequence itself, the instrumentation available, and the level of experience of the instrument operator. Current trends in amino acid sequencing include the use of mass spectrometry for obtaining a primary sequence from low and in some instances subpicomole amounts of peptides generated from gel-separated samples (58). In addition, much greater emphasis is being placed on using amino acid composition and mass spectrometric data to identify proteins via protein database searches without resorting to Edman degradation.

INTERNAL PROTEIN SEQUENCING

One- and two-dimensional PAGE offer powerful methods for the isolation of microgram quantities of individual proteins (59,60). Two-dimensional gels (in which the first dimension is usually isoelectric focusing and the second is SDS PAGE) are generally considered the method of choice for highest-resolution separation of complex protein mixtures at the microgram level and are often used to study the phenotypic-dependent alterations of protein expression in total cellular extracts or enriched cell fractions.

Either one- or two-dimensional PAGE is also often used for final purification of proteins destined for N-terminal sequence analysis. In either case the separated proteins are then electroblotted onto a PVDF membrane, first described as a support for protein microsequencing 10 years ago (55), stained with a dye such as Amido Black or Coomassie Blue, and the band of interest excised and placed in an automated peptide/protein sequencer. However, if the

protein has a blocked (e.g., acetylated) amino terminus (estimated occurrence of this modification is approximately 80% in soluble proteins from Ehrlich Ascites cells [53]), no useful sequence data will result. In addition, there are other reasons that may eliminate the direct N-terminal sequencing approach, including the need for noncontiguous stretches of primary sequence data for DNA cloning and/or the need to generate peptides that could be used for rapid protein identification via an increasing array of mass spectrometric approaches. All these considerations inspired the development of protein digestion methods that can be carried out in gel slices and on PVDF membranes. Although proteolytic digestion and peptide purification have been essential methods for the protein chemist in the study of protein structure and function, novel approaches were needed that conserved the limited quantities of available protein.

In 1987 Aebersold et al. (61) described a method for generating internal sequence from tryptic peptides recovered from proteins electroblotted to nitrocellulose. In rapid succession, methods were reported for in situ digestion of protein bands from Coomassie Blue–stained gels (62,63), proteins bound to PVDF (64), and cationic derivatized PVDF (65). It soon became apparent that microscale generation and isolation of internal peptides were extremely useful in obtaining primary sequence information from N-terminally blocked proteins, and internal sequence analysis radically changed the approach taken in protein sequencing laboratories. Additional refinements that improved each procedure (66–71) resulted in the rapid emergence of internal sequence analysis as a technique for obtaining sequence data from low abundance proteins and has created demands for these analyses that often are associated with unrealistic expectations.

In keeping with its role of education and implementation of new techniques and methodologies, the ABRF created the Internal Protein Sequence Research Committee in 1995 with the purpose of helping member laboratories evaluate or implement internal protein sequence analysis in their laboratories. The study goals that the Internal Protein Sequence Research Committee seeks to achieve are fivefold: (*1*) provide a mechanism for ABRF laboratories to anonymously compare their internal sequencing capabilities with those of other core laboratories; (*2*) provide a reasonable sample and well-proven protocols to facilitate introduction of this technology into laboratories that do not offer these services; (*3*) obtain data that can help determine the relative efficacy of internal sequencing from PVDF blots versus gel samples; (*4*) determine if there are any significant commonalities among the best in-gel and PVDF digestion protocols to help optimize these protocols, and (*5*) compile data obtained by multiple laboratories on the same "unknown" sample, to define more realistic expectations for internal sequencing.

The results of the two ABRF studies completed provide a basis for estimating the amounts of protein that are likely to be required for internal sequence analysis as well as the protein- and methodological-dependent limitations inherent to this approach and their probable impact on the results. Refer to the work of Williams and coworkers (47) for the details of the 1996 study. In brief, each ABRF study involved a microscale enzymatic digestion of protein bound to a membrane support or within an SDS PAGE, Coomassie Blue–stained band, followed by elution of the resultant peptides into a volume of buffer that often ranges from 50 to 200 μL. This peptide mixture can then be subjected directly to mass spectrometry and/or the peptides can be fractionated and a limited number individually sequenced by traditional chemical (Edman) degradation (see "Protein Sequencing" for a brief description of Edman degradation).

Although it is possible to use mass spectrometry to directly sequence individual peptides from complex protein digests, the expense (often more than $400,000) of the necessary equipment and the considerable expertise needed to successfully carry out this approach and to accurately interpret the data has so far limited its availability to a very small fraction of core laboratories. Increasingly, however, a much larger fraction of core laboratories are being equipped with the instrumentation needed to determine the masses (but not the sequences) of many of the peptides present in proteolytic digests. The resulting peptide masses are then searched against peptide mass databases that contain theoretical masses for all peptides expected from digesting known proteins with trypsin and other proteases. Although peptide mass searching provides an extremely rapid approach to identifying known proteins (72–75), which usually requires the use of only a small fraction of the digest, we believe most laboratories recommend that such an identification be confirmed by mass spectrometry or Edman sequencing of at least one peptide.

Microanalytical preparation of peptides from in situ proteolysis for Edman sequence analysis usually employs reverse-phase HPLC using a C18 [$CH_3(CH_2)_{17}$,-] stationary phase that is covalently linked to a silica-based resin packed into a 2.1-mm or smaller internal diameter column that is most often equilibrated with 0.05–0.1% trifluoroacetic acid in water. Peptides are eluted by linear acetonitrile gradients that extend from 0–5% (v:v) in the beginning of the gradient to 80–100% (v:v) at the end of the gradient. One or more peptides are selected for Edman degradation, with or without prescreening by mass spectrometric analysis (76), and the primary sequence is used to search protein and DNA sequence databases (GenBank, Protein Identification Resource [PIR], European Molecular Biology Laboratory [EMBL], Swiss Protein) to determine whether the protein has been previously identified.

As mentioned, two studies of these analytical strategies have been carried out by the ABRF Internal Protein Sequence Research Committee. The 1996 study was a comparative HPLC mapping study in which the participants received 70 pmol each of two recombinant proteins, 28 kDa and 30 kDa, which were identical except for an insert in the 30-kDa protein that generated a 15-residue tryptic peptide unique to the 30-kDa protein. A mixture of these two proteins was separated by one-dimensional SDS PAGE and either provided as Coomassie Blue–stained in-gel samples or electrophoretically transferred to PVDF membranes and stained with Amido Black. A synthetic peptide in which the sequence of the 15-residue unique peptide had been randomized served as an external standard calibrant. This standard was used to normalize data from various laboratories for use of different flow cell path lengths, flow

rates, absorbance wavelengths, and so forth. In-gel and PVDF blanks and representative protocols for each type of sample were provided. Participants who requested samples were asked to (*1*) perform a tryptic digestion of the 28-kDa, 30-kDa, and blank samples and subject all three digests plus the external standard to comparative HPLC; (*2*) identify the target peptide by its presence in the 30-kDa chromatogram, absence in the 28-kDa chromatogram, and elution near that of the external standard peptide; and (*3*) determine the amino acid sequence of the target peptide by traditional Edman degradation and/or mass spectrometric analysis.

For the 1997 Internal Sequencing Study, participating laboratories were asked to perform a tryptic digest on 50 pmol of a known 41-kDa recombinant protein, either in-gel or on PVDF, and to identify the target peptide contained within. A predigested sample of a recombinant protein containing a 23.5-kDa portion of the 41-kDa protein was supplied to assess the ability of the participating laboratory's instrumentation to perform the chromatography required to separate tryptic digestion mixtures. An external peptide standard was supplied that had similar, but not identical, chromatographic behavior to the target peptide. This peptide standard was used by the participants to help identify the target peptide and by the Internal Protein Sequence Research Committee to calculate the relative recoveries of tryptic peptides from each participating laboratory. In-gel and PVDF blanks and representative protocols for each type of sample were provided. In addition to providing a predigested sample, the 1997 study differed further from the 1996 study in that whereas the 1996 target peptide sequence was not in any commonly used database and was thus unique, the 1997 target peptide corresponded to an expected tryptic peptide from a protein whose sequence is included in all commonly used databases. Thus, the 1997 target peptide sequence could be deduced by utilizing observed peptide masses and/or partial Edman or mass spectrometric fragmentation data to search sequence databases.

Figure 2 shows one of the data sets that were returned in the 1997 study. In this instance, the participating laboratory carried out both in situ gel and on-PVDF membrane digests; as evident from this figure, both approaches provided excellent results. Although almost all significant absorbance peaks are unique to the samples, the digests carried out on "blank" gel and PVDF pieces reveal a few absorbance peaks that can be readily eliminated from further study based on their appearance in these control digests. These peaks may result from trypsin autolysis products, buffer-related contaminants, reagents used in SDS PAGE, or residual Coomassie Blue or Amido Black stain.

Several important conclusions follow from the data that resulted from the 1996 and 1997 studies, as summarized in Table 3. First, because hydrolysis and amino acid analysis of representative gel and PVDF bands from the 1997 study indicated that almost threefold more protein was present in the gel bands, the 41-kDa protein used in this study probably has a blotting efficiency of only 19/50 pmol (Table 3), or 38%, which is much lower than the >80% efficiency reported previously (77). Second, although the apparent recovery of the 41-kDa gel band following SDS

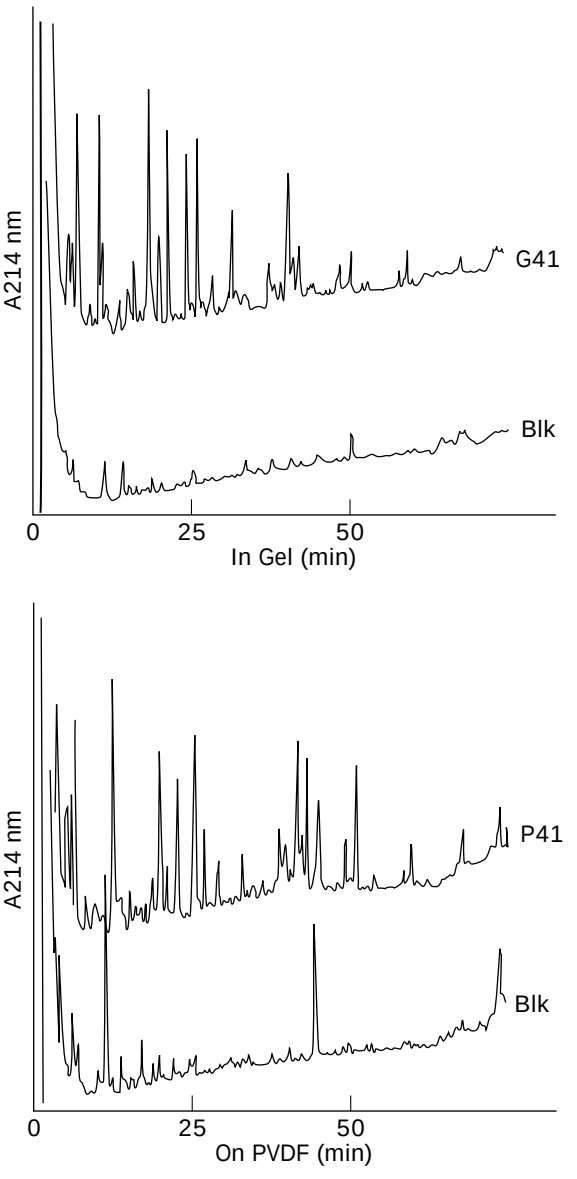

Figure 2. HPLC chromatograms submitted by participant 5 in the 1997 ABRF Internal Sequencing Study. The upper two chromatograms were obtained from tryptic digests of 50 pmol of the 41-kDa protein that were carried out either in the Coomassie Blue–stained gel band (upper panels) or on the Amido Black–stained PVDF membrane (lower panels). In both cases the corresponding digests carried out on blank sections of gels or PVDF membranes are shown in the lower chromatograms. HPLC was carried out at 50 μL/min on a 1- $\times$ 100-mm C18 column that was equilibrated with buffer A (2% acetonitrile, 0.057% trifluoroacetic acid in water) with detection at 214 nm. Peptides were eluted with linear gradients to 40% B (60 min), 60% B (65 min), and finally to 100% B (100 min). Although hydrolysis and amino acid analysis of several gel and PVDF protein bands indicated almost three-fold more protein in the gel samples (Table 3), the similar peak heights suggest a similar final yield of peptides from both the PVDF and gel samples. This suggests the facility that submitted the data may have obtained higher relative peptide yields from its PVDF as opposed to their in-gel digests.

Table 3. Summary of ABRF Internal Sequencing Studies

Parameter	In-Gel		On PVDF	
	1996[a]	1997	1996[a]	1997
Amount of protein subjected to SDS PAGE	70 pmol	50 pmol	70 pmol	50 mol
Amount of protein in stained gel or PVDF band[b]	ND	52 pmol	ND	19 pmol
Median sequencing yield from target peptide[c]	2.3 pmol	8.9 pmol	2.5 pmol	2.9 pmol
Overall target peptide yield[d]	6.4%	24%	7.6%	8.0%
Target peptide recovery from stained gel or PVDF band[e]	ND	23%	ND	21%

ND, no data.
[a]See Ref. 47 for further information regarding assumptions that were made to calculate overall peptide yield and other data from the 1996 study.
[b]As estimated by acid hydrolysis of the gel or PVDF band followed by amino acid analysis.
[c]Yield of valine (4) and of phenylalanine (3) in the target peptides used in the 1996 and 1997 studies, respectively.
[d]Calculated from the estimated initial peptide sequencing yield in cycle 1 (which was based on the median sequencing yield from the target peptide corrected to cycle 1 based on an estimated repetitive yield of 90%) divided by the estimated amount of protein loaded onto the SDS polyacrylamide gel.
[e]Calculated from the estimated initial peptide sequencing yield divided by the amount of protein in the stained gel or PVDF band.

PAGE and staining with Coomassie Blue was high, a previous study (70) demonstrated recoveries as low as 44% following SDS PAGE, Coomassie Blue staining, and washing of gel bands that contained relatively low molecular weight proteins. Hence, in the case of the six proteins (which had a median size of 15 kDa) used in this study (70), the median recovery of protein after washing of the Coomassie Blue–stained gel bands before in-gel digestion was 68% of the amount loaded onto the gel. Taken together, these data demonstrate that some proteins exhibit unusually high losses during electrotransfer to PVDF membranes, whereas other proteins exhibit unusually high losses using in-gel digestion methods.

Comparison of the overall target peptide yields for the two ABRF studies (Table 3) suggests that even when similar in-gel approaches are used, there can be substantial differences in the recovery of an individual peptide from two different proteins. As calculated from the estimated initial amount of peptide that actually sequenced versus the amount of protein subjected to SDS PAGE, the overall target peptide recovery from the 1996 in-gel samples was 6.4% as compared with 24% in 1997. This four-fold difference in peptide recovery makes it difficult to provide a precise answer to the often asked question of how much protein is needed for internal sequencing. Clearly, the answer can vary by at least fourfold, depending on the protein of interest, assuming, of course, that the amount of the protein of interest that was subjected to SDS PAGE is accurately known. Because we believe the most common means of estimating the amount of protein submitted for internal sequencing (comparative staining intensity) is also subject to at least two- to fourfold variability (depending again on the protein of interest), it is quite possible that a state-of-the-art core laboratory might correctly provide a fourfold or greater range in response to the question of how much protein is needed for internal sequencing. Alternatively, they may suggest an amount of protein that is sufficiently large that the internal sequencing project will likely succeed even if the protein in question stains more intensely with Coomassie Blue or Amido Black than an average protein and/or if peptide yields from this protein are below average. In view of the apparent fourfold or greater range in peptide yields following in situ enzymatic cleavage of different proteins, it is also apparent that studies and publications based on results from only a few nonrepresentative proteins may underestimate the amount of an average protein that may be needed to succeed with the same procedure. In this regard, it appears that neither of the two proteins used in the studies summarized in Table 3 are average. That is, the average recovery of 409 peptides that were sequenced from in-gel digests of 191 "unknown" proteins was 12.2% (70). In contrast, the 6.4% target peptide recovery for the 30-kDa protein used in the 1996 ABRF study (Table 3) suggests that this protein may be more difficult than an average protein to digest, and the 24% average in-gel target peptide recovery in the 1997 ABRF study (Table 3) suggests the 41-kDa protein used in this study may digest in a gel matrix much better than does an average protein.

As one means of approaching the question of how much protein is generally needed for internal sequencing, this question was asked of the participants in the 1997 study, which determined that the median response was 50 pmol protein. The results from the 1997 study indeed suggest that a core laboratory that routinely offers internal sequencing will indeed usually succeed if 50 pmol or more protein is subjected to SDS PAGE. Hence, 83% of the core laboratories that attempted to sequence a single peptide derived from the 41-kDa protein distributed in the 1997 ABRF study succeeded in identifying the protein based on database searches of the resulting sequence. Obviously, the percentage of laboratories that could have succeeded in this study is higher than 83%, because many laboratories isolated numerous other peptides from this protein in addition to the target peptide and many of these were probably suitable for sequencing. It appears from the 1997 ABRF Internal Sequencing Study that the 50-pmol estimate is sufficiently robust that even when one step in the procedure does not proceed optimally (such as the much lower than average blotting efficiency of the 41-kDa protein used in the 1997 study), usable internal sequences are nonetheless likely to be derived from the sample.

Another important response in the survey portion of the 1997 ABRF study was the answer to the question of what percentage of received samples are already in the databases. Because the median response was 75%, it is clear that the overall goals of internal protein sequencing will increasingly shift to protein identification (i.e., proteome

research) and to the elucidation of posttranslational modifications that usually cannot be predicted a priori from the ever-increasing wealth of cDNA sequences in nonredundant databases and that mass spectrometry will play an ever-increasing role in this endeavor.

Finally, the answer to the question of which approach (in-gel or on-PVDF digestion) is best for internal protein sequencing is that the two methods appear to be quite comparable. That is, when peptide recoveries are calculated from the Edman sequencing yields divided by the amount of protein in the stained gel or PVDF band (as opposed to the amount that was loaded onto the gel), the target peptide recoveries for both PVDF and gel samples were just above 20% in the 1997 study (Table 3). The optimal method for a specific project depends on the protein of interest and the personal preferences and level of expertise that the core laboratory workers to whom the sample will be submitted has with each of these approaches. Based on two ABRF studies, each of which involved about 40 core laboratories, we conclude that if a 50-pmol protein sample is subjected to SDS PAGE and then prepared according to the protocol recommended by the core laboratory to which the sample will be submitted, the probability of obtaining internal peptide sequences is likely to be much higher than 83%.

PEPTIDE SYNTHESIS

The goal of peptide resource laboratories is not only to supply the biomedical researcher with the high-quality peptides critical for scientific research at an affordable cost but also to actively research, test, and design new investigative peptides. To meet this challenge, the peptide chemist must be aware of, be able to learn, and be capable of instituting the latest techniques of peptide chemistry and evaluation. The ABRF Peptide Synthesis Research Committee was established to assist personnel of its member facilities in attaining this goal.

Use of peptides is diverse, ranging from use as antigens for the production of antibodies and as enzyme substrates or inhibitors to use for structure–function studies, for screening purposes, or as agonists or antagonists in biological assays and systems. For these applications, either large amounts of a small number of peptides or small amounts of a large number of peptides are usually necessary. More peptides with modifications are required to address important scientific questions such as the roles of phosphorylation and dephosphorylation in cell signaling. Peptide chemists are in the process of improving and developing new strategies for synthesis and evaluation of modified peptides. Examples of other modifications include biotinylated and fluoresceinated peptides for detection and quantitative assays, modifications that allow cross-linking on exposure to ultraviolet light, cyclized peptides for enhanced stability leading to enhanced biological activity, and a variety of other modifications of both the amino- and carboxy-termini and modifications of amino acid side chains.

To achieve the goal of supplying necessary, critical peptides for research, the following two components are essential: skilled, knowledgeable personnel and state-of-the-art instrumentation. Peptide synthesis laboratory personnel must be flexible and learn and institute new technologies quickly. Automated instrumentation belies the actual skill and experience required for peptide laboratory personnel. Peptide synthesis is not just "button pushing." Each peptide can vary considerably in the amount of design and planning required for synthesis. Some peptides require only routine synthesis, cleavage, desalting and/or purification, and analysis, whereas others may generate unique challenges at any or all phases of production. Many of these challenges lead to research projects involving collaboration between the peptide chemist and the biomedical researcher.

The laboratory must contain or have access to state-of-the-art instrumentation. The standard peptide synthesis instrument that produces a single peptide at one time is becoming inefficient except in cases of producing longer peptides. New instruments are being designed for multiple arrays and for more stringent chemistries and synthesis conditions. New instrumentation under development that can produce multiple peptides at one time with on-line cleavage is becoming state of the art. Though not perfected, these instruments can meet the demand for the production of large numbers of peptides. With the ability to produce large numbers of peptides comes the need to desalt and purify peptides efficiently and in a timely manner. HPLC systems are being developed to provide autoinjection and autocollection of either large numbers or large amounts of sample. As discussed later, the optimal means to ensure that the correct peptide has been made is by mass spectrometric analysis.

The Peptide Synthesis Research Committee's raison d'être has been to evaluate the quality of peptides produced by its member laboratories and to introduce and analyze new chemistries and technologies in solid-phase peptide synthesis. Since its inception in 1990 the Peptide Synthesis Research Committee has addressed several aspects of peptide production. The first two studies (17,20) were designed to determine and address potential problems in synthesis, cleavage, and side-chain deprotection. For peptide analysis, mass spectrometry with an accuracy of one atomic mass unit was found to be essential. HPLC and capillary electrophoresis are useful for quantitation but can be misleading. A single peak on a chromatogram can represent an incorrect peptide. HPLC is most useful for purification and collection. AAA is useful for quantitation but cannot identify specific problems, only that a problem may or does exist. Amino acid sequence analysis is costly, time-consuming, and cannot aid in identifying protected amino acids. Mass spectrometry proved to be most useful in identifying problems in synthesis, cleavage and deprotection, and identification of correct peptides.

Because cleavage from the resin was shown to be more problematic than synthesis or side-chain deprotection in

the first and second study, this step was specifically addressed in the third study (27). However, no correlations could be found between common side reactions occurring during cleavage and specific cleavage methods. The human element may play a critical role in the quality of peptide production.

The fourth study (32) was undertaken to determine if core laboratories had improved from the first study; therefore, the exact same peptide was requested for analysis as was requested in the first study. The submitted peptides were found to have increased considerably in quality from the first to the fourth study (in the first study, 78% of submitted samples had less than 25% of the correct product in contrast to the fourth study, in which 93% contained greater than 25% of the correct product). The sixth study (45) showed even greater improvement (almost 95% of the submitted samples contained greater than 70% correct product).

The fifth study (36) addressed problems in disulfide bond formation and introduced cyclization to the member laboratories. It was found that peptide cyclization can be performed on a routine basis with high yield. The sixth study (45) was undertaken to examine potential problems in racemization. It was found that histidine racemization may not be a major problem, but researchers should evaluate their peptide application beforehand to determine whether racemization is important. If even low levels of racemization could pose a potential problem, the racemized peptide can be separated from the correct peptide by HPLC techniques.

In the seventh study, the Peptide Synthesis Research Committee introduced and analyzed phosphorylated peptides requested from its member laboratories. This study was initiated because peptide modifications are becoming necessary for a number of applications. One very important modification is the role of phosphorylation in cell signaling and transduction. This study should determine whether it is feasible to synthesize posttranslational peptide modifications, such as tyrosine phosphorylations.

Other important observations and conclusions drawn from the studies conducted by the Peptide Synthesis Research Committee include the following: A shift in the type of chemistry used in solid-phase peptide synthesis has occurred from Boc to Fmoc chemistry (from 50% in 1991 [17] to 98% in 1996 [45]). This is probably due to Fmoc chemistry being safer, more flexible, and less problematic. One observation that has been repeated with each year's study is the unexpected occurrence of human errors in peptide synthesis. Each year's study contains a few surprises. For example, one year a submitted test peptide was synthesized in the wrong direction. It is not known whether these incorrect peptides are mainly due to inexperience or to human error, but they should convince all concerned that postsynthesis peptide analysis is critical. The best combination of techniques to ensure the correct product is HPLC (see Fig. 3) and mass spectrometric analysis (see Refs. 17, 20, 27, 32, 36, 38, 44, and 45).

The peptide laboratory must be flexible and capable of constantly changing to meet the needs of biomedical research. Academic peptide laboratories cannot compete with commercial peptide facilities without support from

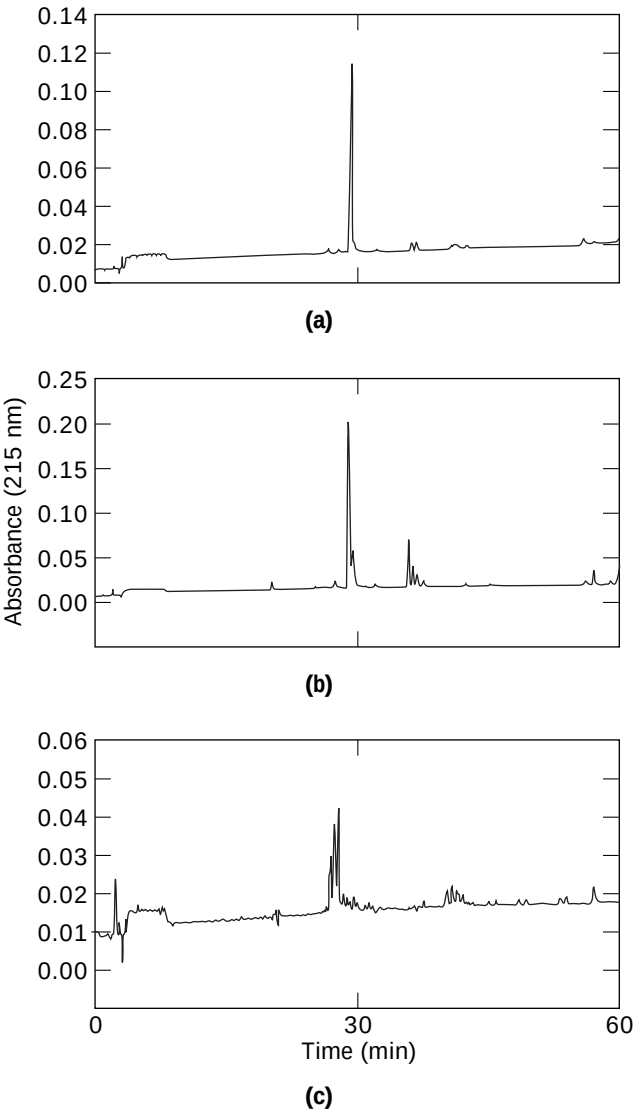

Figure 3. Analytical reverse-phase HPLC chromatograms from three peptide samples submitted in the ABRF 1995 Peptide Synthesis Study. Biomedical researchers should determine whether their studies require purified (greater than 70% correct peptide) or highly purified (greater than 95% correct) peptides. If the study does not require highly purified material, then considerable time and cost can be saved. Usually 70% correct peptide can be obtained with a good synthesis followed by a desalting step. To obtain highly purified peptides, HPLC is usually necessary. Examples of the linear peptide used from the ABRF 1995 study are shown (36). **(a)** Greater than 96% pure peptide; **(b)** good peptide, greater than 76% pure; **(c)** poor synthesis. The major peak by HPLC from any synthesis should always be analyzed by mass spectrometry to ensure that the peak represents the correct peptide.

their institutions. The rationale for institutional support is the availability of advice, consultation, potential collaboration, potential for modifications and chemistries not readily available through commercial ventures, and reduced cost to the investigator. The common goal of the peptide chemist and biomedical researcher should be scientific endeavor and not profit or monetary gain. The future of

peptide laboratories will definitely include new chemistries, new peptide and amino acid modifications, the synthesis of longer, larger peptides, and new instrumentation. Perhaps in the future, combinatorial libraries may be generated for basic research or such exotic chemistries as peptide nucleic acids will be utilized. The ABRF Peptide Synthesis Research Committee will continue to assist its members with these challenging and changing goals.

CARBOHYDRATE ANALYSIS

R. REID TOWNSEND
University of California–San Francisco
San Francisco, California

Determining the monosaccharide content of glycoproteins (*1*) provides the basis for further structural studies, (*2*) suggests classes of oligosaccharide chains, (*3*) provides unequivocal evidence that the polypeptide chain is glycosylated, and (*4*) may serve as a measure of production consistency for therapeutic glycoproteins. The presence of GalNAc (as $GalNH_2$ after de-*N*-acetylation from acid hydrolysis) suggests mucin-type *o*-linked structures. Only Man and GlcNAc suggest oligomannosidic-type structures; GlcNAc, Man, Gal, and Fuc suggest lactosamine-type oligosaccharides; and Glc and Gal suggest glycosylation of hydroxylysine and hydroxyproline residues. Historically, monosaccharide analysis has been a three step process of (*1*) release of residues from oligosaccharide structures and the polypeptide backbone (*2*) derivatization for gas chromatography (GC) or HPLC, and (*3*) chromatography with quantitative detection. It is well recognized that breakage of glycosidic and protein–sugar bonds by acid hydrolysis or methanolysis is often incomplete and results in some destruction of monosaccharide residues, although many studies have been performed to optimize the yield of released monosaccharides. For GC, volatile monosaccharide derivatives must be prepared (78,79). For HPLC, derivatization is used to increase hydrophobicity for reverse-phase chromatography and to increase the sensitivity of detection (for review, see Ref. 80). The chemical diversity and lability among neutral, amino, and anionic classes of monosaccharides necessitates different release and derivatization methods to analyze all of the sugars from a glycoprotein. The detection of carbohydrates on gold electrodes in a low-volume flow cell after separation using high-pH anion-exchange chromatography (HPAEC) obviates the need for derivatization of neutral, amino, or anionic monosaccharides in samples that contain ~100 pmol of individual monosaccharides (for review, see Ref. 81). The commercialization of HPAEC with pulsed amperometric detection (PAD) has resulted in a wider availability of monosaccharide analysis using a single method. Most recently, fluorophore-based methods, which are available in a kit format from vendors, should further increase the general availability of monosaccharide analysis. Finally, the oligosaccharides on a single protein occur as an array of structures whose proportions are difficult to quantify, and the type and proportions of structures can vary from lot to lot, even after isolation from the same source.

In 1995 the ABRF Carbohydrate Analysis Research Committee (CARC) initiated a study to determine the ability of research laboratories and core facilities to identify and quantify carbohydrates (43), which are commonly found in N- and O-linked oligosaccharides of glycoproteins from serum, cell membranes, and recombinant expression systems. Test sample A was ultrapure grade bovine serum albumin from Calbiochem (San Diego, California), and test sample B was bovine fetuin, purified by the Spiro method from Gibco (Grand Island, New York). The two test samples were lyophilized from water and quantified by hydrolysis followed by amino acid analysis. Based on the average of the values for alanine and valine, test sample B contained 25 nmol fetuin, which was chosen because it is one of the most well-characterized glycoproteins (82–88). All participating laboratories ($n = 29$) correctly identified which sample was glycosylated. In 14 cases the glycosylated sample was identified by AAA or colorimetric assays. The amino acid compositions were analyzed further using PROPSEARCH (89), which can be accessed via the Web site *(www.embl-heidelberg.de/aaa.html)* to identify the test samples as bovine serum albumin and bovine serum fetuin. Monosaccharides were quantified using HPAEC PAD (14 laboratories), HPLC after precolumn derivatization with 1-phenyl-3-methyl-5-pyrazolone (90) (one laboratory), gas chromatography and mass spectrometry (four laboratories), or gel electrophoresis after derivatization with 2-aminoacridone (one laboratory) (91).

Analysis of the glycosylated test sample by 4 CARC laboratories and 10 participating laboratories using HPAEC PAD gave the following results (in mol/mol of protein): GalN, 2.3 ± 39%; GlcN, 16 ± 23%; Gal, 12 ± 44%; and Man, 9 ± 55%. (The error is expressed as percent standard

Table 4. Monosaccharide Composition of Bovine Fetuin as Determined by HPLC (Mole Sugar per Mole Protein)

Monosaccharides	Literature[a] (1984–1991)	CARC[b] (1995–1996) (%)	External laboratories (%)
GalNAc (3)[c]	1.2–3.5	2.7 ± 20[d]	2.2 ± 41
Man (9)	6.4–8.3	9.6 ± 15	8.0 ± 50
GlcNAc (15)	11.5–16.4	17.2 ± 9	15.2 ± 27
Gal (12)	9.3–13.0	12.4 ± 24	11.6 ± 43
Neu5Ac (12)	7.2	14.8 ± 9.5	15.2 ± 27

[a]Reviewed in Ref. 78.
[b]Values after iterative analyses by CARC.
[c]Values in parentheses are theoretical and estimated.
[d]Based on the amino acid analysis of the bovine fetuin test sample (25 nmol from an average of alanine and valine content). The percent standard deviation is given in terms of σ_{n-1}.

deviation.) The results from GC analysis (alditol acetate and trimethylsilyl derivatives) from four laboratories also showed large errors: GalNAc, 1.7 ± 43%; GlcNAc, 9.2 ± 36%; Gal, 13.6 ± 35%; and Man, 9.6 ± 26%. The analysis of *N*-acetylneuraminic acid by both the CARC and participating laboratories gave a lower percent standard deviation by both HPLC (15.2 ± 17%) and GC (13.2 ± 23%). Finding these errors too large, CARC undertook a systematic internal study to identify sources of error in monosaccharide analysis by HPAEC PAD. First, it was established that interlaboratory variability was significantly greater than the analysis of the same bovine fetuin sample when performed on a single instrument over a 6-month period: GalN, 2.4 ± 8.8%; GlcN, 16.4 ± 8.6%; Gal, 12.8 ± 15% and Man, 7.8 ± 4.6%. Because all studies were performed with external standards, monosaccharide standards from four CARC laboratories were analyzed in the same laboratory. The percent standard deviation was no greater than 15% and for most monosaccharides was less than 5%, indicating that standard preparation was not a major contributor to the error among CARC laboratories. Based on literature reports and experience within CARC laboratories, standard hydrolysis conditions were adopted for neutral and amino sugars (2 M trifluoroacetic acid for 3 h at 100 °C) and sialic acids (2 M acetic acid for 3 h at 80 °C). Because monosaccharides can be destroyed under acid hydrolysis conditions used for their release, CARC used external standards that had been hydrolyzed under the mentioned conditions. Untreated external standards and standards that had been subjected to the same hydrolysis conditions as the glycoprotein were then compared. Unexpectedly, the amino sugar electrochemical responses in the hydrolyzed standards were increased as much as twofold, suggesting that the higher values observed for amino sugar determination, both in some CARC and participating laboratories, were due to this phenomenon. The lower peak areas were attributed to either selective loss of amino sugars through the injection path or reaction of free amino groups on the standard nonacetylated sugars with the aldehyde functions of the monosaccharides in both the standard mixture and hydrolyzates.

To control further for variability associated with hydrolysis of samples, a single hydrolyzate of the bovine fetuin sample was prepared in one laboratory (in a single vessel) and then distributed to the other CARC laboratories for analysis by HPAEC PAD. Hydrolyzed, external monosaccharide standards were also used. The following reduction in percent standard deviation was observed from four CARC laboratories: GalN, 2.7 ± 20%; GlcN, 17.2 ± 9.1%; Gal, 12.4 ± 22%; and Man, 9.6 ± 15%. In summary, by adopting standard hydrolysis conditions, ensuring that the external standards prepared in different laboratories gave similar responses and using hydrolyzed external standards, the interlaboratory error of HPAEC PAD analysis was significantly improved; however, interlaboratory error remained greater than those observed using a single instrument.

Table 4 compares the monosaccharide compositions of bovine fetuin from literature values with those obtained by CARC after the iterative analyses discussed earlier and with those from participating laboratories, all using HPLC. Overall, the mean values obtained by both the CARC laboratories and the participating laboratories vary by no more than two residues; however, the error range associated with the external study was significantly greater. The theoretical values (indicated in parentheses in Table 4) were estimated from the oligosaccharide structures and the number of modified sites on the protein. Bovine fetuin has three N-linked sites that contain biantennary (84,86) and triantennary structures (82,87,88; Fig. 4). In addition, at least three O-linked sites, occupied with sialylated di- and tetrasaccharides (83,85; Fig. 4), are present (83). The value of three GalNAc residues assumes complete site occupancy of three O-linked sites; however, it is well recognized that glycosylation at serine and threonine residues is frequently not stoichiometric. An approximately threefold range of values has been reported in the literature and by the external laboratories participating in the 1995–1996 study for the GalNAc composition of fetuin (Table 4). The CARC laboratories found an average value of 2.7, with a range of 2–3 residues.

If all three N-linked sites are fully occupied, nine Man residues would be present in fetuin. The value obtained by CARC approached this value, with an average of eight reported in the external study and a larger error. The theoretical value of 15 for GlcNAc accounts only for the composition of three triantennary structures; however, the O-linked tetrasaccharide also contains GlcNAc (Fig. 4). Whether the value of 17 residues from the CARC analyses reflects a significant amount of the tetrasaccharide in fetuin will require further studies. The 12 theoretical Gal residues are estimated from three triantennary structures and three O-linked disaccharides, and the 1995–1996 results approach this value (Table 4). The determination does not indicate the presence of biantennary structures which have one less Gal residue, nor the tetrasaccharide, which has one more Gal residue. Complete sialylation of 12 Gal residues would result in 12 Neu5Ac residues. The greater value for Neu5Ac indicates complete sialylation and is also consistent with the presence of the known tetrasialylated triantennary structures in bovine fetuin (87,88).

Overall, these results show that quantitative monosaccharide analysis in combination with amino acid analysis, to determine the amount of protein, gives molar ratios of sugars to protein that are in agreement (within one to two residues) with the oligosaccharide content. However, these studies have also shown that there is a significantly larger error associated with analyzing the same hydrolyzate on different instruments (43). Future studies will focus on the reanalysis of the same test sample to identify factors that are related to differences in instrument configurations and interlaboratory analyses.

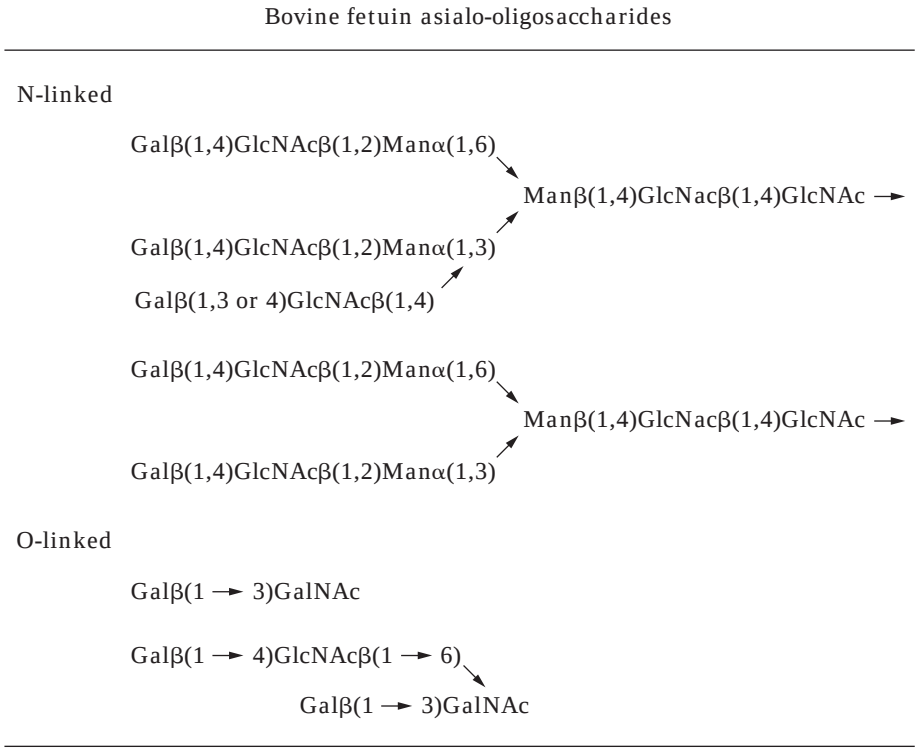

Figure 4. Structures of bovine fetuin asialo-oligosaccharides.

The dramatic growth in the use of molecular biology methods in biomedical research over the past 15 years has seen a corresponding increase in the number of core laboratories engaged in providing essential DNA chemistry services, especially automated DNA synthesis and DNA sequencing. To effectively utilize these resources, it is important for the investigator to have realistic expectations regarding the current capabilities of this technology. To determine the level of technology that can be routinely reached, provide a means of self-evaluation, and gain valuable comparative data beneficial to the field, the ABRF regularly surveys member laboratories and tests facility capabilities through distribution of "unknown" samples for analysis. Two ABRF committees have been established to evaluate nucleic acid chemistries. The Nucleic Acids Committee has published three studies since its inception in 1991, the first designed to assess the type of nucleic acid services provided by core facilities (24), the second designed to assess the accuracy of automated DNA sequencing services (29), and the most recent designed to determine the quality of synthetic oligonucleotides produced by member laboratories (33). The tremendous increase in use of automated DNA sequencing led to the establishment of a second committee in 1995 whose focus is specifically DNA sequencing. The DNA Sequence Research Committee recently completed a general survey and a study designed to assess member laboratories' capabilities in sequencing a moderately difficult GC-rich template (39; *http://www.dfci.harvard.edu/abrfdnaseq*). The results of the most recent of these studies are summarized in the following and provide an overview of the current capabilities of core laboratories that provide DNA synthesis and DNA sequencing services.

ABRF DNA Synthesis Studies

The ABRF has conducted two studies regarding DNA synthesis in core laboratories; the first in late 1992 was a survey designed to obtain information on instrumentation used, favored chemistries, modifications, charge-back fees, and so forth (24). The most recent study was conducted in April 1995 when member laboratories were again asked to respond to a brief survey but were also asked to provide the crude trityl-off, deprotected, and lyophilized products from a 25-base and 50-base 0.2-mmol-scale DNA synthesis for analysis by the Nucleic Acids Committee (33). Seventy-one laboratories participated in the survey and submitted 208 oligonucleotides prepared on a distribution of instruments from various vendors that was essentially unchanged from the 1992 survey. New developments in instrumentation (higher capacity or throughput, lower reagent consumption), lower reagent prices, and increasing competition from commercial providers has led to substantial reductions in charge-back fees; the median rates for oligonucleotide synthesis decreased 20–30% from the previous study to $1.90/base for the 40-nmol-scale synthesis (the actual total cost of synthesis is estimated to be $3.80/base, assuming an institutional subsidy of 50%). Median annual output from these facilities had increased more than 20% to 1,440 oligonucleotides per year. Although new developments in DNA synthesis chemistry have occurred (e.g., fast deblocking reagents), most respondents (80%) continued to use phosphoramidites with the conventional *N*-benzoyl and *N*-isobutyryl protection groups and controlled pore glass (CPG) supports, which suggests that these traditional reagents continue to provide the highest overall satisfaction.

The synthetic oligonucleotides submitted to the committee were analyzed by capillary electrophoresis (CE) to estimate overall yield and purity and were used as primers in DNA sequencing reactions as a functional measure of quality. Overall yield by CE of most of the oligonucleotides was very good. Purity ranged from 14 to 95%, with an average of 74% for 25-mers (Fig. 5) and from 1 to 92% with an average of 50% for 50-mer (data not shown). Average median coupling efficiencies of 98.9% for 25-mers and 98.7% for 50-mers were calculated. Coupling efficiencies of >98% are usually guaranteed by reagent and instrument manufacturers, and this number has been used previously as a minimum standard. Thus, the vast majority (approximately 85%) of crude oligonucleotides submitted for analysis exceeded the minimum standard. To put coupling efficiencies into perspective, it should be noted that with a coupling efficiency of 98%, the maximum yield of desired product for a 25-mer, 50-mer, and 100-mer synthesis would be 61%, 37%, and 14%, respectively, with the remaining material in each preparation resulting from $n - 1$, $n - 2$, $n - 3$, . . . species. Because most facilities perform quality assurance measures and offer purification services, many of the substandard oligonucleotides would have been detected or eliminated before distribution.

As an additional measure of quality, the crude 25-mers were tested for their ability to function as primers in automated DNA sequencing reactions. A total of 103 of 104 25 mer submitted generated sequence data, and most of the data were remarkably good. Four primers produced perfect sequences over a 400-base window downstream from the primer target; half generated fewer than four errors (including insertions, deletions, substitutions, and ambiguities), and only those in the bottom quartile generated more than seven errors. The number of sequencing errors generated by each 25-base primer was compared with the CE-measured purity of that primer (see Fig. 5). Surprisingly, primer purity does not strictly correlate with sequencing fidelity. Primers that were >70% pure generally produced sequence data with an accuracy >97.5% over the 400-base window. Primers with a purity <70% yielded mixed sequencing results, although 18 of 25 primers that were only 54–70% pure still generated good (<10 errors) sequence data. Overall, more than 85% of the crude 25-mer oligonucleotides yielded unedited sequence data that were >97.5% error free over the 400-base test window. Because unprocessed postsynthesis samples were requested, these results also suggest that purification or desalting provides only marginal benefit for the synthesis in which the average coupling efficiency exceeds 98.5%.

ABRF DNA Sequencing Studies

The ABRF has conducted two formal studies that focus exclusively on DNA sequencing services. A 1995 survey, conducted by the Nucleic Acids Committee (29), was designed to determine the accuracy of sequences obtained using dye-primer or dye-terminator chemistry and *Taq* polymerase. A standard double-strand DNA template was mailed to 80 member laboratories; 44 responded by submitting 83 DNA sequence data sets for analysis. These were grouped by chemistry utilized (dye terminator or dye primer) and whether postrun editing was employed (edited or unedited). The results showed that, using *Taq* polymerase, dye-primer chemistry provided the longest and most

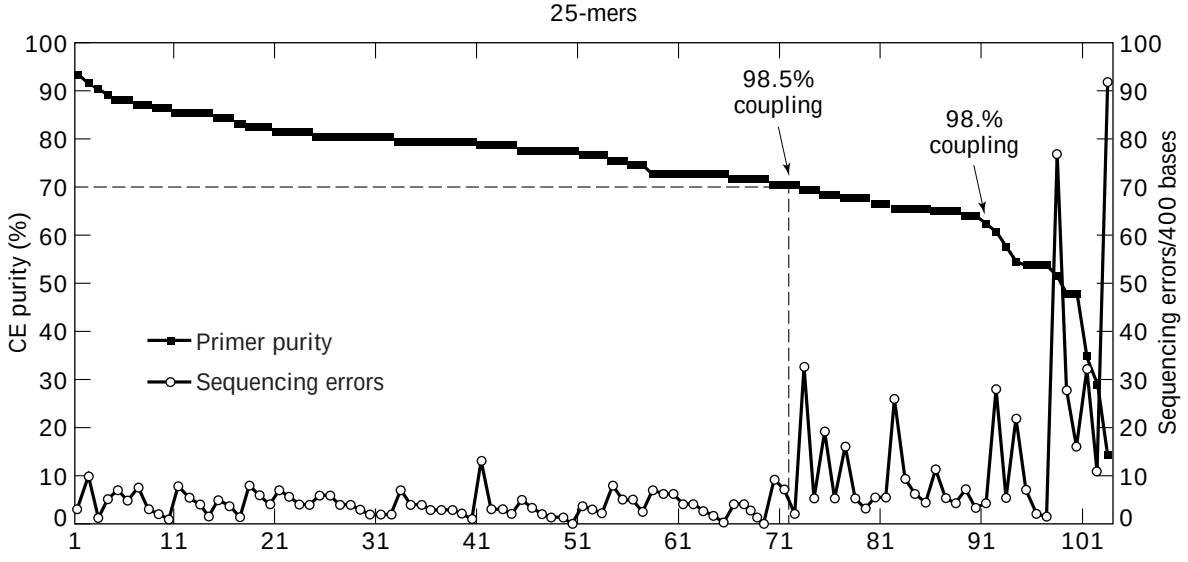

Figure 5. Oligonucleotide purity and performance as sequencing primers. Purity and sequence performance of 25 mer. The capillary electrophoresis (CE) determined purity (■) of the 25-mer oligonucleotides is illustrated in descending order from highest (95%) to lowest (14%) purity. Also plotted is the number of sequencing errors (○) (deletions, insertions, miscalls, and ambiguities) found in the first 400 bases of unedited, automatically called sequence when the 25 mer were used as sequencing primers. CE purity of 70%, representing approximately 98.5% average coupling efficiency, is indicated. The industry standard 98% average coupling efficiency is indicated.

accurate sequence. Edited dye-primer data were >95% accurate out to 400–450 base pairs, whereas edited dye-terminator data were accurate at this level only to 300–350 base pairs. However, most laboratories in this sampling (75%) prefer the dye-terminator protocol, presumably because of its versatility and convenience. Laboratories that manually edit dye-primer data were able to obtain an additional 100 base pairs of data. Surprisingly, editing of dye-terminator data did not increase the length of read for this template.

The DNA Sequence Research Committee's 1996 survey was designed to assess member laboratories' ability to sequence a moderately difficult double-stranded plasmid DNA sample containing a GC-rich insert (69% GC over 926 base pairs) while studying the effectiveness of protocols developed for GC-rich samples, changes in sequencing chemistry, performance according to sequencing hardware, the type of products used, and the effect of editing. In addition, a questionnaire was included to allow comparisons with previous studies (6,7,24). Responses to the questionnaire revealed that the number of facilities performing automated DNA sequencing and the number of samples sequenced per year continues to grow. In 1989, 12 laboratories participated in the survey and reported sequencing an average of 240 templates per year. In comparison, in 1993, 37 laboratories reported sequencing an average of 2,100 templates per year, and the 1996 survey showed 53 laboratories sequencing an average of 4,560 templates per year, of which 76% were double-stranded plasmids and 21% were polymerase chain reaction (PCR) products. Fluorescent techniques were used by all contributing facilities in 1996, dye-terminator chemistry was used by 82%, and the new TaqFS (Perkin Elmer/Applied Biosystems Division [PE/ABD]) enzyme was used by two-thirds. The 53 laboratories that participated in the 1996 study generated 78 sequencing data sets for analysis. The majority of respondents submitted data obtained using dye-terminator sequencing chemistry and the enzyme TaqFS. The sequences were ranked according to length of entirely correct sequence. Keeping in mind that this was a difficult sequence and a routine run was requested, the average length of correct unedited sequence for all machines was 284 bases and the longest was 615 bases. Gel length, manual data review, and sequencing chemistry all influenced sequence accuracy and length. The average correct unedited length of read for PE/ABD Stretch instruments equipped with 36- or 48-cm plates was 362 bases compared with an average of 232 bases for all other instruments. In several direct comparisons, it was shown that an average of 157 more bases of correct sequence were obtained by manual editing for this difficult template. Some facilities submitted data plus or minus dimethylsulfoxide (DMSO) in the sequencing reactions. In most cases DMSO increased the length of correct sequence; however, many of the top-ranked responses did not use DMSO. The 1997 study focused on elucidating the benefits of DMSO, altered thermocycling procedures, and editing when sequencing difficult GC rich templates. A summary of the average error-free length of read depicted by machine, well to read (length of the gel), and a comparison of edited versus unedited sequence can be seen in Figure 6.

In summary, studies conducted by the ABRF reveal that the vast majority of DNA core facilities that offer DNA synthesis services produce synthetic oligonucleotides of high quality. The typical facility in 1996 utilized cyanoethyl phosphoramidite chemistry to produce more than 1,400 synthetic oligonucleotides per year. The average charge-back fee was $1.90/base for 40-nmol scale (an estimated total cost of $3.80/base assuming an institutional subsidy of 50%). Surprisingly, even crude primers of relatively low purity were found to function well when used in automated DNA sequencing. Primers with a purity of >70% were found to function well as DNA sequencing primers without any further purification or even desalting, whereas primers with purity <70% were less likely to function well in DNA sequencing reactions. The average DNA core laboratory that offered automated DNA sequencing services in 1996 typically used dye-terminator chemistry and TaqFS polymerase. A median of 4,560 templates per year were sequenced for an average fee of $29.50/template (estimated total cost $59/template assuming an institutional subsidy of 50%). Minimum template requirements were 0.5–1.0 μg DNA, from which the user could expect to obtain 400–800 base pairs depending on the length of the gel. A recent study (39) has shown that postrun editing of the raw data can substantially increase the sequence accuracy from difficult GC-rich templates when using the most popular chemistry and enzyme.

Often regarded as a supportive or adjunct technique by biomolecular resource laboratories, and initially employed by them largely as a procedure for the quality control of synthetic peptides (17), mass spectrometry is rapidly becoming a major analytical tool for biopolymer analysis (in several instances it has become the only available tool for their structural analysis). With the advent of electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI) methods, mass spectrometry has become a popular and powerful method for analyzing large biopolymers such as peptides, proteins, and both native and modified oligonucleotides (92–97). No longer an exercise reserved for specialty laboratories, the use of mass spectrometry for sequencing picomole quantities of peptides and proteins is becoming widespread (see test sample results later in this article), with a few laboratories able to achieve results in the femtomole range (98,99). Used in conjunction with automation and databases, such sequence and fragmentation mass data can provide identification of biologically interesting proteins isolated by two-dimensional gel electrophoresis (100–102). This technique, when applied to the study of cellular response to a given stimulus as reflected by its entire complement of proteins

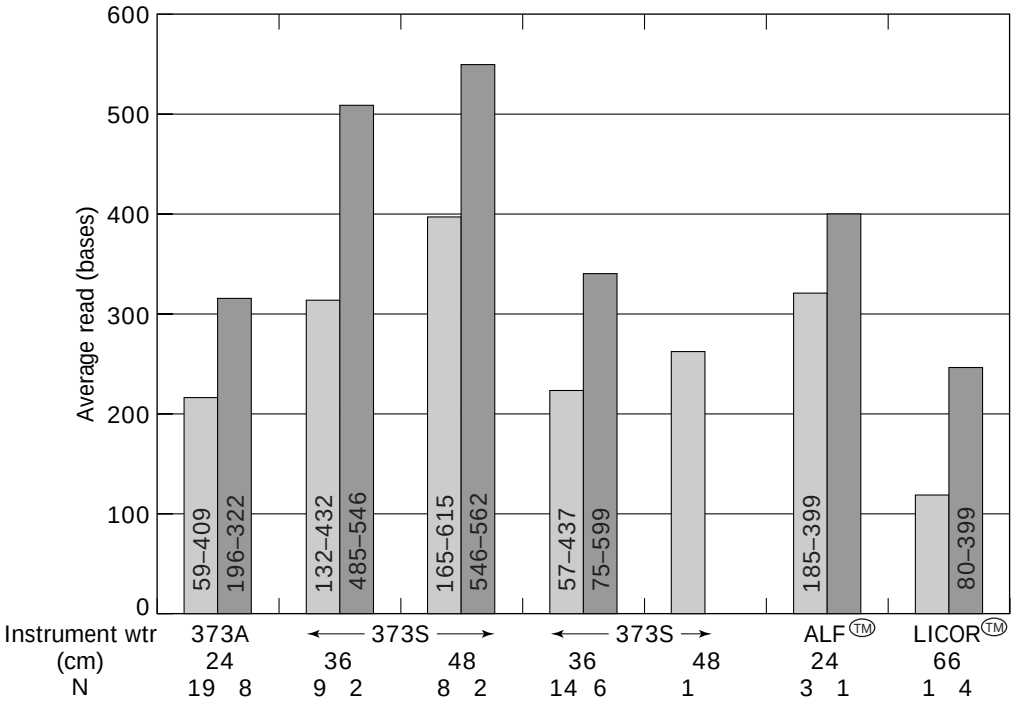

Figure 6. A summary of the average error-free length of read depicted by machine (instrument) and well to read (WTR; length of the gel in centimeters). Values for unedited sequences are open bars, and values for edited sequences are shaded bars. Ranges and the number of samples per group *(N)* are shown.

at a particular point in time, has come to be known as proteome science (103) and is an area of intense effort. If compared with the conventional N-terminal sequence analysis by Edman degradation, the direct generation of peptide fragments and their sequence analysis within coupled mass analyzers (MS/MS) is faster and more sensitive (although data interpretation can sometimes take longer) (104). It has the advantage that modified amino acids can be identified more easily and that a blocked N-terminus does not present a problem for a successful analysis. On the other hand, amino acids of equal mass (such as isoleucine and leucine) generally cannot be distinguished, and glutamine and lysine, which differ by only 0.036 mass units, are determined only with difficulty or after chemical modification of lysine. Another disadvantage is that sequence analysis utilizing mass spectrometric techniques is limited to relatively short peptides. Peptides longer than about 25 amino acids can be sequenced with mass spectrometry, but only if special techniques (which may not be generally available in core laboratories) such as ladder formation through cyclic chemical degradation are employed or by the use of exoproteases such as carboxypeptidase and aminopeptidase (105,106). This allows readout of the sequence by a single mass determination. Automated sequencing by Edman degradation is often less ambiguous and easier to interpret than de novo sequence analysis of peptides by mass spectrometry, which remains a somewhat laborious technique that requires great expertise. Nevertheless, for the identification of peptides and proteins of known sequence, mass spectrometry has become the method of choice.

The goals of the ABRF Mass Spectrometry Committee include determining current state-of-the-art mass spectrometry capabilities in resource laboratories, providing test samples to permit anonymous self-evaluation, and fostering mass spectrometric techniques relevant for the biochemist. As part of an initial research study, the committee conducted a survey designed to obtain information about current mass spectrometric capabilities in 284 ABRF laboratories. The survey revealed that close to 90% of the respondents were engaged in mass spectrometry, and the respondents expressed a desire to receive a test sample designed to address basic issues of mass accuracy and resolution. In addition, the test sample would measure how well the laboratories identified peptides in mixtures that utilize mass spectrometric data with database analysis. To assist them in the identification of the unknown sample, participants were allowed to use adjunct methods such as HPLC separation of components, amino acid analysis, and enzymatic digestion by endo- and exoproteases. The more advanced laboratories were invited to perform collisional activated dissociation (CAD) and/or postsource decay (PSD) fragmentation to achieve direct mass information on fragments and to use this information for the process of identification.

Initial Results of the Survey

As mentioned, 95 out of 107 (88.8%) laboratories that responded reported using some form of mass spectrometry. The majority of the laboratories had only recently added the technique; 19 had less than 1 year experience, 60 re-

ported between 1 and 10 years experience, and only 8 reported more than 10 years experience in mass spectrometry. More than 98% of the mass spectrometers were reported to have been obtained commercially, and although most laboratories had only one, surprisingly, six laboratories reported having more than three. The choice of hardware showed about half (52.5%) that used MALDI or time of flight (TOF) and close to 37% used ESI/quadrupole instrumentation. A few used the newer technology of ESI quadrupole ion trap analysis. Only two laboratories reported using fourier transform ion cyclotron resonance mass analyzers (FTICR). According to the results, the most frequently analyzed samples were peptides and proteins, but 36 laboratories reported doing carbohydrate or glycoprotein sample analysis and 24 reported analyzing oligonucleotides, and other samples were lipids, peptide nucleic acids (oligonucleotide analogs that have a peptidelike backbone), and small organic molecules. Most sites ask for 1 to 10 pmol of sample for a mass determination. Surprisingly, and despite recently reported and dramatic results using mass spectrometry as the sole means for the identification of proteins (98,99), a majority surveyed said they perceived mass spectrometry as a supportive technique.

Finally, to gauge current interest, respondents were asked what they felt was most important in terms of addressing the future needs of the core laboratory in the field of mass spectrometry. The highest responses were increased testing, more education in mass spectrometry, mass spectrometric techniques, evaluation of instrumentation, and methods development.

Preliminary Results of the Analysis of ABRF MS1 and MS2 Test

Participants were asked to analyze two samples. MS1 was *N*-acetylated porcine angiotensinogen with average mass 1,801.085. MS2 was the same peptide mixed in equal portions with the *N*-acetylated peptide from human, mass 1,802.075. The two peptides differed only in four residues at their C-termini. Laboratories were asked to determine these values with highest accuracy and to report both mass values and resolution (calculated by the full width, half mass [FWHM] method) as a test of ability to separate closely spaced ions. Participants were told that the second sample contained two peptides and that HPLC might be required to separate them. Also, it was suggested that certain other procedures such as AAA, exoprotease or endoprotease digestion, and CAD or PSD fragmentation might be helpful in identifying the peptides.

Preliminary results based on 26 sites reporting show an average error of 387 ppm (this is equivalent to 99.96% accuracy and gives an uncertainty of ± 0.8 Da for a 1.8-kDa peptide). This amount of error is close to the difference in mass of the two peptides in MS2. Routine introduction of error at this level would prevent the distinction of an amidated from a free carboxylic acid at the C-terminus of a 2-kDa peptide. Error ranged from a high of 1,873 ppm (99.81% accuracy) to a low of 3 ppm (99.9997% accuracy). Interestingly, the error spread for two samples reported by a single site ranged from a low of 5 ppm to a high of 1,327 ppm, with an average spread of 227 ppm. Because it is assumed that the same technique and hardware were used to determine both samples, the explanation for this difference in accuracy may lie with the particular methodology employed or operator technique. The overall dependence of accuracy on hardware was similar for the two most prominent types, with values ranging from 8 to 541 ppm for ESI or quadrupole equipment and 3 to 1,435 ppm for MALDI or TOF. Resolution varied widely, with a high of 10,606 measured with a quadrupole ion trap. Values ranged from 514 to 3,001 FWHM for ESI or quadrupole and 120 to 5,457 for MALDI or TOF instruments. Five laboratories correctly identified both peptides, and 13 identified at least one of the peptides. Thus nearly 70% (18 of 26) of the respondents were able to identify one or both peptides. This result demonstrates that a significant number of resource laboratories possess a high degree of development both in the ability to use mass spectrometry and in the sophisticated adjunct methods such as database analysis for the identification of peptides and proteins.

Conclusions

The results of the survey and test sample analyses showed that although the average resource laboratory is relatively young in the field of mass spectrometry it already possesses a high degree of expertise not only for the accurate measurement of peptides but also in the ability to analyze a diverse set of sample types, to employ advanced techniques, and in general bring mass spectrometry to bear in a concerted way with other established methodologies in solving difficult analytical problems in biology. This was exemplified by the many laboratories that correctly identified test samples not only from mass measurements but also by combining data from AAA enzymatic digestion, and advanced mass spectrometric techniques. Results clearly demonstrated the high general expertise and awareness of many laboratories of a wide variety of database search algorithms and the ability to access them via the Internet.

This initial research study better defines the work of the mass spectrometry research committee. Based on the results of the survey and test samples, future studies may now be devised to focus exactly on the interests of laboratories engaged in the application of mass spectrometry to problems of biological significance.

SURVEYS OF CORE LABORATORIES

RONALD L. NIECE
University of California–Irvine
Irvine, California

KATHRYN M. IVANETICH
University of California–San Francisco
San Francisco, California

The typical, or average, biotechnology core laboratory can be characterized by a description of the instruments, space, staff, budget, and performance parameters for the resources provided. This information has been periodically obtained from general surveys of ABRF member laboratories. The first survey to provide a formal description of biomolecular core laboratories was conducted in 1987 (5);

it identified several services including protein/peptide sequencing, AAA, HPLC purification of proteins and peptides, peptide synthesis, and DNA synthesis, which are now considered traditional services. The most recent published data from a survey of facility operations (7) have shown that core facilities have been quick to incorporate new instrumentation into their repertoire and now offer technologies as diverse as capillary electrophoresis, DNA sequencing, mass spectrometry, and carbohydrate analysis (see Fig. 7). The survey data also show that many core facilities are resources not only for their home institutions but for outside investigators as well. These core facilities offer a broad range of services (Fig. 7), with outside charges usually being higher than in-house charges (7).

Combined data from several surveys of ABRF member core laboratories (7,34) have shown that academic institutions and research institutes house more than three-quarters of member laboratories, and industry has most of the remaining 25%, with only a small percentage of such core facilities in governmental settings (universities excluded). Core facilities require instrumentation, suitable laboratory and office space, appropriately trained personnel, and financial resources. A typical core facility is staffed with four full-time staff members, including one member with a doctoral degree, one with a master's degree, and two with bachelor's degrees. Directors have a median of 13 years experience in the analysis and synthesis of biological molecules, and staff have a median of 6.9 years experience (34). A typical facility houses six major instrument systems (50) in 1,000 sq. ft. of laboratory space. An average, noncapital, annual operating budget is $250,000, half of which comes from charge-back fees for services and reagents. Nearly all core facilities require substantial subsidization, averaging 50% of total operating budget, to cover the difference between user fee income and total expenses.

Performance with respect to the quantity of sample needed or scale of synthesis, turnaround time, and charge for selected services is listed in Table 5. The level of subsidy an institution provides its core facility is largely determined by the portion of operating budget that the facility obtains from its users. For highly subsidized facilities the user charges are relatively low, reflecting the high subsidy; for the 1–2% of facilities that operate without subsidy, the charge is the actual cost of performing the service, which very likely is much higher than the corresponding charge from a heavily subsidized facility. The spread in charges as shown by the large standard deviations may reflect both differences in subsidy and specifics of what is included in the standard charge. Both lower subsidy from institutional sources and higher levels of performance by the facility (including sensitivity, scale, extent of service, and turnaround time) are reflected in higher charges for users. Services for outside users generally incur an additional charge.

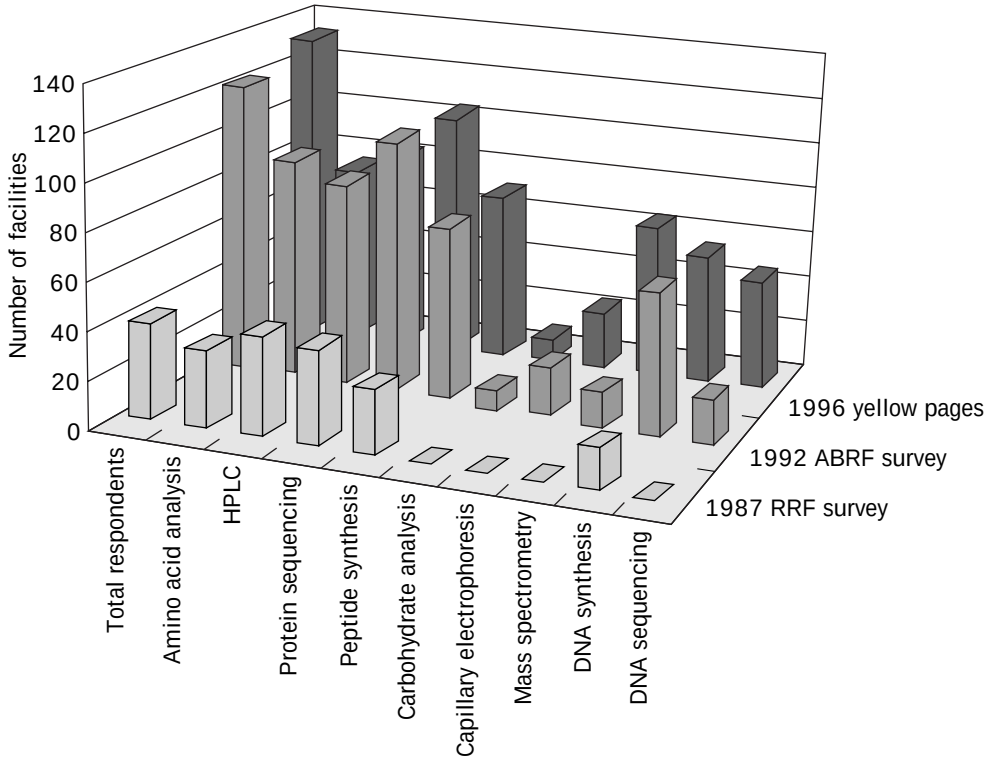

Figure 7. The number of core facilities offering selected services. Data from survey of laboratories interested in the informal organization, Research Resource Facilities (RRF) (5), respondents to survey conducted by the ABRF Survey Committee in 1992 (7), and the 1996 ABRF Membership Directory, Section II (Yellow Pages): Facilities Offering Services to Outside Investigators (available from ABRF business office or ABRF Web site).

Table 5. Services, Turnaround, Charges, and Costs Determined from ABRF Surveys

	Scale of service		Turnaround (days)	In-house charge ($)		Subsidy (% of operating costs)	Calculated cost without subsidy ($)
	Mean ± SD	Units	mean ± SD	Setup mean ± SD	Per cycle mean ± SD	mean ± SD	
Amino acid analysis	32 ± 220	μg	6 ± 4	35 ± 19		45 ± 45	64
HPLC	0.51 ± 1.4	nmol	7 ± 6	106 ± 74		47 ± 39	200
Protein sequencing	73 ± 92	pmol	9 ± 7	117 ± 79	17 ± 10	42 ± 41	788[a]
Peptide synthesis	0.56 ± 1.3	mmol	20 ± 12	194 ± 156	35 ± 12	35 ± 36	1,214[a]
Carbohydrate analysis	81 ± 74	μg	6 ± 4	20 ± 14			
Capillary electrophoresis	17 ± 18	pmol	3 ± 2				
Mass spectrometry	0.15 ± 0.2	nmol	6 ± 4	74 ± 48		30 ± 33	106
DNA synthesis	0.2 ± 0.1	μmol	4 ± 2	22 ± 13	3 ± 1	21 ± 33	123[a]
DNA sequencing	2 ± 2	μg	6 ± 4	41 ± 32		30 ± 37	59

Note: Mean ± standard deviation (SD) for scale of service with units noted, anticipated turnaround time for completion of the synthesis or analysis, in-house charge with setup and per-cycle charges (where appropriate), subsidy, and calculated charge for full cost recovery.
[a]Protein sequence (25 residues), synthetic peptide (15 residues), oligodeoxyribonucleotide (25 bases).
Source: Data from Ivanetich et al. (7).

The self-reported data on performance in the member laboratories collected by the surveys describe analytical capabilities in operating laboratories. This assessment of performance level is corroborated by the analysis of results from the "unknown" samples distributed by the ABRF research committees (see other sections of this article). In addition, members of ABRF have critiqued instrumentation by rating performance, service, technical support, and manufacturer-provided reagents. These evaluations, provided by many instrument users, have helped guide manufacturers in meeting the needs of the research and quality control communities by identifying deficiencies and useful features (11,50). A continuing concern of core facilities and their users has been the cost of consumables (7,11) because these expenses most frequently are included in the portion of operating costs that is not subsidized.

A number of trends can be discerned from the responses to these surveys conducted over a period of nearly 10 years. First, the number of core facilities continues to increase, from 146 ABRF member facilities in 1988 to well over 300 today. The average operating budgets of these facilities have increased from $158,000 to $279,000 per year; the level of institutional subsidization has remained fairly constant at approximately 50%. Although the majority of ABRF member facilities are rooted in protein chemistry, the number of core facilities that provide DNA chemistry services has increased substantially. For example, the number of ABRF core laboratories that offer DNA sequencing has doubled in the most recent (1996) survey. Although costs for protein chemistry services have either remained steady (e.g., amino acid analysis) or increased (e.g., peptide synthesis and protein sequencing), the cost of DNA chemistry services has declined dramatically. DNA synthesis costs decreased ~74% between 1988 (5) and 1993 (7). Core facilities are often the providers of advanced technology, as evidenced by the rapid implementation of new instrumentation and methodologies. Mass spectrometry was not listed as a service by any of the respondents in 1987, but in 1992 more than 10% offered the service and in 1998 nearly half of the respondents offered mass spectrometry (K. Ivanetich, unpublished data).

In summary, the average core facility characterized by survey data includes six instrument systems operated by four staff in about 1,000 sq. ft. Services offered include the traditional protein/peptide sequencing, AAA HPLC purification of proteins and peptides, peptide synthesis, and DNA synthesis and newer technologies such as capillary electrophoresis, DNA sequencing, mass spectrometry, and carbohydrate analysis. Most core facilities receive about 50% of their operating budgets from institutional funds to supplement their cost-recovery income. Core facilities evaluate instrument performance and service and technical proficiency through anonymous surveys. These data identify instrument performance levels and define the state of the art in real-world settings.

The roles of analytical resource facilities in biotechnology range from supporting early research and discovery efforts to conducting validated testing for product development. Facilities that comply with the specific regulations governing product manufacturing and testing can also test drug products manufactured for commercial purposes. There are significant differences in the documentation and compliance requirements placed on analytical laboratories depending on how a client intends to use the data generated. Discussions between the client and the facility should identify these considerations, preferably before the analyses are conducted. If the facility can meet the client's quality and compliance needs, using a contract analytical facility can provide numerous advantages in biotechnology product development.

Most resource facilities have the instrumentation and expertise needed to investigate and physicochemically characterize many biomolecules of interest. In the research and discovery phase, most investigations are aimed at identifying active moieties. A company's research and development team could contract with a resource facility to perform selected analytical techniques that may yield critical clues about the nature of the biomolecules being studied. This strategy leverages the research and development resources across a greater breadth of technologies than may be available in-house.

In later developmental phases, an analytical profile or physicochemical "fingerprint" of the product in its final purified form may be needed. The objectives include determination of the composition of the biological material, its impurities or degradation products, and its stability under various conditions. These data may be used to establish the product's identity, purity, potency, and strength. As in discovery, the analytical methods employed may go beyond a company's in-house capabilities.

Some analytical methods, such as protein or DNA sequence analysis, are needed for only short periods in the product's development cycle. Final product characterization studies may utilize numerous methods but only on a few lots of material. Methods used in stability studies may be required only at periodic intervals over the study's lifetime. Rather than establishing and maintaining a complex analytical laboratory, clients can choose a facility with the exact instrumentation needed to perform a given analysis. A client can stay abreast of advances in technology each time a new study is contracted by choosing laboratories with the desired analytical capabilities. In addition, highly skilled resource facility scientists can assist in planning the appropriate experiments needed to obtain the best results. Finally, outsourcing selected analytical services allows a company to focus more of its internal resources on controlling the critical quality parameters of the product itself.

The level of quality assurance in a resource facility can be matched to the needs of the client base. For any laboratory, clients (and staff) are principally concerned with data integrity. Properly functioning instrumentation, adequate documentation of experiments, and traceability of results to the samples tested are minimal expectations in all laboratories. If the objective of the analysis is to provide information used in product discovery, additional quality measures may be employed. Calibration of equipment, controlled temperature storage of materials, expiration dating of reagents and materials, and documentation of these and other routine laboratory activities demonstrate the quality control of facility operations. In addition, when sample storage, handling and preparation, general and specific experimental protocols, instrument operation parameters, and data analysis methods are well documented according to established facility procedures, the client may consider such a laboratory well suited to provide reliable, reproducible analyses on which to base product design decisions.

A sometimes misused designation for general laboratory quality measures is the term good laboratory practices (GLPs). GLPs are a specific set of U.S. Food and Drug Administration (FDA) requirements for nonclinical (i.e., animal-based) laboratory studies conducted to support product development in the preclinical safety phase (107). The GLPs apply to the procedures used to characterize the test article (the substance used for dosing in the animal and toxicology experiments) to determine its stability, homogeneity, and concentration (108).

The GLP regulations include requirements that must be met by contract facilities that perform specified parts of the total study. At this phase, product's dosing formulation—usually a mixture—is being analyzed rather than the purified active biomolecule. Although a biomolecular resource facility may support the study with selected biochemical analyses, it typically does not perform the entire GLP study. The extent to which the GLP regulations apply to a laboratory depends on the role it will have in designing, conducting, documenting, archiving, and auditing the quality assurance of the study.

One element of setting up a GLP study is the designation of two key parties: a study director and a quality reviewer. The responsibilities of these entities are outlined in the regulations. Also included in the regulations are laboratory operational measures aimed at ensuring the quality of the testing results, such as those listed earlier. These measures are sometimes called good laboratory practices in casual use. When selecting a facility that claims to be a GLP laboratory, a client should clarify the meaning of this designation, discuss the role of the laboratory in the overall study plan, and define the directing and reviewing activities to prevent any misunderstandings.

Analytical procedures to support the chemical, manufacturing, and controls (CMC) sections of pharmaceutical product applications are more likely performed by contract resource facilities. Typically, this function is termed *characterization* of the product. Analytical tests such as protein sequence analysis, mass spectrometry, and AAA may be among these procedures. For these types of analyses, GLP conditions are not formally required, particularly the establishment of the study director and quality reviewer. However, facilities that implement some of the operational elements of quality described in the GLP regulations are better able to provide traceable, auditable proof of the analyses performed. As such, clients can have more confidence in reporting these results in the product application for regulatory approval.

Analytical resource facilities may be contracted to perform lot release testing on commercial products. The U.S.

regulations governing such testing are called current good manufacturing practices (cGMPs) and are published in the *Code of Federal Regulations* section 610 for biological products (109) and sections 210 and 211 for pharmaceuticals (110). There are significant regulatory requirements for virtually every aspect of laboratory operations, including the physical environment in which the laboratory is housed. An analytical laboratory that is designated cGMP must meet stringent quality measures including instrument and equipment standard operating procedures, established method testing procedures, personnel training procedures, data review and approval, and archiving of all files associated with laboratory activities and results. In addition, most process and testing methods are expected to be validated. Modifications to any of these operating procedures or validations must be controlled via an established change control system. Before contracting with (or designing) a laboratory for cGMP testing, the facility should be audited by individuals knowledgeable in both the federal regulations and analytical laboratory operations to ensure the facility meets or exceeds the level of quality expected.

Another type of quality designation that some analytical laboratories may obtain is the ISO 9000 series of measures (American National Standards Institute, 11 West 42nd St., 13th Floor, New York, NY [111]). These measures were established to provide defined levels of quality metrics in businesses ranging from law firms to lamp manufacturing and can be applied to resource facilities. The basis of these measures is to define and document the quality system of an organization: namely, to designate the responsible individual and the method of data management. ISO 9000 registration is obtained when the organization seeks and passes inspection from an accredited third party (112,113). Certification is conferred for a specified period of time, after which reinspection and recertification are required. ISO 9000 certification adds to the quality of an analytical facility in direct proportion to the level of operations already present. Usually, such laboratories are relatively small organizations with clearly defined roles and responsibilities. Interviews with facility directors and audits of laboratories allow the client to assess the quality system in place and to evaluate its integrity.

An additional global regulatory initiative is taking shape in the European Union (European Standard EN 46001 [see Ref. 114]). Similar to the ISO 9000 requirements, EN 46000 is currently expected to apply to a specific classification of medical products, although the nature of the regulations may expand in the future. Likewise, quality principles are being codified in many other countries around the world. This trend reflects a movement toward global harmonization of quality practices and product regulation, as seen in activities by the International Committee on Harmonization (see Ref. 115).

It is important to note that these quality and compliance designations are not mutually inclusive or exclusive. A laboratory may be ISO 9000 registered without complying with the GLP or cGMP regulations. Samples designated for a GLP study may be handled in the same facility that performs analyses for other, nonregulated studies, as long as the GLP samples are handled in accordance with applicable FDA regulations. Both the client and the resource facility must understand the differences among the various quality measures to have confidence in the compliance of laboratory operations and the appropriate use of the data generated.

In general, analytical resource facilities are ideally equipped to provide the various types of biomolecular analyses required for biotechnology products. As analytical methods and techniques evolve, these facilities are positioned to incorporate technical advances as ongoing improvements to their services. In addition, many of these laboratories may be able to provide the level of quality needed to support specified regulatory uses of the data obtained. As partners in product development, these facilities provide highly skilled, technically advanced teams of scientists with the instruments and expertise needed to perform complex, ever-changing methods. Additionally, as regulatory agencies begin to accept specified biotechnology products for licensing (116), adopting a strategy of outsourcing special bioanalytical services may prove to be an effective way to manage product development costs while ensuring the quality of biotechnology products.

EFFECTIVE USE OF BIOMOLECULAR RESOURCE FACILITIES

CLAYTON NAEVE
St. Jude Children's Research Hospital
Memphis, Tennessee

Progress in biomedical research is becoming increasingly dependent on the utilization of shared resources or core facilities. These facilities typically provide biotechnology reagents and services that require skilled staff and expensive instruments that are most effectively and economically provided by an institution in the form of shared resources. Such core facilities span a broad range in the size and spectrum of services and reagents offered and may include protein or DNA sequencing; DNA, RNA, or peptide synthesis; mass spectroscopy; carbohydrate analysis; and many other possible services. Because the use of sophisticated instrumentation is high in these core facilities, the investigator often assumes that these are turnkey operations (i.e., submit a request, get a reagent or result). In reality, these resources play a critical partnership role in the research endeavor and should be viewed as such to succeed. If you have a core facility available that provides the services you require, the following suggestions may help optimize your use of their expertise.

Before Submission of a Request

Familiarize Yourself with the Core Facilities Available to You and the Range of Expertise, Services, and Reagents They Provide. Knowing that the protein core facility at your institution can or cannot sequence proteins at the femtomole level or knowing that the DNA core facility at your institution will only accept DNA sequencing templates cloned into specific vectors may influence your experimental design. If cost is a deterrent, communicate with the facility to understand the basis for its service charges; some fa-

cilities and services are highly subsidized by their host institutions and some are not (see the "Surveys of Core Laboratories" section of this article). One of the reasons for the seemingly high charges at your facility may be that its degree of subsidization via nonuser fee income is much less than the ~50% average level (7); hence, its charges may cover much more than just 50% of the cost of providing the requested service.

Talk to Your Core Facility Director and Staff before You Write the Grant, Design the Protocol, Plan the Experiment, or Run the Sample That Will Utilize Their Facility. Communicating with facility staff will ensure that funds can be budgeted for the needed analyses and syntheses, and the core laboratory can verify that the biotechnological aspects of the proposal are indeed reasonable. Proposing to load an SDS PAGE gel slice directly onto a protein/peptide sequencer or proposing a postsource decay (sequencing) study on a laser desorption or TOF mass spectrometer that is not equipped with a reflectron would not enhance the probability of your grant application being funded. Take advantage of the resource of expertise and services available.

Understand the Limits of the Technology. For instance, although protein hydrolysis and amino acid analysis provide the amount of individual amino acids in a protein or peptide sample, they do not provide the number of amino acid residues unless an accurate mass is available, the sample is pure, and corrections are made for peptide bonds that are difficult to hydrolyze and for loss of less-stable amino acids.

Follow Your Core Facility's Sample Preparation Guidelines. Proper sample preparation is probably the most important step in ensuring success with most biotechnology chemistries. Preparation of clean DNA templates for automated sequencing is a classic example; follow the guidelines given to you explicitly and you will greatly increase your probability of success. Consult with facility staff in planning the appropriate sample preparation strategy before sample submission.

After Receipt of Your Data or Reagents

Understand the Significance of the Data Produced. If your DNA sequencing facility provides you with four-color electropherograms and unedited sequence data, you must be aware that miscalls occur and that it is your responsibility to evaluate the quality of the data and correct errors. Suppose you have submitted a sample for MALDI or TOF mass analysis and the observed mass differs from the predicted by 0.01% using reflectron mode analysis. Is this within the accuracy range of the instrument (thus helping to confirm the identity of the peptide) or does this suggest the presence of a modification? To assess significance, you must familiarize yourself with the technology in use to judge the results obtained. Obviously, the core facility staff will help you with this assessment, but the ultimate responsibility is yours.

Work with the Facility to Correct Any Real or Perceived Deficiencies. If you are unhappy with the results obtained, talk to the facility's staff or director. If problems do occur, your input and experience can often be critical in diagnosing and correcting difficulties. On the other hand, the problems that you believe are present (e.g., absence of cysteine during the amino acid sequencing of a peptide known to contain this amino acid) may reflect an oversight or lack of knowledge on your part (in this case the failure to appropriately modify all cysteine residues before submitting the sample for amino acid sequencing).

What Should You Do If Your Core Laboratory Does Not Provide the Service You Need? First, ask why this particular service is not available. There are many reasons why a given service may not be available, including insufficient demand, staff, expertise, equipment, or space to justify offering the service. For instance, many core laboratories do not offer automated C-terminal protein sequencing because of the relatively meager demand, the large amounts of protein required, and the relatively few amino acid residues that can be sequenced. It is thus important to first determine why the service is not available. Second, if there is sufficient demand to justify the addition of this service, help the core laboratory bring this new service to fruition. Third, ask for a referral, because your core laboratory may well know an outside core laboratory that is particularly well suited to providing the requested service. In this instance, it is important to tell staff at your core laboratory what happened at the outside core laboratory so they may better advise others who follow.

Support Your Core Laboratory. A close partnership between the core laboratory and its users is critical for success. Just as the user needs access to state-of-the-art biotechnologies, the core laboratory can only succeed with the support of its users. Support includes acknowledging all services provided by the core laboratory and forwarding reprints of these publications to the core laboratory, responding to requests made by the core laboratory for research proposals and other support of their shared instrumentation grant applications, and helping the core laboratory gain institutional support, which may range from subsidization of operating costs (to help lower user fees) to equipment acquisitions to gaining additional space. Finally, because much of the work carried out in core laboratories goes without reward in terms of publications, be appreciative of the efforts of core laboratory staff and do not hesitate to coauthor publications with them when their efforts and input go beyond that which justifies a simple acknowledgment.

FUTURE OF CORE LABORATORIES

JOHN STULTS
Genentech
San Francisco, California

What does the future hold for core laboratories? The needs of the biological community are changing rapidly, as are

the economics and technology of science. As a result, the twenty-first century will present challenges and exciting new possibilities for core laboratories.

Paradigm Shift in the Postgenome Era

The single most important transforming factor in the immediate future is the availability of enormous amounts of genomic sequence. Partial nucleotide sequences from human expressed sequence tags (ESTs) (117,118) already number in excess of 1,000,000 (119). Complete genomes have been sequenced for a number of organisms, including *Saccharomyces cerevisiae* (120). The imminent completion of a number of other genomes, including human, and the advent of the postgenome era will provide an information resource previously unimaginable. This information glut will trigger a paradigm shift in the ways that core laboratories operate and in the services they provide. The emphasis on sequence determination for new proteins, particularly by DNA sequencing and cloning, an overwhelming and perhaps inordinate goal of biology for the past 20 years, will give way to renewed emphasis on biological principles and protein function and its relationship to structure (121). For core laboratories, this information will likely mean that much of traditional protein sequence determination will give way to protein identification via an array of rapidly evolving approaches and technologies, many of which utilize mass spectrometry, and that traditional DNA sequencing will give way to powerful genetic analysis techniques based on hybridization to high-density DNA oligonucleotide arrays (122).

Automation

Automation of many tasks will continue to be a key factor in further reducing operating costs and increasing productivity and reproducibility. Proper, efficient sample preparation for analysis has been and will continue to be a bottleneck for rapid and reliable analyses, making it a primary target for automation. DNA synthesis chemistries and instrumentation have already reached a state of extremely high throughput and reliable operation that is perhaps manifested best by the 10-fold reduction in the in-house charge for a 25-mer DNA oligonucleotide that has occurred over the past 10 years (5,33). Instrumentation is now available that can synthesize and, in some cases, automatically purify 48 or more DNA oligonucleotides. DNA sequencing is rapidly approaching high-throughput operation such that some instruments can analyze as many as 96 samples in parallel. To keep pace with this instrumentation, increased attention is being given to the use of robotics to automate DNA template preparation. Peptide synthesis is moving more and more toward automation and high-throughput operation with the availability of instruments capable of synthesizing 12 or more peptides followed by the cleavage of the newly synthesized peptides from their solid supports. In the case of both DNA and peptide synthesis, increased automation accompanied by decreased reagent costs due to the smaller synthesis scales adopted has resulted in further cost reductions. Amino acid analysis has been a reasonably high-throughput method for years, with a typical instrument able to complete an analysis in 1 h. Protein sequencing remains slow by comparison, yet its operation continues to be simplified and its sensitivity of detection increased, and automated operation for analyzing multiple samples in tandem is now available. In contrast, mass spectrometry is inherently a rapid technique. Automation of mass spectrometry, although done for years with GC and MS, has only recently become available for protein and peptide analysis. The capabilities of the instrumentation are sure to keep advancing; in general, the higher the throughput of the instrumentation, the more suited it is for use in core laboratories.

Future Opportunities

Undoubtedly, the availability of the sequences of the approximately 100,000 human proteins will pose many more questions than it answers and will spawn a new area of investigation called proteome research. This availability will also result in a renaissance in studies directed toward understanding how protein structure relates to function. In their simplest form, the questions are as follows: What are the functions of these proteins? How do they accomplish their tasks? How can we take advantage of this knowledge to intervene in a bewildering array of diseases? It is not difficult to illustrate our ignorance in this regard. Currently, the only reliable means for predicting three-dimensional structure and function from a newly discovered protein sequence is to carry out a database search and hopefully identify homologous proteins in the same family or in other organisms. If the sequence is truly unique, no laboratory currently is capable of accurately predicting the function of this protein, its three-dimensional structure, or how the intricate folding of its one-dimensional amino acid sequence gives genesis to function. Compared with the 100,000 human proteins, the current availability of only a few dozen structures for protein–ligand complexes surely pales in comparison and bodes extremely well for increasing the need for identifying sites of protein–protein and protein–ligand cross-linking and for the use of synthetic peptide analogs and other approaches to identify active sites in proteins. Similarly, opportunities for core laboratories abound in terms of the biophysical instrumentation (e.g., spectrofluorometers, scanning and isothermal calorimeters, analytical ultracentrifuges, surface plasmon resonance, and circular dichroism instruments) needed to quantitatively characterize these interactions.

All these factors suggest that the future of biotechnology core laboratories is indeed bright and far more interesting than in the past, with the tedium of determining primary sequences being replaced rapidly by the more interesting and pertinent task of determining the reason for that order. Core laboratories are a tremendous intellectual and biotechnological resource whose importance can only be increased by the increasing financial constraints that helped promote their rapid emergence and by the ever-increasing complexity that seems to lie beneath each biochemical and biomedical discovery. Although core laboratories are synonymous with sophisticated instrumentation, in the end it is the efforts of people that lead to advancements in science. Ultimately, it is the interdisciplinary knowledge, research experience, dedication, and

ingenuity of core laboratory personnel that will lead to their continued importance and success.

ACKNOWLEDGMENTS

We especially thank all past and present members of all of the ABRF Research Committees that compiled the data on which much of this article is based and all of the member laboratories who participated in this research. Special thanks are given to all the individuals who reviewed sections of this article for their critical insights and to the National Science Foundation (DIR9003100), the Department of Energy (DE-FG02-95ER61839), and all past and present ABRF members and corporate sponsors who have provided support for the ABRF.

PROFESSIONAL SOCIETIES, SOCIETY FOR INDUSTRIAL MICROBIOLOGY (SIM)

CHRISTINE L. CASE
Skyline College
San Bruno, California

ROBERT SCHWARTZ
Abbott Laboratories
North Chicago, Illinois

OUTLINE

BACKGROUND OF THE ORGANIZATION

The Society for Industrial Microbiology (SIM) is a nonprofit professional association dedicated to the advancement of applied microbiological sciences, especially as they apply to industrial products, biotechnology, materials, and processes. A primary objective of SIM is to serve as a liaison among the various specialized fields of applied microbiology. It promotes the exchange of scientific information through meetings and publications.

Industrial microbiology is the application of scientific and engineering principles to the processing of materials by microorganisms or other biological agents to create useful products for the benefit of humankind. These microorganisms may be natural isolates, laboratory-selected mutants, or genetically engineered microbes. Members of SIM include bacteriologists, molecular biologists, mycologists, chemists, engineers, geologists, marine biologists, and plant pathologists. These scientists, engineers, technicians, administrators, and educators represent many organizations in industrial, educational, federal, and state laboratories, and are involved in research, process development, production, and quality control for a wide variety of products and services including antibiotics and other pharmaceuticals, vaccines, diagnostic tests, foods, and beverages; biocides; microbial products such as enzymes, amino acids, and carbohydrates; agricultural biotechnology; oil recovery and mining; and bioremediation. SIM sponsors an annual scientific meeting as well as special topic conferences.

In 1995, then-president-elect of SIM, Steve Orndorff, commissioned the Strategic Planning Committee with responsibility for charting a course for SIM for the next 5 years. The committee developed a statement of the mission, visions, and values of SIM as well as a strategic plan. These concepts were published for comment by the membership, and after due consideration were formally adopted by the board to become part of the society's formal charter.

Mission: To enhance and strengthen the professional activities of all those who practice, teach, or study microbiological and related sciences to solve practical or industrial problems for the benefit of humanity. We do this by providing high-quality publications, informative and congenial scientific meetings, synergistic career development interactions, practical education of our successors, and effective advocacy of relevant issues.

Vision: To be the most valued representative of professionals in our field. To be the most productive catalyst of career development interactions in our field. To be the most widely acclaimed organizer of scientific conferences in our field. To be the most respected publisher of scientific work in our field.

Values: We perform to the highest standards of professional integrity and scientific ethics. We direct our intellectual resources to benefit and protect humankind. We respect and treat fairly our employees, colleagues, employers, and suppliers. We inform and educate the public within the framework of our nonprofit status. We rely for our effectiveness on the productive volunteerism of our members. We value the benefit of interactions between scientists with common interests. We hold ourselves accountable for being responsible public citizens and scientists. We take responsibility for educating and nurturing our successors.

In 1996, the board of directors recommended to the membership to change the society's name to the Society for Industrial Microbiology and Biotechnology to reflect the careers and technologies that have developed since the 1980s. In 1998, the society membership rejected the name change (390 to 369 votes) in favor of remaining the Society for Industrial Microbiology.

The common denominator of applied or industrial microbiology is microbial science in the service of humans. In fact, the science of microbiology developed from problems associated with some microbial processes that had immediate application to humans. Microorganisms have been used for the production of food, clothing, and drink for centuries but leavening bread, fermenting wine, producing vinegar, and retting flax had been practiced in ignorance. It was not until 1864 that Louis Pasteur defined the role of microorganisms in fermentations. Industrial microbiology was slow to develop after Pasteur's initial experiments, probably because of the lack of good culture methods and selective media. In the late 1800s, Jokichi Takamine brought the Koji process for producing amylase to the United States. He received the first U.S. patent on an enzyme production process and established the first fermentation company in the United States (1). Except for a few outstanding contributions mainly involving lactic acid, acetone–butanol fermentations, and production of yeast and yeast products, industrial microbiology did not progress very rapidly until after 1900. Samuel C. Prescott initiated the first course in industrial biology in 1896 at the Massachusetts Institute of Technology. The first textbook in industrial microbiology was not published until 1940, however (2).

Industrial microbiologists in the 1940s worked with deterioration of military material, solvent fermentations, and penicillin production. As these scientists began to accumulate experimental results, there was a natural desire to share their findings with scientific colleagues at a national society meeting and in scientific journals. However, there was no central organization in which to share their findings because these scientists came from a variety of scientific specialties including plant pathology, medical laboratories, materials engineering, and academic mycology and bacteriology. Moreover, it was difficult for a purely practical paper in microbiology to secure a place on the program of existing societies or to find an opportunity for publication in the established journals. These scientists became unhappy, and a conflict developed between basic and applied microbiology practitioners. In 1951, the Society of American Bacteriologists (SAB) authorized a new journal called *Applied Microbiology*. However, the first issue was not published until January 1953.

The decision to publish *Applied Microbiology* took too long in the minds of the industrial microbiologists of the

late 1940s. By that time, industrial microbiologists felt that applied and industrial aspects of microbiology were being neglected by the SAB. Walter Ezekiel, Bureau of Ordnance, Department of the Navy (Washington, D.C.) wrote to and spoke with a number of individuals during the summer and autumn of 1949 and suggested formation of a new Society for Industrial Microbiology. Ezekiel arranged with Raymond L. Taylor, associate administrative secretary of the American Association for the Advancement of Science (AAAS), to schedule and advertise a meeting of interested persons during the AAAS meeting in New York (3). Ezekiel published a short announcement of the meeting in *Science*, in which he stated that "a new society of industrial microbiologists is to be organized to cover the borderline work in application of microbiologic knowledge or processes to work with industrial materials. The society plans to handle . . . microbiologic manufacturing processes and microbiologic assay. The organization meeting will be held December 29 at 4:00 P.M. at the Hotel McAlpine Ballroom" (4).

On that date, more than 250 interested persons met in the ballroom of the Hotel McAlpine in New York City. There, it was decided to form a new society to affiliate with the newly formed American Institute of Biological Sciences (AIBS). Charles Thom, Northern Regional Research Laboratory (Peoria, Ill.) was elected acting chair and Charles L. Porter, Purdue University (West Lafayette, Ind.), acting secretary. Ezekiel's motion to establish a scientific organization known as the Society for Industrial Microbiology, with its general scope the field of microbiology as applied to industrial materials and processes, was passed. It was decided at that meeting, over the objections of a few, that the group would meet the following year, again with AIBS. Thom appointed the following members of the Organizing Committee: Maynard M. Baldwin (Battelle Memorial Institute, Columbus, Ohio), F. G. Walter Smith (University of Miami Marine Laboratory, Coral Gables, Fla.), Earnest A. Walker (U.S. Department of Agriculture, Washington, D.C.), William L. White (Farlow Herbarium, Harvard University), Ezekiel, and Porter (5).

The committee met several times during the first year to prepare a program and write a constitution for the new society in preparation for the first annual meeting to be held with AIBS at Ohio State University, September 11–13, 1950. In Ohio, Thom was elected the first president and Porter the secretary-treasurer. In 1951, the new SIM met with AIBS at the University of Minnesota and Thom was elected president for a second term. In 1952, the meeting was held at Cornell University.

The need for an interdisciplinary society first conceived by Ezekiel became apparent, and membership grew at a rapid pace. In 10 years, membership in the new society had grown from 75 to 550. SIM was incorporated as a nonprofit organization in 1960 in Washington, D.C. Membership reached 2,000 in 1989. In 1989, Paula Myers-Keith was the first woman elected president of SIM. For many years, the annual meetings were held along with AIBS on university campuses. In 1967, SIM held its first independent annual meeting, at the University of Western Ontario. Since 1985, all annual meetings have been held at commercial convention centers rather than universities. The annual meeting is a weeklong event featuring plenary sessions, roundtables, poster sessions, workshops, and extensive technical exhibits.

Between 1960 and 1970, SIM sponsored summer institutes on microbiological problems of current interest with topics including industrial microbial genetics and federal regulations for disinfectants, drugs, and cosmetics. In 1960, SIM sponsored the initial conference on antimicrobial agents. This was a mammoth undertaking for the small organization, and sponsorship was subsequently released to the American Society for Microbiology (Interscience Conference on Antimicrobial Agents and Chemotherapy, ICAAC) (6). In 1978, the Alma Dietz actinomycete roundtable discussions were included and have since become a part of all subsequent annual meetings.

In 1987, reaffirming its commitment of service to the microbial biotechnologist, SIM approved the organization of the Special-Topic Conference Series. These conferences run 2 to 3 days and usually result in the production of a monograph. Initiated by George Somkuti (president, 1985–1986), the first event in the series was the International Conference on the Biotechnology of Microbial Products: Novel Pharmacological and Agrobiological Activities (BMP), held March 13–16, 1988. BMP is held every 3 years. Since then, SIM has sponsored or cosponsored special conferences on a regular basis. Other conference series include Recent Advances in Fermentation Technology (RAFT), initiated in 1995. RAFT is held biannually and is cosponsored with the Biochemical Technology Division of the American Chemical Society. The aim is the free exchange of newly developed fermentation technologies related to current highly productive, consistent, scaleable, and economic processes. Fermentation microbiology, biochemistry, biocatalysis, and biochemical engineering aspects are explored. The Sixth Genetics and Molecular Biology of Industrial Microorganisms (GMBIM) Conference, cosponsored with Indiana University Institute of Molecular and Cellular Biology, was held in 1996 at Indiana University. This continuing series provides a forum for academic and industrial scientists to exchange information on the latest developments in the genetics and biochemistry of microbes of industrial interest.

The business of SIM is conducted by the board of directors (which is elected by the membership), 12 standing committees, and the executive secretary. The board consists of the president, president-elect, secretary, treasurer, past president, and four directors. In 1959, as president of SIM, Porter said, "There are a number of organizations including the Society of American Bacteriologists and the American Chemical Society which have grown so large that they have become unwieldy. The administration of these groups has lost personal contact with the membership . . . They must enforce rules and regulations which hamper individual initiative, incentive, and recognition. At their meetings the sessions devoted to volunteer papers are so clogged that each presentation is limited to 10 or 12 minutes. . . . Membership beyond 1200–1500 should be discouraged, for then, we like other groups mentioned, would lose that personal contact which is one of the principal attractions" (7).

At present, most of the membership is in the United States, but interest in industrial microbiology is international and SIM has more than 200 members in 38 countries outside the United States. Employment opportunities in industrial microbiology and biotechnology have increased dramatically since 1959; consequently, SIM now has a membership of more than 1,900, in addition to 75 corporate members. However, SIM continues to foster an environment in which individuals are recognized and have opportunities to participate. Modern communications including the Internet are available so that members have fast and easy access to society resources via electronic mail and a World Wide Web home page. At the annual meetings, speakers give 30-minute presentations of their work. Additionally, there are numerous opportunities for members to serve on committees and become officers. Local sections provide more opportunities for scientists, engineers, technicians, and students to meet and form personal contacts.

AWARDS

SIM has established the Committee on Awards and Honors to provide monetary and honorary awards to its members and others eminent in the field. Awards are made at the annual meeting. In 1967, the first Charles Thom Award was presented to Kenneth B. Raper (president, 1952–1953). This award is bestowed annually to persons making outstanding contributions in the field of industrial microbiology. The second Thom Award was presented to Arthur M. Kaplan (president, 1960–1961) at the 1970 annual meeting held at the University of Rhode Island. The Charles Porter Award of Merit is given in recognition of outstanding contributions to the growth and success of SIM. The first Porter Award was given to Earnest A. Walker in 1960.

A fellowship status was approved by the SIM membership at the 1984 Annual Business Meeting. Fellowship is a membership grade of distinction in the Society acknowledging significant research and/or service contributions to the professions of applied microbiology. A sustained record of such contributions while a member of SIM is the main criterion for consideration to fellowship. No more than 10% of the members are eligible for fellowship status at any given time. The first group elected as SIM fellows in August 1985 were Arnold L. Demain (president, 1990–1991), Arthur E. Humphrey, Richard P. Elander (president, 1973–1974), Warren P. Iverson, Clifford W. Hesseltine (president, 1957–1958), H. Boyd Woodruff (president, 1954–1956), Leland A. Underkofler (president, 1967–1968), Kaplan, and Raper.

The Selman A. Waksman Teaching Award was established in 1989, and the first recipient was Douglas E. Eveleigh. The award is presented to a recipient every other year at the annual meeting. The nominee must be an active, full-time professor at a recognized institution of higher education for a minimum of 10 years or have attained emeritus status. The nominee must be actively involved in research in an area of industrial or applied microbiology or biotechnology. Annually, SIM present the Student Abstract Award for the best abstract submitted for the annual meeting.

The Panlabs Award Lecture is sponsored by Panlabs and is presented by individuals of world renown in the field of microbiology. Each Panlabs Lecturer presents an address at the annual meeting. The Schering–Plough Research Institute Young Investigator Award is made to a society member who is under 36 years of age at the time of nomination. The nominee must have made a significant contribution in industrial microbiology or biotechnology that indicates promise of a professional career of merit. This award is made on alternate years with the Waksman Teaching Award.

LOCAL SECTIONS

Regional groups called local sections are governed by their own constitutions and elected officers. Local sections provide an opportunity for individuals involved in biotechnology to meet, discuss topics of interest, attend talks given by noted industrial and academic speakers, and attend local symposia on important contemporary subjects. Membership includes all interested microbiologists, chemists, and engineers from students to advanced industrial, academic, and government professionals.

PUBLICATIONS

SIM News is the official publication of the society. It was first published in 1951 and entitled *SIM News Letter*; the name was changed in 1972. *SIM News* is distributed bimonthly to all members. It contains technical review articles, news of special significance in the field of applied microbiology, and reports of many activities of the society including local sections reports, placement opportunities, and meeting notices.

The first volume of *Developments in Industrial Microbiology (DIM)* was published in 1960. This peer-reviewed annual publication contained papers from the annual meeting. *DIM* was published annually for 30 years (31 volumes).

The *Journal of Industrial Microbiology and Biotechnology (JIMB)* is an international, peer-reviewed journal that seeks to further scientific knowledge and to disseminate information in biotechnology, fermentation and industrial microbiology, biodegradation, biodeterioration, quality control, and other areas of applied microbiology. The concept for a new technical publication for the society was presented by SIM President C. Herb Ward (1983–1984), and the first issue of *JIMB* was published in March 1986 as the *Journal of Industrial Microbiology (JIM)*. The first editor in chief was George E. Pierce. The name *JIM* was used continuously through 1996, when the board of directors adopted the new name, *JIMB*. *JIMB* will consider publication of original research papers, critical reviews, short communications, and letters to the editor. All papers submitted are subject to peer review.

The *Developments in Industrial Microbiology Series* complements *JIMB* and *SIM News* by providing in-depth reviews of specific subject areas. The monographs are focused on topics of interest to scientists in industrial and environmental microbiology. Authors for the individual

series are identified from presentations at special conferences sponsored by SIM and selected symposia at the annual meeting. The address for SIM is 3929 Old Lee Highway, Suite 92A, Fairfax, VA 22030-2421. Internet: ⟨*info@simhq.org*⟩⟨*www.simhq.org*⟩.

PROFESSIONAL SOCIETIES, THE PROTEIN SOCIETY

ROBERT NEWBURGH
The Protein Society
Bethesda, Maryland

Protein science is the study of proteins. The development of new techniques, including those from molecular biology, analytical chemistry, immunology, spectroscopy, diffraction, and computations, has provided opportunities to probe structural and functional relationships of proteins in detail undreamed of until recent times. These opportunities underscore the importance of broad interactions among investigators of diverse backgrounds to resolve fundamental questions. The Protein Society was established in 1986 to promote these interactions by providing regular opportunities for protein scientists to exchange ideas, findings, and techniques via both scientific meetings and the society's journal, *Protein Science*.

The goal of the society is to promote the discipline of protein science by these means:

1. Promoting research and scientific endeavor in the field of protein science
2. Promoting education in protein science to a wide variety of constituencies including established investigators, young scientists, students, others interested in science, and physicians interested in diseases pertinent to the field
3. Promoting and extending current understanding of the importance of protein science, particularly in regard to the methods, concepts, and problems of structural biology, cell and molecular biology, and biotechnology, as they relate to the behavior and properties of proteins.

The society attempts to foster effective interactions between investigators who share these interests. To further this objective, the society seeks to expand its membership and activities in ways that will enhance interpersonal communication among scientists.

To achieve these goals, the society invests its resources in

1. Management of the Society
2. Conduct of scientific meetings
3. Publication of scientific research
4. Educational activities
5. Fostering relations with scientists in other countries interested in protein science

Further information regarding the society can be obtained from the executive officer, Dr. Robert Newburgh, The Protein Society, 9650 Rockville Pike, Bethesda, MD 20814-3998 (phone 301-571-0662; Fax 301-571-0666; e-mail newburgh@protein.faseb.org).

OUTLINE

INTRODUCTION

Traditional biochemical processes can be characterized into three major operational divisions: *(1)* the upstream process, which deals primarily with preparation and pre-

treatment of the raw material from which the specific target product is to be directly or indirectly obtained, *(2)* the actual production phase, in which the chemical transformation of the raw material takes place to produce the end product in which the desired target product is obtained along with associated by-products, and *(3)* the downstream processing, which is specifically involved with the recovery and purification of the target product. Progress in the area of recombinant DNA technology has made it commonplace to clone and express specific products for diagnostic and therapeutic applications within a variety of host microorganisms. This advancement has resulted in a pace of development of production phase technology that has far surpassed that of the recovery and purification areas. Recent years have seen significant advances in this latter area, and, with the incorporation of affinity-based interactions, it is now possible to include more powerful and specific operations for improving the overall efficiency of the recovery process (1).

Downstream processing refers to the collective set of operations involved in obtaining the target product in its required end form. The name derives from its relative position to the actual production stage in the process flow sheet. Factors such as the starting concentration of the target product, its final required purity, and the type of impurities to be removed dictate the exact choice of operations, and the sequence is necessarily adapted for each particular process. The use of microorganisms in biochemical processes makes cell harvesting, disruption (for the product residing within the cytoplasmic spaces as an intracellular product), and solid–liquid separation essential initial stages in the sequence of operations. Processes in which the product is expressed as an extracellular component require no cell disruption stage, although clarification of the feedstock from whole cells or cellular debris is always essential before subsequent treatment. The common solid–liquid separation methods traditionally used are centrifugation (2,3) and cross-flow microfiltration (4). The use of aqueous two-phase systems for primary treatment of feedstock (5) and cell debris removal has also been reported (6–9).

Biochemical product recovery nearly always involves one or more packed bed chromatographic processes as an often essential step of the separation protocol, usually in the secondary and final purification stages (10). It has now developed into a powerful tool for product separation at the analytical and preparative (11) scale of operation. The wide variety of modes of interaction between the solubilized product and ligands on the solid adsorbent (11–13), ease of scale-up and cleaning-in-place procedures, commercial availability of equipment and consumables, and the well-documented operation have given this technology wide acceptance in academic and commercial research and development. There is now a significant amount of information on the optimization of chromatographic separations (14). However, full utilization of its potential implies clarification of the biological feedstock before application onto a packed bed, failing which bed blockage is inevitable.

This article describes in some detail the use of expanded bed chromatography, which has been described as the only new unit operation that the bioprocess industry has seen for decades (15). This technique offers the possibility of directly applying the unclarified feedstock onto the bed, bypassing the conventional solid–liquid separation techniques while simultaneously capturing the desired product from the liquid phase. A typical sequence of separation operations is shown schematically in Figure 1, in which the relative position of expanded bed chromatography is also indicated. As will become clear from the description of its operation, the incorporation of this unit will enable facilities to replace cost-intensive and often problematic solid–liquid separation techniques such as centrifugation and cross-flow microfiltration. In addition, there is the added benefit of a chromatographic step early in the separation protocol. One must bear in mind that this technology is still in its development phase, and it is too early yet to conclude that it will become an integral part of a downstream processing protocol. However, as witnessed from the Second International Conference on Expanded Bed Adsorption recently held in the United States, there has been a growing awareness of the potential of the technology and it may indeed prove to have a promising future in bioseparations.

Before a detailed description of various aspects of expanded bed systems, a point of explanation should be made

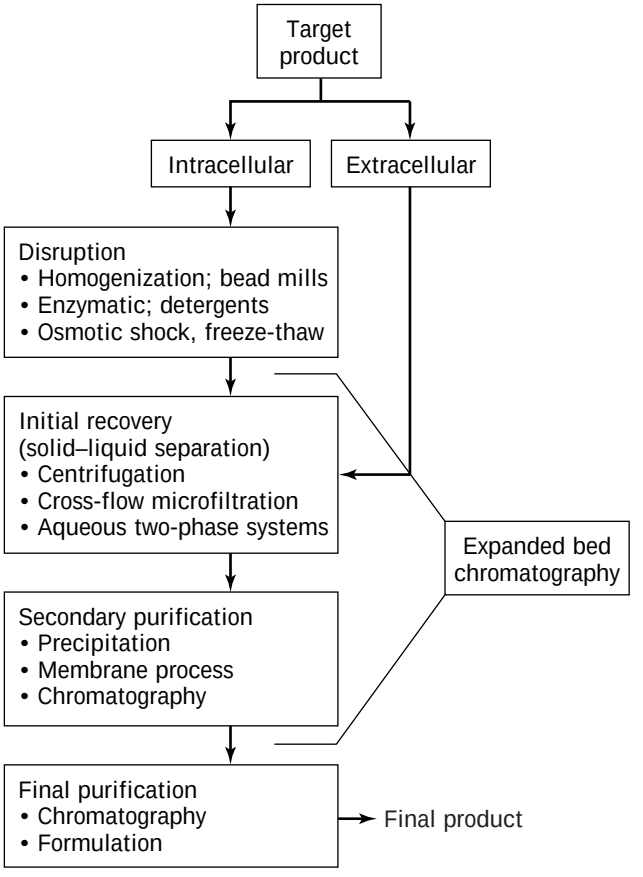

Figure 1. Typical sequence of operation in the recovery and purification of proteins from biological feedstock. The relative position of expanded bed as a viable alternative operation is also indicated.

regarding the use of the terms *fluidized bed* and *expanded bed*. During the initial development of this technology, the terms were often used exclusively of one another. In classical chemical engineering operations, fluidized beds were associated with catalytic reactors in which a high degree of solid–fluid mixing was maintained to ensure good heat and mass transfer. Expanded beds, on the other hand, would benefit product capture if good plug-flow-type hydrodynamics could be obtained. Clearly mixing needed to be minimized and bed stability ensured. The two terms were clearly in contradiction with each other; to maintain the existence of the critical difference, the use of the term *fluidized beds* was avoided in the context of biological separations by *expanded beds*. Over the years, however, this distinction has eroded, and now both are interchangeably used to mean essentially the same thing. The same applies in this article.

THEORY

To understand the physical process by which an expanded bed is obtained and some of the basic expressions describing its various states, we begin with a settled bed of adsorbent packed in a column with no top flow adapter. When an upward flow of liquid is introduced at the lower end, there is a tendency for the adsorbent particles to move in the direction of flow. This movement occurs only when the liquid velocity exceeds the minimum fluidization velocity of the particles. The bed then undergoes a transient expansion phase, at the end of which the adsorbent particles attain a steady position when the upward force due to the liquid flow exactly counterbalances the downward gravitational force on the particles. The bed is then said to be fluidized and will remain in this state as long as the two forces counterbalance each other.

When the fluid velocity equals the minimum fluidization velocity of the particles, the bed is said to be in a state of incipient fluidization. At this point the bed can be considered packed for the purpose of estimating the pressure drop across it and fluidized for calculating the buoyant weight of the particles. By using the Ergun equation for pressure drop and equating the two forces, we obtain an expression for the minimum fluidization velocity:

$$150\,\frac{(1-\varepsilon_{mf})^2}{\varepsilon_{mf}^2}\cdot\frac{\mu\cdot u_{mf}}{d_p^2}+1.75\,\frac{1-\varepsilon_{mf}}{\varepsilon_{mf}^2}\cdot\frac{\rho u_{mf}^2}{d_p}=(1-\varepsilon_{mf})(\rho_p-\rho)g \quad (1)$$

The pressure drop term on the left-hand side of equation 1 has two parts; the first term denotes the contribution due to laminar flow, and the second is due to turbulent flow. Depending on the flow regime, one could simplify the expression by neglecting the appropriate term. In the laminar flow region, the minimum fluidization velocity can be derived from equation 1 as

$$u_{mf}=\frac{\varepsilon_{mf}^2}{150(1-e_{mf})}\cdot\frac{1}{\mu}\,d_p^2(\rho_p-\rho)g \quad (2)$$

The physical parameters that affect the velocity at which a settled bed of particles begins to fluidize can be seen from equation 2 and are the viscosity of the fluid, the particle size of the adsorbent beads, and the density difference between the adsorbent and the liquid. An accurate estimate of the bed voidage at the point of minimum fluidization is also important for estimating u_{mf}. For spherical particles, 0.4 is always a good first approximate valid when the packing is not overly compact. Wen and Yu (16) have found a value of 0.42 to be satisfactory.

Once the bed is in a fluidized state, a simple relation exists between the bed voidage and the fluid velocity. This relation is valid over a given range of the latter, and the most commonly used relationship is that described by Richardson and Zaki (17), which relates the superficial fluid velocity, the terminal settling velocity of the particle, and the bed voidage. The relationship is expressed as

$$\frac{u}{u_t}=\varepsilon^n \quad (3)$$

where n is the Richardson–Zaki coefficient. The determination of n and u_t is usually obtained from a logarithmic plot of experimentally determined values of the bed voidage and the corresponding flow velocity and forms a fundamental part of the study of these systems.

However, bed voidage is not an easily measured parameter and would in turn require further experimentation. A more convenient approach is to use the relationship between the bed voidage at a given bed expansion, ϵ, in terms of the expanded bed height, H_{exp}, the initial (or settled) bed height, H_o, and the voidage of the settled bed ϵ_o. Thus we have

$$\varepsilon=1-\frac{H_o}{H_{exp}}\cdot(1-\varepsilon_o) \quad (4)$$

The ratio H_{exp}/H_o is referred to as the degree of bed expansion. Experimentally, one would measure the stable expanded bed height, H_{exp}, at a given flow velocity through the column (18–20). The data can then be plotted to obtain n and u_t for the bed. Analysis of equations 3 and 4 shows us that a high u_t for a particle results in a lower bed expansion and vice versa.

The terminal velocity is the upper limit of validity of the Richardson–Zaki expression, indeed of fluidization in general. At a fluid velocity equal to the terminal velocity of the particles, the particles are no longer suspended in the fluid but travel along with it. In the context of expanded bed chromatography, this leads to what is known as elutriation, where the adsorbent particles are physically removed from the column. Clearly, the latter phenomenon is highly undesirable, and it is therefore essential that for effective operation of expanded beds, the velocity range lies well within the limits of the minimum fluidization velocity at the lower end and the terminal velocity at the higher. The value of u_t can also be determined theoretically from Stokes law; thus

$$u_t=\frac{d_p^2(\rho_p-\rho)g}{18\mu} \quad (5)$$

The coefficient n has been estimated by Richardson and Zaki (17) to be a function of both the particle to column diameter and the Reynolds number. The correlations are valid for uniform spherical particles $>100\ \mu$m in size. Garside and Al Dibouni showed that a different set of correlations are required when the fluidized bed voidage is greater than 0.85. Two expressions were proposed by them—one general type and a second similar to the Richardson–Zaki type of formulation. Both are valid over the entire range of Reynolds number. Some common expressions developed by different workers for estimating the values of n and u_t are shown in Table 1. Values determined experimentally or through the correlations are used for comparative evaluation of different adsorbents for their potential use as fluidized bed adsorbents. The equations are a simple and effective starting point for evaluating some of the fundamental characteristics of an expanded bed.

PRINCIPLES OF OPERATION

The operational procedure for protein recovery using an expanded bed is similar in principle to that of a conventional packed bed column and is schematically depicted in Figure 2. As mentioned in the previous section, the initial step involves formation of the stable expanded bed from its settled or packed state. This is done by first moving the top flow adapter to a sufficient height to permit free movement of the top of the bed in the upward direction of liquid flow. When flow of the equilibrating buffer is initiated, bed expansion occurs and the top of the bed rises. The bed height increase is usually characterized by a linear phase followed by a progressively reducing nonlinear rate of change until a final stable height is achieved. This expanded height depends on a number of physical factors of the system, which are described in the next section. Once a stable bed has been obtained, the top flow adapter is usually repositioned to lie anywhere between 1 and 15 cm above the top of the bed. The actual position depends on the mode of operation employed (see later section). With the top adapter in position, the bed is essentially ready for initiation of feedstock load.

The flow is then switched from the buffer to the unclarified feedstock, usually by an appropriate valve mechanism. During the feedstock load, the solid matter, consisting of cell debris or sometimes whole cells, travels directly through the column while some of the solubilized products are adsorbed onto the column. Ideally there will be no retention of the particulate debris within the column, but in practice one could well observe a degree of nonspecific binding to the adsorbent particles. This issue becomes of particular relevance during cleaning-in-place and column regeneration. Feed load is usually terminated when the outlet concentration of the product being recovered is approximately 5–10% of its concentration in the feed. At this point the inlet flow is then switched back to the equilibrating buffer to wash out the residual particulate matter from the expanded bed.

When the outlet liquid is completely clear of insoluble material, the product can be eluted from the column, most commonly in the packed mode and after the bed is first allowed to settle by terminating the flow of liquid. The top flow adapter is then lowered onto the settled bed, bringing it to a packed mode. The bound products are then eluted by the appropriate elution buffers, usually in a single step because specific separation is not the primary objective at this stage of the recovery process. When elution is complete, the column is regenerated and where required cleaned. The bed is then expanded with the equilibration buffer and made ready for the next cycle of feedstock load.

Bed Stability

The sequence of steps in the operation of an expanded bed is relatively straightforward and simple to incorporate. As

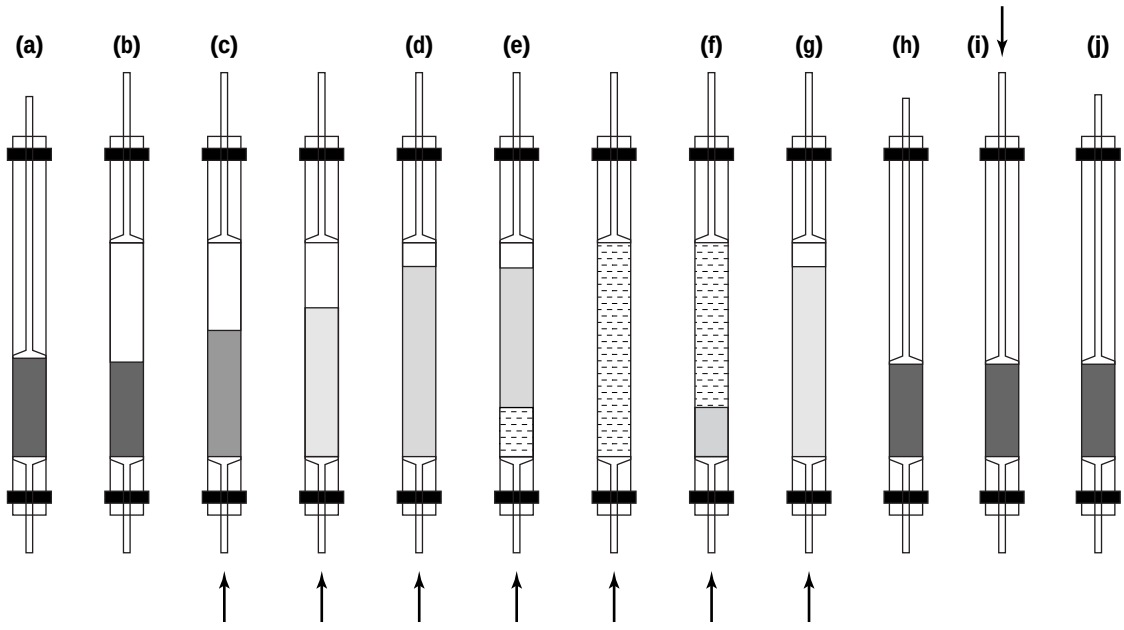

Figure 2. The various stages of operation of expanded bed chromatography from start-up to column regeneration. **(a)** Starting with a settled bed of adsorbent, **(b)** the adapter is moved up to remove any limitations on the movement of the bed. **(c)** Liquid flow through the column is then initiated from the bottom in the upward direction, during which time the bed undergoes a transient phase until **(d)** it finally reaches a stable steady-state height. The bed is equilibrated with buffer and **(e)** feedstock load initiated until the column is saturated, as seen from the breakthrough of bound product from the column. **(f)** The load is terminated and buffer wash started until **(g)** all the homogenate is washed out from the column. **(h)** The flow is then terminated, the bed allowed to settle, and the flow adapter lowered to attain a packed bed configuration, after which **(i)** the products are eluted, usually in the reverse direction. **(j)** The column is then cleaned and regenerated and made ready for the next run.

described earlier, the first step is obtaining a stable expanded bed; although not immediately obvious, this is a critical requirement with implications for overall process efficiency. A stable bed can be defined as one in which the liquid–liquid and solid–liquid mixing is low. Bed stability becomes a necessary requirement for good plug-flow-type hydrodynamics, which in turn affects the product binding characteristics. This is best quantified through residence time distribution (RTD) studies by analyzing the outlet profile of a tracer pulse in exactly the same manner in which it would be done for a packed bed system. Tracers such as acetone are effectively used in the absence of any particulate material. However, RTD experiments conducted in the absence of such particulates only indicate the state of the bed before feedstock load is initiated. Unlike packed bed chromatography, in which the hydrodynamics of the bed can be assumed to be more or less the same throughout the load phase, expanded beds are more than likely affected to a certain degree by the presence of the particulate matter. Although the influence need not necessarily be significant, it is nevertheless an important point to remember when conducting stability tests in these systems.

The tracer outlet profile can be evaluated by the moments rule to obtain an estimate of the Peclet number or the vessel dispersion number (21), defined as

$$\mathrm{Pe} = \frac{u}{D_{\mathrm{ax}} \cdot L} \tag{6}$$

where D_{ax} is the liquid axial dispersion coefficient. Values of Pe greater than 40 are considered acceptable in terms of the flow hydrodynamics. The Peclet number is used interchangeably with the Bodenstein number, defined in the same manner and used extensively by Karau et al. (20) and Thommes et al. (22).

For the experienced user of expanded bed chromatography columns, the power of visual observation, although highly qualitative and impossible to validate, can often prove to be sufficient in ascertaining the extent of bed stability. Liquid–liquid (and thus solid–liquid) mixing is often a result of radial flow inequalities. Some of the common causes are poor distribution at the inlet to the column (which often transmits through the full length), inaccurate vertical alignment of the column (which is particularly important in scale-down systems), and aggregation of the adsorbent particles (which leads to significant variation in the bed voidage along the length of the column and thus affects the flow pattern). The consequential gross flow inadequacies can be more than sufficiently detected by the naked eye, and although an accurate determination of the Peclet number is not possible, visual observation often gives sufficient indication when a bed has yet to reach a

stable configuration. Experience clearly plays a significant role in the use of visual observation as a tool for determining bed stability, and it has only limited applicability. Nevertheless, it may often prove sufficient when a rigorous residence time distribution experiment is not essential.

Stability of expanded beds is achieved through the inherent particle size distribution of the adsorbent. From the theory of fluidization outlined in the previous section, smaller particles fluidize more readily than larger ones in a given liquid stream, assuming that the particles are uniformly dense. For fluid velocity ranging between the minimum fluidization velocity of the smaller particle to the terminal velocity of the larger one, different situations arise, as depicted in Figure 3. As the flow velocity is increased such that $u_{mf,large}$, $u_{t,large}$, $u_{t,small} > u > u_{mf,small}$ the smaller particles fluidize and attain a steady-state position somewhere along the length of the column. Continual increase in the flow until $u_{t,large}$, $u_{t,small} > u > u_{mf,small}$, $u_{mf,large}$ results in both the small and large particles being fluidized. However, the increased flow velocity requires a longer column length for the inertial forces to drop to the level to be sufficiently counterbalanced by the buoyant force of the smaller particles. It therefore attains its steady state higher up along the column relative to both its initial position and that of the larger particle. A further increase such that $u > u_{mf,large}$, $u_{t,small}$ would wash the small particles out from the column and move the steady-state position of the larger particles higher up. Finally, when $u > u_{t,large}$, the larger particles are also elutriated.

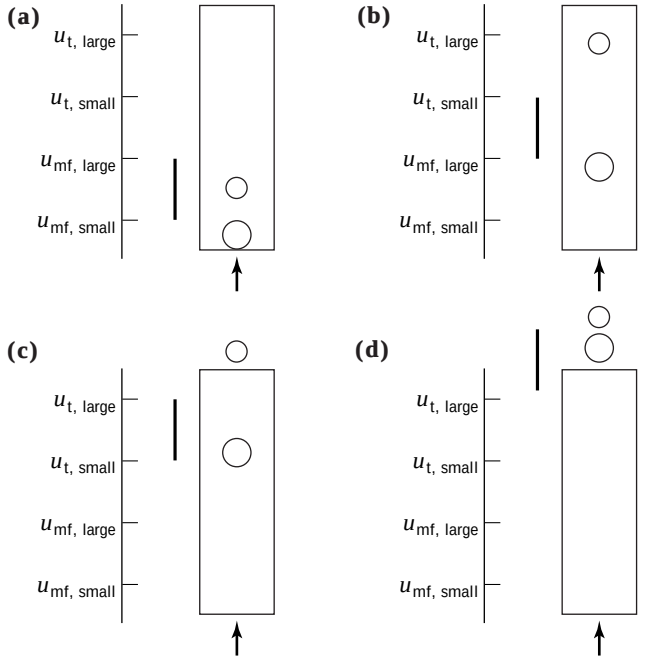

Figure 3. Schematic diagram showing the effect of flow velocity on the fluidization of two particles of different sizes. **(a)** As the flow velocity is increased such that $u_{t,large}$, $u_{t,small}$, $u_{mf,large} > u > u_{mf,small}$ the smaller particles fluidize and attain a steady-state position somewhere along the length of the column. **(b)** Continual increase in the flow until $u_{t,large}$, $u_{t,small} > u > u_{mf,large}$, $u_{mf,small}$ results in both the small and large particles being fluidized. The increased flow velocity, however, requires a longer column length for the inertial forces to drop to the level to be sufficiently counterbalanced by the buoyant force of the smaller particle. It therefore attains its steady state higher up along the column relative to both its initial position and that of the larger particle. **(c)** A further increase such that $u_{t,large} > u > u_{t,small}$, $> u_{mf,large}$, $u_{mf,small}$ would wash the small particles out from the column and move the steady-state position of the larger particles higher up. Finally, when $u > u_{t,large}$ the larger particles are also elutriated. The vertical line shows the flow velocity range on a relative scale between the limits.

Extending the preceding discussion to an expanded bed of adsorbent with a defined particle size distribution means that the particles will be stratified along the length of the column. This is schematically depicted in Figure 4 for a bed of adsorbent in the settled and stable expanded states. In the absence of gross flow inequalities, each particle remains in its steady-state position, with the larger ones at the bottom or inlet to the column and the smaller ones near the top (23). This configuration can be maintained indefinitely. In reality there is localized movement of the particles, but it contributes little to liquid–liquid mixing within the system.

The other most notable method for stabilizing fluidized beds is through the use of magnetic fields (24–27). A magnetic material is incorporated within the adsorbent beads, and the superimposition of the magnetic field acts to limit the movement of the adsorbent particles. The flow of particulate-laden feedstock can often be conducted at relatively higher flow velocities, enhancing the efficiency of its wash through the column.

Modes of Operation

Although stability has been discussed in terms of liquid–liquid and solid–liquid mixing, bed height movement must be considered. Because the top of the bed is not restricted in any way, changes in the flow or physical properties of

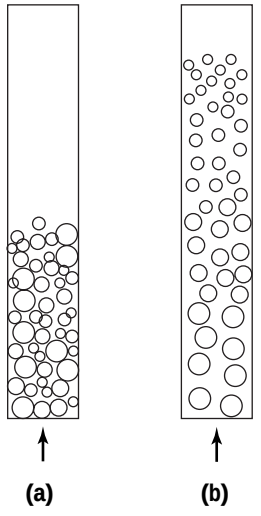

Figure 4. Schematic diagram showing the stratification of particles based on size along the length of the column going from **(a)** the randomly distributed settled bed state to **(b)** the stable expanded one.

the inlet liquid directly, although not always instantly, influence the bed height. Thus, when switching between buffers of different viscosities, densities, or both, the bed exhibits a concomitant movement to achieve a stable height corresponding to the new physical conditions to which it has been subjected. This movement is also seen when feedstock load onto a stable expanded bed is initiated. The significantly different physical properties of the particulate containing feedstock from the equilibrating buffer implies that on switching to feedstock, the bed height will change to a new stable position, assuming that the flow rate through the entire operation is kept constant. Consequently, there are two distinct possibilities for modes of operation of the bed:

1. In a *constant flow rate* mode, the bed is operated with the flow rate maintained at its initial value, allowing the bed height to vary if necessary. Because biological feedstocks are in general more viscous and dense than the standard buffers commonly used in biochemical processes, switching from buffer to feedstock load is manifested in terms of the expanded bed height increasing through an initial transient phase to a new position. This increase is further influenced by the presence of particulate matter.Two operational implications arise as a result. Firstly, the position of the top flow adapter needs to be managed appropriately, either through continuous repositioning during the course of the run or by selecting an initial position significantly higher than the top of the bed before the feedstock load. In this mode the gradually increasing bed voidage during the course of feedstock load would be beneficial in the context of solids removal. Protein adsorption could be adversely affected, however, because of increasing mass transport distances, likely making it a critical rate limiting step in the process. The latter effect would be more pronounced for high molecular weight proteins.
2. In a *constant bed height* mode the bed is maintained at its initial expansion, and any tendency for the bed height to change is corrected by appropriate adjustment in the flow rate. An obvious advantage is that there is no need to adjust the position of the top flow adapter, simplifying equipment design. It is imperative, however, to be able to monitor the top of the expanded bed and any changes that it undergoes to effectively control flow rate.Protein adsorption in this case would perhaps be more efficient but would be offset by slower solids removal because of the progressive reduction in the flow rate to maintain the bed height at its initial level. The extent to which flow rate adjustment is required depends on the percentage of solids in the feedstock, with their removal being hindered at the higher solid content.

EQUIPMENT

Because of the nature of the feedstock typically used in expanded bed chromatography applications, the equipment varies from that used in conventional packed bed chromatography, although in principle the equipment undergoes only minor modifications. Certain design considerations with respect to the column and flow distributor would need to be satisfied, as discussed in the following sections.

Column

Expanded bed chromatography is a low-pressure operation that requires minimal modification of conventional packed bed columns. A principle design consideration is the inlet flow distributor, which must be able to handle particulate material in the feedstock being loaded onto the column. This aspect is discussed in detail later. Another point of practical relevance is that the column must be of sufficient length to handle the desired degree of bed expansion. Two- to threefold bed expansions are typical; for a settled bed height of 20 cm, this translates to a minimum of 60-cm column length. In practice, columns are usually 1 m long so that the top flow distributor can be suitably positioned to allow for an increase in bed expansion when unclarified feedstock is being processed in the column.

The commercially available columns now range from 2.0 to 1,200 cm in diameter. The first column to be marketed was the STREAMLINE 50™, which is extensively used by researchers today. Given the potential for commercial application, the subsequent generation of columns was scaled up to 20, 60, and 120 cm in diameter. Although useful for process scale operations, the size clearly limited their use for methods development and process validation work. Scale-down of the expanded bed columns followed, and column sizes of 2.0 and 2.5 cm are now available. I conducted the first scaled-down validation, and data from columns sizes of 0.5, 1.0, 5.0, and 25.0 cm in diameter showed excellent correlation in expansion properties and protein adsorption breakthrough.

Table 2 shows the major suppliers of the expanded bed chromatography columns and available specifications. Included in the table is the small glassware company that tailor-made the small-diameter columns I used in the scaled-down studies described earlier. These columns are fitted with a sintered glass disk as the inlet and outlet flow distributor. Columns up to 20 cm in diameter are constructed of glass, and larger ones are made from stainless steel. Glass columns have the advantage of allowing visualization of the process. This observation is particularly useful when column blockage results in excessive back pressure, reducing the flow through the column and causing the bed to rapidly settle.

Flow Distributor

The importance of the flow distributor at the inlet has been a neglected issue in column design. There are several parallel requirements, beginning with the need for a uniform distribution of the liquid at the column inlet. A degree of variation from this ideal situation is always encountered, and this particular parameter is not considered to be critical in determining the overall performance of the bed. One of the reasons is the higher ratio of length to diameter, which offers a dampening effect for poor flow profiles that

Table 2. Commercial Suppliers of Columns for Expanded Bed Chromatography

Supplier	Column diameters (cm)	Materials	Distributor type

result from maldistribution at the inlet. A more relevant requirement of flow distributors in the context of expanded bed chromatography is that it should allow free passage of the particulate material present in the feedstock. The high voidage of the bed itself permits almost unhindered flow, and bed blockage is therefore more likely to be a problem at the flow distributor. Although larger pore sizes are clearly beneficial in overcoming this limitation, it is also important to remember that the adsorbent particles themselves must be retained within the column.

The most common distributor type is the perforated stainless steel plate fitted with a stainless steel wire mesh on top. This type is found in all of the Amersham Pharmacia Biotech (APB) columns available commercially. The number of holes in the perforated plate depends on the column diameter it fits. The wire mesh serves to prevent the liquid from jetting into the bed at the column inlet by offering a distribution surface. It also has a dual purpose of preventing the adsorbent particles from leaking out from the bottom of the column. De Luca et al. (19) have investigated bed expansion characteristics using distributors with various numbers of orifices and arrangements from the center. The settled bed height and bed expansion were found to be important parameters that influence mixing within the bed.

Although all expanded bed work using APB columns relies on these distributors, little has been published about the problems of blockage when using unclarified feedstock. This is not to say that the problem is nonexistent. Column back pressure buildup occurs because of gradual accumulation of the particulate material in either the pores of the perforated disk or the space between the disk and the mesh. In new columns and those seeing their first feedstock challenge subsequent to cleaning and regeneration, the buildup is relatively slow, and a much longer load time is possible before the column needs to be back flushed to clear the appropriate blockage. Back flushing is usually done by reversing flow direction for a short period, often at an enhanced rate. When the loading is resumed, the back pressure will be at its initial value; however, the buildup to the next back flush condition often occurs more quickly. The procedure can in principle be repeated until the end of the load cycle. The exact length of the initial and subsequent load periods depends on the parameters of the systems in question, including the solids concentration in the feedstock, the type of flow distributor, and the flow rate. Thus no reports on investigations of the influence of different parameters on the load efficiency of flow distributors have been published.

An interesting approach to flow distributor design has been adopted by UpFront Chromatography (Denmark). Its novel method essentially bypasses the conventional type of distributor and mesh from the flow path of the feedstock. In contrast to the commonly used method for load described earlier, the UpFront system introduces the feedstock from a side inlet and above the bottom support mesh. Distribution of the material is ensured through the use of a stirring device located immediately above the bottom support mesh. Although distributor blockage is clearly avoided in this system, the stirring speed needs to be carefully selected, balancing the requirement for uniform distribution over the inlet area with the need to avoid vortex formation and increased liquid–liquid mixing in the column itself. The scale-up potential of this distributor type needs to be addressed. The company manufactures 2-, 5-, and 20-cm-diameter columns using this technology.

Bioprocessing (England) has another approach to obtaining uniform flow distribution. Standard chromatography columns in which beds of glass ballotini are placed directly above the bottom support mesh are used. The expanded bed adsorbent is then added on top. When flow of buffer is initiated through the column, the bed of adsorbent fluidizes but the glass ballotini do not because of their significantly higher density. Uniform distribution is obtained, and the mixing of adsorbent and ballotini beads is avoided. Proper selection of ballotini size is important. The smaller ones have been shown to offer better distribution, equivalent to the use of a perforated disk with many orifices. However, one must remember that smaller particles have a lower minimum fluidization velocity, and the selection needs to balance the need for small-sized ballotini with maintaining a larger difference in the minimum fluidization velocity between it and the adsorbent beads.

Adsorbent

As with packed bed chromatography, the adsorbent must offer a basis for interaction with the solubilized components of the feedstock to enable product capture. In addition, expanded bed adsorbents must also possess good fluidization characteristics. During the flow of particulate bearing feedstock through an expanded bed, the adsorbent should, under the flow conditions employed, remain in a fluidized state and not tend to elutriate from the column. This can be achieved if the terminal settling velocity of the adsorbent is significantly higher than any of the other solid matter present in the system. The three physical properties of the system that most significantly influence the terminal velocity of the adsorbent—particle diameter, density difference between the particle and the liquid, and liquid

viscosity—can be seen from the Stokes equation, described earlier.

Liquid viscosity is essentially dependent on the feedstock and is for the most part not an adjustable parameter, although some feed pretreatment is certainly possible. However, regarding the adsorbent, one can essentially experiment with the particle diameter and the density difference between the adsorbent and the liquid. The problem of suitably dense adsorbents can be offset to some extent by using size as a parameter for increasing the terminal velocity of an adsorbent particle. Thus a material of lower density and higher particle size can be used in expanded bed chromatography. However, a significant disadvantage lies in the resulting increase in mass transport resistance. The diffusion time is related to the square of the particle diameter; pore diffusion thus becomes the rate-limiting step in larger particles. Another disadvantage of expanded beds is increased interparticle distances, which may lead to slower transport of solute from the bulk to the surface of the adsorbent. The presence of particulate debris may cause further mass transport limitations and pose problems of adsorbent fouling and pore blockage.

The optimal adsorbent for use in expanded bed chromatography should therefore be small and very dense, and, as with any chromatography adsorbent, the dynamic bed capacity (DBC) should be acceptably high. There is an intrinsic link between these different parameters for effective expanded bed operation. DBC can be improved by using smaller particle sizes; however, efficient removal of the particulate debris present in the feedstock is an essential process requirement, and the two conditions can be simultaneously satisfied through the use of high-density adsorbents. Although good adsorbent design is critical in expanded bed operation, only limited work has been undertaken on its improvement, and most applications of this technology thus far have centered on the use of commercially available material. Only a few such materials exist currently. Table 3 summarizes some of the more common adsorbents currently used in expanded bed applications.

APPLICATIONS

The growing realization of the potential of expanded bed chromatography is borne out by the rapidly increasing number of reported applications of this technology in biological product recovery. The growth of this subject area over the last decade can be judged by following the literature for reported work during that period. The pioneering work in this field by Chase and coworkers relied on the use of conventional packed bed chromatographic adsorbents (28,29). Yeast cell homogenates were also commonly used in model systems. They are a suitable starting material given the many proteins present, any one of which can be targeted for recovery by expanded bed operation and offering the scope for use with ion exchange and affinity adsorbents (30,31).

Applications of expanded bed chromatography for the recovery of product directly from feedstock has moved on from the yeast homogenate systems that were studied a few years ago. There are now examples of applications for the recovery of both native and recombinant proteins from yeast (32) and bacterial cells (33–35), milk (36), and monoclonal antibodies from hybridoma cells.

The examples mentioned are but a few of the growing list of new applications that are being reported. The recently held Second International Conference on Expanded Bed Chromatography gives further evidence of the growing awareness of the potential of this technology in biological product recovery (see the book of abstracts for further information). In following the work in this area, it is obvious that the applications are for the most part based on conventional operational procedures and differ only in the system for which the recovery is being studied. Although the theory-oriented investigations have strived to tackle interesting issues of this technology, the applications mostly been bound by conventional operating protocols, similar to what has been described in the previous sections.

Two applications warrant specific mention because of their novel and interesting approach and are briefly highlighted. The work by Chase and coworkers on the use of a continuous countercurrent extractor (37–39) extends the

Table 3. Commercial Suppliers of Tailor-Made Adsorbents for Expanded Bed Chromatography

principles of expanded bed chromatography to continuous protein separation. A perfluorocarbon-based adsorbent (40) was pumped between four different contactors, each representing in sequence one of the four stages (i.e., load, wash, elution, and regeneration). Crude unclarified feedstock was pumped into the first contactor and product obtained from the third. The use of a specific affinity ligand permitted highly purified product to be collected at the outlet of the elution stage.

Another interesting methodology has been demonstrated by Lyddiatt and coworkers in which a fluidized bed was coupled with batch fermentation for direct product removal through either continuous or intermittent recycle of the reactor contents through the fluidized bed. Inherent problems of holding the fermentation material outside the controlled reactor environment were addressed through the use of a multibed manifold comprising smaller beds. Each bed was operated until the adsorbent was saturated and then removed from the flow loop for product recovery, cleaning, and regeneration.

Expanded bed protein adsorption has now reached a stage in its development where a good understanding of the potential and drawbacks can be effectively assessed. Issues related to the bed design, performance, and application have been addressed in the literature. Although the potential of this technology is well accepted, it is dangerous to assume that it will offer the solution to many recovery and separation problems. Many aspects are still either not considered important or not understood. The worth of the technology will be seen only when they become an integral part of bioprocesses. Toward this goal, the first step may already have been taken: There is now at least one report of a biotechnology company having patented a process for plasmid DNA production in which expanded bed adsorption is incorporated in the purification protocol.

OUTLINE

INTRODUCTION

Because some protein components, such as the tyrosine side chain, have negligible solubility in water, proteins in solution exist in a precarious equilibrium. Most proteins form oligomers or aggregate at higher densities, a phenomenon that can to some extent be prevented by the addition of solvent additives (1) and mutations targeted to surface areas involved in aggregate formation (2). Solvent additives have proved invaluable in areas ranging from protein formulation for drug purposes to sample preparation for high-resolution structure determination techniques. Using cosolvents is, however, a matter of trial and error, with little framework for predicting their effects or even optimizing concentration. This is partly because of the inherent problems in following the early stages of protein aggregation.

This article summarizes biophysical techniques useful for measuring solubility and following precipitation. Maintaining solubility depends on subtle interactions of side chains and backbone atoms to balance the cavitation energy needed to maintain a solvent pocket for the bulk of the protein by the energy of interaction of hydrophilic groups with the solvent. Traditionally, proteins are presented as unique but ill-characterized globules remarkable only with respect to size and net surface charge. Direct methods to determine the characteristics of the protein surface may allow a better accounting for protein–solvent interactions in the presence of cosolvents. Energy functions that account for the various forces on the protein have been derived; their application to different solvents is now being tested. Interpreting empirical data to derive atomic solvation parameters or deriving bulk solvent parameters may lead to a thermodynamic or kinetic accounting for the effect of cosolutes on protein stability and solubility.

Designing mutations that prevent aggregation can be greatly helped by a high resolution three-dimensional structure of the protein–protein complex. A relatively unsophisticated home computer or work station now allows easy assess to the steadily increasing data banks of detailed 3-D protein structures, which were previously accessible only with expensive viewing systems. Faster and more efficient computational methods have greatly expanded our abilities to model protein structures by homology to proteins of known structure or ab initio using protein threading and other algorithms from the primary sequence. Thus, a section is also dedicated to methods for obtaining and using structural information to predict areas of the protein that may be involved in oligomerization and aggregation.

METHODS FOR MEASURING SOLUBILITY AND PROTEIN ASSOCIATION

For details about the molecular interactions involved in complex formation, many methods measure the absorption or scattering of some form of electromagnetic radiation by the sample (UV/vis and IR/Ramen spectroscopy, light scattering, laser light scattering, neutron diffraction and X-ray crystallography) (3). A beam of radiation sent through the sample can:

1. Pass through the sample unchanged
2. Be absorbed by the sample and emitted at the same wavelength
3. Be absorbed by the sample and emitted at a different wavelength
4. Be scattered by the sample

Various methods can be used to detect the effects of the sample on the beam (4). Figure 1 is a summary of methods aligned according to the electromagnetic radiation spectrum. At opposite ends of this spectrum lie the two highest resolution methods, X-ray crystallography and NMR spectroscopy, which yield complete structural information at the atomic level. However, combining results from lower resolution methods can be used to develop a working model of complexes and to obtain information about the aggregation process. In the simplest and most commonly used method to measure protein concentration and aggregation, a coherent beam of visible or UV light is passed through the sample. The light emerging on the other side of a cuvette of known path length is measured and related to the concentration of the sample. Some information about the nature of the sample can be obtained by observing how much light is absorbed when the wavelength is varied over the whole spectrum (a so-called UV/vis scan). In large proteins, the tryptophan side chains within the protein may be shielded, and as the protein unfolds, this tryptophan absorption at 280 nm becomes more pronounced. Absorption in the visible range is usually due to the presence of a chromophore (e.g., Haem absorption) or particulates. Fluorescence spectroscopy measures the energy of the emitted light, and laser light scattering measures the angle of the reflected light to determine particulate size (5). Many other, more advanced methods, summarized in Table 1, have been used to measure the quaternary state of proteins in solution.

Combining Methods to Follow Aggregation and Precipitation and Determine the Structure of Complexes

The size of small complexes in solution can be accurately determined by equilibrium centrifugation, native gel electrophoresis, or gel sizing chromatography (using for example Sephadex beads or HPLC). However, these methods are not particularly useful for studying aggregated protein. In vitro aggregation can have many forms, extending from a drastic, sudden precipitation of large flocculent masses of protein, often visible to the naked eye, to the gradual formation of tiny, invisible particles. The most valuable experiments look at the initial phases. The simplest direct quantitation of aggregation is thus to measure the absorption of visible light by the sample, if the particles are small enough to remain in solution, or to follow the precipitation by the drop in UV absorption of a protein solution where the particles are allowed to settle or are removed by centrifugation. If aggregation is related to unfolding, it may be possible to follow the increase in OD_{280} (as the tryptophan residues become exposed upon unfolding) and then its decrease as the protein aggregates.

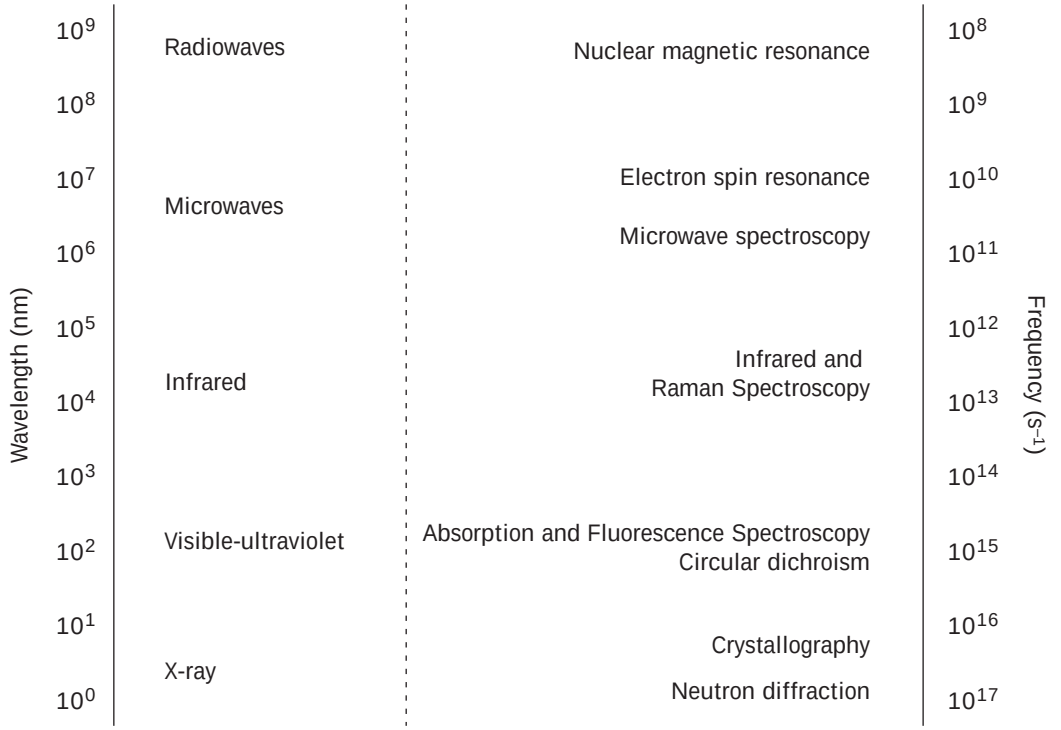

Figure 1. Methods used for analyzing the structure of biological molecules and complexes thereof as a function of position in the electromagnetic spectrum.

Table 1. Physical Methods for Monitoring Changes in Protein Structure and Interprotein Interactions Involved in Aggregation

Method (abbreviation)	Brief description	Protein needed[a]	Sample preparation/ buffer interference[b]	Best used for
Equilibrium (ultra) centrifugation (EC)	Protein complex is centrifuged at high speed in a density gradient, and its equilibrium position used to determine the size of the molecule or complex.	High	Gradient components may affect protein association.	Determining the oligomeric or aggregation state of soluble complexes. Insoluble aggregates settle at the bottom of the tube or float on the surface of the gradient.
Gel sizing chromatography (GSC)	Soluble proteins are passed over a column of porous polymer. Molecules small enough to enter the pores are held back and elute according to size, larger ones pass through unimpeded with the void volume. Can be done with capillary HPLC columns on the microscale.	Moderate to high	Sample should be concentrated for application, a step that may induce aggregation or oligomerization.	Sizing small, soluble complexes of proteins; large aggregates either elute with the front or precipitated at the top of the column (latter may slowly redissolve, giving unreliable data).
Polyacrylamide gel electrophoresis (PAGE)	Proteins are separated according to size by electrophoresis through acrylamide gels of varying density. Proteins may be detected in a variety of ways: by staining, autofluorescence, or after transfer to a membrane, by reaction with a specific antibody or nucleic acid fragment.	Concentrated sample required, but small amounts of protein may be visualized by silver or gold staining.	If the sample is not to be eluted for further analysis, apply less protein and use more sensitive dyes for accurate size determination.	Sizing small, soluble complexes of proteins; large aggregates stick in the slot.
UV/Vis absorption (UV-abs)	A beam of coherent light is passed through the sample, and the absorption by the protein constituents is measured. Proteins absorb between 210 and 220 nm because of orbital transitions of the peptide backbone, which are overwhelmed by that of the side chains of D, N, E, Q and R, and at 280 nm because of aromatic side chains of W, Y, F; chromophores in the protein may absorb throughout the visible range as well.	Low	Only for protein in solution; samples should be diluted to be in the linear range of the spectrophotometer	The denaturing effect of cosolvents on proteins; following aggregation by decrease in the fluorescence absorption and/or increase in absorption in the visible range.
Fluorescence transfer (FT)	A fluorescence acceptor and donor group are coupled to a protein. When excited by light, the quenching of donor fluorescence by the acceptor serves as a measure of the distance in the complex between them.	High	Only for protein in solution, buffer interference; requires coupling of donor and acceptor molecules usually to free cysteine groups in the proteins.	Distance between labeled side chains in a single molecule or oligomer; most useful with protein complexes with a well-established 3-D structure.

Table 1. Physical Methods for Monitoring Changes in Protein Structure and Interprotein Interactions Involved in Aggregation (*continued*)

Method (abbreviation)	Brief description	Protein needed[a]	Sample preparation/ buffer interference[b]	Best used for
Optical rotatory dispersion (ORD)/ Circular dichroism (CD)	In ORD, the rotation of a beam of polarized light by the sample is measured by a coupled polarizer/photomultiplier on the exit side of the cuvette. The angle of rotation of the second polarizer to obtain the highest intensity of emitted light is plotted as a function of the wavelength. In CD, molar ellipticity is measured as the difference in absorbence by the sample of an incident beam rotated to the left or right (I_L and I_R) by a timed electric field change. A photomultiplier on the exit side measures absorbence as a function of time, and a microprocessor interprets the data to determine the mean residue ellipticity (which is proportional to $I_L - I_R$) as a function of wavelength.	Moderate	Only for protein in solution, buffer interference possible.	Secondary structure of proteins in various media; also to follow changes in the secondary structure as a function of denaturation or aggregation. Computer-aided spectral interpretation can be used to obtain more complicated data about the protein configuration.
Electron microscopy (EM)	In vacuo, a beam of electrons is passed through a target with the (usually stained or coated) object affixed to it or imbedded in a matrix to obtain a 2-D image. In essence, one measures the electron density of the sample after coating to obtain a 2-D image. Cryo-EM techniques use unstained samples embedded in vitreous ice. High-speed calculations can be used to phase many images of particles (6,7).	Low	Fixation/staining may be needed. Consistent sample preparation, crucial to the cryo-EM technique, can be quite difficult.	Determining the ultrastructure of large, electron-dense, complexes; particularly useful to determine the shape of particles and their size distribution. Current resolution is in the range of 10 Å.
Electron diffraction (ED)	By tilting the target during EM and measuring reflection of the electron beam at various angles from the incident, a 3-D image can be reconstructed.	Low to high	2-D crystals or membrane patches; viral particles.	Obtaining ultrastructural data about regularly structured monolayers such as the membranes of purple bacteria.
Scanning tunneling microscopy (STM)	The electron stream from the object is detected across a vacuum barrier by a sensitive probe. The microscope itself is in reality the probe, and the name comes from the tunnel current, which flows when there is a small electric current between the tip of the probe and the conducting surface to be scanned (which should be less than 1 nm away).	Low	Resolution is higher for conductive samples; fixation/ staining may be needed for proteins and nucleic acids.	Determining the shape and size of fixed and coated large complexes or protein-DNA complexes; resolution is theoretically at the atomic level; suited to the study of larger protein aggregates because it gives a 3-D image directly without the image reconstruction methods used for 3-D transmission EM images.
Atomic force microscopy (AFM)	Technique (also called scanning probe microscopy) related to STM and using similar apparatus, more suited to biological samples because it is done under a solvent phase rather than in vacuo (8). Very little different from hydration STM, based on the electrical conductivity of molecularly thin water layers that adsorb to the sample surfaces in a humid atmosphere.	Low	Attachment to a surface necessary, can be done in a variety of solvents.	Direct viewing of the ultrastructure of large, not necessarily regular biomolecular complexes without staining. Methods are being developed for viewing protein-RNA complexes.

Table 1. Physical Methods for Monitoring Changes in Protein Structure and Interprotein Interactions Involved in Aggregation (*continued*)

Method (abbreviation)	Brief description	Protein needed[a]	Sample preparation/ buffer interference[b]	Best used for
Fourier transform-infrared absorption (FTIR)	Absorption of light in the infrared region (2.5–250 μm) by the sample is measured and the output beam resolved by Fourier transformation. *IR difference spectra*, deconvoluted in the amide I band region (between 1620 and 1700 cm^{-1}) can show secondary structure in terms of % α-helix, β-sheet, etc. (9,10).	High	Can also be used for precipitates.	Determining secondary structure elements and alterations thereof under different conditions.
Infrared attenuated total reflection spectroscopy (IR-ATR)	Infrared beam is reflected through an optically transparent germanium plate coated with sample; internal reflections along the plate increases sensitivity.	Low to moderate	Membrane patches attached to a special plate.	Membrane protein interactions with each other and external molecules.
Scanning fluctuation correlation spectroscopy (FCS)	Measures particle number concentrations by monitoring spontaneous equilibrium fluctuations in the local concentration of fluorescent species in a small (femtoliter) subvolume of a sample.	Low	Little problem with buffer interference	Detect molecular aggregation for dilute, submicromolar samples by directly counting particles.
Elastic (classical, static) laser light scattering (SLLS)	For elastic (classical, static) light scattering, the scattering of a beam of polarized laser light as it passes through the sample is measured and the obtained scatter factor can be used to calculate both the weight average molecular weight of the particles in solution as well as the radius of gyration.	Moderate	Scattering methods are usually not greatly affected by the buffer.	Determining the size of aggregates and precipitates. To obtain the scattering weight of a particle, one measures the scattering factor at several different scattering angles (q) and then plots the scattering factor as a function of q. Extrapolating back to $q = 0$ will yield the scattering weight.
Quasielastic (dynamic) laser light scattering (DLLS)	Similar to SLLS; but changes in the frequency from the translational (Brownian) movement of the scattering particles are also measured. The broadness of the intensity distribution of the emitted light for frequencies around the primary monochromatic beam frequency is directly related to the diffusion coefficient of the particles, which can then be related to the hydrodynamic radius if a model for the particle shape is available.	Moderate	The beam should not be strong enough to damage the sensitive biological specimen.	Kinetics of particle coagulation by following the decrease in diffusion coefficient as the particle size increases (11); determine particle molecular weight as a function of time; to follow course of aggregation in any solvent; compare samples in different buffers if viscosity is accurately measured.

Table 1. Physical Methods for Monitoring Changes in Protein Structure and Interprotein Interactions Involved in Aggregation (*continued*)

Method (abbreviation)	Brief description	Protein needed[a]	Sample preparation/ buffer interference[b]	Best used for
Raman, Raman resonance (RRS)	Light scattered at the incoming frequency, so-called Raleigh scattering, is measured in classical (elastic) and quasielastic (dynamic) light scattering. A small fraction of the laser light is scattered at frequencies higher (anti-Stokes) and lower (Stokes) than the incident beam. These scattered beams are measured in Raman scattering, which has many variations.	High	Sample fluorescence may interfere with Raman resonance measurement of precipitates.	Follow quaternary interactions of soluble complexes and to compare the secondary structures of proteins under various conditions; to compare the effects on secondary structure of precipitating agents.
Neutron scattering (NS)	Scattering of a neutron beam by the sample is measured.	High	Beam time is limited.	Determining the size of larger proteins and complexes.
Mass spectrometry (MS)	The magnetic field induced deflection of a vaporized, ionized molecule is used to determine its mass. Types are characterized by the method used to ionize and detect the sample. Advanced computational methods can be used to interpret structural data from the cracking pattern of larger molecules.	Varies	Usually protein is bound to a solid (e.g., nitrocellulose).	Very accurate molecular weight of monomers; use in combination with chemical cleavage methods may aid in determining tertiary and quaternary structure. Electrospray ionization (ESI-MS) has been used to characterize complexes of proteins and protein/nucleic acids (12).
Electron spin resonance (ESR)	Microwaves are absorbed by paramagnetic substances, and the change in the energy level of the electron spins measured.	Moderate		Structure and dynamics of lipid membranes; free radical detection in proteins; state of transition metals in proteins.
Nuclear magnetic resonance (NMR)	A concentrated solution of sample, possibly isotopically enriched for nuclei with a magnetic moment different from 0 (^{1}H, ^{13}C, ^{15}N, ^{31}P), is subjected to a high magnetic field. In the most common method, after the sample is pulsed, the decay in amplitude of the emitted radiowaves with time is measured and converted to a frequency spectrum by Fourier transformation. The magnitude and direction of the pulse can be altered to detect certain types of interactions between nuclei. The strength of the local magnetic field around an individual atom is decreased by the presence of covalently bound or spatially close neighboring groups, causing changes in the position of the resonance lines (chemical shifts) in the output frequency spectrum. Peak intensities in NOESY spectra reflect the distances between individual spins. Distance geometry methods and restrained molecular dynamics calculations are used to calculate the 3-D structure of proteins or protein–protein complexes.	High	Most solvents interfere with measurements. Labeling of the sample with stable isotopes may be necessary. Oligomers may be artificially generated by the high protein concentration required for measurement.	Determining the exact tertiary structure of small proteins, nucleic acids, and complexes. Combining results from different NMR experiments can be used to monitor changes in the resonance frequencies upon complex formation, and thus give specific information on binding sites. Various techniques (e.g., resonance transfer) can be used to measure interactions between two molecules even without establishing a structure. See Ref. 13 for a discussion of NMR techniques to study protein complexes.

Table 1. Physical Methods for Monitoring Changes in Protein Structure and Interprotein Interactions Involved in Aggregation (*continued*)

Method (abbreviation)	Brief description	Protein needed[a]	Sample preparation/ buffer interference[b]	Best used for
Protease mapping (PM)	Fragments left after cleaving with a site-specific protease are analyzed (by gel chromatography and sequencing or MS/MS sequencing) to determine surface accessible areas	High	Need to have specific sites for proteases in the protein; buffers should not interfere with techniques used to identify protein fragments.	Tertiary structure of an isolated protein or protected areas in complexes.
Chemical-based cleavage (CC)	Like PM, but an activated metal ion cleavage agent is incorporated at a free sulfhydryl group, and the cleavage is triggered by chemical or physical stimuli.	High	Buffers used cannot stimulate cleavage or interfere with subsequent methods to determine the size and constitution of fragments; need free sulfhydryl groups in the protein	Tertiary structure of an isolated protein or areas of contact in complexes.
Surface plasmon resonance biosensors (SPR)	A surface plasmon is an oscillation of free electrons that propagates across the surface of a conductor, typically a thin film of gold or silver. The sample to be measured is immobilized on one side of the gold film, e.g., in a hydrogel, and plasmon excitation is started with a beam of light. The intensity of plasmon generation (measured as the reflected light reaching the detector) is related to the refractive index of the sample. This can be altered by flowing a binding substance over the surface where it is immobilized.	Low to moderate	No labeling of the biomolecules is required, but the two media must have different refractive indices. To avoid rebinding artifacts, the bound protein should not be overloaded.	Real time analysis of (unlabeled) protein binding reactions (14).
Total internal reflection fluorescence (TIRF)	Fluorescently labeled proteins in aqueous solution interact with a solid phase (e.g., fused silica) coated with bilayers of synthetic phospholipids, unlabeled proteins, or even whole cells.	Moderate	Two media must have different refractive indices.	Determining interactions between membrane-bound and free proteins.
Small-angle X-ray scattering (SAXS)	The scattering of X-rays at small angles can be used to obtain greater resolution of X-ray crystal structures.	Moderate	Crystals required and special detection/computation systems.	Resolving the structure of large complexes to higher resolution than possible with diffraction data alone.
X-ray diffraction (XRD)	A protein crystal is bombarded with a high intensity X-ray beam of known wavelength and polarity. The diffraction pattern of the emitted energy, measured as spots on X-ray film or using an area detector, can be used to determine the position of individual atoms in the 3-D structure of the protein or complex.	High	Crystals required and extensive experimentation must be done to solve the phase problem.	The only method now in use that can give the 3-D structure of large, regular protein complexes at the atomic level. Adaptations are now being developed to use it to determine dynamics as well.

Note: Data presented with respect to the protein requirements, impedance by common buffers, and the type of information obtainable about the protein in solution or precipitate. For more details, see related references in Table 2; for general information about the methods, see Galla (4), cited specific references, or other books on protein characterization techniques.

[a]Protein concentration required for measurement. Low is in the nM–μM range, high means 0.1 mM or higher. Note that highly concentrated protein solutions are usually required to obtain crystals and that a lot of protein is wasted during the process of crystallization. Thus, one needs to start with about 100 mg of purified protein for X-ray analysis, although only a few μgs may find their way to the beam.

[b]Buffers used for sample preparation for all methods should be sterile and ultrafiltered (0.45 μ or smaller pore diameter filter) to remove particulate matter. Buffer requirements for various methods are discussed in the references given.

Although rapid onset suggests aggregation is a noncontrolled process, there are reports of sequence specificity based on the pattern of higher molecular weight aggregates seen on gels (15). An approximately similar pattern of bands was seen, whether a protein formed inclusion bodies alone or in the presence of another aggregating protein. Although this would indicate that each protein was only aggregating with itself, the authors could only study aggregates small enough to enter a nondenaturing gel, and a substantial portion of the protein in all the experiments remained at the top of the polyacrylamide gel (PAG). More recent data using computer simulations and light scattering suggest a cluster–cluster mechanism rather than a stepwise monomer addition polymerization (16). The aggregation of polypeptide chains during refolding occurred by multimeric polymerization, in which two multimers of any size could associate to form a larger aggregate and did not require a sequential addition of monomeric subunits.

Generally, combinations of methods are applied to proteins, such as the HIV-Rev, where it is important to determine the 3-D structure, but problems arise in obtaining this by high resolution methods. The Rev protein, whose function is to move viral unspliced RNA from the nucleus to the cytoplasm, is essential for the establishment of infection. Although establishing its 3-D structure would be very useful for designing inhibitors that could be used therapeutically, severe aggregation problems have hindered its characterization by X-ray or NMR spectroscopy. Data from STEM, cryo-EM of lysine cross-linked filaments, and Raman spectroscopy have been used to develop a low resolution (21 Å) model of Rev filament structure that may be useful in designing inhibitors (17). Structural modeling tools possibly useful for this protein are discussed later. To further illustrate how the methods of Table 1 can be applied to study the interaction of proteins, Table 2 is a list of some of the protein complexes that have been studied by combining biophysical methods.

CHARACTERIZING PROTEIN–SOLVENT INTERACTIONS

Protein Stability in a Practical Sense

As Privalov has pointed out (85), if one assumes that all deviations from the X-ray crystal structure represent a new and separate state of a protein, the net thermodynamic stability of a protein at any temperature above a few degrees Kelvin is essentially zero. The thermodynamic framework works well for small molecules that can assume a limited number of stable conformations. However, proteins change conformation continuously; phenylalanine side chains are often free to rotate around the Cβ-phenyl bond and as many as 40% of the amide protons of a protein exchange with the solvent in a few seconds (86). Solvent effects make these dynamic considerations even more complicated; the rate of hydrogen exchange of a protein changes when even the isotopic nature of the solvent is changed (87).

To simplify the problem, thermodynamic stability has been defined as the energy needed to switch the protein structure from a folded, active native state (in reality a collection of substates around a mean native structure) to a completely unfolded, denatured state. Formation of the denatured state in a dilute protein solution can be induced by slowly increasing temperature until the transition is indicated by extreme changes in the protein's activity or protease susceptibility, or in the protein's characteristic UV absorption, circular dichroism, or more recently, NMR spectrum. The temperature at which this change occurs is referred to as the thermal denaturation temperature, or T_d. Thermodynamic stability data can be collected in a few hours, but the measurements cannot be done at high-protein density because aggregation usually precedes total denaturation. The T_d varies considerably from one protein to another and is a function of the pH and other properties of the solution in which the measurement is made. The free energy of unfolding ($\Delta G^\circ_{\text{unfolding}}$), which can be calculated from the T_d, is approximately 12 $\pm$ 5 kcal/mol at 30 °C for all proteins. This number is equated with the free energy of stabilization of proteins in aqueous solution according to the two-state model (88). As native, properly folded structures aggregate less than unfolded, denatured ones, there is an intimate relationship between solubility and thermodynamic stability. However, although extreme differences in the T_d can be used as a direct indication of the stability of the protein structure (peptides may lose their secondary structure at T $<$ 12 °C, whereas thermophilic proteins retain it in a boiling water bath), the T_d of typical proteins is in too narrow a range to serve as an indicator of structure or purity. We know that proteins vary greatly in their stability in solution or the dry state. It has been shown that the $\Delta G_{\text{unfolding}}$ for RNase T1 can be almost doubled by adding 0.2 M Na_2HPO_4 or certain other salts, but the increase amounts to only 5 kcal/mol (86). Many additives that stabilize proteins against aggregation do not affect the T_d. Aggregation occurs at temperatures well below the T_d for proteins, indicating that a protein need not unfold completely to aggregate.

Thus, other methods must be used to determine protein stability in solution under nonextreme conditions. A two-state model ignores the less abrupt (and therefore less easy to measure) changes in the protein structure that precede complete unfolding. Such changes, coupled with an increased rate of aggregate-producing encounters, probably lead to temperature-dependent protein precipitation. Stability for practical purposes is the empirically determined resistance of a protein to oligomerization or to inactivation by other mechanisms. Stability can then be equated with the persistence of solubility or activity and determined kinetically as the protein half-life (measured by protein concentration or activity after centrifugation) in a solution of specified pH, solute concentration, and temperature (1).

The kinetic method of measuring stability requires several days and moderate amounts of protein. To shorten the time required for kinetic measurements of solution stability, an additional stress can be put on the system by agitating it or adding a protease. For example, resistance to mechanical shaking was found to be a useful indicator of solution half-life for 10 enzymes present in liver extracts (89). Use of more sensitive methods to detect protein aggregation should reduce the protein required for stability measurements. Osmolytes useful for formulating recombinant human growth hormone and interferon-γ were de-

Table 2. Model Systems for the Study of Protein Aggregation

Model system	Studied with	Examples and key results
		Multiprotein complexes
Ribosomes	XRCrys, SANS, EM, neutron diffraction	Early crystals of ribosomes from thermophilic organisms diffracted to >20 Å were used for comparing the exterior structure with EM photos. Crystals diffracting to <5 Å were used, combined with image reconstruction, to determine structural details (18). Neutron diffraction of ribosome crystals was used to localize the RNA within the core of the particles using difference maps prepared at different D_2O/H_2O (altering the relative concentrations of D_2O and H_2O in the solvent changes the relative diffraction caused by RNA or protein in the crystals) (19). Freezing crystals stabilized them in the X-ray beam. A 37-Å resolution 3-D structure of ribosomes from rabbit reticulocytes was calculated from electron micrographs of uranyl-acetate stained single-particle specimens (20); whereas cryo-EM and neutron scattering data can be used to model the protein/nucleic acid interactions (21).
Nucleosomes	EM, XRCrys	The crystal structure of the nucleosome core particle was developed to high resolution using a variety of isolation and protein techniques and modern image analysis (22).
Photosynthetic reaction center and other membranes	EM, XRCrys, NMR, electron diffraction	Crystals diffracting to ~3 Å resolution required the development of small amphiphilic molecules (23). Other techniques include NMR of ^{19}F-labeled bacteriorhodopsin fragments in a membrane-like milieu (24) and IR difference spectra to monitor structural changes in ^{15}N-labeled or deuterated bacteriorhodopsin (25). EM of purple membranes from bacteria are a natural 2-D crystalline array of lipids and bacteriorhodopsin. As the array is only one unit cell thick, it is not suitable for X-ray analysis, but yields electron diffraction patterns with spots to beyond 4 Å resolution. By tilting the sample, a series of patterns are obtained that can be converted to a 3-D model of the structure of bacteriorhodopsin in the membranes (26, 27). EM images the hexagonally packed regular protein monolayer from the cell wall of the bacterium *Deinococcus radiodurans* (28).
Virus assembly	CD, EM, XRCrys, SAXS, STM	CD showed the membrane-associated coat protein of bacteriophage M13 (5.2 kD) changed from an α-helical conformation when it was in a membrane environment (i.e., in solution with cholate or in the capsid) to a β-sheet form when aggregated (aggregation followed with PAGE) (29). NMR studies of detergent-solubilized M13 coat protein, in combination with the results of sedimentation equilibrium, Raman and CD studies, indicated two conformers that represent the nonequivalent monomers of an asymmetric dimer (30) STM was used to view bacteriophage T4 polyheads (31). Small-angle X-ray scattering was used to follow the rapid assembly of tobacco mosaic virus protein induced by a temperature jump. The minimum counting time was 7.5 seconds (32). Assembly of the icosahedral shells of the dsDNA bacteriophages, herpesviruses, and acid adenoviruses requires proteins not found in the mature virion, termed scaffolding proteins. The bacteriophage P22 precursor procapsid contains approximately 300 scaffolding molecules within a shell composed of 420 coat protein subunits (33). Cryo-EM has been used to characterize the scaffolding/assembly of herpes simplex virus particles (34).
Antibody–antigen interactions	XRCrys, NMR, SLLS, DLLS, STM	Crystal structures of antibodies or bacterially produced antibody fragments with peptide antigen (35) or proteins can diffract to <2.5Å (36) and can be used to identify the atomic features of the binding site. NMR studies of binding of an antibody fragment (Fab) to a peptide (37). As the on/off rate of the peptide is short compared to the spin-lattice relaxation time of the Fab and peptide protons, a NOESY spectrum in the presence of a vast excess of peptide has extra cross-peaks (transfer NOEs) that are due to magnetic exchange between the bound and free peptide fractions and are not present when the peptide and Fab are present in a 1:1 ratio (38). Dynamic light-scattering measurements of antibody–antibody complex aggregate formation indicated fractal dimensions rather than a defined geometric shape (39). STM ultrastructural images of unstained immunoglobulin G, air dried on the surface of highly oriented pyrolytic graphite (HOPG), required only 1 μl of a 0.5 mg/mL solution of protein in 50 mM of tris buffer (40).
Casein micelles	SANS, light scattering, EM	Neutron scattering from suspensions of casein micelles measurements were combined with EM data to characterize the structure as packed micelle monomer subunits (41).

Table 2. Model Systems for the Study of Protein Aggregation (*continued*)

Model system	Studied with	Examples and key results
Inclusion body formation	EM, SLLS	The traditional method to determine the presence of aggregation after differential centrifugation is gel electrophoresis (also coupled with immunoblotting or isoelectric focusing [42]). Inclusion bodies contain protein polymers (43,44) resistant to SDS and β-mercaptoethanol solubilization. Inclusion bodies (IBs) are seen as electron dense particles in EM thin sections of whole *E. coli* cells; the morphology of isolated IBs was studied by scanning and freeze-etch EM (45). IBs (at least the polymeric forms that will enter a PAG) appear to consist of only one protein, not nonspecific coaggregates with other proteins (15). More recent data using computer simulations and light scattering suggest a cluster–cluster mechanism rather than a stepwise monomer addition polymerization (16).
β-amyloid fibril formation	CD, static and dynamic light scattering	β-amyloid peptide (A-β) is the primary protein component of senile plaques in Alzheimer's disease patients. Assembly of synthetic A-β into amyloid fibrils in phosphate-buffered saline was followed by static and dynamic light scattering. CD was used to show A-β's structure varied when dissolved in organic solvents commonly used in neurotoxicity assays. In pure DMSO, A-β had no detectable β-sheet content; in 0.1% trifluoroacetate, the peptide contained one third β-sheet; and in 35% acetonitrile/0.1% trifluoroacetate, A-β was two-thirds β-sheet, equivalent to the fibrillar peptide in physiological buffer (46).
Bacterial flagella assembly, microtubules	EM and cryo-EM	EM demonstrated in vitro reconstruction of organelles such as *Salmonella* flagellar filaments (phosphotungstic acid stained preparations) (47) and microtubules (frozen hydrated or glutaraldehyde/tannic acid fixed and stained) (48).
Lipoxygenase substrate binding	EMR, X-ray absorption spectroscopy, infrared CD magnetic CD	Spectroscopic studies, including electron magnetic resonance, X-ray absorption spectroscopy, infrared circular dichroism, and magnetic circular dichroism, have been applied to compare lipoxygenases from varied sources and with different substrate positional specificity. Soybean lipoxygenase-1 contains a novel three-turn π-helix near the iron center (49).
Nucleotide binding	NMR	The conformation of MgATP bound at the active site of *Salmonella typhimurium* 5-phospho-α-D-ribose 1-diphosphate synthetase (PRibPP synthetase) (50) and conformations of the adenosine moiety of MgADP and MgATP bound to rabbit muscle creatine kinase (51) have been investigated by 2-D transferred-NOE spectroscopy (TRNOESY).
Fibrinolase/Zn binding	NMR and CD	The Zn binding enzyme fibrolase (pI is 6.7) shows a minimum in its solubility profile (which can be followed with CD or NMR spectroscopy as a structural change) below pH 5. Zn loss, induced by rising temperature or lowered pH or adding chelators (EDTA, DTT), leads to a rapid loss of α-helical structure, exposure of hydrophobic residues, and aggregation (52).
Calmodulin/Ca	XRCrys, SANS	Small angle X-ray and neutron scattering of calmodulin in complex with two peptides (53).
		Specific protein interactions
Profilin/actin	XRCrys	Crystals of profilin/actin diffracting to 1.8-Å resolution required ATP hydrolysis to form and a 3.2 M ammonium sulfate/ATP bathing solution for stability (54).
RecA protein/DNA	EM, SANS, STM	RecA protein complexes with itself and with DNA were characterized under various conditions by combining EM and small-angle neutron scattering (55) STM images to a resolution of a few nM has been obtained for coated specimens of RecA bound to DNA (56).
Other protein DNA complexes	EM, STM	A combination of electron microscopy, image analysis, 3-D reconstruction (57) and STM has been used to show that the active form of the DnaB protein, the primary replicative helicase in *E. coli*, is a hexamer. Depending on the presence of different nucleotide cofactors (ATP, ATP γ-S, AMP-PNP or ADP), two different hexameric forms of the DnaB ring were found, one with a three-fold symmetry and one with six-fold symmetry. EM and image analysis was used to establish the relative orientation *E. coli* RuvA and RuvB bound to model Holliday structures (58,59).
Clotting factors with inhibitors	XRCrys	Crystals structures of the complex of thermitase (279 amino acids) with the inhibitor Eglin C (70 amino acids), resolved to <2 Å resolution (60) and human α-thrombin with its inhibitor hirudin to 2.3 Å resolution (61).
Cyclosporin/cyclophilin	XRCrys, NMR	NMR of the binding of cyclophilin to cyclosporin indicate that cyclosporin A and FK506 (but not rapamycin) undergo drastic conformational changes when bound to their respective binding proteins (62).

Table 2. Model Systems for the Study of Protein Aggregation (*continued*)

Model system	Studied with	Examples and key results
α-Crystallins	EM, SLLS, DLLS	Dynamic light scattering data (determine particle molecular weight as a function of time) combined with EM to determine shape of aggregates of bovine α-crystallin. Static light-scattering data indicated that the sample preparation methods used for (negative staining) EM had induced some particle breakdown (63).
Making lac repressor tetramer into a dimer or monomer; mechanism of isopropyl 1 thio-β-D-galactoside (IPTG) binding	SAXS, SANS, XRCrys, SDM, equilibrium sedimentation, fluorescence emission quenching	Tetrameric (4×360 amino acid) wild-type lac repressor was modeled based on scatter data (size and shape of tetramer) initially until a crystal structure was available. Targeted SDM-generated monomers formed preferentially dimers or did not associate, while retaining DNA binding function. A point mutation (Y282D) was sufficient to disrupt tetramer formation and generate monomeric protein (64). IPTG (inducer) binding reduced the fluorescence emission intensity of the repressor in solution. Low concentrations of IPTG reduced the fluorescence quenching effect of KI on the emission intensity (65).
Making a dimer from monomeric staphylococcal nuclease	XRCrys, sedimentation equilibrium	A serendipitous mutant of staphylococcal nuclease (6 amino acids in a surface loop, Δ114–119) forms a stable dimer ($Kd < 10^{-8}$ M). The carboxyterminal helices of each monomer swap places in the dimer (66).
		In vitro aggregation
	Light scattering, laser light transmission fluctuation	For monoclonal antibody aggregation in the presence of antigen, the estimates of the radius of gyration in solution, as measured by both classical and dynamic light scattering, agreed very well with those estimated from electron micrographs of the same aggregates (67). The aggregation of low-density lipoprotein (LDL) induced by acetylation, carbamylation, maleylation, or oxidation was evaluated by laser light transmission fluctuation. Aggregated LDL, but not unmodified monomer, stimulates the uptake of cholesteryl ester in arteriosclerotic cells (68).
Protein denaturation	CD, FTIR, IR-ATR, RS, SLLS, NMR	Raman spectroscopy has been used extensively to study the quaternary interactions of hemoglobin and to compare the secondary structures of proteins under various conditions (69,70). For example, 10–20% solutions of α-chymotrypsin and chymotrypsinogen were used for a Raman spectroscopic analysis of secondary changes induced by pH and pressure (71). A relationship between the salt type and concentration used for precipitation of α-chymotrypsin and the disordering of the secondary structure was determined from Raman spectroscopy (72). When the method was extended to another 11 proteins, the general result was that the precipitated protein contained on the average a higher percentage of β-sheet structure as determined by the amide I band intensity and location; the effect was more pronounced when the chaotrophic salt KSCN was used compared to the structure stabilizing salt, Na_2SO_4 (73).
Salt precipitation of protein	RS, SANS, fluorescence scatter peak, SLLS, DLLS	SANS in combination with ultracentrifugation has been used to determine the particle weight of malate dehydrogenase from a halophilic bacteria in different salt solutions. In 1–2 M NaCl solution, the protein is a stable dimer and binds much more water and NaCl than in low salt solution, where the salt-loving protein unfolds (74). Stopped-flow turbidimetry has been used to derive a kinetic model for the precipitation of α-chymotrypsin by different salts (75).
Crystallization pathways	Fluorescent light scattering, EM, SLLS, DLLS	Quasielastic light scattering study of the effect of salts on lysozyme and concanavalin A showed precipitating salts decrease translational diffusion coefficient, whereas those furthering crystallization do not change it and solutions remain monodisperse with increasing salt (76). Light scattering studies of solutions of canavalin at a fixed salt concentration (where the protein was known to form rhombohedral crystals) (77). Stereo-electron microscopy of frozen specimens used to characterize crystallization methods for lysozyme and tomato bushy stunt virus particles (330 Å). Crystallization intermediates had a more compact structure than aggregates that lead to amorphous precipitates (78). A symmetric dimer of a polypeptide in an organic solvent suggested as a model for the effects of crystal packing and solution dynamics on structure determination by X-ray crystallography and solution NMR methods (79).

Table 2. Model Systems for the Study of Protein Aggregation (*continued*)

Model system	Studied with	Examples and key results
Complexes with phospholipids and surfactants	Solid state NMR, NMR, ATR/IR, ESR	The complete structure determination of a polypeptide in a lipid bilayer derived from solid-state NMR observations (80). IR has also been used to study the binding of CO_2 to carbonic anhydrase and mutants thereof (81), and combinations of ^{31}P-NMR and ATR-IR have been used to study pulmonary surfactants (82,83). The interaction of phospholipid with (*R*)-3-hydroxybutyrate dehydrogenase, a phosphatidylcholine-requiring membrane enzyme, has been studied using ESR spectroscopy of spin-labeled lipids, both as ordered multibilayers and in lipid vesicle suspensions (liposomes) (84).

Note: The systems described in this chapter are amenable to characterization by several methods. See the section under the appropriate method for details and references. CD = circular dichroism; EM = electron microscopy; FTIR = Fourier-transformed infrared spectroscopy; IR-ATR = infrared attenuated total reflection spectroscopy; RS = Raman spectroscopy; SE = sedimentation equilibrium; SANS = small-angle neutron scattering; SAXS, small-angle X-ray scattering; SLLS/DLLS = static or dynamic laser light scattering; STM = scanning tunneling microscopy; XRCrys = X-ray crystallography.

tected by their ability to protect the native state of the protein against the stress of emulsification in organic solvent and re-extraction into buffer. Recovery of native protein was determined by native size exclusion HPLC followed by circular dichroism (CD), both rapid techniques that require relatively little protein (90).

Determining the Surface Charge and Hydrophobicity of a Protein

Again, practicality dictates the use of chromatographic methods to determine the approximate surface charge and hydrophobicity of a protein in solution. Because aggregation of integral membrane proteins after transfer to an aqueous environment is a well-described phenomenon (91), there is a tendency to regard precipitation in aqueous solvents as an indication that a protein is hydrophobic. In reality, all proteins are to some extent hydrophobic, with tightly packed cores that exclude water (92,93), and even proteins with many polar residues at their surfaces, such as interferon-γ and RNase A, will aggregate at high concentrations.

As with stability, the surface charge of a protein is not easily defined. An isoelectric point (pI) measured by isoelectric focusing or chromatofocusing indicates the pH at which the protein has no net charge at very low salt concentrations (high ionic strength prevents proper electrophoresis and interferes with the establishment of the ampholyte-pH gradient). These methods cannot be used for proteins (e.g., T7RP) that precipitate in low salt buffers. Further, the effective pI of a protein is greatly affected by buffer conditions. Due to the binding of salt, one cannot assume that a protein in solution will be negatively charged at a pH above its pI in a solution containing salts or metal ions (e.g., acidic caseins bind Ca^{2+} and appear positively charged at pH 7 (16). Oligomerization can alter the apparent isoelectric point of a protein by more than a pH unit, as has been shown for insulin (94).

At pH 7.5 and 50 mM salt, most proteins will bind to DEAE-coupled (positively charged) resins if they are negatively charged and to phosphate and other negatively charged resins if they are positively charged. The degree of surface charge can be estimated from the salt concentration required for elution from DEAE or CM-conjugated resin columns; this can also give indirect evidence about the degree of surface exposure of altered residues. For example, when positively charged residues (Arg10 or Lys7) were changed to uncharged glutamine by site-directed mutagenesis from the N-terminus of RNase A, the mutants eluted at lower salt from CM-Sepaharose at pH 8 than did the wild type; the double mutant did not bind to the column at this pH (95). Similarly, C-terminal deletions of human interferon-γ eluted at progressively lower salt concentrations from CM-Sephadex as more positively charged residues (Lys [K] and Arg [R]) were deleted (Table 3).

Later in the purification, after the solubility of the protein has been better defined, chromatofocusing in an appropriately stabilizing buffer can be used to more accurately estimate the protein's pI. Once one has enough purified protein, the pI can be determined by measuring the amount of KOH necessary to increase the pH of a solution of protein in buffer from 2.5 to 11 compared to that needed to titrate the buffer alone. Gel methods for following the changes in surface charge during protein folding and aggregation have also been developed (42).

Similarly, binding to resins coupled with hydrophobic groups, such as Phenyl- or Octyl-Sepharose® (Pharmacia) indicates the presence of hydrophobic residues at the protein surface. Proteins are applied in high salt (0.7 to 1 M ammonium sulfate), which increases hydrophobic interactions, and then eluted with a decreasing salt gradient. Most proteins elute between 0.5 and 0.1 M salt; very hydrophobic proteins will not elute into low salt buffer unless the polarity is decreased by adding ethylene glycol. If a protein does not bind to Phenylsepharose, it either has a very hydrophilic surface (e.g., RNase A) or is aggregated.

One can determine the hydrophobicity of a purified protein or follow changes in exposure of hydrophobic groups during folding by measuring interaction with a hydrophobic dye or radioactive tracer [e.g., 1-anilino-8-napthalenesulfonate (98), or ^{125}I-TID, 3-(trifluoromethyl)-3-(*m*-^{125}iodophenyl)diazirine (99)].

Empirical Models for Salting-in and Precipitation with Various Agents

Empirical Models to Account for Salt/pH Effects. Generally, charged proteins can be salted-in by counterions. This

Table 3. Proteolytically Cleaved Human IFN-γ Elutes from CM-Sephadex at Progressively Lower Salt Concentrations Depending on the Number of Positively Charged Residues Removed from the C-Terminal

Human IFN-γ	C-Terminal	[NACl] eluted
Full length	– PAAKTGKRKRSQMLFRGRRASQ	300–500 mM
IFN-$\gamma\Delta$12	– PAAKTGKRKR	200–300 mM
IFN-$\gamma\Delta$14	– PAAKTGKR	80–100 mM

Note: After overnight cleavage at room temperature with one unit of either the protease Factor Xa (Biolabs) (for the Δ12 protein) or Endopeptidase Arg-C (Sigma) for the Δ14 protein, samples were diluted fivefold with 10 mM $NaHPO_4$ buffer, pH 5.7, and applied to small columns of CM-Sephadex C25 (Pharmacia) (96,97). The indicated eluates were then concentrated by centrifuging in Centricon-3 microconcentrators (Amicon). After automated Edman degradation, which indicated that the N-terminus of the proteins was unaltered, the number of amino acids deleted was determined by electrospray ionization mass spectroscopy.

is caused by the ion binding to the protein and neutralizing the net charge at its surface (see Table 4 for dielectric constants of common ions). The solubility of lysozyme, a positively charged protein, was shown to vary more with the nature of the anion added than the cation; the anion dependence followed the Hofmeister series (100). On the other hand, the solubility of caseins with pI between pH 3 and 5 varies with the nature of the cation: sodium, potassium, and ammonium caseinates are soluble; calcium caseinates form micelles (101). Casein solubility varies inversely with the atomic radius of the divalent cations added; Zn^{2+} and Cu^{2+} are more effective precipitants than Co^{2+} (102).

The interaction of salts as a function of pH with very soluble proteins can be accounted for mathematically, on a case-by-case basis. Detailed studies have been reported for a few proteins, including porcine pancreatic amylase (103) and ovalbumin (104). The latter study found that at 30 °C, the solubility of ovalbumin (C_o) in ammonium sulfate solutions of varying concentration C_A could be described by the simple quadratic equation:

$$\log_{10}(C_o) = 5.06 - 0.006t\text{-}0.205\ C_A + 0.5(\text{pH-}4.58) + 1.1(\text{pH-}4.58)^2$$

where concentrations of both ovalbumin and ammonium sulfate are expressed in g/100g H_2O, and 4.58 is the isoelectric point of ovalbumin. The data agreed quite well with earlier measurements made at 18 °C if the temperature correction was added.

Precipitation with Polyethylene Glycol and Other High MW Polymers. Precipitation as a means of purifying or storing a protein in a dry state must be done in such a way that after removal of the precipitant, a soluble and active product is obtained. Organic solvents that perturb the aqueous shell around the protein (ethanol, acetone, and even trichloroacetic acid [105]) are used industrially for large-scale protein precipitation, where maintaining a low temperature during the procedure is usually required, but the most useful general precipitants are those that do not denature the protein, such as polyethylene glycol (PEG). Models for precipitation with such compounds are usually based on excluded volume, meaning that the protein is forced into a progressively smaller area as the polymer occupies more of the solvent until the critical solubility limit of the protein is reached.

One recent study analyzed precipitation of common proteins (bovine serum albumin, human serum albumin, and ovalbumin) with various weights of PEG, and assumed:

1. the protein is globular and has homogenous surface properties
2. the precipitating polymer is linear, nonionic, and homogenous

With regard to the first assumption, the model is only useful for charged proteins if the ionic strength of the solvent is adjusted to minimize electrostatic protein–protein interactions (106). To predict the phase diagram, the Gibbs free energies (evaluated using a second-order perturbation

Table 4. Electronegativity Values for Protein Atoms and Common Ions Associated with Proteins

Electronegativity of protein atom constituents		Ionic character of bond and (percent ionic)		Electronegativity of ions	
H	2.1	C-H, S-H	0.4 (4%)	Li	1.0
C	2.5	C-O	1.0 (22%)	Na	0.9
N	3.0	N-C	0.5 (7%)	K, Rb	0.8
O	3.5	OH	1.4 (39%)	Ca	1.0
S	2.5	NH	0.9 (19%)	Cu	1.9
P	2.1	P-O	1.4 (39%)	Zn	1.6
				Fe	1.8
				Cl	3.0
				F	4.0

theory around a hard sphere as the reference) of protein in the solid and liquid phases were equated. Protein solubility was lowest (concentration of protein in the solid phase increased) for higher polymer concentrations, larger protein sizes, higher molecular weight of polymer, weaker protein–polymer interactions, poorer solvent, higher ionic strengths, and pH values close to the isoelectric point (107).

Because precipitation models are typically based on data for large, quite soluble proteins with the polymer used for precipitation of the same size and at about the same density as the protein being precipitated, it is difficult to apply the results directly to most laboratory-scale processes. Here, typically, the polymer greatly outweighs the protein in solution, and the intrinsic solubility of the protein is much less than the standard proteins.

Models for Determining the Effect of Co-solvents on Protein Folding

Accounting for the interaction between parts of the protein and the surrounding solvent is one of the most rapidly developing areas in protein folding. There are several theories to explain the effects of denaturants and osmolytes on protein solubility. The eventual outcome of this work is to understand how a protein folds, with an eye to predicting tertiary from primary structure. Determining the effects of osmolytes and denaturants on protein stability in solution should enable us to predict a priori what cosolutes are best suited to a protein of a given composition.

Osmolytes have strikingly different effects on different proteins. One cannot simply add any osmolyte to a protein solution and assume it will increase solubility; indeed, addition of carbohydrates or other osmolyte to a concentrated protein solution will often induce precipitation. The osmolytic amino acids betaine and proline, which protect *Escherichia coli* against urea and salt stress (108), can destabilize DNA helices (109). Adding side chains to betaine generated forms that are protective against high salt but not urea and vice versa (108). Curiously, although osmolytes have the general property of increasing the net solubility of proteins in solution, that is, one can achieve a higher concentration of the protein before aggregation occurs, none of the individual amino acids are more soluble in the osmolytic solutions for which there are data (0.5 M sucrose [110]; 1 M trimethyl amine *N*-oxide [TMAO] [111]). There is also no really significant increase, regardless of side chain, in amino acid solubility in the presence of 2 M urea, although a cyclic glycine dipeptide designed to mimic the backbone unit is about 20% more soluble (111).

The Thermodynamic Approach. The thermodynamic approach is based on the relative ability of molecules to stabilize the native state or the denatured state, thus accounting for their effects in a thermodynamic framework. As one cannot explain the specificity of osmolytes by difference in solubilities of the amino acid side chains, the preferential hydration theory suggests that osmolytes are repelled from the surface of the protein, whereas denaturants bind. The basic theory resembles the excluded volume theory of protein precipitation and deals with the protein as a hydrated ion. The binding of water molecules to the surface of the protein serves to shield charges and protect the protein from interaction with other proteins. According to the model, the concentration of the cosolvent in the immediate vicinity of the protein is either less than (for osmolytes) or greater than (for denaturants) that in the bulk solution. Thus, the water shell around a protein in osmolytic solution will be relatively richer in water molecules than the bulk solution. The theory assumes first that such a concentration gradient surrounding the protein exists and that this can serve as a driving force for stabilization.

The concentration of cosolvent near the protein surface is not easily measured. Experimental results to demonstrate that this is different from that in the bulk solution are based on measurements of the partial molar volume of the protein in various solutions or more recently, infrared spectroscopy to measure O-H stretching rates in the vicinity of the protein (112). Barrier effects caused by the presence of high concentrations of cosolvents in the binding of CO to myoglobin have been analyzed by frequency resolved calorimetry (113). To develop more general ways to account for the effects of solvent at the protein surface, computer models have been developed. Explicit modeling of solvent, by inserting the protein into a shell of solvent of varying thickness, is computationally inefficient. Drastic perturbations have to be imposed in the unfolding simulation, such as high temperature or pressure or by applying special algorithmic means to unfold a protein (114–116), which are likely to induce pathways not found in nature. Alternatively, one can implicitly model solvent molecules, in an approach based on the continuum approximation and the calculation of the solvent accessible surface area (SASA).

This approach was experimentally validated by a recent statistical data analysis that showed that for 45 proteins, the measured free energy and heat capacity of unfolding correlates directly with the change in SASA during the process (117). A recent method was introduced to efficiently calculate the SASA (118). By changing the protein–solvent interaction via the SASA and extrapolating to zero cosolvent concentration, a folding pathway that should have more physiological meaning can be induced and monitored.

In this case, the protein–solvent interaction term E_{hyd} is computed in the continuum approximation by

$$E_{\mathrm{hyd}} = \sum_{i=1,\mathrm{atoms}} \sigma_i A_i$$

where A_i is the SASA of atom i and σ_i is a solvation-parameter (119–121) depending on the atom type and solvent composition. A variety of data are available for the determination of σ_i values for individual protein atoms. Several such atomic solvation parameter (ASP; σ_i) sets have been derived (119,120,122–126) based on deriving a transfer free energy (ΔG_{tr}) for moving organic molecules (usually amino acids or their analogues) from one medium to another. Determination of the ΔG_{tr} can be calculated from the relative solubility of the groups in the two media. In the latter case, solubilities in the two solutions (C_w and C_s for maximal solubility in water or alternative solvent, respec-

tively) yield ΔG_{tr}, by assuming that the ratio of the activity coefficients is ~1, according to the equation (127):

$$\Delta G_{tr} = RT \ln \frac{C_w}{C_s}$$

These ΔG_{tr} values can be directly related to the accessible surface area of each amino acid (A_i) by the equation: $\Delta G_{tr} = \Delta\sigma_i A_i$, and it is assumed for parameter extraction that the ΔG_{tr} of a residue R is the sum of the free energies of each atom:

$$\Delta G_{tr}^{R} = \sum_{\text{atoms}j} \Delta\sigma_j A_j$$

Eisenberg and McLachlan (119), in one of the earliest systematic studies, used data from Fauchère and Pliska on the energy of transfer of amino acid side chains from *n*-octanol to water (128) to derive a set of five ASP values ($\Delta\sigma$(C), $\Delta\sigma$(N/O), $\Delta\sigma$(O−), $\Delta\sigma$(N+), $\Delta\sigma$(S)). Their calculated ΔG_{tr} for the side chains using this set was linearly related to the observed values, and others have shown that the parameter sets, with slight modification, can drive disturbed structures back to their native state (118,129–131). Although one can also expand the parameter list by distinguishing aliphatic, methylene or carbonyl-C, and backbone or guanidyl nitrogen atoms, too many parameters may be detrimental in determining accurately the effect of the interaction. Other data well suited to the derivation of ASPs are those for the transfer potential of side chain analogues to a vapor phase (132) or based on measurement of the hydration enthalpy of *N*-acetyl amino acid amides (133), or the isoentropic pressure coefficients of tripeptides (134). Data are also available to derive ASP sets for solvents containing denaturants (135) or osmolytes (110).

There are data available for the solubility of protein components in ethanol, octane, and other solvents that could be used to derive ASPs for calculation purposes and direct data for purifying proteins with aqueous ethanol extraction, or following the unfolding of proteins or peptides in various solvent conditions (136,137). As the ability of water-miscible organic solvents to solubilize naphthalene is logarithmically related to the concentration at which they denature well-known proteins (trypsin, cytochrome *c*, chymotrypsinogen, chymotrypsin, laccase, and myoglobin) (138), ASP sets derived for one solvent may be related to other solvents according to simple correlation constants.

In support of using such ASPs, the hydrations seen around atom types in protein crystals (Table 5) show specific chemical interactions of the individual atoms with water that are unaffected by the crystal lattice. Neutral and negatively charged oxygen atoms are the most hydrophilic, followed by positively charged nitrogen atoms, neutral nitrogens, carbons, and sulfurs ($O^- \sim O > N + > N \gg C \sim S$, where ~ means approximately the same).

Interactions between protein and bound water are fundamentally similar to those between protein and bulk fluid water, measured in partition experiments (139). The linear correlation coefficient of the data from Table 5 with side-chain free energy of transfer between cyclohexane and water (132,140) was $r = -0.95$ and with residue retention on reversed-phase HPLC using a pH 7.5 average scaler $= -0.93$ and $r = -0.86$ for the data of Fauchère (128).

The Kinetic Approach. A kinetic-based accounting for the effects of cosolvents on aggregation is based on their alteration of bulk solution properties, primarily the viscosity, macroscopic dielectric constant, and the chemical potential, which affect also the unfolding of the protein and its thermodynamic equilibrium energy. These changes can also have pronounced effects on the kinetics of unfolding, refolding, and transitions between substrates, which must be dealt with to account for the effects of osmolytes on aggregation and solubility. Aggregation, the major barrier to obtaining clear thermodynamic data, accelerates with increasing protein concentration. This strongly suggests that protein precipitation is directly related to the rate of protein–protein interaction. Kinetically, the role of osmolytes in maintaining proteins in equilibrium solution can be described by equations initially based on Newton's law of viscosity and Archimedes' principle. A protein in solution is in buoyant equilibrium with the water structure and viscosity-based forces accelerating its precipitation. To remain in aqueous solution, the protein must inhabit a cavity in the solvent structure somewhat larger than its surface area. The energy to create such a cavity has been estimated, based on the surface tension of water being 72 dyn/cm, to be 104 cal/Å/mol (141). This energy must be offset by the energy of binding of water molecules to the charged groups on the protein molecule. This may explain why more highly charged proteins, such as RNase A, are quite stable in solution in the presence of moderate amounts of salt, in contrast to proteins with large hydrophobic surface areas. A compact globular shape has the lowest surface area; unfolding the protein increases its surface area (and area for interaction with other molecules) and alters its specific density. For example, for a protein in a temperature gradient, the change in velocity of the molecule can be summarized as a function of the (temperature-dependent) viscous forces [$\nabla \cdot \tau$] and buoyant forces [$\rho\beta g\Delta T$]:

$$\rho \frac{Dv}{Dt} = -[\nabla \cdot \tau] - \rho\beta g(T - T)$$

where ρ is the specific density (mass/unit volume), g is the gravitational constant, and β is the coefficient of volume expansion.

The second term in kinetic effects in protein unfolding states simply that the viscosity of the solution will affect the time required for folding, an effect summarized (142) as:

$$\bar{t}(n) = t_0 e^{(\Delta E(n)/k_b T)^2}$$

where $t(n)$ is the lifetime of a typical microstate, and t_0 is the time scale for a typical motion of a large segment of the chain, which is a factor of the local barriers and the solvent viscosity. For the case of viscosity (friction) effects on geminate binding reactions, please see Ansari et al. (143) for a restatement of Kramer's law in order to apply it to proteins.

In addition, one must account for changes in the dielectric constant of the medium and for the polarizability (α) of the protein and its cosolvents on the interaction energy between protein particles as a function of distance (R). Classic thermodynamics says that this energy, for an oscillating system with no limits on the sphere of motion, should be:

$$\Delta E(R)_{\text{dis}} = -3hv/4(\alpha^2/R^6)$$

where the oscillator energy hv can be equated with the ionization potential (IP). Thus, the energy of interaction decreases as the distance between particles decreases to the sixth power and the polarizability increases. As the distance between particles decreases directly with the concentration of the protein, small increases in concentration will greatly accelerate the aggregation rate.

With respect to the ionization potential, the constituent atoms of proteins, with the exception of hydrogen, have very similar electronegativity values (Table 4), and most of the bonds within a protein are basically covalent. Note that hydration is seen in crystal structures at precisely the atoms in proteins where the ionic character of the bonds is most pronounced (Table 4). Obviously, substituting a hydrogen atom for any of the alkali metals will increase the local dipole moment within the protein. The polarizing effect of substituting a larger ion is intermediate. These considerations may be used as the basis for analysis of salt interactions with proteins, if the surface charge is known. Although such models will still require experimentation, they may be used as an optimization framework that may reduce the data needed.

COMPUTER DESIGN OF MORE SOLUBLE PROTEINS

Combinations of the methods discussed in the first section have been used to generate mutants of insulin with altered oligomerization and solubility and to change the lac repressor from a tetramer to a dimer or monomer, to name but a few examples (see Table 2). Residues involved in aggregation were identified with the help of a detailed 3-D structure, generated by high-resolution methods, and site-directed mutagenesis was used to test which residues could be altered without affecting function or the global fold of the protein (144). All these studies required years of work. Fortunately, computational advances now allow us to have a reasonable view of the protein structure for many proteins based on their sequence homology to other proteins. This sort of modeling can be implemented to solve problems even during the initial isolation of a protein of known sequence. As discussed elsewhere (2), there are a few empirical rules for identifying areas of proteins that cause aggregation. The few good examples of controlling aggregation of proteins through alteration of primary structure started from high resolution X-ray crystallographic or NMR structures of protein complexes or oligomers. It is now possible to view the 3-D structure of proteins whose coordinates have been deposited in the protein data base (PDB) (for downloading from the Internet, see the notes to the Internet site "Pedro's Macromolecular Tools") on a regular Macintosh or PC terminal; stereo viewing software can also be had for a reasonable price. Good viewing systems such as the Silicon Graphics Indigo series or the Evans and Sutherland Molecular Graphics systems allow more detail and sophisticated, real-time rotation of the molecule. Even when the 3-D fold of the protein is known, it is still not easy to identify aggregation sites; one can, however, identify surface-exposed amino acid stretches that might be involved in aggregation or intermolecular contacts rapidly and test the effects of site-directed mutagenesis at these positions on solubility. New methods for mimicking protein folding by computer allow hope that we may soon be able to identify problem areas in the primary sequence. Two basic assumptions may greatly simplify calculations of the protein aggregation problem:

1. Protein folding proceeds first by folding into a series of domains, which then interact with each other specifically to form the final stable global structure.
2. During this process, certain domains may form inter- rather than intramolecular contacts. Once two molecules are so intertwined, their residual domains may be forced to associate with other molecules, leading rapidly to a mass of partially folded, interlocked protein monomers. This idea, based on the domain swapping hypothesis of Bennett et al. (145), is from structural analysis of oligomeric proteins, including *Diphtheria* toxin, staphylococcal nuclease, α-spectrin, and antisialidase, with swapped domains ranging from 14 to 252 amino acids.

The problem would then become identifying probable domains within the protein that are sufficiently separated during folding so as to allow another molecule to intercalate during the folding process. One can view surface groups on proteins, searching for areas of exposed hydrophobic surface, for example, that may be involved in aggregation. There are also specific programs that allow one to view the dynamics of interaction between molecules (DOCK, from Kuntz's group at UCSF, can be obtained over the Internet). DOCK is most suitable for viewing the interaction between small sections of the molecule and small

Table 5. Hydrations Seen in Crystal Structures

Protein atom group	Atom types included in group	Water ions/occurrence
Neutral O	Q, N, D, T, Y and all carbonyl O atoms	0.53
Negative O	D and E side chain O	0.51
Positive N	H, K, R side chain N except Arg Nε, which is fairly nerutral	0.44
Neutral N	W, N and Q side chain N and Arg Nε, plus all main chain N	0.35
Carbon/sulfur	All carbon and sulfur atoms	0.08

ligands. For example, the 3-D structure of neurotrophin (also called p75NGFR or LANR) was modeled by its homology to regions in the receptor of tumor necrosis factor. Hypothetical complexes of this neurotrophin model structure with nerve growth factor were then modeled with DOCK 3.5. Viewing of hundreds of predicted orientations with MIDAS revealed similarities between motifs in ligand-binding domains of the neurotrophin and tumor necrosis factor receptor and pinpointed differences that could account for specificity (146).

However, experimental structural data are not available for most proteins, and structures of complexes of proteins are even rarer. For a significant percentage of newly identified protein sequences, which have homology to a protein of known sequence homology, one can predict with some degree of confidence their overall topology and stretches of amino acids likely to be surface exposed. This does not mean that such models can replace experimental data. The protein-folding problem is mathematically described as a system with frustration, because the number of computing steps required to solve the problem increases faster than any power of the size of the system (147). This section covers some of the possibilities for using sequence data and molecular graphics tools to generate model 3-D structures. Some programs from the Internet are presented in addition to the self-correcting distance geometry (SECODG) approach to the modeling being developed in the computational biology group of the UTMB. Several different pathways, starting from an initial sequence alignment, can be used to obtain such constraints (Fig. 2).

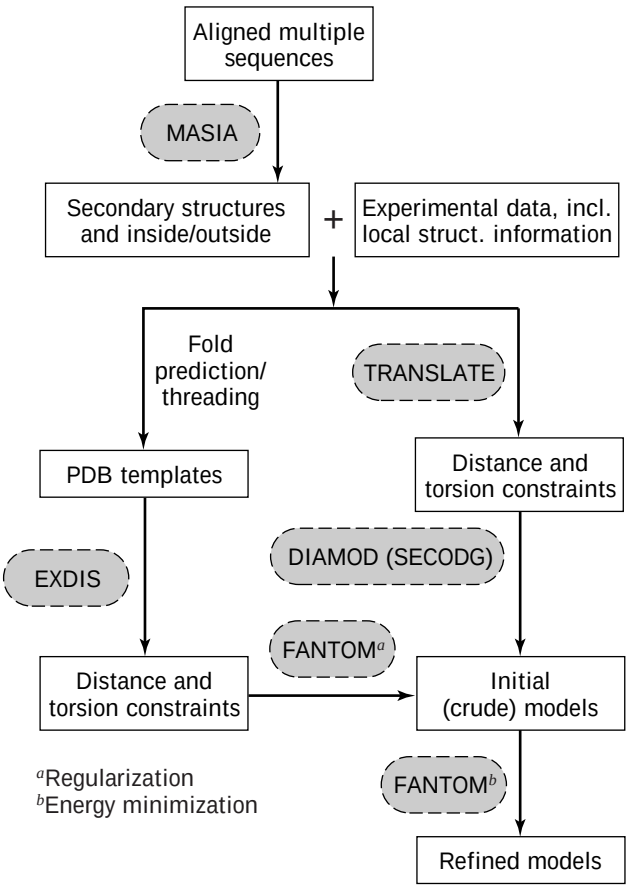

Figure 2. Flow chart describing protein modeling strategies depending on the degree of homology of the protein sequence to those of known structure. The *shaded boxes* enclose names of computational biology software that is being developed in the computational biology group at UTMB. The left and right sides of the flow chart represent procedures for generating models by independent routes. See text for details. *Source*: Figure kindly supplied by Dr. Kizhake Soman of UTMB, who retains copyright.

Automatic Homology Modeling

If a structure for a protein with significant (>30 to 40%) sequence identity exists, a 3-D-structure model can be obtained over the Internet. For example, we tested SWISSMODEL using a 62-amino-acid section that aligns with other homeobox proteins from the Pem protein (involved in control of hormone generation in the testes). The murine Pem homeodomain homologous area

RQMPLQGSRFAQHRLRELESILQRTNSFDVPREDL
DRLMDACVSRVQNWFKIRRAAARRNRR

sequence was cut out of a text file and pasted into the appropriate area of the form for submission to SWISSMODEL, a program on the Internet that is underwritten by Glaxo Research and constructed by Peitsche. An e-mail response with coordinates for a 3-D structure based on the structure of the Fujitaratsu homeodomain (PDB files 21FJL and 11 FJL) was returned quickly. Although for proteins with sufficiently high homology to one in the PDB the template selection is automatic, it is always a good idea to choose an appropriate model oneself by extensive homology (BLAST or equivalent) searches before requesting the modeling.

SWISSMODEL uses the PDB to obtain structural information and automatically generates a model for sequences that share significant similarities with at least one protein of known 3-D structure. Given an unknown sequence, SWISSMODEL uses a FastA and BLAST search to determine what protein in the PDB could be a possible structural homologue based on the degree of primary sequence similarity. A sequence with a FastA score 10 SD above the mean of the random scores and a Poisson unlikelihood probability P(N) of 10–5 will be considered. The program as of 1998 requires at least 35% residue identity with 40% of the target sequence (or overall 25% identity). The automatic alignment tool used within the program suite is SIM, but the user on a second level can choose to submit other alignments or structures for use in the modeling (148). Hyperlinks between SWISSMODEL and the 2-D gel electrophoresis data bank of SWISS-2DPAGE (see *http://expasy.hcuge.ch*) can be used to map *E. coli*, *Haemophilus influenzae*, *Mycoplasma genitalium*, *M. tuberculosis*, and *Bacillus subtilis* sequences on the basis of charge and size to proteins seen on the gel grid. A similar gel database is being accumulated for yeast and human proteins (149).

The ease, speed, and impressive level of prediction of SWISSMODEL is certainly a tribute to the Glaxo team. A significant amount can be learned from visualizing the structure using Midas software on a Silicon graphics ter-

minal, and residues involved in DNA binding, on the basis of the homologous protein used to develop the model, can be predicted. However, the program only works for proteins where a high degree of sequence homology exists to protein of known structure. By some estimates, only 10 to 15% of *E. coli* proteins have a suitable modeling template in the PDB using the above cutoff levels of residue identity; one would anticipate an even lower probability for an unknown mammalian sequence. For our example, when the whole PEM protein sequence, or even the 63-amino-acid sequence mentioned earlier that aligns with many other homeodomain proteins, was sent in the same fashion to SWISSMODEL and submitted without naming a target protein for modeling, the program was unable to generate even a model of the area that contained the homeobox. A second problem with using such simple models to design site-directed mutagenesis experiments is that although the program will be able to predict a global fold for the protein, local conformations that can account for specific properties are less easy to predict. For this reason, developing a working model (as of the date of this article) means using manually interactive programs that require more work on the part of the investigator.

Other methods are available from the Web and should also be investigated. For example, one can use the TOPITS program, which threads protein sequences onto model structures (150). Here, sequence residue identity is less important than the stability of the final structure. An example of using this program is shown in Figure 3.

Modeling Using Self-Correcting Distance Geometry with the Programs CLUSTAL, MASIA, NOAH, DIAMOD, and FANTOM to Develop a 3-D Model of a Protein

Figure 2 summarizes methods used by our group for structure prediction based on a unique algorithm based on self-correcting distance geometry (SECODG) from Dr. Werner Braun and coworkers. The SECODG-based program suite has the advantage that experimental results can be directly incorporated into the modeling process by manual insertion of distance constraints (DCs), limits on the distance between two atoms in a 3-D structure. Experimental DCs can be derived experimentally from NMR or crystal data or from other types of biophysical data, for example, from knowing where secondary structure elements lie, which two cysteine residues form a disulfide bond, or which residues lie within the active site (which means they must lie within a certain distance from each other). The method starts with BLAST searches and multiple sequence alignment to determine whether a structure exists for a protein with reasonable sequence homology. If a homologous structure is available, the PDB coordinates can be regularized and DCs extracted automatically by related software programs.

Step 1: Proteins with a significant identity pattern to the test protein are searched for in a protein sequence database (for example, SWISSPROT).

Step 2: CLUSTALW (downloaded from the Internet) is used to align the best-matched proteins in a block to identify areas of high homology with other proteins. These sequences are then used to search for known 3-D structures in the PDB, a composite of tertiary structure details.

Step 3: The program MASIA (formerly MULTAN [130]) analyzes the aligned sequences and identifies areas of probable secondary structure.

Step 4: The results from steps 2 and 3 are combined to generate a list of distance and dihedral angle constraints. These constraints can be combined with results from other biophysical methods, such as knowledge of where disulfide links and active site residues are in proteins.

Step 5: The SECODG-based package of NOAH/DIAMOD then uses these constraints to generate a family of structures that best fit these constraints. The NOAH program is a structure-based filter, which means in simple terms that it uses a rough 3-D structure to determine whether a list of distance constraints is internally consistent.

Step 6: The local structure is refined using the energy minimization program FANTOM, to determine structures with lowest energy.

For examples of how this method can be applied to real situations, see the discussion by Mumenthaler and Braun (130). Figure 4 is an example of the structure generated by this method, before energy minimization, for the rat and murine Pem homeodomains by the author and Hong Yao Zhu (Univ. of Texas Medical Branch).

Modeling Complexes

Modeling the interaction of several molecules is important for our understanding of aggregation. Extensive modeling studies for protein complexes has been done, for example, to analyze the allosteric mechanism of the tetrameric lac repressor. Here, years of site-directed mutagenesis studies were done before a crystal structure of the repressor was available for study (152). If crystal structures of the proteins involved are available, and there is some biophysical data about the binding site, one can make relatively exact models using graphics programs such as MIDAS.

Of course, a model must be validated experimentally and theoretically. Tests for structure validity can be based on a binary code where all residues are considered polar except for seven nonpolars (CILMFWV). The arrangement of hydrophobic and polar residues alone as evaluated by a scoring scheme (hydrophobic fitness score) (153) recognized the native fold out of 2,000 near-native structures generated for each of five small monomeric proteins. Other tests for structural validity based on identifying structures with minimum thermodynamic energy are being developed.

Protein Design

The field of protein design (designing proteins that fold in a certain manner) is proving to have nearly as much impact on our understanding of protein folding as the direct measurement of natural proteins. Proteins can be designed to have a specific overall structure with defined secondary elements and selected for solubility (154,155). There have been several recent protein design projects that have illus-

Figure 3. Output files from the TOPITS program (151) for template proteins when an alignment of HIV-Rev protein sequences was submitted as input. Listed are the best 16 hits of protein structures whose folds Rev is predicted to adopt. EALI = alignment score; LALI = length of the alignment (between rev and each of these proteins); IDEL = number of inserted residues; NDEL = number of insertion points; ZALI = alignment score based on which the list has been ranked; PIDE = % pairwise sequence identity; and PDB-ID = the 4-letter PDB code for each protein. For reliable predictions, ZALI > 3.0. Thus, the fold prediction only reflects remote homology with Rev. *Source*: Unpublished data used with the kind permission of Kizhake Soman and Werner Braun, Structural Biology, UTMB Galveston, who retain copyright.

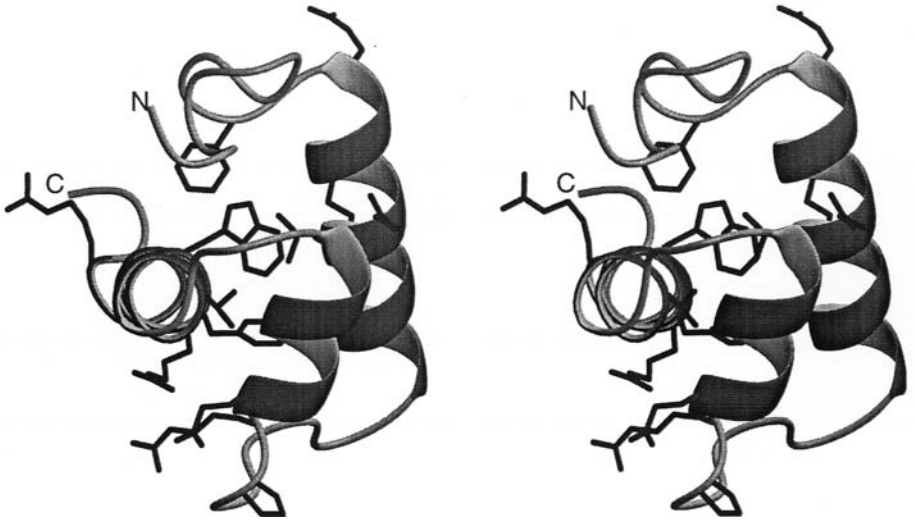

Figure 4. Stereo view of a model structure for the murine PEM homeodomain region, derived by homology modeling based on the 1TTF structure in the PDB using the DIAMOD program. The side chains shown are identical in both the modeled sequence and the template structure. *Source*: Unpublished data from the author and Dr. Hong Yao Zhu, who retain the copyright.

trated how well we can plan a primary sequence that will form a desired structure. Although the design of α-helical proteins is fairly advanced, β-sheet design is still hindered by solubility problems.

For this reason, the Paracelsus prize (small in cash value but honorable in the extreme) was claimed many years after it was offered to any group who could change the structure of a protein from helical to a sheet (or v.v.) without altering more than 50% of the residues. The winning protein was a composite of an area of protein G that formed a β-sheet, which was altered to a four-helix bundle by substituting residues at discrete positions from the ROP protein. Helix-forming residues were inserted, and residues known to favor sheet formation were removed (156). Despite the apparent difficulty humans have in changing the structure of a peptide from α-helical to β-sheet, such a mechanism has been proposed for natural puzzles. For example, aggregation of the proteins associated with scrapies is suggested to be a conversion from a largely helical conformation to a β-sheet-based structure in the aggregate (157,158).

Computational methods have also been introduced into the area of protein design. For example, a protein that contained no histidine, cysteine, or chelated metal ion was designed that exactly fit the X-ray crystal structure of the zinc finger protein. The structure of the synthesized model protein, which required no metal ion for maintenance, was determined by NMR to be identical to the original Zn finger region (159). With time, similar modeling algorithms will presumably allow the design of proteins that match in both structure and their functional abilities, for example, DNA binding (160,161).

CONCLUSION

The study of protein oligomerization with various methods is leading to a better understanding of the atomic basis for aggregation. Many different forms of biophysical data can be used to develop better models of the processes. Understanding how the interactions between solvents and the structure of proteins affects interprotein contact will help design better methods for controlling aggregation and processes dependent on resolubilizing proteins after precipitation.

ACKNOWLEDGMENTS

I wish to thank all my coworkers at UTMB, particularly Kizhake Soman, Hong Yao Zhu, Yuan Xu, Robert Frackiewicz, and Werner Braun, Wayne Bolen for sharing unpublished work and critical thoughts, and David Volk for critically reading the manuscript. The work related to Figures 2 to 4 was supported by grants DE-FG03-96ER62267 from the Department of Energy and #454940 from the John Sealy Memorial Endowment Fund. I also thank those who sent reprints during the preparation of this work and apologize in advance to any authors whose work, as a result of my oversight, is not adequately cited here.

High-density cultivation
Proteolysis
Secretion
Temperature effect

OUTLINE

INTRODUCTION

My first publications on techniques to avoid the formation of inclusion bodies in *Escherichia coli* (1,2) were met with many positive responses. Many others had experienced the problems summarized in the second column of Table 1 and were tired of dealing with "solutions of renatured proteins" that were in reality particulate microdispersions of inactive protein. They also shared my concern that proteins treated with strong denaturants were not the best starting point for biophysical studies, especially in cases where the specific activity had not been determined previously. Techniques such as protein NMR revealed structural heterogeneity in proteins purified from inclusion bodies (IBs), and few proteins purified from IBs have been useful therapeutically.

However, a recent review of the literature would indicate that renaturation from IBs, probably because it was the earliest-described method for producing large quantities of protein in *E. coli*, is still the predominant method. Generally, if isolation from IBs does not work, usually for the reasons in the second column of Table 1, the next step is to express the protein in yeast, insect cells, or transfected mammalian cells. Although expression in yeast is a fine alternative (see Refs. 3 and 4 for a summary of methods), both of the latter methods are significantly more expensive than bacterial cell culture. Insect cell cultivation is an excellent method for production of larger proteins, but stably transformed lines are given to variability, tests for expression are time-consuming, and the scale-up is more difficult than with bacteria or yeast.

Isolation from inclusion bodies is frequently used to purify proteins for characterizing the results of site-directed mutagenesis, precisely the area where accurate determination of specific activity and physical properties is most needed. University groups, who often appear to be racing with competitors to study the greatest number of mutants in the shortest time, frequently resort to IB purification schemes. Having little access to bioreactors and fermentors, they rely on shaker flask cultivation. The medium during growth in shaker flasks rapidly becomes anaerobic and acidic, meaning that the bacteria are struggling to grow and not able to produce optimal levels of product. Under these conditions, significant production requires completely subverting the bacterial metabolism into recombinant protein production, which usually means the use of induction methods such as temperature shock that favor IB production.

Obtaining an apparently pure protein in solution after renaturing from IBs is no guarantee of activity (5). For example, human tyrosine kinase Lck was completely inactive if expressed insolubly in *E. coli* and renatured from inclusion bodies. The protein was active, however, as measured by autophosphorylation, if solubly expressed by coproduction with either gro ESL or TRX (6).

Further, a mutant of a protein that renatures well from IBs may differ considerably from the wild type in solubility as well as specific activity. Ribonuclease A is probably the most common model for protein refolding experiments. However, a graduate student with experience in expressing RNase A mutants in *E. coli* and isolating them from IBs was unable to obtain any of a mutant that represented the ancestral protein of the hooved animals (the gene contains 16 amino acid changes chosen by evolutionary considerations). Undergraduate students in a lab course recloned the gene into an *E. coli* secretion system (7), expressed the mutant protein in a soluble form, and were able to determine its specific activity with respect to that of the modern protein (author's unpublished results).

As illustrated by the this example, expressing recombinant proteins solubly does not necessarily require great expertise. However, unlike expression in IBs, which can be done under relatively uncontrolled conditions, high-level expression of proteins in a soluble form requires control over many variables during growth and induction. These include temperature, medium pH, oxygenation, and concentrations of essential nutrients such as glucose (or glyc-

Table 1. Perceived Advantages and Actual Disadvantages of Expressing Recombinant Proteins as Inclusion Bodies in *Escherichia coli*

Advantages of IBs	Disadvantages
Many mutants can be tested because a single flask (or multiplate well) per mutant suffices for comparative studies.	Mutants of proteins can differ greatly in their specific activity and ability to refold.
High expression level means reduced fermentation costs.	Refolding shifts problems and costs downstream.
Production can be monitored with PAGE or immunoblotting.	Production cannot be monitored directly by activity.
Cytoplasmic proteins are washed away, simplifying purification. 95% purity can be quickly achieved.	The other 5% contaminants are hydrophobic, insoluble membrane proteins and cell wall fragments
Removal of cytoplasmic proteins early means less proteolysis.	Significant proteolysis accompanies refolding in dilute solution
The major contamininants are oligomers and misfolded or proteolyzed forms of the desired protein.	Separation of multiple forms of the same protein is the most difficult purification step.
The pL promotor induced by raising temperature often yields where other systems fail.	If the protein does not refold well, another expression system will still be needed.

erol) and toxic by-products of the bacteria, including acetate and carbon dioxide. Several industrial biotechnology groups have developed elegant solutions for all the problems encountered in soluble expression (8,9). Presumably because of stability problems with respect to both the host strain and plasmid, continuous culture methods are generally not used. The highest-yielding processes to date are based on fed-batch technology, which is also the standard for antibiotic production.

Most researchers wish to obtain their protein in a soluble form with a minimum amount of work. I thus begin by suggesting alterations in growth conditions that can be tested with most expression systems. The second section then discusses alternative host strains and plasmids that are better for directing soluble protein expression. The third section is devoted to discussing ways of altering the protein itself to avoid IB formation.

Today, bacterial culture and cloning techniques are used by many whose specialties are far removed from the area of microbiology. For this reason, the fourth section contains detailed suggestions for preparing and maintaining stock cultures and inocula, as well as a phage-free environment. One must stress the importance of good sterile technique, a topic that is never presented in other areas of the physical sciences. The last section includes tips on maintaining solubility during harvesting and the preliminary washing/lysis steps. Cosolvents for retaining solubility of proteins in solution are discussed elsewhere (10).

ALTERING GROWTH CONDITIONS TO INCREASE SOLUBLE PROTEIN EXPRESSION

Lowering Growth Temperature

For intracellular production, simply lowering the growth temperature (*T*) (1,11) can greatly increase the soluble fraction of protein. Table 2 lists many recombinant proteins from many different sources that are more soluble when expressed in *E. coli* at a lower growth temperature. The list includes several fusion proteins, for example, mouse DNA polymerase delta expressed as a glutathione-*S*-transferase conjugate (19). Although most of the examples in Table 2 used 25–30 °C for production, there is evidence that one can lower the temperature much further to increase the yield of soluble protein. The vaccinia virus large subunit of ribonucleotide reductase (vvR1, 87 kDa) was completely insoluble in *E. coli* when expressed at 37 °C, but mostly soluble if induced at 15 °C (29). The quantity of soluble and insoluble human androgen receptor (AR) fusion protein produced at different times following induction at 12, 22, and 37 °C indicated that while much more insoluble protein was expressed at higher temperature, soluble receptor expression was much higher at the lower temperatures. The amount of soluble protein did not correlate well with the ligand-binding capability of the receptor, indicating there was some bacterial factor needed for folding to a binding-competent state whose capacity was exhausted at higher expression levels (there is little evidence of proteolytic degradation of the cytosolic fraction from their gels) (15). Six different areas of the protein were converted to insoluble protein at the higher temperatures.

There is a lower limit of about 8–10 °C below which *E. coli* will not grow at all. In general, K12 strains grow very slowly below 23 °C; at 10 °C only a few dozen proteins are produced (42).

Point mutations may make a protein more or less prone to temperature-induced aggregation. For example, human triose phosphate isomerase is soluble at 37 °C during production in *E. coli*, as are two mutants, Met14Gln and Arg98Gln, which are partially and completely inactive, respectively. The (inactive) protein containing both mutations, however, was produced in a soluble form only at a growth temperature of 28 °C (43).

Although in some cases the production of soluble protein may appear to be the same at different growth temperatures (44), lowering the growth temperature has two additional great advantages. The first is that at lower temperature the O_2 solubility in the growth medium is much higher. Thus the cell density can be increased before the culture grows anaerobically. Anaerobic growth, and particularly the production of acetate, has been shown to limit cell growth and the production of protein (45).

The second advantage is that several plasmid expression systems have been shown to be more stable when bacteria are grown at lower temperatures. This may be due to the fact that the half-life of the antibiotics used to select plasmid-bearing bacteria during the cultivation also have a longer half-life at the lower temperature.

Table 2. A Few Proteins That Are More Soluble When Produced in *Escherichia coli* Grown at 30 °C or Less

Protein	Ref.
Animal / mammalian	
Bovine heart mitochondrial ubiquinol–cytochrome *c* reductase (fusion protein)	12
Chick brain β-tubulins, 33 kDa	
Chicken riboflavin carrier protein	13
Cystic fibrosis transmembrane conductance regulator (fused to glutathione-*S*-transferase)	14
Human androgen receptor (AR) fusion protein	15
Human initiation factor-4E	16
Human Interferon-α2	
Human Interferon-β	17
Human Interferon-γ	
Human transforming growth factor-β	18
Human triose phosphate isomerase double mutant (M14Q/R98Q)	
Mouse DNA polymerase delta	19
Murine cAMP-dependent protein kinase (catalytic subunit)	20
Murine Mx	
Rabbit muscle glycogen phosphorylase	21
Rat phosphatidylinositol transfer protein	22
Regulator of chromosome condensation (RCC1)	23
Xenopus Cu, Zn superoxide dismutase	24
Plant	
Radish 3-*OH*-3-methyl glutarylcoenzyme A reductase	25
Rice lipoxygenase L-2	26
Yeast α-glucosidase P1	27
Viral	
Herpes simplex thymidine kinase fusion protein	28
Vaccinia virus large subunit of ribonucleotide reductase (vvR1, 87-kDa)	29
Yeast / fungal	
Cephalosporin-C acylase from Pseudomonas N176	30
Isopenicillin-*N*-synthases	31
Bacterial	
Bacteroides fragilis metallo-β-lactamase (truncated protein)	32
Diphtheria toxin and fusion proteins thereof	33
Heparinase II and III from *Flavobacterium heparium*	34
Lycopene cyclase from *Erwinia uredovora*	35
P22 tailspike	36
Ricin A-chain	37
Salmonella typhimurium CheY mutant	38
Salmonella typhimurium tryptophan synthetase C-terminal deletions	39
Shigella flexneri invasion plasmid antigens his-fusion	40
T4 DNA polymerase	41

Note: Where no reference is cited, the data are from Ref. 11. Proteins are not listed that are produced in a soluble form at 30 °C but for which no comparative data is provided in the reference concerning solubility at a higher growth temperature.

Higher growth temperature can also inhibit processing. When chicken riboflavin carrier protein, a phosphoglycoprotein, was expressed in the T7 system, at 37 °C, two products were seen in whole cells lysates for protein with and without the pelB leader sequence encoded in the pET20b vector. Protein solubilized primarily from IBs did not contain the signal sequence, which was also absent in soluble protein expressed at 22 °C (13).

Possible Reasons for the Effect of Temperature. The reasons for the effect of lowering growth temperature are hard to pinpoint. The temperature effect is not simply due to slowing the production rate of the protein or to a decreased growth rate. The rate of synthesis of a particular protein does not necessarily increase with temperature. The protein Mx was sequestered into IBs at 37 °C, regardless of the absolute production rate (which was controlled by varying the distance between the Shine–Dalgarno sequence and the initial ATG in otherwise similar expression plasmids) (11). Further, decreasing the growth rate in other ways does not increase soluble expression; to the contrary, substrate limitations lower recombinant protein expression (9).

It is possible that compartmentalization of protein production is more efficient at the lower growth temperature. For example, RNase A was insoluble at 37 °C when produced cytoplasmically, but soluble at this temperature when directed to the periplasm/medium in a secretion system (7). In mammalian cells, proteins expressed in the nucleus were more susceptible to thermal denaturation in situ compared with those expressed in the cytoplasm (46).

Another possibility is the presence or lack of some proteins important for folding or aggregation at the different temperatures. Phosphorylation may occur at the higher temperature, thus altering the characteristics of the protein, as has been shown for Gro EL (8). Proteolysis increases at higher temperatures, as does the catabolism of amino acids involved in central metabolic pathways, such as serine (47). Studies of the expression of various heat shock proteins, which are induced by growth at higher temperatures, have indicated that their presence alone cannot mimic the effects on cell growth of increasing temperature. Indeed, as we will see in the section "Altering the Host Strain and Vector to Direct Soluble Expression", coexpression of some of these proteins can selectively increase the amounts of soluble recombinant protein. A possible explanation for the effect of primary sequence on IB formation is discussed in the section "Altering the Protein for Solubility."

Medium Composition

Use of a defined medium (i.e., one in which poorly defined nitrogen sources such as yeast extract or casein hydrolysate are not used) is preferable. Several defined media have been developed to allow high-density bacterial growth (48). Glycerol may be a better carbon source than glucose because less acetate is produced (45). In general, growth limitations should be avoided, with the exception of expression with negatively regulated induction systems, such as those based on the tryptophan promotor. Batch

feeding during induction has been shown to increase protein yield considerably. Mathematical models have also been developed to aid in increasing cell density (49).

Before eliminating casein hydrolysates from the growth medium, as one does for example in producing labeled proteins for NMR experiments, one should insure that their presence is not essential for controlling protease activity. Addition of protease inhibitors to the growth medium, in the form of an ill-defined extract of potato, was essential for production of interferon in *Bacillus subtilis* (50). Specific inhibitors of toxic enzymes may also be added to the growth medium. Yields of vvR1, for example, were improved by adding the ribonucleotide reductase inhibitor hydroxyurea (29).

Adding compatible cosolvents during the culture may also help maintain solubility, whereas in some cases their positive effect may actually be during harvesting (see section "Controlling Other Variables That Affect Solubility"). Increasing medium osmolarity by the addition of nonmetabolizable sugars may also increase protein solubility at higher temperatures: 0.4 M sucrose in the growth medium increased the production of soluble β-lactamase protein (51). There seem to be relatively few examples, however, where compatible cosolvents have been tried, perhaps because the levels of the compounds must be optimized and their use can greatly increase medium costs. The solubility of bovine heart mitochondrial ubiquinol–cytochrome *c* reductase, expressed as a fusion protein with glutathione, was improved by adding 2.5 mM betaine and 440 mM sorbitol to the growth medium. Presumably, the increased osmolarity of the growth medium forced the uptake of betaine and a corresponding increase of glycyl-betaine within the cells (12).

Good aeration, even beyond the O_2 uptake requirements of the culture, can increase production of proteins in *E. coli*. Rapid aeration reduces the concentration of CO_2 and acetate, both of which can be toxic. High acetate production has been implicated in reducing yields, especially in shaker flasks, even when the pH is controlled by using highly buffered media. Strains that produce less acetate have been created by metabolic pathway engineering; however, these may grow too slowly to be useful. Controlling the growth conditions of a prototrophic strain with few mutational markers so that it did not experience anerobiosis or stress has been shown to be a more useful way to reduce acetate production in large-scale, high-density culture (9).

Proteins induced under stress conditions may serve to control the production of acetate. The universal stress protein (USPA), a 13.2-kDa protein, is induced by a variety of stress conditions. This protein's role during stress may be to control the pathways of glycolysis, because mutants in the USPA gene secrete large amounts of acetate (52).

Other methods to increase the oxygen availability may be preferable to heavy aeration, which can lower the yields of secreted proteins by increasing the shear force (increased agitation) and denaturation at the air–liquid interface of bubbles. For example, surface aeration with supplemental O_2 was used to produce interferon-α in *Bacillus subtilis* because large activity losses were found when air or even plain nitrogen was bubbled through a solution of medium and the purified protein (53). The antifoam agent needed to control foaming at high volumetric airflow rates (VVM) can also seriously lower yields, especially for secreted proteins, and should be used sparingly.

Induction Conditions

The amount and time of inducer addition should be strictly controlled. Many have found it advantageous to induce at low cell density in shaker flask culture to insure that the cells are growing actively. However, in a bioreactor with efficient batch feeding and good aeration, much higher densities can be used. A higher cell density may be preferable with induction at very low temperatures, as for example when using a cold shock promotor, because the cells will grow quite slowly after that point. Most industrial processes use very high cell density; for example, production of the fusion protein of fibroblast growth factor–Saponin (a mitotoxin designed to treat cancer and restenosis) relied on fed-batch cultivation with a rich medium feed to reach A_{600} = 85 before inducing with isopropyl-D-thiogalactopyranoside (IPTG) at 30 °C (pET11a vector/BL21 [DE3] host). The yield of soluble mitotoxin, which could be isolated in good yield using heparin affinity chromatography, was 2.2 mg/L/A_{600} (54). The concentration of inducer may also be important; several authors have reported better yields of soluble protein if the IPTG inducer concentration was reduced from the usual 1 mM (22,23,55). Yields of vvR1, for example, were improved by inducing at a low cell density and using a low concentration (0.05 mM) of IPTG (29).

ALTERING THE HOST STRAIN AND VECTOR TO DIRECT SOLUBLE EXPRESSION

Choice of Host Strain

Expression versus Transformation. Correct host strain selection is also essential. Table 3 lists the markers carried by a few commonly used *E. coli* strains. Although some of their markers may determine how well a strain produces protein, several of them are potentially dangerous leftovers selected for the use for which the strain was originally designed. For example, *supE* is an amber suppressor that inserts a glutamine at UAG codons; it was added to strains of *E. coli* to allow the replication of early M13 vectors. These vectors were required to contain amber mutations that would control their propagation on accidental release, according to NIH guidelines that no longer apply (62). For this reason, older bacterial strains with fewer markers may be preferable for production purposes (9).

Careful cultivation and preservation of host strains is essential for optimal production. Because host strains for protein production often do not transform well, strains such as JM101 or HB101 are used for transformations after ligation or for vector propagation. Choose a host strain that is suitable for the problem at hand.

Low Protease Strains and Those with Better Redox Characteristics. Use of protease minus host strains (63) is often an advantage. *E. coli* BL21 (DE3), a protease-deficient strain, was used to express bacterial glutamyl tRNA re-

Note: See tables by Sambrook et al. (61) for more strains and an explanation of the abbreviations.

ductase. The synthesis of 5-aminolevulinic acid (ALA) and porphyrins, which were secreted into the medium, could be used to follow the production of the protein, which was soluble when produced at 37 °C (64).

Protease-minus strains of *E. coli* are particularly valuable for production of soluble proteins and those expressed from secretion vectors. A *lon*$^-$ *htpr*$^-$ strain (lacking the lon protease of *E. coli* [65]) significantly increased the production of RNases in a secretion system (7), and the strain SG21173 (*lon*$^-$, *htpR*$^-$, *clp*) was used to express the human T-cell receptor V beta 5.3 under the control of the hybrid trc promoter containing the *E. coli* heat-stable enterotoxin II (STII) signal sequence for protein secretion (66). There are also strains that facilitate the formation of disulfide bonds in the reducing environment of the cytoplasm (67). These should be considered for expression of proteins with multiple cysteine disulfides.

Coexpressing Other Proteins. Cocloning of molecular chaperones, which can include such diverse molecules as thioredoxin reductase (68) and, for membrane proteins, phospholipids (69) can be of help, but they must be selectively chosen (Table 4). Coexpression of the *E. coli* heat shock protein GroESL has solubilizing effects only on certain mammalian proteins. For example, coexpression of GroESL increased the solubility of four of eight mammalian proteins (c-myb, CRE-BP1, p53, and the *Xenopus* protooncogene product Mos), while coexpression of thioredoxin increased the solubility of these and the other four (SnoN, c-Myc, adenovirus E1A, and the human tyrosine kinase Lck) (6). Thioredoxin also increased the production of antibodies (68).

There is also a report that association with GroEL actually decreased the solubility of the cystic fibrosis transmembrane conductance regulator (expressed as a glutathione-*S*-transferase fusion protein). A 60-kDa protein coeluted from affinity columns with the protein and was shown by sequencing to be GroEL. The authors were able to break up the complex and purify the protein (which was induced at 25–28 °C) by adding 5 mM MgATP to the bacterial extract and incubating at 37 °C (14).

Vitreoscilla hemoglobin

Other reports indicate that GroESL may have a solubilizing effect only at certain temperatures. The aggregation of preS2-*S′*-*β*-galactosidase, a three-domain fusion protein in the cytoplasm of *E. coli*, was reduced three- to sixfold by cooverexpression of the DnaK and DnaJ molecular chaperones over a wide range of growth temperatures (30–42 °C), while an increase in the concentration of the GroEL and GroES chaperonins had a significant effect only at 30 °C. Coimmunoprecipitation experiments confirmed that preS2-*S′*-*β*-galactosidase formed a stable complex with DnaK, but not with GroEL, at 42 °C. When the intracellular concentration of chromosomal heat shock proteins was increased by overproduction of the heat shock transcription factor *σ* (33), or by addition of 3% ethanol (v/v) to the growth medium, a two- to threefold higher recovery of active enzyme was observed at 30 and 42 °C, but not at 37 °C. The overexpression of all heat shock proteins or specific chaperone operons did not significantly affect the synthesis rates or stability of preS2-*S′*-*β*-galactosidase and did not lead to the disaggregation of preformed inclusion bodies. Rather, the improvements in the recovery of soluble and active fusion protein resulted primarily from facilitated folding and assembly. The authors suggested that titration of the DnaK–DnaJ early folding factors may trigger the formation of preS2-*S′*-*β*-galactosidase inclusion bodies (70).

Coexpression of proteins that improve solubility or the overall growth of the bacteria can also be useful. For example, coexpression of *Vitreoscilla* hemoglobin can increase the total cellular protein of various common *E. coli* cloning strains (JM101, pRed2 and W3110) and *B. subtilis* (71). Their production characteristics should also be improved because onset of oxygen limitation is delayed (72). Cocloning demonstrated that the function of at least one of the six homologous insulin-like growth factor binding proteins is to assist in the formation and maintenance of the native disulfides of IGF-I (73).

Cocloning of specific antibodies to the protein may increase yields. For example, the heat-induced aggregation of carboxypeptidase A could be greatly reduced in vitro in the presence of monoclonal antibodies that did not inhibit its activity (74). In addition, coexpression of tRNA genes for the preferred mammalian codons may increase the expression of mammalian genes in *E. coli*. For example, the

expression of argU tRNA enhances expression of interferon (coded from the mammalian sequence) in *E. coli* (75).

Alternative Hosts to *E. coli*. Despite the millions of different bacteria in nature, very few are used currently as hosts for protein production. *E. coli* itself, isolated originally from infant diarrhea, was chosen as an experimental strain by Jacques Monod soon after World War II because it was relatively nontoxic and grew quickly. Other bacteria that have been used as hosts for recombinant protein production were selected because they were known for medical reasons (*Straphylococci*, *Bacillus calmette-guerin*), were approved for use in some food-related applications (*Lactobacillus* [76]), or were used industrially for enzyme or antibiotic production (*Bacillus subtilis* and *Bacillus amyloliquefaciens*).

B. subtilis systems, based on previous industrial processes for enzyme production, are mostly suitable for the production of stable proteins that are resistant to proteases (77). If the basic problems of protease degradation and processing problems that may lead to insoluble product (53,78) can be avoided, there are several good expression vectors, including one based on the α-amylase signal sequence and promotor (50). *Bacillus licheniformis*, useful for producing bacterial enzymes on the industrial scale (79), has been used to produce active human IL-3 of therapeutic quality (80). *B. calmette-guerin* has been used to produce a *Schistosoma mansoni* antigen (81). *Lactobacillus lactis*, found in cheese cultures, is also a useful expression host (82) and may have promise for vaccines (83).

Recently, *Staphylococcus carnosus* was used for surface display of a malaria antigen (84), and a secretion/expression system in *Salmonella* has been suggested for vaccine production (85). There are "shuttle vectors" available that can function in both *E. coli* and various alternative host bacteria. For example, expression of *Trympanosoma cruzi* polyantigens using the vector pRIT21, which contains the origins of replication for both *E. coli* and *Staphylococcus aureus*, allowed expression in both strains. Seven different antigens showed less proteolysis when secreted from *S. aureus*; with purification yields of 80%, between 4 and 16 mg/L of the different antigens for vaccine production were obtained (86).

Various *Vibrio* species were used to express the nontoxic B-subunit of *E. coli* heat-labile enterotoxin linked to a 27-residue C-terminal fragment of Pol, the catalytic subunit of DNA polymerase of herpes simplex virus type 1. The highest yields were reported to be 3.5 mg/L; 0.3 mM EDTA added to the growth medium blocked proteolysis of the secreted protein (87).

Altering the Vector

Choice of Promotor. Using a prokaryotic promoter that is tightly regulated and can be induced to express large amounts of protein at low temperatures (23–30 °C) is essential for soluble expression. For example, expression levels in the T7 system can be increased by tighter transcriptional control before induction (88). In view of the effect of temperature on solubility, it is interesting that a whole group of *E. coli* proteins is induced when the culture temperature is lowered to below 20 °C. The promotor for one of these genes, cold shock promotor CspA, is the basis of a vector developed specifically for low-temperature induction of recombinant proteins (89). The expression levels possible with this promotor at the optimal induction temperature compare favorably with those obtained with the tac promotor (90). The Csp promotor has the advantage that temperature shift alone induces production. It should certainly be considered for expression of highly aggregation-prone or unstable gene products.

Older promotors, such as those based on the tryptophan operon, are useful for low-temperature expression, as is a modified tryptophanase promotor (91). Secretion of specific proteins from *E. coli* is already possible using a variety of vectors (7,92). Secretion expression systems are particularly suited to mutant analysis (93) because the culture supernatant can be directly analyzed. Further study of the factors affecting transport of proteins is needed.

Selecting Signal Sequence or Fusion Partners. The sequence of the protein itself can be altered by adding linkers to improve protein folding, solubility, protease resistance, yield, and secretion into the culture medium (Table 5). Expression of small proteins or fragments of a larger protein may be possible only if the desired sequence is expressed as a fusion protein (98). The *E. coli* maltose binding protein (MalE) is particularly useful because fusion molecules with it, besides being easily purified, are often secreted. For example, CD4, the human T-lymphocyte receptor for the AIDS virus, HIV, as well as many different functional deletions that retained their ability to bind monoclonal antibodies and HIV gp160 and inhibit HIV binding to $CD4^+$ cells, were fused as multiple repeats to both ends of a single MalE molecule. The hybrid molecules (expressed in L-broth at 30 °C) were exported into the periplasm (95). Pollen major allergen Bet v1 from *Betula verrucosa* (White Birch) has been cloned and expressed in *E. coli* as a fusion with maltose-binding protein and a factor Xa proteolytic cleavage site. The cloning strategy, based on a polymerase chain reaction, positioned the factor Xa proteolytic site so that the authentic amino terminus of Bet v1 was generated after cleavage. Fusion protein (expressed solubly at 37 °C) was isolated by amylose affinity chromatography and enzymatically cleaved by incubation with factor Xa (99). The kringle V domain of the lipoprotein apolipoprotein(a) from human liver was solubly incubation with factor Xa (99). The kringle V domain of the lipoprotein apolipoprotein(a) from human liver was solubly expressed in *E. coli* as a MalE fusion protein. As with the other MalE fusions, this protein was purified by amylose–agarose affinity chromatography by eluting with 10 mM maltose (100).

Several linkers, such as hexahistidine, can aid in the detection and purification of recombinant proteins. Most vectors also include a protease site between the linker and the protein. The 54-kDa subunit of the canine signal recognition particle (SRP) was expressed *E. coli* using a T7 expression system with an amino-terminal extension encoding an initiating methionine and 10 histidine residues followed by an enterokinase cleavage site. His-SRP (54 kDa) was purified to give a single band on SDS-PAGE in 20% yield (0.3 mg from 500 mL culture) (101). The hexo-

Table 5. Linkers That Improve the Solubility of Fusion Proteins or Allow More Specific Purification

Linker	Comments
Calmodulin (94)	Calmodulin binds to phenol sepharose tightly.
E. coli maltose binding protein (MBP or MalE)	Purify fusion protein by binding to amylose beads and eluting with maltose. Secretion into the periplasm of soluble fusion protein is often possible even with 37 °C growth. Proteins and deletions thereof may be cloned at either or both ends (95).
Glutathione-*S*-transferase (GST)	Purify fusion protein by binding to glutathione beads. Fusions may be more soluble.
Hexa- (or more) polyhistidine linker	Allows purification with metal chelate columns.
Thioredoxin (TRX)	Very commonly used vector system. Antibodies to thioredoxin may be useful in purifying the fusion proteins (96).
Ubiquitin (97)	Easily cleavable fusion protein.

kinase of *Schistosoma mansoni* has been expressed in *E. coli* as a fusion protein including an N-terminal polyhistidine tag and enterokinase cleavage site. The enzyme was purified by metal chelate chromatography to > 95% homogeneity, based on analysis by SDS gel electrophoresis and isoelectric focusing (102). This sort of expression system has the advantage that the protein can often be expressed without an N-terminal methionine, but the disadvantage that yields are reduced due to the additional processing step. Even specific proteases may cleave the protein itself. Thus initially high expression levels may turn into disappointing bottom-line figures.

Thioredoxin fusions of many proteins are soluble, especially if produced at a lower growth temperature, active in some cases before removal of the thioredoxin portion, and may be purified by heating lysates to 80 °C. A-DDDDK-linker, the recognition site for mammalian intestinal protease enteropeptidase, allows removal of the thioredoxin moiety (103). IGF-1 was more than 100 times more soluble when fused to one or two Z-domains (from Staph protein A), and the solubilizing effect could also be seen during in vitro refolding (104).

There is a fine interplay between the temperature effect on solubility and the linker. For example, the solubility of the his fusions with the IpaC invasion plasmid antigens of *Shigella flexneri* (antibodies to which may be useful in treating Shigellosis dysentery) was improved by production at 30 °C. However, no protein was found when the IpaB antigen was similarly cloned. Both histidine-linked proteins were partially soluble at 37 °C if expressed as fusions with Trx (40).

Human osteocalcin (hOC), a 49–amino acid peptide produced mainly by bone osteoblasts, was fused to the glutathione S-transferase (GST) gene, and the fusion protein was produced mainly in a soluble form. The affinity-purified fusion protein was cleaved with activated protease factor X, releasing the rhOC portion. The structure of rhOC was confirmed by mass spectrometry and amino acid sequencing (105).

Changing Codon Use without Altering Sequence. Bacterial and mammalian codon usage differ significantly. Genes for several proteins have been synthesized to reflect the bacterially preferred codons for degenerate amino acids and to eliminate elements in the noncoding region of genes that lower productivity. For example, RNase A was expressed at a much higher level when synthesized from a synthetic gene that reflected codon usage than was its murine counterpart expressed from the natural mammalian gene (7). Alternatively, one can look for specific mammalian codon usage in the cDNA that may inhibit translation. For example, 4.9% of the adult isoform of human cardiac troponin (288 amino acids) is arginine coded by the (rarely used in *E. coli*) codons AGG and AGA. Changing two areas where these codons occurred consecutively (AGG [165] and AGG [166], and AGG [215] and AGG [216]) to the bacterially preferred codon CGT increased expression 10-fold (one pair); there was a 40-fold increase when both pairs of the rare arginine codons were replaced (106). In a similar example, electrospray ionization mass spectrometry of recombinant link module from human tumor necrosis factor–stimulated gene 6 protein revealed that much of the protein was a mixture of forms where between one and four of the arginine residues had a lysine substitution. When the AGA codons for the arginine residues were substituted to the bacterially preferred codon CGT, the substitution problem was eliminated, and the level of expression was greatly increased (107). One can also try using strains that express tRNAs for the mammalian preferred codons, as already discussed.

A combination of methods may be necessary. For example, the aggregation of the vaccinia virus large subunit of ribonucleotide reductase (vvR1, 87 kDa) (29) was prevented by lowering the induction temperature to 15 °C, the cell density during induction, and the concentration of the inducer (to 0.05 mM IPTG). Addition of hydroxyurea, an inhibitor of ribonucleotide reductase, further increased production of soluble vvR1 in a dose-dependent manner.

ALTERING THE PROTEIN FOR SOLUBILITY

Why Do IBs Form?

The reason for the formation of IBs has been the subject of much debate since the phenomenon was first observed. An answer to this question is vital to achieving maximum soluble expression in *E. coli*. Lowering growth temperature to achieve more soluble protein does not work for all proteins; further, we do not understand the physical characteristics that account for why some proteins are perfectly soluble even at 42 °C, but point mutations thereof can render the proteins insoluble at all temperatures. Size is not

a variable because even very large proteins (e.g., heparinases II and III, see Table 2, are over 700 amino acids long) can be expressed in soluble form.

Although even point mutations can render proteins more or less soluble (for reviews see Refs. 2 and 108), specific effects cannot be directly related to hydrophobicity (Gravy scores [31]) or content of a specific amino acid such as cysteine or proline. A multifactorial analysis (109) also did not yield a satisfactory explanation for the effect of sequence on solubility.

The only general observation is that there is a good deal of misfolded protein and proteolytic fragments in IBs. IB formation in *E. coli* was probably first observed when cells were treated with amino acid analogues (110); this relationship between abnormal protein and aggregation has been born out by other studies. In general, proteolysis accompanies IB formation (11); indeed several authors attributed the effects of a lower growth temperature on solubility to reduced proteolytic cleavage of their proteins (17,55). Certain intermediate states in protein aggregation are detectable by some physical techniques but difficult to define at the sequence level (111).

Two recent observations may shed some light on the process of aggregation. The first is that protein aggregates, as viewed by PAGE, appeared identical in the presence or absence of another protein. Thus the protein appeared to aggregate only with itself and not to coaggregate with a potential partner (112). Of course, the authors could not analyze the more insoluble, larger molecular weight aggregates that did not penetrate into the gel, but the results strongly suggest that aggregation follows a very specific pathway.

The second observation is that the oligomers seen in many crystal structures are not due to the monomers aligning themselves at surface-exposed hydrophobic sites. Rather, the monomers actually exchange a whole section of the protein to form a compact structure. Requirements for the swapped domain are that it have both a hydrophilic and hydrophobic face and that it be joined to the rest of the protein by a flexible linker. "Domain swapping" is one possible mechanism for aggregation that accounts for many of the observations about IB formation (113):

- *Specificity*. The swapped domain is connected to the oligomeric partner in much the same way as to the original monomer.
- *Speed*. Thermodynamically speaking, the major barrier to overcome during the initial formation of the dimer molecule is the barrier toward simultaneously opening two monomers that lie within a permissible distance of one another to permit establishing a bond. Once a dimer has formed, however, addition of another monomer requires only the opening up of one more molecule at a time. Thus aggregation will proceed quite quickly once the initial template exists.
- *Proteolysis*. IB formation is usually accompanied by proteolysis, and proteolytic fragments are often seen in solubilized preparations from IBs. If one assumes that a long, flexible linker joins the swapped domains, this essentially unstructured area would present a good site for the attack of proteases. The domains liberated by hydrolysis of the linker might serve as fragments to further participate in the aggregate formation.
- *Association with synthesis*. Pulse labeling studies with *E. coli* overexpressing the *Salmonella typhimurium* gene *CheY* have shown that newly formed protein aggregates more quickly than existing protein (38). However, preexisting protein can also become involved in IBs if incubation is continued for a sufficiently long time (11). This makes sense if one assumes that protein immediately after synthesis is not yet completely folded. Possibly the stable domains fold first, followed by the folding of the whole protein. A protein in solution exhibits a certain amount of folding-out (so-called breathing) that can be observed by techniques such as hydrogen exchange. Presumably, new protein whose secondary structure is formed but is still unfolded at the tertiary level can exchange domains easily, whereas existing protein can join the aggregate only at the appropriate stage in its breathing state. The movement increases with temperature, which can also account for the observed temperature dependence of aggregation. Aggregation would thus be one aspect of the protein solution half-life, which can be related to temperature by an Arrhenius plot ($\ln k$ vs. $1/T$, where k is an intrinsic instability constant and T is the temperature in °K) (114).
- *Irreversibility*. Because the area of the domain that is swapped is substantial, the energy required to form (and hence to separate) oligomers is very large. The domain-swapping model can also explain to some extent the influence of heat shock proteins and chaperonins on solubility.
- *Other Miscellaneous Observations*. It has also been noted that there is active protein in IBs (115), which suggests strongly that the protein is not completely misfolded. Some IBs have the ability to be separated by ion exchange. Also there is a lack of a general relationship between protein sequence and aggregation. Domain swapping accounts quite neatly for the effects of specific point mutations (116) and their corresponding supressors on the solubility of proteins (117).

If one accepts that domain swapping is involved in oligomer formation, designing peptides to prevent aggregation may be a greatly simplified process, especially if a crystal structure is available or one has knowledge of interacting faces withing the protein. One can direct changes in the protein itself to inhibit its aggregation, or design peptides that will bind reversibly to these sites and prevent the initiation of aggregation (106).

These peptides need not be very large; for example, a simple tetramer, Arg-Gly-Asp-Ser, from fibrinogen was sufficient to inhibit the aggregation of platelets (118). A few discrete amino acid changes at the end of the B-chain of insulin considerably reduced the oligomerization state (119).

Two examples show that this mechanism can be exploited if one can detect amino acid regions in turns. In the first, a monomeric λ-cro protein was made from the homodimer by duplicating the dimer interface region (six amino acids) at the C-terminus of the molecule. The monomeric mutant was more thermostable and appeared from NMR studies to have a solution structure similar to that of the dimer (120). *E. coli* maltose-binding protein is soluble, but a double point mutant (Gly32Asp/Ile33Pro) is insoluble whether it is targeted to the cytoplasm or periplasm by expression without or with its signal sequence, respectively. These mutations are located in a turn/loop region between two helical regions in the crystal structure (121).

Mutation to Increase Solubility

Single point mutations may greatly improve solubility, whereby the observed increase in soluble protein may also be a secondary effect of increased stability to proteolysis or improved interaction with a chaperone (122). Single point mutations may alter the effect of temperature on solubility. The solubility and stability to proteolysis during production in *E. coli* of a 101–amino acid fragment from the human respiratory syncytial virus (RSV) major glycoprotein (G-protein) was significantly improved by altering several phenylalanine residues. Two cysteine-to-serine changes, did not affect the solubility or stability of the gene product. The mutant G-proteins appeared antigenically similar to the parent and had similar secondary structures (123).

Destruction due to proteases can be minimized by identifying degradation "hot spots" in proteins (124). Some of these sites have been discussed elsewhere (2,108). It should be noted that such sites in mammalian proteins may be one mechanism for controlling their activity. For example, proteolytic cleavage at the C-terminal of human interferon-γ, which also occurs in blood, can increase activity several fold. Efficient production of this cytokine in *E. coli* was possible only if the N-terminal residues Cys-Tyr-Cys, which are also not found in serum isolates, were removed from the coding sequence (125).

CONTROLLING OTHER VARIABLES THAT AFFECT SOLUBILITY

Inoculum Preparation and Storage

One of the greatest causes of variation in the production of proteins in bacteria is plasmid and host strain instability. The plasmid should be checked periodically during large-scale cultivation. Loss of plasmid, or alterations, including changes in the sequence of the desired protein or even deletion of the whole segment and insertion of unrelated DNA into the plasmid, can occur. Several different insertion sequences are known in *E. coli*. Correct preparation of inocula to minimize variation is essential and is thus dealt with here in some detail.

Most strain stability problems are not discussed openly in papers dedicated to studying the proteins themselves (with notable exceptions [126]). Because many expression problems can be ameliorated by care in preparing the inoculum, a detailed protocol is included here for several stages.

The following general recommendations are made for the start of culture:

1. Larger inocula are preferred.
2. Glycerol cultures should not be reused, and they should never be stored at temperatures above -70 °C.
3. Glycerol cultures should be made from the first culture after a transformation.

Glycerol Culture Preparation and Storage. The following protocol proved reliable for culture of various *E. coli* strains producing interferon and other proteins in differing vector backgrounds:

1. A transformation was done by standard protocols (62), and the bacteria were grown up on selective solid medium.
2. Five to six colonies from the transformation were picked individually into numbered flasks containing 50 mL of selective media (L-broth plus antibiotic) and grown up on a shaker to midexponential phase. Then between 50 and 100 glycerol cultures were made from each flask by combining 0.4–0.5 mL of the culture with 0.5 mL 50% glycerol in L-broth. (In practice, sterile Eppendorf tubes—with a freezer-safe lock closure—or cryotubes were filled with the glycerol solution, closed, and autoclaved. The culture was added sterilly and the tube was reclosed.) The cultures were stored on ice for 2 h, frozen overnight at -20 °C, and then moved to -70 °C or liquid nitrogen storage. In addition, $2\times$ 1 mL of each culture was centrifuged (5 min centrifugation in a cold room in an Eppendorf centrifuge) and the pellet frozen for plasmid analysis.
3. The remaining culture was induced in an appropriate fashion, the cells were lysed, and the amount of protein or its activity was determined. A plasmid prep was made of the selected colony, and the restriction map compared to that expected. The culture with the highest yield was chosen for further analysis (assuming its restriction map was in order), and the other cultures and the glycerol cultures made from them were discarded.*Note*: It is unwise to ignore oddities in the restriction map. Because 1 μL of a commercial *Eco*RI or *Bam*HI preparation will cut an entire miniprep of plasmid completely in a matter of minutes, unexplainable high molecular weight bands are probably not residual host DNA. Unexpected bands may indicate either latent bacteriophage contamination or insertion sequences in the plasmid. When in doubt, throw it out (the culture that is) and do another transformation.
4. To each of the chosen glycerol cultures, afix a freezer-stable label with the plasmid name, host strain, resistance marker, date, and initials of the experimenter. Cultures should be stored in numbered boxes, and a file kept of their location in the -70 °C

or liquid nitrogen storage. Excess glycerol cultures of strains no longer in use should be weeded at regular intervals (it is best not to wait until the compressor needs replacing or the contents of the freezer must be moved).

Cultures prepared and selected in this fashion are relatively stable; the author recently prepared Mx protein from a culture that had been frozen in a −70 °C freezer (with all the temperature variations that can represent) for more than 10 years. Nonetheless, one should maintain a good plasmid library of minipreps of vectors as the ultimate backup.

Trouble-Shooting Protein-Producing Recombinant Bacteria

Most host *E. coli* strains carry a portfolio of mutations that may be essential to their success in producing protein. Several cloning and expression strains and their genotypes are listed in Table 5. The requirements for a cloning strain (basically, high efficiency of transformation) are different from those for a good expression host. The latter should grow vigorously on minimal media and be low in proteases, whereas the former, such as HB101, should have few host restriction systems and high sensitivity to the selection marker. Do not store host strains on agar plates in the cold room; the best method is to prepare them as glycerol cultures and store at −70 °C or liquid nitrogen temperature.

It is vital to continuously monitor the quality of these host strains, especially when several researchers share stock cultures. For best results, one should prepare several hundred glycerol cultures of common host strains when they are obtained in the lab. One of these should be used per experiment, preferably by adding the whole 1 mL to 50 mL of growth media used to induce transformation phenotype. Although not suitable for long-term storage or in cases where a high yield is necessary from the transformation, competent cells can be stored frozen and used for several weeks after. When performing a transformation, a control plate of competent cells with no DNA added should be used to test for development of antibiotic resistance. Look for differences in the characteristic color, size, and odor of host strain colonies streaked on a nonselective agar medium.

If necessary, one can test the host strain for the presence of markers. Reversion to a protease-producing phenotype can be detected by plating on agar containing 1% casein. A complete listing of the meaning of various markers for *E. coli*, with alternate notation possibilities, can be found on the internet (61); the more common mutations are described by Sambrook et al. (62).

Protecting Your Cultures from Contamination. When bacteriophages were first introduced, in the 1960s, several labs were sufficiently afraid of their invasiveness as to limit work with them to discrete areas. This procedure should be adhered to today. A wide-spread M13 phage contamination can be caused from one shaker accident that is not adequately cleaned up, and months and even years of subsequent work can be wasted if the problem is ignored. Because switching to an F^- *E. coli* strain will limit possible hosts, the best method is to prevent the original contamination.

Frequent hand washing with antiseptic hand soap and even wearing disposable gloves is essential to avoid cross-contamination of cultures when handling plasmids and other replication-competent nucleic acids. Surfaces should be covered with absorbant paper that is changed regularly, preferably at the end of every experiment. The counter underneath and all cold room surfaces should be washed down with 2% chlorine bleach or Javell water, or 0.5% hydrogen peroxide, frequently. Isolation precautions such as those used throughout the medical field and the food preparation industry should be automatic during work with recombinant organisms. One should avoid touching hair or face during work, and long hair should be tied back. Protective coats should be removed at the door to the lab and never worn in public areas, especially lunchrooms.

Discourage other groups from using your shakers unless they are willing to conform to the following rules, which seem to be obvious:

1. All cultures must be stoppered properly (preferably with a cotton wad wrapped in cheese cloth or some other thick filtering substance) and the stopper fixed in position with tape so that it will not fly off during culture. Aluminum foil is not adequate. Flasks should fit the holder, and one should avoid wrapping paper towels and such around smaller flasks to accommodate them to a larger holder. Multiple test tube cultures must be in a properly secured rack, not taped to the side of a flask holder.
2. Flasks should be removed from the shaker area or room if additions are made after inoculation.
3. The shaker should be cleaned often with an antiseptic solution.
4. UV sterilization using a fluorescent light (one with a time switch can be installed for little expense in any area) is an excellent method to halt the growth of microorganisms, if the light has not been used for more than 300 h of operation and is not left on for more than 15 min at a time. Improperly used, UV irradiation is worse than no sterilization at all because a weak light can select for mutant bacteria that will be resistant to most killing methods. An easy way to determine if the lamp is still in order is to inoculate an agar plate with 1 mL of a dense culture of bacteria (preferably an aerobic spore former such as *Bacillus*, but *E. coli* will do) and leave it open under the lamp for 15 s (time accurately!). If any colonies grow on the plate after 24 h at 30–37 °C, install a new fluorescent bulb.

Fermentor Culture Starting from Glycerol Cultures. Even a 30,000-L fermentor can be inoculated from 1 mL of culture if the plasmid is stable. Do not reuse a glycerol culture; use it once and dispose of it.

Several methods can be used to determine plasmid stability as a function of culture time. One can compare the specific plasmid content of the bacteria at the end of a plasmid miniprep and determine the colony-forming units of a transformation into HB101 or a high frequency of transformation strain.

Stability of Selection Stress. Most antibiotics (in particular, penicillin derivatives) should not be stored in frozen aqueous solution, nor should antibiotic-containing agar plates be stored before use. The half-life of the closed β-lactam ring is extremely short in aqueous solution, particularly at neutral pH. Ampicillin should be dissolved in sterile water, filter sterilized, and added to the growth medium as close to time of inoculation as humanly or mechanically possible.

Before ignoring this caveat, note that those frozen ampicillin solutions inherited from the previous lab generation, while most certainly lacking their ability to lyse bacteria, may inhibit growth of nontransformed bacteria. Week-old refrigerated antibiotic-containing plates used for transformation selection will show no colonies for the control Ca^{2+} cells. As the transformed bacteria grow, they secrete β-lactamase that, coupled with the instability of the antibiotic itself at 37 °C, will rapidly eliminate any selective pressure in that area of the plate (or in the vessel during a large-scale cultivation). The invisible nontransformed bacteria will start to grow. Colonies picked from the transformation plates will perforce contain nontransformed but not necessarily nonviable bacteria. The initially inhibited nonproducers will be able to grow, diluting the plasmid bearers and lowering yield. If the plasmid confers any negative growth characteristics, the plasmid-containing bacteria will rapidly become the minority in the culture vessel. Additional proteins from all those nonproducing bacteria will render the purification even more difficult.

Maintaining Solubility during Harvesting and Cell Lysis

If one is fortunate, the protein to be isolated has distinct characteristics that separate it from the pack. Unfortunately, the majority of naturally occurring proteins are moderately hydrophobic, with a pK_a of between 6 and 7. This means they will elute from hydrophobic interaction columns at salt concentrations between 0.1 and 0.5 N, and from ion exchange resins with the vast majority of bacterial proteins. Thus a typical protein, if expressed at low concentration in the bacterial cytoplasm, will be difficult to separate by general methods of purification and may be destroyed by proteases before ever being seen on a gel.

Here, IB formation would appear to confer an enormous advantage. The protein is clearly visible from the earliest stages of expression on a polyacrylamide gel, and an apparently purified preparation can be quickly obtained. The denaturants used at the early stages of preparation inhibit most proteases, and the overall yield, estimated visually, would seem to be very high.

The apparent ability to wash away contaminants from IBs is often a Trojan horse. Membrane fragment and other insoluble proteins persist through many detergent washes (indeed, there is a report that some proteins are rendered insoluble by these agents, particularly Triton X-100). These high molecular weight, often highly modified proteins are not always visible on gel electrophoresis because they "stick in the slot" or do not stain with silver stain reagents or Coomassie blue. An even greater problem arises: the protein is contaminated with proteolytic fragments, alternate folded forms, and oligomers of itself. If solubly expressed protein requires isolation from bacterial proteins with similar characteristics, the problem in IB schemes comes down to isolating the protein from what is essentially the same protein. This is the hardest of all purification steps.

Even proteins that are initially soluble in the bacteria may be induced to aggregate, sometimes irreversibly, during cell breakage and washing. Aggregation and proteolysis can be minimized by adding a proteolysis inhibitor to the cell culture at the end of growth and maintaining a low temperature during centrifugation. Especially on the large scale, this may require special cooling equipment for centrifuges, and small batch processing for producing cell lysates using high-pressure equipment such as a Manton/Gaulin or French press.

As noted earlier, detergents such as Triton X-100 and Nonidet P-40 can render proteins insoluble when added during cell washing/breakage steps. However, others have noted that extraction with 1% Triton X-100 was necessary for obtaining high yields of bovine heart mitochondrial ubiquinol–cytochrome *c* reductase (fusion protein with glutathione). They solved later aggregation problems by resolubilizing the protein in the detergent dodecyl maltoside in 300 mM NaCl; the resultant protein appeared active because it gave a blue shift in the visible spectrum when incubated with ubiquinone (12). The preliminary breakage steps to maintain the solubility of T7 RNA polymerase had to be done in buffer containing large amounts of glycerol and detergent to prevent the protein from precipitating. Once its extremely narrow solubility range was determined (10), the purification was straightforward.

Even the pH of the extraction buffer can have a profound effect on solubility. For example, UMP-kinase from *E. coli* was insoluble if extracted from cells with a pH 7.4 Tris buffer, but was soluble if 1 mM UTP was added to this buffer or if 100 mM borate buffer pH 9 was used for the extraction. Reversible aggregation could be induced by adding Mg to the UTP-containing solutions or lowering the pH. A point mutant, D159N, was soluble at up to 5 mg/mL at pH 7.4 (127).

As the last example demonstrates, the effects of point mutations on solubility do not fit easily into a clear set of empirical or theoretical rules. The reader is referred to Refs. 92 and 108 for further examples and discussion.

CONCLUSIONS

Proteins produced in a soluble form in bacteria are easier to purify and work with than those refolded from inclusion bodies. Expression of soluble proteins can be improved by judicious choice of the vector and host strain, and manipulation of the inoculation, growth, and induction conditions. Very high per liter yields of purified product have been achieved, and the overall yield for some secretion systems is higher than those possible with inclusion bodies.

OUTLINE

INTRODUCTION

Protein glycosylation, the addition of sugar residues to the polypeptide backbone, is the most extensive of all the cellular posttranslational modifications made to proteins in the eukaryotic cell. It entails attachment and remodeling of oligosaccharides in the endoplasmic reticulum (ER) and Golgi apparatus prior to secretion of the protein or its appearance at the cell surface (1,2). Almost all proteins on the mammalian cell surface (including receptors) are glycoproteins (3), and the majority of secreted proteins are also glycosylated (with notable exceptions such as insulin, growth hormone, and some interleukins). Glycosylation has been shown to influence the secretion, solubility, stability, antigenicity, and blood clearance of glycoproteins. In some cases, carbohydrates form part of the ligand binding site. In cases where this does not occur, the influence of carbohydrates may be overlooked until the protein enters animal and human clinical trials. There have been four major areas of advance in recent years:

1. Development of methods for the accurate structural analysis of carbohydrates attached to glycoproteins (glycans)
2. Cloning of key glycosyltransferase enzymes in the glycan biosynthetic pathways.
3. Understanding the cellular influences on protein glycosylation.
4. Understanding the varied biological functions of carbohydrates in glycoproteins.

In this article the methods and findings that underpin the science of glycobiology are reviewed, with particular focus on their application in the biotechnology industry. Differences in carbohydrate structures that may arise from choosing alternative gene expression systems and cell culture conditions are discussed, together with methods of carbohydrate analysis that are appropriate at each stage of product development. For reviews of other aspects of glycobiology the reader should consult reviews on biosyn-

thetic pathways (4,5), the biological properties of carbohydrates (6), and the cellular influences on the glycosylation process (2,7).

Oligosaccharide Structures

Three distinct types of glycosylation are known to occur in higher plants and animals, two of which are shown in Figure 1:

1. N-linked glycosylation of proteins; oligosaccharides are attached to the amino group of asparagine residues, usually within the sequence Asn-X-Ser/Thr.
2. O-linked glycosylation; smaller oligosaccharides are linked to serine or threonine residues.
3. Glucosamine and mannose residues are incorporated into the glycosyl–phosphatidylinositol (GPI) anchor of some membrane proteins.

In addition, single fucose residues (8) or small glycans linked via Asn-X-Cys have been found on some blood proteins (9).

N-Linked Glycosylation

N-linked glycosylation is characterized by a glycosidic bond to the R-group of an asparagine residue of the peptide backbone. A tripeptide core or the consensus peptide sequence Asn-X-Ser/Thr (where X is any amino acid apart from proline) must be present for this particular form of glycosylation. The presence of this amino acid sequence by no means guarantees its glycosylation, because other factors such as protein secondary structure and its folding status within the ER are important influences (10,11). For example, the immunomodulator interferon-γ (IFN-γ) has two potential N-glycosylation sites (Asn_{25} and Asn_{97}), but exists in three glycoforms: doubly glycosylated (at both Asn_{25} and Asn_{97}), singly glycosylated (at Asn_{25} only), and nonglycosylated (12). Similarly, in the blood protease tissue plasminogen activator (tPA), only two N-glycosylation sites (Asn_{117} and Asn_{448}) are fully occupied: Asn_{184} is only 50% glycosylated due to steric hindrance (11).

N-linked oligosaccharides fall into three structural categories: complex, high-mannose (or oligomannose), and hybrid, dependent on the extent of glycan remodeling in the later stages of the glycosylation process (Fig. 1). All three categories contain the same chitobiose core structure of two *N*-acetylglucosamine (GlcNAc) units attached to the asparagine containing sequon, which is extended by three mannose (Man) units, with a single fucose (Fuc) residue sometimes attached to the GlcNAc of the reducing end (next to its peptide attachment site).

1. Complex oligosaccharides contain two or more branches attached to the core, and the terms *biantennary*, *triantennary*, and *tetraantennary* reflect the number of branches. Sugar residues such as GlcNAc, galactose (Gal), *N*-acetylgalactosamine (GalNAc), Fuc, and sialic acids (*N*-acetyl [NeuAc] and *N*-glycolyl [NeuGc] neuraminic acids) extend the structures.
2. Oligo (5–9) and high-mannose (>9 Man) structures contain only mannose residues attached to the core structure.

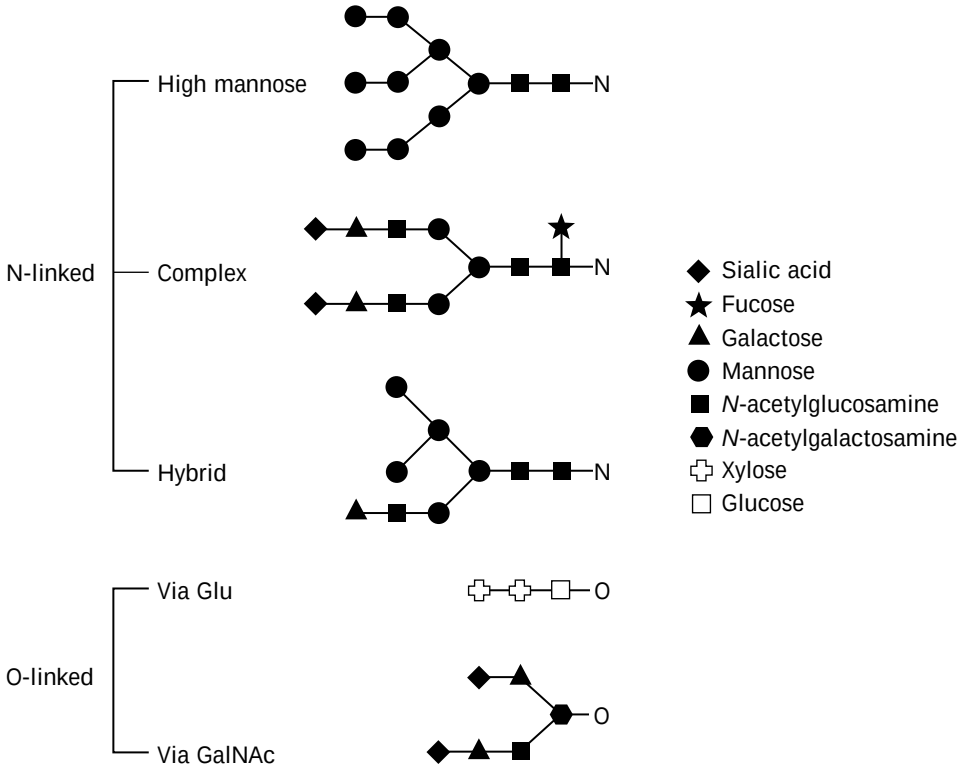

Figure 1. Common oligosaccharide structures found on glycoproteins.

3. Hybrid structures contain at least complex sugar-containing antennae, with other α1-3 branches containing only mannose residues.

N-glycosylation occurs in both the ER and Golgi apparatus and is controlled by a large number of glycosyltransferases and glycosidases. Glycosyltransferases are grouped into families, based on the type of sugar they transfer to the protein (e.g., galactosyltransferases and sialyltransferases) (5). Theoretically, if all enzymes in the pathway are fully active, the required donor sugar nucleotides are present, and no structural hindrances are present, all glycans will be fully processed into complex structures terminating in sialic acids. But in practice, this is rarely observed and a mixture of partially and fully processed glycans is more typical of N-linked glycoproteins.

Figure 2 shows a simplified pathway in the biosynthesis of *N*-glycans. A common core glycan ($Glc_3Man_9GlcNAc_2$) is built on a dolichol pyrophosphate lipid carrier, first in the cytoplasm and then in the ER. This oligosaccharide core structure is attached to the target asparagine of the nascent polypeptide chain as it enters the ER. The enzyme responsible for catalyzing this reaction, oligosaccharyl transferase, is closely associated with the ribosome (step 1). Within the ER lumen the three terminal glucose units are removed by α-glucosidases to give $Man_9GlcNAc_2$ (steps 2 and 3) that is further modified to $Man_8GlcNAc_2$ by α2-mannosidase (step 4). This trimmed structure is no longer recognized by the ER chaperone calnexin and is transported to the *cis*-Golgi via an intermediate compartment. Here it is further trimmed by additional mannosidases until a $Man_5GlcNAc_2$ structure remains (step 5), which is a substrate for GlcNAc transferase I to add GlcNAc to the 1-3 antenna (step 6). The presence of the GlcNAc on this arm of the glycan acts as a signal for possible further modifications. These include the removal of further Man residues (mannosidase II, step 7); addition of antennary GlcNAc (via GlcNAc transferase II, step 8), and bisecting GlcNAc residues (via GlcNAc-transferase III); creation of further branches (via GlcNAc-transferase IV and V); and core α6-fucosylation (step 9).

Therefore, the absence GlcNAc transferase I activity, or the subsequent removal of GlcNAc, as has been suggested for some insect cell lines (13), may result in simple oligomannose or hybrid structures being present on the mature glycoprotein. There appears to be no requirement for more complex glycan processing to precede secretion of glycoproteins from the cell or their appearance on the plasma membrane. Certain pathways are mutually exclusive, for example, the addition of a bisecting GlcNAc residue via GlcNAc-transferase III can prevent further branching of the antennae by GlcNAc-transferase V. The final stages of *N*-glycan processing take place in the *trans*-Golgi and involve the addition of galactose and sialic acids (steps 10 and 11), and α1-6- or α1-3-linked fucose residues. It is the presence and activity of these Golgi enzymes that gives rise to differences in glycan structures (microheterogeneity) produced by alternative cell hosts; these factors vary with culture conditions. Certain cell types posses unusual glycosyltransferases that facilitate the addition of cell-specific glycan structures. For example, up to 20% of IgG molecules produced by human B-lymphocytes possess a bisecting GlcNAc residue β1-4-linked to the central β-linked mannose of the core glycan, which can play a role in antibody-dependent cell-mediated cytotoxicity (ADCC). The GlcNAc transferase III enzyme required for this modification is not active in all cells, indeed only certain rodent cell lines such as the rat Y0 myeloma are able to produce recombinant antibodies containing this bisecting residue (14). Another example is sulfation of antennary GalNAc residues in certain pituitary glycoprotein hormones such as luteinizing hormone (LH), thyrotrophin, and proopiomelanocortin (15). The specific GalNAc transferase and a terminal GalNAc sulfotransferase recognize protein motifs in the nascent peptide (e.g., Pro-Leu-Arg) and are mainly restricted to the anterior pituitary gland. Therefore, only cell lines derived from the pituitary gland or endothelium (such as At20 and 293 cells) are able to perform this sulfation (16).

O-Linked Glycosylation

O-linked glycosylation is a simpler process involving a smaller number of sugar residues (typically 1–6) and occurs exclusively in the Golgi apparatus, where a core GalNAc residue attaches via an O-glycosidic bond to the R-group of serine or threonine (Fig. 1). There is no obvious and invariant peptide sequon surrounding the serine or threonine attachment site, although a computer algorithm has been devised to predict the likely occupation of potential sites, based on sequences in other O-linked glycoproteins (17). Large structural proteins such as mucins have multiple O-linked oligosaccharides, which may dominate the mass of the mature glycoprotein. Also, regions that contain high proportions of serine, threonine, and proline have been shown to be extensively glycosylated. For example, immunoglobulin class A_1 contains a proline-rich hinge region between the Fab and Fc regions. Of the 21 amino acids within this hinge, there are 10 Pro, 5 Ser, and 4 Thr; and the 5 Ser are all O-glycosylated (18). Several core O-linked oligosaccharides have been described attached to serine or threonine, which can be elongated by addition of further Gal, GlcNAc, Fuc, and sialic acid residues.

Glycophosphatidylinositol Residues

Carbohydrates are also components of the glycophosphatidylinositol (GPI) anchor used to secure certain proteins to cell membranes (19). All have the common core structure ethanolamine-PO_4-Man-Man-Man-$GlcNH_2$-myoinositol-PO_4-lipid. Ethanolamine forms a bridge to the membrane protein, and the inositol phospholipid is inserted onto the lipid bilayer of the cell's plasma membrane. There are certain protein-specific and species-specific modifications to this basic structure (for further information see Ref. 19).

INFLUENCES ON THE GLYCOSYLATION PROCESS

Ultimately, the process of glycosylation is controlled by the activity of glycosyltransferases and glycosidases, the ac-

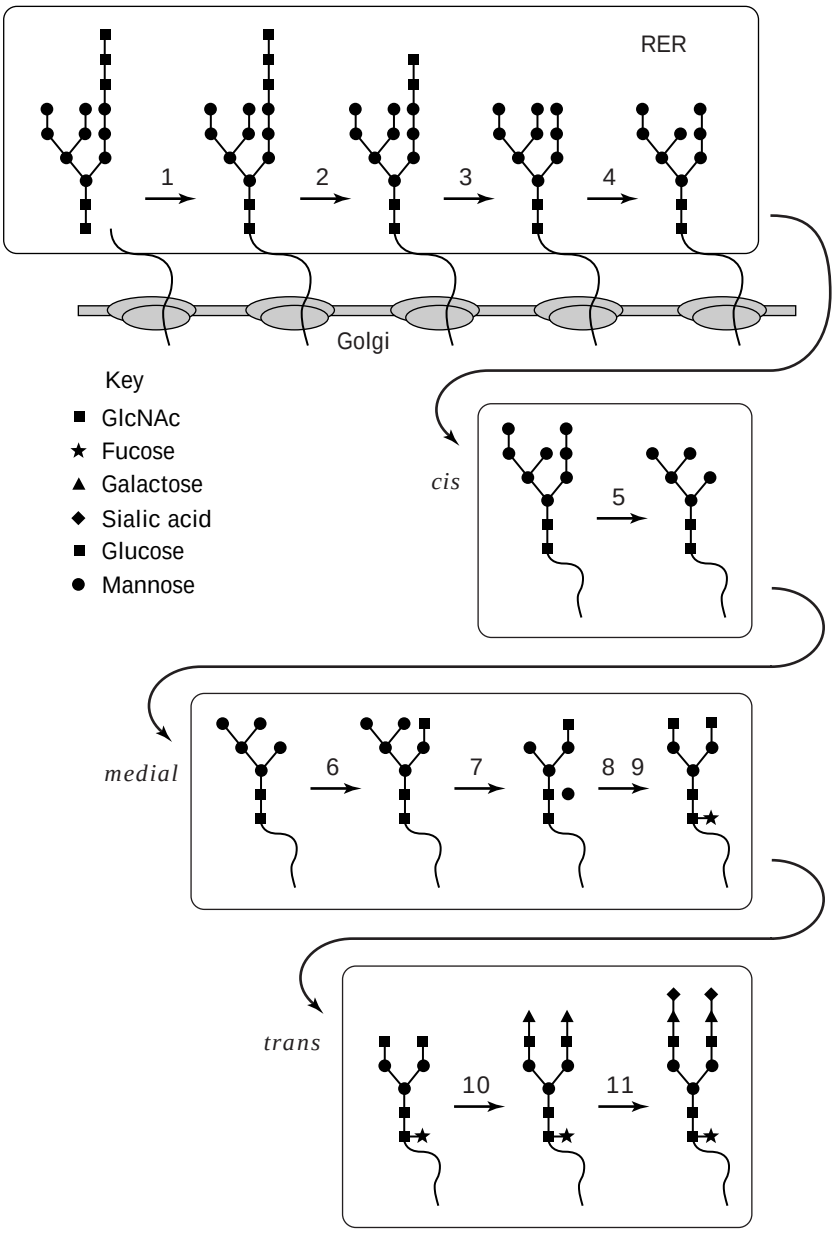

Figure 2. Steps in the N-glycosylation pathway. RER, rough endoplasmic reticulum.

cessibility of their glycan substrates on the glycoprotein, and the availability of cofactors and nucleotide sugar donors (e.g., CMP-NeuAc, GDP-Man, and UDP-GlcNAc). At the cellular level, these control points are influenced by the secondary and tertiary structure of the protein in the ER and Golgi, and the host cell type chosen for the recombinant protein expression and its physiological status.

As more recombinant glycoproteins are used therapeutically and for vaccines, the importance of correct glycosylation has become evident. The availability of alternative expression systems for producing recombinant glycoproteins, together with advances in analytical methods for glycans, has enabled comparisons to be made between glycoproteins from different sources. Crucially, the authenticity of recombinant glycoproteins compared to their natural human counterparts can be assessed, and choices made, concerning the most appropriate expression system.

Host Cell Line

Microbial cells are often the first choice for recombinant protein expression because of their high yields and simple media components. However, common bacterial expression systems such as *Escherichia coli* are incapable of expressing large proteins with authentic mammalian-type glycosylation. Hypermannosylation (the addition of a large number of mannose residues to the core oligosaccharide) is a common property of most yeast strains and can compromise the efficacy of recombinant protein vaccines (20). There is also some evidence to suggest that different O-glycosylation sites are used by yeast and mammalian cells (21).

The few studies reporting the production of therapeutic proteins in plants have suggested smaller *N*-glycan structures are present compared with mammals and lack outer residues such as sialic acids, which may compromise activity. Another obstacle may be the presence of potentially allergenic residues such as core α1-3-linked fucose and xylose (22) and substantial activity of endoglycosidases causing glycan cleavage.

The baculovirus-infected insect cell expression system has been used to express complex proteins and its short production time gives it an advantage over stable mammalian expression systems. Several cell lines have been developed using this technique, including *Spodoptera frugiperda*–derived cell lines Sf9 and Sf21 and *Estigmena acrea*–derived cell line Ea4. Some studies have shown that this system can attach complex oligosaccharides (23) using Sf9 cells, although this result is controversial because other researchers have shown that only simple oligomannose structures can be observed with Sf9. Other insect cell lines differ in their glycosylation capacity; for example, the Ea4 and *Trichoplusia ni* (TN-368) cell lines have been shown to add some complex antennary (GlcNAc and Gal) residues to glycoproteins (24,25).

Although most mammalian cell lines studied possess the intracellular machinery to perform complex N- and O-linked glycosylation to produce proteins that are not dissimilar to those of humans, there are some notable exceptions. Mouse and pig cells have a tendency to add NeuGc instead of NeuAc as the terminal sialic acid of glycoproteins. In contrast, NeuGc is absent from adult humans (due to inactivation of the CMP-NeuAc hydroxylase gene), and the NeuGc residue can be immunogenic (26). Rodents and pigs, like most mammals, express the enzyme α1-3-galactosyltransferase, which generates Galα1,3-Galβ1,4-GlcNAc residues on membranes and secreted glycoproteins. In humans, apes, and Old World monkeys the gene has become inactivated through frameshift mutations. For further details of specific glycosylation machinery in different cell types the reader is referred to another review (2).

Relatively few studies have been reported on the glycosylation of recombinant proteins expressed in the milk of transgenic animals. Those published from experiments in transgenic goats (27) and mice suggest that a lower level of sialylation and higher fucosylation may be achieved. It is now feasible to remodel glycoproteins in situ by the transgenic expression of extra glycosyltransferases in the mouse mammary gland (28). The use of human host cell lines poses a significant risk of retroviral transmission and is not generally favored by the regulatory authorities. Additionally, the transformation event required in most cases to produce a stable cell line may itself result in altered glycosylation profiles (29).

Cell Culture Conditions

It is well documented that the cell culture environment can influence both the macroheterogeneity and microheterogeneity of oligosaccharides in recombinant glycoproteins by affecting both the glycan biosynthetic process and the secretion or release of degradative enzymes, such as exoglycosidases (30). The process of adaptation from serum-containing to serum-free medium may lead to more heterogeneous glycans production in recombinant BHK-21 cells (31) and may improve galactosylation in recombinant CHO cells (14).

The ambient glucose concentration affects the amount of glycosylation of monoclonal antibody produced by human hybridomas in batch culture (32), and of IFN-γ produced by CHO cells in continuous culture (33). However, both lipids and nucleotides are also required for glycan biosynthesis. Lipid supplements alone or in combination with lipoprotein carriers can improve the N-glycosylation site occupancy of IFN-γ (34), and provision of cytidine and uridine can also alter protein glycosylation capacity of hepatocytes by increasing the availability of nucleotide sugars (35). Substances that are commonly used to increase productivity, such as sodium butyrate, should be checked for their influence on glycosylation (36).

Over time, an increase in the percentage of oligomannose (predominantly $Man_5GlcNAc_2$) and truncated structures has been observed in batch and fed-batch cultures of NSO myelomas producing recombinant IgG (37) and in interferon-γ made by recombinant CHO cells (38). Perfusion or chemostat culture of BHK-21 and CHO cells leads to a more consistent glycosylation pattern over time, and perturbations of nutrient availability (glucose or amino acids) can lead to changes in macroheterogeneity (33). Mild hypoxia has minimal effects on the glycosylation of tPA produced by recombinant CHO cells (39) but influences the level of sialylation of recombinant FSH (40). Similarly, pH changes within the range 6.9 to 8.2 in the cell culture medium do not have a dramatic effect on the glycosylation profile of recombinant placental lactogen expressed in CHO cells, however there is some evidence for underglycosylation outside this range (41). Increases in the concentration of ammonium ion in the culture medium above 2 mM may compromise sialylation (42). Degradative glycosidase enzymes have been detected in CHO cell lysates and culture supernatants, and sialidase is most active at neutral pH (43). This sialidase has been purified from culture supernatant of CHO cells (44) and can degrade glycans from proteins such as recombinant gp120. Although CHO cells also produce an α-L-fucosidase, this enzyme is incapable of releasing core fucose from intact recombinant glycoproteins (45). Sialidase, β-galactosidase, β-hexosaminidase, and fucosidase can also be detected at low levels in supernatants from mouse 293, NSO, and hybridoma cells, but the sialidase activity is much lower than that found in CHO cells (46). For more information, see GLYCOSYLATION OF RECOMBINANT PROTEINS.

EFFECTS OF GLYCOSYLATION

The presence, extent, and type of glycosylation influence the functional and structural properties of glycoproteins. Therefore, data acquired on the structure–function relationships of glycans present on one recombinant glycoprotein cannot always be applied to another. A complete listing of the structure–function relationships of glycans found on glycoproteins is beyond the scope of this article

(see Refs. 6 and 47); however, the main processes on which protein glycosylation has been shown to exert influence are the following:

1. Pharmacokinetics and clearance in vivo (particularly influenced by the extent of sialylation)
2. Immunogenicity, which is carbohydrate residue specific
3. Protein solubility and protease resistance (6,7)

REGULATORY CONSIDERATIONS

Because of the efficacy and safety considerations, both the Food and Drug Administration in the United States and the European Medicines Agency now demand more comprehensive carbohydrate analysis before licensing recombinant glycoproteins. It is important to understand that some degree of heterogeneity exists in most natural as well as recombinant glycoproteins. Therefore, current guidelines accept glycan heterogeneity, but it must be shown to be consistent within prescribed boundaries between lots of the finished product. The inherent glycan heterogeneity and its manipulation by genetic or enzymatic engineering poses interesting challenges to the patenting of glycoprotein drugs, and several patents have already been filed that claim to alter the glycosylation process for biotechnological purposes.

STRATEGIES FOR ANALYSING GLYCOPROTEINS

See also GLYCOSYLATION OF RECOMBINANT PROTEINS. Much of the increased knowledge concerning the influences on the glycosylation pathways and the biological significance of glycan variations has derived from recent advances in complex carbohydrate analysis. Using the appropriate equipment and techniques, it is now possible to unequivocally recognize most glycan structures and deduce their relative proportions in a complex glycoprotein. Current efforts are focused on improving the sensitivity of such techniques and making them more user friendly.

Sample Preparation

The glycoprotein must first be isolated and purified, and it is essential to know if it is secreted or membrane bound. The two classes of glycoproteins have different physicochemical properties; hence, the isolation protocol has to be adjusted for each type, with detergents usually required for membrane-bound proteins. Common precipitation and chromatographic techniques used for protein purification can generally be applied to glycoproteins. Chromatographic techniques tend to be based on charge, size, or affinity, and it is worth noting that of all the common sugar residues found in glycoproteins only the sialic acids are charged (negative). Also, protein A from *Staphylococcus aureus* Cowan I strain or proteins G and C from *Streptococcus*, which are commonly used to purify IgG, are both glycosylation independent. The purity of the glycoprotein can be assessed using SDS-polyacrylamide gel electrophoresis (expect multiple bands for complex glycoproteins and/or oligomers). Its yield can be quantified using protein stains (Bradford or Lowry method), A_{280}, HPLC, or immunoassays. We recommend performing at least two different assays to estimate protein yield because errors at this stage may have disastrous consequences for further analysis.

Preliminary Analysis

The simple SDS-PAGE gel analysis can be extended to yield data on the extent of protein glycosylation. For example, a portion of the sample can be digested with PNGase F (Oxford Glycosciences, U.K.) (to remove any *N*-glycans) and a combination of sialidase and *O*-glycanase (to remove *O*-glycans), and its mass shift compared on gels to that of undigested glycoprotein. Alternatively, kits are available, such as the FACE system from Dextra Laboratories (Reading, U.K.), which use a combination of isoelectric focusing gels and carbohydrate stains. Bear in mind that there are many other causes of protein heterogeneity than glycosylation: modifications such as proteolysis are common and will result in multiple bands. These preliminary tests are useful in estimating the degree and type of glycosylation and will help determine the final glycosylation analysis strategy.

Lectin blots may also be used to detect certain sugar residues or linkages (48). Lectins are carbohydrate-binding proteins that have been used successfully to identify and even isolate some glycoproteins. Lectin blots are a convenient way of identifying glycoproteins run on SDS-PAGE gels and then transferred to nitrocellulose sheets by techniques analogous to Western blotting. The blots are washed, blocked, and then incubated with the desired lectin that is already conjugated to a convenient enzyme (e.g., alkaline phosphatase or peroxidase) or light-generating compound. Control experiments using an appropriate competing saccharide should be run to verify that specific binding is being observed. Even using these controls, there are incidents of false identification, and we are reluctant to rely on these methods entirely. Similarly, colorometric assays are available to approximate the percentage of total sugars in each sample, but these assays are not very sensitive (5–10 nmol).

Glycopeptide Preparation

Glycopeptide preparation is often a prerequisite to establishing the location and structures of individual glycans within a complex glycoprotein. Controlled proteolytic cleavage may be carried out with enzymes such as trypsin and chymotrypsin (49). The exact protease to be chosen for depends on the size of the glycopeptides and its peptide substrate specificity; chemical cleavage, such as with cyanogen bromide, may also be employed. Care should be taken to prevent incomplete or nonspecific digestion because this can compromise the subsequent resolution of individual glycopeptides by reverse-phase HPLC (see later). Before enzyme or chemical cleavage it is desirable to modify any disulfide bonds present in the glycoprotein (50). This can be accomplished by reduction and carboxymethylation in the presence of a denaturant (8 M urea).

Releasing Glycans from Glycoproteins

There are a plethora of chemical and enzymatic methods that have been used to release carbohydrates from glycoproteins, with varying degrees of success (Table 1). The enzymatic methods (such as peptide-*N*-glycosidase F [PNGase F]) (see Table 2) used to cleave the glycosidic linkage between GlcNAc and the asparagine of N-linked glycans) generally preserve intact the peptides and glycans, but sometimes there are concerns over their efficiency (51). Most chemical cleaving methods such as hydrazinolysis (a nonselective method for releasing glycans using anhydrous hydrazine to cleave both N- and O-glycosidic bonds [Fig. 3]), tend to destroy the peptide at the glycosylation site(s). There is also a risk of further breakdown to monosaccharides and their degradation products; therefore the reaction must be carefully controlled (52). A clean-up step is often required before progression to further analysis. Following these preliminary steps (not all may be required), the analysis should progress to a combination of one or more of the techniques listed next. The strategy routinely used by us is described in Figure 4.

Gas–Liquid Chromatography

Gas–liquid chromatography GLC methods are highly efficient for the analysis of carbohydrates released from glycoproteins, especially volatile monosaccharide derivatives. A mass spectrometer can be connected to the GLC and used to characterize these resolved peaks, in comparison with known standards. Identification of each peak is achieved by the combination of its mass and the relative retention times (53). However, these GLC methods have largely been superseded for more complex oligosaccharides by HPLC alternatives, due to increased sensitivity, which enables smaller sample sizes to be analyzed.

High-Performance Liquid Chromatography

Analysis of glycopeptides or carbohydrate chains released from glycoproteins often requires high-resolution methods such as HPLC. The most common mode of HPLC for glycopeptide purification is reverse-phase HPLC (RP-HPLC), which separates on the basis of peptide, glycopeptide, or glycan hydrophobicity. Other modes employed are normal-phase partition and ligand exchange (49). RP-HPLC requires the presence of hydrophobic groups such as N-Ac-, deoxy-, -OMe, or OAc groups for longer retention time and better separation. Oligomannose- or high-mannose-type oligosaccharides (which have only two N-Ac groups) are retained on the RP-HPLC column and are not well resolved compared with complex-type oligosaccharides. Glycopeptides, released sugars (chemically or enzymically), or derivatized glycans can be resolved by HPLC and can be analyzed on a mass spectrometer. A common use for this technique is the separation of glycopeptides corresponding to individual glycosylation sites within a glycoprotein, following controlled proteolysis (50). The resultant glycopeptides are then analyzed by mass spectrometry and exoglycosidase arrays.

Table 1. Glycosidase Enzymes Used for Selective Cleavage of Oligosaccharides for Structural Analysis

Methods	Comments
Mild acid hydrolysis	Quantitative release of terminal nonreducing fucose
Strong acid hydrolysis	Quantitative release of hexose, deoxyribose, pentoses, and hexosamines
Methanolysis	Quantitative release of neutral monosaccharides and hexosamines
Hydrazinolysis	Nonselective release of glycans by cleaving both N-linked and O-linked bonds; can be optimized for specific N-linked or O-linked cleaving
Smith degradation	Quantitative release of monosaccharides
Acetolysis	Cleaves 1-6-linkages in oligosaccharides

High-Performance Anion Exchange Chromatography with Pulsed Amperometric Detection

Another procedure for the direct analysis of carbohydrates uses the high-performance anion-exchange mode (utilizing pellicular resin columns) of HPLC with pulsed amperometric detection (HPAE-PAD, pioneered by Dionex [54]). This is suitable for the analysis of released N- and O-linked glycans in quantities >0.2 nmol (55). Oligomannose-type glycans are eluted at low alkali concentrations, and an increase in the content of neutral sugar residues results in higher retention times. The negatively charged glycans that contain sialic acids are retained most. The method can also be used for analyzing released monosaccharides, such as resolving different forms of sialic acids, with a detection limit of around 20 pmol.

Capillary Electrophoresis

Capillary electrophoresis (CE) is an emerging technology that may be used for direct analysis of oligosaccharide derivatives (56). The main advantages of CE are its simplicity and high resolving power. There are a number of modes of operation that have been developed for CE, for example, free-zone capillary electrophoresis (CZE), micellar electrokinetic capillary chromatography (MECC) (57), affinity electrophoresis, gel electrophoresis, isoelectric focusing (IEF), and isotacophoresis. The method can be used for resolving released glycans, glycopeptides, or glycolipids (58), and the sensitivity of CE can be improved by employing a laser-induced fluorescence detector (59).

Mass Spectrometry

Mass spectrometry has proved to be an invaluable tool for glycosylation analysis. There are a number formats that can be used, such as electrospray ionisation mass spectrometry (ESI-MS) (60), liquid chromatography mass spectrometry (LC-MS) (61), and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) (49,50) (Fig. 4). In MALDI-TOF, which is more tolerant to common salts, a variety of matrices have been developed to maximize ionization of glycopeptides or released glycans (62).

Table 2. Glycosidase Enzymes Used for Selective Cleavage of Oligosaccharides for Structural Analysis

Enzyme	Source	Specificity	pH
PNGase F	*Flavobacterium Meningosepticum*	N-Glycosidic linkage between GlcNAc and asparagine	7.0
Endoglycosidase H	*Streptomyces plicatus*	Oligomannose and hybrid-type *N*-glycans within the chitobiose core	5.0
α-L-Fucosidase	*Aspergillus niger*	Fucose α1-2-galactose	3.8
	Bacillus fulminans	Fucose α1-2-galactose	6.6
	Clostridium perfringens	Fucose α1-2-galactose	6.0
	Corynebacterium	Fucose α1-2-galactose	8.5
	Almond emulsin	Fucose α1-3 and 4-GlcNAc	5.5
	Bovine epididimis	Nonspecific	6.5
	Charonia lampas	Nonspecific	3.3
	Turbo cornutus	Nonspecific	4.0
α-D-Galactosidase	*Aspergillus niger*	Galα1-3Gal	4.5
	Coffee bean	Nonspecific	6.0
	Fig	Nonspecific	6.0
β-D-Galactosidase	Jack bean	Galβ1-6GlcNAc > Galβ1-4GlcNac > Galβ1-3GlcNAc	3.5
	Streptococcal 6646K	Galβ1-4GlcNAc > Galβ1-3GlcNAc	5.5
	Aspergillus niger	Galβ1-4GlcNAc > Galβ1-6GlcNac > Galβ1-3GlcNAc	4.0
α-D-Mannosidase	Jack bean	Manα1-2 > Manα1-6 > Manα1-3	4.0
	Aspergillus niger	Manα1-2 and Manα1-4 > Manα1-6 > Manα1-3	4.5
	Aspergillus saoti	Manα1-2	4.5 5.0
β-D-Mannosidase	*Helix pomitia*	$ManGlcNAc_2Asn$	4.5
β-*N*-Acetylgalactosaminidase	*Aspergillus niger*	GalNAc (terminal)-Ser	3.5
β-*N*-Acetylhexosaminidase	Jack bean	GlcNAcβ1-2,3,4,6	6.0
	Aspergillus niger	GlcNAβ1-3,4	5.0

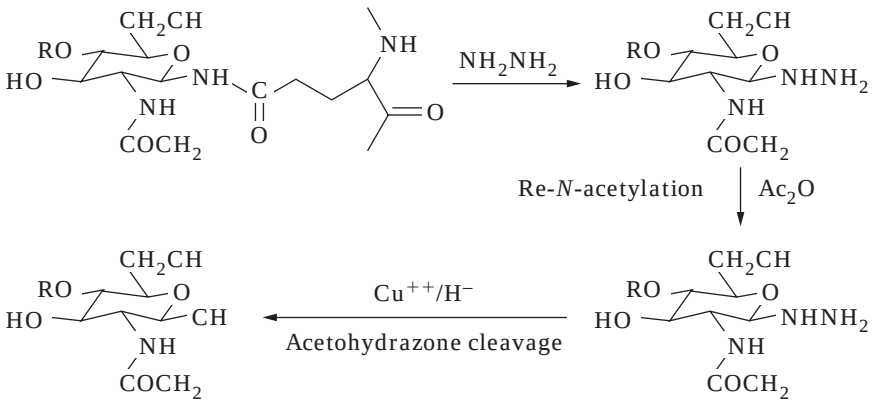

Figure 3. Hydrazinolysis reaction used to release glycans from glycoproteins.

Exoglycosidase Arrays

One of the most powerful methods for the elucidation of glycan structure uses an array of exoglycosidases (Table 2). These enzymes recognize predominantly the terminal nonreducing monosaccharide residues of glycans, glycopeptides, or whole glycoproteins and can be used to determine the anomeric configuration and glycosidic linkage of this terminal. Time can be saved by constructing a parallel array of these enzymes in combination (63), and the resultant mixtures can be analyzed by mass spectrometry (30,49) or by HPAE (64). Here, differences in mass or resolution time corresponding to the loss of specific sugar residues are determined.

Sialic Acid Analysis

Because of the importance of sialic acid in influencing half-life and protein stability, sialic acid analysis acquires a special significance, particularly for biopharmaceuticals destined for human therapy. Sialic acid is a collective term used to describe several derivatives of neuraminic acid. The neuraminic acid occurring in glycoproteins is usually substituted with an *N*-acetyl or *N*-glycolyl group in a species-specific fashion (2). Sialic acids can also be derivatized with *O*-acetyl, *O*-lactyl, or *O*-methyl groups, but these are rarer in natural glycoproteins. Each type of sialic acid has a characteristic mass/charge ratio that is recognizable by mass spectrometry; however, for detailed quan-

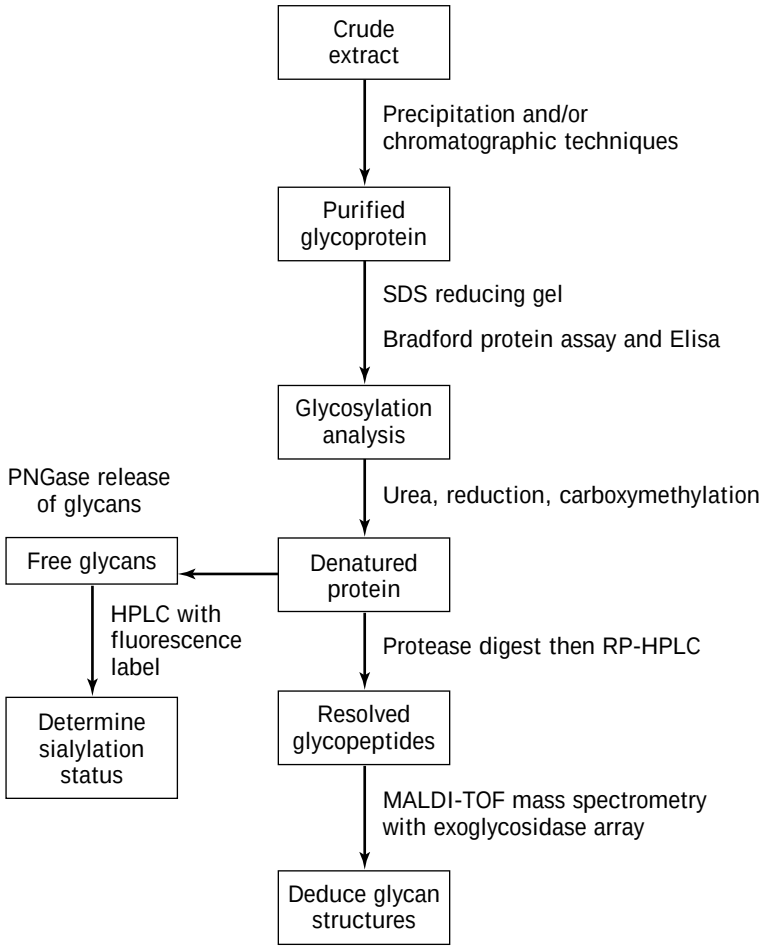

Figure 4. A strategy for glycan analysis at each glycosylation site.

tification it is often necessary to release the sialic acids from the glycoprotein by acid hydrolysis or by linkage-specific neuraminidases (65). Released sialic acids can then be analyzed by HPLC or HPAE (see earlier).

CONCLUSIONS

Glycobiology has advanced dramatically as people become aware of the biological implications of carbohydrate heterogeneity. Over the past five years, there has been a move away from simple monosaccharide composition analysis or gel estimates of glycan heterogeneity toward more sophisticated forms of analyses using techniques such as CE, mass spectroscopy, fluorescence HPLC, and HPAE. Regulatory authorities such as the U.S. Food and Drug Administration are demanding increasingly sophisticated carbohydrate analyses as part of the product or process validation (66). In addition to these analytical trends, there is increasing awareness of the relevance of glycosylation in producing a product with a good therapeutic profile and a high degree of batch consistency.

OUTLINE

INTRODUCTION

For the large-scale production of proteins, complex separation procedures are necessary after protein synthesis by living cells is completed. In comparison to downstream processing in the chemical industry, the separation of proteins must be very gentle to conserve the native structure, which means that in general near-neutral pH values and moderate temperatures ($\leq$30 °C) must be maintained. Important objectives in separation are high selectivity and yield because multistep procedures are usually required. Because of the polar character and high molecular mass of proteins, several unit operations common in the chemical industries cannot be applied, for example, distillation or extraction into organic solvents. Aqueous two-phase systems, however, can be used with advantage for protein isolation by liquid–liquid extraction. The technique is based on the incompatibility of two different hydrophilic polymers in the common solvent water or the reversible hydration of oxygen in polyethers.

In an aqueous liquid–liquid extraction process, cells and cell debris and other unwanted substances should remain in one phase while the desired protein is partitioned into the other phase, preferentially the top phase. The phases are separated and further processed until the desired level of product purity is reached. The extraction of proteins is performed preferentially at early stages of an isolation process using cell homogenates or whole fermentation broth because this allows the concomitant removal of solids, a product enrichment and concentration in a single step.

Partitioning of proteins by aqueous liquid–liquid extraction has been well described (1–6) and finds increasing application for large-scale processes in industry. For further reading the monographs by Albertsson (4) and especially by Walter et al. (5) are recommended. The latter gives detailed information about handling principles and applications. The Aqueous Two-Phase (a.k.a. Biphasic) Systems Community home page has a bibliography compiled by Harry Walter that contains more than 1,000 files of journal publications on aqueous two-phase systems published between 1956 and 1996: *http://radar.ch.ua.edu/~aq2phase/*

BIOCHEMICAL FUNDAMENTALS

Miscibility gaps exist in different aqueous systems; these are based on polymer–polymer interactions, polymer–salt interactions, or thermoseparation. A special case is affinity extraction, which can be viewed as a reactive extraction process. For further descriptions see “Alternative Two-Phase Systems”.

Principles of Aqueous Two-Phase Extraction

Most of the hydrophilic, natural, and synthetic polymers are miscible with water and show phase separation in a mixture with another polymer or salt. The phase diagram of polyethylene glycol (PEG) and potassium phosphate in Figure 1 demonstrates the miscibility of polymer and salt phases. Above the curve (binodal) the system separates into two liquid phases. If PEG and salt are mixed in a percentage represented by a point *M* above the binodal, the mixture separates along the tie-line. The composition of the two resulting phases are represented by the cross-points of the tie-line and the binodal. The volume ratio of the PEG-rich phase to the salt-rich phase is given approximately by the ratio of the tie-line sections *MB* and *TM*. The critical point is reached when the tie-line is represented by only one point on the binodal. At the critical point, the addition of an infinitesimally small amount of water results in two phases of equal volume and composition; therefore, any added component should have a partition coefficient *K* of 1, where *K* is defined as the ratio of concentration in the top ($c_{i,\mathrm{T}}$) and bottom phase ($c_{i,\mathrm{B}}$)

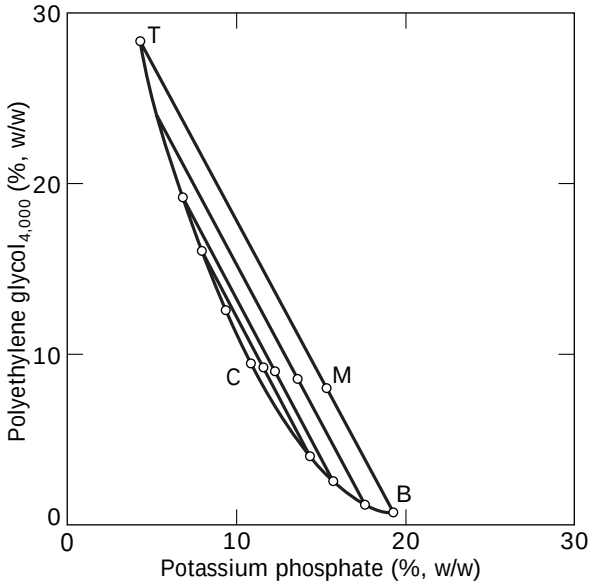

Figure 1. Phase diagram of PEG 4,000–potassium phosphate at 20 °C. *Source*: Ref. 4.

$$K = \frac{c_{i,T}}{c_{i,B}} \tag{1}$$

With increasing length of the tie-line the composition of the phases at equilibrium diverge and consequently K changes.

It must be noted that phase diagrams are altered by addition of other components in sufficient concentration such as cell homogenates and different salts (7,8). Nevertheless, the phase diagram is useful for the selection of phase systems. Many phase diagrams of polymer–polymer and polymer–salt systems can be found in Refs. 4 and 6. An extraction system is usually designed such that the wanted protein partitions predominantly to the top phase (PEG, in this case) and the undesired material including cells and cell debris partitions to the bottom phase (salt). The separation power of a system is characterized by the yield Y, the separation factor G, depending on the volume ratio R, and K. The yield in the top phase is defined as

$$Y_T = \frac{n_T}{n_T + n_B} \tag{2}$$

or consequently as

$$Y_T = \frac{1}{1 + \left[\frac{V_B}{V_T} \cdot \frac{1}{K}\right]} \tag{3}$$

where n is the molar quantity of the desired protein in the volume of the top (V_T) and bottom phase (V_B), respectively. G is defined as the product of the partition coefficient K and the volume ratio R. The definition of the volume ratio is given in equation 5.

$$G = K \cdot R \tag{4}$$

$$R = \frac{V_T}{V_B} \tag{5}$$

Y, K, and R affect each other. Usually Y_T increases if K is increased at a constant R or if R is increased at a constant K (Figure 2).

K does not depend on the concentration of the protein i, so long as the concentration c_i is much smaller than the concentration of the phase-forming polymers, and no complex formation takes place. According to Bronstedt (9), there exists an exponential relation between K and the surface area (molecular mass) of i:

$$\ln K_i = \frac{\alpha \cdot A_i}{k \cdot T} \tag{6}$$

α is a factor related to the chemical potential, A_i is the surface for interaction, k is the Boltzmann constant, and T is the absolute temperature. Thus, cells and cell debris should exhibit one-sided partition approaching zero or infinity even at low values of α because of their large value of A, while metabolites should have K values approximately 1 and proteins usually between 0.1 and 10. The relation between $\ln K$ and A has been capitalized in a process to isolate hepatitis B surface antigen particles (molecular weight, $\simeq$ 1 to 2 million Da) as a hepatitis B vaccine from recombinant yeast cultures (10). Equation 1 is valid for the equilibrium between two liquid phases only; however, sometimes a solid phase seems to be involved and rather large values of K may result as a consequence of preferential solubility of i under extraction conditions in the top phase of PEG–salt systems (11). In such a case, K will increase with c_i.

Factors Determining Partitioning

The forces that cause partitioning can be explained in a first approximation by splitting the partition coefficient into increments:

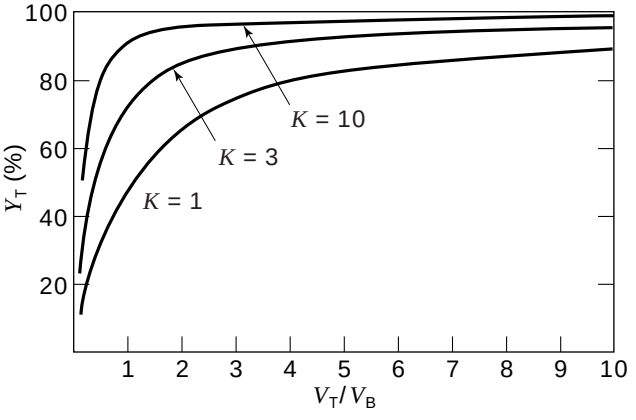

Figure 2. Interdependence of yield (Y), partition coefficient (K), and volume ratio (R). *Source*: Ref. 8.

$$\ln K = \ln K_{ion} + \ln K_{hphob} + \ln K_{hphil} + \ln K_{conf} + \ln K_{lig} \quad (7)$$

where K_{ij} denotes the partition coefficient from charges or hydrophobic or hydrophilic forces or its dependence on conformation or ligand interaction, respectively (12). Only $\ln K_{lig}$ is to some extent predictable. For this reason, affinity extraction is much studied, because the affinity interaction can be made to dominate ln *K*. Even in the absence of affinity interactions many parameters will influence the partitioning of proteins in aqueous two-phase systems, affecting the partition coefficient and the selectivity.

These factors are as follows:

- Selection of component(s) to form a two-phase system
- Concentration of polymers used
- Molecular weight of the polymers
- Type and concentration of ions
- pH
- Temperature
- Addition of other agents (e.g., chaotropic agents) (13,14)
- Concentration of cells and cell debris added

The strong influence on the partition of only small changes in the system composition is shown in Figure 3, where the partition coefficient for L-2-hydroxyisocaproate dehydrogenase is changed significantly by addition of potassium phosphate and the resulting change of the tie-line.

The molecular mass of a given polymer can strongly influence the partition of a protein. The partition coefficient can be increased by increasing the molecular mass of the bottom phase forming polymer (for example, dextran 1) or by lowering the average molecular mass of the top-phase-forming polymer, most often PEG (1,4). The latter represents a fast and convenient way to increase protein yield in the top phase and is aided by the fact that the polymerization of ethyleneoxid can be easily adjusted to yield different molecular weight fractions of PEG. Several fractions are commercially available and are included in the pharmacopoeia of many countries. Changes in pH affect the ionization of side chains of the protein and therefore the charge and polar/hydrophobic balance of the surface; it will also alter the ionization of some weak and multivalent acids present in the extraction mixture leading to changes in *K*. pH values are easily manipulated in the range of protein stability. The addition of ions has a remarkable effect on *K* (1,4) by altering the length of the tie-line and the solvating power in PEG–salt systems as well as changes in the electrochemical potential across the interface in polymer–polymer systems.

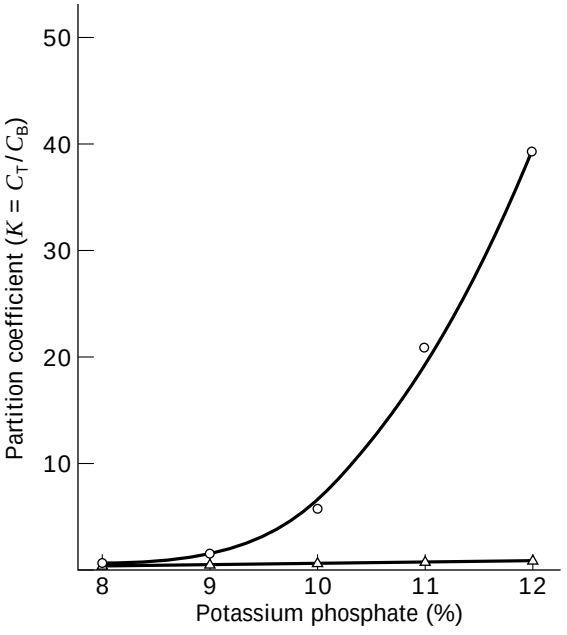

Figure 3. Partition of L-2-hydroxyisocaproate dehydrogenase (○) and D-lactate dehydrogenase (△) as a function of potassium phosphate concentration. *Source*: Ref. 15.

The search for a separating system of a new protein is usually carried out by trial and error guided by the heuristic rules discussed previously. A series of phase systems differing in one parameter are produced in the scale of 5.0–10.0 g using a statistical design. A nice example of a statistical approach is shown by Hart et al. for the isolation of nonnative IGF-I (16). *Y*, *K*, and *R* are determined as well as protein concentration. From this information, a useful extraction system can be derived that can be further optimized with regard to specific goals, such as product yield and quality. Other criteria for optimization are biodegradability, ease of recycling, toxicity of phase-forming chemicals, physical properties of extraction systems, and last although not least the total costs (see "Economic Aspects").

For research purposes, the most investigated system is the PEG–dextran (1) combination. Both polymers are commercially available in different molecular weight fractions. For technical applications, fractionated dextran is too expensive; crude dextran may be used in low concentrations (17,18), but results in high-viscosity bottom phases. A less expensive possibility is PEG–salt systems, which are commonly used for large-scale applications (8). Other alternatives are reported (19,20). When substituting other polymers for dextran, for example, the limiting concentration for phase separation needs to be considered as well as product yield and quality. Combinations of the different systems are possible, like polymers and surfactants (21,22) or affinity partitioning combined with temperature-induced phase separation (23).

For large-scale operations, questions of waste disposal and the possibility of recycling auxiliary chemicals are of increasing interest for environmental as well as economic reasons. These topics are discussed separately under "Applications".

Thermodynamics

Phase separation in aqueous systems and partitioning of proteins are governed by thermodynamic forces. Because thermodynamics including mathematical models of aqueous two-phase systems cannot be explained in a few sentences, the reader is referred to the literature. For a

broader introduction, the review by Cabezas (24) should be consulted.

Phase separation is based on the Gibbs free energy of mixing and will occur if ΔG^{mix} of two phases becomes energetically more favorable than ΔG^{mix} of a single phase:

$$\Delta G^{mix} = \Delta H^{mix} - T\Delta S^{mix} \quad (8)$$

where ΔH^{mix} and ΔS^{mix} are the enthalpy and entropy of mixing and T is the temperature. ΔG^{mix} is related to the excess enthalpy G^e by

$$\Delta G^{mix} = G^e + RT \sum_i x_i \ln x_i \quad (9)$$

where x_i is the mole fraction of the different phase components i.

There is a large diversity of polymer–polymer models available, such as Edmond and Ogston-based models using McMillan–Mayer or Hill virial expansions (25,26), Flory–Huggins–based lattice models using the classical polymer solution theory (27,28), the UNIQUAC lattice model (29), integral equation theory-based models (30), the VERS model based on group contributions of salt and polymer (31), and the excluded volume theory based on statistical geometric arguments (32). A comprehensive discussion can be found in a recent paper by Johansson et al. (33). The problem for most of these models is that they include theories derived for gases or crystalline solids. They have advantages and disadvantages, such as too many parameters, time-consuming experiments to obtain parameters, and derived parameters that are valid only for a certain range of conditions.

An interesting approach to solve binodales for PEG–dextran systems is shown by Baughman and Liu (34). They used about 100 different binodales and protein partitioning data from other investigators as raw data for an expert system based on a neural network, resulting in quantitative predictions for unknown phase diagrams. To predict protein partition away from the isoelectric point the results were not satisfactory, however. In polymer–salt systems most of the electrostatic interactions are screened by the high salt concentration of the phases, which makes modeling more complicated. Only a few models have been developed based on virial expansions (31), integral equation theory (30), and a potential of mean force model including fluctuation solution theory (35).

Until now a reliable prediction of protein partitioning in aqueous two-phase systems for a random protein has not been possible. The systems are too complex, depending on pH, salt, polymer, protein structure, temperature, specific interactions, and charge distribution on the protein surface. The aim to minimize experiments for certain systems and predict trends is advancing. The problem with the model experiments is that they rely upon commercially available cheap proteins, which have strong specific interactions, however, such as lysozyme or α-chymotrypsin in which dimerization or self-digestion occurs. These effects in aqueous two-phase systems have not been studied extensively. Work has been done to predict peptide partitioning (27,36–38). Predictions have improved over recent years for certain peptides and amino acids, but depending on the sequence, predictions do not work well yet in general.

The diverse models describe phase separation reasonably well but a state-of-the-art model is not available (24). The interaction between proteins and solutions needs more attention to understand protein partition and describe it in quantitative terms based on fundamental principles. This goal will be elusive for quite some time to come. Fortunately it is very easy to determine K values experimentally so long as an appropriate specific assay is available.

ALTERNATIVE TWO-PHASE SYSTEMS

In addition to the commonly used polymer–polymer and polymer–salt systems, there are some alternative, also well-investigated, aqueous two-phase systems.

Affinity Extraction

Ligands covalently bound to one of the phase-forming components are useful to direct the extraction of certain proteins because the ligand will predominantly partition with the polymer in one phase. There exists a linked equilibrium of partition and complex formation, as shown in Figure 4. The extraction efficiency depends on the number of binding sites of the protein and the dissociation constant of the complex. The latter may be different in the top and bottom phase (39,40).

Affinity ligands can be cofactors or inhibitors of the target protein. General ligands based on textile dyes are more often used than natural ligands. Besides textile dyes, metal chelators are attractive as general ligands. These are robust, cheap chemicals applicable in PEG–salt systems and offering useful selectivity. The syntheses of PEG derivatives has been described by Harris (41). Johansson et al. (42) investigated the partition of phosphofructokinase from yeast. The partition coefficient increased by a factor of 10^4 compared to physical extractions using the pseudo-affinity ligand cibacron-blue in an affinity process (Fig. 5).

The effectivity of affinity extraction was also demonstrated by Kroner et al. (43). With increase of the amount of PEG blue, the partitioning coefficient K increases. A yield of 98% could be obtained thereby with a single extraction step. Other parameters than the ligand concentration (43) are the polymer concentration (44), the kind of salt and its concentration (42), the pH value (45), the temperature (45), and the addition of free ligands (44,45). Useful models describing affinity extraction have been derived by Cordes et al. (40) and Suh and Arnold (46).

An example of screening for a suitable dye can be found in a patent of Guliano and Szlag (47) describing experiments with the triazin dyes Cibacron-Blue FGF, Procion Turquoise H-A, Procion Green HE-4BDA, and Procion Red HE-3B to separate alcohol dehydrogenase. Large-scale applications of affinity extraction are listed later. Reviews of polymer–ligand systems have been published by Johansson (48) and Johansson and Tjerneld (49). It can be expected that specific ligands originally selected from libraries of suitable synthetic chemicals or peptides for affinity

chromatography will find applications also in affinity extraction.

Detergent-Based System

A recent development is the two-phase extraction in aqueous two-phase systems based on nonionic detergents carrying ethylenoxide groups as the hydrophilic moiety. The protein is partitioned using only one auxiliary chemical. The principle is shown in Figure 6. At low temperature, a homogeneous phase containing micelles of the detergent and fermentation broth exists. The detergent interacts preferably with hydrophobic proteins. As soon as the temperature is increased above a certain system-dependent temperature, turbidity develops as an indicator of phase separation. The so-called cloud point depends mainly on the average number of ethylene oxide groups; a narrow range is desirable. A C12EO5 detergent, for example, has a cloud point between 23 and 25 °C. The phase separation depends on the reversible, temperature-induced dehydration of the ether oxygens in the detergent and leads to a detergent-rich and a detergent-depleted phase in equilibrium. The micelles are believed to aggregate into laminar structures carrying hydrophobic proteins into the so-called coazervate phase, which may still contain 70–80% water (50).

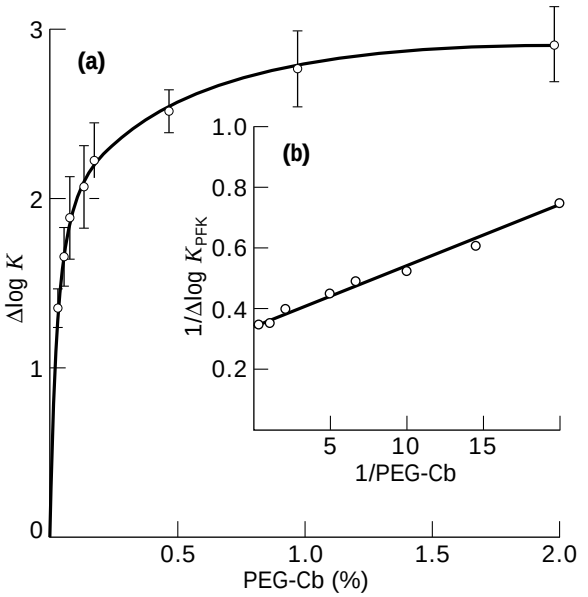

Figure 5. Changes of the partition coefficient of phosphofructokinase depending on the amount of added ligand. *Source*: Ref. 42.

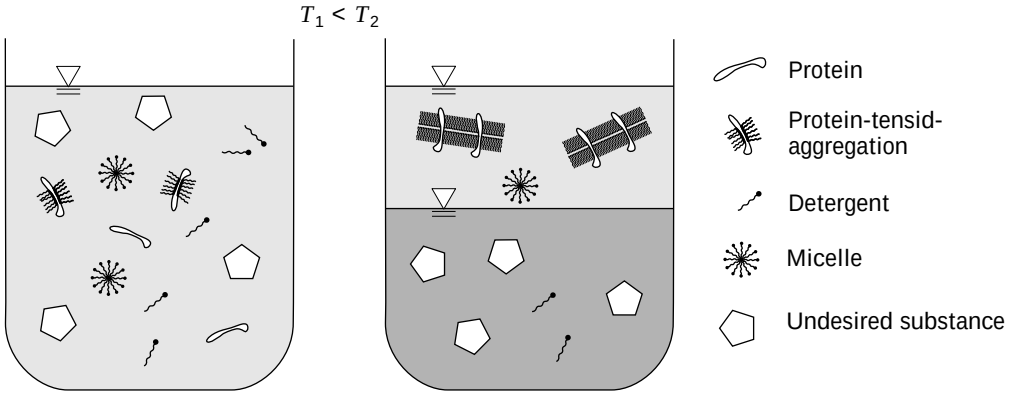

Figure 6. Schematic illustration of aqueous detergent solutions below and above the cloud point.

Bordier (51), Minuth et al. (52), and others investigated cloud-point extraction of proteins. Nonionic or zwitterionic detergents are most useful for the separation of membrane proteins (53,54). A complete process design for the purification of cholesterol oxidase is presented in Figure 7. A scale-up study indicated that the rather low density difference in detergent-based systems limits phase separation by centrifugation in the initial step (56).

It has been shown that the detergent for extraction of hydrophilic proteins and membrane-bound proteins should be chosen with respect to its hydrophile–lipophile balance (HLB) (57). Table 1 shows partitioning results using Tritons with different HLBs for the separation of an endopeptidase in the presence of sodium chloride. Yield, concentration factor, and partitioning coefficient increased significantly with an increasing HLB.

Reversed Micelles

Because it is similar to aqueous liquid–liquid extraction, reversed micellar protein extraction is mentioned here briefly. Reversed micelles extract proteins into the water pool contained in the micelles present in an organic solvent depending on the isoelectric point of the protein and therefore pH and ionic strength in the process solution. The principle is shown in Figure 8. The organic solvent allows the organization of the reversed micelles and the separation of the bulk water from the water pool in the micelles.

Extraction into reversed micelles has been investigated for several industrially relevant proteins, but these are apparently not yet used in industry (58,59). The major remaining problem is the difficult reextraction of the bioactive protein into an aqueous phase and the reuse of reversed micelles.

Thermoseparating Polymers

Certain polyethylene–polypropylenoxide copolymers also show reversible dehydration of the oxygen groups in an interesting temperature range and have been investigated by Alred et al. (60), Johansson et al. (61), and recently by Persson et al. (62) for application in aqueous two-phase systems. Usually a polymer–polymer system is used in the first step selected to partition the protein in the copolymer-rich phase. After primary phase separation, the solution is heated above the cloud point, which results in phase separation under conditions in which the protein is almost exclusively found in the polymer-depleted phase.

APPLICATIONS

Technical Aspects

Aqueous liquid–liquid extraction uses the same principles as the well-known chemical process of liquid–liquid ex-

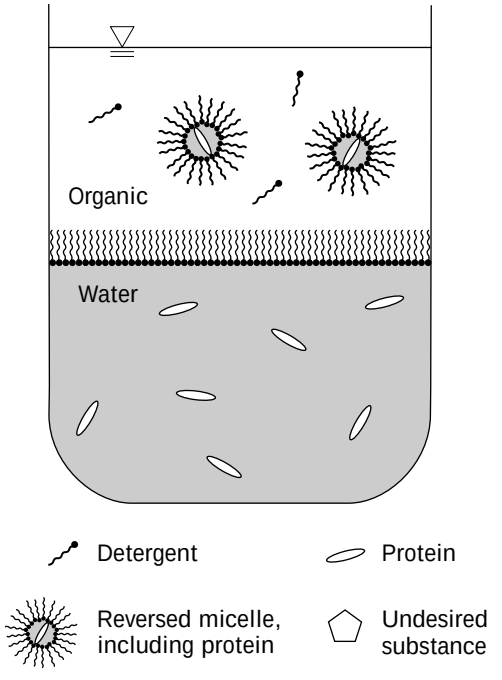

Figure 8. Operating principle of extraction into reversed micelles.

traction. Therefore similar, commercially available equipment may be used for mixing and phase separation. The physical properties of aqueous two-phase systems, however, are very different from those of solvent–water systems. The most notable difference is the dramatically lower interfacial tension (Table 2).

In general, for the purification of an intracellular protein the cells are disrupted, the phase-forming components added, and the pH adjusted; the suspension is then mixed to reach equilibrium. In large-scale processes this is done in a stirred vessel with baffles or using static mixers (63). An extremely low energy input is needed because of the low interfacial tension of the whole system. The approach to equilibrium is surprisingly fast (≤30 s), as demonstrated by Fauqueux et al. (64), provided turbulent mixing is ensured. After equilibration is reached the phases should separate into a top and bottom phase. This separation can be done under unit gravity or can be speeded up by centrifugation. The latter is recommended if the viscosity is high or the density difference between the phases is low (8). Centrifugation gives higher yields as entrainment is avoided at higher *g* forces; optimal feed rates of the suspension up to 3 L/min corresponding to residence times of about 16 s have been reported using small disk stack separators (8).

After the initial separation step, the top phase is often mixed with salts to generate a secondary phase system. Conditions are selected such that the protein of interest is partitioned to the bottom phase and can be further processed after phase separation (Fig. 9). Other possible procedures for the isolation of proteins from polymer phases are centrifugation, adsorption, ultrafiltration, or electrophoreses (66). In large-scale processes, ultrafiltration or diafiltration is used to concentrate and condition the product from the secondary bottom phase. The top phase may be recycled (52,67). A secondary bottom phase may be applied under certain conditions to a chromatographic support, such as hydrophobic interaction matrices.

Extraction usually is performed in the batch mode, but often it may be more cost-effective to use a continuous process. In general there are three possibilities of continuous processing in production lines: the co-, cross-, and countercurrent flow. The three modes are illustrated in Figure 10, and a comparison of specific properties is shown in Table 3. In large-scale processes the counter-current method should be the most efficient because of a higher yield and lower consumption of chemicals (63). Countercurrent extraction has been studied for the multistep procedures discussed next. The continuous cross-current extraction has been investigated experimentally in pilot scale. Enzyme extraction has been successfully carried out using more than 500 kg yeast per day in a computer-controlled process (68). The procedure could also be applied to extract enzymes continuously from bacterial cell homogenates (69).

To achieve a higher purification, multiple partition steps would be required. Not every multistage apparatus used in the chemical industry for liquid–liquid extraction is suitable for operation with aqueous phases as the physical properties of the two phases are too similar and the interfacial tension too low. The performance of the Graesser contactor has been best investigated. For the separation of α-lactalbumin from whey, a space time yield of 29 g/L reactor volume and day was achieved (70). The speed of rotation in the "raining bucket contactor" had to be reduced from the usual 20 U/min to 2–5 U/min, working with PEG–salt systems (71). In addition, the rotational direction was reversed to reduce the intensity of mixing and to avoid flooding. Other apparatus investigated for multistage extractions are mixer-settler, Kühni columns (72), the Podbielniak extractor (1), and spray columns (73). All can be operated successfully with specific precautions against flooding. Changing operating conditions such as pH or the length of the tie-line, however, may be more effective for protein purification than multiple partition steps.

At Miles Inc., a conventional downstream process was compared to an operation using aqueous two-phase systems and *Bacillus* alpha-amylase as an example (74). The latter was carried out in a 50,000-L large-scale process (Fig. 11). In this example the extraction process in aqueous two-phase-systems required fewer steps, resulting in higher yield and lower costs.

Recycling of Process Chemicals

To lower high chemical and waste disposal costs, recycling or recirculation of the auxiliary chemicals is recommended. Recycling of phosphate by crystallization at 6 °C has been described from solid-free process streams (8). The successful recirculation of most of the PEG has been demonstrated by Papamichael et al. (75) and of detergents by Minuth et al. (55) (see Fig. 7). The recovery of salt from the primary bottom phase was accomplished by Greve and Kula (76) making use of miscibility gaps in the ternary-phase systems—water–salt–lower aliphatic alcohols (Fig. 9). The authors also presented an economic analysis (76). In principle, the material balance of the auxiliary chemicals introduced into the process stream to accomplish phase separation can be closed more than 90% by recycling, yielding cost-effective and environmentally acceptable procedures.

Large-Scale Applications

tion is scarce. In Table 4, a list of patents and large-scale applications (beginning in 1982; minimum, 24-kg cells) described in the literature is compiled. The size of the operation reached 50,000 L or more (74). Usually centrifugation is preferred in the initial phase separation. (An example is illustrated in Fig. 11.)

Scale-Up. One big advantage of aqueous liquid–liquid extraction is the ease of scaling up. Hart et al. (89), Schütte et al. (93), and Kroner et al. (94) showed that scale-up is feasible by proportional linear increase of the amount of ingredients. The necessary centrifugation equipment is commercially available and can be selected using the Sigma concept. In Figure 12, scale-up data of Kroner et al. (94) are presented for the purification of formate dehydrogenase from *Candida boidinii* in PEG–potassium phosphate. A scale-up of nearly 40,000 was carried out for different separation steps without significant changes in yield.

Economic Aspects. The costs of the protein recovery and enrichment by aqueous liquid–liquid extraction is of course highly dependent on the actual system, scale, etc. As an example Kroner et al. (95) analyzed the cost structure for extraction and compared the economics with other downstream separation methods employed as alternatives for the purification of intracellular fumarase from *Brevibacterium ammoniagenes* in a 100-kg batch process. With a

system of PEG and potassium phosphate, an overall yield of 70% was achieved by a two-step extraction. The cost structure of the extraction is shown in Table 5. Even if prices have changed meanwhile, the table still gives some idea about the relative cost distribution of material, labor, energy, and investment for the different process steps.

In Figure 13, a comparison of the cost factors and the total costs of the initial recovery operations is shown (95). Data in Table 5 and in Figure 13 are calculated from equation 10, which is derived from coefficients used for the cost calculation in the chemical industry and normalized for the yield:

$$T = \frac{1.13M + 2.6L + 1.13E + 0.13I}{Y} \qquad (10)$$

where the letters represent costs for T, total production; M, material; L, labor; E, energy; I, investment (capital); and Y, yield.

Aqueous two-phase extraction is a low-energy, labor-requiring technique with comparatively low investment costs and high material costs. These high costs for auxiliary chemicals can be lowered by a good choice of volume ratio and by new phase systems and especially by the development of recycling processes (65). The process time can be decreased dramatically by centrifugal separation, resulting not only in high space time yields but also in improved product quality because of the absence of significant proteolytic degradation (96,97). Economic aspects of affinity extraction have been discussed by Johansson et al. (45) and Cordes et al. (18). In such cases, economics rely heavily on the initial costs and the reusability of the affinity ligand.

For a valid evaluation, it is important to realize that extraction constitutes an integrative technology; it achieves removal of solids and an increase in the specific activity of the product in a single step. In addition, in most cases the product can be separated from high molecular weight nucleic acids and its concentration can be increased, improving the performance of subsequent separation steps. An industrial total cost comparison between a downstream process using aqueous two-phase systems and a conventional one is shown in Figure 11. A cost reduction of 35% to 50% was achieved for the separation of *Bacillus* alpha-amylase.

CONCLUSION

Liquid–liquid extraction of proteins using aqueous two-phase systems is a comparatively new but nevertheless

well-investigated technique for the isolation and separation of proteins. It is apparently not yet widely used in industry, but the number of industrial applications seems to have increased in recent years due to the effectiveness and ease of operation on a large scale. Intensive research is going on worldwide with respect to practical applications and theoretical understanding. Together with increases in production size for pharmaceutical proteins, this will make liquid–liquid extraction in aqueous two-phase systems a more common unit operation in the biotechnological industry.

OUTLINE

INTRODUCTION

The yeast *Saccharomyces cerevisiae* is an excellent host for production of nonglycosylated secreted proteins possessing disulfide bonds. As a microbial eukaryote, yeast possesses the protein folding and conformational proofreading apparatus of the endoplasmic reticulum and Golgi apparatus, yet it is amenable to high cell density fermentation in large, process-scale fermenters. Effective exploitation of the yeast cell's secretory capacity can produce yields in the gram per liter range of secreted, active protein.

YEASTS

The most widely studied yeast is *S. cerevisiae*, which is used as a model system for many studies of eukaryotic cell biology (1). As a result, a rich knowledge base is available concerning the physiology and genetics of *S. cerevisiae*, for example, the entire genome sequence has been obtained. Alternative yeasts have also been exploited for protein expression, such as *Pichia pastoris*, *Kluyveromyces lactis*, and *Hansenula polymorpha*. In particular, use of *P. pastoris* is widespread, and a kit is commercially available. In most cases, these nontraditional yeasts have been found to secrete many-fold higher levels of heterologous protein than *S. cerevisiae* (2,3). More recent studies have indicated, however, that the intrinsic secretory capacity of *S. cerevisiae* is inefficiently exploited by the most commonly used multicopy plasmid vectors; when chromosomal integrating vectors are used, the secretory capacity of *S. cerevisiae* is comparable to or greater than that of *P. pastoris* (4,5). Reviews of *P. pastoris* are available elsewhere (2); this article focuses on *S. cerevisiae*. Rather than exhaustively reviewing all facets of *S. cerevisiae* expression, the approaches expected to be of most practical value are highlighted. An excellent, more comprehensive review of yeast expression is available elsewhere (6).

PROTEINS SUITABLE FOR SECRETION IN YEAST

Yeast expression is used to best advantage for proteins whose native route of synthesis is the eukaryotic secretory pathway, a classification that includes most pharmaceutical proteins. Yeast is not well suited for producing glycosylated proteins destined for therapeutic administration, because of the introduction of immunogenic sugar linkages and the absence of sialic acid in yeast glycosylation. Nonmammalian glycosylation does not preclude yeast expression of glycoproteins for analytical, diagnostic, or other in vitro applications, however. A partial list of proteins industrially produced in *S. cerevisiae* for clinical trials is presented in Table 1 (7). Noteworthy yeast-produced commercial products are human insulin, granulocyte-macrophage colony-stimulating factor, and hepatitis B vaccine. A potentially important product class for yeast expression is single-chain antibody fragments and immunotoxins; many such therapeutics are currently in development (8).

VECTORS

Although the most commonly used *S. cerevisiae* vectors are based on the 2μ multicopy plasmid, amplifiable integrating vectors can offer strong advantages and are generally preferable for high-level secretion.

2μ Plasmids

Most laboratory strains of *S. cerevisiae* possess 50 to 100 copies of a circular plasmid called the *2*μ *plasmid* because of its dimensions observed by electron microscopy. The native 2μ plasmid does not confer a measurable growth phenotype, but represents parasitic selfish DNA and is apparently maintained simply as a result of effective amplification, replication, and partitioning mechanisms. Numerous expression vectors containing all or part of the 2μ plasmid have been constructed (9). 2μ-Based vectors exhibit broad clonal variation in copy number and are mitotically unstable. Controlled amplification of 2μ-based plasmids has been accomplished by overexpression of the FLP recombinase that converts θ replication intermediates to a rolling circle mode of amplification (9). 2μ vector copy numbers can also be amplified by use of faulty selection genes such as *leu2-d* or *ura3-d*, which are required at several hundred copies per cell to support growth (10,11).

Integrating Vectors

Chromosomal integration of heterologous expression cassettes takes advantage of the extremely high fidelity of the

replication and partitioning apparatus used by the yeast cell to maintain its own genome. Vectors can be integrated either by homologous recombination or retrotransposition.

Homologous Recombination. The predominant majority of recombination events in *S. cerevisiae* are homologous, and vectors can be precisely targeted to particular chromosomal locations by restriction digestion in a segment of the vector identical to the chromosomal target sequence (12). Several integrating vectors have been developed that are targeted to multiple chromosomal targets. These vectors are typically integrated at one to three locations in iterated repeats, a configuration that can lead to instability if gene amplification reduces growth rate due to constitutive heterologous gene expression. The ribosomal DNA repeats have been used as integration targets (13), and Ty retrotransposon sequences have also been targeted. Several groups have developed δ vectors that are targeted to the 150 to 200 copies of the Ty long terminal repeat that are dispersed throughout the yeast chromosomes (14–19). The δ vectors have shown particular promise, increasing heterologous secretion 5 to 10 fold over levels achieved using 2μ plasmids (15,16). The recombination event that integrates the δ vector is reversed at a frequency of approximately 10^{-4}, looping out the vector sequences from the chromosome. If constitutive expression is used, clones with reduced copy number can quickly outgrow the amplified clones, resulting in substantial instability (18,20). If a strongly repressible promoter such as the GAL promoter is used instead, amplified expression cassettes are completely stable for more than 50 generations in the absence of antibiotic selection, because there is no growth selection against the amplified clones (16,20).

Retrotransposition. Expression cassettes can be inserted within inducible yeast retrotransposons and chromosomally integrated at dispersed sites via the processes of transcription, reverse transcription, and integration used by native yeast retrotransposons. Vectors of this type have been constructed from Ty1 and Ty3 retrotransposons (21,22). A key advantage of this approach is the dispersed nature of gene amplification, which reduces instability caused by recombination between iterated repeats. One disadvantage of this approach is that relatively low numbers of integration events occur at each round of amplification. A potential regulatory difficulty with this approach is the error-prone nature of the reverse transcription process, which could potentially introduce novel mutations in each integrated expression cassette.

SELECTION MARKERS

Nutritional Markers

Almost all yeast genetic studies not related to heterologous protein production use recessive chromosomal mutations with nutritional deficiency phenotypes. These mutations are complemented by plasmid-borne wild-type genes that allow transformants to propagate on medium lacking key amino acids or nucleotides. The genes and corresponding nutrients most commonly used are *URA3* (uracil), *TRP1* (tryptophan), *HIS3* (histidine), *LEU2* (leucine), and *ADE2* (adenine.) These genetic selection markers are often inserted into 2μ plasmids to select for plasmid maintenance. A refinement of this approach is to use a promoter-deleted version of the selection gene that is required at high amplification to support growth. The *leu2-d* and *ura3-d* alleles have been used in this way to select for very high 2μ copy numbers (10,11).

Dominant Markers

Dominant markers have two key advantages: the capability to transform polyploid industrial yeast strains and the capability to select for increasing gene dosage by increasing levels of the toxic selection compound. Several antibiotic resistance genes have been used as dominant markers for yeast transformation, but the most commonly used is the *G418* resistance gene from the *E. coli* transposon Tn903 (23). When used without a yeast promoter, expression of $G418^R$ is weak enough to provide a selectable advantage by increasing gene dosage. *G418* resistance is approximately proportional to the number of integrated copies of the Tn903 $G418^R$ gene (16). The *CUP1* copper metallothionein gene has also been used as a dominant selection marker, with the phenotype of increased copper resistance (24).

Autoselection

An essential gene can be used as the selectable marker in a strain with the chromosomal copy of that gene deleted. This approach allows the use of complex media without antibiotics, and has been used with *ura3fur1* (25) and Δ*tpi* (26) strains. Cells that lose the plasmid and its associated essential gene by segregational instability simply stop growing.

TRANSCRIPTIONAL PROMOTERS

Constitutive

Given that individual glycolytic enzymes can constitute several percent of the cell's total protein, the strong promoters from these genes are often used for constitutive heterologous expression. The most commonly used constitutive promoters are from the *PGK* and *GAP* genes (27,28). However, the use of a constitutive promoter for high level heterologous secretion is inadvisable because of inevitable negative growth phenotypes associated with high-level secretion, which in numerous studies have been shown to select for outgrowth of nonexpressing cells or cells with reduced expression (6,18,29,30).

Inducible

The GAL1 promoter is particularly well suited for heterologous expression because transcription is very tightly repressed in the presence of glucose, yet it is induced more than 1,000-fold by switching the carbon source to galactose. The wild-type levels of the Gal4p transcriptional activation protein can become limiting when multiple GAL1 promoters are induced, but this limitation can be overcome by single-copy inducible overexpression of Gal4p from a GAL promoter (31). Glucose-repressible promoters such as ADH2 and hybrid GAP/ADH2 promoters have also been used (32). However, difficulties may arise with such promoters during high cell density fermentations in balancing the central carbon metabolism against the requirement to repress heterologous expression during the growth phase. Glucose concentration is typically kept low during high cell density fermentation to prevent overflow metabolic production of ethanol resulting from the Crabtree effect, but this may lead to early induction of gene expression and growth defects. The CUP1 copper inducible promoter can be tuned across a 25-fold induction range by varying copper concentration in the growth medium (33). However, maximal induction occurs at copper concentrations that can have toxic effects on cell physiology, and basal expression in the absence of added copper could produce counterselection against gene amplification.

SIGNAL PEPTIDES

The most widely used leader peptide for heterologous secretion in *S. cerevisiae* is that of pre-pro α factor (34). This leader peptide is often found to be the most effective when compared with other signal peptides. The signal peptide is cleaved by signal peptidase after endoplasmic reticulum membrane translocation, and the pro region is cleaved C-terminal to a Lys-Arg site by the Kex2 protease in the Golgi apparatus. Another signal peptide that has been used frequently is the invertase signal peptide, which does not have an associated pro region.

POST-TRANSLATIONAL PROCESSING

Secreted proteins undergo a number of processing steps after translocation into the lumen of the endoplasmic reticulum: disulfide bond formation, folding, subunit assembly, glycosylation, and site-specific endoproteolytic processing. The endoplasmic reticulum and Golgi apparatus contain high concentrations of specialized chaperones, foldases, and enzymes dedicated to the task of conformational maturation of secreted proteins before release to the extracellular space (35). Many of these processing steps are performed inefficiently or not at all by bacteria, but yeast's secretory processes closely mirror those of mammalian cells (with the exception of glycosylation).

Protein Folding and Conformational Proofreading

Proteins do not exit the endoplasmic reticulum until they have folded correctly (36). The mechanistic details of this conformational proofreading process have not been completely elucidated, but they involve addition and trimming of glucose residues for glycoproteins and binding to the lectinlike chaperone calnexin. Two practical consequences of this proofreading step are of critical significance for heterologous protein production by secretion: (*1*) only correctly folded protein appears in the growth medium, obviating the need for refolding procedures; and (*2*) protein folding in the endoplasmic reticulum constitutes the key rate- and yield-limiting step in high-level heterologous protein secretion. Consequence *1* provides one of the major advantages of using yeast for protein production. Consequence *2* has motivated researchers to intensively study and manipulate the endoplasmic reticulum protein folding machinery in order to increase secretory capacity.

Most secreted eukaryotic proteins possess disulfide bonds. These covalent cross-links between cysteine side chains stabilize the folded conformation of a protein. As

the number of disulfides in a protein increases, the combinatorial possibilities for incorrect cysteine pairings during folding grows geometrically. The endoplasmic-reticulum-resident foldase enzyme protein disulfide isomerase (PDI) catalyzes thiol–disulfide exchange to shuffle among possible disulfide pairings until the most stable folded conformation is attained. Overexpression of PDI in yeast can significantly improve secretion of some heavily disulfide bonded proteins (37,38); it is not a panacea, however. Secretion of some proteins is unaffected by PDI overexpression despite possession of disulfide bonds (37).

Another endoplasmic-reticulum-resident chaperone whose function in heterologous secretion has been closely examined is BiP, an hsp70 homologue. Although fulfilling an essential role in membrane translocation and subunit assembly, BiP levels are clearly not limiting for heterologous secretion in yeast or mammalian cells. Less clear is whether reduction of BiP levels is beneficial for secretion, because secretion of three heterologous proteins was decreased in yeast by reduction of BiP levels (39), whereas secretion of some proteins has been increased in mammalian cells by reducing BiP (40). The likely source of this discrepancy lies in the proteins studied; those proteins whose secretion is increased at low BiP levels are either mutant proteins with folding defects or subunits lacking stabilizing partners for a complex. It is possible that overexpression of other endoplasmic-reticulum-resident soluble or membrane bound chaperones and foldases could prove fruitful for heterologous secretion; such candidates include GRP94 chaperones, peptidyl prolyl isomerases, and redox foldases related to PDI such as EUG1 and ERP72.

Kex2p Endoproteolytic Processing

The Golgi-resident Kex2p endoprotease cleaves polypeptides C-terminal to Lys-Arg in unstructured regions of the protein. Kex2p removes the α-factor pro region from the α-factor peptide and heterologous fusion proteins. The sequence requirements for the amino acids adjacent to the Lys-Arg cleavage site have not been completely determined. In many cases, cleavage is efficient and the protein's native N-terminus is produced. For some proteins, however, Kex2 cleavage is inefficient, and a dipeptide spacer must be inserted at the junction to achieve efficient cleavage (41). This dipeptide may be tolerable as part of the protein product, or alternatively it may be removed by cathepsin-C processing (42). Undesirable Kex2 cleavage may also occur at internal Lys-Arg sites of a protein (43). This problem may be circumvented either by deletion of the *KEX2* gene or by alteration of the Lys-Arg sites by site-directed mutagenesis.

Glycosylation

S. cerevisiae covalently attaches polysaccharide structures at the same Asn-X-Ser/Thr sites recognized by mammalian cells. Although the core glycosylation structures initially added in the ER are identical for yeast and mammals, yeast subsequently adds extended mannose chains that are not capped with sialic acid and can be immunogenic. Although hypermannosylation can be reduced or eliminated by use of a *mnnl mnn9* strain (44), the absence of mammalian-type outer-chain glycosylation makes all yeasts undesirable hosts for expression of therapeutic glycoproteins.

SUPERSECRETION MUTATIONS

A classical genetic approach to strain improvement is to screen for spontaneous mutations that increase secretion of the protein of interest. Although such mutants may be difficult to analyze because of mutations at multiple loci or dominant alleles, the practical value of this strategy can be significant (45–48). One of the best characterized supersecretion mutants is the *pmr1* mutation, which involves loss of function of a calcium pump localized in the Golgi (45). How this causes substantial increases in heterologous secretion is not clear.

HIGH CELL DENSITY FERMENTATION

S. cerevisiae can be grown to cell densities of more than 100 g cell dry weight per liter in industrial-scale fed-batch fermentation (49,50). In such fermentations, glucose feed can be controlled by measurement of the respiratory quotient to prevent overfeeding and generation of ethanol. In the absence of instrumentation to measure the respiratory

Table 2. Genetic Components of *S. cerevisiae* Expression/Secretion Systems

quotient, an exponentially increasing feed rate can also achieve high cell densities.

CONCLUSIONS AND RECOMMENDATIONS

Some of the most commonly used genetic components of heterologous secretion systems for *S. cerevisiae* are summarized in Table 2, and the recommended approach is highlighted in boldface. Amplifiable chromosomal integration vectors provide excellent mitotic stability and can improve secretion yields by an order of magnitude relative to 2μ plasmids. The *G418*^{R} dominant selectable marker enables tuning of gene amplification via increasing antibiotic resistance and allows use and optimization of complex media without auxotrophic nutritional constraints. Constitutive transcriptional promoters are not recommended because of counterselection against high-level expression and consequent strain instability. The GAL promoter provides a combination of near complete repression during a glucose fed growth phase, followed by strong induction upon feeding of galactose. The pre-pro α-factor leader peptide generally provides maximal targeting efficiency, and there is generally little benefit in examining several different leader peptides for comparison. The recommended combination of a δ integrating vector with *G418*^{R} selection, a GAL promoter, and pre-pro α-type leader peptide has been applied to secrete 400 mg/L of active bovine pancreatic trypsin inhibitor (BPTI) in shake flask cultures of *S. cerevisiae*, by comparison with 10 to 40 mg/L secreted with a constitutive promoter and 2μ plasmid (16). This specific productivity exceeds that reported for BPTI secretion in *P. pastoris* (4), demonstrating that efficient exploitation of *S. cerevisiae* can eliminate apparent differences among yeast species in their capacity for heterologous protein secretion.

OUTLINE

INTRODUCTION

Protein ultrafiltration (UF) is a pressure-driven membrane process used for the concentration or purification of protein solutions. UF membranes typically have mean pore size between 10 and 500 Å, which is intermediate between reverse osmosis (RO) and microfiltration (MF). Although UF has often been viewed as a purely size-based separation, with species larger than the membrane pores being fully retained while smaller species pass freely, separation in UF actually occurs because of differences in the rate of filtration of different components across the membrane in response to a given pressure driving force. Solute filtration rates, and thus the membrane selectivity, are determined by both thermodynamic (e.g., partitioning) and hydrodynamic (e.g., transport) interactions. UF is currently used throughout downstream processing for protein concentration, buffer exchange and desalting, protein purification, virus clearance, and clarification. Buffer exchange and desalting are typically accomplished using a diafiltration (DF) mode in which the low molecular weight components are washed away from the protein by simultaneously adding fresh buffer (or solvent) to the feed during UF. Protein purification is accomplished using high-performance tangential flow filtration (HPTFF), with the product collected in either the retentate or filtrate depending on the relative filtration rates. Virus filtration (VF) uses larger pore UF membranes that are permeable to protein but provide significant virus removal.

PRINCIPLES OF ULTRAFILTRATION AND HIGH-PERFORMANCE TANGENTIAL FLOW FILTRATION

Background and Theory

General Operating Principles. Although protein UF has been used in the laboratory since the turn of the century, large-scale industrial applications of UF only date back to about 1970. The key breakthrough was the development of the asymmetric membrane by Loeb and Sourirajan and the subsequent extension of this technique to the production of UF membranes by Michaels and colleagues at Amicon. These asymmetric membranes have a very thin skin (approximately 0.5 μm thick) that provides the membrane its selectivity and a more macroporous substructure that provides the required mechanical and structural integrity. The thin skin results in much higher filtration rates than obtainable with homogeneous membranes, significantly reducing the required membrane area or process time. Typical process fluxes in UF range from 25 to 250 L m^{-2} h^{-1}. Operating pressures are generally in the range of 0.2 to 4 bar, which are much lower than the 25 to 80 bar required in RO to overcome the large osmotic pressure of the retained salts. UF membranes are available with a variety of pore sizes and can be cast from a range of base polymers, each having unique physical and chemical characteristics.

Most large-scale UF devices use tangential flow filtration (TFF), also referred to as a cross-flow configuration, in which the feed flow is parallel to the membrane and thus perpendicular to the filtrate flow (1). This allows retained species to be swept along the membrane surface and out

the device exit, significantly increasing the process flux compared to that obtained with dead-end operation. A concentration boundary layer consisting of a high concentration of retained solutes typically develops at the upstream surface of the membrane. This highly concentrated region reduces the effective pressure driving force and can cause extensive membrane fouling from protein adsorption, denaturation, precipitation, or aggregation. The performance of many TFF systems is determined almost entirely by the rate at which these retained solutes are transported away from the membrane and back into the bulk solution, a phenomenon referred to as concentration polarization. A variety of membrane modules have been developed to achieve the desired mass transport rates while maintaining high membrane packing densities, and these are discussed in some detail in "Modules and Devices". Most units are produced in modular form to allow easy replacement and scale-up. Membrane devices are available with surface areas as small as 50 cm^2 for bench-top operation to more than 200 m^2 for large-scale processing. Dead-end (or normal flow) filtration is used primarily for laboratory-scale separations and for systems in which the retained species are present at very low concentration. For example, dead-end MF cartridges have been used extensively for sterile filtration, in which the retained species are present at very low concentration. Similar modules can be used for virus removal.

Conventional UF has traditionally been used to separate solutes that differ by more than 10-fold in size, making it ideal for protein concentration and buffer exchange (2). UF processes are thus used throughout the downstream purification, often to condition the product before or immediately after a chromatographic column. The fairly limited selectivity of UF has generally been attributed to the wide pore size distributions in commercial membranes, the presence of significant bulk mass transfer limitations in existing modules, and membrane fouling phenomena. Recent work (3) has demonstrated that membrane systems can be used for protein–protein separations, even for proteins with very similar molecular weight, using a process known as HPTFF. High selectivity values are obtained in HPTFF by careful choice of both membrane and buffer conditions, with the latter chosen to maximize the difference in hydrodynamic volume for the two proteins. Concentration polarization is exploited to enhance, rather than limit, solute separation. Membrane fouling is controlled using appropriate fluid dynamic and mass transfer conditions. High yields and purification factors are obtained using a diafiltration mode. The net result is that HPTFF provides a competitive separation process that complements chromatographic techniques for protein purification.

Membrane Transport. Theoretical analyses of solute and solvent transport through UF membranes are generally developed using either the Kedem-Katchalsky or Stefan-Maxwell descriptions of irreversible thermodynamics (4). The filtrate flux J (equal to the volumetric filtration rate normalized by the membrane surface area) is proportional to the effective pressure driving force (5):

$$J = L_p[\Delta P - \Sigma(\sigma_i \Delta \Pi_i)] \quad (1)$$

where L_p is the overall permeability (equal to the reciprocal of the overall resistance), and ΔP is the transmembrane pressure. L_p is only equal to the clean membrane permeability (evaluated from water flux data obtained with the clean membrane) in the absence of irreversible fouling. The osmotic reflection coefficient (σ_i) provides a measure of the membrane selectivity: $\sigma_i = 1$ for a solute that is completely retained and $\sigma_i = 0$ for a solute that is completely permeable. The osmotic pressure difference across the membrane ($\Delta \Pi_i = \Pi_w - \Pi_f$) is a function of the solute concentration at the upstream surface (C_w) and in the filtrate solution (C_f). Although protein osmotic pressures are typically small for $C < 10$ g/L, $\Delta \Pi_i$ can be comparable to ΔP during UF because of the buildup of retained protein at the membrane surface (see "Concentration Polarization").

The solute flux N_s (in units of grams protein collected in the filtrate per membrane surface area per time) is conveniently expressed as (6)

$$N_s = J S_\infty C_w \quad (2)$$

where S_∞ is the intrinsic (or asymptotic) sieving coefficient, which is approximately equal to $1 - \sigma_i$ based on Onsager reciprocity. Equation 2 is valid only under conditions where the solute flux is dominated by convection; a more detailed analysis accounting for the coupling between convection and diffusion is given by Opong and Zydney (6). The asymptotic sieving coefficient is determined by thermodynamic partitioning of the solute into the membrane and the relative rate of solute transport through the pore (7):

$$S_\infty = \phi K_c = C_f / C_w \quad (3)$$

where K_c is the hydrodynamic hindrance factor, C_f is the filtrate concentration, and C_w is the retentate concentration at the membrane wall. The hydrodynamic hindrance factor accounts for the additional drag on the solute because of the presence of the pore wall. Theoretical analyses for a hard sphere in a cylindrical pore indicate that K_c only varies between 1.00 and 1.47 (8); thus S_∞ is determined primarily by the equilibrium partition coefficient (ϕ), which is a function of both steric (size) and long-range (e.g., electrostatic) interactions. The electrostatic energy of interaction between a protein and a pore has three distinct contributions (9). In UF systems, the dominant factor is typically the charge on the solute (σ_s). The ϕ decreases with increasing σ_s because of the increase in free energy associated with the distortion of the electrical double layer surrounding the protein caused by the presence of the pore wall. This can be interpreted as an increase in effective protein size (or hydrodynamic volume) associated with the diffuse ion cloud (10). This effect is the basis for the 100-fold decrease in S_∞ with decreasing salt concentration seen for bovine serum albumin (11). There are also contributions from the double layer surrounding the pore wall (which reduces the effective pore size) and from direct charge–charge interactions, with the latter causing an increase in ϕ when the solute and pore have opposite charge.

In the absence of long-range interactions, the sieving coefficient for a spherical solute in a cylindrical pore is (7)

$$S_\infty = (1 - \lambda)^2 \quad (4)$$

where λ is the ratio of the solute (r_s) to pore radius (r_p). Thus, even a membrane with a single pore size has a gradual decrease in S_∞ because of the reduction in accessible pore volume with increasing r_s. The retention characteristics of commercial UF membranes are more complex because of the broad distribution of irregularly shaped pores. A simple approximate analysis yields (12)

$$S_\infty = \exp(-r_s/s) \quad (5)$$

where s provides a measure of the mean pore size. In this case, S_∞ approaches zero asymptotically because of the presence of a small number of very large pores. The effects of different pore size distributions on S_∞ are discussed elsewhere (12).

Concentration Polarization. One of the critical factors determining the overall performance of any UF device is the rate of protein transport in the bulk solution adjacent to the membrane. The filtrate flow causes an accumulation of partially (or completely) retained solute at the upstream surface of the membrane, a phenomenon referred to as concentration polarization. The solute concentration thus varies from its maximum value at the membrane surface (C_w) to its bulk value (C_b) over the thickness of the concentration boundary layer (δ). Most analyses of concentration polarization have used the simple stagnant film model originally presented by Michaels (13):

$$J = k \ln([C_w - C_f]/[C_b - C_f]) \quad (6)$$

where the solute mass transfer coefficient (k) is equal to the ratio of the solute diffusivity (D) to the boundary layer thickness (δ). More rigorous analyses of solute transport indicate that equation 6 is valid at low degrees of concentration polarization, with the actual concentration dependence becoming more complex at high C_w/C_b (14). The wall concentration increases with increasing filtrate flux, causing an increase in $\Delta\Pi$ and a reduction in the effective pressure driving force (equation 1). This negative feedback balances any increase in applied pressure, with the net result that the flux approaches a nearly constant, pressure-independent value at high ΔP (Fig. 1). High wall concentrations can also reduce L_p through irreversible fouling or the formation of a protein gel on the membrane surface. In the latter case, the pressure-independent flux is determined by the maximum solubility or gel concentration for the protein. Although this gel polarization model has been used quite extensively, the calculated values of C_w are device-dependent and are often in poor agreement with independent estimates of protein solubility (8).

Theoretical analyses of solute mass transfer coefficients (k) in laminar flow are generally based on the Leveque solution (1):

$$k = 0.807(D^2\gamma/L)^{1/3} \quad (7)$$

which predicts a two-thirds power dependence on the protein diffusivity (D) and a one-third power dependence on shear rate (γ). Empirical correlations for k have been developed from pressure drop data using the Chilton-Colburn analogy with a power law dependence on feed flow rate around 0.5 for spacer-filled channels and near 1.0 for turbulent flow (8). The most accurate method for evaluating the mass transfer coefficient, particularly for modules with complex fluid flow characteristics (see "Modules and Devices") is to fit equation 6 to actual filtrate flux data. The simplest approach is to evaluate k from the slope of a plot of the pressure-independent flux as a function of $\ln(C_b)$ (assuming a fully retentive membrane). This requires minimal experimental data, but the results can be in considerable error because of uncertainties in the limiting flux. In addition, the resulting value for k is only valid under conditions of very high polarization; the behavior at lower degrees of polarization can be considerably different because of the concentration dependence of the solution viscosity and protein diffusivity (8). The mass transfer coefficient can also be evaluated by fitting filtrate flux versus ΔP data to equations 1 and 6 simultaneously, which was the approach used to generate the solid curves in Figure 1. This requires an estimate of the process membrane permeability, which can be evaluated from buffer flux data obtained with the fouled membrane, and an expression for the protein osmotic pressure as a function of C_w. The osmotic pressure can be evaluated independently, or it can be described using a simple polynomial expansion, in which case k and the osmotic coefficients are fit simultaneously. van Reis et al. (15) developed a novel approach that eliminates the need to assume a specific functional relationship for $\Delta\Pi$ by simultaneously analyzing J versus ΔP data obtained at different C_b.

The accumulation of retained solute at the membrane also affects protein retention. Equation 6 can be rearranged to evaluate the observed protein sieving coefficient using $N_s = JC_f$, yielding (6)

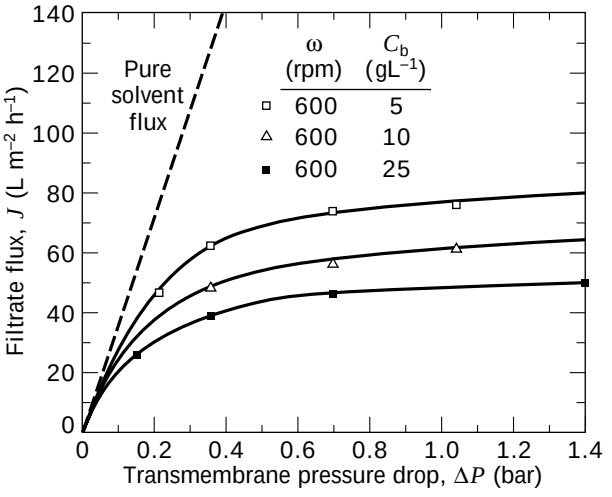

Figure 1. Filtrate flux as a function of transmembrane pressure for stirred-cell UF of BSA solutions of different bulk concentrations (C_b) using a constant stir speed (ω). Solid curves are model calculations based on equations 1 and 6. *Source*: Figure adapted from Opong and Zydney (6).

$$S_o = C_f/C_b = S_\infty/((1 - S_\infty) \exp(-J/k) + S_\infty) \quad (8)$$

At low filtrate flux, $S_o = S_\infty$ because C_w is approximately equal to C_b. The observed sieving coefficient increases with increasing flux, approaching a value of 1 (i.e., $C_f = C_b$) at very high flux as long as the membrane is at least partially permeable to the solute and the required wall concentration ($C_w = C_b/S_\infty$) is physically attainable. Typical experimental results for bovine serum albumin are shown in Figure 2. The solid curve is the model calculation using equation 8. The slight increase in S_o at very low filtrate flux is because of the diffusive contribution to protein transport through the membrane (6).

Membrane Properties

Membrane Chemistry and Morphology. Almost all UF membranes have an anisotropic or asymmetric structure, with the membrane selectivity determined by a thin skin layer and the mechanical integrity provided by a much thicker macroporous support. Most asymmetric UF membranes are prepared by immersion casting (8). A thin film of a polymer solution is spread on a suitable porous or woven support (e.g., polyethylene). The cast film is then immersed in a nonsolvent (often water). Diffusional exchange occurs between the solvent and nonsolvent, causing phase separation of the polymer solution and subsequent gelation of the polymer-rich phase. This gives the membrane a nodular morphology with the pore size determined by the size and spacing of the polymer-rich globules. The asymmetric structure develops because of mass transfer (kinetic) effects, such as growth and coalescence of polymer-rich globules before gelation (8). Large tear-shaped macrovoids often form beneath the membrane skin because of interfacial instabilities or the growth of polymer-lean regions in the film (16). Membranes with macrovoids have high permeability but lower maximum pressure limits. More importantly, defects can form if the macrovoids extend up to (or through) the skin. Hollow fiber membranes are also made by phase inversion with the polymer solution extruded through an orifice into a gelation bath while a second gelation medium is pumped into the fiber lumen. Skin layer(s) develop on the inner or outer surface, depending on the properties of the gelation media. Composite membranes are produced using multiple casting steps. For example, very uniform UF membranes that are free of macrovoids can be produced by casting a thin (5 to 10 μm) polymer film on a MF substrate (17). These membranes are particularly attractive for virus filtration where the presence of even trace defects leads to poor virus removal.

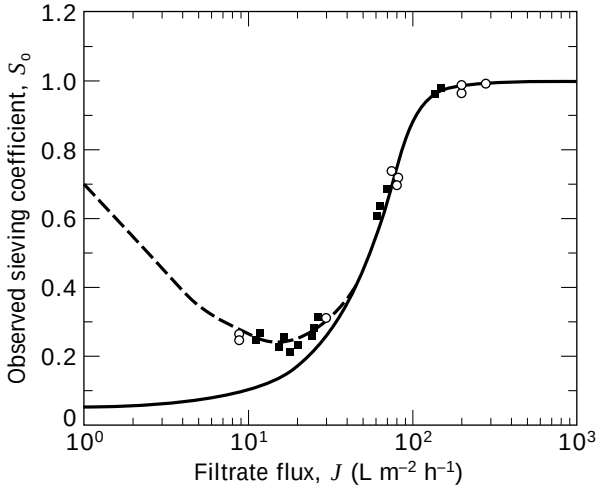

Figure 2. Observed sieving coefficient as a function of filtrate flux for the UF of BSA through a 100-kD poly(ether sulfone) membrane. Solid curve is model calculation based on equation 8. Dashed curve accounts for diffusive contribution. *Source*: Figure adapted from Opong and Zydney (6).

UF membranes can be cast from a wide range of polymers, including polysulfone, poly(ethersulfone), polyamides, polyimides, poly(vinyl chloride), polyacrylonitrile, poly(vinylidene fluoride), regenerated cellulose, and cellulose acetate. Cellulosic membranes bind the least amount of protein but can be damaged by harsh cleaning protocols. The synthetic polymers have much greater chemical and thermal stability but are more susceptible to protein fouling. Ceramic membranes, produced by slip-casting of Al_2O_3 or acid leaching of SiO_2 (18), have very high thermal and chemical stability but tend to be considerably more expensive than polymeric membranes. Many membranes are modified during or after casting by inclusion of polyvinylpyrrolidone in the initial polymer solution, sulfonation of cast polysulfone, radiation-grafting of methacrylate monomers to polyamides, or coating with hydroxypropyl cellulose (19). These modifications increase membrane hydrophilicity and alter membrane surface charge, but they can reduce long-term chemical and thermal stability.

Membrane Characterization. Information on UF membrane characterization most commonly provided to end users consists of water flux measurements, solute retention tests, selected protein binding data, chemical compatibility, and thermal limits. Water flux data provide a measure of the membrane permeability as determined by evaluating the filtrate flux (filtration rate normalized for surface area) as a function of the transmembrane pressure (ΔP). Normal flow filtration devices yield a linear relationship between flux (J) and transmembrane pressure as long as membrane compaction is avoided. The situation is more complex in TFF because the conversion of feed flow to filtrate flow creates a nonlinear pressure drop through the feed channel. A correct value for the permeability of a membrane in a TFF device can be obtained by measuring flux versus transmembrane pressure and extrapolating $J/\Delta P$ versus ΔP to $\Delta P = 0$. Membrane permeability is primarily determined by pore size distribution, porosity (pore density), membrane thickness, and solvent viscosity. Several issues should be considered when judging membrane permeability. The type and quality of water used for the tests can have a significant influence on the results. The pH and ionic strength of the water can influence the flux because of charge interactions, and contaminants can foul the membrane during the test. It is also important to carefully control and report the temperature of the test because permeability is linear with viscosity. As previously men-

tioned, membrane compaction and device configuration can also play a significant role in these tests. It should be noted that membrane water permeability data are of minimal value unless used in conjunction with other membrane characterization information. Water permeability data are not predictive of process fluxes because of significant differences in fouling behavior of various membrane chemistries. Polysulfone membranes typically have much higher water permeability values than regenerated cellulose membranes, whereas the latter membranes typically have higher process permeability values as a result of their inherent low fouling characteristics with most biotechnology feedstreams.

It is important to consider the intended use of membranes when selecting a retention test. The process objectives, and hence the criteria for membrane selection, are very different for protein concentration, buffer exchange, virus–protein separations, clarification, or protein purification. Retention testing of UF membranes involves measurements of solute transmission. Sieving coefficients (S) or retention coefficients (R) are determined by analyzing the solute in the feed and filtrate streams under specific process conditions.

$$S = C_f/C_F \tag{9}$$

$$R = 1 - S \tag{10}$$

Tests are carried out using either single solutes or multiple solutes in separate experiments. The most commonly used single solutes are polymers [such as poly(vinylpyrrolidone)], proteins and viruses. The purpose of the retention tests are to provide nominal molecular weight cutoff values for each membrane. Single-solute retention tests are the easiest to perform and provide either the least or most useful data, depending on the chosen solute and test conditions. Single-solute tests performed by membrane manufacturers typically involve the use of one or several experiments with solutes that are partially retained by the membrane. This information is of limited value for protein concentration and buffer exchange applications because the coefficients of partially retained solutes are not predictive of the retention values one would obtain for a highly retained solute. The retention of solutes with $R = 0.3$ and $R = 0.9$, for example, do not provide guidance on the molecular weight of a solute with a retention coefficient of $R = 0.999$, which is what one would strive for in a protein concentration–diafiltration operation. In all applications (UF, VF, and HPTFF), retention coefficients will also be highly dependent on fouling, buffer chemistry, and fluid dynamics. Furthermore, there is a lack of standardization of retention testing protocols between manufacturers. Different solutes, buffers, and fluid dynamic conditions are used. In addition, the protocols for assigning nominal molecular weight designations (for example, the molecular weight of a solute that has a retention coefficient of $R = 0.9$) are not even standardized within a given company. It is therefore imperative that the end users perform their own retention testing on the solutes of interest under conditions that are a linear scale-down of the intended process.

The mixed dextran test (20) provides an alternative methodology for membrane characterization. A mixture of several polydisperse dextrans are used with the feed and filtrate streams analyzed using size exclusion chromatography (SEC) with an on-line refractive index (RI) detector. Column calibration is performed using several narrow molecular weight distribution standards. The SEC chromatograms represent the solute concentrations (RI absorbance) as a function of dextran molecular weight (elution time). A continuous retention curve (retention versus molecular weight) can hence be generated by constructing a curve using equations 9 and 10 with the feed and filtrate concentrations represented by the respective chromatograms. Because the SEC chromatograms provide elution times for every molecular weight fraction, it is not necessary to use dextrans with tight molecular weight distributions. Mixed dextran tests performed under conditions of constant mass transfer coefficient and flux are a useful tool in comparing the relative retention characteristics of various UF membranes. The method is a good quality-control test for both membrane manufacturers and end users. The method can also be used to derive information on pore size distributions (21). Some predictive power can also be derived from this methodology by converting both dextran and protein molecular weights to equivalent hydrodynamic volumes (22).

A more sensitive method of characterizing UF membranes involves the principle of liquid–liquid pore intrusion. Two highly immiscible liquids, such as solutions of a sulfate salt and a poly(ethylene glycol) are contacted through mixing to reach equilibrium partitioning. The membrane to be tested is primed with one of the liquids so that all the pores are filled. After draining the feed channels, the second fluid is introduced into the system. The first fluid is then displaced out of the pores by the second fluid, and the flow rate is measured as a function of transmembrane pressure. The resulting data provide information on pore size distribution and can be correlated with the nominal molecular weight cutoff. It has also been demonstrated that this methodology can be used as an excellent quality-control test for membranes used in HPTFF applications because performance can be correlated with protein sieving data (23).

Protein binding studies are often performed to contrast the relative behavior of various membrane chemistries. The data generated in these studies can be useful as a general guide. It is important, however, to recognize that protein adsorption will be highly dependent on pH, ionic strength, and the specific isoelectric point and hydrophobicity of a particular protein. It is also useful to note that most membranes will not cause significant protein losses from adsorption because of the relatively low binding capacities (1 to 10 mg/m^2), the small surface areas required (0.01 m^2/g), and the high protein concentrations (0.05 to 1 g/L) obtained in modern biotechnology processes. This is even true for processes such as MF, VF, and HPTFF, in which the product may be exposed to the internal surface area, which is 10 to 500 times the frontal membrane area. Chemical and thermal limits for membranes are determined by characterizing the membranes (using the techniques described herein) both before and after controlled

exposure. Membrane manufacturers often perform additional tests to determine pore size distribution, porosity, morphology, thickness, charge, process flux, and mechanical strength (compaction, tensile strength, and delamination). Pore size distribution and porosity can be determined by either mixed dextran, liquid–liquid intrusion, mercury intrusion, air–liquid intrusion (for large pore sizes), thermoporometry, scanning electron microscopy, or atomic force microscopy. Membrane morphology and thickness are determined by either scanning electron microscopy or transmission electron microscopy. Membrane charge can be determined by streaming potential measurements and is of particular use in HPTFF. Process fluxes provide some complementary information to the water permeability values provided by manufacturers but are best carried out by the end user on the specific application of interest. Determination of mechanical strength should include testing of membrane compaction, tensile strength, and ability to withstand reverse pressure. Soft membranes are susceptible to membrane compaction under process conditions. Membrane compaction can easily be determined by measuring water permeability as a function of transmembrane pressure throughout the desirable ΔP range. Tensile strength is most relevant to the membrane manufacturers and is analyzed using specialized equipment that measures the elongation of the membrane as a function of applied force. The reverse pressure limits of membranes are important to the end user, because unintended pressure spikes may occur during processing with resultant delamination of the membrane and subsequent product loss. Testing is done by subjecting the membrane to reverse pressure cycles at various pressures, followed by retention testing as outlined earlier.

Integrity testing of UF membranes can be performed by bubble-point measurement, air-diffusion flow measurement, or the liquid–liquid intrusion method just described. Bubble-point determinations involve measuring a gas flow rate through a membrane at increasing levels of pressure. The bubble point is determined by an inflection in the flow rate versus pressure curve indicative of liquid displacement out of the pores. Bubble-point measurements are primarily used for MF membranes that have bubble point values in the 1 to 6 bar range (for 0.65 to 0.1 μm pore sizes) using water as solvent. Bubble-point measurements of UF membranes are only practical when using much lower surface tension solvents, because the bubble point values using water as a solvent often exceed the pressure ratings of either the membrane or device. UF membrane integrity is therefore commonly performed using air (or nitrogen) diffusion methods. Air diffusion measurements are done at a single pressure and strive to detect abnormally high flow rates because of convective flow through membrane defects that are large enough to permit the bubble point to be exceeded.

Membrane Fouling and Regeneration. Membrane fouling is a critical factor in almost all UF processes. Fouling refers to the irreversible alteration in membrane properties caused by specific physical or chemical interactions between the membrane and the various components present in the feed. Fouling can occur because of protein adsorption, deposition, precipitation, denaturation, and aggregation, all of which affect membrane performance as well as product yield and quality. The rate and extent of fouling are determined by the morphological and chemical characteristics of the membrane, the fluid mechanics in the module, and the buffer chemistry (24). In addition, protein aggregation or denaturation can occur during repeated pump passes, with these species then deposited on the membrane during UF. Static protein adsorption (in the absence of filtration) generally attains monolayer values on the accessible membrane surface (25), with less adsorption on hydrophilic membranes. As discussed previously, adsorptive losses are small even when the protein has access to the internal pore surface. The convective filtrate flow during UF causes significant additional fouling that can be well beyond that associated with simple adsorption. Thus, considerable care must be taken in predicting fouling levels from static protein binding data. The initial fouling during MF is often caused by physical deposition of large protein aggregates on the membrane surface (26). Protein fouling in UF is strongly influenced by the magnitude of the local protein concentration at the membrane surface, with high values of C_w leading to increased adsorption, precipitation, aggregation, or denaturation. Protein fouling is generally maximum near the protein isoelectric point (27) and is enhanced under conditions where the protein and membrane have opposite charge. The extent of fouling is very sensitive to start-up conditions, with less fouling seen when the system is slowly ramped to the desired filtrate flux or transmembrane pressure (3).

Membrane cleaning or regeneration is performed whenever the flux or selectivity drop below some minimally acceptable level. In addition, membrane disinfection and sterilization must be performed between process runs even in the absence of significant fouling. Cleaning can be accomplished by physically removing the foulants from the membrane, for example, by fluid recirculation at zero transmembrane pressure, backflushing with negative ΔP, or mechanical scrubbing (generally limited to large diameter tubular modules). Chemical cleaning is done using appropriate detergents, acids, alkalis, enzymes, or chelating compounds. These cleaners must effectively displace, solubilize, or chemically modify the foulants while not exceeding the mechanical, thermal, or chemical limits of the membrane polymer or module. For example, cellulosic membranes are highly susceptible to damage by extremes of pH and temperature (28). Polysulfone and poly(ether sulfone) membranes are much more stable, with some manufacturers reporting acceptable performance even after limited exposure to temperatures as high as 125 °C (29). These membranes can also be operated over a wide range of pH (1 to 13) and can tolerate low levels of chlorine (up to 200 ppm). Alkali cleaners (e.g., NaOH) are particularly effective for removing biological foulants (30). Many alkali cleaners are used in combination with chelating agents (e.g., citrate or EDTA) to remove free Ca^{2+} and Mg^{2+} to prevent precipitation of saponified fats and oils (8). Detergents such as SDS are also effective in many systems. Enzymatic cleaners can be used for membranes that are unable to withstand elevated temperatures, strong chemicals, or pH extremes, but these solutions tend to be

very expensive and care must be taken to ensure complete removal of residual proteases. Membrane cleaning remains very much an art, with the development of an optimal cleaning cycle for a given application determined largely by trial and error.

Sodium hypochlorite (NaOCl) is used extensively for chemical disinfection of membrane systems. Hypochlorite is most effective at low pH, but it is very corrosive under these conditions (31). Disinfection is typically performed at pH≈10 using fairly concentrated solutions (0.25 to 4% NaOCl). Other oxidizing agents used for membrane disinfection include hydrogen peroxide (H_2O_2) and peracetic acid ($CH_3COCOOH$) (32). Peracetic acid is attractive because it is fast-acting, and it decomposes into the nontoxic acetic acid. Sodium bisulfite ($NaHSO_3$), a strong reducing agent, can be used for disinfection of membrane systems that would be degraded by strong oxidizing agents such as hypochlorite (33). Steam sterilization can be performed on disassembled membrane systems in an autoclave, but the membrane unit must then be aseptically attached to the remainder of the presterilized system (34). Steam-in-place (SIP) is the preferred method of sterilization, with the entire unit exposed to flowing steam as part of the completely assembled filtration system. Minimum requirements for an effective steam sterilization are 15 min exposure to steam at 121 °C and 1 bar pressure. Effective validation of SIP procedures is essential (35). Membrane systems can also be sterilized using ethylene oxide (EtO) or chlorofluorocarbons (CFCs), but these gas sterilization procedures require fairly long incubation periods to ensure complete deactivation of all microorganisms and spores (35). Gamma irradiation can also be used, although some membrane materials (e.g., PTFE and cellulosics) are damaged on exposure to high radiation doses (35).

Modules and Devices

The membrane module is the physical unit that houses the UF membrane in an appropriately designed configuration. The module must provide physical separation of the retentate and filtrate streams, mechanical support for the membrane, high membrane packing densities, easy access for cleaning or replacement, and scalability. In addition, the feed channel must provide adequate bulk mass transfer rates without excessive feed flow rates. Many of these criteria are to a large extent contradictory, for example, devices with large membrane packing densities are generally more susceptible to particulate fouling and more difficult to clean. A number of commercial UF modules have been developed, differing primarily in the size and shape of the feed (and filtrate) flow channels. These are conveniently classified into five distinct types: flat-sheet cassettes, spiral-wound modules, hollow-fiber cartridges, tubular modules, and enhanced mass transfer modules. The latter category includes a wide range of system geometries and operating strategies. Additional information on the economics, fluid mechanics, and mass transfer characteristics of these modules are available in Zeman and Zydney (8).

Flat-Sheet Cassettes. Flat-sheet (also known as plate-and-frame) cassettes were among the earliest configurations developed for large-scale commercial applications. The module uses a support plate (which also defines the filtrate flow path), membrane, and channel spacer (which defines the retentate flow path) in a sandwich configuration (Fig. 3). The membranes can be sealed to the plates using gaskets, in which case the module (stack) is hydraulically clamped to form a tight fit. Alternatively, the membranes can be directly bonded or glued to the plates using heat sealing or an appropriate adhesive to form an integral membrane element. Several of these elements or plates are then stacked together and clamped to form a complete module. The feed flow is distributed among the different channels at one end of the device, and the retentate is collected at the opposite end. The filtrate is manifolded separately from the feedstream and can be combined within or outside the module depending on the particular device design. The feed channel is typically 0.03 to 0.1 cm in height. The channel can either be fully open or it can use an appropriate screen (typically a polypropylene mesh) to promote local mixing and improve mass transfer. The small channel height leads to relatively high membrane packing densities (generally 300 to 500 m^{-1}) and low hold-up volumes, which is particularly attractive for recovery of high-value products. Open channel cassettes are less susceptible to plugging and operate with smaller pressure drops (feed minus retentate pressure). However, backflushing may not be possible because the membranes are effectively supported only on one side.

Spiral Cartridges. Spiral-wound cartridges are constructed using flat-sheet membranes in the form of a pocket consisting of two membrane sheets separated by a highly porous permeable mesh that provides physical support for the membrane and defines the filtrate flow path (Fig. 4). The membranes are sealed along three edges to form a pocket using an appropriate epoxy or polyurethane adhesive. The open side of the pocket is attached (glued) to a central perforated tube that collects the filtrate flow. Several pockets are wound in a spiral configuration around a single collecting tube using a feed-side (polypropylene) mesh as a spacer between the pockets to establish the desired feed channel thickness. The use of multiple pockets reduces the total path length and pressure drop for the filtrate flow. The entire spiral is generally wrapped with fiberglass tape or shrink wrap for added mechanical strength and to prevent unwrapping of the spiral under pressure. The spiral-wound element is fitted into a tubular steel or plastic pressure vessel with an antitelescoping device placed at both ends to prevent distortion of the spiral during operation. This also allows several spiral elements to be inserted into a single tube. Pressurized feed solution flows through the plastic screens along the surface of the membranes with the retentate collected out the other end of the device. Filtrate flows into the closed membrane pockets and flows in a spiral path inward to the central tube. The region between the outer edge of the spiral element and the inside of the cylindrical housing is sealed to avoid fluid bypass. Spiral cartridges that direct the feed flow in the spiral direction and the filtrate flow in the axial direction have also been produced. Spiral-wound cartridges have relatively high membrane packing densities and very effective mass transfer characteristics because of the feed-side spacers. The cartridges also have fairly low energy costs because they provide effective mass transfer at relatively low flow rates. The primary disadvantage of the spiral wound modules is that they are highly susceptible to particulate fouling because of the narrow and irregular flow path through the spacers. In addition, the dead space between the outer edge of the element and the cylindrical housing is difficult to clean and highly susceptible to bacterial contamination. This is sometimes overcome by allowing a very limited feed bypass to continuously flush the annular space. There can also be problems with the integrity and chemical resistance of the seals used to form the pockets, particularly for repeated applications using strong cleaning solutions.

Hollow-Fiber Cartridges. Hollow-fiber cartridges use an array of narrow bore (self-supporting) fibers, typically with an anisotropic structure. Fiber diameters range from about 200 to 2,500 μm, with the fiber wall around 200 μm in thickness. The dense skin layer is typically at the lumen side of the fiber, although it can also be placed on the outside. A parallel array of 50 to 10,000 fibers is potted at the ends in an epoxy or polyurethane resin within a cylindrical cartridge of plastic or steel to form a tube that is machined to expose the open bores (lumens) of the fibers (Fig. 5). These modules are generally operated with the feed flow into the fiber lumens, with the filtrate moving in a radial direction outward through the fiber walls. The cartridge is typically equipped with a single feed inlet, a retentate outlet, and two filtrate ports (one near each end of the unit). The feed and filtrate flows can be cocurrent or countercurrent. Hollow fiber devices have high packing density because of the narrow diameter of the individual fibers and the ability to pack the fiber bundles tightly in the cylindrical cartridge (shell). The use of small diameter fibers

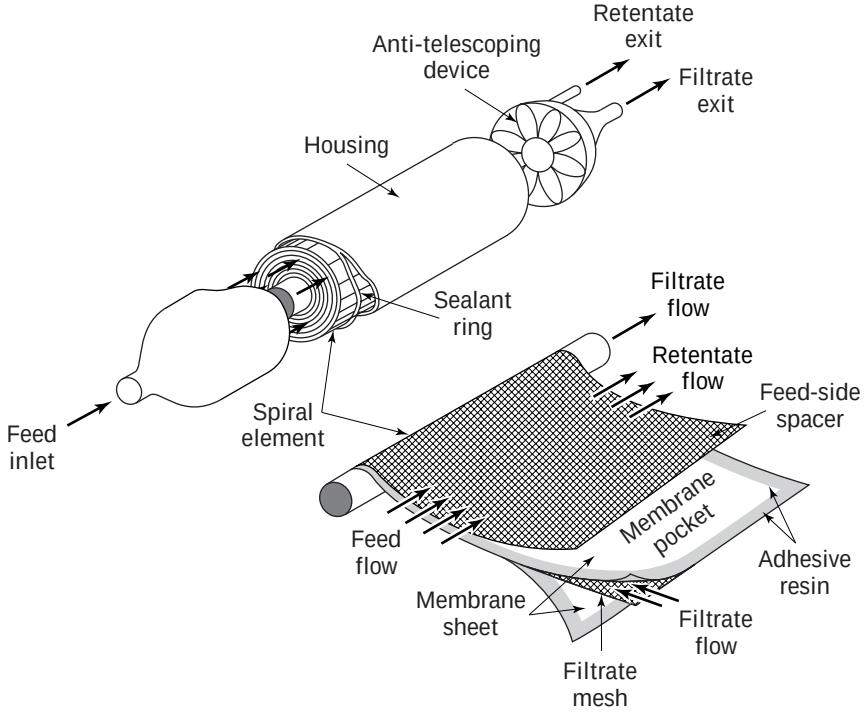

Figure 4. Schematic drawing of spiral-wound module showing membrane pocket. *Source*: Adapted from Ref. 8. Courtesy of Marcel Dekker, Inc.

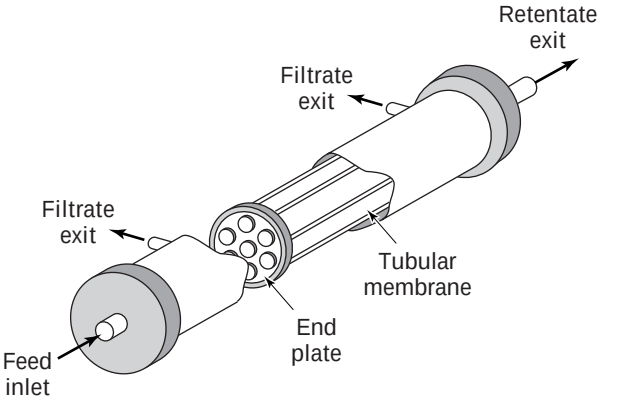

Figure 6. Schematic drawing of tubular module. *Source*: Adapted from Ref. 8. Courtesy of Marcel Dekker, Inc.

can provide effective mass transfer at relatively low feed flow rates. The absence of any spacers or multiple sealing procedures reduces labor costs involved in assembly. The hollow fiber membranes are self-supporting, which often allows them to be cleaned by backflushing of the device either by reversing the direction of the filtrate flow or by reversing the feed flow with the filtrate ports closed. One disadvantage of the hollow fiber modules is that they are susceptible to particulate plugging. Fiber breakage can also be a problem, so it is critical to follow the manufacturer's recommendations with respect to operating pressures. Fiber breakage can often be difficult to detect. Several manufacturers recommend using a modified bubble-point test to detect ruptured fibers.

Tubular Modules. Tubular modules are very similar in design to the hollow-fiber cartridges described in the previous section but use much larger diameter tubes (typically 0.3 to 2.5 cm). The tubular membranes are not self-supporting (with the exception of some inorganic membranes). The membranes are usually cast in place within a porous support tube made of fiberglass, ceramic, plastic, or stainless steel. The individual tubes can be placed inside a plastic or stainless steel sleeve to form a single tube cartridge, or they can be packed together in small bundles that are kept in place using an appropriate end plate (Fig. 6). The feed flows through the bore of the tubes, while the filtrate flows in a radial direction outward across the membrane and support tube where it is collected from the filtrate outlet ports. The two streams may be cocurrent or countercurrent. Inorganic membranes are typically made in a honeycomb monolith (18) in which the membranes are arranged in a parallel array. The unit is housed in an appropriate plastic or stainless steel cartridge. Tubular modules are typically operated in the turbulent flow regime to obtain effective mass transfer in the large diameter tubes. The primary advantages of the tubular modules are their resistance to particulate plugging and ease of chemical or mechanical cleaning. Physical cleaning of the membranes can be affected by passage of a rubber sponge, a scouring ball, or a narrow rod through the bore of the tubes. It is also possible to replace individual tubes in the multielement units in the field, resulting in a considerable reduction in membrane replacement costs and an increase in the overall unit lifetime. The primary disadvantages of the tubular modules are the low membrane packing densities ($<100\ m^{-1}$), high hold-up volumes, large feed flow rates, and high capital costs (including high floor space requirements).

Enhanced Mass Transfer Devices. Enhanced mass transfer modules exploit flow instabilities or turbulence to increase the transport of retained solutes. A variety of devices have been designed using pulsatile flow or membranes with pronounced surface corrugations (36). Alternatively, systems have been developed in which the feed flow generates secondary flow patterns or vortices. The most successful of these to date has been the rotating cylinder device originally proposed by Hallstrom and Lopez-Leiva (37). The feed flows into a thin (0.05 to 0.10 cm) annular region between two concentric cylinders, one (or both) of which is porous and has a membrane bound to the surface. The filtrate is collected in the central chamber (for a device with membrane on the inner cylinder) or in a separate annular filtrate region adjacent to the outer porous cylinder. The inner cylinder in these devices is rotated at high speed (typically >3,000 rpm) to induce Taylor vortices, which are caused by the centrifugal forces acting on the rotating fluid as it moves around the cylindrical flow path. The vortices effectively mix the fluid near the surface of the membrane, increasing the feed-side mass transfer coefficients. Mass transfer in the rotating system is determined almost entirely by the rotation rate of the inner cylinder, which effectively decouples the mass transfer characteristics from the feed flow rate. Consequently, rotating devices can be operated at very low feed flow rates. The use of low flow rates can be particularly attractive for many high viscosity applications. However, the rotating systems have very large capital costs, they are difficult to scale-up, and there is concern about long-time performance of a device with so many moving parts. In addition, membrane packing densities are low, and it is difficult to develop and maintain effective seals in such a rotating system.

Belfort et al. (38) and Winzeler (39) independently proposed using a vortex-flow system based on Dean, rather than Taylor, vortices. Dean vortices are induced by centrifugal forces exerted on a fluid as it flows inside a highly curved channel. This can be accomplished using spiral wound flat sheet membranes, with the channel curvature adjusted to maintain the Dean vortices throughout the system, or with hollow-fiber membranes wound around a central core at an appropriate pitch in a screwlike geometry (40). Both systems generate counter-rotating vortices that effectively depolarize the concentration boundary layer, but without the need for any moving parts or seals. Available data on the Dean vortex systems are very encouraging (38). These units have not yet been commercialized, so it is impossible to evaluate their economics and overall performance characteristics.

Another approach to achieving high mass transfer is to move the membrane, with the bulk of the fluid remaining largely stationary. For example, Vigo et al. (41) developed a module in which a cylindrical membrane is vibrated (longitudinally) inside a concentric cylindrical housing. Culkin and Armando (42) developed vibratory shear enhanced processing (VSEP) in which a stack of parallel circular membrane disks is spun at high speed inside a concentric cylindrical housing using a torsional spring. Shear rates at the membrane-feed interface can be as high as 150,000 s^{-1} for a 60-Hz oscillation. The high shear rates obtained in these systems can result in dramatic improvements in filtrate flux; however, important questions remain about the scalability and robustness of these modules as well as the overall economics.

High-frequency transmembrane pressure pulsing can also be used to enhance mass transfer. In contrast to classical backflushing, in which the reverse filtration occurs after several minutes or hours of normal filtration, transmembrane pressure pulsing is performed with a frequency around 0.1 to 1 Hz (43). The back pressure pulse is applied using nitrogen or air pressurization, with the frequency and duration of the pulse set using computer-controlled solenoid valves (43). Very short forward filtration times are used to prevent significant concentration polarization or fouling, thereby maintaining high average filtrate flux. Data for filtration of albumin–immunoglobulin mixtures showed more than an order of magnitude increase in flux (44), but a corresponding reduction in protein retention. Although transmembrane pressure pulsing systems appear to have excellent performance characteristics, they have not yet been used in large-scale commercial applications.

Process Configurations

Batch. UF and HPTFF processes consist of various combinations of concentration and diafiltration steps. A concentration step is either the main objective of the process or may be used as a means to optimize a subsequent diafiltration step (see "Design Equations" and "Process Optimization"). Concentration steps are carried out in either batch or fed-batch mode. In a batch mode, the entire volume of feed is contained within the recycle tank, as illustrated in Figure 7. Batch mode operations use a minimum

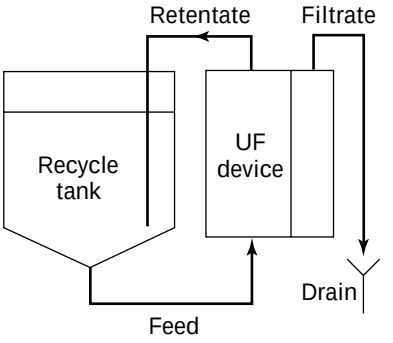

Figure 7. Batch-mode UF for a retained product.

of hardware, provide simple manual or automatic control, and provide the highest flux rates. Although the initial and final retentate concentrations are the same regardless of process configuration, the batch operation gives higher flux rates than a fed-batch operation because the bulk concentration follows a more dilute path from initial to final concentration. The disadvantages of a batch configuration can include less flexibility in using the same system for multiple processes, increased difficulty in designing a well-mixed system, and difficulties in obtaining high concentration factors. Mixing is important both to keep the bulk concentration at a minimum and for efficient buffer exchange during diafiltration. High concentration factors can in some cases be obtained in a batch mode using tanks with two or more sections of progressively decreasing diameters.

Fed Batch. A fed-batch configuration uses an additional tank to feed into the recycle tank, as shown in Figure 8. Fed-batch configurations are commonly used in industry to obtain high concentration factors, provide flexibility for use in multiple processes, and provide well-mixed low hold-up retentate reservoirs for efficient diafiltration. In choosing a fed-batch configuration, several trade-offs must be carefully considered. For a given membrane area, process time will increase with the use of a fed-batch configuration because of the increase in bulk concentration compared to a batch operation. In addition, the number of times the retained solute passes through pumps and valves in the recycle line will increase because of the longer

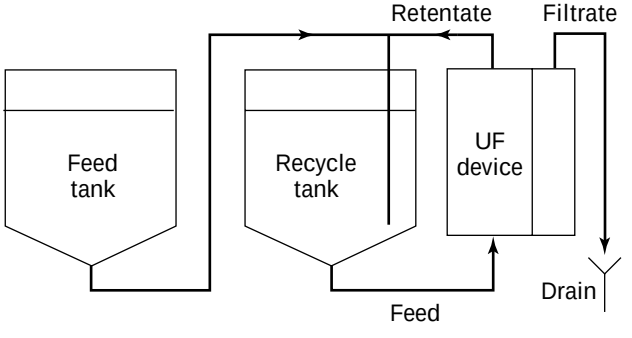

Figure 8. Fed-batch mode UF for a retained product.

processing time and the smaller retentate volume. An increased number of pump and valve passes can lead to shear-induced cell lysis and protein denaturation and aggregation. Protein denaturation in pumps and valves is believed to be the result of protein–gas interfaces (45) formed as a result of microcavitation.

Diafiltration. Diafiltration is an operation in which a solvent or solution (typically a buffer) is added to the recycle tank simultaneously with filtration (Fig. 9). The most common form is constant retentate volume diafiltration in which the buffer is added at the same rate as the filtrate rate. In UF processes, diafiltration is used to perform buffer exchange if the product is in the retentate, or to enhance yields if the product is in the filtrate. In HPTFF, diafiltration is used to achieve purification. In certain processes, it can be advantageous to perform simultaneous dilution or concentration with diafiltration (46). Optimization of diafiltration processes will be described in "Fluid Dynamics and Process Control" for UF and in "Process Optimization" for HPTFF.

Cascade Systems. In several plant designs, it may be advantageous to use cascaded process configurations. These configurations include both open-loop and closed-loop designs. In both configurations, the filtrate from the first stage is used as a feed to the second stage. In the open-loop design, the filtrate from the second stage is directed to drain while a replacement buffer is added to the first stage. In the closed-loop design (Fig. 10), the filtrate from the second stage is used as the diafiltration buffer for the first stage, thereby significantly reducing the amount of buffer required for the process. Cascade systems can be used to couple multiple process steps into a single operation. For example, a MF step used to harvest protein from a culture can be cascaded with a second-stage UF step to achieve simultaneous harvest and protein concentration. In HPTFF, two-stage cascade systems can be used in a similar manner when the product of interest is in the first-stage filtrate. Once a normal diafiltration has been performed on the first stage to achieve optimum buffer conditions (see "Buffer Chemistry"), a closed-loop configuration can be used to obtain a very large number of diavolumes by reusing a volume of buffer that is equal to the volume of retentate. It should be noted that the retentate volumes in the first- and second-stage tanks do not have to be the same. In cases where the buffer cost is very high, one might also consider using such a configuration even when the product is in the first-stage retentate if economically justified. Cascade configurations with more than two stages can also be used in processes where it is desirable to separate a feedstream into more than two fractions.

PROCESS DESIGN

Ultrafiltration

Buffer Chemistry. Buffer exchange is often used to condition a product for subsequent loading onto a chromatographic column or for final formulation. The buffer chemistries used in ultrafiltration are hence often dictated by the preceding and subsequent steps in the process. Because of the very large amounts of protein processed per surface area of membrane, ultrafiltration can be used with a wide range of ionic strengths and pH values without significant adsorptive product loss. As discussed previously, adsorptive yield losses are usually insignificant ($<0.01\%$) for products in the retentate and can be limited to less than 5% for products in the filtrate. Although UF is routinely used to provide buffer exchange in preparation for subsequent processing, it can be advantageous to consider selecting buffer conditions for the sake of optimizing the UF step. Changes in pH and ionic strength can be made to affect protein solubility, stability, adsorption, and hydrodynamic volume. These parameters are directly linked to yield losses incurred at the membrane surface (see "Fluid Dynamics and Process Control"). In addition, buffer chemistry plays an essential role in membrane fouling, which can have a significant impact on process fluxes even when adsorptive product losses are minimized. The mass transfer coefficient can also be significantly enhanced by changes in buffer composition resulting in enhanced fluxes, reduced membrane area, and minimal volumetric hold-up losses. In general, higher fluxes are obtained at pH values either above or below the protein isoelectric point and at low to moderate ionic strength.

The theoretical removal of low molecular weight components during diafiltration is discussed in "Design Equations." It is important to note that one cannot assume that the retention coefficient for these components is zero despite the fact that the membrane may have a molecular weight cutoff an order of magnitude larger than the molecular weights of the components. Deviations in theoretical clearance of low molecular weight components can result from poor mixing in the recycle tank but can also result from buffer conditions. The use of detergents in either the feed material or in the diafiltration buffer can cause incomplete diafiltration if the critical micelle concentration is exceeded. Buffer components are entrained in the micelles, which may be retained by the membrane depending on micelle size and membrane molecular weight cutoff. It is generally advisable to avoid the use of detergents in UF for these reasons. Charged membranes may cause Donnan exclusion effects that result in increased retention of ionic solutes of all sizes. It has also been observed that low molecular weight ionic solutes can have

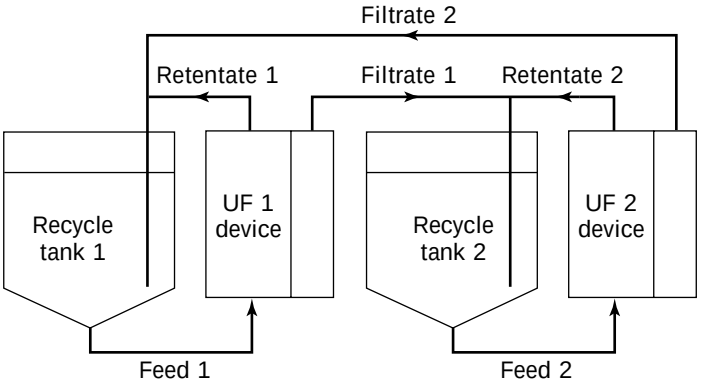

Figure 10. Two-stage closed-loop cascade configuration.

increased clearance, possibly as a result of Donnan exclusion by retained solutes.

Membrane Selection. Membrane selection should start with the choice of a high-quality vendor because robustness, reliability, and reproducibility of biotechnology manufacturing operations are of paramount importance. Consistent membrane and device characteristics can be as important to product quality, yield, and economics as are the inherent differences between various membranes and devices. The most important engineering parameters to consider during membrane selection are product retention, process permeability, mechanical strength, and chemical compatibility. Adsorptive properties play an important role in determining process permeability but are often less important with regard to product loss. Membrane chemistry should therefore be chosen in conjunction with the choice of buffer chemistry. Membrane charge should also be considered with regard to potential Donnan exclusion effects, as discussed previously. Water permeability values should not be used as a selection criteria since they are not predictive of process performance. Pore size distributions, porosity, morphology, and membrane thickness are only of indirect importance, because these parameters affect the ultimate retention, permeability, and mechanical characteristics of the membrane. As previously discussed ("Membrane Characterization"), retention properties should be determined on the actual solute under process conditions because marker studies can be completely misleading. Rules of thumb for selection of a membrane molecular weight cutoff relative to a protein molecular weight should also be avoided because protein hydrodynamic volumes vary drastically with pH and ionic strength (10) and because membrane manufacturers have not standardized their membrane characterization and nomenclature for UF membranes. The mechanical strength of a membrane can be important with regard to membrane compaction and reverse pressure tolerance. Membrane compaction can influence process permeability if retentate pressure limits are exceeded. The reverse pressure limits of a membrane are also important, because reverse pressure spikes are very difficult to avoid in industrial UF systems. The resulting membrane delamination can have a catastrophic impact on process yields. Chemical compatibility needs to be considered for the intended feedstream and the regeneration chemicals. Polysulfone and modified polysulfone membranes tend to have much broader chemical compatibility than regenerated cellulose membranes, but they also require much harsher chemical conditions for regeneration because of their inherent fouling characteristics. Long-term stability of membranes in bacteriostatic storage solution must also be carefully considered for economic reasons. The long-term stability of UF membranes should be evaluated by studying product retention as a function of membrane storage time in the chosen storage solution.

Fluid Dynamics and Process Control. Ultrafiltration processes can been performed using constant transmembrane pressure (ΔP), constant flux (J), or constant retentate wall concentration (C_w). The primary benefit of constant transmembrane pressure UF processes is the inherent simplicity of control, especially in manual systems. The feed rate is ramped up to the set point value, and a retentate valve is partially closed to achieve a specified retentate or transmembrane pressure:

$$\Delta P = (P_F + P_R)/2 - P_f \quad (11)$$

where P_F is the feed pressure, P_R is the retentate pressure, and P_f is the filtrate pressure. Note that this equation is an approximation because the pressure drop along the feed channel is not truly linear because of conversion of feed to filtrate. If the feed stock viscosity changes during the process, one can adjust the retentate valve closure to maintain either constant retentate or transmembrane pressure. This is easily accomplished in both manual and automatic systems and often requires minimal adjustments after the initial set point has been achieved. The retentate pressure can also be controlled by using a gas overlay on the recycle tank. The feed rate and transmembrane pressure are empirically optimized by measuring the flux as a function of bulk solute concentration at various feed rates and transmembrane pressures. It is also important to measure solute sieving as a function of bulk concentration and flux. Even very small sieving coefficients may result in substantial product loss when a large number of diavolumes are required in DF processes. For example, a sieving coefficient of $S_o = 0.01$ will result in a 10% product loss during a 10-diavolume buffer exchange process (see equation 17).

In certain applications, it is not possible to maintain constant transmembrane pressure without severe reductions in filtrate rate. It has been demonstrated that one can obtain higher overall throughput in these applications (such as clarification) by operating at constant flux (47). This can be done by regulating the retentate pressure control valve or by using a pump on the filtrate line. The latter alternative provides more precise control and is easier to use in manual systems. Optimization is typically done through empirical studies varying feed rate and flux and determining process throughput, filtrate clarity, and product sieving.

In a third method of process control, the flux is varied with both retentate concentration and mass transfer coefficient to maintain a constant wall concentration of retained species (evaluated from equation 6). Control is performed using a control loop that measures flux and controls the transmembrane pressure with a retentate control valve to maintain a constant wall concentration (Fig. 11) throughout the concentration (15):

$$J = k \ln(C_w V / C_0 V_0) \tag{12}$$

where J is the flux, k is the mass transfer coefficient, C_w is the wall concentration of the retained solute, V is the retentate volume, V_0 is the initial feed volume, and C_0 is the initial retentate concentration. The benefits of constant C_w control are that product yield is maximized, product quality is ensured, membrane area is minimized, and process time is consistent and independent of membrane permeability. Process control for constant C_w during a concentration phase requires an automated system. Constant retentate volume DF using constant C_w, however, can easily be performed using either manual or automatic control because the C_w set point is maintained at a constant flux. Adjustments for changing mass transfer coefficients can be made during the DF process. The optimum C_w is determined by minimizing yield losses attributable to sieving, adsorption, solubility, and volumetric hold-up. (Fig. 12). The feed rate is optimized by evaluating a tradeoff between

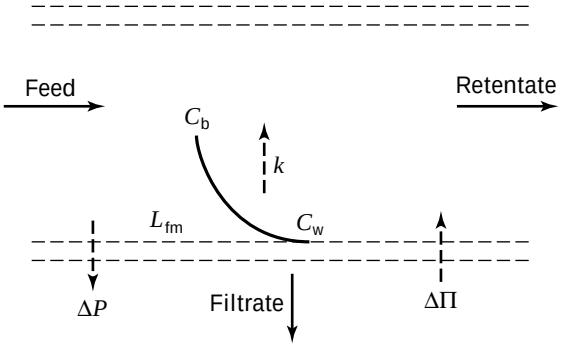

Figure 11. The concentration of a fully retained solute at the membrane wall (C_w) depends on the bulk concentration (C_b), the transmembrane pressure (ΔP), the fouled membrane resistance (L_{fm}), the osmotic pressure ($\Delta\Pi$), and the mass transfer coefficient (k). *Source*: Reprinted from R. van Reis et al. (15). With kind permission of Elsevier Science–NL, Amsterdam, The Netherlands.

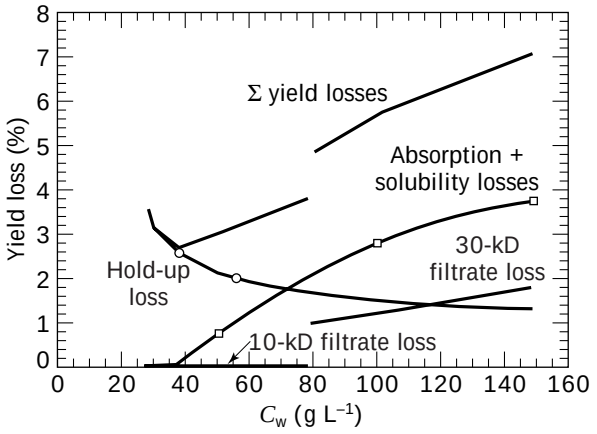

Figure 12. Yield losses in UF as a function of the wall concentration (C_w). Filtrate, adsorption, and solubility losses were determined with 0.1 to 0.4 m^2 linear scale-down devices. Hold-up losses were derived from data obtained with 5-, 21-, 63-, and 85-m^2 systems. *Source*: Reprinted from R. van Reis et al. (15). With kind permission of Elsevier Science–NL, Amsterdam, The Netherlands.

increased mass transfer coefficient (which increases flux and reduces membrane area for a given C_w) and an increased number of pump/valve passes (which may increase protein denaturation). The mass transfer coefficient can be calculated as:

$$k = aQ^b D^{2/3} \tag{13}$$

where a and b are coefficients determined for the specific UF module, Q is the feed flow rate normalized for membrane area, and D is the solute diffusivity. A typical constant C_w process is shown in Figure 13.

Design Equations The yield and purification obtained in UF can be evaluated from a mass balance, typically assuming a constant sieving coefficient. The fractional retentate product yield in a batch process is

$$Y_r = (V_0/V_F)^{-S_0} \tag{14}$$

where V_F is the final retentate volume, V_0 is the initial retentate volume, and S is the sieving coefficient. The analogous yield for a product in the filtrate can simply be calculated as

$$Y_f = 1 - Y_r \tag{15}$$

For a fed-batch process, the retentate yield is given by

$$Y_r = [1 - (1 - S_o) \exp(-S_o(V_0/V_F - 1))]/S_o(V_0/V_F) \tag{16}$$

and the corresponding filtrate yield can be calculated by combining equations 15 and 16. The retentate yield during constant retentate volume diafiltration is derived as

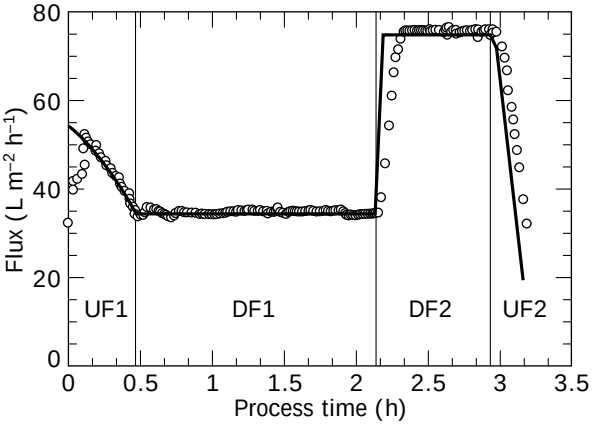

Figure 13. Predicted filtrate flux (solid line) and actual filtrate flux (open circles) for a constant C_w UF/DF process as a function of process time. Concentration of a recombinant antibody from 4 to 10 g L^{-1}, followed by a 10-diavolume buffer exchange and final concentration to 45 g L^{-1}. The increased fluxes during DF2 and UF2 process steps are the result of an increase in mass transfer coefficient and optimum C_w after the initial buffer exchange (DF1).

$$Y_r = \exp(-S_o N) \tag{17}$$

where the number of diavolumes is given by

$$N = V_D/V \tag{18}$$

where V_D is the DF buffer volume, and V is the constant retentate volume. It is often useful to combine and rearrange equations 14 and 17 to determine the retention coefficient required to obtain a desired retentate yield for a batch UF and constant volume DF process as

$$R = 1 + \ln Y/(\ln(V/V_0) + N) \tag{19}$$

For a filtrate product, the required retention coefficient is

$$R = 1 + \ln(1 - Y)/((\ln(V/V_0) + N) \tag{20}$$

DF processes are often used to remove undesirable low molecular weight components. The residual concentration can be calculated as

$$C = C_0 \exp(-S_o N) \tag{21}$$

Buffer exchange may also involve the addition of a new component:

$$C = C_i(1 - \exp(-N)) \tag{22}$$

where C_i is the bulk concentration of the component that is being added during diafiltration. Simultaneous addition and removal of a component may also occur in cases where the initial buffer and the DF buffer have a common component. The concentration of such a component can be calculated by adding equations 21 and 22. Process time and membrane area can be minimized by operating DF processes at an optimum bulk concentration (48):

$$C_b^* = C_w/e \tag{23}$$

By combining equations 23 and 6, with $C_f = 0$ for a fully retentive membrane, it has been shown (15) that the optimum diafiltration flux at C_b^* can be derived as

$$J^* = k \tag{24}$$

High-Performance Tangential-Flow Filtration

UF has been limited to separating solutes that are at least 10-fold different in size. In contrast, HPTFF enables the separation of solutes without limit to their relative size. HPTFF can even be used to perform reverse separations in which the higher molecular weight solute passes through the membrane while the lower molecular weight solute is highly retained. High-resolution separations are accomplished by exploiting concentration polarization, optimizing buffer chemistry, and using highly selective UF membranes. The performance of HPTFF is quantified by two dimensionless numbers, Ψ and $N\Delta S$:

$$\Psi = S_2/S_1 \tag{25}$$

$$N\Delta S = (JAt/V)(S_2 - S_1) \tag{26}$$

where Ψ is the selectivity, S_1 and S_2 are the respective sieving coefficients for the less and more highly retained species, N is number of diavolumes, A is membrane area, t is process time, and V is retentate volume. Membrane area and process time can be chosen to satisfy economic and manufacturing criteria independent of other variables. The retentate volume can be optimized separately. It is therefore useful to initially evaluate the selectivity (equation 25) and $J\Delta S$ values, which only depend on three simple experimental parameters:

$$J\Delta S = J(S_2 - S_1) \tag{27}$$

The next three sections will describe how buffer chemistry, membrane selection, and fluid dynamics are optimized. The final section will describe the mathematical basis and use of optimization equations and diagrams.

Buffer Chemistry. Selecting buffer pH and ionic strength are of paramount importance to achieving optimum separation performance in HPTFF. By operating close to the pI of the lower molecular weight solute and far away from the pI of the larger molecular weight solute, one can take advantage of differences in hydrodynamic volume and charge (3). The electric double layer that surrounds charged solutes increases the effective hydrodynamic volume as determined by SEC (10). Direct charge effects can also be exploited by using a membrane that has the same charge as the retained solute. In addition, the conformation of a molecule, and hence the hydrodynamic volume, may be changed under highly charged conditions. Use of charge effects are optimized by operating at low ionic strength (Fig. 14). The optimum ionic strength is generally achieved

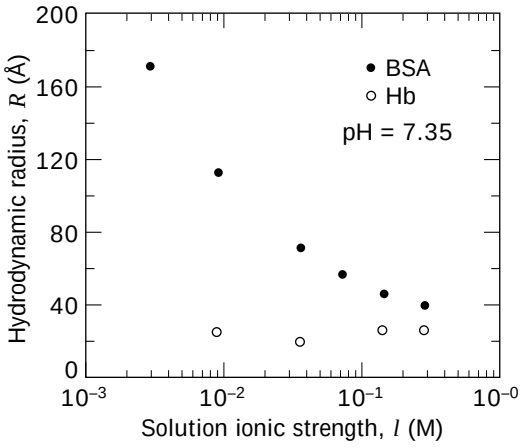

Figure 14. Effective hydrodynamic radius of BSA and hemoglobin (Hb) as a function of solution ionic strength. Calculated values of R were determined from retention time measurements in SEC using narrow molecular weight distribution dextran standards for calibration (10).

by using the lowest possible value while still maintaining an adequate pH buffering capacity. The buffering capacity of proteins at high concentrations near the membrane wall must be taken into account. Even in cases where there is no difference in pI between the solutes, it is advantageous to optimize both pH and ionic strength because the hydrodynamic volumes can be adjusted to increase selectivity and $J\Delta S$ for a given membrane molecular weight cutoff (3). This also reduces the need to have a large selection of different molecular weight cutoff membranes for HPTFF. Hydrodynamic volume and charge effects can also be altered by using buffering ions that have different protein binding characteristics (49). Rapid process development can, however, often be accomplished by testing just a few pH values around the pI of the lower molecular weight solute with a single buffering species at a concentration of 10 mM. As in all purification process development, it is important to ensure that the buffer composition does not cause undesirable biochemical alterations to the product and that product solubility is maintained at the concentrations incurred at the membrane wall (see "Fluid Dynamics and Process Control").

Membrane Selection. The general considerations for UF membrane selection outlined in "Membrane Selection" also apply to HPTFF. The selectivity and $J\Delta S$ that can be achieved with a membrane is determined by the pore-size distribution and membrane chemistry. Pore-size distribution affects both selectivity and $J\Delta S$ by altering the solute sieving coefficients and the filtrate flow distribution (8). Membrane chemistry has an indirect impact on the pore-size distribution because membrane formation conditions are linked to the casting solution chemistry. Membrane chemistry also plays a significant role in fouling, which in turn influences the selectivity and $J\Delta S$ values. Finally, the charge versus pH profile of the membrane can be selected to influence both charge repulsion and fouling. It should be noted that selective fouling of a membrane can actually be used to enhance separations because the pore-size distribution can be reduced and the surface charge can be altered. Using these guidelines, it is often possible to narrow down the choice to one or two membranes before proceeding with fluid dynamic optimization.

Fluid Dynamics and Process Control. The intrinsic sieving coefficient for a solute is defined by equation 3. The intrinsic sieving coefficient depends on the size and charge characteristics of both the solute and the membrane pores. Buffer optimization and membrane selection have hence focused on establishing conditions that provide the best differential intrinsic sieving coefficients for the solutes to be separated. The observed sieving coefficient of a solute, however, depends not only on the intrinsic sieving coefficient but also on the concentration of solute at the membrane wall. The wall concentration is determined by the mass transfer coefficient and the filtrate flux. The observed sieving coefficient is related to the intrinsic sieving coefficient (S_∞), mass transfer coefficient (k) and flux (J) by equation 8. It is therefore clear that the optimization of HPTFF is strongly influenced by concentration polarization effects. Concentration polarization has often been cited in the literature as one of the reasons why UF has not been successfully used for high-resolution separations. It has been demonstrated (3), however, that concentration polarization can be used to enhance, rather than limit, the resolving power of UF membranes. Key differences used in HPTFF methodology (50,51) include operating below the transition point (Fig. 15) and minimizing the transmembrane pressure gradient along the length of the filtration module. Although conventional UF has often sought to maximize flux by operating above the transition point, it has been shown that the optimum selectivity and $J\Delta S$ (a differential mass flux) occur below the transition point (3). It has also been demonstrated that membrane fouling is more consistent and can be controlled below the transition point (15). Optimization of HPTFF fluid dynamics can therefore be reduced to a set of simple experiments in which module geometry, feed flow rate, and filtrate flux are investigated. The results are evaluated by measuring selectivity (Ψ) and differential mass flux ($J\Delta S$) as a function of these variables.

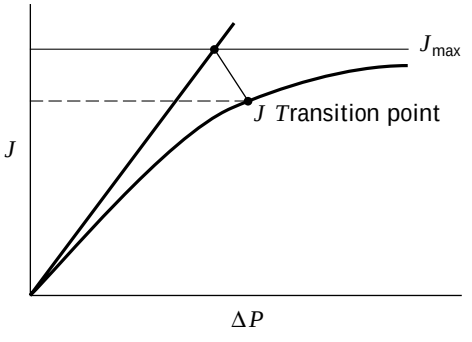

Figure 15. Typical flux versus transmembrane pressure curve showing the transition point flux at the inflection point (50). The optimum selectivity (Ψ) and differential mass flux ($J\Delta S$) occur below the transition point flux.

Process Optimization. The goal of process optimization is to achieve product quality specifications with the best combination of yield and purification factor using an economic amount of membrane area and providing an acceptable process time. Yield, purification factor, membrane area, and process time can be evaluated by using an optimization diagram (52) for either retentate product (Fig. 16) or filtrate product (Fig. 17). The optimization diagrams consist of a family of curves with the dimensionless parameters selectivity and $N\Delta S$. The family of curves in the optimization diagrams are mathematical expressions that link the yield and the purification factor to selectivity and $N\Delta S$ values. The equations are derived (52) as

$$P_R = Y_R^{1-\Psi} = \exp(N\Delta S) \quad (28)$$

$$P_F = Y_F/(1 - (1 - Y_F)^{1/\Psi}) = Y_F/(1 + (Y_F - 1)\exp(N\Delta S)) \quad (29)$$

where P is the purification factor, and Y is the fractional yield in the retentate (R) and filtrate (F). Both retentate and filtrate product processes operate along lines of constant selectivity. In the case of a retentate product, the process starts at a purification factor of 1 and a fractional yield of 1 and proceeds along a constant selectivity line up to the limit of $N\Delta S$ with an increasing purification factor and a decreasing yield. Conversely, the filtrate process starts at zero yield and a purification factor that numerically equals the selectivity (52) and proceeds along a constant selectivity curve with increasing yield and decreasing purification factor up to a limiting $N\Delta S$ value. Different experimental conditions (buffer chemistry, membrane chemistry and pore size, and fluid dynamics) can now be compared by evaluating the impact of selectivity and $J\Delta S$ on yield and purification factor. Selectivity and $J\Delta S$ often reach maxima under different experimental conditions. The best combination of selectivity and $J\Delta S$ depends on the overall process objectives and can be evaluated by comparing yield and purification factors for different combinations of these parameters using the optimization diagrams. As part of this analysis, $J\Delta S$ is converted to $N\Delta S$ by including membrane area, process time, and retentate volume according to equation 26. The membrane area and process times are chosen to provide acceptable economics, system hold-up volume, and process time. The retentate volume must be optimized. Decreasing the retentate volume (while maintaining a constant mass of solute) decreases the amount of buffer required for the process and can also decrease the amount of membrane area required for a given process time. This must be balanced against the increase in the number of pump and valve passes that occurs at increased concentrations, which can adversely impact product quality (see "Fluid Dynamics and Process Control").

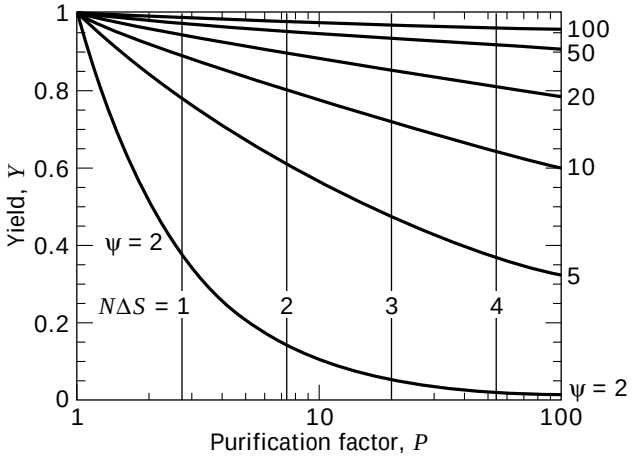

Figure 16. Optimization diagram for product in the retentate. The process follows a constant selectivity (Ψ) curve starting at a fractional yield $Y = 1$ and can be operated up to a maximum $N\Delta S$, which depends on the experimental $J\Delta S$ value and the ratio of membrane area (A), process time (t), and retentate volume (V). *Source*: Adapted from R. van Reis and S. Saksena (52). With kind permission of Elsevier Science–NL, Amsterdam, The Netherlands.

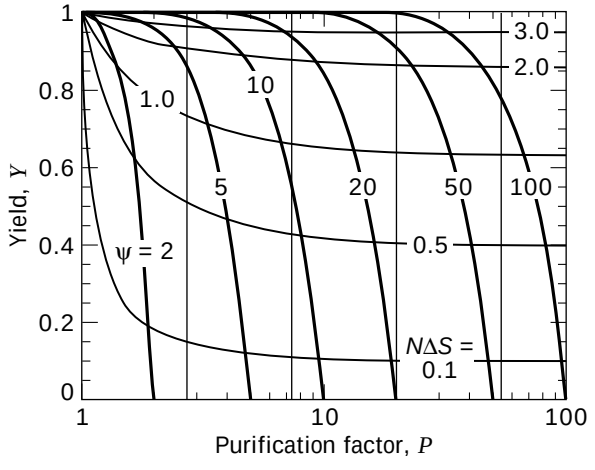

Figure 17. Optimization diagram for product in the filtrate. The process follows a constant selectivity (Y) curve starting at a fractional yield $Y = 0$ and can be operated up to a maximum $N\Delta S$, which depends on the experimental $J\Delta S$ value and the ratio of membrane area (A), process time (t), and retentate volume (V). *Source*: Adapted from R. van Reis and S. Saksena (52). With kind permission of Elsevier Science–NL, Amsterdam, The Netherlands.

Scale-Up

Effective commercial implementation of UF and HPTFF requires accurate and dependable scale-up of these membrane processes. It is also important to be able to scale-down existing manufacturing processes for further optimization, validation, and troubleshooting. Scale-up in UF and HPTFF obviously requires use of the same membrane material and pore size as well as the same module configuration and channel height at all scales of operation, with the membrane area scaled proportional to the filtrate volume. The most effective approach to scale-up is linear scaling, in which the pressure, fluid flow, and concentration profiles along the length of the filtration module are all kept constant when changing scale of operation (53). Be-

cause the local retentate velocity, solute concentration, and fluid pressure vary with position in the channel because of fluid removal and frictional pressure losses, linear scaling can only be achieved by keeping the channel length constant. Thus, the increase in membrane surface area required for large filtrate volume operation must be accomplished by increasing the number of parallel channels or fibers. It is also possible to increase the channel width in flat-sheet cassettes, although some care must be taken to ensure that this does not alter the fluid flow profiles in different size modules. Linear scaling of hollow fiber systems is relatively straightforward using modules with equal length but different numbers of fibers. Equal flow distribution between fibers and between fiber cartridges is easily accomplished with appropriate cartridge housings and piping manifolds. Linear scaling of flat-sheet designs has also been achieved using careful system design to ensure equivalent flow distribution, channel height compression, and entrance and exit effects at the small and large scale (53). Linear scale-up of hollow-fiber and flat-sheet devices over at least a 400-fold range of membrane area has been done successfully without intermediate pilot scale tests (53). Spiral-wound modules have a more limited range of linear scalability because pressure losses on the filtrate side will vary as the membrane area is changed, particularly in the design of very low area ($<0.1\ m^2$) modules. Linear scaling can also be developed for spiral devices in which the feed flow is in the spiral direction (with the filtrate flow in the axial direction), and these modules should provide enhanced mass transfer through the formation of Dean vortices. Linear scaling of the other enhanced mass transfer modules discussed in "Modules and Devices" can often be difficult to achieve over a wide range of membrane surface area because of practical limitations on system geometry and design.

OUTLINE

INTRODUCTION

Proteolytic cleavage, the hydrolysis of peptide bonds in a protein, is a ubiquitous reaction in nature catalyzed by enzymes called proteases. Whether the purpose served is digestive scavenging of nutrients or regulation of a critical physiological process such as blood coagulation, proteases play an essential role in the growth and survival of all living organisms. Because of their abundance and importance, the reaction mechanisms of proteases have been studied more extensively than any other class of enzyme. Many of the first high-resolution X-ray crystal structures of proteins were obtained for proteases. Recently, our understanding of the mechanism of rate acceleration used by proteases and the structural basis for their specificity has improved dramatically through the use of a powerful recombinant DNA technique called site-specific mutagenesis. Developed in the early 1980s, site-specific mutagenesis is a method whereby one or more specific residues in the amino acid sequence of a protein can be removed or, more commonly, replaced with another amino acid via mutagenesis of its corresponding cloned gene (1). The contribution to catalysis of an amino acid functional group in the active site of an enzyme can then be determined directly (2). Because of the valuable insight into the reaction mechanism of proteases afforded by site-specific mutagenesis studies and high-resolution X-ray crystallography, there has been significant progress made in the design of new protease-inhibitor drugs as well as the development of proteases with improved properties for medicinal and industrial applications.

REACTION MECHANISMS

Mechanistic Classification of Proteases

Enzymes that hydrolyze peptide bonds can be grouped into two subclasses, exopeptidases and endopeptidases, depending on where the reaction takes place in the polypeptide substrate. Exopeptidases cleave peptide bonds at the amino or carboxyl ends of the polypeptide chain, whereas endopeptidases cleave internal peptide bonds. Based on their reaction mechanism, proteases may be further classified into four groups: serine, cysteine, aspartic, and metallo (3). The name of each class is derived from a distinct catalytic group involved in the reaction. The active sites of serine and cysteine proteases use serine hydroxyl and cysteine thiol side groups, respectively, as the attacking nucleophiles during catalysis. Their reaction pathway entails formation of a covalent intermediate between the nucleophile and the carbonyl carbon atom of the scissile peptide bond. By contrast, the mechanism of hydrolysis for aspartic and metallo proteases does not involve a covalent intermediate because the nucleophile for both of these enzymes is a water molecule. The different functional groups for each protease reaction mechanism affect their active pH range as well as the types of inhibitors suitable for

inactivation. Indeed, measurements of the pH dependence for activity and reactivity with a set of class-specific inhibitors are typical laboratory methods for determining the mechanistic class of an unknown protease (4). Before describing each mechanism of catalysis in detail, it should be noted that the reaction pathways in all four protease classes share multiple common elements:

- Binding of the substrate polypeptide into a channel or pocket on the enzyme surface
- Nucleophilic attack on the carbonyl carbon of the scissile peptide bond by either oxygen or sulfur
- General base-assisted catalysis for removal of a proton from the nucleophile
- Stabilization of the tetrahedral transition state intermediate formed at the carbonyl carbon of the scissile peptide bond
- General acid-assisted catalysis for transfer of a proton to the amine leaving group

A description of substrate binding and the contribution of binding forces to catalysis and specificity will be discussed in a later section. The focus of this section will be the catalytic groups responsible for carrying out the chemical steps in the reaction.

Serine Proteases

The name *serine protease* refers to the nucleophilic serine residue located in the enzyme active site. In addition to the catalytic serine residue, this protease class is distinguished by having essential aspartate and histidine residues that together form a catalytic triad (Fig. 1). Serine proteases are prevalent in both prokaryotic and eukaryotic organisms and can be further classified into three families according to their structural homology to chymotrypsin, subtilisin, and wheat serine carboxypeptidase II (5,6). A fourth family of serine proteases has recently been identified based on amino acid sequence homology to prolyl oligopetidase (7). The catalytic serine and histidine residues in this enzyme have been identified by covalent modification with active-site-specific chemical reagents (8,9). Although it is expected that a catalytic triad is present in the prolyl oligopetidase family of serine proteases, identification of the catalytic aspartate awaits having a three-dimensional structure of the active site.

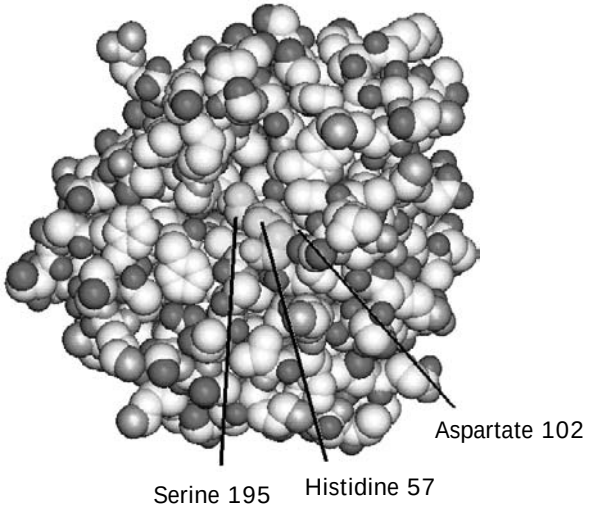

Figure 1. Three-dimensional structure of α-chymotrypsin. Residues forming the catalytic triad—serine 195, histidine 57, and aspartic acid 102—are located at the base of the substrate binding cleft. *Source*: Courtesy of Dr. Richard Bott, Genencor International Inc.

Chymotrypsin, a mammalian digestive enzyme, was the first protease to have its three-dimensional structure determined by X-ray crystallography (10). Other mammalian proteases structurally homologous to chymotrypsin but with different specificity are the digestive enzymes trypsin and elastase, and thrombin, which has specificity similar to trypsin and plays a critical role in blood clot formation. Subtilisin is a bacterial serine protease secreted extracellularly for the purpose of scavenging nutrients. Not all subtilisin-like serine proteases are bacterial in origin. Precursors of bioactive proteins such as hormones and neuropeptides are cleaved by serine proteases with greater structural homology to subtilisin than to chymotrypsin (11). The structure of wheat serine carboxypeptidase II has only recently been determined (12). Not only are the tertiary protein folds completely different for each structural family, the order of the catalytic triad residues in the amino acid sequence are also different. The arrangements are histidine-aspartate-serine, aspartate-histidine-serine, and serine-aspartate-histidine for chymotrypsin-like, subtilisin-like, and serine-carboxypeptidase-II-like serine proteases, respectively. Despite these differences, however, their reaction mechanism and geometry of catalytic residues are nearly identical and are believed to have arisen from different ancestral proteins through a process of convergent evolution.

Hydrolysis of amide and ester substrates by serine proteases follows an acyl transfer reaction pathway:

$$E + S \rightleftharpoons ES \xrightarrow{P_1} EP_2 \xrightarrow{H_2O} E + P_2$$

where ES represents the noncovalent enzyme-substrate Michaelis complex, EP_2 is the acylenzyme intermediate, and P_1 and P_2 are the reaction products generated during acylation and deacylation, respectively. Evidence for the acyl transfer mechanism was obtained from numerous kinetic studies using activated ester substrates where deacylation is the rate-determining step in the reaction such that accumulation and partitioning of the intermediate could be monitored (13). Further support came from direct crystallographic observation of a stable elastase acylenzyme intermediate formed at low temperature (14). X-ray crystal structures also revealed key structural features related to the reaction mechanism of serine proteases: the catalytic triad comprising serine 195, histidine 57, and aspartate 102 (residue numbers are from the chymotrypsin

amino acid sequence), and the oxyanion hole formed by the main chain NH groups of serine 195 and glycine 193 (15). A schematic of the reaction mechanism for serine proteases is illustrated in Figure 2. Formation of the covalent acylenzyme intermediate involves the nucleophilic attack of serine 195 on the substrate carbonyl carbon atom and release of the product P_1. This step is believed to proceed via general base-catalyzed transfer of a proton from the side chain hydroxyl group of serine 195 to the imidazole nitrogen of histidine 57, stabilization of the tetrahedral transition state by hydrogen bonds formed between the negatively charged carbonyl oxygen atom and the main chain NH groups of serine 195 and glycine 193, and general acid-catalyzed transfer of the proton of histidine 57 to the amine leaving group. Deacylation is essentially the same reaction except the attacking nucleophile is a water molecule bound at the site vacated by the P_1-leaving group. The pH dependence for catalysis by serine proteases follows the protonation state of the catalytic histidine residue. Chymotrypsin and subtilisin are active at neutral pH and above where the histidine side group is deprotonated. In contrast, wheat serine carboxypeptidase II is most active in the pH range of 4.5 to 5.5, suggesting an unusually low pK_a for its catalytic histidine residue. Although the role of the catalytic triad and oxyanion hole in the acyl transfer reaction mechanism of serine proteases was de-

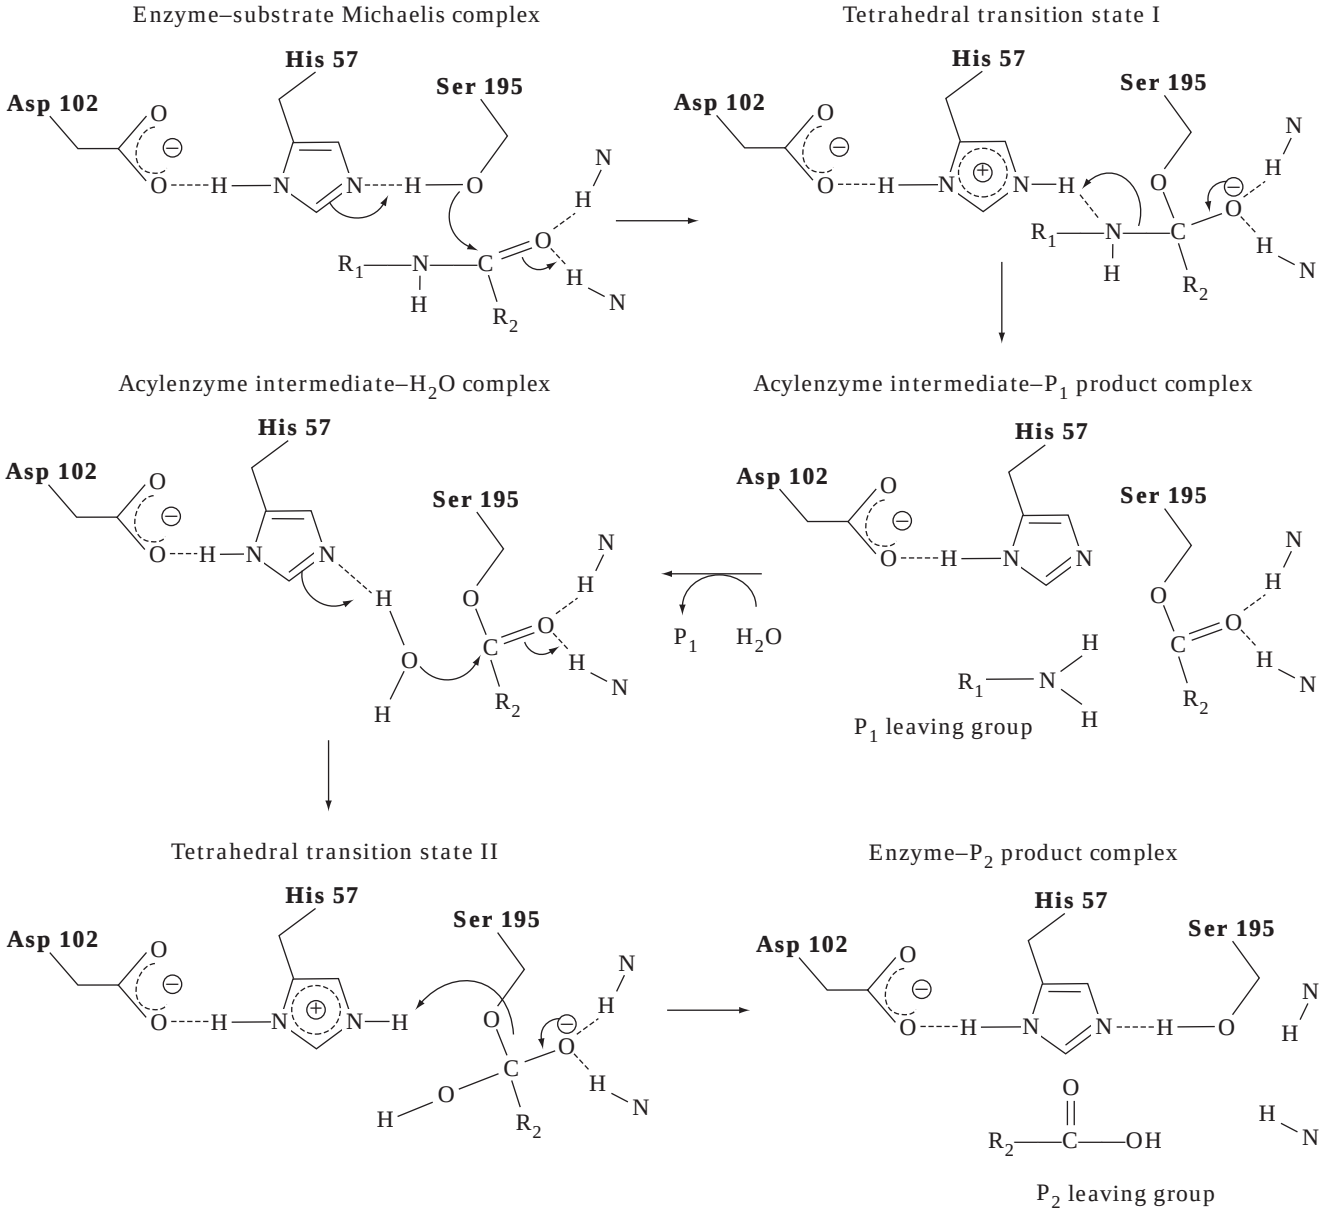

Figure 2. Schematic of the reaction mechanism in serine proteases. Nucleophilic attack of serine 195 on the peptide substrate bound in the substrate binding cleft forms an acylenzyme intermediate that is then hydrolyzed by a solvent water.

scribed more than 20 years ago, there continues to be considerable interest in understanding the fundamental source of their catalytic power.

Site-specific mutagenesis has been used extensively as a tool to better understand the catalytic mechanism of serine proteases. To assess the importance of transition-state stabilization, this technique was first applied to the oxyanion hole of subtilisin BPN' (16,17). Unlike chymotrypsin, where both hydrogen bonds stabilizing the substrate oxyanion are formed with main chain NH groups, the oxyanion hole in subtilisin BPN' consists of the main chain amide group of the catalytic serine 221 and one of the two protons on the side chain nitrogen atom of asparagine 155. Removal of the latter hydrogen bond via substitution of asparagine 155 with an amino acid lacking the necessary functional group or side chain geometry to form a good hydrogen bond to the oxyanion results in a reduction in the rate of catalysis by two to three orders of magnitude. In a similar fashion, the catalytic significance of aspartate 102 in trypsin was investigated by substitution with asparagine and replacement of each residue in the catalytic triad of subtilisin BPN' (serine 221, histidine 64, and aspartate 32) with alanine (18,19). The substitution of alanine for serine and histidine separately in subtilisin BPN' reduced the rate of catalysis by a factor of 10^6, whereas replacement of aspartate 32 with alanine led to a 10^4-fold loss in activity. Simultaneous substitution of all three amino acids in the catalytic triad of subtilisin with alanine also reduces catalysis by a factor of 10^6, illustrating the cooperative nature of these residues in catalysis. Assigning a functional role for aspartate 102 in the mechanism of serine proteases has been less straightforward than for either serine 195 or histidine 57. Initially, it was believed the high nucleophilicity of serine 195 was generated via a charge relay network in which histidine 57 accepts a proton from serine 195 and transfers another proton to aspartate 102 (20). This double-proton transfer reaction, however, has not been supported experimentally. It is now believed that aspartate 102, through a hydrogen bond to the side chain of histidine 57, plays the crucial roles of orienting histidine 57 in the correct tautomeric form to accept a proton from serine 195 and stabilizing the positive charge formed on histidine 57 in the transition state. Recently, it has been debated whether formation of a low-barrier hydrogen bond between the catalytic aspartate and histidine residues in the reaction transition state is an important feature in the catalytic mechanism of serine proteases (21–25). Although this issue remains to be resolved, it is evident that interactions between multiple residues work synergistically to stabilize the oxyanion transition state formed in the reaction mechanism of serine proteases (26).

Cysteine Proteases

The functional roles of cysteine proteases are quite broad, and members of this enzyme class are found in animals, plants, bacteria, and viruses. Like serine proteases, hydrolysis of amide and ester substrates by cysteine proteases follows an acyl transfer reaction pathway (equation 1), but the attacking nucleophile is the thiol group of an active-site cysteine residue instead of a serine hydroxyl group. The plant enzyme papain is the most extensively studied cysteine protease and the first to have its three-dimensional structure determined (27). It is a globular protein with the active site located in a cleft at the interface of two domains. The pH activity profile of papain is a bell-shaped curve centered about pH 6, with activity dependent on formation of a thiolate-imidazolium ion pair between the catalytic residues cysteine 25 and histidine 159. The loss in activity in the acidic pH range is attributed to protonation of cysteine 25 with an apparent pKa of 4, whereas the drop in activity in the basic pH range is attributed to deprotonation of histidine 159 with an apparent pKa of 8.5 (28). The side chain of asparagine 175 is hydrogen bonded to the imidazole of histidine 159, forming a cysteine-histidine-asparagine triad similar to the serine-histidine-aspartate catalytic triad found in serine proteases. The functional role attributed to asparagine 175 is that of orienting the imidazole ring of histidine 159. The importance of this residue for catalysis has been confirmed by screening of site-specific random amino acid replacements at position 175 in papain for catalytic activity (29). Glutamine at position 175 was found to have weak activity whereas no activity was observed for 11 other amino acids incorporated at position 175. Although a complete description of the acylation and deacylation steps in the reaction pathway of papain remains to be defined, it is clear there are significant differences in the mechanisms of cysteine and serine proteases.

Cysteine proteases have been referred to as activated enzymes because their thiolate-imidazolium ion pair present in the ground state obviates the need for general base-catalyzed removal of a proton to generate the nucleophilic thiolate anion in acylation and for general acid catalyzed proton transfer from histidine 159 during deacylation (30). A schematic of the reaction pathway for papain is shown in Figure 3. After formation of the noncovalent enzyme-substrate Michaelis complex, acylation proceeds via nucleophilic attack of the cysteine 25 thiolate anion on the carbonyl carbon of the substrate scissile bond. Breakdown of the tetrahedral transition state into a covalent acyl–enzyme intermediate is facilitated by rotation of the imidazole ring of histidine 159 and general acid-catalyzed transfer of its proton to the amide nitrogen of the leaving group. Hydrolysis of the acyl–enzyme intermediate during deacylation is base catalyzed with transfer of a proton from a water molecule to histidine 159 to generate the OH-nucleophile. Until recently, the existence of an oxyanion transition state in both acylation and deacylation has been the subject of considerable debate. A putative oxyanion hole in papain has been described comprising the main chain amide proton of cysteine 25 and the side chain NH_2 group of glutamine 19. Substitution of alanine and serine for glutamine at position 19 in papain via site-directed mutagenesis resulted in mutant enzymes having 60- and 600-fold decreases in catalytic efficiency, respectively, compared to wild-type enzyme (31). The effect of these mutations on the catalytic activity of papain are somewhat smaller than that observed for analogous mutations in the oxyanion hole of subtilisin. However, these results clearly demonstrate the importance of oxyanion stabilization in the reaction mechanism of cysteine proteases.

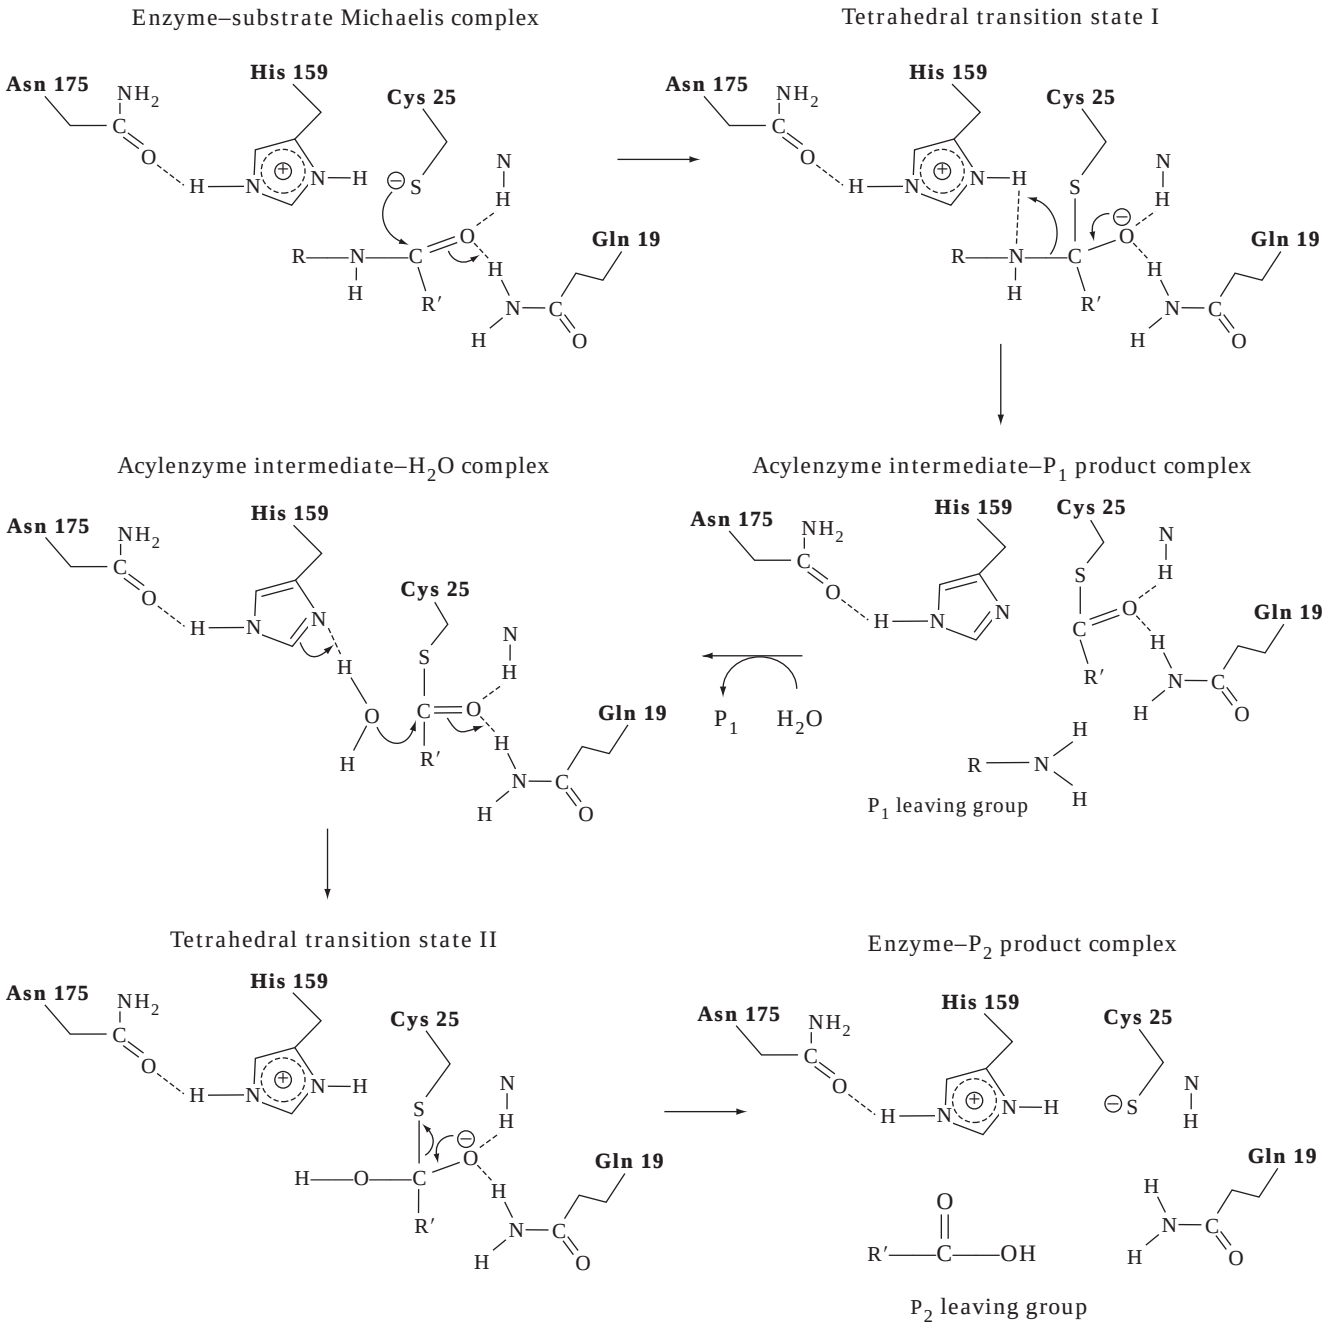

Figure 3. Schematic of the reaction mechanism in cysteine proteases. Nucleophilic attack of the thiolate anion of cysteine 25 on the peptide substrate bound in the substrate binding cleft forms an acylenzyme intermediate that is then hydrolyzed by a solvent water.

Aspartic Proteinases

The aspartic proteinases are named for the essential catalytic role of two aspartic acid residues. The three-dimensional structures for aspartic proteases of mammalian, fungal, and viral origin are quite comparable to each other. These enzymes are composed of two structurally similar domains with the active site formed within the cleft between each domain, much like the active site in cysteine proteases. Further, each domain contributes one of the two aspartate residues, aspartate 32 and aspartate 215, critical for catalysis (residue numbers are from the pepsin amino acid sequence) (32). The pH activity profile of aspartic proteinases is a bell-shaped curve, with activity dependent on protonation and ionization of the carboxylate group of aspartates 32 and 215, respectively. Most aspartic proteases are active in the range of pH 2 to 4, and in the past, this class of enzymes was referred to as acid proteases. Renin is one exception where activity is in the pH

range of 5.5 to 7.5. Inhibition by pepstatin is an important feature common to all aspartic proteases. Pepstatin, a natural microbial hexapeptide containing a statine residue, is believed to be a mimic of the reaction-transition state. Crystal structures of aspartic proteases with various analogues of pepstatin have provided valuable insight in elucidating the reaction mechanism and for the purpose of designing inhibitor drug molecules (33).

Unlike serine and thiol proteases, proteolytic cleavage of peptide bonds by aspartic proteases does not proceed via a covalent acyl intermediate. A water molecule bound at the active site between the carboxylates of aspartates 32 and 215 is believed to be the attacking nucleophile. Attack of the water on the scissile carbonyl is facilitated by the general base and general acid functions of aspartates 215 and 32, respectively. As shown in Figure 4, the ionized aspartate 215 abstracts a proton from the water nucleophile, and aspartate 32 transfers its proton to the carbonyl oxygen. Stabilization of the tetrahedral intermediate is achieved through hydrogen bonds formed between the gem-diol and the negatively charged aspartate 32 and between the aspartate 215 and one of the hydroxyl oxygens. Breakdown of the intermediate and release of products is facilitated by transfer of the proton from aspartate 215 to the amine nitrogen of the leaving group and deprotonation of the statinelike hydroxyl by aspartate 32. Additional stabilization of the tetrahedral intermediate via hydrogen bonds from the side chain of tyrosine 75 has also been proposed. Substitution of tyrosine 75 with other amino acid residues in calf stomach chymosin and *Rhizomucor pusillus* pepsin by site-directed mutagenesis results in modified enzymes with dramatically altered catalytic activity, suggesting a critical role of this residue for catalysis, presumably via formation of hydrogen bonds to one of the hydroxyls formed in the transition state (34).

Metallopeptidases

The catalytic activity of metallopeptidases is dependent on the presence of one or two metal ions, most commonly zinc, bound at the active site. The reaction mechanism for the two-metal ion enzymes remains to be fully understood, although they clearly comprise a class of metallopeptidases distinct from that of the single-metal ion enzymes. Significant differences in amino acid sequence and tertiary structure are observed both for single- and two-metal ion metallopeptidases isolated from bacteria, fungi, and higher organisms. Crystal structures have recently been determined for three different aminopeptidases having two-metal ions at their active site (35–37). The identification of catalytic groups and elucidation of a reaction mechanism for single-metal ion metallopeptidases is based largely on crystallographic structural analyses of the bacterial endopeptidase thermolysin and the pancreatic exopeptidase carboxypeptidase A (38). Although the three-dimensional structures of these two enzymes are very different, they share a similar orientation of reactive groups, suggesting convergent evolution of a common reaction mechanism. Like cysteine and aspartic proteases, single-metal ion metallopeptidases are typically bilobal proteins with the active site located at a cleft formed at the junction of the two domains. Another feature in common with aspartic proteases is formation of a noncovalent intermediate during catalysis, because the attacking nucleophile in the single-metal ion metallopeptidases is a zinc-bound water molecule.

Figure 5 shows a schematic of the reaction mechanism for thermolysin. Binding of substrate at the active site displaces the water nucleophile toward glutamate 143, with the carbonyl oxygen of the scissile bond polarized by the positively charged zinc ion. Glutamate 143 functions as a proton shuttle during catalysis, similar to the role of histidine in the catalytic triad of serine proteases. General base-catalyzed transfer of a proton from the nucleophilic water to glutamate 143 facilitates attack of the hydroxyl anion on the substrate carbonyl carbon atom. This proton is then passed to the amide nitrogen of the leaving group. Not surprisingly, substitution via site-specific mutagenesis of glutamate 143 with alanine in the metallopeptidase from *Bacillus subtilis* results in complete loss of enzyme activity (39). The negatively charged oxyanion formed in the transition state is believed to be stabilized via hydrogen bonds to the side groups of histidine 231 and tyrosine 157. Replacement of histidine 231 with alanine or phenylalanine by site-specific mutagenesis of the thermolysin-like endopeptidase isolated from *B. stearothermophilus* leads to a large reduction in k_{cat} and little change in K_M

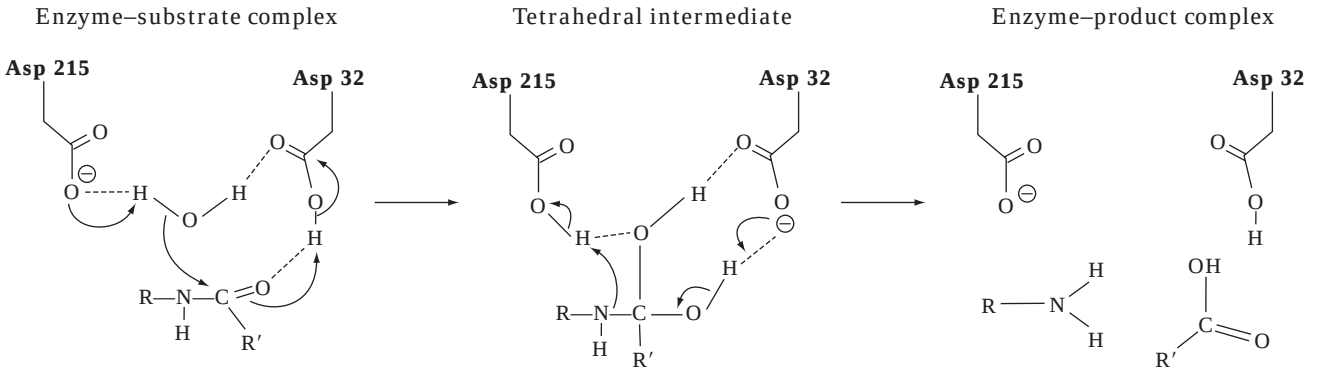

Figure 4. Schematic of the reaction mechanism in aspartic proteinases.

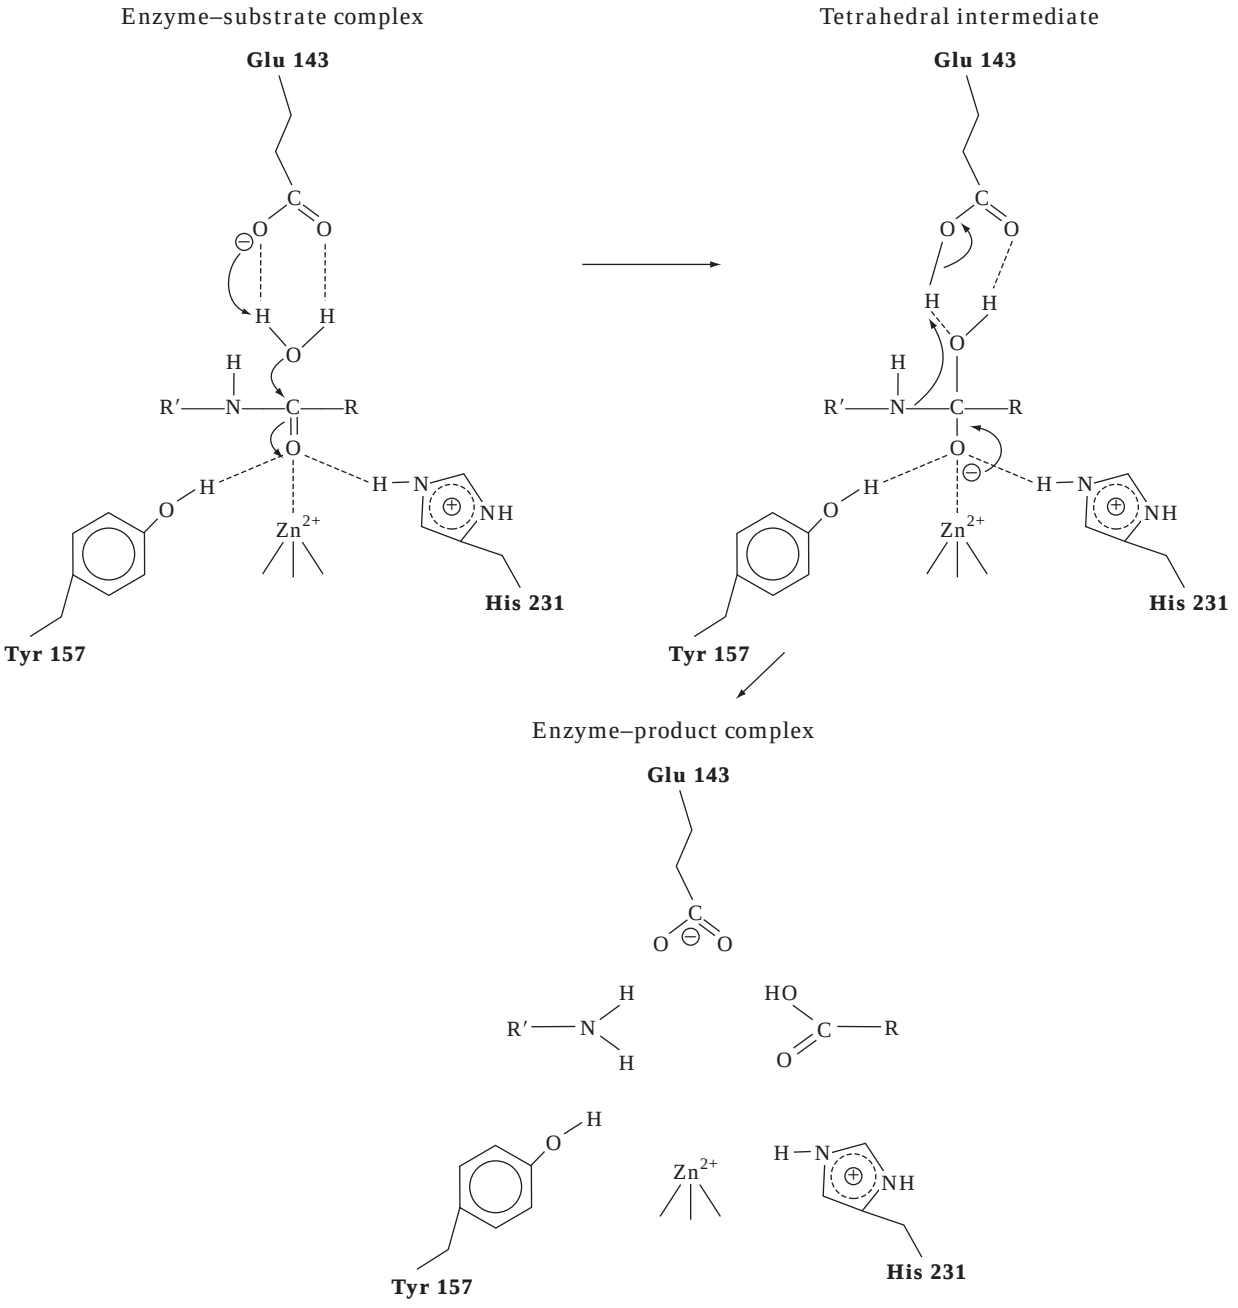

Figure 5. Schematic of the reaction mechanism of metallopeptidases.

(40). This result is consistent with assigning the role of transition state stabilization for histidine 231. A similar effect is obtained where arginine 127 in carboxypeptidase A, a mammalian exopeptidase, is substituted by site-specific mutagenesis with either alanine or methionine (41). The X-ray crystal structure of carboxypeptidase A reveals that arginine 127 is located at an active-site position equivalent to histidine 231 in thermolysin. Stabilization of the transition state in carboxypeptidase A is achieved via electrostatic interaction between the oxyanion and the positively charged guanidinium side group of arginine 127.

BINDING ENERGY IN CATALYSIS

A key feature used for rate acceleration by all four protease families is lowering of the reaction activation barrier through stabilization of the tetrahedral intermediate. Removal of the catalytic triad in the serine protease subtilisin via site-specific mutagenesis leads to an enzyme still capable of a 1,000-fold enhancement in the rate of peptide bond hydrolysis compared to the nonenzymatic reaction (16). Although much of the rate acceleration observed in the catalytically impaired subtilisin enzyme is likely attributable to the presence of a functional oxyanion hole,

the contribution of additional binding energy to catalysis is also possible. The γ-hydroxyl group of threonine 220 in subtilisin has been shown to stabilize the oxyanion transition state independent of the oxyanion hole (42). In addition, the role of long-range electrostatic interactions in subtilisin catalysis has been explored via measurement of the contribution of charged residues on the enzyme surface to binding of a transition state analogue inhibitor (43). Interaction of the substrate peptide chain with residues along the protease binding cleft is another source of stabilization energy.

The substrate binding cleft of proteases is often quite large, with numerous regions of contact, called subsites, for binding amino acid residues of the polypeptide substrate (44). Figure 6 shows the structure of a peptide substrate bound into the binding cleft of the serine protease subtilisin. Hydrogen bonding, salt bridge formation, and hydrophobic interactions between substrate and subsite residues create significant levels of binding energy important in determining substrate specificity and in facilitating catalysis. The rate of catalysis for the aspartic proteinase pepsin is observed to increase progressively as the length of the substrate polypeptide chain increases (45). Dramatic alterations in the substrate specificity profiles and catalytic activity of numerous proteases have been achieved via substitution of a limited number of subsite residues by site-directed mutagenesis (46). Protein structure outside of the binding cleft has also been found to affect the rate of peptide bond hydrolysis. For example, a recent site-specific mutagenesis experiment that altered the substrate specificity of trypsin to match that of chymotrypsin revealed that in addition to changes in the specificity pocket of the binding cleft, recruitment was required of two surface loop sequences that do not contact bound substrate (47). Although a description of the structural mechanism for how these loops influence catalysis remains to be determined, the importance of long-range enzyme–substrate interactions for transition-state stabilization is clearly apparent.

The catalytic triad residues serine 221, histidine 64, and aspartic acid 32 are also shown. *Source*: Courtesy of Dr. Richard Bott, Genencor International Inc.

FUTURE DIRECTIONS

More than 50 years ago, Linus Pauling proposed that enzymes accelerate chemical reactions by providing a flexible template for binding the transition-state structure of a substrate molecule rather than its ground state (48). The structure-activity relationships elucidated from investigations on the reaction mechanisms of proteases provide an experimental framework that supports Pauling's theory on how enzymes catalyze chemical reactions. Although protease reaction mechanisms are still not completely understood, it is evident that essential catalytic groups can be readily identified from X-ray crystallographic and site-specific mutagenesis studies. The importance of having detailed information about the active-site geometry and chemical bonds stabilizing the reaction transition state has been established for the development of inhibitor drugs to treat protease-related diseases (49). Our knowledge of protease structure and function will also enable the facile discovery of new proteases from genetic sequence databases. The amount of genomic information available to researchers is growing at a fast rate. There are now 45 in-progress and 20 complete prokaryotic genome sequences, and 17 in-progress and 1 complete eukaryotic genome sequences available for analysis on the Internet (*www.mcs.anl.gov/home/gaasterl/genomes.html*). Computer searches for homologous sequence alignments and functional motifs such as metal–ion binding sites can rapidly identify protein sequences having similarity to a particular protease family. Monitoring of expression or genetic variability of the newly discovered gene via high-density DNA array technology can further our understanding of the physiological role of the new protease and its possible clinical significance (60).

The wealth of information known about protease reaction mechanisms has also led to exciting new applications of protein engineering in the creation of novel biocatalysts. For example, the activity of serine proteases for hydrolysis of amide and ester bonds can be modified by altering their active site structure via chemical modification or site-specific mutagenesis (51–55). Such a change in reaction specificity minimizes product degradation in protease-catalyzed peptide synthesis reactions. Incorporation of selenium at the active center of subtilisin results in an enzyme having significant peroxidase activity (56). More

recently, a protease having novel specificity was created via incorporating the catalytic triad of serine proteases into the substrate binding site of a nonprotease enzyme (57). The success of these and other experiments with proteases demonstrate the feasibility of redesigning the structure of a protein to produce a catalytic activity or specificity unobtainable from a naturally occurring enzyme.

OUTLINE

INTRODUCTION

Pseudomonads are known to be widely encountered in nature, occupying niches ranging from contaminated soil to infected mammalian tissues. The extraordinary metabolic versatility of these species has been noticed since the early days of their study (1,2), probably because of the capability of many pseudomonads to share and acquire genetic information required to degrade a large number of compounds (3,4).

Because of the wide variety of degradation reactions and metabolic pathways existing in nature, it is not surprising that screening programs have led to the isolation of numerous bacterial strains, capable of using countless substrates. Interestingly, many substrates that can be degraded by *Pseudomonas* species include not only water-soluble chemicals but also highly hydrophobic and toxic compounds. The observation that (partially) purified enzymes and even intact cells can be efficiently used in mixed-solvent systems or in the presence of anhydrous solvents has led to widespread study and application of biocatalysts in organic synthesis during the past two decades.

The growing demand for optically pure drugs and agrochemicals, devoid of enantiomeric ballast, and the improvement of chemical catalysts have initiated development toward enantiospecific synthesis routes for chiral substances. However, the production of enantiopure products using chemical catalysts is not always feasible, and alternative chemical routes usually tend to be tedious, involving costly and dirty process steps. Therefore, biocatalysis exploiting the enzymatic activity of cells evolved in nature presents a valuable tool, with a large economical potential, for organic synthesis (Fig. 1).

BIOSYNTHESIS

A well-known biotechnological production process for a natural compound on an industrial scale with the help of *Pseudomonas* strains is the production of vitamin B-12 by *P. denitrificans* (7), which is especially efficient in media (such as beet molasses) that are rich in betaine (8,9). The production of vitamin B-12 by methylotrophic *Pseudomonas* sp. AM-1 on the cheap carbon source methanol (10) has not been able to replace the successful original industrial process (7).

Microbial polysaccharides are important biotechnological products that have found applications in the food, agricultural, and chemical industries (11–13). Exopolysaccharide production is common to *P. fluorescens*, *P. putida*, *P. aeruginosa*, *P. cepacia*, and other *Pseudomonas* (14–16). These compounds are believed to serve as a defense mechanism against the host immune system and as protection against bacteriophages or dehydration. Plant pathogens may use it as an anchoring material (17). Surfactants excreted by hydrocarbon degrading species improve the mobilization and bioavailability of mineral oils in soil (18,19).

The production of *Pseudomonas* exopolysaccharides such as alginate from *P. aeruginosa* and gellan gum from *P. elodea* have been commercialized, but these polysaccharides have not reached the level of application of xanthan gum, the principally used microbial polysaccharide from *Xanthomonas campestris* (17). The role of alginates in cystic fibrosis has triggered numerous scientific efforts to elucidate the molecular biology of their synthesis (20–22), which may well result in more efficient ways to produce this polysaccharide that is frequently applied to immobilize cells and enzymes in biotransformation procedures.

Other biopolymers that are of industrial importance are the bacterial polyesters: poly-3-hydroxyalkanoates (23,24). These biopolymers are biodegradable and provide an environmentally friendly alternative to common plastics. The commercialization of Biopol, a poly-3-hydroxybutyrate-poly-3-hydroxyvalerate copolymer from *Alcaligenes eutrophus* by Zeneca (ICI) has been realized (25), and the development of other biodegradable plastics is underway.

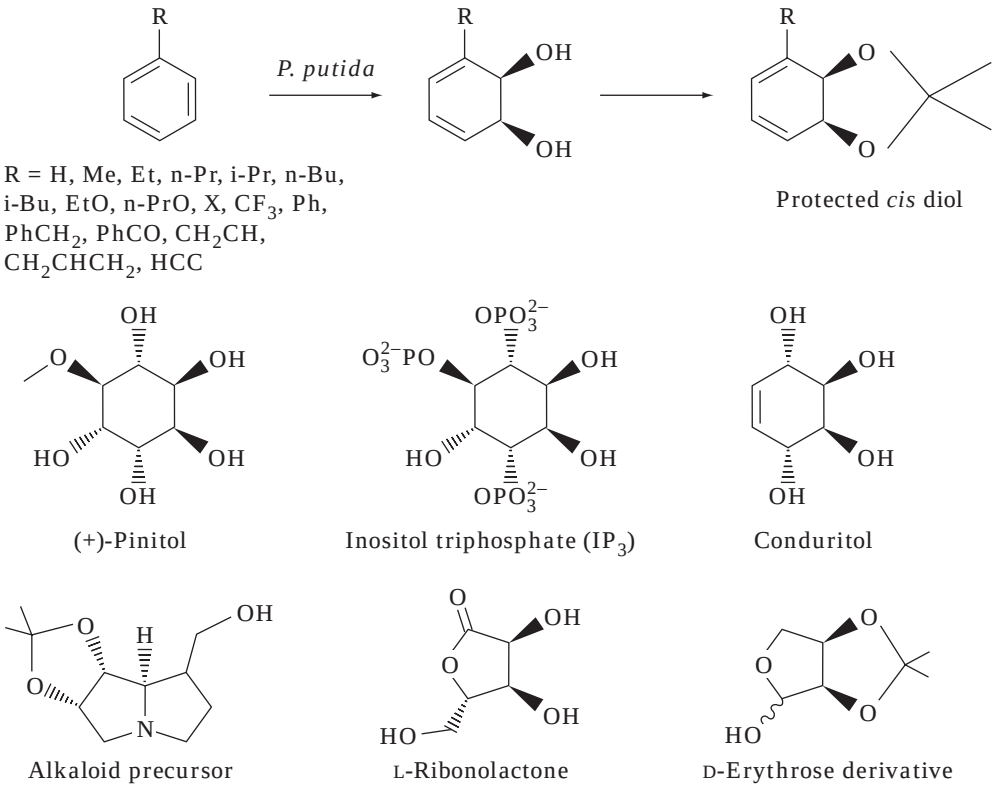

Figure 1. Synthesis of variously substituted *cis*-dihydrodiols by *P. putida* and several examples of complex molecules made using this synthon (5,6).

Poly-3-hydroxyalkanoates from *P. oleovorans* (26), an alkane-degrading microorganism (27,28), are of particular interest, because these bacterial polyesters can be produced with variable side groups, depending on the (co)substrate added to the culture (24,29,30). Biopolymers with variable-length side chains, unsaturated side chains, and aromatic pendant groups have been produced by this microorganism (24), but large-scale commercial application of these medium-chain-length poly-3-hydroxyalkanoates has yet to be realized.

BIOTRANSFORMATIONS

The use of enzymes in biocatalytic processes, either in (partially) purified form or in whole cell systems, is not evenly distributed over the different enzyme classes, defined by the Nomenclature Committee of the International Union of Biochemistry and Molecular Biology (formerly Enzyme Committee [EC]) (31).

Biocatalysts based on the hydrolases (EC class 3) are most used in synthetic reactions, because these enzymes are cofactor independent; are often secreted from the cells into the extracellular medium, facilitating their isolation, and in some cases are commercially available. Furthermore, many hydrolases have been shown to maintain their activity in media containing bulk amounts of hydrophobic, organic solvents. Oxidoreductases (EC class 1) are relatively complex enzymes that require cofactors and frequently consist of more than one protein component and are therefore mostly used as whole cell biocatalysts. Despite their complexity and difficulty of handling, these biocatalysts are important tools by virtue of their regio- and stereoselectivity. The enzymes that catalyze addition–elimination reactions, lyases (EC class 4), are underrepresented in biotransformations, although some biocatalysts of this type are used on a large scale in industrial applications, such as for the production of acrylamide (32). The development of biocatalysts that catalyze group transfer reactions (transferases, EC class 2) or isomerizations (isomerases, EC class 5) as well as ligase-based biotransformation reactions (EC class 6) is in a relatively early stage, with few realized industrial applications. Enzymes of these classes generally are highly substrate specific, which makes them less suited for wide-range biocatalytic applications.

Redox Reactions

Oxidation and reduction reactions catalyzed by oxidoreductases require cofactors, such as $NAD(P)^+$ or NAD(P)H, as electron acceptors or donors. Because the addition of cofactor to an enzyme reaction mixture in stoichiometric quantities is economically unfeasible, oxidative and reductive bioconversions are usually performed using whole cell cultures, where metabolically active cells efficiently recycle the cofactor. However, recent developments of efficient in situ cofactor regeneration systems (5,33) have stimulated the use of dehydrogenases in enzymatic biocatalyses.

Useful oxidoreductases encompass predominantly dehydrogenases, which catalyse the addition or elimination of hydrogen, and oxygenases, catalyzing the direct incorporation of molecular oxygen into organic molecules. Known hydrogenation reactions catalyzed by pseudomonads include the reduction of various aliphatic, cyclic, and aromatic ketones and aldehydes (34–36). *Pseudomonas*-catalyzed oxidations of hydroxy groups have been reported for substrates such as morphine, codeine, and (*S*)-malic acid (37,38).

Monooxygenases are a class of oxygenases that catalyze the addition of single oxygen atoms introducing hydroxy groups or epoxy moieties to aliphatic and olefinic compounds as well as aromatic rings. Additional reactivities include Baeyer-Villiger reactions, sulfoxidation reactions, and oxidative dehalogenations (5,39). The former two reaction types appear as promising alternatives to chemical synthesis pathways because of their (stereo-) specificity. Monooxygenase-catalyzed dehalogenation reactions performed by pseudomonads have not proved useful for synthetic biotransformation reactions. On the other hand, these reactions are of importance for biodegradation purposes.

Dioxygenases, a second class of oxygenases, drive the dihydroxylation of aromatic compounds to optically active *cis*-diols (Fig. 1). Often, these monooxygenase and dioxygenase-catalyzed hydroxylation reactions represent the initial steps in microbial degradation pathways of organic compounds. With the necessary genes in hand, recombinant strains have been developed that catalyze these initial oxidation reactions only, without further degradation, yielding specifically oxidized organic bioconversion products (40,41).

Generally, these enzyme systems possess a broad substrate range as well as a high regio- and stereospecificity (Fig. 2). In addition, different enzyme systems have been shown to ideally complement each other, such as the alkane hydroxylase system (EC 1.14.15.3) from *P. oleovorans* (43) and xylene oxygenase (EC 1.14.15.-) from *P. putida* mt-2 (44). For example, xylene oxidizes pendant methyl groups on aromatic rings (45), whereas alkane hydroxylase does not accept toluene derivatives as substrates but will introduce a terminal hydroxy group on ethyl side chains (46,47).

Because of their versatility and specificity, these enzyme systems represent valuable biocatalysts for the synthesis of chiral organic compounds, and they are being exploited in industrial applications for the production of fine chemicals (48,49) and pharmaceuticals (50).

Group Transfer Reactions

Transferases catalyze group transfer reactions. Although some acyltransferases, alkyltransferases, amino transferases, glycosyl transferases and phosphoryl transferases have found their way into biocatalytic processes, the application of transferases from pseudomonads on an industrial scale is rare.

Transferase-catalyzed reactions reported in the academic and patent literature include amino- (51,52), glycosyl- (53,54), and phospho-transfer reactions (55). The alkyl transfer reaction for the formation of L-serine from the achiral amino acid glycine and methanol was realized using serine hydroxymethyl transferase (EC 2.1.2.1) from *Pseudomonas* MS31, depicted in Figure 3 (56).

Hydrolyzations

Most industrial and laboratory enzyme processes are based on hydrolases. These enzymes do not use cofactors, usually consist of one catalytic component, and are readily available from commercial suppliers. Furthermore, the ability of hydrolases to catalyze synthesis reactions in nonaqueous environments has been thoroughly investigated and has provided paths to synthesize complex esters and amides.

Processes with pseudomonad hydrolases include reactions for the cleavage of ester, amide, and glycosidic bonds, the hydrolysis of epoxides to diols and nitriles to carboxylic acids, and the dehalogenation of chlorinated organic compounds (5,57). Their principle value lies in their contribution to the enantiopure synthesis of chemicals, often achieved by resolving racemic starting compounds or intermediates readily obtained from inexpensive precursors by chemical synthesis (Fig. 4). Also, many enzymatic reactions proceed under milder conditions and produce less-hazardous waste products compared to the chemical reaction alternative (5), which explains why especially nitrilases are chosen even when chemo-, regio- or enantioselectivity is not required for the synthesis of carboxylic acids from nitriles.

Hydrolytic reactions catalyzed by *Pseudomonas* enzymes are used as intermediate steps in various industrial processes for the synthesis of compounds such as natural and unnatural amino acids and peptides, organic acids, alcohols, and esters. Applications of these products range from food additives and agrochemicals to pharmaceuticals, including antibiotics, anticancer drugs, anti-inflammatory drugs, and β-blockers.

Lipases are the most applied hydrolases in biotransformations because these enzymes are highly enantioselective and are readily available from commercial suppliers. The pseudomonads are particularly rich in catalytically useful lipases. Lipases (EC 3.1.1.3) from *P. fluorescens*, *Pseudomonas* sp., *P. cepacia*, and *P. aeruginosa* have been and continue to be major players in the field of enantioselective ester hydrolysis and esterification reactions with technical or commercial applications (59–61). (Fig. 5)

Interestingly, proteases (EC 3.4.-.-) from pseudomonads have not received much attention, and they are hardly commercially available, although these hydrolytic enzymes obtained from other sources (e.g. subtilisin, chymotrypsin, papain) are very frequently used in many industrial and laboratory applications.

The discovery that many hydrolytic enzymes function well in organic solvents has lead to an even broader application spectrum of these biocatalysts, because it is possible to use substrates and to produce products unstable in water systems, and synthesis reactions have become feasible in low-water systems by eliminating the hydrolytic reaction dominant in aqueous media (62). For example lipases can be directed to catalyze esterifications or transesterifi-

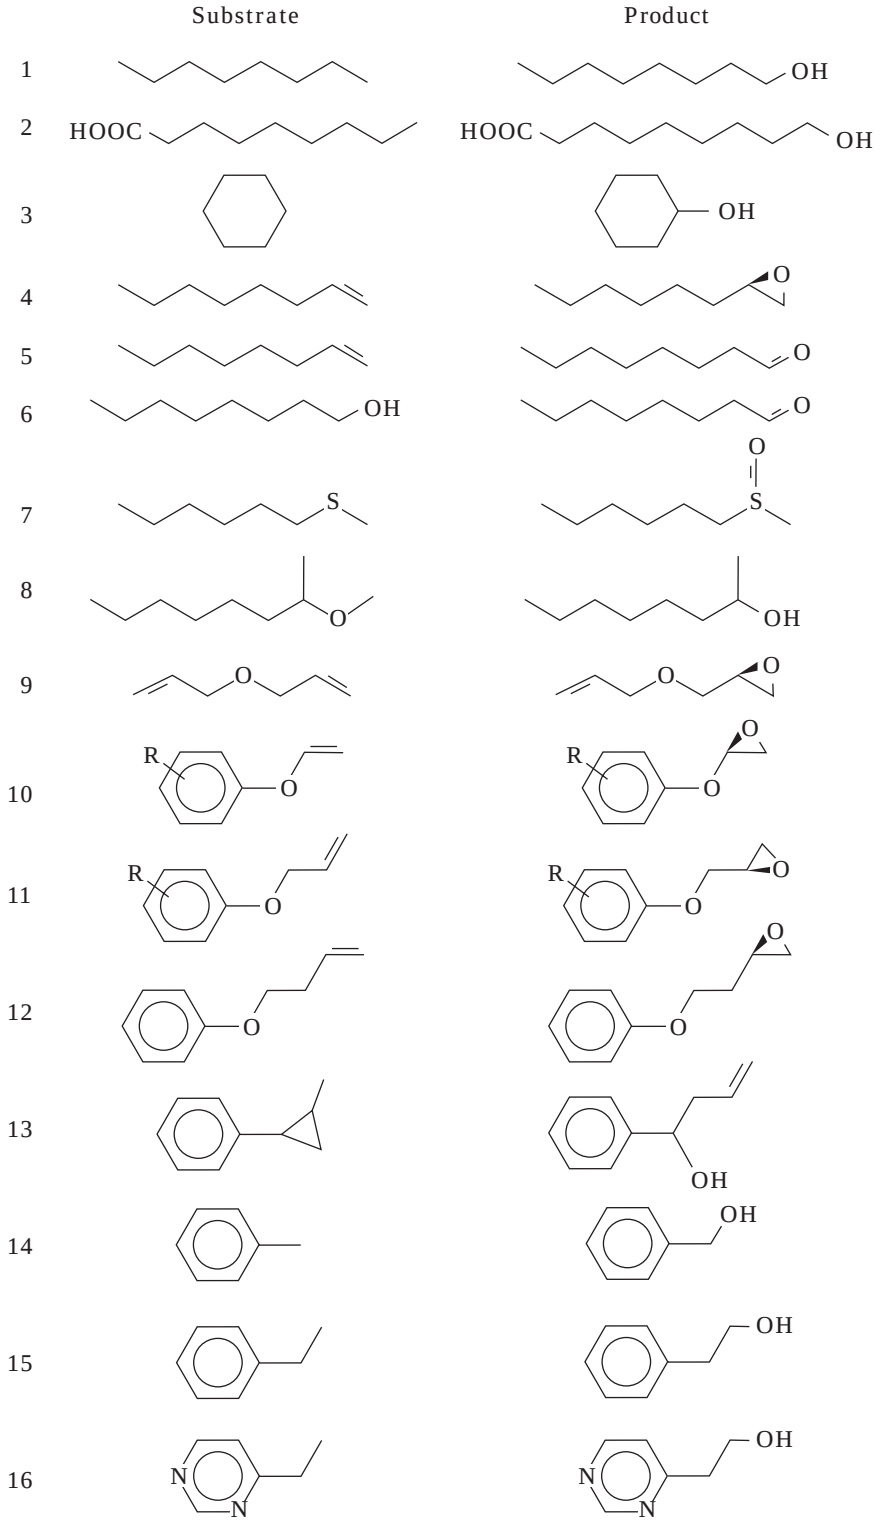

Figure 2. Substrate range of the alkane hydroxylase system (EC, 1.14.15.3) (42). Examples of the classes of substrates are shown. 1, C6–C14 alkanes to corresponding 1-alkanols; 2, C6–C12 fatty acids to ω-hydroxy fatty acids; 3, cyclohexane to cyclohexanol; 4, C3–C12 1-alkenes to 1,2-epoxyalkanes; 5, 1-octene to 1-octanal; 6, 1-octanol to 1-octanal; 7, methyl hexyl thioether to corresponding sulfoxide (and heptylthiol); 8, branched ethers to alcohol (demethylation); 9, diallyl ether to corresponding epoxide; 10, ring-substituted allylbenzene to 3-phenyl-1,2-epoxypropane; 11, ring-substituted allyl phenyl ethers to corresponding epoxides; 12, substituted allyl benzyl ethers to corresponding epoxides; 13, (*R*,*S*)-*trans*-2-phenyl-1-methylcyclopropane to 1-phenyl-3-butene-1-ol; 14, toluene to benzylalcohol; 15, ethylbenzene to 2-phenylethanol; 16, ethyl-substituted heterocyclic 5- and 6-membered aromatic rings to corresponding alcohols.

cation reactions such as acylation or alcoholysis. Increased conformational and thermal stability of water-soluble enzymes in hydrophobic solvents allows features such as molecular imprinting, by lyophilizing the enzyme from an aqueous solution at an ideal pH or in the presence of the preferred substrate, enzyme activity and specificity can be influenced (63).

Addition and Elimination Reactions

Lyases catalyze additions to double bonds or eliminations that generate double bonds and are specific for carbon–carbon, carbon–oxygen, carbon–nitrogen, carbon–sulfur, carbon–halide, or phosphorus–oxygen bonds. A strong enantioface discrimination during addition reactions is typ-

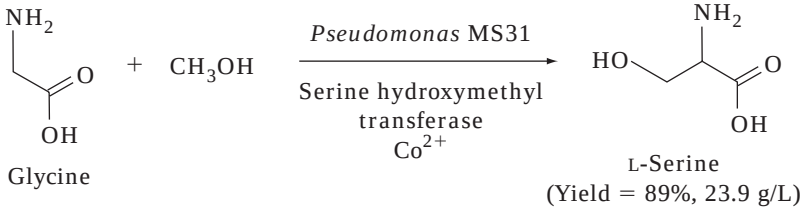

Figure 3. Biotransformation of glycine to L-serine using *Pseudomonas* (56).

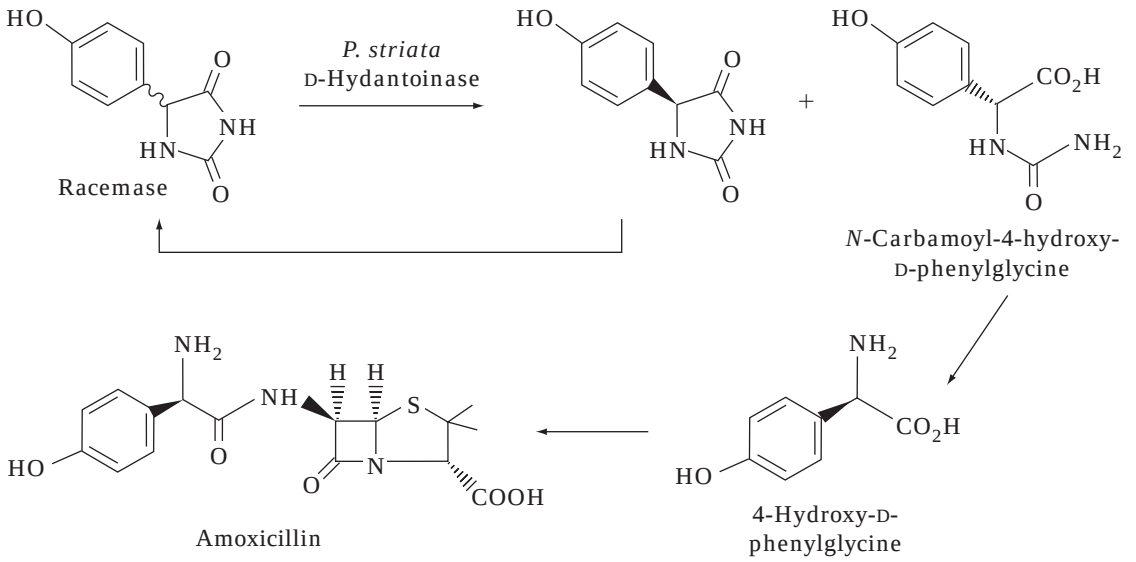

Figure 4. Amoxicillin production with a *P. striata* hydantoinase, a hydrolase that cleaves hydantoin rings to linear hydantoic acids (58).

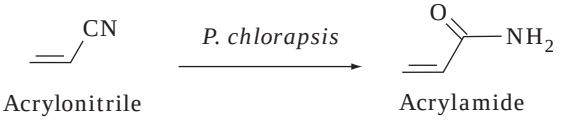

Figure 5. The production of acrylamide from acrylonitrile by Nitto using *P. chlorapsis* or *R. rhodochrous* J1 acrylonitrile hydrolyase (nitrile hydratase) (32).

ical of lyases, and lyase-catalyzed eliminations are as a rule also highly enantioselective, which makes them useful tools for chiral synthesis (64). Unfortunately, most lyases have a narrow substrate spectrum, which limits the applicability of these enzymes in biocatalytic processes (5).

Nevertheless, a number of industrial applications exploiting *Pseudomonas* lyases do exist (57). These include aminolyases for the synthesis of the artificial sweetener aspartame, L-aspartyl-L-phenylalanine methyl ester (51,65,66); carnitine hydrolyase (EC 4.2.1.89), containing whole cells of *Pseudomonas* sp. used by Lonza to produce the food additive L-carnitine (67,68), and haloyases, used for the synthesis of D-cysteine derivatives, important building blocks for the semisynthetic production of cephalosporin, (*S*)-carboxymethxy-D-cysteine. Originally, the hydrolyase acrylonitrile hydrolase from *P. chlororaphis* B23 (EC 4.2.1.84) was used as a catalyst for the production of acrylamide from acrylonitrile by the Nitto company on a scale of 30,000 tons per year (59), but since 1991 *R. rhodochrous* J1 has been used for production because of its superior reaction characteristics (69).

Isomerizations

Amino acid racemases (EC 5.1.1.10) catalyze the interconversion of D- and L-amino acids and play an important role in the industrial production of some amino acids, because racemization of the undesired or nonconverted enantiomer makes a 100% yield of the desired enantiomer attainable (59). In a number of processes, multienzyme reaction mixtures that include racemases have been used for the stereoselective synthesis of various amino acids (70,71) (Fig. 6).

The use of carbohydrate isomerases from pseudomonads is limited, but some processes have been described for the synthesis of fructose, mannose, and psicose (53,72,73).

Ligations

Ligases catalyze the joining of two molecules at the expense of the hydrolysis of a high-energy phosphate bond and are of particular use in molecular biology. In the bio-

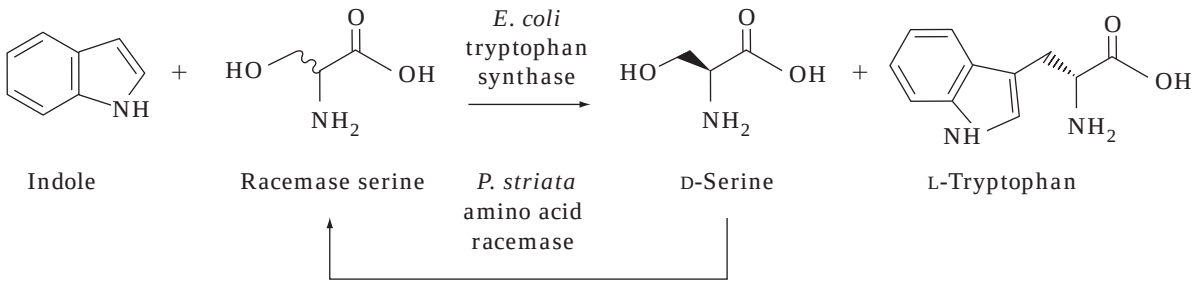

Figure 6. The Mitsui Toatsu process for production of L-tryptophan using serine racemase from *P. striata* (69).

transformation field, however, these enzymes are applied to a very limited extent (31).

Phenyl acetyl CoA ligase (EC 6.2.1.21) from *P. putida* M has been used in conjunction with *Penicillum chrysogenum* acyl-CoA:6-APA acyltransferase to produce a variety of penicillin analogues (74). Because of the wide substrate range of the enzymes involved (75), this system allows the in vitro synthesis of a wide variety of β-lactam antibiotics such as 3-furylmethylpenicillin and several ketoalkylpenicillins (76,77).

BIOPROCESS TECHNOLOGY

Toxicity of Apolar Organic Solvents

Many substrates and products involved in biosynthesis and biotransformation reactions inhibit the catalytic activity of cells or enzymes above critical concentrations. Which organic solvents cause inhibitory effects is most reliably predicted by the logarithm of the octanol-water partitioning coefficient (log*P*) (78). In general, complete biocatalyst inhibition is observed when apolar compounds with a log*P* below 2 are added to liquid cell suspension cultures at or above water-saturating concentrations. Above values of 4 to 5, inhibitory effects are markedly reduced. Gram-positive bacteria, which remain active in the presence of solvents with log*P* values above 4.5 to 6, show a higher sensitivity to solvents than Gram-negative bacteria, of which *Pseudomonas* species belong to the most resistant, where growth is observed in the presence of solvents with log*P* values as low as 3 (79–81).

Unless specific interactions with enzymes exist that limit growth, apolar chemicals generally harm cells as a result of their partitioning into the cell membrane bilayers. As a consequence, higher membrane fluidity and permeability results, leading to the loss of cell functionality and eventually cell lysis (82–84).

To withstand the exposure to organic solvents, cells react by increasing their membrane hydrophobicity and by decreasing membrane fluidity. The latter compensates the fluidizing effects of solvent molecules intercalated in the lipid bilayers, whereas changes in hydrophobicity have been observed to reduce the partitioning of solvents to the membranes (85,86). These effects are achieved by the incorporation of longer C_{18} fatty acids and proteins into the cell membrane, by modulation of the ratio between saturated and unsaturated fatty acids, by changes in the phospholipid composition, and by conversion of *cis*-unsaturated fatty acids to their *trans*-isomers (87–90). For a comprehensive review on the subject of cellular adaptation to organic solvents, see the work by Weber and de Bont (91).

Strain selection (92,93) and genetic engineering (94–96) are increasingly providing strains with improved resistance against elevated concentrations of organic chemicals. Alternative strategies to minimize cell damage and growth inhibition include cell immobilization (97–99). A range of carrier materials has been used with cells either adsorbed to the surface or entrapped within beads and gels. Examples of such materials are Celite, calcium alginate, κ-carrageenan, polyurethane, polyacrylamide, silicon, and chitosan (100,101). However, it must be considered that cell immobilization introduces an additional diffusion barrier, which can lead to mass transfer limitations (102).

Despite these advances, special procedures during bioprocess operations are nevertheless required to avoid toxic effects by harmful substrates and products when high productivities and high final product titers are to be attained in commercial applications. Strategies to attain this goal are described in the next section.

Controlled Substrate Feed

To avoid substrate inhibition, it is necessary to feed toxic starting compounds to a cell culture or an enzyme-containing reaction mixture in a controlled way, at a rate that avoids substrate accumulation to inhibitory levels. This is achieved either by supplying volatile compounds via the gas phase (103,104) or via controlled liquid feeds (105,106) in laboratory as well as production-scale reactors.

An alternative way—limited to laboratory studies—to eliminate substrate inhibition is to add toxic starting material dissolved in apolar carrier solvents, such as hexadecane and other high log*P* solvents. Because hydrophobic substrates mainly partition into the apolar solvent, they are less exposed but still well available to the biocatalyst residing in the aqueous phase of the two-liquid phase mixture (Fig. 7). Thus, higher quantities of toxic material can be added to the reaction mixture without encountering inhibitory effects. An example where such a two-liquid phase operation may in the future be scaled up for production purposes is the biosynthesis of functionalized poly-3-hydroxyalkanoates (PHA) from toxic precursors (24,107).

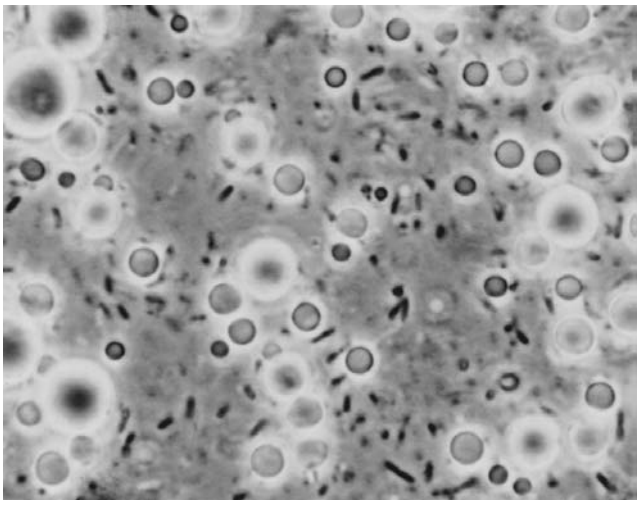

Figure 7. Micrograph of two-liquid phase medium. *P. oleovorans* cells (dark rods) are suspended throughout the continuous aqueous phase. The organic solvent *n*-octane is dispersed as fine droplets, with an average diameter in the order of 10 μm.

These precursors must be present in concentrations below inhibiting levels, but above limiting concentrations, because cells accumulate PHA as a carbon storage material only in abundance of the carbon source (108). Because the second liquid phase will buffer fluctuations of substrate uptake rate, as a result of continuously varying substrate uptake rates in batch and fed-batch processes, concentrations should be controlled more easily within the required narrow range.

In Situ Product Extraction

To obtain high titers of toxic or inhibitory products, it is necessary to continuously remove product from the reaction vessel. Depending on the nature of the product and the bioprocess involved, various methods are feasible.

Two-Liquid Phase Operation. By operating a two-liquid, aqueous-organic phase system, it is possible to continuously extract hydrophobic products formed by the biocatalyst residing in the aqueous phase (Fig. 7). As a result, cells and enzymes see less of the toxic products accumulating mainly in the organic phase during the course of the bioprocess, thus enabling higher final product titers to be attained. Compounds successfully produced in such in situ extraction processes include aliphatic and aromatic epoxides (41,109,110), alcohols (111,112) optically pure derivatives of citronellol (113) and organic acids (114). These biotransformations have been limited to laboratory scales; however, various industries are developing related processes.

Model studies have shown that the extractant can be separated from the aqueous phase by thermal and physical means (115) or, as recently developed, by continuously removing the organic solvent from the reaction mixture during the biotransformation step by in situ centrifugation (116). Product isolation and purification from the organic phase proceeds via conventional, chemical downstream processing techniques (117,118).

Solid Phase Extraction. Solid adsorbents have been successfully used to recover small molecules such as acetone, butanol, terpenes, aromatic amino acids, and steroids from fermentation broth. In these procedures, cells are first removed from the medium (119,120) or they are immobilized on solid carrier material (121). Solid adsorbent in situ recovery procedures have also been used in the presence of living cells, for example, to achieve enhanced production of antibiotics by streptomycetes (122), or mycobacteria (123). The addition of solid adsorption material such as XAD-4 to cultures was especially useful for adsorption of alkaloids from plant cell cultures (124–126). Solid adsorbents can be added into the bioreactor either directly or separated from the cells by a membrane. Alternatively, culture medium can be cycled from the bioreactor via an external loop through a packed or fluidized adsorption bed (127).

Membrane Separation. When using (partly) purified enzymes in biotransformation processes, it is often important to recycle the biocatalyst to optimize productivity and to minimize operation costs. This may be achieved by immobilizing the enzymes to a solid support and filtering the reaction mixture either continuously during the biotransformation reaction or batchwise at the end of the bioconversion step. Alternatively, soluble enzymes may be used in a homogeneous reaction mixture with ultrafiltration membranes used to separate the high molecular weight enzymes from the low molecular weight metabolites (128).

In oxidoreductase catalyzed-reactions, cofactors such as $NAD(P)^+$ and NAD(P)H are required as electron acceptors or donors. Because the addition of these metabolites in stoichiometric amounts is uneconomical, they must be regenerated. This can be achieved by supplementing the reaction mixture with a second enzyme, which catalyzes a redox reaction running in the opposite direction (129). For example, formate dehydrogenase (EC 1.2.1.2) added together with formate catalyzes the oxidation to carbon dioxide, thereby recycling the electron acceptor NAD^+ to NADH, which can again donate electrons to the desired enzymatic reaction (35). Because the native cofactor permeates through ultrafiltration membranes, NAD has been covalently bound to a water-soluble polymer, such as poly(ethylene glycol) (PEG).

OUTLOOK

Ongoing studies to elucidate anabolic and catabolic pathways and to characterize the enzymes that catalyze the individual reactions will, together with a multitude of screening programs, undoubtedly lead to further discoveries and applications of new and useful biotransformation reactions. In this process, genetic engineering will continue to play an important role for the characterization of enzymes as well as their production by cultures of cloned enzyme producing organisms. Genetically engineered whole cell biocatalysts can be beneficial when undesired

side reactions of the host organism hamper a process and when space and time yields are insufficient. Modern techniques promise to allow an even more effective construction of biocatalytically active cell strains than is achieved today. By exerting a more sophisticated control over enzyme expression and regulation as well as by designing whole cell biocatalysts containing genetic information from various sources, whole cell biocatalysts tailor-made for specific processes will evolve.

New process technologies, useful for biotransformation reactions, that have been developed during recent years include in situ product removal (127), membrane reactor systems (128), and two-liquid phase bioprocesses (130). These techniques significantly widen the potential of biocatalysis, opening applications involving cofactor-dependent enzyme processes, bioconversions of toxic compounds, and syntheses of organic molecules in organic media. Thus, reactions catalyzed by biological systems, which formerly were restricted to the field of chemistry, have become feasible. Chemistry and biology are moving together to provide interchangeable tools for the efficient production of important chemicals useful in diverse applications in medicine, agriculture, and nutrition.

OUTLINE

WHAT IS PULLULAN?

Pullulan is a water-soluble extracellular polysaccharide synthesized by the yeastlike fungus *Aureobasidium pullulans* (formerly named *Pullularia pullulans*) from a variety of mono- and disaccharides (1). It is generally accepted that pullulan is a neutral glucan that consists of either a linear chain of D-glucopyranosyl units that alternate regularly between one (1→6)-α-D and two (1→4)-α-D linkages, or a linear polymer of maltotriosyl units connected by (1→6)-α-D linkages (Fig. 1). However, pullulan containing 5–7% maltotetraosyl units has also been reported for several strains of *A. pullulans* (2,3).

Freeze-dried pullulan is white in color, tasteless, odorless, nonhygroscopic, nontoxic, biodegradable, and edible. It is insoluble in many solvents including methanol, ethanol, and acetone, but soluble in water to form a transparent, colorless, viscous, and adhesive solution. Shaped bodies as well as very thin pullulan films 0.01 mm thick can be formed. Thin films of pullulan are colorless, transparent, tasteless, odorless, tenacious, resistant to oil and grease, unaffected by small thermal variations, impermeable to oxygen, nontoxic, biodegradable, and edible (4,5).

Numerous applications of pullulan are claimed in a large number of patents. A comprehensive review of the applications of pullulan in food and drugs, as well as on the potential uses of pullulan in industrial and medical applications, is reported elsewhere (6).

Generally accepted chemical structure of pullulan: (**a**) chemical formula; (**b**) ball-and-stick model for one hypothetical conformation of three maltotriose units; (**c**) space-filled model for one hypothetical conformation of three maltotriose units. *Source*: The ball-and-stick and space-filled models were kindly provided by Professor Josée Brisson from the Chemistry Department, Laval University.

PROCESS TECHNOLOGY FOR THE PRODUCTION OF PULLULAN

The general process flowchart in Figure 2 illustrates the five main steps in the production of pullulan by fermentation: culture medium preparation, inoculum preparation, fermentation, product separation and purification, and product alteration. This five-step general process flowchart for the production of pullulan by fermentation applies for small-scale laboratory experiments as well as large-scale commercial production of pullulan.

Step A. During the culture medium preparation step, appropriate quantities of raw materials to be used as culture medium ingredients are to be formulated, weighed, and dissolved in water. The ingredients are chosen and formulated in such a way to provide the exact amounts of carbon, nitrogen, and mineral salts required for cell growth and pullulan synthesis during the fermentation step. The pH of the solution is adjusted to the desired value; the medium is then sterilized, either in a fermenter or in a separate feed tank.

Step B. The inoculum preparation step consists of producing a large quantity of microorganism to seed or to inoculate the sterilized culture medium obtained at the end of step A in order to start the fermentation (step C). The appropriate strain of microorganism is selected, then propagated by successive fermentations from a small volume of a pure culture to obtain a large volume of microbial cell suspension required for inoculum purposes. In the industrial production of pullulan, the amount of inoculum required to seed the production fermenter may vary from hundreds to thousands of liters of microbial cell suspension. The inoculum culture-to-medium ratio used may also vary from 0.1% v/v to 10% v/v. Usually, larger inoculum

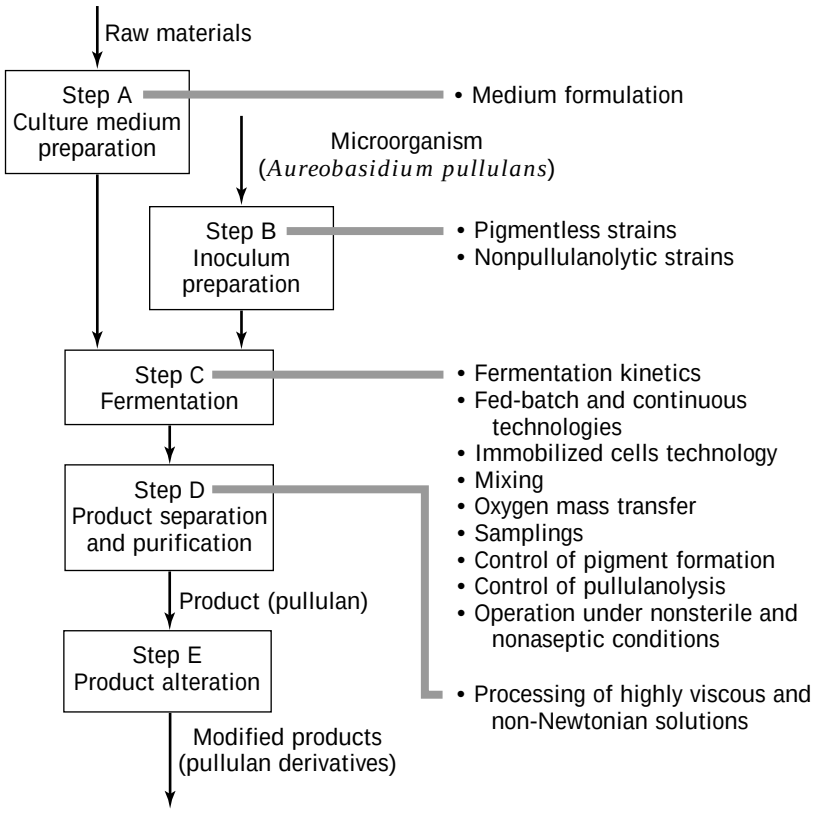

Figure 2. Five-step general process flowchart for the production of pullulan by fermentation. Research and development requirements for technology improvement are indicated for each step.

ratios are suitable for laboratory-scale fermentations, and smaller ratios are more practical for industrial-scale productions.

Step C. The fermentation step is the biosynthesis of pullulan from a carbon source by living and growing microbial cells in the fermenter under sterile and aseptic conditions. The fermentation technology for pullulan production may be batch mode, fed-batch mode, or continuous mode, using either free or immobilized cells. Batch fermentation using free cells of *A. pullulans* is still the most popular technology used in pullulan production in small as well as in large scales. The duration and the performance of the fermentation step are determined by the kinetic behavior of the combined system of microorganism–medium–fermentation conditions. It means that each specific strain of microorganism, in a specific culture medium (ingredients and composition), and under a specific set of fermentation conditions will respond with a specific fermentation kinetic behavior. Therefore, knowledge of fermentation kinetics is important for choosing the best fermentation technology and conditions for each specific strain of microorganism in a specific culture medium. During the fermentation step, operating conditions such as pH, temperature, oxygenation (by aeration), and mixing (by agitation) are either artificially controlled by maintaining each one at a certain value for a specific time period, or simply uncontrolled.

Step D. When the fermentation step is completed, the resulting fermented broth is a mixture of solids in suspension (which consists of microbial cells and cellular debries) together with dissolved solids in the aqueous solution (which comprise water-soluble pullulan synthesized during the fermentation, residual ingredients from the culture medium, and extracellular metabolites produced and excreted during the fermentation). In the product separation and purification step, solids in suspension are first separated from the culture medium by centrifugation or filtration. The obtained liquid phase containing soluble pullulan is then decolorized using activated carbon to remove the black pigmentation that is produced by *A. pullulans* during fermentation. The decolorized liquid phase is further purified to remove small molecular compounds (residual ingredients, extracellular metabolites), then dewatered and dried to obtain pullulan as a final product in solid form. The dewatering operation usually consists of the precipitation of pullulan from the aqueous solution using acetone, methanol, or ethanol as a solvent (Fig. 3).

Step E. The product alteration step is necessary only when modified pullulan or pullulan derivatives are desired as final products. Technologies are available to chemically modify pullulan in order to improve its existing properties and/or to impart newly desired properties to pullulan. Examples of such pullulan derivatives are presented in Table 1 (5,7–15).

COMMERCIAL PRODUCTION OF PULLULAN

At the present time, the only known commercial producer of pullulan by the fermentation process is the Hayashibara Co., Ltd. in Japan. Figure 4 illustrates the detailed flowchart for the commercial production of pullulan by this particular company (16). Note that it matches very well the

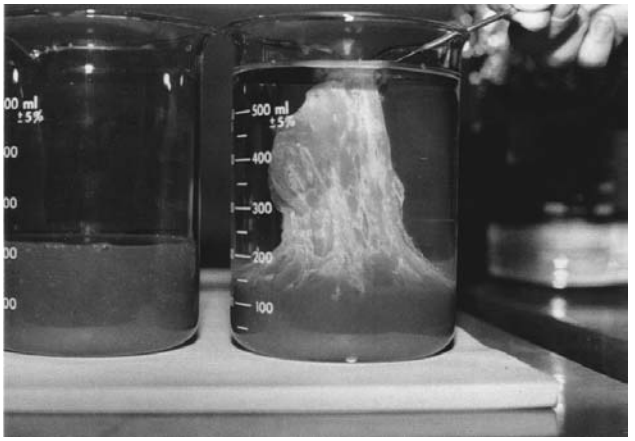

Figure 3. Solvent precipitation of pullulan: Pullulan, which is soluble in the fermentation broth (yellow solution), becomes insoluble in methanol (clear liquid). The fibrous texture appearance of the precipitated pullulan indicates that this polysaccharide has very high molecular weight.

five-step general process flowchart for the production of pullulan by fermentation shown in Figure 2.

The culture medium used consists of a carbon source (partial starch hydrolyzate with dextrose equivalent [DE] around 50% at a concentration from 10 to 20%), a nitrogen source (formulated from corn gluten, soybean protein, peptone, nitrate salts, and ammonium salts), and other mineral salts. The initial pH is within 5–6.8.

The inoculum is prepared from selected mutant strains of *A. pullulans* AHU 9553, *Dematium pullulans* IFO 4464, and *Pullularia fermentans* var. *fermentans* IFO 6401. The mutant strains used as production strains must have the least black pigment, require the shortest duration of fermentation, and give the highest yield of pullulan.

The fermentation is carried on in batch mode for approximately four days in a conventional fermenter, with special consideration to ensure adequate aeration and agitation of the highly viscous fermentation broth. The temperature is maintained at 30 °C and aeration at 0.5 VVM (volume of air per volume of culture medium per minute). The kinetic behavior of commercial pullulan fermentation corresponds very well with those reported in the scientific literature (17–20). The pH of the culture medium decreases sharply during the first day and remains constant at around pH 3.5 to the end of the fermentation. Cell growth and pullulan synthesis occur during this low and constant pH period. The concentrations of cell mass and pullulan continue to increase in the fermentation broth until the end of the fermentation. However, the molecular weight of pullulan in the fermentation broth increases to a maximum value of around 2,000,000–3,000,000 in the early stage of fermentation, then drastically decreases to very low molecular weight toward the end of the fermentation. This decrease is presumably caused by the action of a pullulan-decomposing enzyme, which is also synthesized by the microorganism during the fermentation period. Consequently, the viscosity of the fermentation broth, which results from both pullulan concentration and pullulan molecular weight, increases rapidly in the early stage of fermentation to over 300 cP, then reduces to less than 100 cP at the end of the fermentation. By controlling the fermentation conditions (phosphate content and initial pH), Hayashibara Co., Ltd. obtains a pullulan product that ranges from 50,000 to 500,000 MW.

The pullulan recovery and purification operations depend on the desired quality of pullulan product for specific applications (Fig. 4). Hayashibara Co., Ltd. defines three different pullulan grades: (*1*) Product I (crude pullulan culture and its concentrate) for use as an industrial adhesive, dispersant, and coagulant; (*2*) Product II (cell-free, decolorized pullulan, containing some minerals, mostly sodium chloride) for use as a raw material for various industries, including the food processing industries, as well as a base material for the production of pullulan derivatives; and (*3*) Product III (cell-free, decolorized, and desalted pullulan), which is highly purified pullulan in white powder for making films and shaped articles.

The annual production of pullulan by Hayashibara Co., Ltd. is 200 metric tons and the ex-factory sale price of pullulan PF-20 (Product III) is 2300 JP_1 (approximately 17 US$) per kilogram (personal communication with Dr. K. Okada, Overseas Business Development, Hayashibara Co., Ltd., April 6, 1998).

RESEARCH AND DEVELOPMENT REQUIREMENTS FOR TECHNOLOGY IMPROVEMENT

Pullulan fermentation, like numerous other extracellular polysaccharide fermentations, is one of the most challeng-

Table 1. Pullulan Derivatives

Modified pullulan	Imported properties	References
Esterified pullulan	Various degrees of water insolubility	5
Etherified pullulan	Various degrees of water insolubility	5
Hydrogenated pullulan	High heat resistance	7
Pullulan sulfate and its salts	Anti–peptidic ulcer; low blood anticoagulation	8
Carboxylated pullulan	High solubility in cold water	9

ing bioprocesses for engineers and scientists seeking ways to improve fermentation technology. Four groups of problems associated with pullulan fermentation still require better solutions in order to increase the performance of the fermentation process and lower product recovery costs.

Problems Due to Viscosity of the Fermentation Broth

The evolution of rheological properties of the fermentation broth during batch fermentation of *A. pullulans* has been studied in detail (17). In batch fermentation, the culture medium initially exhibits Newtonian behavior, and then the rheology of the broth progressively changes to a highly viscous and non-Newtonian behavior. The rheological properties of the fermentation broth may be described by two different parameters: the field apparent viscosity and the non-Newtonian flow behavior index, which can be expressed with the following rheological model:

$$\eta = K\dot{\gamma}^{n-1} \tag{1}$$

where η is the apparent viscosity, K is the consistency index, n is the flow behavior index, and $\dot{\gamma}$ is the shear rate. This equation shows that, in non-Newtonian fluids, the value of viscosity obtained depends on the rate of shear at which the viscosity is measured. The viscosity of a non-Newtonian fermentation broth is commonly standardized by its field value, which is the value measured at the unit rate of shear. Such values of the field apparent viscosity are independent of either rotational speed or geometrical configuration of the viscometer used.

It would be tempting to believe that the viscosity of the fermentation broth increases steadily throughout the fermentation to follow the increase in pullulan concentration. In fact, in the case of pullulan, the field apparent viscosity of the fermentation broth increases slowly during the ini-

tial phase of fermentation, then rises rapidly to its maximum value, and finally decreases toward its initial value. The maximum values of the apparent field viscosity, as well as the time when these maximum values occur, depend on fermentation conditions such as initial pH of the culture medium and age of inoculum (Fig. 5). The results of Figure 5 are very informative in the sense that the large differences observed for the maximum values of the field apparent viscosity can be directly attributed to the length of the pullulan chain or to the average molecular weight of pullulan, because the concentrations of pullulan in the fermentation broths are approximately the same around the fifth day of fermentation. The decrease in the field apparent viscosity during later stages of each fermentation, when the polysaccharide concentration has leveled off, is called pullulanolysis, which relates to the depolymerase secreted by *A. pullulans*. The evolution of the field apparent viscosity of the fermentation broth depends also on other factors such as the aeration rate (VVM) and the level of dissolved oxygen concentration (mg/L) during pullulan fermentation (21).

The flow behavior index characterizes very well the average length of the pullulan chain (22). It is therefore interesting to monitor this rheological parameter during the course of the fermentation to observe changes in pullulan average molecular weight. At the beginning of a typical pullulan fermentation, the culture medium is Newtonian (non-Newtonian index $n = 1$). The non-Newtonian index of the fermentation broth decreases slowly during the initial phase of fermentation, then drops rapidly to its minimum value, and finally rises toward its initial value. Therefore, throughout the fermentation the broth becomes more and more pseudoplastic (non-Newtonian index <1), then returns toward its initial Newtonian behavior. The minimum values of the non-Newtonian index as well as the time when these minimum values occur depend on fermentation conditions such as initial pH of the culture medium and the age of inoculum (Fig. 6). The rheological behavior of such non-Newtonian solutions has a profound impact on the flow characteristics within the fermenter. The apparent viscosity decreases when the fluid is in motion. This reduction in apparent viscosity with the velocity of the fluid is more pronounced as the flow behavior index is reduced.

The observed rheological properties of the fermentation broth in Figures 5 and 6 result from the combined contribution of the pullulan concentration and the average length of the pullulan chain. Both pullulan concentration and pullulan average chain length in the fermentation broth are continuously changing during batch fermentation. Therefore, from the results in Figures 5 and 6, it is not possible to say how and how much these two parameters contribute to the observed rheological properties. LeDuy et al. (17) have recovered pullulan from fermentation broths at 1, 3, 5, and 8 days of a batch fermentation

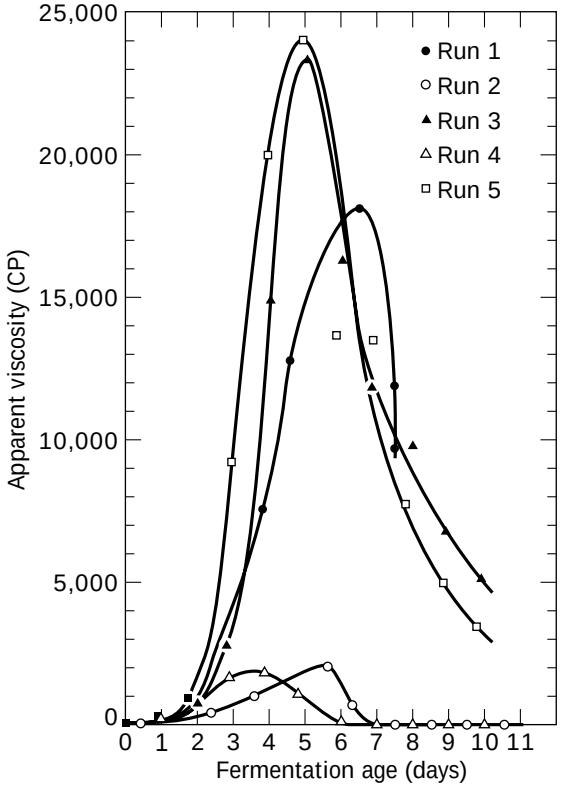

Figure 5. Evolution of the field apparent viscosity of the fermentation broths under various conditions of initial pH and inoculum age. *Source*: From Ref. 17, reproduced with permission.

(run 3 from Figs. 5 and 6), freeze-dried it, and then dissolved the recovered pullulan in water to form solutions having a pullulan concentration varying from 0.125 to 2.0 g/L. The field apparent viscosities and the non-Newtonian indices of these solutions were measured and are presented in Figure 7. At the same concentration of pullulan, the field apparent viscosity of pullulan solution recovered from the early stage of fermentation is higher than that recovered from the later stage, indicating that the pullulan recovered in the first days of fermentation has higher molecular weight than in subsequent days. The opposite phenomenon is observed for the non-Newtonian index. At the same concentration of pullulan, the non-Newtonian index of pullulan solution recovered from the early stage of fermentation is lower than that recovered from the later stage, indicating that the pseudoplasticity of the pullulan solution is directly related to the high molecular weight of pullulan. Each set of curves prepared with pullulan recovered after the same fermentation time in Figure 7 shows the very important contribution of pullulan concentration on the field apparent viscosity as well as on the non-Newtonian index of the pullulan solution. Higher pullulan concentration leads to higher field apparent viscosity and larger pseudoplasticity.

Thus, any fermentation process aiming to achieve high-yield production of high molecular weight pullulan still provides tremendous engineering challenges in mixing, oxygenation, and sampling during the fermentation, as well as the major challenge of removal of microbial cells from the highly viscous fermentation broth in the product separation and purification step. To clearly illustrate the difficulties involved in dealing with a highly viscous fermentation broth, Figure 8 shows a typical fermentation broth flowing out of a fully opened large-size sampling tube under the compression of the aeration gas inside the fermenter. During pullulan fermentation, the nonhomogeneous mixing problem is always observed, even in a laboratory-scale fermenter. The fermentation broth inside the fermenter tank segregates into two regions having different characteristics, with an active core around the impeller where the culture medium is well mixed and properly aerated. This core is separated from the innermost zone by a fictitious boundary, a stagnant fluid region characterized by a total lack of agitation and aeration (Fig. 9). Some authors even discuss the formation of three distinct mixing regions: a small central region (often referred to as a cavern) in the vicinity of the impellers where the turbulence is important, an annular section characterized by slow fluid motion, and finally, a stagnant outer region where the

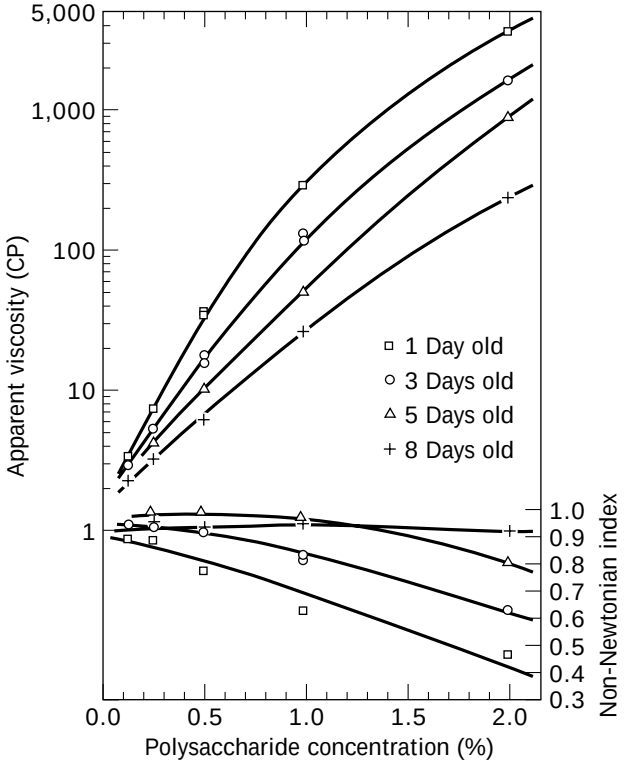

Figure 7. Variations of field apparent viscosity and non-Newtonian index as a function of the concentration of pullulan in a solution and the pullulan chain length. Figure 8. Highly viscous fermentation broth of *A. pullulans* in a sucrose medium: the broth slowly flowing out of a fully opened large-size sampling tube under the compressed air inside the fermenter.

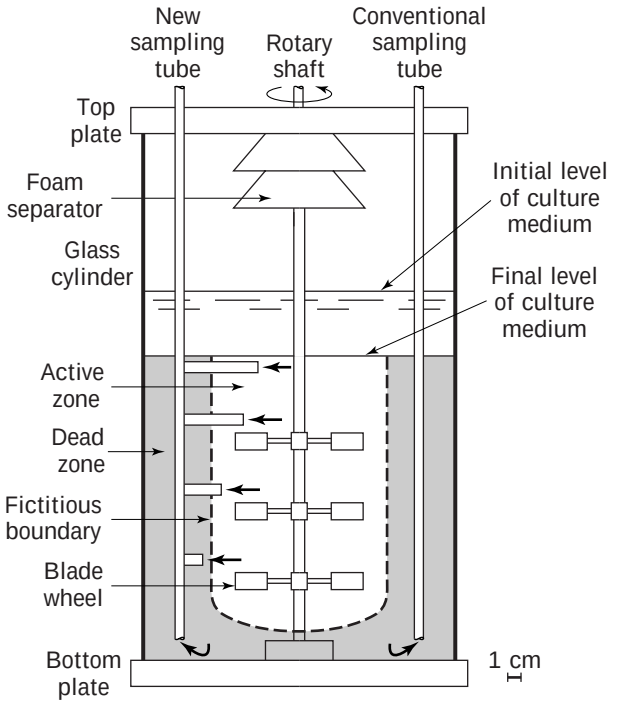

Figure 9. Active zone and stagnant zone of the highly viscous fermentation broth in the fermenter during the pullulan fermentation. Configurations of both conventional and newly improved sampling devices are shown. *Source*: From Ref. 23, reproduced with permission.

fluid is motionless and the apparent viscosity very high (24). The energy imparted to the fluid by the rotating impellers is dissipated in a restricted region of the total volume of the fermentation broth. The high viscosity combined with the non-Newtonian behavior creates major difficulties in sampling, oxygen mass transfer, mixing, and downstream processing. These are briefly analyzed in turn.

Process Monitoring and Sampling. With the absence of homogeneous conditions throughout the fermentation vessel, it is only possible to monitor locally the dissolved oxygen concentration and the pH. This also applies to any novel sensor for monitoring other fermentation process variables such as the *A. pullulans* population (25). These values will therefore depend greatly on the position of the various probes. The same phenomenon applies also to the fermentation broth sampling port. The geometry and the location of the conventional sampling tube, as provided in fermenters by manufacturers (Fig. 9), shows that the samples are taken very frequently from the stagnant zone, where the data are not representative for the entire culture medium content. A newly improved sampling device was designed and tested in a 7-L fermenter (23) and enables one to obtain a more representative sample because it draws a sample from different locations within the culture vessel (Fig. 9). Nevertheless, because of the evolving and shear-dependent viscosity, it is not guaranteed that a uniform sampling in all branches of the sampling tube will be achieved. Thus, the sampling of representative samples and process monitoring of highly viscous fermentation broth in larger-scale fermenters having nonhomogeneous mixing remains a challenge that one should not overlook.

Oxygen Transfer. Pullulan fermentation is an aerobic fermentation. It was demonstrated that oxygen is essential for the biosynthesis of pullulan by *A. pullulans*. In a growth medium, pullulan yield and synthesis rates are proportional to the oxygen availability. However, under a controlled oxygen environment in a nongrowth (nitrogen-free) medium, pullulan yield and synthesis rates are inversely proportional to the oxygen concentration in the culture medium (26). During the fermentation, air is continuously provided to the culture medium to supply oxygen to the microbial cells. However, oxygen molecules in the air bubbles have to move into the fermentation broth and then diffuse through this liquid phase to reach the microbial cells in order to be used for the growth and biosynthesis of pullulan. With the highly viscous fermentation broth in pullulan fermentation, the oxygen mass transfer process is very difficult and remains a major engineering challenge for the future. Indeed, as the fermentation broth becomes increasingly viscous, the gas bubbles in the peripheral stagnant zone of the fermenter remain trapped in the motionless fluid and are progressively depleted from their oxygen content. Figure 10 shows a photograph taken during a typical pullulan production where the fermentation broth and gas bubbles in the outer region remained stagnant for long periods.

The evaluation and comparison of the performance of oxygen mass transfer within a mixing vessel is usually quantified by the volumetric mass transfer coefficient $K_L a$. The overall oxygen transfer rate from air bubbles to the fermentation broth (dC_L/dt) is the product of the volumetric oxygen transfer coefficient ($K_L a$) and the mean concen-

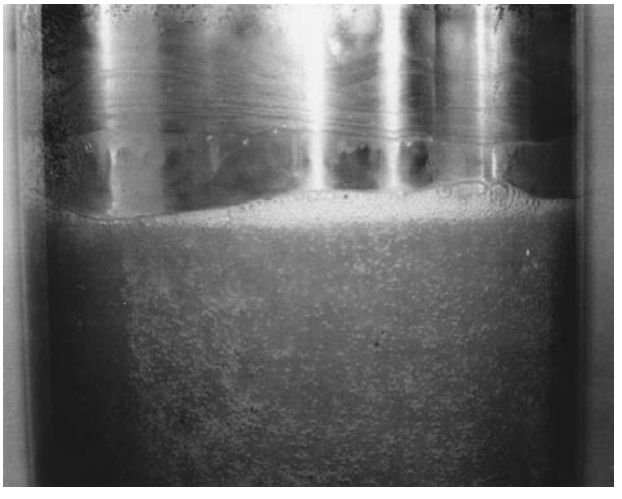

Figure 10. Mixing and mass transfer challenges in pullulan fermentation. The picture is taken when the agitator equipped with Ruston turbines is rotating at 500 rpm. The layer of fermentation broth adjacent to the fermenter wall remains stagnant with trapped air bubbles.

tration driving force of oxygen in the fermentation broth ($C^* - C_L$):

$$\frac{dC_L}{dt} = K_L a(C^* - C_L) \quad (2)$$

where C_L is the dissolved oxygen concentration in the fermentation broth and C^* is the saturated dissolved oxygen concentration in the fermentation broth that is the solubility of oxygen under the fermentation conditions. According to equation 2, one possible way to improve the oxygen mass transfer rate is to improve the mean concentration driving force of oxygen in the fermentation broth ($C^* - C_L$) by increasing the solubility of oxygen in the liquid phase. The solubility of oxygen in the fermentation broth, C^*, during the fermentation can be enhanced either by using oxygen enriched gas, up to pure oxygen, in aeration or by pressurizing the fermenter headspace (commonly referred to as hyperbaric fermentation). For practical and economic reasons, the use of pure oxygen is not feasible in large-scale fermenters. On the other hand, enriched gas would be used only when air would not suffice to maintain the desired dissolved oxygen concentration within the fermenter, because high oxygen concentration in the fermentation broth may enhance the biosynthesis of the black melanin pigment, which is undesirable (26).

The effects of pressure on the growth of *A. pullulans* and the synthesis of pullulan have been studied in a specially designed fermenter and fermentation system (Figs. 11 and 12) (27). It is reported that for all volumetric airflow rates in the range of 0.2 to 2.0 VVM, the production of biomass increases with pressure up to a critical value, which ranges from 0.50 MPa to 0.75 MPa, at which point a drastic decrease in biomass production and a change in cellular morphology occur. Above the critical pressure, *A. pullulans* forms aggregates of irregular shape that are fairly uniform in size under each set of fermentation conditions. In general, larger aggregates of approximately 8 mm are associated with a higher pressure level (1.48 MPa) and aeration rate (2 VVM). The details of *A. pullulans* aggregates are shown in the scanning photomicrographs in Figure 13. The same pattern is also observed for pullulan synthesis: it increases with pressure up to approximately the same critical pressure, then decreases drastically beyond this value. Much more investigation is required to better understand the behavior of hyperbaric pullulan fermentation before reaching a practical and economic solution for this technology.

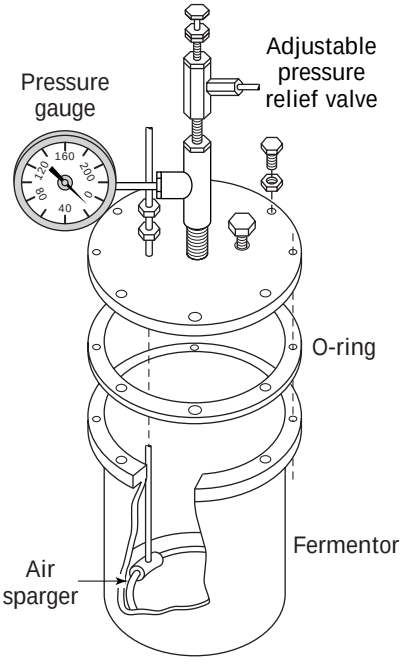

Figure 11. The specially designed fermenter for studying pullulan fermentation under hyperbaric conditions. *Source*: From Ref. 27, reproduced with permission.

A second way to improve the oxygen mass transfer rate is to increase the volumetric oxygen transfer coefficient ($K_L a$) by using better mixing devices. It has been clearly shown that $K_L a$ is not uniform throughout most mixing vessels. It is usually large in the vicinity of the mixing element and lower further away. It is evident from Figures 9 and 10 that any mixing device that can reduce or even eliminate the dead zones in the fermenter will have a chance to provide better volumetric oxygen transfer to the pullulan fermentation broth and in addition create more homogeneous operating conditions throughout the fermentation vessel. An adequate uniform mixing would also contribute to the maintenance of gas bubbles with high oxygen content and therefore keep the oxygen gradient at a high level. Several unconventional mixing devices have been designed and studied. These are the reciprocating plate mixer, the helical ribbon mixer, and the helical ribbon screw mixer.

Although the physical properties of the fluid and operating conditions, used by many authors, are hardly comparable over a wide range, their results have a common trend of increasing oxygen mass transfer coefficients with increasing agitation and gasflow rate. The efficiency of mixing devices, evaluated in terms of $K_L a$, is usually correlated in terms of power input per unit volume (P_G/V_L) and superficial gas velocity (U_G), using the following expression:

$$K_L a = C\left(\frac{P_G}{V_L}\right)^{\alpha} (U_G)^{\beta} \quad (3)$$

The correlation coefficients C, α, and β depend on the nature of the fluid, the geometrical configuration of the mixing element, and the hydrodynamic regimes of the fluid (28,29).

The biochemical engineering group at Laval University has been interested for the last decade in developing a relatively new type of bioreactor, the reciprocating plate bioreactor (RPB). The RPB (Fig. 14a) consists of a stack of perforated plates that undergoes reciprocating vertical motions inside the fermenter. The RPB, with its particular geometry, possesses the desired attributes to produce efficient mixing, with the result that microorganisms, nutrients, and air bubbles are properly distributed (31). In the RPB, the perforated plates occupy the total cross section

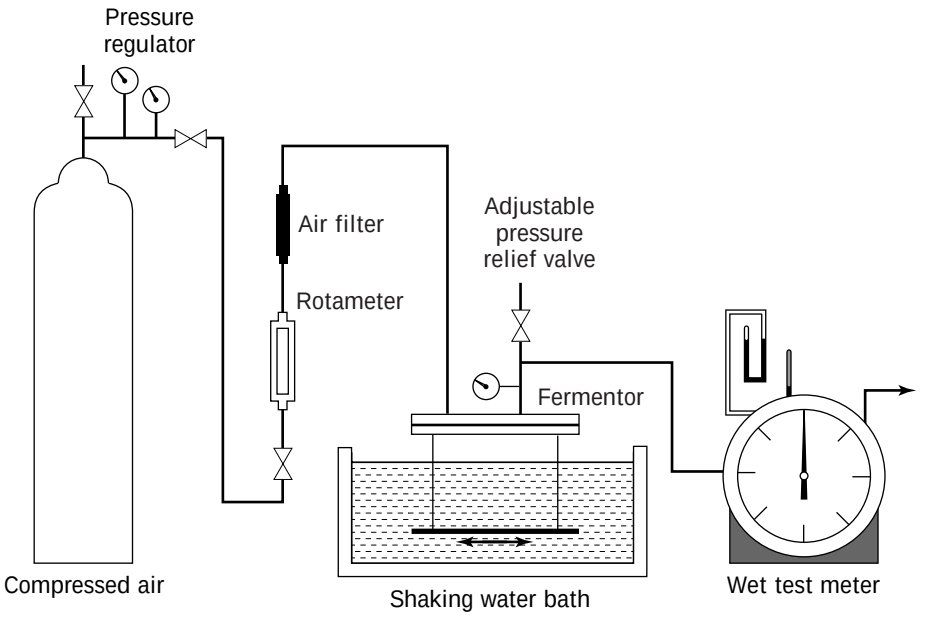

Figure 12. The fermentation setup for studying pullulan fermentation under hyperbaric conditions. *Source*: From Ref. 27, reproduced with permission.

of the fermentation vessel so that the upward and downward movements of the plate stack lead to uniform mixing. Three different RPBs with aspect ratios ranging from 0.08 to 0.5 have been characterized with fluid models and pullulan fermentation (21,28,30). Audet et al. (29) have performed experiments to evaluate the influence of polysaccharide concentration and molecular weight on oxygen mass transfer in the RPB. They used model fluids consisting of different concentrations of dextran (another water-soluble microbial polysaccharide) of different molecular weights to simulate the pullulan fermentation broth at different stages of fermentation. They correlated their results using equation 3 and reported that the correlation coefficients C, α, and β in this equation also depend on the polysaccharide concentration, the polysaccharide molecular weight, and the hydrodynamic regime of the solution.

The most recently constructed RPB was designed to be identical, except for the mixing mechanism, to a stirred-tank (radial-type mixing device) bioreactor that was built simultaneously. The schematic diagram of the experimental setup of the RPB is shown in Figure 15. Each bioreactor has a total volume of 22.5 L and a working volume of 18 L. The two bioreactors, using a series of mixing elements, were initially characterized in water for their ability to produce high K_La values. A total of five plate stacks were used in the RPB. Each plate stack consists of 6 (plate stacks PA, PB, and PC) or 12 (plate stacks PD and PE) perforated stainless steel plates, 221 mm in diameter and 1.25 mm thick, mounted on a central shaft and uniformly distributed with a distance of, respectively, 50 and 25 mm between adjacent plates. The diameters of perforations were 6.35 mm for plate stacks PA and PD, 12.7 mm for plate stacks PB and PE, and 19.05 mm for plate stack PE. A total of five mixing elements were used with the radial-type bioreactor: assemblies containing one, two, or three identical Rushton turbines (RT1, RT2, and RT3, Fig. 14b), and a helical ribbon impeller with or without surface baffles (HR and HRB, Fig. 14c). A more complete description is presented by Gagnon et al. (32).

These bioreactors were first characterized in terms of oxygen mass transfer (32). Typical plots of the oxygen mass transfer coefficient in water as a function of the power input per unit volume are presented in Figure 16 for all mixing devices at one superficial gas velocity. All mixing devices show identical patterns. For lower power inputs per unit volume, the oxygen mass transfer, K_La, is constant and varies only with the gas superficial velocity. At a certain power input per unit volume, K_La starts to increase rapidly with the power input per unit volume. Perez and Sandall (33) and Nishikawa et al. (34) previously observed these two distinct regimes of operation with Rushton turbines.

The two bioreactors were then used in an investigation undertaken with the objective of comparing experimentally the performance of four different mixing devices for the production of pullulan (30). The four mixing devices include two different reciprocating plate stacks (PA and PB), the assembly of three Rushton turbines (RTB), and the helical ribbon impeller (HR). These four fermentations were performed with an equal level of power input per unit volume (1,000 W/m^3) and gasflow rate (0.5 VVM or 9 L/min) during the entire fermentation. The evolution of the concentrations of biomass, pullulan, and dissolved oxygen during each fermentation are presented in Figures 17–19. Under identical power inputs per unit volume, better cell growth and pullulan synthesis were obtained with the reciprocating plate mixer that had larger perforations. The helical ribbon mixer gave the poorest cell growth and pullulan synthesis. However, pullulan of the highest molecular weight, as indicated by its highest fermentation broth viscosity, was obtained with the helical ribbon mixer.

The evolution of dissolved oxygen (Fig. 19) clearly shows that the RPBs are more efficient at maintaining a high and homogeneous level of dissolved oxygen within the fermen-

tation broth. For the other two mixing devices, it can be stated that the local dissolved oxygen varied greatly and was always very low in the vicinity of the dissolved oxygen probe.

Guerinik (35) has modified the helical ribbon impeller by adding a central screw installed on the rotating shaft to provide the pumping action on the fermentation broth in order to enhance its circulation inside the fermenter. He also found that pullulan fermentations using the helical ribbon screw mixer resulted in a higher concentration of pullulan of higher molecular weight as compared with that obtained using standard Ruston turbines.

In a recent study, Tanguy et al. (36) proposed a dual coaxial impeller composed of a Rushton turbine and a helical ribbon impeller, both rotating clockwise but at different speeds. They have shown that the hybrid mixer system outperforms the standard helical ribbon impeller when the fluid rheology changes with time. These hybrid systems could be used advantageously in pullulan fermentation.

Product Separation and Recovery. The first operation in the product separation and purification step (Step D in Figures 2 and 4) is the removal of *A. pullulans* cells from the highly viscous fermentation broth. This is done by either centrifugation or filtration. The fermentation broth has to be diluted many fold to lower its viscosity prior to the centrifugation or filtration operation. The resulting large volume of diluted processing broth leads to higher operating

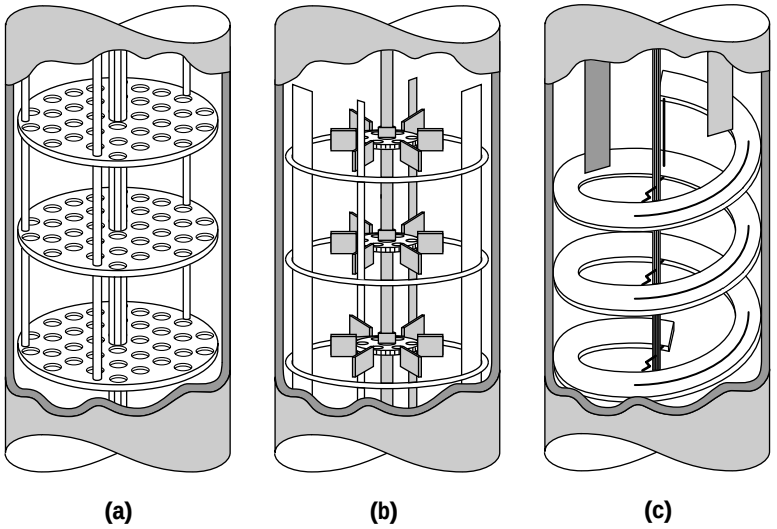

Figure 14. Mixers used in pullulan fermentations: (**a**) the reciprocating plate mixer; (**b**) the Rushton turbines; (**c**) the helical ribbon mixer. *Source*: From Ref. 30, reproduced with permission.

costs in the subsequent steps of pullulan purification, especially in the solvent precipitation step. In order to eliminate the presence of cells in the highly viscous fermentation broth, attempts to immobilize *A. pullulans* cells on solid supports and to use immobilized cells in pullulan fermentation has been reported. The utilization of immobilized cells for this purpose is not feasible because considerable numbers of cells leak into the fermentation broth (37). In addition, because pullulan synthesis is partially growth associated, it is inevitable that some cells will be present in the fermentation broth.

Problems Due to the Sterile and Aseptic Conditions Requirement

At the present time, pullulan production by fermentation is carried under sterile and aseptic conditions, which require very high capital and operating costs as in the case of pharmaceutical production. If pullulan is to be produced for use as bulk chemicals and/or bulk commodities, its production costs have to be greatly lowered. The technological challenge is to develop a nonsterile and nonaseptic fermentation process for the production of pullulan. A bistaged pH process has been developed for this purpose (18). In batch fermentation, the pH of the culture medium decreases rapidly from its initial value of 5.0 to the final value of 2.5 within the first 12–36 h and then self-stabilizes at this value until the end of the fermentation. It is observed that most of the polysaccharide from the batch fermentation process was synthesized during the self-stabilized acidic phases. Experiments on the effect of the initial pH on the fermentation reveal that at very low initial pH values, such as pH 2, the polysaccharide production is insignificant. However, the biomass concentration obtained under these conditions is very high. This interesting phenomenon served as the basic principle for the development of the bistaged pH fermentation process. In this process, the first stage of fermentation is conducted at a very acidic pH for the best production of biomass. When the biomass concentration reaches its maximum value, the second stage of fermentation is initiated by adjusting the medium pH to a higher value for promoting the synthesis of pullulan. The bistaged pH process enhances the pullulan concentration in the medium, influences the rheological properties of the fermentation broth, and has a potential of operation under nonsterile and nonaseptic conditions. During the first stage of fermentation, the microbial contamination could be eliminated due to the very low pH of the medium. During the second stage of fermentation, the contamination could be minimized to an insignificant level due to the high concentration of *A. pullulans* already present in the culture medium. This bistaged pH process could be applied to batch or continuous fermentation processes.

Problems Due to Melanine Pigmentation

Aureobasidium pullulans is also known as a black yeast because of its characteristic black pigmentation associated with mature cells (Fig. 20). The pigment, melanin, is synthesized from the pentaketide pathway in which 1,8-dihydroxynaphthalene is the direct precursor (38). Both intracellular and extracellular melanin are synthesized during the later stage of fermentation where the cell morphology changes from swollen cells to true chlamydospores (39). Thus, melanin production occurs simultaneously with pullulan synthesis, resulting in a dark green to black fermentation broth at the end of the fermentation. This is an undesirable feature for industrial production of pullulan because decolorization (melanin removal) is required during the product separation and purification operations (Step D of Figures 2 and 4). The synthesis of melanin by *A. pullulans* depends on the culture conditions, such as carbon source and concentration, nitrogen source and concentration, oxygen concentration, and trace minerals (26,40,41) (Fig. 20). Therefore, such conditions can serve as control variables to minimize melanin synthesis during the pullulan fermentation process. However, the most promising solution to the problem of melanin production during fermentation may be the use of nonpigmented strains of *A. pullulans*, which may be obtained by mutation (42).

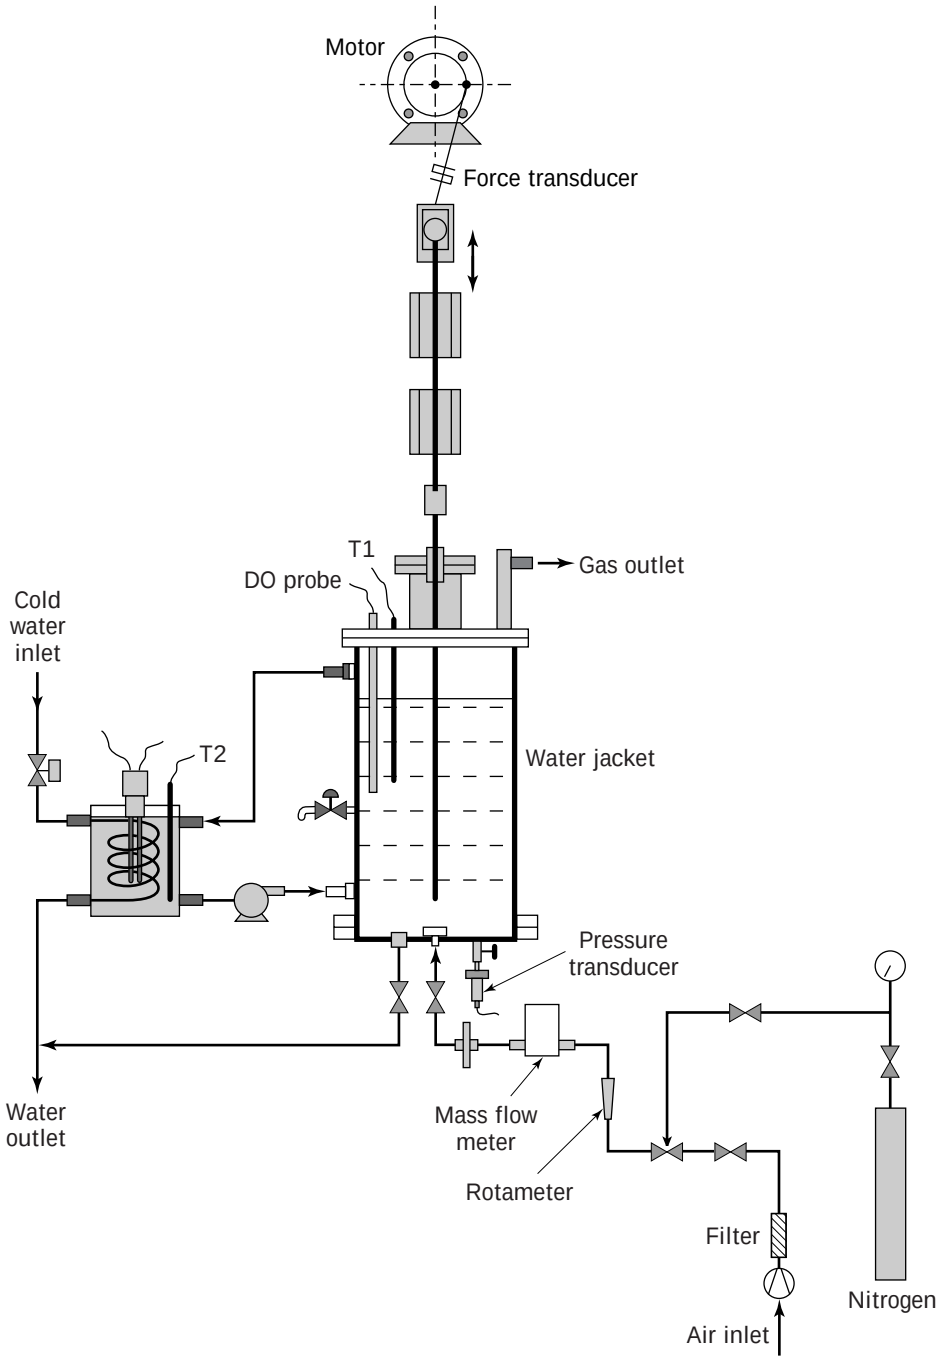

Figure 15. Schematic diagram of the experimental system showing the reciprocating plate bioreactor. *Source*: From Ref. 32, reproduced with permission.

Problems Due to Pullulanolysis during Fermentation

Pullulanolysis is the breakdown of high molecular weight pullulan in the fermentation broth into lower molecular weight pullulan by the depolymerase activity of *A. pullulans*. The pullulanolysis always occurs during the progress of fermentation and is responsible for the decrease of viscosity of the fermentation broth during the later stage of fermentation. The presence of an extracellular endoamylase is suggested as the cause of the observed phenomenon (43). It is not clearly understood why *A. pullulans* produces the pullulan-destructive endoamylase during the synthesis of pullulan. The resulting consequence of the pullulanolysis is that only low molecular weight pullulan is obtained at the end of the fermentation. The pullulanolytic breakdown of the pullulan product is worsen when a high-shearing mixing device such as the Rushton turbine is employed in the fermenter (30,35). Thus, if the high molecular weight pullulan is desired as a final product, the fermentation has to be stopped after approximately 24 h, when the molecular weight of pullulan is at its highest value (44,45). This is not, however, an economically feasible solution for industrial practice because the fermentation

efficiency (expressed as grams of pullulan produced per 100 g of supplied substrate) is very low after this short period of fermentation. A more effective but challenging alternative solution is to acquire more knowledge on the pullulanolysis phenomenon by research, then to develop the technology for the suppression or the inhibition of endoamylase synthesis by *A. pullulans* during the pullulan fermentation.

OUTLINE

INTRODUCTION

Liquid transfer is a vital component of most biotechnology processes. There is possibly more information available on pumps than any other single piece of equipment (pumps being a very common piece of rotating equipment, second only to the electric motor) existing in a typical plant, so this section must be a rough introduction to hydraulic theory. This article provides a basic understanding of pump mechanics, nomenclature, and principles and sufficient information to begin the selection process of a new pump.

THEORY

Before a specific selection can be initiated, the operating conditions the pump will be expected to meet must be understood. Breaking down the system into clearly defined and agreed-upon components will not only simplify calculations, and help guarantee nothing is overlooked, but also make it easier to evaluate the consequences of changes to any part of the system. There are universally understood and applied ways of breaking down a system, recognized by all pump manufacturers and users.

Flow

Capacity is expressed in flow/unit of time, commonly gallons per minute (gpm) or per hour (gph), or as cubic meters per hour (m^3/h).

To convert from volume to gallons:

$$1\ ft^3 = 7.48\ gallons$$
$$1\ m^3 = 264.2\ gallons$$

It is important to be realistic with estimates, because accurate pressure loss calculations depend on an accurate flow rate. Overestimating will result in equipment that will need to be valved back or slowed down to produce the demands actually required or in oversized/overpriced pumps.

Head

Head is the accepted hydraulic term for pressure. It is most commonly expressed in pounds/inch^2 (psi), or feet of head. The concept of a linear unit being used to express pressure can be most easily visualized as taking a resistance to flow and mentally converting it to a vertical column of water, such that the weight of this imaginary column is equivalent to the resistance of the considered section. Any pump that can push fluid against a column of water of the height thus calculated will be able to deliver flow against the system used to make the calculation.

To convert from psi to feet:

$$1\ psi = 2.31\ ft\ of\ water$$
$$1\ ft\ of\ water = .433\ psi$$

Most pipe friction loss charts express their losses as feet of head per 100 feet run of pipe, and all losses given as psi can be converted to feet by the above conversion factors (see Specific Gravity for adjustments given liquids heavier or lighter than water).

This linear unit has become the most common choice for hydraulic pressure (in the sense of resistance to flow) because:

- It is easily visualized.
- A linear unit fits into most hydraulic formulas (velocity, horsepower, specific speed, etc.).
- It compensates for various specific gravities before inclusion.
- It provides a common unit for all components of the total head that can then be added together to arrive at total resistance.

Types of Head. The total head referred to above is made up of four components. Any resistance to flow will fall into one of the following categories.

Static Head (ΔZ). Static head refers to the elevation differential between the source level of the liquid and the elevation at the destination. In other words, the elevation differential the pump must overcome. Caveats to this are:

- If a line enters at or near the bottom of a destination tank, the liquid level *in* the tank is considered the appropriate one, not where the pipe makes its entry (the pump must overcome the weight of the column *inside* the tank as part of its pressure capability).
- The vertical ups and downs are irrelevant (they will be accounted for later under Friction Head); the elevations at the beginning and end of the line are the ones used for ΔZ.
- The pump's position in relationship vertically to either the source or destination point is also irrelevant.

Static head is easily expressed in feet.

Pressure Head (ΔP). Pressure head is the differential in pressure at the ends of the system, the inlet and outlet, expressed in feet. An example would be a vacuum tank at the source; it provides resistance to flow (the vacuum holds back the fluid) and must be overcome by the pump. Resistance to flow from vacuum can be converted to feet of head by the following:

$$1\ inch\ mercury\ (Hg) = 1.133\ ft\ of\ water$$

Pressure at the discharge end (a pressurized tank or injection into a pressurized line) also needs to be added into the total and is included in ΔP.

Velocity Head (H_V). Velocity head is that energy necessary to overcome inertia. It is calculated by

$$H_V = V^2/2g$$

where V = velocity through the piping lines (in feet/second), and g = 32.2 ft/s^2, the acceleration caused by gravity at sea level.

Velocity head is reasonably estimated by taking the average velocity in a system and applying the formula. However, given a maximum average velocity of less than 8 ft/s in most systems, H_V is usually a relatively small number (less than 1 ft in the average 8 ft/s example above) in a typical hydraulic calculation and almost always ignored.

Friction Head (H_F). Friction loss is usually the largest individual component of total head for most calculations. There are formulas available for its calculation given various types of pipe, fittings, valves, and filters in texts, but fortunately there are charts in existence giving the calculated heads. Pipe losses themselves are usually expressed in feet of head/unit of length (usually 100 ft). Fitting losses are expressed either in equivalent feet of straight pipe to be added to the run of actual straight pipe for what is called an *equivalent feet of pipe* to be used in the calculations. Or, charts may give the actual loss per each fitting. Losses through valves, filters, and such are often expressed in psi or feet of loss per valve. Each component in a line must be considered, and a grand total for the system is arrived at as a total of the individual pieces.

The friction loss numbers will always vary considering the flow through the line; higher flows mean more drag and therefore more resistance. Filters will vary with flow and also condition of the filter element. It is common practice to use worst-case conditions.

Total Head (H_M). The four individual elements listed previously are added together for the *total mechanical*

head (H_M, also known as mechanical head, total dynamic head [TDH], or simply total head). They are the components for Bernoulli's formula, modified for the pump industry, given as:

$$H_M = \Delta Z + \Delta P + H_V + H_F$$

Adjustments to Head. There are qualities a liquid can possess that will affect the H_M.

Specific Gravity. Specific gravity (SG) is the direct numeric ratio of the weight of a particular liquid to the weight of water. Given that at certain standard conditions water weighs approximately 8.34 lb/gallon, anything heavier than that would have a specific gravity greater than 1.0 (for example, a liquid weighing 16.68 lb/gallon would have an SG of 2.0), anything lighter less than 1.0. Specific gravity will affect a conversion from psi to feet as follows:

$$\text{psi} = (\text{feet of water} \times \text{SG})/2.31$$

or

$$\text{feet of water} = (\text{psi} \times 2.31)/\text{SG}$$

Specific gravity will also directly affect horsepower because of the extra torque needed to overcome the additional weight of the liquid (as will be shown under Horsepower).

The second quality a liquid possesses that directly affects total head calculations is its *viscosity*. Most pump selection charts assume waterlike viscosity (1 centipoise [cps] or 31 Saybolt second universal [SSU]). The viscosity of liquids thicker than water affects pumps in several ways:

- It affects friction loss calculations; losses are higher with more viscous liquids. There are separate charts used for liquids more viscous than water.
- It affects horsepower. Manufacturers often provide specific charts to give the added torque needed to overcome viscosity.
- It affects the very capability of a pump to even *deal* with a product. Centrifugal pumps especially have limited abilities to handle viscous products.

Viscosity is usually expressed in the referenced units (cps or SSU), but there are many others. Viscosity can vary under dynamic conditions. Specifically:

- If a liquid becomes thinner under shear, it is *thixotropic* (example: paint).
- If it becomes thicker under shear, it is *dilatant* (example: taffy).
- If it becomes thinner only after exceeding a certain minimum threshold of shear, it is *plastic* (example: ketchup).
- If a liquid is unaffected by shear, it is *Newtonian* (example: water).

As mentioned above, viscosity affects centrifugal pumps in their very ability to pump a liquid; with viscous fluids their pressure capability falls off, the flow capability falls off even more, and their efficiency may fall off to a point where their use is totally unacceptable. Positive displacement pumps are affected in the speed they can turn and still move product without starving at the inlet. Manufacturers provide charts giving maximum speed for varying viscosities, for adjustments needed to horsepower to drive the unit with a thicker product, and perhaps for minimum port sizes necessary to allow product to get in quickly enough.

If the viscosity of a product is unknown, many pump manufacturers provide services wherein a liquid's viscosity will be tested, often at no charge, in exchange for the opportunity to quote their pumps.

Horsepower

Given the results of the total head calculations above, it is possible to make accurate calculations of the horsepower necessary to drive a particular pump.

The basic horsepower formula is

$$\text{HP} = (\text{gpm} \times H_M \times \text{SG}) \div (3{,}960 \times \text{eff.})$$

where gpm = flow (in gallons/min); H_M = total mechanical head (in feet); SG = specific gravity; eff. = efficiency (expressed as a decimal; e.g., 50% would be .50). *Note*: 3,960 is a constant, derived from the horsepower units and the weight of water.

A variation of this formula, commonly used for positive displacement pumps wherein specific gravity has already been calculated into the total head before being expressed as psi, is

$$\text{HP} = (\text{gpm} \times \text{psi}) \div (1{,}715 \times \text{eff.})$$

The 3,960 constant has been changed to 1,715 to provide for psi as a pressure unit by dividing by 2.31.

Often, viscosity will affect the horsepower as calculated above; in those cases manufacturers will provide correction factors for differing viscosity. The Hydraulic Institute has generic charts for centrifugal pumps that seem to work fairly well for almost all manufacturers, although some especially high-efficiency pumps claim to outperform the charts and therefore provide their own correction factors.

Net Positive Suction Head

Net positive suction head (NPSH) is the hydraulic term referring to the pressure under which liquid enters the pump, not only in terms of what the existing system is able to provide but also in reference to what any particular pump needs in order to function properly. It is an absolute unit, always expressed relative to absolute zero (as opposed to gauge units, whose values are always in reference to normal atmospheric pressure, called zero gauge). If a pump does not receive the liquid under sufficient pressure, it will cavitate.

Cavitation. Liquids will stay in liquid form only if sufficient atmospheric or system pressure is available to prevent it from going off to vapor. Even cold water, for exam-

ple, will flash off into vapor in a strong enough vacuum, outer space as an obvious example. All liquids have a predictable vapor pressure necessary to keep them in their liquid state, varying up or down respectively as the liquid is heated or cooled.

This is of particular interest in hydraulics because of the often high vacuum present at the inlet of a pump. If the pressure provided by the system is less than the liquid's vapor pressure, the pump will undergo a physical process called cavitation. This action varies in specifics from centrifugal to positive displacement type pumps, but the general process is always approximately the same:

- The liquid finds itself in an area of low pressure, the pump's inlet port.
- If the pressure is *too* low (less than the liquid's vapor pressure at the operating temperature), it undergoes a state change from liquid to vapor. Because the vapor is not free to escape, it stays entrained in the liquid and assumes a bubble (spherical) shape.
- The vapor bubbles are carried further into the pump with the flow of surrounding liquid.
- Eventually the low-pressure bubbles and surrounding liquid find themselves in a higher pressure area as they near the pump discharge.
- The higher pressure causes the vapor bubbles to implode (collapse). This implosion is called cavitation.

The implosion of the low pressure vapor bubbles makes a very identifiable sound; in centrifugal pumps it produces a rattle, sounding like gravel is being carried through the housing; in positive displacement pumps the sound is more percussive, often *very* loud. In both cases the implosion of the vapor bubbles is damaging to the pump itself and often to the product. Centrifugal impellers and positive displacement pump rotors will actually have material removed by the very powerful implosions, shafts can be deflected to the point of fatigue, higher horsepower is required, and performance will be negatively affected.

Net Positive Suction Head Required. Manufacturers can test their pumps to see exactly how much positive suction pressure is necessary at various flows to keep their pumps from cavitating. This is called the net positive suction head required ($NPSH_R$). Typically, the greater the flow, the more pressure necessary because of the higher velocities going through the housing. A possible exception: at extremely low flows, the slippage caused by recirculation within the housing in some centrifugal pumps may create low pressure areas, sometimes low enough to fall under a liquid's vapor pressure and allow cavitation. This is called either suction or discharge recirculation cavitation, depending on where it physically occurs in the pump housing. Manufacturers determine the $NPSH_R$ from empirical data. They set up a test skid wherein they can gradually restrict flow into a pump, constantly monitoring the performance with pressure gauges and flow meters. Eventually they find a point at which the restrictions affect performance an agreed-upon minimum amount (3% below normal curve is the current standard). The pump is considered to be cavitating, and this point is registered on a chart. The same process is performed for a number of flows, and an $NPSH_R$ curve is generated. $NPSH_R$ curves are assumed to be drawn using 60 °F water; adjustments can be made later for other liquids.

Net Positive Suction Head Available. Net positive suction head available ($NPSH_A$) is the pressure any particular system makes available at a pump's inlet under operating conditions. It is a total of several factors. After calculation (or determination by an actual physical test), it will be compared to the pump's $NPSH_R$. Also by previous agreed-upon standard, $NPSH_A$ must exceed $NPSH_R$ by a minimum of 2 ft for a pump to be considered acceptable. This is a controversial issue; some people believe that this differential is insufficient, that the $NPSH_R$ chart represents the point at which the pump is *already* cavitating, a 2-ft differential is often too low; and that a sliding scale of minimal percentages by which $NPSH_A$ should exceed $NPSH_R$ would serve the user better. However, at this time the 2-ft differential is still accepted by most hydraulic engineers.

$NPSH_A$ is calculated by the formula:

$$NPSH_A = H_{ATM} \pm \Delta Z - H_F - H_{VAP}$$

where H_{ATM} = atmospheric pressure in absolute units, expressed in feet (atmospheric pressure at sea level = 14.7 psi = 33.9 ft); ΔZ = elevation differential from liquid level to pump's inlet (in feet). If the liquid level is above the pump inlet, the number will be positive (+), if below it will be considered a negative (−); H_F = friction loss in suction line only (in feet); and H_{VAP} = vapor pressure of liquid at operating temperature (in feet).

H_{ATM} and H_{VAP} are available from various reference books; H_F and ΔZ are calculated as in the section on Friction Head.

$NPSH_A$ can be determined on an operating pump by installing either a compound or vacuum gauge at the pump's inlet and by taking this reading and subtracting the liquid's vapor pressure (which will not be indicated on the gauge: H_{ATM}, H_F, and ΔZ will all be indicated by the gauge reading).

As stated earlier, the results of the calculation (or gauge reading $-H_{VAP}$) should be compared to the manufacturer's $NPSH_R$, a minimum 2-ft differential necessary to guarantee a pump will not cavitate. The $NPSH_A$ calculation is valuable for several reasons:

- It can show us beforehand whether a pump will cavitate after installation.
- It indicates the area most easily altered to eliminate existing cavitation and how much it needs to be altered. For example, if H_F is high, it may be lowered with larger pipe or fewer elbows. If ΔZ is low (or even negative), we can pick up positive head by raising the source tank.

If a system is still cavitating, and the $NPSH_A$ calculation does not indicate an easy correction, it may be that a pump with a lower $NPSH_R$ is needed. There are whole

classes of pumps considered low NPSH that typically have requirements below 1 ft or 2 ft.

CENTRIFUGAL PUMPS

Pumps generally are divided into two main classifications, centrifugal and positive displacement (PD). There are many subclassifications. Several will be listed here later according to their suitability for use in bioprocessing, including a few that seem to cross the boundaries of centrifugal and PD. The vast majority of pumps in use are centrifugal because of the many advantages of centrifugal design (to be listed later), but bioprocessing has unusual demands, and the percentages of positive displacement pumps in use is significantly higher than in other industries.

Principals of Operation of Centrifugal Pumps

Centrifugal pumps (Fig. 1) consist of

- A rotating impeller
- An impeller housing (volute) to channel the flow from the suction port to the discharge port
- A power source, usually an electric motor
- A connection from the motor to the impeller; either the motor shaft itself, or sometimes a separate shaft extension
- A mechanical seal assembly to seal liquid inside the liquid-end assembly at the point where the shaft goes through the backplate.

There are many designs of impeller, having to do with whether the vanes are enclosed by shrouds or not (open or enclosed; open is cleaner, but less efficient; enclosed has less slip and is therefore more efficient, but is much harder to clean and to inspect); number and angle of the vanes themselves (influencing the shape of the pump curve); and diameter and thickness of the vanes themselves (deeper vanes give more flow, larger diameters mean more pressure capability). Manufacturers can create impeller designs for very specific sets of conditions. A centrifugal pump's simple design means that

- Centrifugal pumps are usually less expensive (often *considerably* less expensive) than PD pumps.
- Centrifugal pumps can be close-coupled, meaning they can be mounted directly on the face of specially designed close-coupled motors, a rare feature on PD pumps, helping keep them inexpensive (and also compact).
- Their flow is relatively pulsation free.
- Because of the inherent slip caused by the generally open nature of the impeller/volute package, there is a maximum pressure (shut-off head) a centrifugal pump can develop. This also means they can be easily controlled by regulating valves and often do not need pressure relief valves or controls in the system because HP loads actually decrease when flow is valved back.
- They are easy to maintain and repair.
- They are easily adapted to sanitary standards.

There are also disadvantages possessed by centrifugal pumps that are often especially significant in bioprocessing.

- Their inherent slip means they do not handle viscous materials well. The rule of thumb is anything over 2,000 SSU (about 500 cps) is usually considered too viscous for a centrifugal pump.
- Because pressure is generated by vane tip speeds, centrifugal pumps are not by nature easily adapted to high-pressure applications. This can be overcome to a degree by running them especially fast (designs exist that run at over 10,000 rpm) or by incorporating multistage designs wherein a chain of impellers is mounted on a common shaft, each impeller boosting the pressure of the impeller preceding it.
- Centrifugal pumps must be run at relatively fast speeds to develop sufficient impeller vane tip velocity to generate reasonable head (usually a minimum of 1,200 rpm). PD pumps, on the other hand, are often run efficiently at well under 100 rpm. This minimum speed means that centrifugal pumps are not usually good in low shear applications.
- The minimum speed also means that centrifugal pumps are not efficient with low-flow applications; turning slowly to limit flow means all pressure capability is gone. Even very small centrifugal pumps are often rated at 10 gpm or more; they will run at lesser flows by regulating them back in any of various fashions (regulating valves, inverters, bypass lines), but they are not efficient at very low flows.
- The presence of a mechanical seal means that abrasive products are a potential problem, not only because of the limited life of the components, but also for the danger of materials wearing off the faces and

Figure 1. Centrifugal pump. *Source*: Courtesy of Tri-Clover Inc., Kenosha, Wis.

entering the product stream. There are designs that remove seals from the product flow (double mechanical seals) or eliminate seals altogether (magnetically driven pumps, or pumps with gas injection seals), but they are often expensive and sometimes not available in sanitary designs.

Types of Centrifugal Pumps

End Suction. By far the most popular general classification of centrifugal pump is the end-suction design. Liquid enters through the suction port in the center of the housing, is picked up by the leading edge of the impeller, has energy imparted by the impeller's rotation, and exits tangentially at the discharge port on the volute's periphery. End-suction centrifugal pumps are available as close coupled (mounted directly onto a motor's face) or pedestal mounted (the pump is a separate entity with its own shaft/bearing housing, connected to the motor by a flexible coupling, the assembled package bolted to a common base). Close-coupled design is generally preferred because of lower cost, its more compact design, and its inherent alignment between components, but pedestal-mounted pumps often have more space for special seal options and often will adapt more easily to any special motor requirements.

Magnetically Coupled. One way to arrive at a seal-less design and remove the difficulties of seal compatibility (see Mechanical Seals) is to adapt the standard end-suction design. Rather than the motor shaft extending directly through the mechanical seal and into the liquid end of the pump, it drives a large, hollow rotating magnet. The liquid end of the pump is in a sealed housing and fits up against the motor with a magnetized impeller extended into the hollowed-out area of the drive magnet. As the motor shaft rotates the hollow drive magnet, the impeller is pulled along. Because of the lack of a direct connection between the motor and impeller, magnetically driven pumps can handle only limited viscosity or specific gravity before the impeller decouples (uncouples). They can be very inexpensive in smaller designs, but the price escalates quickly as they get larger. Often, soft-start motors are necessary to prevent decoupling. At present, there are no sanitary-design magnetically driven pumps, but they will undoubtedly be available soon.

Multistage. Centrifugal design is normally best suited for medium-to-high flow, low-head applications such as liquid transfer. When the many advantages of centrifugal pumps makes them the design of preference, but the total head necessary exceeds that available from standard models, multistage pumps may provide an alternate to PD pumps. Impellers are staged, one after another in a line, and are driven by a long common shaft. Internal channels see that the first impeller's discharge is fed to the inlet side of the second, which discharge feeds the third, and so forth. Pressure is cumulative, but the flow is limited to that which can be carried by any individual impeller. The only restriction to the number of stages, and therefore the total pressure possible, is the housing-pressure limitations. This design carries all the advantages of standard centrifugal pumps, except they are not as easy to repair (impellers must be removed in series, and clearances can be difficult to adjust), and they are not necessarily inexpensive. There are sanitary designs available.

POSITIVE DISPLACEMENT PUMPS

Design and Principles of Operation

Positive displacement pumps make-up the second major classification of pumps used in the bioprocess industry today. In contrast to centrifugal pumps, discussed earlier, PD pumps function on a very different principle: that compressing a fluid volume will increase the ability of the fluid to do work. This change in volume takes place within the pump cavity as the pump drives or pushes that volume to the outlet, thereby increasing the pressure on that volume of fluid to be equal to the pressure at the pump outlet or discharge. An example of this principle is a simple syringe. As the syringe plunger is pushed in, the fluid within the syringe will begin to be exposed to a higher pressure as the volume holding the fluid decreases. The higher pressure then drives the fluid out the end of the syringe. In both the syringe and a pump, the pressure that the pump will generate is controlled by the resistance to flow that the fluid is exposed to as it leaves the pump discharge. Unlike dynamic or centrifugal pumps, this creates a situation whereby the PD pump can become overpressurized. The PD pump will continue to drive fluid forward regardless of the level of resistance. This overpressurization will only be relieved by either a pressure relief device on the discharge side of the pump or through the slip that is experienced as the pump operates.

Slip, in a positive displacement pump, is defined as an efficiency calculated by taking the amount of fluid that escapes the encapsulated volume as the pressure of the fluid volume increases and dividing by the amount of fluid delivered. The escaping fluid is driven back to the inlet or low-pressure side of the pump through clearances within the pump. By knowing the amount of slip that the pump is experiencing, one can calculate the pump efficiency. Typically, PD pump efficiencies are relatively high, 80 to 90%, and will increase as the fluid viscosity, discussed earlier, increases.

Advantages. Advantages that can be found in using PD pumps in the bioprocess industry include:

- The ability to deliver a constant flow rate; the discharge rate for a PD pump is relatively constant, against a varying discharge pressure.
- They function well at a low-flow rate; the PD pump can deliver a low-flow rate at a high discharge pressure and still maintain a high efficiency as compared to centrifugal pumps.
- They function well at high viscosity; the PD pump can easily be adjusted to handle high viscosity liquids and, in fact, will run at a higher efficiency as the higher viscosity acts to reduce the amount of slip experienced by the pump.

- They have the ability to self-prime; most PD pumps will act to create a vacuum at the pump inlet. This vacuum will then pull liquid into the pump cavity.
- PD pumps can easily be made to sanitary design specifications.

Disadvantages. Disadvantages that can be found in using PD pumps in the bioprocess industry include:

- Overpressurization can occur; a flow restriction on a PD pump will build pressure until that pressure is relieved. An internal or external pressure relief valve may be required for safe operation of the pump.
- Pulsing flow will occur; the design of PD pumps is such that usually they will cause pressure pulsation as they maintain flow rate. This pressure pulsation can act to damage discharge piping caused by excessive vibration. A pulsation dampener may be required.
- High flow rates are hard to maintain; high flow rates may be hard to achieve even with large pumps because the maximum pump speed may be limited by the viscosity and suction port size.
- Power limitation; because the discharge pressure is directly proportional to the horsepower required, very high discharge pressures may require a very high horsepower, which may exceed the physical strength of the pump.

Types of Positive Displacement Pumps

Gear Pumps. Gear pumps (Fig. 2) comprise, perhaps, the most common PD pump in industry. They have wide acceptance because of low cost and simple construction. In general, gear pumps are made in two very distinct designs. The first is the external gear pump. This design uses two meshed gears that rotate in opposite directions. The first gear is driven by the pump motor, referred to as the driven gear, and the second gear is driven by the first and is called the pump gear. Fluid enters and exits the gear housing perpendicular to the gear mesh, with the incoming fluid being trapped within the gear teeth as the opening mesh creates a vacuum pulling liquid in. This trapped liquid rotates on the outside of the gears and is expelled at the pump discharge port as the gear teeth again start to mesh. The fluid is forced out of the gear housing at the higher pressure of the discharge side of the pump.

The other type of gear pump used in industry is the internal gear pump. The internal gear pump works under the same principle as the external gear pump; however, the gears are configured such that a smaller, off-center, internal gear is placed inside a planetary gear. The internal gear meshes with the inner teeth of the planetary gear to create the pumping action. In this design, the larger planetary gear is the motor driven gear, with the inner gear acting as an idler. The gap created by mounting the internal gear off center is filled with a crescent-shaped scraper. This scraper acts to seal the inlet port from the discharge port and reduces the amount of slip in the pump. This pump is slightly more expensive, but is quieter and often longer lived.

Air-Driven Double-Diaphragm Pumps. Double-diaphragm pumps (Fig. 3) are a unique type of PD pump. The design of a double-diaphragm pump is made up through the porting of four check valves and two dia-

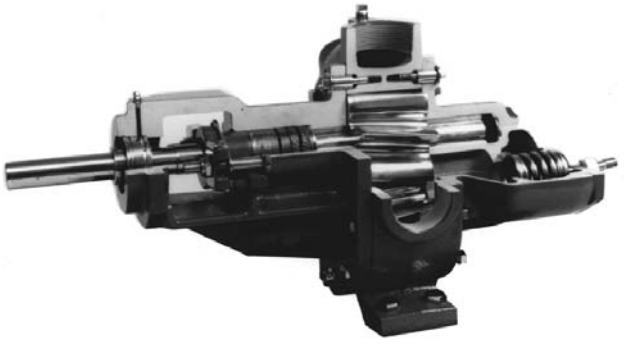

Figure 2. Gear pump. *Source*: Photo used by permission of Roper Pump Company.

Figure 3. Double-diaphragm pump. *Source*: Courtesy of Wilden Pump Company.

phragms mounted in parallel. The two diaphragms are connected to an air-driven piston. The operation of the pump has liquid entering a common inlet port and the liquid separating and alternately flowing through one of two check valves, the check valve that is exposed to the opening diaphragm. At the same time, on the opposite side of the closed check valve, the closing diaphragm is expelling fluid at a discharge pressure (limited by the air supply pressure that powers the pump). The fluid being expelled pushes open the check valve exiting the closing diaphragm section and pushes closed the check valve on the opening diaphragm. This action cycles back and forth as the air piston that drives the two diaphragms moves in and out. Because both diaphragms are attached to the same shaft, when one diaphragm is opening, the other is closing.

Progressing Cavity Pumps. Progressing cavity pumps (Fig. 4) have a special design that allows for very gentle pumping of highly viscous liquids. Most progressing cavity pumps are made up from a single helical (metal) rotor rotating inside a (elastomeric) double helical stator. Cavities formed by this combination of rotor and stator progress down the length of the rotating shaft as the shaft turns. The function of the rotor is very similar to that of a screw pump slowly pushing the pumped liquid forward toward the discharge of the pump. Pressure is developed because close clearances between the rotor and stator minimize the amount of slip that is found in the pump. Further, because the pump is well suited to pumping high-viscosity liquids, this action is even better utilized.

Flexible Impeller Pumps. Flexible impeller pumps (Fig. 5) make up a class of very inexpensive PD pumps that can be easily adapted to many applications. Flexible impeller pumps work on the principle of a multivaned rubber impeller rotating in a housing that is cammed such that the vanes are pushed close as the impeller rotates. This closed impeller expels fluid out the discharge of the pump and at the same time pulling liquid into the suction port. This action creates a vacuum at the suction port. Vacuum values as high as 22 in Hg are easily achievable. The major drawback of this style of PD pump is the inability of the pump to run dry. Dry running of this type of pump will quickly erode the rotor.

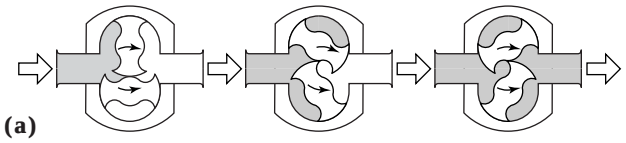
Circumferential Piston Pumps. Circumferential piston pumps (Fig. 6a) are used in the bioprocess industry to transfer a wide range of both raw material and finished products. The circumferential piston pump works with two opposing hemispherical rotors spaced 180° apart. These two rotors turn in opposite directions much like that of the external gear pump; however, the action of the circular piston moving past the suction port creates a vacuum that draws fluid into the pump cavity. This fluid, which is trapped between the sides of the rotating piston and the pump housing, travels around the pump casing and is discharged at the pump outlet as the piston of the opposing rotor pushes the trapped liquid into the outlet of the pump. This action alternates from pump rotor to driven rotor as trapped fluid is pushed into the pump outlet. This pump design requires that the rotors of the pump not come in contact with one another. To accomplish this, the rotors are driven with a gear housing that contains supporting shafts, bearings, and timing gears. It is therefore very clean and ideally adds no metal to the product.

Lobe Pumps. Very similar in design to circumferential piston pumps, lobe pumps (Fig. 6b) also use a gear housing containing supporting shafts, bearings, and timing gears. The rotors of the lobe pump rotate in opposite directions, creating a low pressure or vacuum at the pump inlet as the lobes separate. The fluid drawn into the pump cavity



(a)

(b)

Figure 6. (**a**) Circumferential piston pump; (**b**) Lobe pump. *Source*: (**a**) courtesy of Waukesha Fluid Handling; (**b**) courtesy of ITT Sherotec.

is trapped in the valley of the lobe and rotated to the outlet of the pump where the trapped fluid is forced into the pump outlet as the opposing rotor lobe rotates into the lobe valley containing the trapped liquid. This action alternates from rotor to rotor similar to that found on the circumferential piston pump. The lobe pump is somewhat less shear intensive as compared to the circumferential piston pump and is more easily cleaned when cleaning a pump in place.

Peristaltic Pumps. Peristaltic pumps (Fig. 7) are very common throughout the bioprocess industry. They can be found in all size ranges, handling flows on the laboratory bench of 3 to 4 mL/min to flow rates on the production floor of 30 to 40 gpm. The basic design of the pump functions through the progressive squeezing of tubing by rollers mounted to a rotating plate. The rollers trap fluid within the tubing and rotate it to the outlet. They are self-priming and have the major advantage that the fluid only contacts the pump tubing so sealing the pump is not required. The action also minimizes the amount of shear that the pump fluid is exposed to.

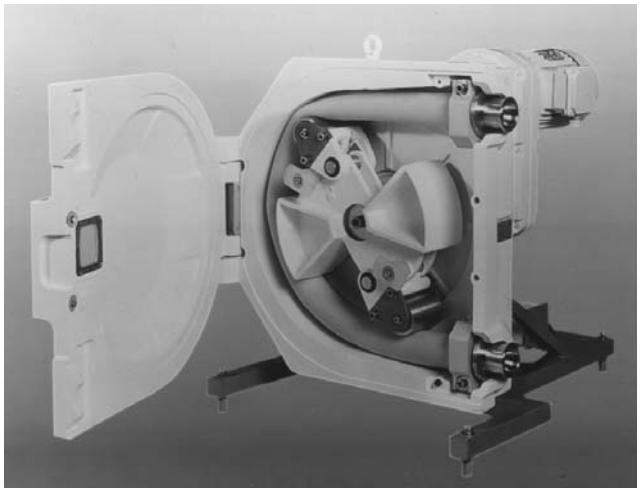


Figure 7. Peristaltic pump. *Source*: Courtesy of Watson-Marlow Inc.

Nutating Disk-Type Pumps. Nutating disk-type pumps (Fig. 8) are new to the bioprocess pump market and provide for advantages typically found in several different types of older pump designs. The principle that drives this class of PD pumps is the action of a wobbling disk within the pump cavity. This disk can be used to trap a volume of fluid between it and the stationary pump housing. The trapped fluid is pushed toward the pump outlet through this wobbling action and the use of a scraper gate that rides on the width of the rotating disk.

DRIVERS

The most popular choice of drivers for pumps, by far, is the AC motor. They have become the standard because they

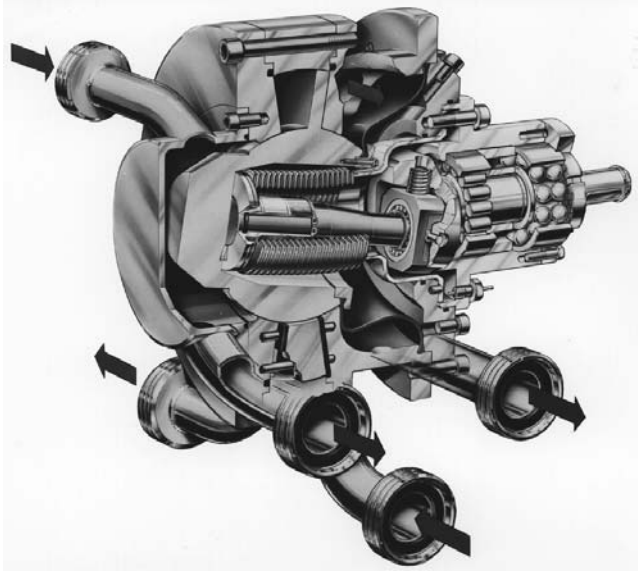

Figure 8. Nutating disk-type pump. *Source*: Courtesy of KSI.

are inexpensive and long lived, have relatively few moving parts, and are available from a large variety of sources, in a large variety of styles and enclosures. They are relatively quiet (typically between 70 and 85 decibels), efficient (often over 90%), and institutions exist (National Electrical Manufacturer Association [NEMA]) that guarantee a certain degree of interchangeability from manufacturer to manufacturer. Typically, only if an AC motor is unacceptable are other choices considered. Considerations include style, electrical specifications, and enclosure.

Style

Close coupled, foot-mounted motors are common for centrifugal pumps that will accept this. Standard horizontal foot-mounted motors are needed when pedestal-mounted centrifugal pumps have been chosen. PD pumps usually need motors with gear boxes integrally mounted to achieve the low speed necessary. Because most pump suppliers sell their pumps as motor and pump packages, the user is not usually concerned with physically matching the components, but should understand the principles.

Electrical Specifications

Unlike the general motor style, it is the user's responsibility to know the electrical systems the drive will be expected to operate under. Concerns the supplier must address will be:

- *Phase*: Single phase is available for small horsepower drivers (below 5 hp), and common for fractional horsepower, but three phase is available for fractional and large integral motors.
- *Voltage*: in the United States, standards are 115 or 230 V for single phase and 230 or 460 V for three phase, but others voltages exist. Because motors are good for $\pm 10\%$, there is some flexibility.
- *Frequency*: 60 Hz is the standard in the United States, but 50 Hz exists all over the world. Motors tolerate only $\pm 5\%$ frequency variation.

Enclosure

The desired enclosure is an important consideration. Standard types available are open drip-proof for environments where the motor will be protected from atmospheric dangers; totally enclosed, fan cooled (TEFC) for areas where the motor will be exposed to light moisture; explosion proof where a UL rating is necessary and the motor's ability to keep sparks from escaping is crucial for safety considerations; and common in bioprocessing, the wash-down enclosure where the area the unit is to be mounted in will be periodically hosed down.

NEMA is an organization that has written a standardized list of motor dimensions such that a user may substitute one brand for another in confidence that the new motor will physically interchange. This is done by a series of frame designations, such that a brand A motor in, for example, frame 145TC will exactly fit in place of a brand B motor of the same frame.

An accessory often considered today is the frequency inverter, which varies frequency and voltage in such a fashion as to allow an AC motor to act as a variable speed device. This has many advantages in addition to allowing a user to dial in more precisely the desired flow, such as the ability to control speed remotely, and to be able to start up a pump slowly to minimize start-up damage to the pump and the motor.

Other options to an AC motor are gasoline or diesel engines for areas where electrical power is unavailable, and more and more commonly, compressed air drives. Air motors have the advantages of being inherently explosion proof and being able to stall without incurring damage, but have the disadvantages of needing very dry compressed air and of being relatively inefficient. DC power is used in some very small pump packages, but is uncommon.

SPECIAL CONSIDERATIONS FOR BIOPROCESSING PUMPS

Sanitary Standards

The main standard for the sanitary design and construction of pumps to be used in the bioprocess industry is the 3A Standards (Code of Federal Register Title 21, part 177). These standards govern certain design modifications that are key elements in maintaining sanitary conditions within a pump. These guidelines cover surface finish, materials of construction, fabrication, and other areas. The sanitary design of a pump must also comply with all other applicable standards, including FDA, cGMP, and the ANSI/ASME standards for food, drug, and beverage equipment.

Materials of Construction and Surface Finishes

The most commonly found material of construction for pumps in the bioprocess industry is austenitic stainless steel alloys. Austenitic stainless steel alloys used in the construction of sanitary stainless steel pumps include AISI types 304, 304L, 316, and 316L. Analysis of the makeup of these alloys reveals that a major element in all stainless steel alloys is iron. Iron alone is quickly attacked by most fluids, but in the presence of chromium in correct combinations of Ni, C, Mn, P, Mo, Si, and S, the ability of stainless steel to withstand corrosion is excellent. This, plus its low carbon content and its ability to be easily welded, machined, and polished, makes 316L the most popular material of construction for pumps in bioprocessing. Product-contact surface finish is critical in most bioprocess systems because of the need to preserve sterile or sanitary conditions. All product contact surfaces must be free of cracks, crevices, and occlusions that can harbor and promote bacteria growth. Surface finish in most pumps is obtained through the use of mechanical polishing and electropolishing. This surface treatment will result in a surface finish that would measure at approximately 15 Ra surface roughness.

Mechanical Seals

Theory. Mechanical seals (Fig. 9) are a standard product used in the manufacture of most pumps to seal between

Figure 9. Mechanical seals. *Source*: Courtesy of the Durametallic Company.

the rotating pump shaft and the pump cavity. The type of mechanical seal used to seal the pump cavity is a key component of most pumps used in the bioprocess industry. The mechanical seal that is placed into pumps must serve two functions:

- Provide a barrier to the atmosphere
- Contain the fluid in the pump cavity without affecting fluid quality

Bioprocess pump seals are designed to be easily cleansed and not harbor bacteria. However, for them to be used in pumps for sterile fluids, particular modifications are required. These modifications include changes in the seal design, placement of the seal within the pump housing and selection of seal materials.

A discussion on mechanical seals is best started with a brief background on how mechanical seals work. A single mechanical seal works with two very flat surfaces, one a rotating face element and the other a stationary face element. These faces ride on one another with an ultrathin layer of fluid between the seal faces. When the fluid enters the zone between the two faces, the fluid temperature rises owing to the frictional resistance of one face on the other. If the seal is functioning correctly, the fluid will vaporize as it exits this zone and enters the atmosphere. This principle applies to most single mechanical seals in bioprocess pumps. The key to this functioning correctly is to have proper force pushing the rotating element on to the stationary seat. The force can be obtained either mechanically or hydraulically. The mechanical force is provided by a compressed spring. The hydraulic force, found in a hydraulically balanced seal, uses the pressure inside the pump head to push the rotating element to the stationary seat. Both of these methods are used in bioprocess pumps seals to produce a force that will generate enough friction between the faces to vaporize the fluid just before it leaves the seal faces without causing the faces to wear too quickly or generate too much heat.

If the mechanical seal is to function as described and provide a sterile barrier between the atmosphere and the fluid within the pump cavity, certain modifications are required to the seal design. First, a secondary mechanical seal is needed behind the primary inboard seal. This combination is referred to as a double mechanical seal. Second, both of these seals are placed into a stuffing box or gland that is attached to the pump where the rotating shaft enters the pump head. This is done so that a flushing fluid can be run between the two seals. The fluid barrier will guard against any contaminants from the atmosphere penetrating into the fluid within the pump cavity. The flushing fluid is pushed through the stuffing box under pressure so that a positive pressure on the outboard seal stops contaminants from entering the stuffing box. A secondary function of the seal flush liquid is to provide a certain amount of cooling to the seal faces.

The requirement that the seal contain the fluid within the pump cavity without affecting the fluid quality necessitates changes in the way the inboard seal functions. Fluid in the pump cavity is kept pure by ensuring that a positive pressure is maintained on the pump side of the inboard seal. This pressure functions in the same manner as that on the outboard seal; however, it should be greater than the stuffing box pressure to ensure that any leakage through the seal passes from inside the pump into the stuffing box. This will prevent the passage of contaminants from the stuffing box into the pump cavity. The seal designed for this configuration creates some problems.

First, if the inboard seal fails, product can be lost though the flush outlet of the stuffing box. Second, if the fluid in the pump contains active organisms that must be contained, these organisms could pass into the seal flush. The common flushing procedure for double mechanical seals in this situation is to maintain the stuffing box at a higher pressure than the pump side inboard seal pressure. In the case of seal failure, the flush fluid would move into the pump head, and no product would be lost. This arrangement can present problems if particulate, worn from the seal faces, is forced into the pump cavity by the high stuffing box pressure, thereby contaminating the fluid in the pump. Applications should be reviewed to determine which flushing configuration is most applicable.

The mechanical seal chosen for an application should be constructed of the highest quality FDA-approved materials of construction to provide a reliable, long-lasting seal. The face and rotating element materials should be selected for fluid compatibility, hardness, and flatness. Commonly used materials include tungsten carbide, silicone carbide, ceramics, carbon graphite, and stainless steel. The supporting items of the seal, including the springs, cups, O-rings, drive collar and set screws, should also be selected for fluid compatibility and performance characteristics. These pieces will function as a system to provide a reliable seal.

Static Seals

Static seals within pumps used in the bioprocess industry fall into two categories. These categories are elastomer O-rings and flat gaskets. O-rings are more commonly used in modern pump designs because they can be sized to properly seal flat or round pump components within the pump

design. Further, O-rings and their corresponding O-ring grooves can be easily configured to minimize any fluid entrapment and provide a cleanable crevice-free seal. O-rings are commonly used to seal pump shafts to mechanical seals and pump coverplates to pump housings. The O-ring material is selected based on the required durometer (hardness) and material compatibility with the sealed fluid. Commonly found materials include Viton®, EPDM, Buna-N, Silicone, and Kalrez®.

Flat gaskets are less common in modern pump designs; however, they are used when maintaining clearances within the pump design is critical. As with O-rings, they can also be constructed of an elastomeric compound, but it is also common to see them made from such materials as paper or PTFE (Teflon®).

Aseptic Modifications

Sterile fluids require systems that are capable of being steamed-in-place (SIP). To minimize downtime and preserve the integrity of the sterile atmosphere within the pumping system, pumps can be modified so they can be fully steamed-in-place. Most pumps can be steamed-in-place if they are designed in accordance with 3A standards. These standards, as mentioned earlier, will specify proper surface finish, impeller, and seal design. Further, the pump must utilize a seal that will allow for full steam penetration under pressure. Because proper steam flow is required to maintain saturated steam within the pump being sterilized, steam flow is enhanced in pumps by providing a means of condensate removal. As steam sterilizing the pump cools, it will form condensate. For proper sterilization to occur, this condensate must be removed from the pump quickly, preventing cold spots from forming. Hence, there is often the need for the pump to be self-draining by adding a tangential bottom drain.

Water-for-Injection Modifications (Centrifugal Pumps)

The design of centrifugal pumps make them very well suited to the application of pumping sterile water for injection (WFI). Because WFI must be kept moving at high temperature and high velocity within a piping system, a standard sanitary centrifugal pump can be modified to handle this application. The first modification is to the surface finish and materials of construction. The pump should be constructed of AISI Type 316L stainless steel that has been finished so that the surface roughness measures approximately 15 Ra. Second, all elastomeric components of the pump should be selected to be compatible with the WFI. This requires matching compatibility for temperature. Typical materials include steam resistant Viton® or EPDM. The third measure is the correct configuration of the mechanical seal to be used. This should be selected to reduce the chances of contamination. The last typical modification includes the addition of a casing drain to promote the removal of condensate during the steam sterilization of the WFI pump.

TROUBLESHOOTING

There is a general theme in successful troubleshooting. Specifically:

1. Make sure the system is fully understood (to eliminate oversights).
2. Narrow down or isolate potential sources of the problem.
3. Determine all possible causes within these areas.
4. In order of probability, go through them one by one.

The difficult step is often number 3, but all four hold potential hazards and solutions.

1. System analysis can be tedious. Fear of asking what appear to be obvious questions can tempt one to give this step short shrift. However, if problems began after a change in the system, system analysis will usually hold the answer. Walking through a typical flow pattern and questioning each step is often helpful. Keep in mind that flow at any division seeks equilibrium; flow will divide such that resistance to flow on one side given its gallonage will exactly equal the resistance to flow on the other side with the remainder of flow. Double checking that the pump in question will, in theory, meet the system conditions may be also be appropriate.

2. In many cases, narrowing down whether a problem is in the system or the pump can be affected by switching pumps in an installation containing one that is working well. If the problem follows the pump, it is in the pump; if it stays with the line, it is in the system. In other cases, noises can be isolated by separating various components of a system to determine if they continue or cease. The motor sometimes can be separated from the pump, for example, or suspect components temporarily removed. Valving can sometimes isolate pumps or piping sections to check the results.

3. There are usually more possible explanations for a problem than a typical manufacturers' lists provides. Following is a sampling of potential causes for a few specific complaints. Creativity is essential in this step, with nothing *ever* taken for granted. Often, a marginal explanation tentatively or casually offered up will be immediately recognized by an engineer and the problem solved.

4. There will always be possibilities (listed in the following section) that are more likely to occur than the others, depending on the symptoms. Of these, the most easily checked should be the first inspected, and then the more difficult. At times there are two simultaneous flaws in a system, making checking of individual items fruitless. In these cases, logic will be of more value than experiment.

Suggestions for a few common problems follow.

Low Flow

Centrifugal Pumps Only

1. Reverse rotation (*Note*: a centrifugal impeller flings the liquid as opposed to scoops it, if there is ever a question as to rotational arrows. A centrifugal pump will pump if turning in reverse, but with low flow and pressure and higher horsepower because of lowered efficiency).

2. More head than originally calculated.
3. Clogged impeller.
4. Wrong impeller diameter for conditions.
5. Cavitation (see earlier section).
6. Impeller clearances worn too large.
7. Motor speed slower than nameplate indicates.
8. Impeller spins loosely on shaft.
9. Broken coupling.
10. Viscosity has increased.
11. Vortexing in source tank.
12. Air in tank introduced from splashing or churning close enough to tank outlet to allow air to enter with stream.
13. Wrong pump for conditions.
14. If pump is above source tank, air leak in suction pipe.

Positive Displacement Pumps Only

1. Excess wear on components.
2. Stuck internal check valves, if any.
3. Torn diaphragms, if present.
4. Stuck internal (or external) pressure relief valve.
5. Speed too slow.
6. Cavitation (see preceding section).
7. Wrong pump for conditions.
8. If belt driven, a slipping belt.
9. Broken coupling.
10. Speed not slow enough for viscosity, leading to cavitation.
11. If pump is above source, air leak in inlet pipe.

Cavitation

Note: Cavitation is indicated by crackling noise for centrifugal pumps, by banging for most PD pumps, or by finding that TDH has fallen at least 3% below the standard curve for the particular centrifugal pump.

1. Blocked inlet.
2. Too much friction loss in suction line.
3. Elbow too close to pump suction port (*Note*: The rule-of-thumb is that the elbow should be located no closer than 6 × the suction port diameter).
4. For centrifugal pumps only, running at extreme left end of the curve causing low pressure areas to develop.
5. Suction line with high spot (as opposed to continually rising), therefore, air trap to disturb or restrict flow.
6. Liquid too hot and therefore vapor pressure too high.
7. Elevation differential too great (too much lift).
8. If drawing from closed tank, vacuum level too high, or vacuum level that builds to an unacceptable point as liquid is pumped out.
9. Excess prerotation at inlet of centrifugal, causing flow to enter in wrong pattern for design (*Note*: Rotation against impeller rotation is a positive factor and will move the curve upward, but the more common prerotation in the same direction as the impeller is harmful and may drop the curve).

Motor Overheats

Centrifugal Pumps Only.

1. Too much flow; therefore, further out on curve than calculated.
2. Wrong rotation.
3. Oversized impeller.
4. Unbalanced impeller.

Positive Displacement Pumps Only.

1. Too much backpressure.
2. Binding or rubbing components.
3. In case of progressive cavity, flexible impeller, or other pump with rubbing components, insufficient motor starting torque to get up to full speed

Any Pumps

1. Voltage above ±10% allowed by manufacturers.
2. Frequency beyond ±5% allowed by manufacturers.
3. Bad motor bearing(s).
4. Three-phase motor not getting power to all three lines (single phasing).
5. Cavitation.
6. Misaligned motor/pump shaft, or misaligned pulleys.
7. Undersized cable to motor.
8. Loose connection at motor outlet box or control box.
9. Insulation has broken down through time and use.
10. Cable too long to handle amperage.
11. Ambient temperature too high.
12. Overgreased bearings, causing binding when bearings heat up.
13. On TEFC design, broken or slipping fan.
14. Speed too high for pump.
15. Not enough air movement to keep motor cool because of confined or poorly vented area.
16. If single phase motor, starting windings do not disengage.
17. Viscosity higher than calculated.
18. Pipe torque, causing misalignment and binding.
19. Motor stops and starts too often (consult manufacturer for maximum stops and starts for applicable horsepower, it is probably lower than you think!).
20. Dirty surfaces not allowing efficient cooling.
21. On drip-proof design, internal diffuser or fans not channeling air flow properly.

Noise

Note: Various designs have various degrees of noise considered standard and acceptable. The manufacturer will be able to supply the numbers if given operating conditions.

1. Motor or pump bearings worn.
2. Cavitation.
3. If a PD pump, components hitting or rubbing.
4. If rigidly piped, amplification of what might be considered normal noise through lines into abnormal amounts.
5. If mounted on channel steel base, amplification of noise from pocket of air beneath motor/pump package.
6. Coupling hitting coupling guard.
7. Motor fan hitting fan cover guard.
8. Check valves chattering as they stick.
9. Water hammer (valves must close slowly enough for momentum in line to be absorbed). A rough rule of thumb is $t = 2L/a$, where t = time in seconds for valve to close (minimum); L = length of pipe via longest route, in feet; a = speed of pressure wave in feet/second (an average for water is 4,000 ft/s). An example would be a 200-ft length of pipe handling water, which would demand a valve closing in no less than $2 \times 200/4{,}000 = 0.1$ s to avoid water hammer.

Abnormal Seal Wear

Note: A mechanical seal in a continuous-duty, clean application can be expected to last several years, as a minimum, to as many as 10 years or longer if under absolutely ideal conditions.

Seat Fracture

1. Thermal shock from dry running followed by sudden introduction of cooler liquid, or any sudden drastic change in the temperature or the liquid. Usually appears as a hairline fracture.
2. Seal head installed incorrectly, causing the head to strike the seat.
3. Physical shock from a blow such as being dropped.
4. Water hammer.
5. Pipe misalignment, twisting the bracket holding the seat.

Carbon Washers Wear Prematurely

1. Abrasives (clearly visible by scored faces).
2. Chemical incompatibility between the chemical and either the washer itself, or the binder holding the carbon together.
3. Improper installation, usually with the seal head cocked.

Elastomer Problems

1. Chemical incompatibility. Elastomer may become brittle, softened, swollen, or even totally eaten away.
2. Dry running. Elastomer may look burned or cracked or become brittle and hard.

OUTLINE

INTRODUCTION

Much work has been done on the development of producers of useful metabolites. Metabolic engineering has enabled more scientific and strategic breeding than the conventional method based on mutagenesis followed by selection. In general, the targets for breeding are biosynthetic pathways of the metabolites, and the best example is the metabolic regulatory fermentation of various kinds of amino acids. In contrast, few studies consider energy metabolism as the target of breeding. However, it seems that manipulation of energy metabolism opens up a new dimension in breeding, because the energy status of the cell deeply concerns both regulation of energy production and biosynthesis and assembly of cell materials, although it does not necessarily directly affect the biosynthetic pathways of the desired metabolites. In this article, the development of producers of useful metabolites by the manipulation of energy metabolism is described with special emphasis on our work, which is improvement of the pyruvic acid productivity of a pyruvic acid–producing mutant of *Escherichia coli* K-12 by a defect in F_1-ATPase activity.

ENHANCEMENT OF CENTRAL METABOLISM BY A DEFECT IN THE ACTIVITY OF F_1F_0-ATP SYNTHASE

This section mainly describes our work, which has demonstrated both the enhancement of glucose metabolism and the improvement of pyruvic acid productivity by the introduction of a defect in an energy-producing reaction in an *E. coli* strain.

Improvement of Pyruvic Acid Production by Strain TBLA-1, an F_1-ATPase-Defective Mutant of *E. coli* W1485*lip2*

For the development of producers of useful metabolites, it seems important to consider points both upstream and downstream of the metabolic flow as well as the biosynthetic pathway itself, such as increases in the supply of precursor metabolites that flow into the biosynthetic pathways and the efficient transport of substrates and metabolites across the membranes. Under these concepts, we have focused on the improvement of fermentative production by enhancement of the glycolytic pathway. That is, it was expected that the enhancement of the glycolytic pathway would lead to the improvement of producers through smooth assimilation of substrate carbohydrates.

As a model system to assess this idea, we have established pyruvic acid production by *E. coli* W1485*lip2* (ATCC 25645) (1), a lipoic acid auxotroph of *E. coli* K-12 (2). This system was employed for several reasons. First of all, it was expected that the effect of enhancement of the glycolytic pathway would be obvious because pyruvate is the end product of glycolysis. Second, *E. coli* strain K-12 is suitable for characterization because much information about its genetics and physiology is available. Strain W1485*lip2* requires lipoic acid for its growth and produces a large amount of pyruvic acid in cultures in which lipoic acid is limiting, where the activity of the pyruvate dehydrogenase complex becomes almost negligible (1).

Then, how can we enhance the glycolytic pathway? Much work has revealed that flow in the glycolytic pathway is enhanced by a decrease in the energy level of the cell. That is, under those conditions, phosphofructokinase (PFK) I, one of the isozymes of *E. coli* PFK, and pyruvate kinase (PYK) II, one of the isozymes of *E. coli* PYK, have been shown to be activated by ADP and AMP, respectively (3,4). Therefore, decrease in the energy level of the cell seemed to be effective for enhancement of the glycolytic pathway. To decrease the energy level, it seemed appropriate to impair the generation of ATP through oxidative phosphorylation. For these reasons, we have introduced a defective gene of the α-subunit of F_1-ATPase, *atpA401* (5), into the strain W1485*lip2* by transduction, and obtained an F_1-ATPase-defective mutant, TBLA-1 (6). Both strains

were cultured aerobically in the pyruvic acid production medium, Medium 7 (6), containing 50 g/L of glucose, using jar fermentors with pH controlled at 6.0. As shown in Figure 1, strain TBLA-1 was found to produce pyruvic acid much more effectively than the parental strain in spite of some decreases both in growth rate and in growth level (6). That is, the parental strain, W1485*lip2*, consumed 50 g/L of glucose and produced 25.5 g/L of pyruvic acid after culture for 32 h; under the same conditions, strain TBLA-1 consumed glucose and produced more than 30 g/L of pyruvic acid after culture for 24 h.

Table 1 shows F_1-ATPase activities, fermentation data, and fermentation parameters of various strains. The fermentation data were obtained after culture for 16 h, at which time maximum growth was attained in the strains listed. As seen in Table 1, the level of growth in strain TBLA-1 decreased to 67% of the parental strain because of impairment of oxidative phosphorylation. However, in strain TBLA-1, both the amount of glucose consumed per cell ([B]/[A] in Table 1) and the amount of pyruvic acid produced per cell ([C]/[A] in Table 1) increased by factors of 1.9 and 2.8, respectively, compared with strain W1485*lip2* (6). In strain TBLA-1, the conversion yield of pyruvic acid from consumed glucose ([C]/[B] in Table 1) also increased by a factor of about 1.5 (6). Furthermore, as all of these changes have not been observed in a revertant from strain TBLA-1 (no. 63-1) having a normal level of F_1-ATPase activity (Table 1), it was concluded that the enhancement of pyruvic acid productivity was brought about by the defect in F_1-ATPase activity (6).

Table 1. F_1-ATPase Activities and Fermentation Profiles of Various Strains

Strain	W1485*lip2*	TBLA-1	No. 63-1
F_1-ATPase activity[a]	6.3	0.09	5.7
Growth (A_{590}) (A)	8.5	5.7	7.2
Glucose consumed (g/L) (B)	32.1	40.4	35.6
Pyruvic acid produced (g/L) (C)	13.5	25.9	14.8
(B)/(A)	3.8	7.1	4.9
(C)/(A)	1.6	4.5	2.1
(C)/(B)	0.42	0.64	0.42

[a] μmol min^{-1} mg protein^{-1}.

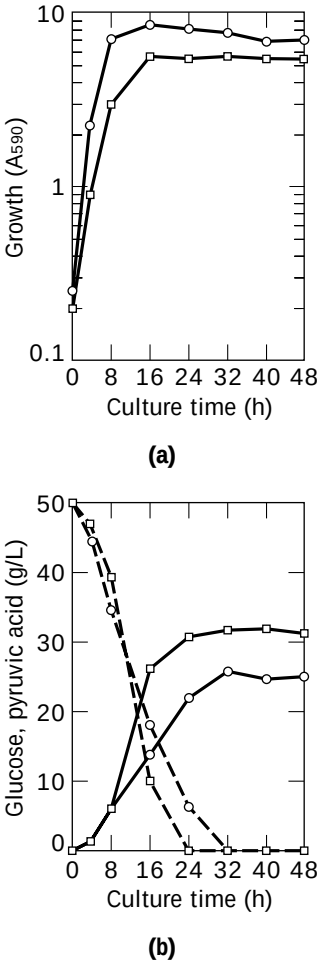

Figure 1. Time courses of pyruvic acid production by strains W1485*lip2* and TBLA-1 (6) showing data for growth (**a**) and pyruvic acid production (**b**). In **b**, *dashed lines* indicate glucose consumption and *solid lines* indicate pyruvic acid production. ○, strain W1485*lip2*; □, strain TBLA-1.

These results seem to be the first example of the application of a mutant defective in energy metabolism in the field of biotechnology. Although we have not optimized culture conditions for pyruvic acid production, the productivity of pyruvic acid in strain TBLA-1 in terms of grams of pyruvic acid produced per liter per hour is quite efficient among the pyruvic acid producers so far reported (7,8). The highest accumulation of pyruvic acid has been reported for the wild-type *Torulopsis glabrata* IFO 0005 (8), which requires nicotinic acid, thiamine, pyridoxine, and biotin for its growth. This yeast strain is capable of producing 57 g/L of pyruvic acid from 100 g/L of glucose in 59-h culture. The commercial importance of pyruvic acid includes its use as a starting material for the synthesis of many drugs and agrochemicals. Especially, pyruvic acid has been used as one of the substrates for the enzymatic production of L-dihydroxyphenylalanine (L-DOPA).

Enhancement of Glucose Metabolism in Strain TBLA-1

In the course of these studies, Jensen and Michelsen (9) reported the physiological characteristics of *E. coli* mutants having deletions in the *atp* operon coding for H^+-ATPase. In the mutants, they demonstrated increases in the oxygen consumption rate and in the level of *b*-type cytochromes by factors of 1.4 and 1.8, respectively, compared with the wild-type strain. It was also found in the *atp* mutant that the flow through the glycolytic pathway increased, and twice as much acetate was produced as a main by-product from consumed glucose. The increased oxygen consumption rate in the *atp* mutants is considered to contribute to the enhanced operation of the glycolytic pathway and to enhanced ATP production by substrate-level phosphorylation through the smooth reoxidation by the electron transport chain of NADH generated from the glycolytic pathway. Also, increase in the content of *b*-type cytochromes seems to contribute to enhanced respiration.

In the cells of strain TBLA-1 growing in pyruvic acid–producing medium, oxygen consumption rates (Fig. 2a), and the content of *b*-type cytochromes were also found to increase by factors of 1.7 and 1.4, respectively, compared with strain W1485*lip2* (10). These changes suggested increases in the amount of some components of the respiratory chain.

In the *E. coli* respiratory chain, two types of NADH dehydrogenases, designated NDH-1 and NDH-2, have been found (11). The expression of the *nuo* operon coding for NDH-1 has been shown to be repressed anaerobically by ArcA, a gene product from *arcA* (*arc* for aerobic respiration control) (12). NDH-2 is specified by the *ndh* gene. The expression of this gene is subject to *fnr* (fumarate nitrate reduction) gene product (Fnr) -mediated anaerobic repression (13). Thus, these two dehydrogenase genes are expressed aerobically and repressed anaerobically. Two types of terminal oxidases, Cyt *o* and Cyt *d*, are known in *E. coli* (14); the former is coded by the *cyo* operon and the latter by the *cyd* operon. The *cyo* operon is expressed aerobically and is repressed anaerobically by both ArcA and Fnr (15,16). On the other hand, the expression of the *cyd* operon has been shown to be regulated by both ArcA and Fnr in such a way that the expression is maximum under microaerobic conditions (15,17,18). To clarify the mechanism(s) for the enhanced respiratory activities observed in strain TBLA-1, it seemed necessary to measure and compare the amounts of the NADH dehydrogenases and terminal oxidases of strains TBLA-1 and W1485*lip2*. This kind of approach might allow us to consider how the energy status of the cells can affect the activities of the oxygen-responding regulators ArcA and Fnr.

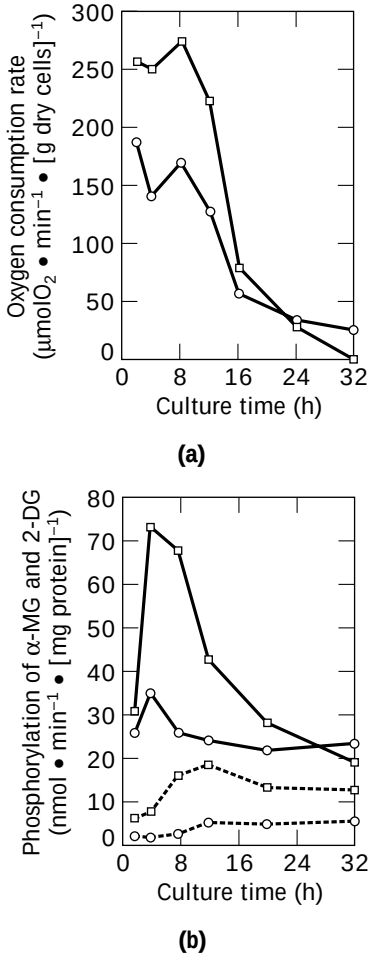

Figure 2. Oxygen consumption rates (**a**) and phosphotransferase (PTS) activities (**b**) of strains W1485*lip2* and TBLA-1 during pyruvic acid production (10) were measured using the cells harvested from the cultures for pyruvic acid production presented in Figure 1. In **b**, *solid lines* and *dashed lines* indicate PEP-dependent phosphorylation of methyl α-D-glucopyranoside (α-MG) and 2-deoxy-D-glucose (2-DG), respectively. ○, strain W1485*lip2*; □, strain TBLA-1.

To elucidate the enhancement of glucose consumption in strain TBLA-1, activities of the phosphotransferase system (PTS) for glucose uptake were measured by phosphoenolpyruvate (PEP) dependent phosphorylation of methyl α-D-glucopyranoside and 2-deoxy-D-glucose using the toluenized cells. We found that these activities were higher in strain TBLA-1 than in strain W1485*lip2* (Fig. 2b) (10). These changes were considered to be important explanations for the higher activities of glucose consumption per cell in strain TBLA-1. PTS not only catalyzes the formation of glucose-6-phosphate on uptake of glucose but also catalyzes the conversion of PEP to pyruvate, seemingly the same reaction as that of pyruvate kinase. Therefore, increase in the activity of PTS found in strain TBLA-1 is considered to be equivalent to the enhancement of glycolysis. Enhancement of glucose consumption has been reported in some *atp* mutants (9,19). However, PTS activities of these mutants under glycolytic conditions have not yet been reported. Therefore, our results are the first implication of the importance of PTS activities in the regulation of glycolysis in *atp* mutants. Furthermore, the increase in PTS activity is considered to lead to increased yield of pyruvate from consumed glucose in strain TBLA-1 because PEP is converted to pyruvate much more effectively with the increased operation of PTS. Rohwer et al. (20) studied PTS activities of a strain of *E. coli* K-12 growing on succinate by measuring initial uptake rates of methyl α-D-glucopyranoside. They found that the uptake rate of the strain decreased when the expression level of the *atp* operon decreased and suggested that the PTS activity decreases under energy-deficient conditions. Thus, it seems quite interesting to examine PTS activities of *atp* mutants in more detail under various culture conditions.

Measurements of the activities of all the glycolytic enzymes revealed that those of phosphoglycerate kinase and PYK-I were higher in strain TBLA-1 than in strain W1485*lip2* during the logarithmic growth phase by factors of about 1.5 at their maxima (10). These differences were considered to be not so distinct as those found in PTS activities. Moreover, so far as the activities of PYK-I were concerned, differences were not observed after the culture had continued for 12 h. However, as these two enzymes are involved in substrate-level phosphorylation, increased activities of these enzymes seem to contribute to the supply of ATP required for the synthesis of cell materials during the logarithmic growth phase. Also, the increases seemed to contribute to increase in the rate of glucose consumption

per cell during the logarithmic growth phase in strain TBLA-1. Because activities of all the glycolytic enzymes were measured with crude enzymes that had been gel-filtered to eliminate low molecular weight materials, the increases in these enzyme activities were not related to activation by low molecular weight ligands such as ADP and AMP.

These interesting changes found so far in strain TBLA-1 are summarized in Figure 3 (21). It became apparent that various kinds of changes that seem to compensate for energy shortage take place in strain TBLA-1, which is defective in F_1-ATPase activity. At present, it is not clear if these changes are indigenous to *atp* mutants. These points need to be investigated using continuous cultures in which the physiological state of each cell is homogeneous and well defined. Investigation of the mechanisms of these changes seems to be quite important and will shed light on the energy metabolism of *E. coli*.

Applicability of a Defect in F_1F_o-ATP Synthase Activity to Other Industrially Important Organisms

It seems interesting to consider whether the enhancement of glucose metabolism and the concomitant improvement of the productivity of a metabolite by the introduction of a gene defective for F_1-ATPase observed in *E. coli* can be applicable to other industrially important microorganisms. To date, other than *E. coli*, physiological changes similar to that observed in *E. coli* mutants (6,9), the enhancement of glucose metabolism and increase in respiratory activity, have also been reported in *atp* mutants of *Bacillus subtilis* (19). It was also demonstrated that the expression of genes coding for some of the respiratory enzymes has also been increased by disruption of the *atp* operon (19). From these observations, it seems that increases in the activities of both rate-limiting enzymes of the glycolytic pathway and respiration for the reoxidation of NADH generated via glycolysis are prerequisite for the enhancement of glucose metabolism. Here, for simplicity, let us consider the possibility of the enhancement of glucose metabolism only from the former aspect, increased activity of rate-limiting enzymes of the glycolytic pathway. Generally in bacteria, PFK and PYK, both of which catalyze the irreversible reactions in glycolysis, have been shown as the control points for the glycolytic flux. In many cases these enzymes are reported to be activated or inhibited allosterically by metabolites of the glycolytic pathway and by adenine nucleotides, and activation is normally observed in response to decrease in the energy level of the cell. Thus, it is expected that a defect in the activity of F_1F_o-ATP synthase lowers the energy level of the cell, thereby leading to the enhancement of glycolysis from the activation of PFK or PYK under those conditions.

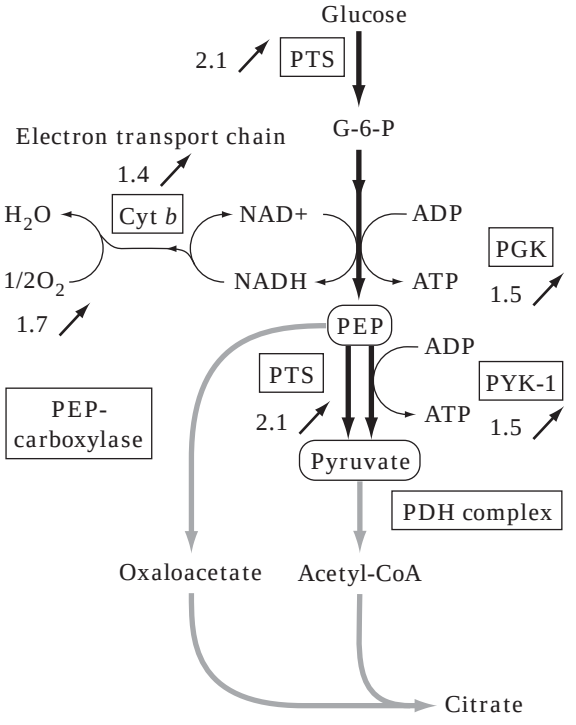

Figure 3. Changes in activities of glucose metabolism in strain TBLA-1 (from 21, with permission of Japan Society for Bioscience, Biotechnology, and Agrochemistry). Each number with an *arrow* shows an increase of the indicated reaction compared with strain W1485*lip2*. The increase for PTS is the average value for PEP-dependent phosphorylation of α-methylglucoside after culture for 4–12 h (Fig. 2b). The increase for oxygen consumption rate is also the average value for 4 to 12 h in Figure 2a. G-6-P, glucose-6-phosphate; Cyt b, b-type cytochromes; PDH, pyruvate dehydrogenase; PGK, phosphoglycerate kinase. Hatched lines indicate weak reactions.

Table 2 summarizes effectors for PFKs and PYKs from some of the industrially important bacteria. As reported (6,9,19), defects in F_1F_o-ATP synthase activity resulted in the enhancement of glucose metabolism in *E. coli* and in *B. subtilis*. Consistently, PFK-1 and PYK-2 of *E. coli* are activated by ADP and AMP, respectively (3,4). In strain TBLA-1 defective in F_1F_o-ATP synthase activity, an increase in the activity of PYK-1 that is different from allosteric activation by fructose-1,6-diphosphate (FDP) (22) was observed (10), suggesting synergistic effect for the increase of PYK activity under glycolysing conditions. On the other hand, the control point of glycolysis has not been established in *B. subtilis* (23). A PFK from *B. stearothermophilus* (24) and PYKs from *B. licheniformis* (25) and *B. stearothermophilus* (26) have been shown to be activated by AMP or ADP, suggesting the possibility of enhancement of glycolytic flux by a defect in F_1F_o-ATP synthase activity. In the case of glutamic acid–producing bacteria, *Brevibacterium flavum* no. 2247 (28,29) and *Corynebacterium glutamicum* (30), the control point for the regulation of glycolysis appeared to be the PYK reaction. A mutant of *B. flavum* no. 2247 defective in ATPase activity has already been isolated in our laboratory. In this mutant enhancement of glucose metabolism has also been observed as in the case of *E. coli* mutants (Yokota et al., unpublished data). Little information is available concerning the regulation of glycolysis in industrially important actinomycetes that produce antibiotics. Purification and characterization of PFK from *Streptomyces coelicolor* A3 (2) have been reported to indicate the enzyme as a regulatory step in the glycolytic pathway (31).

Table 2. Effectors for Phosphofructokinase (PFKs) and Pyruvate Kinase (PYKs) from Industrially Important Bacteria

Organisms	PFK	PYK	References
Escherichia coli K-12	PFK-I Cooperativity (Yes) ADP (+) PEP (−)	PYK-I Cooperativity (Yes) FDP (+) GTP (−) ATP + succinyl-CoA (−)	3,4,22
	PFK-II Cooperativity (No)	PYK-II Cooperativity (Yes) AMP (+)	
Bacillus subtilis 60015	ND	Cooperativity (Yes)	23
Bacillus licheniformis A-5	Cooperativity (No) PEP (−)	Cooperativity (Yes) ADP (+), AMP (+) ATP (−), Pi (−)	25,27
Bacillus stearothermophilus NCA1503 (ATCC7954)	Cooperativity (No) ADP (+) (+), GDP (+) PEP (−)	Cooperativity (Yes) AMP (+), GMP (+) R5P (+) Pi (−)	24,26
Brevibacterium flavum No. 2247 (ATCC14067)	Cooperativity (No)	Cooperativity (Yes) AMP (+) ATP (−), GTP (−)	28,29
Corynebacterium glutamicum M2	ND	Cooperativity (Yes) AMP (+) ATP (−)	30
Streptomyces coelicolor A3(2)	Cooperativity (No) PEP (−)	ND	31
Streptococcus lactis ML3	ND	Cooperativity (Yes) FDP (+) Pi (−)	32

Presence (Yes) or absence (No) of homotropic cooperativity (cooperativity) in the substrate saturation curve for fructose-6-phosphate in the case of PFK and for PEP in the case of PYK. (+), positive effector; (−), negative effector; ND, not determined; FDP, fructose-1,6-diphosphate; Pi, inorganic phosphate; R5P, ribose-5-phosphate; PEP, phosphoenolpyruvate.

The control point for the regulation of glycolytic flux in lactic acid bacteria has extensively been investigated using *Lactococcus* (formerly *Streptococcus*) *lactis* (32). In *L. lactis*, glycolytic flux appeared to be controlled in PYK that has FDP as an activator and inorganic phosphate as an inhibitor. In a glycolysing cell of *L. lactis*, a high intracellular concentration of FDP and a low intracellular concentration of inorganic phosphate have been reported (33), suggesting the presence of an already fully activated form of PYK in the cell. Moreover, in the case of lactic acid bacteria, F_1F_o-ATP synthase has been shown to work in the direction of pumping out protons on hydrolysis of ATP for keeping intracellular pH at neutral under acidic culture conditions. In fact, our work (34) showed that a mutant of *L. lactis* ssp. *lactis* C2 with reduced membrane-bound ATPase activity had almost the same productivity of lactic acid from glucose in a pH-controlled fermentor as that of the parental strain. Thus, glucose consumption per cell did not increase as a result of the mutation. On the other hand, the mutant showed higher acid sensitivity than that of the parental strain, indicating the importance of F_1F_o-ATP synthase in the pH homeostasis of the cell. In acidic culture conditions, higher transcriptional levels of the gene encoding the β-subunit of F_1F_o-ATP synthase and higher amounts of the β-subunit protein than those observed under neutral culture conditions were detected in both strains (35). In contrast, no increase in the transcriptional level of the *atp* operon encoding F_1F_o-ATP synthase was found in *E. coli* in response to acidic culture conditions (36), suggesting the difference of the function of F_1F_o-ATP synthase in different microorganisms. The industrial importance of the mutant defective in the activity of F_1F_o-ATP synthase in the prevention of postacidification of yogurt and fresh cheese has been proposed (34).

From all these examples, mutations in energy metabolism caused by defects in the activity of F_1F_o-ATP synthase are quite interesting for the breeding of industrially important microorganisms. Because of the pleiotropic nature of the mutation, the development of a novel type strain can be expected.

OVEREXPRESSION OF GENES OF ENZYMES INVOLVED IN THE FORMATION OF FUTILE CYCLES

Futile cycles are cyclic metabolic pathways that involve biosynthesis and degradation of certain metabolic intermediates with energy spilling. For example, the coexistence of PFK and fructose bisphosphatase and of PYK and PEP synthase forms futile cycles. The activities of these enzymes are under kinetic control by adenine nucleotides. That is, when the energy level of the cell decreases, glycolytic flow is enhanced, while under energy-sufficient conditions, gluconeogenetic flow is enhanced and thus both enzymes are not activated simultaneously.

Patnaik et al. (37) cloned the PEP synthase gene on a multicopy plasmid, and overexpressed it in *E. coli* K-12 to

form a futile cycle as shown in Figure 4. When the PEP synthase activity was overexpressed 15-fold, an increase in the oxygen consumption rate per cell was observed. Furthermore, an increase in the glucose consumption rate per cell and the excretion of pyruvate and acetate were observed when the activity was overexpressed 30-fold. Patnaik et al. inferred that the increase in PEP concentration due to the overexpression of PEP synthase gene caused the increase in PTS activity, resulting in the enhancement of glucose consumption rate. Similarly, Chao and Liao (38) overexpressed genes of PEP carboxylase and PEP carboxykinase simultaneously in *E. coli* K-12 to form a futile cycle (Fig. 4). Also in this case, with the incremental induction of both enzymes, an increase in the oxygen consumption rate per cell was first observed, and an increase in the glucose consumption rate per cell and excretion of pyruvate and acetate then followed. Chao and Liao concluded that the *arc* system had no relationship to the increase in the oxygen consumption rate.

These physiological changes caused by the overexpression of the genes of the enzymes involved in futile cycles resemble those observed in *atp* mutants (9,19). The operation of futile cycles causes waste of ATP. Therefore, these cells might be suffering from shortage of energy as in *atp* mutants. Although no information is available as to the changes in the activities of PTS and glycolytic enzymes in these cells, it seems interesting to use these futile cycles to improve the fermentative production of useful compounds through enhancement of glucose metabolism.

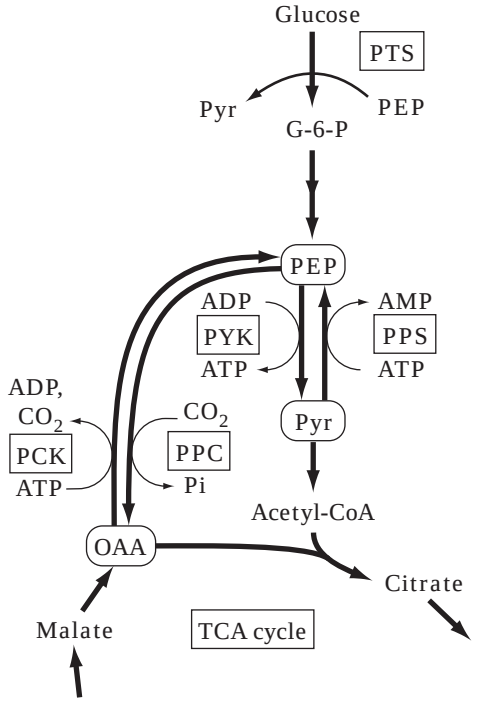

Figure 4. PEP pyruvate and PEP oxaloacetate futile cycles formed in *E. coli* K-12 (from 21, with permission of Japan Society for Bioscience, Biotechnology, and Agrochemistry). Pyr, pyruvate; OAA, oxaloacetate; PPS, PEP synthase; PPC, PEP carboxylase; PCK, PEP carboxykinase, G-6-P, glucose-6-phosphate.

IMPROVEMENT OF PRODUCTION OF USEFUL COMPOUNDS BY THE EXPRESSION OF THE HEMOGLOBIN GENE FROM *VITREOSCILLA*

Finally, in contrast to our concept, we discuss examples in which production of various kinds of useful compounds was improved by increased efficiency of energy production. Bacteria of the genus *Vitreoscilla* are Gram-negative chemoorganotrophs that move by gliding. They are aerobes and use molecular oxygen as the terminal electron acceptor when they live in hypoxic conditions. Under these conditions, a strain of *Vitreoscilla* was found to synthesize a kind of hemoprotein (*Vitreoscilla* hemoglobin, VHb) similar to that of the eukaryotic hemoglobin (39,40). VHb is considered to contribute to the growth of the organism under hypoxic conditions through enhanced diffusion of oxygen into the cytoplasm (41).

When the VHb gene containing its promoter region was introduced into *E. coli* K-12, active VHb protein was produced in response to the decrease in oxygen concentration in the culture medium, as in *Vitreoscilla* cells (42). The regulation of the gene expression was found to be at the transcription level (42). By expression of the VHb gene, various interesting physiological changes were observed in *E. coli* K-12 cells, including increases in growth rate, final growth level, and oxygen consumption rate per cell (43). Moreover, expression of the VHb gene improves various kinds of fermentative production under hypoxic conditions. For example, production of enzymes by *E. coli* (44,45) and by *B. subtilis* (46), production of actinorhodin by *Streptomyces coelicolor* (47), and production of cephalosporin C by *Acremonium chrysogenum* (48) were found to be improved. It should be noted that in contrast to *atp* mutants, enhancement of glucose consumption has not been observed in the *E. coli* K-12 strain expressing the VHb gene (44). Efficient production of these metabolites under hypoxic conditions has much merit in industrial-scale production using large fermentors in which the supply of oxygen frequently becomes a limiting factor.

Figure 5a shows an *E. coli* K-12 cell expressing the VHb gene. It has been assumed that VHb enhances diffusion of oxygen from periplasm to cytoplasm across the cell membrane by reversible association with free oxygen and increases the concentration of effective oxygen ([Oc] + [HbOc]) in the cytoplasm (41,49). In cells of *E. coli* K-12 expressing the VHb gene, a twofold increase in ATP content was found compared with cells without the VHb gene (49). In general, the main terminal oxidase of *E. coli* cells is believed to be Cyt *o* under aerobic conditions; in contrast, under oxygen-limited conditions Cyt *d* becomes the main oxidase. The cells exhibiting increased ATP production with expression of VHb gene were found to possess both types of cytochromes. It has been found that Cyt *d* dose not have proton-pumping activity, although it has a higher affinity to oxygen than Cyt *o*. On the other hand, Cyt *o* has been reported to have proton-pumping activity (50). Based on this information, it has been assumed that in cells without the VHb gene, Cyt *d* works as a main terminal oxidase owing to the low oxygen concentration in the cells (Fig. 5b), whereas in the cells expressing the VHb gene, Cyt *o* as well as Cyt *d* work under the conditions of increased effective

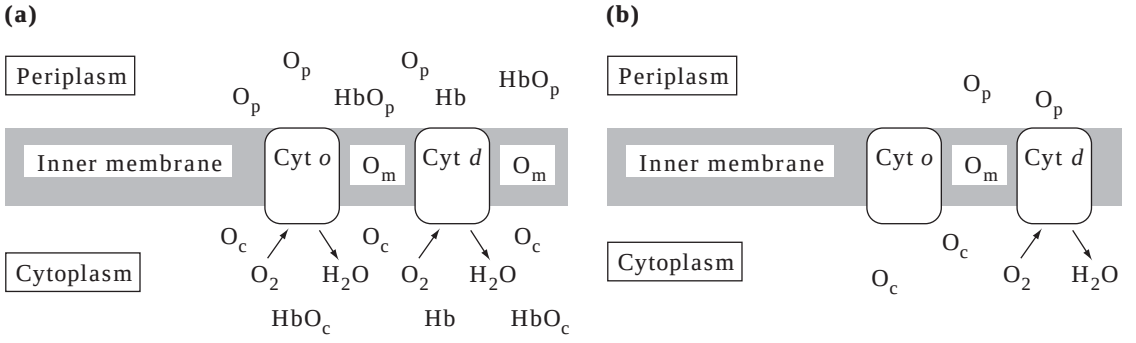

Figure 5. Effect of VHb gene expression on energy metabolism of *E. coli* K-12 (from 21, with permission of Japan Society for Bioscience, Biotechnology, and Agrochemistry). (**a**) Cells expressing VHb gene. (**b**) Cells without VHb gene. O, free oxygen (subscripts p, m, and c denote periplasm, inner membrane, and cytoplasm, respectively); Hb, deoxyhemoglobin; HbO, oxyhemoglobin.

oxygen in the cells (Fig. 5a). Therefore, in the latter case, ATP production by F_1F_o-ATP synthase would be enhanced under the hypoxic conditions caused by the increase in proton motive force. Under these conditions, various kinds of fermentative production would be improved through the enhancement of biosynthetic reactions (49).

CONCLUSIONS

In this article, we have described recent work on the energy metabolism and strain improvement with special emphasis on our work on pyruvic acid production by an *atp* mutant. Improvement of producers of useful metabolites by manipulation in energy metabolism provides not only a new direction in strain improvement but also provides useful information in the basic research of energy metabolism. From the work described, it can be concluded that defects of energy production from the *atp* mutation cause enhancement of glycolysis and thereby are suitable for the improvement of the production of primary metabolites such as pyruvate or amino acids, while the enhancement of energy production attained by the expression of the VHb gene seems to be favorable for the improvement of production of such products as protein and secondary metabolites, which require more energy for biosynthesis.

Reverse micelles

OUTLINE

REVERSE MICELLES

Reverse micelles are fine dispersions of water in organic solvent stabilized by a surfactant molecule. The main property of this system is the coexistence of two completely different microphases in an apparently macrohomogeneous solution. The nature of the surfactant molecules, known as amphiphiles, induces molecular organizates, among which reverse micelles are thermodynamically stable and are formed spontaneously. The solutions are optically isotropic because one solvent is finely dispersed into the other, forming microdroplets that have a diameter on the order of 100 Å.

Formation of Reverse Micelles

The formation of the reverse micelles depends on the relative concentrations of water, surfactant, and organic solvent and can be explained by the energy change caused by dipole–dipole interactions between the polar head groups of the surfactant molecule. This mechanism can be understood by taking into consideration the values of the interfacial tension between water and oil (the term *oil* refers to any hydrophobic solvent). This interfacial tension (with values varying from 30 to 60 dyn/cm) causes a reduction of the surface between the two solvents, which results in their separation. The addition of surfactants induces the formation of micelles because of the reduction of the interfacial tension down to very low values (10^{-5} dyn/cm). The amphiphilic nature of the surfactant molecule causes its self-association in solution. In a reverse micellar solution, the polar head of the surfactant is directed toward the aqueous core of the micelle, and the hydrophobic tail extends into the continuous organic phase (Fig. 1). Depending on the hydrophilic–lipophilic balance (HLB) of the surfactant (i.e, the rate of the weight percentage of hydrophilic groups to the weight percentage of hydrophobic groups in the surfactant molecule), the interface will curve spontaneously toward water or the oil phase, favoring the formation of water-in-oil or oil-in-water structures, respectively. Various types of surfactants have been used as amphiphiles to formulate reverse micellar systems, including natural membrane lipids and artificial surfactants. The most commonly used surfactants are the anionic AOT [bis(2-ethylhexyl) sodium sulfosuccinate]; the cationic CTAB (cetyltrimethyl ammonium bromide); various nonionic surfactants of the Brij, Triton and Tween series; and the zwitterionic biological membrane-forming phospholipids. They can be grouped in three main categories: anionic, cationic, and nonionic, depending on the nature of their polar moiety (Fig. 2).

Cationic micelles are very small ($[H_2O]/[\text{surfactant}] \leq 3$). To increase the micelle size, and thus the amount of water solubilized, a cosurfactant is included in the system, usually an aliphatic alcohol, the cosurfactant being partitionated between the interface and the apolar phase. Anionic surfactants form micellar aggregates of large size ($[H_2O]/[\text{surfactant}] \leq 60$). There is a surfactant concentration under which the reversed micelle formation does not occur the critical micellar concentration (CMC). The CMC depends on the chemical structure of the surfactant, solvent, temperature, and pressure.

The solubilization properties of surfactants are often expressed by a three- or four-component phase diagram, af-

ter determination of regions of optical transparency. From these diagrams, it is easy to calculate the volume of each component and mix them by microinjection of the aqueous buffer solution into a stirred solution of surfactant dissolved in organic solvent in order to obtain a transparent solution. Figure 3 depicts the phase diagram of AOT/isooctane/water, showing the reverse micelles region.

Micelle Size and Structure

The size, shape, and solubilizing ability of the reverse micelles depend strongly on the nature of the amphiphile molecule. The structure of microemulsions has been studied using various techniques such as NMR, electron paramagnetic resonance (EPR), IR, fluorescence spectroscopy, chemical relaxation, and various scattering techniques such as dynamic light scattering, small-angle X-ray scattering, and small-angle neutron scattering.

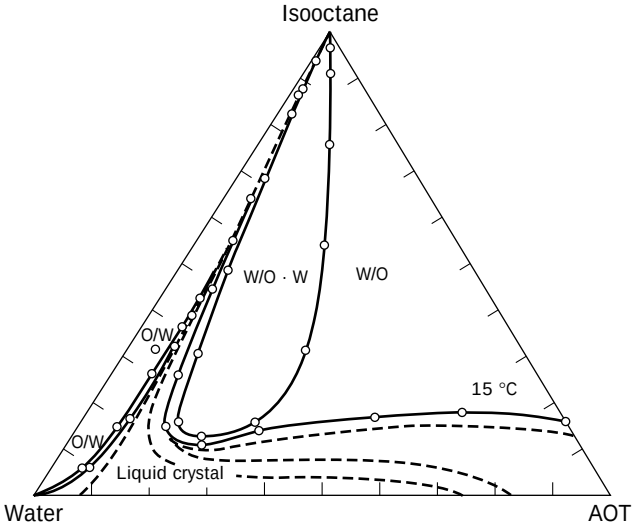

Figure 3. Phase diagram of AOT/isooctane/water, showing the reverse micelles region. O = oil; W = water.

In the majority of the works performed with reverse micelles in biological systems, sodium(bis-2-ethylhexyl)-sulfosuccinate (Aerosol-OT or AOT) has been used as surfactant. This anionic surfactant has the ability to form reverse micelles in a great number of hydrophobic solvents (oils), incorporating considerable amounts of water. The water pools that are formed can have radii from 15 to >100 æ, allowing the solubilization of hydrophilic biomolecules of various sizes.

The structure of the AOT reverse micelles strongly depends on the amount of incorporated water. The water content can be expressed by the molar ratio w_0, with $w_0 = [H_2O]/[AOT]$, reflecting the sizes of the reverse micelles. Many experimental studies using scattering techniques have shown the existence of empirical relations between w_0 and the radius of the reverse micelles (whole microdroplet), for example, $r(nm) = 1.5 + 0.175\ w_0$ (1). Also, for a given w_0 value, the increase of the respective quantities of water and AOT lead to an increase of the number of micelles.

It has been well established from various structural studies that the AOT reverse micelles are spheres formed by a monolayer of AOT molecules surrounding a water core. The water molecules that are located in the close vicinity of the AOT membrane are quite immobilized and possess different properties as compared to bulk water. This is because these water molecules serve to hydrate the polar heads of the surfactant. On the contrary, the water molecules that are situated in the center of the sphere have almost the same properties as bulk water. By increasing

w_0, that is, increasing the amount of water, the overall behavior of the water phase tends to that of normal water.

In general, the physical characteristics of the water in the reverse micelles strongly depends on the value of w_0 and on the nature of the surfactant, and the presence of these differently organized water molecules can be categorized in three different domains in every type of reverse micellar system: *free water*, whose properties and structure become closer to those of bulk water as w_0 increases; *bound water*, whose properties are qualitatively different than those of bulk water because of hydrophilic interactions with the polar head groups of the surfactant; and *surfactant tails*, which penetrate the apolar solvent. When the amount of water is not sufficient to hydrate the surfactant molecules, there is not free water and reverse micelles have only two domains: bound water and surfactant.

Reverse Micelles Dynamics

Reverse micelles are not rigid, impenetrable spheres; they are dynamic entities. In addition to the normal Brownian motions, a number of relaxation processes characterize the monomer, that is, the individual surfactant molecules participating in the micellar aggregate and the water molecules. In contrast to micelles formed in the aqueous solution, the reverse micelles are electrically neutral in their exterior shell, so that no Coulombic repulsions occur, and collisions are frequent. The collision of reverse micelles can be predicted from simple diffusion theory to be on the order of nanoseconds. Not all collisions result in mixing of the aqueous pool. When micelles collide with each other, they may build a transient dimer with a communication channel, which permits the exchange of materials.

Exchange of the contents of reverse micelles is believed to occur by means of a collision–fusion–fission process. The characteristic time for exchange of solubilizates between water pools in AOT reverse micelles has been found to be 10^{-4} to 10^{-6} seconds. The exchange is a function of droplet size and temperature, decreasing with increasing droplet size at a given temperature, and increasing with increasing temperature at a given w_0. The rate of exchange for reverse micelles stabilized by the surfactant alkylarylsulfonate is much slower, of the order of hours, whereas that of CTAB reverse micelles is on the order of microseconds.

pH and Effect of the Ionic Strength in the Reverse Micelles

The pH of the solubilized water in reverse micelles can differ form that of the bulk water, as a consequence of the high concentration of its electric charges caused by the ionization of the polar head groups of the surfactant molecule. For example, in an anionic surfactant reverse micellar system, a decrease the apparent pH of the water within the reverse micelles is observed, and this difference is larger for low w_0.

In studies concerning the role of salts, when salts are present in the aqueous pool of the micelles, it has been found that the ionic strength, the type of salt, and the type of buffer used can affect the size as well as the shape of the reversed micelles.

These two factors, pH and ionic strength, are of particular importance for the encapsulation of enzymes inside reverse micelles in their application in biocatalysis and liquid–liquid extraction of proteins.

ENZYMES, IN REVERSE MICELLES

Enzymes represent novel routes to a number of important products, ranging from β-blockers to synthetic cocoa butter (2). Although they have outstanding catalytic properties, including regioselectivity, stereoselectivity, and enantioselectivity, which can be applied for the preparation of compounds not available by chemical means, their use in organic synthesis is quite limited. The main reason is that most organic compounds of commercial interest are very sparingly soluble in aqueous media used in conventional enzymology. Water is a poor solvent for nearly all applications in industrial chemistry.

Biocatalysts—enzymes, microbial cells, and others—are traditionally applied to aqueous reaction systems, including water-soluble reactants. Since the recent development of biotechnology, much wider applications of biocatalysts have been demanded, for example, bioconversions of biological and xenobiotic compounds having lipophilic or hydrophobic characters. In such bioconversion reaction systems, it is indispensable to introduce organic solvents into the system to improve the poor solubility of the reactants in water. Furthermore, in an attempt to apply biocatalysts for the conversion of petrochemicals, the substrates and products are themselves organic solvents in such biochemical reactions.

The recent realization that enzymes can function also in organic solvents has given the synthetic potential of enzymes a powerful boost for many processes. Other uncommon biocatalysis media are supercritical gases such as CO_2(CO_2SF), liquid membranes, and reverse micelles. The activity and specificity of the enzymes in these uncommon environments are changed. The enantiomeric excesses are normally increased. Several substrates (e.g, lipophilic ones) are better soluble in these media and downstream processing is often easier. Various enzymes (such as alcohol dehydrogenase and esterases, to mention some of them), catalyzed asymmetric redox reactions, stereospecific transesterification, regioselective esterification of sugars, and others have been studied in nonaqueous systems.

Enzymes Inside Reverse Micelles

The use of reverse micelles to solubilize enzymes in organic solvents has attracted considerable interest in the past decade (3–5). A large variety of enzymes, including cofactor-dependent enzyme, have been successfully encapsulated in reverse micellar systems, retaining their catalytic activity. The enzyme molecules can be entrapped in the reverse micelles, avoiding direct contact with the organic medium, potentially limiting their denaturation. The interior of the reverse micelles acts like a microreactor that provides a favorable aqueous microenvironment for enzyme activity as well as an enormous interfacial area through which the conversion of hydrophobic substrates can be catalyzed. Increasing the interfacial area is of great technological interest since this results in the increase of the number of substrate molecules available to react.

When biomolecules such as enzymes are solubilized in reverse micelles, they can be localized in the different microcompartments, depending on their chemical structure or relative solubility in these microphases. The degree of hydrophobicity of the biomolecule plays an important role to the preferential localization among the various microenvironments (water core, bound water, surfactant membrane, and organic solvent). Hydrophilic enzymes are entrapped in the water core, whereas others with an amphiphilic character can be anchored to the surfactant layer, penetrating even in the continuous organic phase (Fig. 4). Recent studies relate the enzyme localization in the different domains of the reverse micelles with their selectivity for various substrates with a different degree of polarity. This hypothesis at least stands for lipase-catalyzed esterification reactions. In addition, this interaction between the enzyme molecule and the interface can explain the different enzyme behavior found in several cases with respect to bulk water.

Solubilization of Enzymes in Reverse Micelles. The most common technique used for the encapsulation of enzymes in the polar core of reverse micelles is the injection method. The protein already solubilized in a concentrated stock aqueous (or buffered) solution is added to the surfactant-containing organic solution upon stirring. With this method, the solubilization is almost instantaneous, and it is possible to control the amount of water present in the system. Another method is to contact the protein solution with the micellar solution upon stirring. Phase transfer will occur, depending on the charge of distribution of the enzyme, surfactant charge, and pH and ionic strength of the aqueous phase. With this method, the enzyme solubilization is slow, but a large amount can be solubilized with minimal values of w_0. A third way of introducing the enzyme is to add the dry enzyme into the empty reverse micelles while aggitating. This technique causes denaturation of the enzyme to a degree. The injection and dry addition methods are commonly used in biocatalytic applications, the latter being suited to hydrophobic proteins. The phase-transfer technique is the basis for extraction of proteins from aqueous solutions. In addition to the method of protein inclusion to the reverse-micelles, other variables that can influence protein solubilization are the size and isoelectric point of the protein, the size of the reverse micelles, the nature of the surfactant used, and the pH and ionic strength of the aqueous solution.

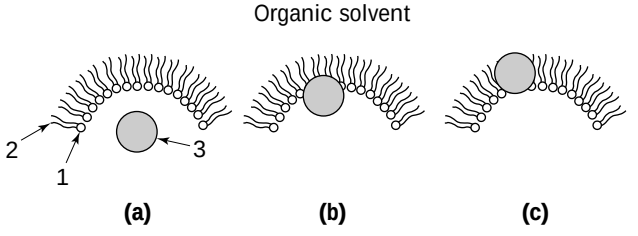

Figure 4. Enzyme localization in reverse micelles depending on the degree of hydrophobicity of the molecule. (**a**) Hydrophilic; (**b**) Amphiphilic, and (**c**) Hydrophobic enzyme. *1*, hydrophilic head of the surfactant; *2*, hydrophobic tail of the surfactant; and *3*, enzyme molecule.

Factors Affecting Enzyme Solubilization. For both the injection and phase contact methods, proteins with a net charge opposite to the surfactant charge and a low ionic strength will favor solubilization. As far as the size of protein molecule is concerned, their solubilization may occur even when the radius of the molecule is larger than the micellar polar core radius. The protein itself probably stabilizes the enlarged micelle, constructing a protective surfactant shell with a certain amount of water. Data support the possibility that there is not a definite maximal molecular size upon which encapsulation in surfactant aggregates does not occur.

The hydrophilic character of large proteins may have a significant role on the formation of reversed micelles. It seems that the hydrophilic proteins will favor the formation of surrounding surfactant shell. This fact could account for the solubilization of large entities, even when the total charge of the macromolecules is identical to the charge of the surfactant heads, thus excluding the formation of micelles via direct electrostatic interactions between the protein and the surfactant layer. This type of interaction within a micellar system can be particularly important for the phase transfer of proteins, applied to the liquid–liquid extraction of proteins and other molecules via reverse micelles. The various parameters affecting this process are discussed in more detail in the section on liquid–liquid extraction.

Enzyme Conformation in Reverse Micelles. Enzyme-containing reverse micellar solutions are optically clear. Thus, spectroscopic techniques, such as ultraviolet (UV), fluorescence, circular dichroism (CD), EPR, and NMR, are able to be used for monitoring the conformation changes that may occur in enzyme molecules upon their solubilization in reverse micelles. Moreover, in this system it possible to precisely control the range of water microenvironments (interfacial/bulk), the size of the micelles by varying the water/surfactant molar ratios, and the role of the chemical structure of the surfactant.

Generally, a more ordered structure has been identified by CD for myelin basic proteins (6) and poly(α-amino acids) (7) in AOT reverse micelles and trypsin and α-chymotrypsin in lecithin reverse micelles (8). UV spectra of enzymes in reverse micelles show little change from aqueous solutions. Fluorescence spectra in reverse micelles are red shifted for some enzymes and blue shifted for others (9,10). An increase in quantum yield has been observed with α-chymothrypsin (10), trypsin (11), pepsin (11), lysozyme (10), and a decrease in quantum yield has been observed for lactate dehydrogenase (12). ^{1}H-NMR studies of some peptides and small proteins show that met-encephalin became more folded, and pancreatic secretory trypsin inhibitor became highly flexible (13). Furthermore, EPR studies have been performed for investigation of structural changes to α-chymotrypsin (14), serum albumin (15), and cutinase (16) upon solubilization in reverse micelles.

The information derived by several studies shows that proteins can be categorized according to the perturbation

of their structure induced by reverse micelles: conformations that are not changed or only slightly changed after incorporation into reverse micelles; conformations that are altered in reverse micelles but unaffected by the amount of water present in the system; and conformations that are altered and that also change as a function of the water/surfactant molar ratio.

Biocatalysis in Reverse Micelles

The first report on enzymes retaining their catalytic activity in reverse micellar systems was in 1978 (2,17,18). Today the number of active enzymes described in reverse micelles has increased to more than 50, including hydrolases, dehydrogenases, and oxidases used in single or multienzyme catalyzed reactions. Enzymatic catalysis in microemulsions has been used for a variety of reactions, such as synthesis of esters, peptides and sugar acetals, transesterifications, various hydrolysis reactions, and steroid transformations. Several applications with potential interest for biotechnological conversions have been developed; some of them are summarized in Table 1.

Enzymatic reactions in reverse micelles are found to obey normal Michaelis-Menten kinetics, but some attention should be given to the way of expressing the kinetic constant K_m. K_m is the substrate concentration where the reaction rate is half the maximum rate. The substrate concentration in a reversed micellar system can be based on the total volume of the system or the water-pool volume of the micelles, but the latter is very difficult to measure. Other factors that have to be taken under consideration is the compartmentalization of the enzyme and substrates between the various microdomains of the reverse micelles and the degree of hydrophobicity of substrate, product, and enzyme molecule, which is related to its localization in the micelles. Several theoretical models have been developed to explain enzyme kinetics in reverse micelles. They are based on different assumptions, such as all droplets in the medium are equal, and there are not any changes in the enzymes kinetic parameters (K_m and V_{max}) during their entrapment in the reverse micelles (the diffusional models). The nondiffusional models are based on the fact that the differences in the kinetic constants with respect to bulk water are caused by conformational changes produced in the reverse micellar microenvironment. Another important parameter obtained from Michaelis-Menten kinetics is the K_{cat}, the turnover number, which is related to maximum reaction velocity. Because K_{cat} is concentration independent, its determination is more straightforward. Turnover numbers for enzymes in reverse micelles are usually dependent on the amount of water present in the system, which is expressed by the molar water-to-surfactant ratio, w_0. This dependence is often a bell-shaped curve, explained by the existence of an optimal inner cavity for catalytic activity, which corresponds to the size of the enzyme. Maximum K_{cat} is sometimes higher than that in aqueous solutions, giving rise to the concept of superactivity (31). This effect can be explained by a greater reactivity of the structured water in the micelle, increased rigidity of the enzyme (32), and enhanced substrate concentration at the enzyme surface (33). Thus, the first parameter that should be considered when studying the enzyme activity in reverse micelles is the amount of the water in the system (w_0). The electric properties of the substrate and surfactant can often have a marked effect on the K_m and K_{cat} constants. When the charges of substrate and surfactant are the same, the differences of K_{cat} and K_m values with those found in water are not significant, but when the charges are different, partition effects are usually observed because of the increase of the substrate concentration near the vicinity of the surfactant layer, hampering their access to the enzyme, which is surrounded by water. α-Chymotrypsin and trypsin encapsulated in AOT and CTAB show a decrease in the second-order rate constant (K_{cat}/K_m). The specificity of the enzymes can also be altered because of the distribution of the substrate between the system phases or interactions with the surfactant layer. An example is the oxidation of aliphatic primary alcohols, catalyzed by alcohol dehydrogenase encapsulated in an AOT/octane system (24). In the reverse micellar system, octanol ($n = 8$) is the optimum substrate, whereas in water the preferred substrate is butanol ($n = 4$) (17). It is profound that these parameters are more accurately determined using the active enzyme concentration, which can be obtained typically by active site titration, for example, based on fluorescence techniques for the active site titration of α-chymotrypsin and lactate dehydrogenase (1). Another parameter to take into account is the pH. When the enzyme is entrapped in reverse micelles, significant shifts of the pH profile usually occur, because of the heterogeneous dis-

Table 1. Examples of Bioconversions in Reversed Micellar Systems

Type of reaction	Enzyme	Reverse micelles
Reduction of decanal	Alcohol dehydrogenase	AOT/isooctane (19)
Polymer synthesis	Horseradish peroxidase	AOT/isooctane (20)
Reduction of ketosteroids	Alcohol dehydrogenase	AOT/isooctane (21)
Oxidation of polyunsaturated fatty acids, linoleic acid	Lipoxidase	AOT/isooctane (22)
Cholesterol oxidation	Cholesterol oxidase	CTAB/octanol/octa ne (23)
Oxidation of aliphatic alcohols	Alcohol dehydrogenase	AOT/octane (24)
Peptide synthesis	α-Chymotrypsin	AOT/isooctane (25)
Hydrolysis of olive oil	Lipase	AOT/isooctane (26)
Inter- and *trans*-esterification	Lipase	AOT/isooctane (27)
Bioluminescent assay	Luciferase	Brij-96/octane (28)
Fatty acid esterification with alcohols	Lipase	AOT/isooctane (29)
Polyol–fatty acid esters	Lipase	AOT/isooctane (30)

tribution of protons inside the polar core of the micelle. Larger shifts of optimal pH occur for small values of w_0. The shifts reported in literature for systems with anionic surfactants are of one to two unities (3).

Lipases in Reverse Micelles

A particular case of enzymatic studies in microemulsions is that of lipases (34). Among the enzymes so far investigated, lipase is one of the most advantageous because it is stable, inexpensive, and widely used in the development of various applications in the detergents, oils and fats, dairy, and pharmaceutical industries. In addition to hydrolysis of triglycerides to glycerol and free fatty acids, lipases can be used in esterification and transesterification reactions in low-water content media. This catalytic process is heterogeneous and can be favored by the use of microemulsion. Lipases are active almost exclusively near interfaces in a classical heterogeneous procedure. There are various reports in the literature concerning studies on the hydrolytic and synthetic action of lipases in different types of microemulsions. Table 2 lists examples of the studies performed so far with lipases from various sources in water-in-oil microemulsions.

Hydrolytic Reactions. Lipase catalyzes the hydrolysis of long-chain aliphatic esters to glycerol and free fatty acids. Several hydrolytic reactions performed by lipases in microemulsion systems have been reported, such as the hydrolysis of triolein and tributyrin by pancreatic lipase in an AOT/octane microemulsion system (35). The same system has been used for the hydrolysis of palm kernel olein by *Rhizopus arrhizus* lipase (36). Hydrolysis of triolein and tributyrin has been reported with the use of *Rhizopus delemar* lipase in AOT/isooctane, CTAB/isooctane, and $C_{12}E_4$/decane systems (37–41). Olive oil hydrolysis by *Candida rugosa* lipase and glycerolysis of triolein by *Chromobacterium viscosum* lipase in AOT microemulsion systems have been performed (42,43). A bioreactor system has been designed that is suitable for continuous glycerolysis of fats and oils, using liposomes as a matrix for adsorbing enzyme and AOT reverse micellar systems, and as a supplier of interfacial area for glycerolysis (45). Palm oil and trimyristine hydrolysis by *Rhizopus* sp. lipases for the production of monoglycerides and diglycerides with a good yield has been also reported in AOT and $C_{12}E_3$ based systems (40,41).

Penicillium simplicissimum	AOT/isooctane (50)

Several parameters play an important role in lipase-catalyzed hydrolytic reactions in microemulsion systems. The reverse micellar structural characteristics, such as the size, shape, and solubilizing ability, which depend strongly on the nature of the polar moiety of the amphiphile used, strongly affect the enzyme activity. Anionic, cationic, and nonionic types of surfactants have been used in various hydrolytic reactions. Among the different systems studied, the anionic surfactants seem to be more suitable for the hydrolytic activity of lipase, as compared to the cationic ones, whereas nonionic systems do not seem adequate for this type of reaction.

Other important parameters affecting lipase activity that have been studied in detail by several groups are pH, temperature, water content (w_0), fatty acid chain length of the triglycerides used as substrates, and enzyme stability. In studies concerning the hydrolysis of triolein by *Rhizopus delemar* lipase, the pH optima were reported to be 6.5 in the anionic systems and 5.8 in the cationic systems, considering as pH values the values of the buffered enzyme solutions used for the preparation of the various microemulsion systems. The pH optimum for the same reaction performed in classic heterogeneous biphasic systems was found to be 5.6. This difference is obviously related to the fact that the pH values within the water-dispersed phase do not necessarily correspond to that in the bulk water. The difference observed between AOT and CTAB systems is possibly the result of the different amounts of bound water and the nature of the ions present in the water pools of each system. In the case of AOT systems, it has been reported that 8 to 10 water molecules are indispensable for hydrating each Na^+ and sulphonate group, whereas for CTAB, only 1 to 3 water molecules per Br^- and ammonium head are enough. In other studies on AOT-formulated microemulsion systems, a pH optimum of 7.1 was reported for lipase from *Candida rugosa* 7.0 for lipase from *Rhizopus* sp.; and a maximum in the range 6.0–7.5 for lipase from *Chromobacterium viscosum*. Temperature also plays an important role in lipase activity in microemulsions; in the case of anionic systems, the optimum temperature is reported to be 30 °C; in cationic systems, 22.5 °C. However, at temperatures lower than 15 °C and higher than 40 °C, the structure of these systems may be considerably altered.

Water content in microemulsions appears to be the most important factor that determines the reaction rates. The molar ratio w_0 ($w_0 = [H_2O]/[\text{surfactant}]$) values are used

to express the water content of the system. Several reports concerning the activity of lipase from various sources as a function of w_0 shows a maximum in the range of 9 to 11. The same pattern is also observed for other enzymes studied in the same microemulsion systems, such as chymotrypsin and pyrophosphatase. However, when reverse micelles based on lecithin were used, the maximum reaction rate was observed at an extremely low water content ($w_0 = 2.2$).

In studies concerning the effect of the fatty acid chain length as well as the type of microemulsion system on the substrate conversion rate, it was found that for microbial origin lipases, triolein was a slightly better substrate as compared to tributyrin, but pancreatic lipase cleaves triolein 15 times more efficiently than tributyrin. Also, the enzyme in anionic microemulsion systems shows a higher affinity as compared to the cationic systems, whereas nonionic systems do not seem adequate for hydrolytic reactions.

One serious problem for the application of lipase to triglyceride hydrolysis is the stability of the enzyme in the microemulsion systems. The size of the microemulsion microdroplet seems to play an important role on the enzyme stability. It has been reported that lipase stability is improved as w_0 decreases. Also, the presence of various additives, such as $CaCl_2$ and casein, considerably increases the stability of lipase in AOT microemulsion systems.

Synthetic Reactions. The hydrolytic reaction catalyzed by lipase is reversible because the enzyme can also catalyze the synthesis and transesterification of triglycerides, under certain conditions. This catalytic process is of great technological interest and may be favored by the use of microemulsions. The lipophilic substrates and products can be solubilized in the continuous organic phase, whereas lipase remains active in the water core of the microemulsion droplets. In this case, specific synthetic reactions can be catalyzed, under mild conditions. The synthesis of triacylglycerol by *Rhizopus delemar* lipase has been reported in a phosphatidylcholine reverse micellar system (27). The esterification of glycerol with oleic acid, catalyzed by *Chromobacterium viscosum* lipase in glycerol-in-oil–type microemulsions of AOT in heptane, and the synthesis of various fatty acid esters in water-in-oil microemulsions, stabilized by CTAB, have also been reported (46). Similar systems have been used for the transesterification of palm oil with stearic acid (47). Synthesis of heptyloleate and the esterification of various triglycerides by *Candida cylindracea* lipase in a microemulsion-like system has been reported using Brij-35 as surfactant (48). The esterification of various alcohols with fatty acids by *Rhizopus delemar* lipase has been performed using nonionic microemulsion systems stabilized by $C_{12}E_4$, with significantly fast reaction rates also reported (49). In this work, it was shown that pH ranging from 3.45 to 8.55 does not affect the reaction rates in this type of microemulsion system. Also, studying the effect of the system's water content showed that when $w_0 < 5$ the conversion is considerably slow, but for $w_0 > 7$ a 90% conversion is attained in 4 h. Esterification reactions of alcohols with fatty acids and synthesis of polyols have been reported (30) using *Rhizopus delemar* and *Candida cylindracea* lipase in AOT microemulsion systems. Recent studies have been reported on the activity of lipases from *Rhizopus delemar, Rhizopus arrhizus*, and *Penicillium simplicissimum* in esterification reactions of various aliphatic alcohols with fatty acids in microemulsions formulated by AOT in isooctane (50). The results showed a remarkable selectivity of the lipases regarding the chain length and the structure of the substrates. *P. simplicissimum* lipase presented higher reaction rates in the esterification of long-chain alcohols as well as secondary alcohols. Primary alcohols had a low reaction rate, and tertiary alcohols had a very slow rate of esterification. Long-chain fatty acids were better catalyzed as compared to the shorter ones. *R. delemar* and *R. arrhizus* lipases showed a preference for the esterification of short-chain primary alcohols, but the secondary alcohols had a low rate of esterification and the tertiary could not be catalyzed. Medium-chain fatty acids were also better catalyzed than the long ones. Fluorescence quenching measurements suggest that there are not any significant changes of the shape and size of the microemulsions caused by the substrates, which could have been related to the enzyme selectivity. In extensive studies using a large number of substrates with different degrees of polarity as well as spectroscopic techniques, this selectivity appears to be related to the localization of the enzyme molecule within the micellar microstructure, because of the hydrophobic/hydrophilic character of the protein and not of a specificity of the enzyme itself. This hypothesis can further be supported if one takes into consideration the structural differences of these lipases.

Kinetic Studies. Lipase-catalyzed hydrolysis of triglycerides in reverse micelles follows Michaelis-Menten kinetics. The release of fatty acids as a function of reaction time at different enzyme concentrations and fixed substrate concentrations (20–40%, v/v, where $[S] \gg K_m$) is proportional to the enzyme concentration. The K_m and V_{max} parameters of the Michaelis-Menten kinetic equation can be determined from the Lineweaver-Burk double-reciprocal plot of the lipase activity only as apparent ones. To find a true K_m, the substrate concentration at the enzyme surface must be used. This requires knowledge of the substrate partitioning between various microphases, as the water pool, the interface, and the bulk organic solvent. The partition coefficient is difficult to be determined experimentally. Another constant obtained from Michaelis-Menten kinetics is the turnover number, K_{cat}, which is related to the maximum reaction velocity. Determination of K_{cat} depends on accurate measurement of active-enzyme concentration in the microemulsion system. Usually, the total enzyme concentration and not the active-enzyme concentration is used for the calculation of K_{cat}. The latter can be achieved by active site titration studies.

Kinetic studies of the esterification reaction on the reaction of ethylene glycol and fatty acids (30) and of lauric acid and (-)menthol (29), catalyzed by lipase in AOT/isooctane/water microemulsion systems, have been described. In the second case, the authors have shown that the kinetics of this synthesis follow a ping-pong Bi-Bi mechanism. According to this mechanism, lipase reacts

with lauric acid to form the lipase–lauric acid complex. The complex is then transformed to a carboxylic–lipase intermediate and water is released. This is followed by an attack of (-)menthol to this intermediate, forming the (-)menthyl laureate. The values of all apparent kinetic parameters were determined, and a model concerning this type of reaction involving two hydrophobic substrates was proposed. According to this, the partitioning of the two hydrophobic substrates between the continuous organic phase and the reverse micelles must be taken into account to determine the real kinetic constants.

Lipase Applications in Reverse Micelles

The potential applications of lipases in biotechnological processes have been the subject of increased scientific, economic, and industrial interest and efforts in recent years. Regioselectivity, stereospecificity, substrate specificity, and low energy consumption are some of the features that make lipase-catalyzed processes an alternative to conventional nonenzymatic reactions. Special attention is given to the transformation of fats and oils as well as the preparation of synthetically useful enantiomers. Among the systems under investigation, the encapsulation of lipases in reverse micelles seems to present several advantages such as greater interfacial area, lower mass transfer limitations, and enhancement of catalytic activity.

The development of a bioreactor that enables reactions in a semibatch or continuous mode allowing the separation of substrates, products, and enzymes is a critical demand in reversed micellar technology today. Recently, two types of reactors have been developed for the glycerolysis of olive oil by lipases. In the first case, the bioreactor, abbreviated as LRM system, uses liposomes for adsorbing the enzyme and reversed micelles as a good supplier of interfacial area for the glycerolysis reaction (45). According to this system, the lipase was adsorbed on the liposomes prepared in a simple manner, and reverse micelles containing the immobilized enzyme were formed by injecting appropriate amounts of glycerol and predetermined amounts of water in AOT/isooctane system. Olive oil in isooctane is fed at controlled flow rates into the bioreactor by pressurizing the reservoir with nitrogen gas. The reaction takes place at 37 °C. The products are obtained from the outlet in a single phase, but the microemulsions are not broken. A microporous membrane is used to separate products formed (oleic acid, monoolein, and diolein) and unreacted substrate (triolein) from the microdroplets containing immobilized lipase. The membrane, made of polysulfone, is about 12.5 μm thick, and the micropores have a maximum diameter of 25 nm. This system presents a long operational stability. The second bioreactor system is a membrane bioreactor for simultaneous lipolysis and bioproducts separation in a reversed micellar system (51). The main purpose of this type of bioreactor is to retain lipase behind the membrane where reaction occurs and to recover the products on the permeate side. The membrane is a ceramic one, resistant to organic solvents, made of a zirconium oxide layer over a porous carbon support with a 10,000 molecular weight cutoff. The inside diameter is 6 mm; the wall thickness, 2 mm; and the effective length, 20 cm. The internal permeation area is 38 cm^2. The reaction mixture is recirculated from the thermostated vessel into the reactor by means of a gear pump flowing tangentially to the membrane. Part of the solution is permeated through the wall of the semipermeable membrane (by connective flow) as a result of the hydrostatic pressure difference, and it is recycled to the reactor. All connecting piping is solvent resistant.

Enzymatic catalysis in reverse micelles has also been performed mostly in batch-type reactors in various other processes. Some examples are the synthesis of peptides by α-chymotrypsin in reverse micelles in a hollow fiber reactor (25), or the production of tryptophan by tryptophanase in a continuous reversed micellar reactor (52).

Liquid–Liquid Extraction of Enzymes Using Reverse Micelles

The application of reverse micelles in the extraction and isolation of enzymes is a promising technique at the downstream biotechnological processes, having interesting advantages over existing processes for large-scale recovery of extracellular enzymes (53). The traditional process of transfer proteins into organic solvents often causes irreversible denaturation of proteins and loss of biological function. A reverse micellar extraction combines the potential for concentration and purification of the enzymes through transfer between aqueous and organic micellar phases. Enzymes can be extracted without loss of activity. Examples of enzyme extraction using reverse micellar systems are summarized in Table 3.

The recovery of enzymes from the aqueous phase involves two steps: forward and back extraction. In the first step, the desired enzyme is transferred selectively from the aqueous phase to the reversed micellar phase, and in the second step, the enzyme is subsequently recovered from the reversed micellar phase by extraction with a second aqueous phase, the micellar phase being recovered for further extractions. The rates of forward transfer from the aqueous to the micellar phase are extremely fast. Upon steering, for example, only a few seconds are necessary for the transfer of cytochrome *c* into a system of AOT/isooctane. The process of back extraction into the new aqueous phase is much slower and requires constant agitation. In ideal conditions, the back extraction of cytochrome *c* can be achieved in several minutes. The distribution of an enzyme between the reversed micellar and the aqueous phase is influenced by several factors such as pH, ionic strength, and surfactant type (anionic, cationic, or nonionic). The pH determines the ionization state of the surface-charged groups of the protein molecule. The solubilization is favored when attractive electrostatic interactions occur between the protein molecule and the surfactant head groups; in this case, the overall charge of the surfactant is opposite to the overall charge of the protein. This implies that, for cationic surfactants, solubilization of the protein in reverse micelles is favored at pH values above the isoelectric point (pl) of the protein, whereas the opposite is true for anionic surfactants. Together with the pH, the ionic strength plays a very important role in protein recovery. The presence of salts in the aqueous phase can alter the equilibrium size of the surfactant aggregates.

Table 3. Examples of Enzyme Extraction Using Reversed Micelles

Enzyme	Reversed micellar system
Trypsin (54)	AOT/isooctane, octane, heptane
Extracellular alkaline protease (55)	AOT/isooctane
α-Amylase (56)	TOMAC/isooctane
Separation of a mixture of cytochrome *c*, ribonuclease, lysozyme (57)	AOT/isooctane
Lysozyme, α-chymotrypsin, pepsin (58)	AOT/isooctane
Isocitrate dehydrogenase, β-hydroxybutyrate dehydrogenase, glucose-6-phosphate dehydrogenase (59)	CTAB/octane/exanol
α-Chymotrypsin (60,61)	NR_4^+/cycloexane
	AOT/octane/water/glycerol
Ribonuclease A (62)	AOT/isooctane

A higher ionic strength will decrease the size of the micelle, and this effect can be stronger for larger ions, which causes shorter electrostatic interactions. Thus, it is possible to achieve a selective transfer based on size exclusion effects. The attraction between the surfactant and the protein is weaker, and this contributes to exclude the protein from the micellar core. When the ionic strength is very low, phase transfer does not occur. The transfer of proteins from an aqueous to a micellar phase requires a minimum of ionic strength in the aqueous phase. In addition to the surfactant charge, other surfactant-dependent parameters have to be taken under consideration, such as the size of the reversed micelles that are formed, the energy required to enlarge the reverse micelles, and the charge density on the inner surface of the reverse micelles.

The liquid–liquid extraction technique in general is well known, and apparatus and scale-up rules have been established for numerous applications, including the use in recovery processes for antibiotics and organic acids from fermentation broths. The forward and back extractions can be performed in a continuous mode, with the reverse micellar phase circulating between the two extraction units. No specialized equipment is required. The process developed for conventional liquid–liquid extraction is, in principle, also suitable for this application. The most important types of equipment are mixer/settler, agitated column, centrifugal, and membrane extractors. At the present time, process development has centered on the use of mixer/settlers and membrane extractors.

CONCLUDING REMARKS

So far, the results derived from studies with reversed micelles show that the use of these systems can reach a considerable biotechnological relevance and be extended to a wide range of applications. In the field of bioconversion, the enzyme solubilization in reversed micelles clearly offers advantages over other techniques, including the very fast reaction rates or the small quantity of enzyme to be used in comparison to other approaches of enzymology in extreme conditions. However, there are a few problems that must be solved in order to take full advantage of this system, such as the need to remove the excess surfactant from the products and to develop appropriate reactors, which will allow the continuous production and in situ recovery of the bioproducts applying new separation techniques, for example, membrane polymers. Another promising field for reverse micellar systems application is in the downstream processing for the separation of other bioproducts besides proteins and peptides, such as amino acids, nucleotides, nucleic acids, solvents, organic acids, antibiotics and steroids.

OUTLINE

INTRODUCTION

Many biotechnology products are manufactured using microorganisms and mammalian cells that behave in a Newtonian manner. In other cases, the product of the culture or the cellular material itself may cause the culture to be

highly non-Newtonian. It is the processing of non-Newtonian materials that can cause major design and operational problems. For example, in most filamentous fermentations in submerged cultures, at the start of fermentation the broth rheology is Newtonian, not too different from water. However, often the microbiological requirements of the fermentation are such that the prevailing operating conditions lead to the development of diverse and complex non-Newtonian broth rheology, and extreme changes in the apparent viscosity of the broth can occur during fermentation (1–3). These changes can cause practical difficulties in maintaining an adequate power input per unit volume in the bioreactor. Subsequently, significant heterogeneity in dissolved oxygen tension and shear rate distribution can occur in the vessel contents (4–6). Consequently, transport processes such as heat and mass transfer and metabolic activity of the cells can suffer, cell damage can occur, and a fall in productivity can result (7–9). The extent of non-Newtonian behavior of the broth is closely related to the growth of the biomass and the development of a three-dimensional network of highly branched hyphae in the case of mycelia microorganisms (10–12). Considerable work has been done in recent years to understand these complex structures by measuring the mycelia morphology in dispersed (filamentous) and pelleted (aggregated) forms (13–17). However, there are as yet no general predictive constitutive equations that can be used confidently for design and scale-up, and even for the same strain there is no consensus of opinion among researchers on the precise effects of mycelia morphology on broth rheology or how the rheology of such systems should be described. The uncertainties associated with the use of predictive rheological equations are to a large extent understandable considering the wide range of parameters that are thought to influence the rheology of the cultures. These include the mode of fermentation (e.g., batch, fed-batch, or continuous), growth rate, level of the dissolved oxygen concentration and pH levels of the culture, level of mixing and shear intensity in the fermentor, and presence of solid debris, impurities, surfactants, and additives. These parameters critically affect the properties of the individual hyphae, for example, their length and length distribution, diameter, and mechanical integrity (strength, rigidity, and flexibility), as well as the physicochemical interactions between the hyphae (compactness, roughness) and between the hyphae and the continuous liquid phase (3,15,18–22). The analysis of rheological data is further complicated by the degree of hyphae aggregation (i.e., formation of clumps) and by the flocculation of clumps (16). The superimposed effects of all these parameters on broth rheology can be difficult to simulate.

Few publications are available on the rheology of non-filamentous cultures. In cases where data are published (e.g., for yeast suspensions), there is considerable disagreement between the results of different researchers (11,23–25). Fermentation cultures and biological solutions that do not exhibit mycelia growth but can show non-Newtonian behavior include high concentrations of single-cell suspensions (e.g., yeasts), high molecular weight fermentation products (e.g., polysaccharides), solutions containing globular proteins, supercoiled plasmid DNA and macromolecules (e.g., membrane protein complexes), chromosomal DNA, and animal cells in solutions in high concentrations (11,26).

This review article focuses largely on the rheology of the microbial suspensions in order to examine some of the key factors that are perceived to affect their flow properties. The intention is to highlight the results of some of the recent research on the interactions between mycelia morphology and culture rheology without emphasizing the effect of rheology on, for example, transport processes such as heat and mass transfer. For these aspects, the reader is referred to other relevant reviews on the subject (4–6, 27–29).

VISCOMETRY

In addition to biomass concentration, the extent of non-Newtonian behavior of fermentation broths is determined largely by the primary properties of the hyphae, which include hyphal morphology and dimensions, hyphal flexibility, and ability to form clumps. The primary properties of the hyphae in turn are critically dependent on the detailed fermentation conditions, making it difficult to develop a satisfactory theoretical simulation of the non-Newtonian behavior of broths.

An alternative engineering approach to the study of flow properties of a fermentation culture is to experimentally develop the flow curve, or shear diagram, which is a plot of shear stress, τ, against shear rate, γ, in the laminar region (Fig. 1). This information is usually obtained in a conventional laboratory viscometer such as the cup-and-

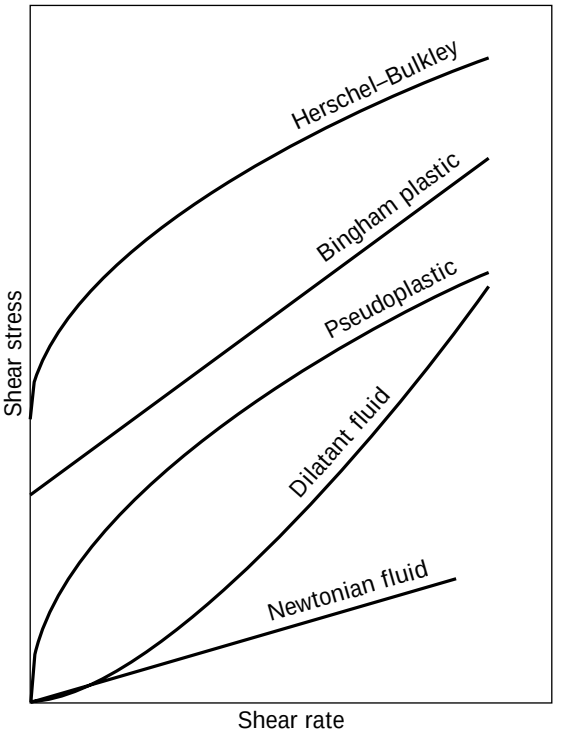

Figure 1. Rheological models.

bob (coaxial cylinder), capillary tube, or a cone-and-plate viscometer. However, most cultures are highly heterogeneous and contain large amounts of insoluble debris and particulate material, which can be fragile and can separate and sediment during rheological measurements. This renders many of the conventional rheometers unsuitable for characterization of biological suspensions. In such cases useful rheological data can be generated indirectly in laminar flow by using a calibrated, scaled-down, "engineering" viscometer, for example, an instrumented pipe flow viscometer or impeller viscometer (16–34). The former is widely used in the biochemical industry for flow characterization and is essentially a cup-and-bob viscometer except that the rotating inner cylinder is replaced by a mixer, (e.g., a turbine, paddle, disc, or helical ribbon) (Fig. 2). From the rheological viewpoint, the basic difficulty in using engineering viscometers is that these instruments do not provide a well-defined and uniform shear field, and therefore, individual elements of fluid are likely to undergo periods of exposure to different levels of shear during measurements. In the case of the impeller viscometer, the evaluation of an average shear rate in the cup is based on an empirical technique originally developed for mechanically agitated vessels by Metzner and Otto (35) and later modified for relatively simple rotating units (e.g., a disc spindle) by Mitschka (36). These techniques have been fully described elsewhere (31,37) and are therefore only briefly reviewed here. The estimation of the average shear rate, γ_{av}, in the cup of an impeller viscometer is based on the assumption that the average shear rate, γ_{av}, is directly proportional to the rotational speed of the impeller, N; the constant of proportionality, k_s, which is generally known as the impeller shear rate constant, is uniquely dependent on the geometry of the impeller viscometer but is independent of the fluid rheology. Thus, $\gamma_{av} = k_s N$. Figure 3 summarizes the experimental procedure used in evaluating the shear rate constant, k_s, for an impeller (viscometer) based on the Metzner and Otto technique. The key steps in the determination of k_s are as follows.

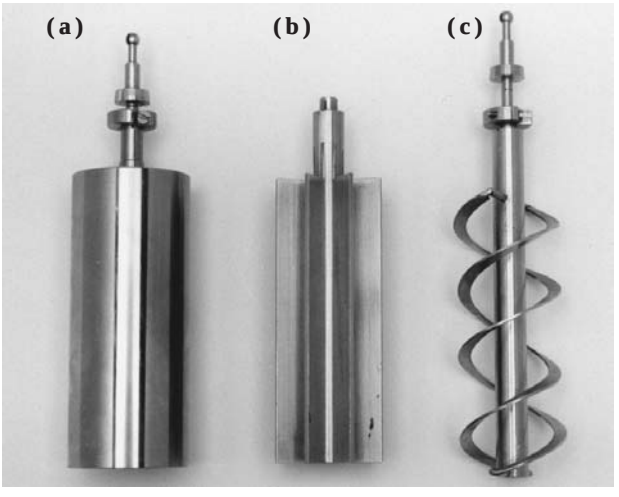

Figure 2. Mixer for rheometers. (**a**) solid cylinder; (**b**) turbine; (**c**) helical ribbon.

1. The laminar Newtonian power curve is obtained for the impeller-cup-and-bob viscometer from a series of measurements of torque and speed using one or more Newtonian liquids.
2. The flow curve is developed for a (model) non-Newtonian liquid, for example, carboxymethycellulose (CMC) solution using a conventional cup-and-bob viscometer.
3. The cup of the impeller viscometer is filled with the (model) non-Newtonian liquid.
4. The impeller speed is set at a predetermined value, N_1, and the corresponding torque, T_1, is measured. These values are used to calculate the corresponding dimensionless power number, $(P_o)_1$, $[P_o = P/(\rho N^3 D^5)]$.
5. From the Newtonian power curve, the Reynolds number, $(Re)_1$ corresponding to $(P_o)_1$ is obtained.
6. Using the definition of the general Reynolds number, $(Re = \rho N D^2/\mu_a)$ and the value of the Re_1 from step 5, the apparent viscosity, $(\mu_a)_1$, is calculated.
7. From the non-Newtonian flow curve the value of the shear rate, $(\gamma_a)_1$, is obtained corresponding to $(\mu_a)_1$.
8. Steps 4 through 7 are repeated for a range of speeds (N_2, N_3, etc.), and these values are plotted against the corresponding values of shear rates ($(\gamma_a)_2$, $(\gamma_a)_3$, etc.).

The plot obtained in step 8 is often a straight line through the origin and has a slope equal to the shear rate constant, k_s. It should be noted that the above procedure is valid only if the measurements of speed and torque (power) fall in the laminar flow region of the power curve, this being the region where the power number is a function of the Reynolds number. For most turbine impellers, the Metzner and Otto technique gives a value of the shear rate constant, k_s, in the range between 10 and 13 (35), whereas for helical ribbon and large paddle impellers its value falls in the range of 26 to 30 (38).

An important practical consideration is the selection of an appropriate rheometer (e.g., a rotating viscometer or a capillary flow rheometer). Different methods of measuring the rheological parameters of a non-Newtonian liquid do not necessarily yield the same result. This is not to say that one method is better than another but merely that it reflects the fact that the liquid flow field is different in the different devices, and the response of a non-Newtonian liquid depends on the flow field to which it is exposed. Therefore, in specifying a value for the apparent viscosity, it is important to quote the means by which the parameter has been measured. Moreover, the method of measurement should be closely related to the application of the final product. For example, for the design of a mechanically agitated bioreactor, an appropriate viscometer is the cup-and-bob or the turbine impeller viscometer, whereas the capillary tube or the instrumented pipeflow viscometer can be used effectively to gather rheological data for pipeline transportation of non-Newtonian biological suspensions. The following discussion is based on rheological data obtained in the former group of viscometers.

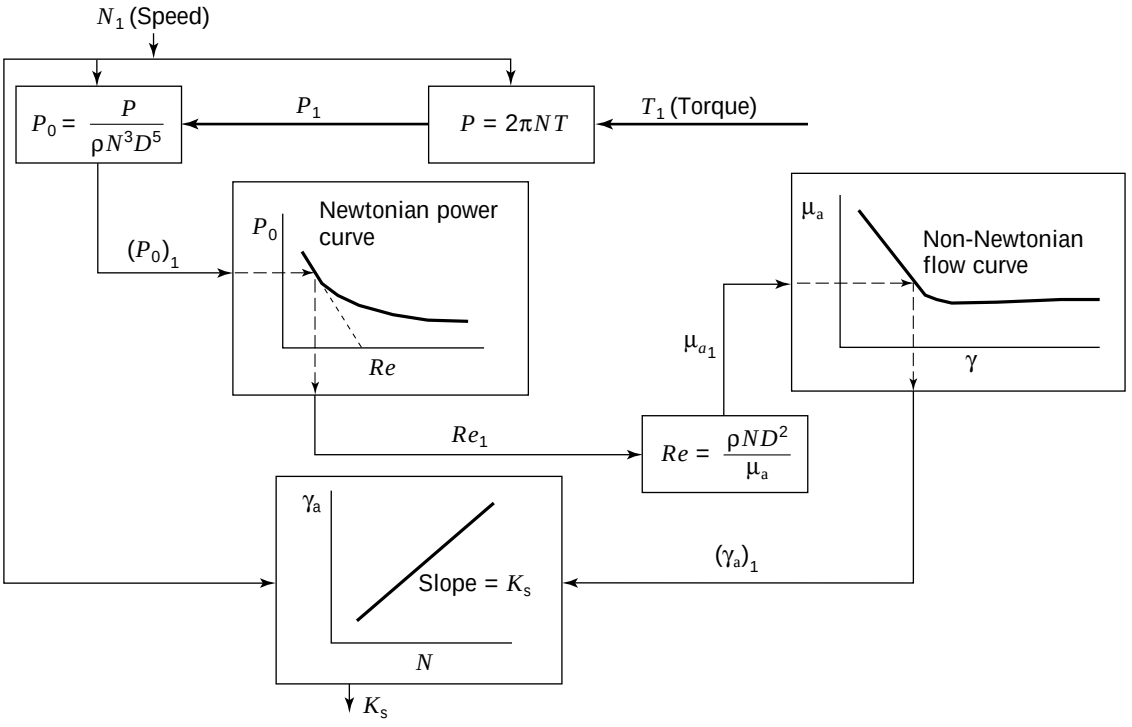

Figure 3. Experimental procedures for calculation of K_s from Metzner and Otto equation.

Commercial Viscometers

Bohlin, Haake, Brookfield, Rheomat, Carrimed, and Rheomatrics are just a few of the more commonly used devices used for the rheological characterization of liquids (39). The first four viscometers are available in both laboratory and portable (battery-operated) form, and some, such as the Brookfield, can also be used on-line. The state of technology has vastly improved over the past two decades, and current instruments such as the Bohlin can be fitted with different heads (e.g., coaxial cylinders, parallel plates, or cone-and-plate geometry) and can perform a variety of measurements including controlled stress and controlled strain measurements. Additionally, the Bohlin rheometer can accurately determine the response of the liquid to more complex types of motion imposed on the sample, including oscillatory motion from which rheological information can be obtained on the viscoelastic properties of the liquid.

These rheometers can be used to develop the non-Newtonian flow curve directly over a wide range of shear rates (10^{-6}–10^{7} s^{-1}) of interest to most process engineering operations (39). The low shear rates represent processes involving, for example, sedimentation of fine particles (10^{-6}–10^{-4} s^{-1}), leveling due to surface tension (10^{-2}–10^{-1}), and gravity drainage (10^{-1}–10^{1}). The medium range of shear rates covers processes such as extrusion, chewing and swallowing (10^{0}–10^{2} s^{-1}), mixing in mechanically agitated vessels, and pipe flow (10^{1}–10^{3} s^{-1}). Shear rates of 10^{3} s^{-1} to 10^{7} s^{-1} occur in operations such as spraying, centrifugation, and high-pressure homogenization.

RHEOLOGICAL MODELS

For design purposes it is often desirable to describe mathematically the information contained in a flow curve by fitting empirical equations to experimental measurements. Numerous flow equations have been proposed to describe the shape of the flow curves, including the Bingham plastic, Herschel–Bulkley, Casson, and power law equations. There is, however, no theoretical justification in recommending any of these equations a priori, and the selection of an appropriate flow equation should be based on practical considerations; the model equation should give an accurate fit of the experimental flow curve, it should have a minimum number of independent constants that are readily evaluated, and preferably the constants should have some physical basis.

A few researchers have reported time-dependent rheology (6,40,41) and viscoelastic behavior (42) for filamentous cultures. However, in the majority of cases the rheology of the cultures appears to exhibit time-independent shear thinning behavior, which can be described adequately by a two-parameter power law equation (31,43,44). This is characterized by a flow curve that, over a reasonable range of shear rate, is a straight line on a logarithmic plot of shear stress against shear rate (Fig. 4). Thus the relation between shear stress, τ, and shear rate, γ, can be written as $\tau = K\gamma n$, in which K is the consistency index and n is known as the flow behavior index and has a value less than unity for most cultures. The value of the flow behavior index gives a measure of the extent of the non-Newtonian behavior of the broth. For $n = 1.0$, the culture has Newtonian flow properties, with $K = \mu$. As n deviates from 1.0, the broth becomes increasingly non-Newtonian.

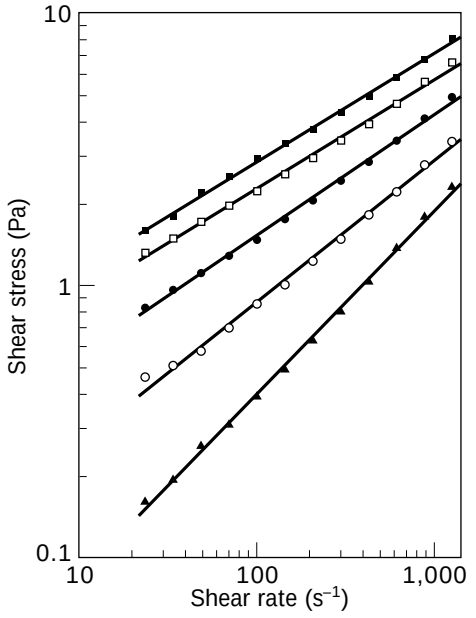

Figure 4. Shear stress against shear rate in log-log scale. Samples from *S. erythraea* (CA 340), fermentation in 7-L stirred bioreactor. Biomass concentration of the samples was between 3 and 12 g L^{-1}. Details of the fermentation areas in Ref. 45.

Flow equations have also been recommended for fermentation cultures based on the Bingham plastic, Casson, and Herschel–Bulkley models, all of which contain a yield stress parameter that needs to be evaluated from experimental measurements (16,42,46). The flow curves of many biological suspensions rise rapidly and then flatten out at relatively low shear rate. Under these conditions it is difficult to differentiate between the power law model and a model containing a yield stress, and very accurate data at quite low shear rates would be required to prove or disprove the existence of "true" yield stress (42,46). In the absence of such information, it seems prudent to use the power law model to describe the rheological data of biological materials over a specified range of shear rate.

RHEOLOGY OF MICROBIAL CULTURES

Filamentous cultures exhibit two extreme types of morphology in submerged culture, highly dense pelleted and free mycelia, with loosely packed mycelium forming a transition between the two types (Fig. 5). The freely dispersed mycelia and its entanglement to form clumps can cause the fermentation to become highly viscous and non-Newtonian. Past studies on morphology have attempted to distinguish between the different types by using various morphological parameters including compactness, roughness, and fractal dimension. These studies show that the compactness of *Penicillium chrysogenum* varies between about 0.3 for highly filamentous structure to close to unity for pellets (16). The fractal of *P. chrysogenum, Streptomyces griseus,* and *Streptomyces tendae* have been measured by Patankar et al. (47) and in our laboratory (45) and seem to vary between 1.9 and 2.7 in filamentous form and between 1.45 and 2.00 in pelleted form (47).

The pelleted type of growth consists of compact discrete masses of hyphae that generally lead to Newtonian behavior of the broth (48). However, in many cases as the size of the pellets increases, the diffusion of nutrients, particularly O_2, into the center of the pellets becomes limited, resulting in low productivity (6,49). Moreover, there are reported cases of cultures consisting of pelleted mycelium that exhibit clear non-Newtonian behavior (50). Great caution must therefore be exercised in generalizing the flow behavior of microbial cultures.

The flow curves presented later are intended to serve as typical rheological examples of real biological microorganisms extensively studied in the past. The discussion examines the effects of some of the important parameters that are perceived to influence broth rheology. For these reasons, the details of fermentation conditions are not included, but where necessary, the reader is referred to other publications and references where further information on the relevant aspects of the work can be found. Additionally, with the exception of the information given in Table 1, a conscious decision has been made to avoid recommending specific constitutive equations because the absolute values of the constitutive parameters K and n are highly system specific and ideally should always be based on experimental flow curves obtained under the actual fermentation conditions for which they are required.

Filamentous Mold Cultures

Numerous publications are available on the rheology of mold fermentation cultures; mostly the mycelium is in the filamentous form because these cultures show strong non-Newtonian behavior. The organisms most widely studied are *P. chrysogenum* and *Aspergillus niger*. Table 1 gives details on the range of parameters used in the rheological characterization of these materials. The non-Newtonian behavior of most of the cultures investigated has been modeled either in terms of a flow behavior index, n, and consistency coefficient, K, of a power law shear thinning equation, or in terms of a yield stress, τ_0, and a plastic viscosity, μ_p, of the Bingham plastic model. In a few cases the Casson model is used, in which case the yield stress, τ_0, and the shear rate coefficient, K_c, are given as the two model parameters. In these studies, plastic viscosity, μ_p, and yield stress, τ_0, in the Bingham plastic model and the consistency coefficient, K, in the power law equation were found to increase and the flow behaviour index, n, decrease with increasing biomass concentration. The increase was found to be nonlinear, and its extent was highly strain dependent (Table 1).

An examination of Table 1 shows that equations are also available in which the rheological parameters have been related to the morphological properties of the individual hyphae. However, recent measurements have shown that in many cases as much as 90% of the mycelium exists in flocculated (clump) form and not in a freely dispersed form, suggesting that rheological parameters are more likely to be related to clump properties and not to the de-

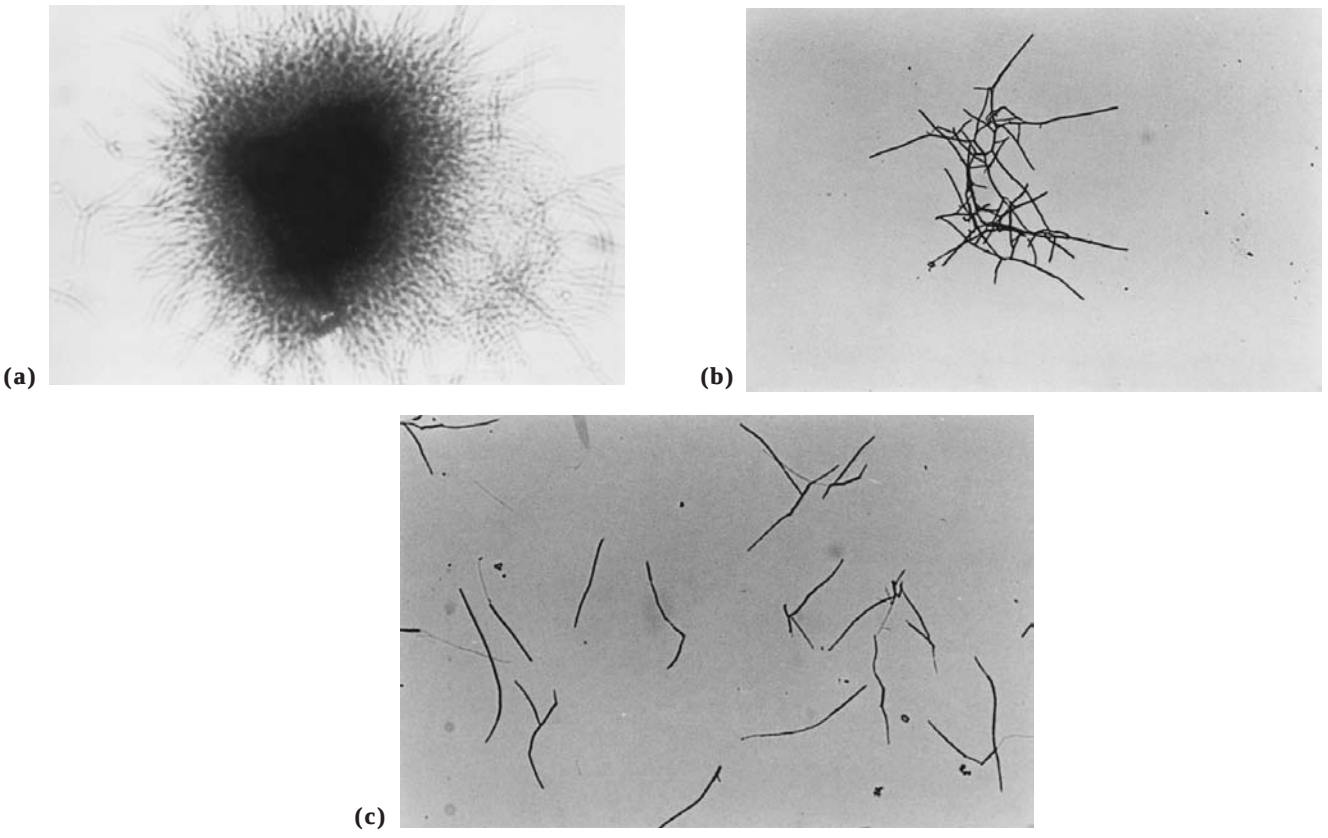

Figure 5. Example of *S. erythraea* (CA 340) morphology. (**a**) Pellet; (**b**) clump; (**c**) dispersed mycelium.

tailed characteristics of the individual hyphae. Recent measurements carried out by Tucker and Thomas (56) and Olsvik et al. (16) appear to support this conclusion and suggest that, for example, the compactness and the roughness of hyphae flocs can be successfully related to the rheological parameter (Table 1).

Filamentous Actinomycetes Cultures

In filamentous form, the sizes of the individual hyphae in the mycelium are generally less than 100 μm, and the broths exhibit considerable non-Newtonian flow behavior (31,46). However, recent experimental evidence obtained in our laboratory using three industrial strains of Actinomyces ranging in size from 15 μm to 25 μm indicated that the properties of the individual hyphae have little effect on broth rheology (3,44). The results of these experiments, discussed in more detail later, also revealed that there was little change in the size of the mean main length of the hyphae, and furthermore very few clumps were observed during hyphal characterization.

Figure 6 shows the variations of n and K of *Saccharopolyspora erythraea* (strain CA 340) mycelia cultures as a function of time of fermentation (45). The data were obtained in a standard coaxial cylinder viscometer using fresh samples of the culture that were removed during fermentation in a 7-L stirred bioreactor (45). The plots shown in Figure 6 are effectively snap shots of a developing rheology, showing the dramatic changes in the non-Newtonian behavior of the fermentation broth during the growth period.

Similar rheological data are shown in Figures 7, 8, and 9, respectively, for the fermentation of industrial strains of *S. erythraea*, *Aspergillus roseorufa*, and *Streptomyces rimosus* (3,44). The data for *S. rimosus* were obtained from an industrial-scale mechanically agitated bioreactor; in the case of *S. erythraea* and *A. roseorufa*, samples were taken during fermentation in a small, laboratory-scale mechanically stirred unit. In all three cases, the broths contained a significant amount of particulate matter, which made the use of a standard cup-and-bob viscometer inappropriate. The rheological parameters plotted in Figures 7–9 were therefore obtained by using a Brookfield 2HA-TDVII Synchro-Lectric rheometer fitted with a disc-spindle impeller, for which the average shear rate at each rotational speed was obtained by using Mitschka's technique, which is described fully elsewhere (36).

Figure 10 shows experimental data on the mean main hyphal length as a function of fermentation time. The width of the plotted lines indicates the 95% confidence limits of the data. Variations of the power law coefficient, K, with time are also shown in Figure 10 for comparison. The mean main hyphal length fluctuates throughout the fermentation time, but no observable trend in the data can be detected for any of the microorganisms. Additionally these plots indicate no correlation between the mean main hyphal length and broth rheology. The mean main hyphal

Table 1. Rheological Correlations for Biological Cultures

length of the three microorganisms shown in Figure 10 are significantly smaller than those reported previously for *Streptomyces clavuligerus* (45–120 mm), and *P. chrysogenum* (e.g., 130–420 μm and 60–120 μm).

An examination of the information given in Table 1 shows that, compared with the fungal cultures, the rheological parameters, K, τ_o, μ_p, and K_c, for example, are less sensitive to changes in the biomass concentration. The effect of dry cell weight (DCW) on the consistency coefficient, K, of *S. erythraea* culture is shown in Figure 11. The similarity of the two profiles in Figure 11 is evident from these plots, and a series of experiments were conducted to examine the factors responsible for the observed dependency of the broth consistency coefficient, K, on DCW. Two fermentation batches were prepared and run in the same way except that only one batch was inoculated with *S. erythraea*. Several samples were taken periodically from each batch for rheological measurements and DCW evaluation. Some of the samples were also centrifuged prior to analysis to remove *S. erythraea* cells and/or medium particulate and insoluble debris. Figure 12 shows the results of these experiments and indicates that for the inoculated batch (A) the profiles of the consistency coefficient, K, and the DCW are similar and increase with fermentation time. However, once the *S. erythraea* biomass was removed by centrifugation (curve B) the broth rheology changed dramatically, the variation in K disappeared, and the flow behavior index increased from its value of about 0.2 to a value close to unity, indicating a change from a highly shear thinning to an almost Newtonian behavior. Samples from the uninoculated batch showed very little change in their rheology, which remained Newtonian practically throughout (curve C). Similar results shown in Figure 13 were observed for the fermentation of *A. roseorufa*, confirming that the high apparent viscosity of the filamentous cultures depends on the presence and concentration of the organisms, and that other constitutive components (e.g., insoluble particulate matter) appear to have little effect on broth rheology, at least for the cases presented here.

The effect of pH of the culture on broth rheology was also investigated, and it was found to have a strong

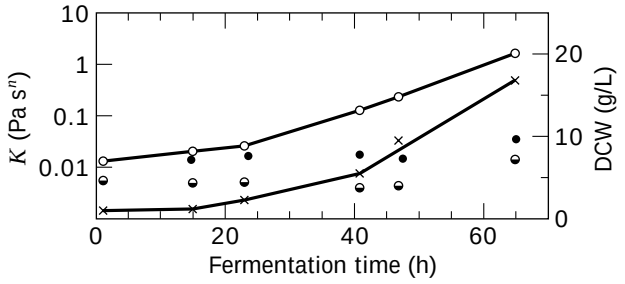

Figure 13. Effect of biomass, insoluble particulate matter, and soluble compounds on rheology of *S. roseorufa* culture.

effect on the extent of non-Newtonian behavior of the culture. This effect was somewhat unexpected and was further investigated for one of the microorganisms, *S. rimosus*. A large sample of the broth was removed from the bioreactor and divided into several specimens. Using concentrated hydrochloric acid and concentrated sodium hydroxide (60% by weight) the pH of each sample was altered to cover the range of pH between 3 and 10, in increments of 0.5 pH. The rheological properties of each sample were then measured using the Brookfield viscometer. Figure 14 shows the effect of pH on both the consistency coefficient, K, and the flow behavior index, n, of the broth. Measurements of the hyphal morphology (not shown) revealed no effect of pH on the mean main hyphal length of the individual hyphae. An important implication of the data in Figure 14, however, is that alteration in charges on and/or close to the surface of the microorganisms, arising from vari ations in pH, could play a role in determining the observed changes in broth rheology. The zeta potential characterizes the nature and the extent of surface charges, and the zeta

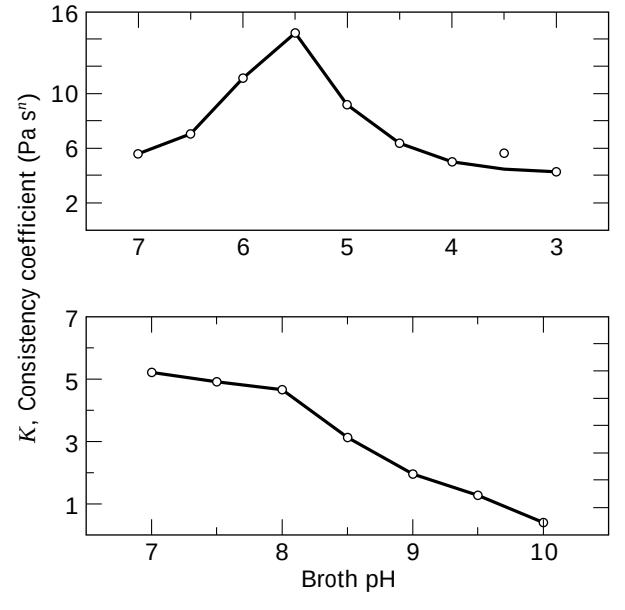

Figure 14. Effect of pH on consistency index of *S. rimosus* culture.

potential–pH profiles of the microorganisms should reflect these effects. No electrophoretic measurements are available in the literature concerning the zeta potential–pH profiles of microorganisms. These profiles should be developed experimentally and studied to examine how they are affected by broth conditions. The results could provide valuable information on the interrelationship between broth rheology, hyphal morphology, and biomass concentration.

CONCLUSION

Considerable experimental work has been published on the rheology of biological suspensions since the 1960s. Advances made in image analysis techniques in the early 1990s resulted in further work on relating the rheological properties to the morphological characteristics of filamentous microorganisms. No consistent opinion has yet emerged on the interaction between the two. Recent developments on the measurement of fractal properties of mycelium may provide a useful basis for further elucidation of these complex interactions.

NOMENCLATURE

Com	Compactness of mycelial aggregate
D	Tank diameter (m)
DCW	Dry cell weight (g L^{-1})
d_p	Diameter of mycelial aggregate (m)
E_c	Volume fraction of wet cells
h_s	Packing factor
K	Consistency index (N sn m^{-2})
K_c	Casson viscosity (N s m^{-2})$^{1/2}$
K_s	Impeller shear rate constant
L_e	Length of the hyphae (μm)
L_{hgu}	Length of hyphal growth unit (μm)
n	Flow behavior index
N	Rotational speed of impeller (s^{-1})
P	Power (W)
P_0	Impeller power number
R	Roughness of mycelial aggregates
T	Torque (N m)
X	Concentration of biomass (g L^{-1})
γ	Shear rate (s^{-1})
γ_{ave}	Average shear rate (s^{-1})
μ_0	Viscosity of cell-free medium (N m^{-2} s)
μ	Viscosity of culture (N m^{-2} s)
μ_a	Apparent viscosity (N m^{-2} s)
μ_p	Plastic viscosity (Pa s)
ρ	Density (kg m^{-3})
τ	Shear stress (N m^{-2})
τ_0	Yield stress (N m^{-2})

OUTLINE

INTRODUCTION

The settling behavior of biological cells with densities different than the fluid is a key factor affecting the performance of roller bottle bioreactors. The fully three-dimensional velocity field in a roller bottle bioreactor was simulated using a finite-element method, and the settling behavior of cells was simulated for both steady and time-dependent bottle rotation rates using particle dynamics algorithms. These simulations were validated experimentally using fluorescent particle tracers. Under steady flow conditions the flow is divided into two regions, one in which the particles settle to the wall and one in which the particles remain suspended indefinitely, but unsteady flow conditions (characterized by repeated reversal of the flow direction) lead to complete cell settling. These observations showed qualitative agreement with culture infection kinetic data in which changes in the roller bottle rotation rate resulted in enhanced infection. The main mixing limitation observed experimentally in roller bottles is very slow mixing in the axial direction, caused by flow segregation at the central plane of symmetry of the bottle. This limitation is readily overcome by imposing a small-amplitude vertical rocking motion to the bottle, forcing fluid to flow through the segregation plane and leading to a completely homogeneous mixture in just a few revolutions of the bottle.

BACKGROUND

Manual and automated roller bottle systems have been used for more than 40 years in the pharmaceutical, biochemical, and medical fields for processes such as cell growth and infection, heterologous glycoprotein production, vaccine preparation, and high-density plant cell cultivation (1–10). Despite efforts by numerous investigators to develop unit operations such as microcarrier culture for the production of anchorage-dependent cells or cell products (11–19), roller bottle systems still persist in research and industry. Additionally, for industrial-scale cell culture production (e.g., vaccines), cells are frequently expanded in roller bottles before transfer to microcarrier cultures for the final growth phase even when unit operation-based systems are utilized (17).

Widespread use of the roller bottle has several reasons. Most notably, the process relies on very simple technology: a horizontal cylindrical vessel is filled approximately one-fourth full and rotated axially; increased production is accomplished simply by increasing the number of bottles. Thus, scale-up development is straightforward, resulting in reduced developmental time lines for industry and faster introduction to market for new products. The system allows constant fluid–gas contact and easy addition of nutrients without interruption of the process. In addition, the process is capable of maintaining sterile conditions for prolonged times, contamination of one or more roller bottles does not necessarily result in the failure of an entire lot, precise control of nutrient and waste product levels is possible, and the direct monitoring of cell growth and metabolism is relatively simple (6).

On the other hand, roller bottles are limited in surface area available for growth and in the volume of harvest fluid obtained. Manpower and facility space requirements are higher than for unit operation systems such as microcarriers because hundreds or thousands of roller bottles can be operated for a single production run, although new automation systems are addressing the manpower issue (10,20). In addition, cell growth and infection are believed to be suboptimal in certain vaccine products because of flow and mixing dynamics, perhaps by preventing infected cells from attaching to host cells attached to the bottle walls (4). Although these issues point toward an obvious need for flow analysis and process design criteria, there have been no published results to date on either of these topics.

The following sections detail computational and experimental characterizations of the fluid flow profiles within rotating roller bottles, including particle trajectories, fluid mixing patterns, and unsteady-state flow strategies. The results point to ways in which cell proliferation and infection can be optimized by simple modifications to roller bottle rotation. This article is organized as follows. First, the numerical method for obtaining the three-dimensional flow solution is described. The flow solution is then validated by comparison with experimental measurements obtained via particle imaging velocimetry. Computationally predicted mixing patterns are compared with mixing patterns obtained by visualization of fluorescent dye streaklines. The model is then used to examine cell motion in the flow field. Computationally predicted cell motion patterns are compared with experimentally observed particle motion patterns obtained via long-time exposure photography of fluorescent particles. Then, particle settling results for the roller bottle under steady flow conditions are discussed and related to cell growth results obtained for various bottle rotation speeds. Finally, attention turns to improving the performance of roller bottles. The use of unsteady motions on the cylinder to enhance cell settling is explored, and the use of rocking flow perturbations to enhance axial mixing is demonstrated. The final portion of this chapter is devoted to conclusions and recommendations for future research.

DEVELOPMENT AND EXPERIMENT VALIDATION OF A COMPUTATIONAL MODEL OF FLUID AND CELL MOTION IN A ROLLER BOTTLE

Flow Field Solution

The three-dimensional flow field for a standard 850-cm^2 roller bottle geometry was obtained using a commercial CFD software package, FLUENT. This and similar software packages have been used by several researchers in the past to solve fluid dynamics problems (21–26). The equations of motion for the flow are the well-known Navier–Stokes equations, which, for a two-dimensional flow, include the momentum equation in two components and the continuity equation:

$$\boldsymbol{u}/t + \boldsymbol{u}\nabla\boldsymbol{u} = -\nabla p + (1/\mathrm{Re})\nabla^2\boldsymbol{u} + (1/\mathrm{Fr}) \quad (1)$$

$$\nabla\boldsymbol{u} = 0 \quad (2)$$

where $\boldsymbol{u}$ is the dimensionless velocity and p is the dimensionless pressure. Re in Equation 1 is the Reynolds number, $\mathrm{Re} = \rho vL/\mu$, where ρ and $\boldsymbol{\mu}$ are the fluid density and viscosity, and v and L are the bottle's linear rotational velocity and the liquid height, respectively; Fr is the Froude number, $\mathrm{Fr} = gL/v^2$, where g is gravity. The rationale for selecting liquid height as the natural length scale for the flow is that the liquid height is the diffusional length scale in the system. Viscous forces can be viewed as diffusive transport of momentum, with the kinematic viscosity (μ/ρ) playing the role of a momentum diffusivity. Hence, the liquid depth is the natural length scale for the action of viscous forces.

The experimental geometry is shown in Figure 1a. To obtain the velocity field, it was assumed that (*1*) the flow is steady, (*2*) the flow is in the Stokes regime (creeping flow conditions), (*3*) the free boundary is both planar and horizontal (effects of surface tension and viscous drag on the boundary are neglected). For the conditions used in the biotechnology industry, Re = 10, confirming the validity of the creeping flow assumption.

The physical domain was discretized using a curvilinear mesh; although the bottle has a total length to diameter ratio of 2:1, because of its symmetry only one-half of the system needed to be simulated, giving a length to diameter ratio of 1:1. The liquid height in the bottle was one-fourth the total diameter, which is typical of industrial practice. A 80 × 20 × 94 structured computation grid was used; Figure 1b represents a schematic of the z-plane grid (for the computation a higher node density was used). An acceptable node density for the computational mesh was found by creating several meshes with different node densities. The number of nodes in the mesh was successively increased by 25% until an average velocity difference of less than 3% was achieved for two successive meshes. The lower node density was then used to generate the computational mesh.

Velocity and pressure fields were obtained via iteration using a Sun SPARC 20 workstation. Approximately 140 Mb of RAM and 60 h of CPU time were required for solution convergence. To determine convergence, a criterion of 10^{-6} was used for each normalized residual velocity and pressure component. Residuals for each iteration were normalized versus the residual values obtained after the second iteration of the solver. To test the sufficiency of the convergence criterion, the simulation was run using convergence criteria ranging from 10^{-5} to 10^{-6} with no significant change in the velocity field when the convergence criteria were varied over this range (<1.0% change in velocity magnitude, on average). Sensitivity analysis (i.e., trajectory closing) showed that such a mesh was sufficiently accurate. These flow data were then used for all subsequent particle tracking simulations.

The condition adopted in the base case simulation was $\Omega = 0.25$ rpm, $\mu = 0.125$ Pa s at room temperature, giving a Reynolds number of Re 1.32. At this Re, the flow can be considered to be in the creeping flow regime. The flow was assumed to be sufficiently slow so that it could be assumed that the free surface was always horizontal and no surface tension effects were present at the bottle walls. The free surface was therefore modeled as a frictionless wall (i.e., a surface that exerts no stresses on the fluid). Several assumptions were also made regarding the particles simulated in the postprocessing program. The particles in the flow were sufficiently dilute so that they did not interact with each other or affect the fluid flow in any way. The particles were assumed large enough so that Brownian forces could be ignored. All the assumptions used here are valid for the majority of industrial uses of roller bottles.

The Fluid Velocity Field in a Roller Bottle

Two flow visualization experiments were performed to validate the simulations. The experiments were conducted in

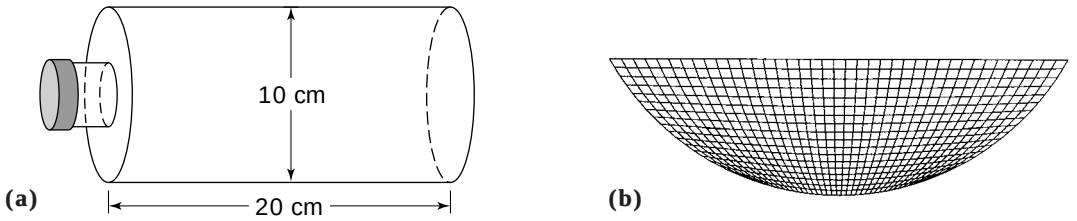

Figure 1. (**a**) Schematic diagram of the roller bottle. (**b**) Schematic diagram of the computational grid used for the simulations.

a glass roller bottle 10 cm in diameter and 20 cm in length. The working fluid was glycerin, which has a density of 1.26 g/cm^3 and a viscosity of 1.25 Pa s. The bottle was rotated using an apparatus that consisted of a set of rollers whose rotation speed and direction were accurately controlled by a computer. The rotation rate for the two experiments performed was 0.25 rpm, giving a Re of 0.13. This flow condition can be assumed to be representative of all conditions in the creeping flow regime, because in this regime the velocity field becomes independent of Re. The velocity field was first validated via comparison with particle imaging velocimetry (PIV) results. The use of particle imaging techniques to study fluid flow problems is well documented in the literature and has been reviewed by Adrian (27). Information that is pertinent to our specific system is provided here. The flow was seeded with 12-μm-diameter silver-coated hollow glass spheres (Potter's Industries) that have a specific gravity of 1.17. These particles are sufficiently small as to provide accurate measurements of the instantaneous velocity field. A 10-mJ New Wave Research pulsed mini-YAG laser was used as the illumination source. The laser beam passed through a series of optical components to produce a sheet of light 1 mm thick (at a focal distance of 1 m). A 32 $\times$ 32 grid was analyzed using cross-correlation data acquisition, with 10 ms between laser pulses. Resultant data from PIV was in the form of velocity direction and magnitude at the center of each interrogation area.

The experimental velocity field was measured in the vertical plane normal to the bottle axis in the middle of the bottle. Figure 2 shows the experimental (Fig. 2a) and computational (Fig. 2b) velocity vector fields. The length and color of the arrows represent the velocity magnitude in the plane, ranging from low (dark blue) to high (red). As seen in this figure, the velocity fields are qualitatively identical, with the exception of some small experimental scattering near the free surface of the liquid.

The computational velocity field was further validated by comparing computational and experimental mixing patterns obtained for passive tracers at the center plane of the bottle. This first step for simulating mixing patterns is to determine the trajectories followed by point particles as a result of the equation of motion:

$$d\boldsymbol{x}/dt = \boldsymbol{v} \tag{3}$$

where $\boldsymbol{x}$ is the particle position and $\boldsymbol{v}$ is the fluid velocity. Figure 3 shows the flow pathlines predicted using 4th-order Runge–Kutta integration of equation 3, which are also the flow streamlines because the flow is steady. A stagnation point is located on the symmetry line at 0.6 unit lengths below the free surface (the unit length is the height of the liquid). A similar approach was used to simulate the evolution of a vertical filament initially placed at the center of the bottle (Fig. 4a). The "line" consisted of 10,000 particles moving at the flow velocity. Figures 4b–4e show the configuration adopted by the line, as revealed by the particle positions, at 4, 8, 16, and 32 bottle revolutions, respectively. As the particles are moved by the flow, the line is twisted around the stagnation point. The line stretch in this steady two-dimensional flow is linear with time. The evolution of a fluid line was also observed ex-

perimentally to verify the simulations. Figure 5 represents the initial condition, which consisted of a vertical streak of dyed fluid placed in the center plane of the roller bottle, and Figure 6 shows the evolution of the streak of dye after 20 revolutions. Once again, excellent qualitative agreement between experiments and simulations was obtained, and it was concluded that the simulations indeed provide an accurate representation of the velocity field in the roller bottle.

Once the computational velocity field was validated, it was used to obtain a detailed characterization of fluid motion in the bottle. To provide a clear illustration of a three-dimensional velocity vector field is not a trivial task. This is accomplished by using two-dimensional cuts of the velocity field, where the in-plane components are shown using a vector and the total magnitude of the velocity field is shown using color contours, with red signifying high velocity and blue indicating low velocity.

Figure 7 shows vertical cross sections at 2-cm intervals through the bottle (i.e., $z = 0.0$ is 0.0 m from the end wall, and $z = 0.10$ cm is at the symmetry plane in the center of the roller bottle). Figure 7f corresponds to the center of the bottle and is therefore identical to Figure 2b. Moreover, Figures 7d and 7e are also identical to Figure 7f, indicating that end effects play little or no role in the fluid flow past 5 cm from the end of the bottle. The velocity field shows both reflection symmetry relative to the center plane (expected from the symmetry of the boundary) and antisymmetry between the left and right sides of the bottle (expected from the creeping flow condition and the rotational symmetry of the bottle). As discussed next, this observation can have important implications because the flow induced by the end walls of the bottle is the only means of axial mixing.

Figure 7a represents the velocity field at the end of the roller bottle. Due to the no-slip condition at the bottle wall, all fluid follows the bottle wall in a counterclockwise direction. When the fluid reaches the free surface (at the right side), it detaches from the wall and flows outward in the z-direction. At the left side, the fluid immediately adjacent to the wall is drawn downward; this motion is "fed" by an inward flow from the z-direction. Figures 7b and 7c show the presence of a high-velocity component near the surface of the liquid, caused by the end-wall effects. However, detailed examination of the velocity vectors displayed

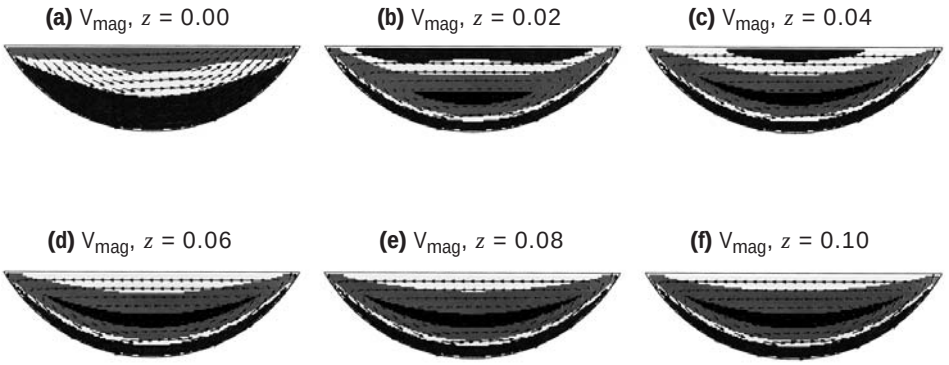

Figure 7. Finite-volume results. Velocity field at several vertical planes spaced along the axis of the bottle.

in Figures 7b and 7c indicates that the *x*- and *y*-components of the velocity field are largely unaffected by end-wall effects; such effects appear primarily in the axial (*z*) component of the velocity field.

The end-wall effects are more clearly shown by a top view of the bottle. Figure 8 shows a velocity contour plot just below the liquid free surface. The end of the bottle is at the bottom of this figure, and the symmetry plane is at the top. Flow in the axial (*z*) direction is clearly visible in this figure. The fluid flows upward from the end wall in the lower right-hand corner, travels in a counterclockwise loop, then flows downward at the lower right-hand corner as a result of the end-wall flow. There is a stagnation point 0.46 cm from the end of the bottle, as shown by the dark blue color. Moving toward the center of the bottle, end effects have less influence on the flow; there is less than 2% difference in the velocity field between the two-dimensional symmetry plane and the plane at 5 cm from the end wall. Similar flow patterns were observed for other values of Re of less than 10.

An alternative illustration of the three-dimensional flow pattern in the roller bottle is obtained by computing the pathlines of the flow. Figure 9 shows six pathlines for fluid particles initially placed 0.2 cm from the bottom of the bottle. The center of the bottle is at the left-hand side of the figure, and the end wall is at the right. Examination of the pathlines from left to right reveals the effect of the end wall on the flow field. The pathline at the center plane is a two-dimensional vertical loop identical to the pathlines observed in Figure 3. Toward the end of the bottle, the pathlines begin to bend near the free surface toward the center of the bottle. All the pathlines shown are closed loops. The pathlines at the center plane of the bottle are two-dimensional loops, and the pathlines away from the symmetry plane are three-dimensional loops. In either situation, however, the same result ensues: fluid particles in the flow remain trapped in the closed periodic orbits and do not contact other portions of the flow. Such regular motion patterns can pose significant barriers to the mixing process. Experimental evidence of this obser-

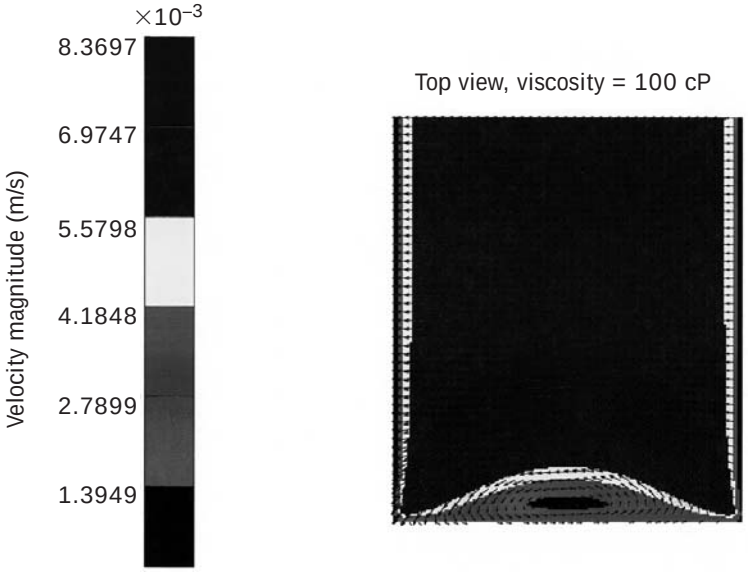

Figure 8. Finite-volume results. Velocity field (*left*) at a horizontal plane near the upper surface of the fluid. *Right*, top view.

vation and approaches for overcoming mixing limitations follow.

The Motion of Cells in a Roller Bottle

The initial point for the modeling of small particles in the flow field is given by the equations of motion proposed by Maxey and Riley (28):

$$m_p \frac{d\mathbf{v}}{dt} = (m_p - m_F)\boldsymbol{g} + m_F \frac{D\mathbf{u}}{Dt} - 6\pi a^2 \mu \int [\pi\nu(t-\tau)]^{-1/2}\left(\frac{d\mathbf{X}}{dt}\right)d\tau - \left(\frac{1}{2}\right) m_F \frac{d[\mathbf{u} - v - (1/10)a^2\nabla^2\mathbf{u}]}{dt} - 6\pi a\mu \boldsymbol{X} \quad (4)$$

where $\boldsymbol{X} = \boldsymbol{u} - \boldsymbol{v} - (1/6)a^2\nabla^2\boldsymbol{u}$.

In these equations, $\boldsymbol{u}$ is the (dimensional) fluid velocity vector, $\boldsymbol{v}$ is the (dimensional) cell velocity vector, a is the cell radius, ν is the fluid kinematic viscosity; and m_p and m_F correspond to the weight of the cell and that of the fluid displaced by the cell, respectively. The five terms on the right-hand side of the equation correspond to buoyancy forces, pressure forces, flow history effects, added mass effect, and Stokes drag forces. This equation can be significantly simplified for the roller bottle problem. Because $\boldsymbol{u}$ is known from the numerical solution of the flow, the relative magnitude of each term can be evaluated. Analysis has shown that the leading order terms are inertia, buoyancy, and drag forces, thus the equation becomes:

$$\frac{d\boldsymbol{v}}{dt} = G\boldsymbol{g} + \frac{1}{S_{tk}}(\boldsymbol{u} - \boldsymbol{v}) \quad (5)$$

where $G = 2(\gamma - 1)gL/[(2\gamma + 1)U^2]$, and $S_{tk} = (2\gamma+1)a^2U/(9\nu L)$; γ is the particle density relative to the fluid density, L is the depth of the fluid, and U is the bottle rotation velocity. If we assume that the particles are cells and the rotation speed and liquid are typical of those used in the biotechnology industry, this equation can be further simplified. Under such conditions, $G \sim O(10^{+3})$ and $S_{tk} \sim O(10^{-6})$, so that the inertial term can be neglected, greatly simplifying the problem. The particle velocity is obtained immediately as

$$\boldsymbol{v} = \boldsymbol{u} + \boldsymbol{V_s}, \quad \boldsymbol{V_s} = \frac{2a^2(\gamma - 1)}{9\nu U}\boldsymbol{g} \quad (6)$$

where $\boldsymbol{v}$, the total particle velocity, is simply the sum of $\boldsymbol{u}$, the fluid velocity, and $\boldsymbol{V}_S$, the particle terminal settling velocity. Once $\boldsymbol{v}$ is known, particle positions are found by numerically integrating the equations

$$\frac{d\boldsymbol{x}}{dt} = \boldsymbol{v} \quad (7)$$

using the standard 4th-order Runge–Kutta method. To understand small particle behavior in a steady rotating roller bottle, equations 6 and 7 are used to simulate the motion of particles on the center plane of the bottle. Figure 10 shows the particle trajectories for a settling velocity $V_s = 0.05\ U$, where U is the nondimensional tangential velocity of the bottle wall. Six particles were initially placed on the vertical center line. The particles showed different behaviors: while the two particles nearest to the free surface reached the rotating wall in a fraction of a bottle rotation, the remaining four particles moved in closed orbits. Such particles will never reach the bottom wall. This simulation indicates that whether a particle settles or not depends not only on its settling velocity, but also on its initial location within the flow field. Moreover, as the settling velocity used in this simulation is much larger than those corresponding to real systems, Figure 10 actually indicates that a substantial fraction of the cells in a roller bottle could actually remain trapped indefinitely in recirculating trajectories within the bottle flow, never reaching the bottle wall.

This simulation result was investigated experimentally by using long-exposure-time photography to reveal the pathline followed by a fluorescent particle with a settling velocity similar to the one corresponding to Figure 9. A 200-μm fluorescent polystyrene particle was placed in the center plane of the roller bottle. This particle had a terminal settling velocity of approximately 0.5 cm/min, or 0.06 U, where U is the linear rotation velocity of the roller bottle. Using long-exposure photography, the particle pathline was photographed for one bottle revolution under fluorescent light (Fig. 11). The original position of the particle was approximately 0.6 length units from the free surface (where the unit length is the height of the fluid). The pathline revealed in Figure 11 closely resembles the pattern shown in Figure 10, which is a simulation for particles of roughly similar settling velocity. When the particle was originally placed in a different location, closer to the bottle center, the particle followed a different closed pathline. When placed close enough to the upper surface, the particle eventually settled and remain attached to the bottle wall.

DETAILED ANALYSIS OF CELL SETTLING

Particle Settling Results

A more complete picture of cell behavior can be obtained by following a large number of particles over a long period of time. Such simulations were conducted by placing 20,000 particles uniformly distributed across the entire central cross section of the bottle and following them for 20 rotations of the bottle. Whenever a particle touched the bottle wall, it was (arbitrarily) assumed that the particle had "settled" and was removed from the simulation. Figure 12 shows Poincaré diagrams obtained from such a simulations for settling velocities $V_s = 0$, 0.02 *U*, 0.05 *U*, 0.1 *U*, and 0.2 *U*. For these simulations, the bottle was rotating counterclockwise at a nondimensional linear velocity of $U = 1.0$. For $V_s = 0$ (Fig. 12a), the structure of the particle positions is identical to those of the flow streamlines, because such particles are in fact fluid particles. As V_s increases, the particle paths are perturbed away from streamlines, but as it is shown in Figure 12b, for $V_s = 0.02$ *U* most particles remain trapped in closed periodic orbits and never reach the bottle walls; only those particles initially very close to the free surface and the bottle wall are able to reach the bottle boundary. As settling velocity increases, more particles settle, but only for large values of V_s (i.e., $V_s = 0.2$ *U*; Fig. 12e) are most particles able to reach the bottle walls.

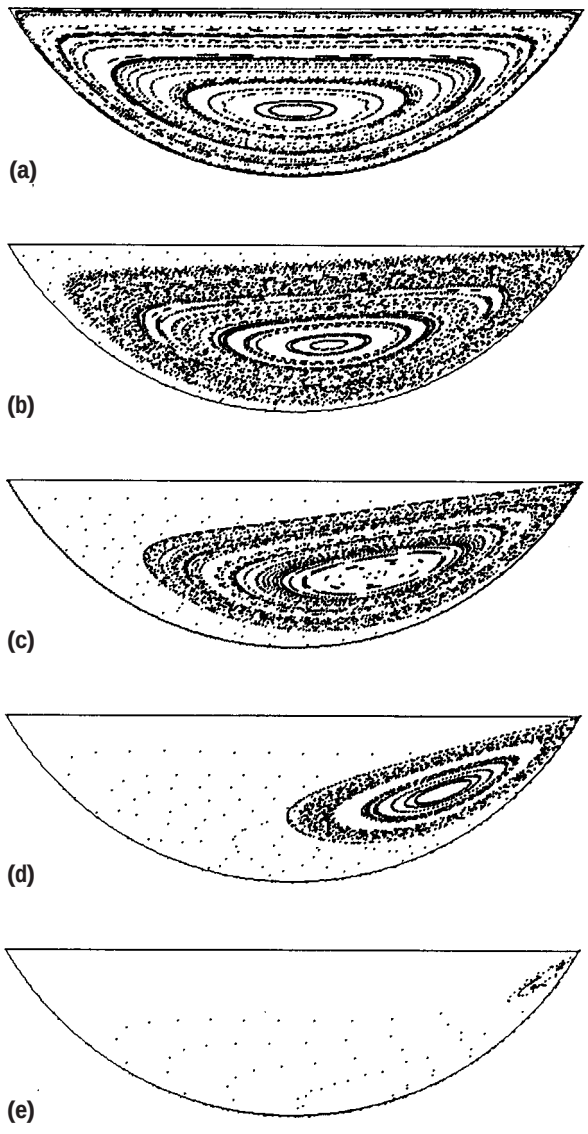

Figure 12. Poincaré diagram of particles, initially distributed uniformly in the central vertical cross section of the bottle, for settling velocities of $V_s = 0$, 0.02 *U*, 0.05 *U*, 0.1 *U*, and 0.2 *U*, respectively, from top to bottom of figure (**a**–**e**).

Although such simulations give information about the dynamic behavior of particle motion, the settling rate cannot be inferred from them. To obtain the spatial distribution of particle settling rate, the settling time of each particle was recorded and plotted as a function of initial particle location. The settling time distribution in the bottle is shown in Figure 13. The bottle is rotated clockwise at a dimensionless linear velocity of $U = 1.0$ at the wall. Results correspond to $V_s = 0.02$ (Fig. 13a), 0.05 (Fig. 13b), 0.1 (Fig. 13c), and 0.2 (Fig. 13d). The colors from dark gray to white represent the particle residence time from 0 to the maximum computing time. The smooth core region in dark gray represents the particles that do not settle at all. For small $V_s = 0.02$ (Fig. 13a), only a narrow strip of particles under the top free surface and near the bottom on the right side of the bottle settle. The width of this strip increases as V_s increases and the size of the red core decreases. The tip of this core region is always at the upper-left corner of the flow and leans to the left side of the bottom of the bottle. At $V_s = 0.1$ (Fig. 13b), most of the particles in the bottle will settle. When V_s is increased to 0.2 (Fig. 13c), almost all the particles settle to the wall. The spatial distribution of particle settling time in the flow is shown clearly by the shades of gray. Short-lived particles are always on the right side of the bottle for this flow direction. If the flow direction were reversed, Figure 13 would appear as a mirror image because of the symmetry of the system. These results clearly reveal that the particle residence time

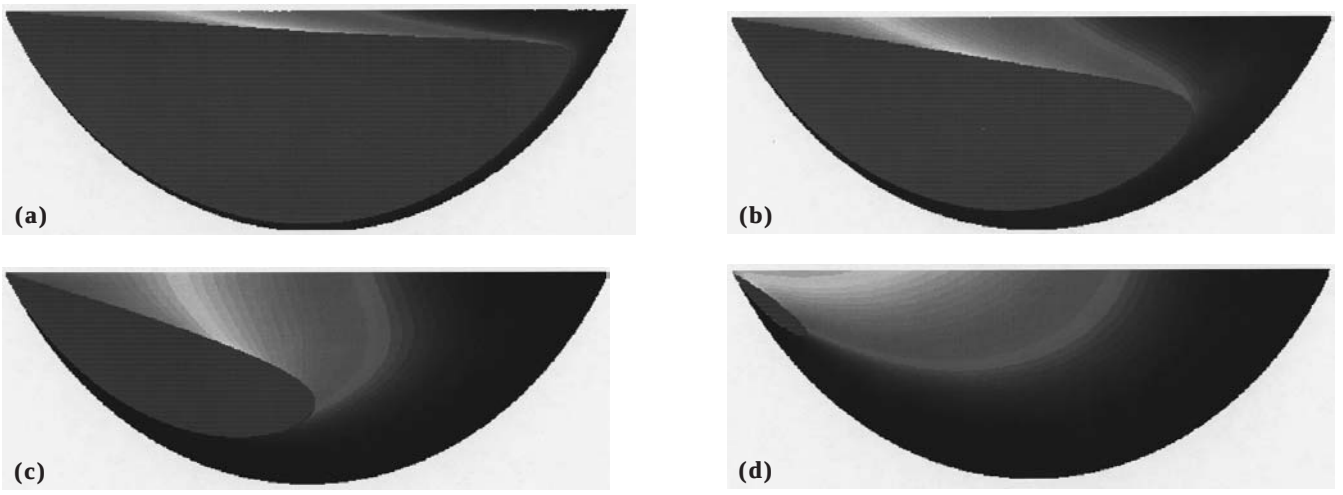

Figure 13. Contour plots of residence time of particles against particle initial position for V_s = 0.02 U, (**a**) 0.05 U, (**b**) 0.1 U, (**c**), and 0.2 U (**d**) after 20 bottle revolutions. The shades in this figure range from dark gray to white, corresponding to zero residence time to infinite residence time.

distribution in suspension is strongly affected by the recirculation of the flow.

The rate of particle settling is shown in Figure 14; the fraction of particles suspended in the flow at a given time is plotted against the dimensionless time, where one bottle revolution corresponds to 12.56 time units. All the settling processes are nonlinear (except for V_s = 0.2). Particles settle to the wall relatively fast at the initial stage, and then the rate of settling (the slope of the curves) levels off in a relatively short time, about 8 to 12 time units. With large settling velocity (V_s = 0.2, the heaviest particles examined), the particles settle at almost a constant rate.

Effects of Bottle Rotation Speed on Cell Culture Experiments

Previous experiments demonstrated that the growth of anchorage-dependent cells and cell culture products (e.g., varicella virus) in roller bottles was much less efficient than that observed in stationary cultures such as T-flasks. It was hypothesized that these differences were caused in part by decreased cell (uninfected and infected cells) sedimentation rates present in the roller bottle cultures as the result of circulating liquid flows that trapped the particles in circular orbits. The decreased sedimentation times resulted in lower cell plating efficiencies for uninfected cells and increased degradation times for virus-infected cells, that were unable to reach the cell culture surface for attachment or infection. To further investigate this hypothesis, the kinetics of virus-infected cell sedimentation and attachment were studied at different rotation rates. The attachment to and growth of cells on the roller bottle surface were also studied to determine the primary mechanism controlling the differences observed in cell growth rates as a function of rotation rate.

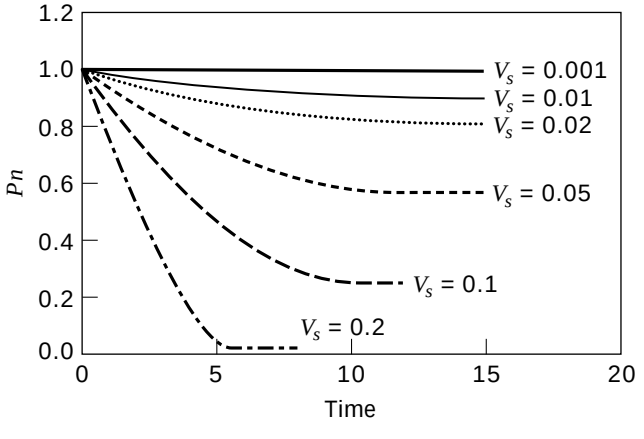

Figure 14. Fraction of particles (Pn) suspended in the flow as a function of time for varied settling velocities (V_s).

Materials and Procedures. Oka strain of varicella was obtained from the Biken Institute, Japan. MRC-5 cells were obtained from ATCC or NIBSC and used to generate a manufacturer's working cell bank (MWCB) at Merck. MEM was manufactured by Merck and supplemented at the time of use with fetal bovine serum (FBS), neomycin, and glutamine. Eagle's basic medium (BME) was purchased from Gibco. Horseradish peroxidase–conjugated donkey antigoat antibody (affinity-purified F[ab′]2 fragment) was obtained from Jackson Immunoresearch Labs (West Grove, Pa. [Cat# 705-036-147]). Goat antivaricella antiserum was obtained from Lampire (Lot 2200). 3,3-Diaminobenzidine (DAB) was obtained from Sigma, prepared as a 25 mg/mL solution in water, and stored at −20 °C. Immediately before use, DAB stock solution was thawed and diluted with a peroxide/nickel enhancing solution (Amersham) in phosphate buffer.

A freshly trypsinized, concentrated cell suspension was placed in roller bottles with MEM growth medium supplemented with 10% FBS, 50 μg/mL neomycin, and 2 mM glutamine. The bottles were incubated at 37 °C and rotated at the desired rate. After 4–6 days (depending on the process used), the roller bottles were refed with fresh nutrient

medium. Roller bottle cultures with an established cell monolayer on the roller bottle surface were infected by the addition of freshly trypsinized, varicella virus-infected MRC-5 cells. The infected cells were added to the liquid nutrient medium in the roller bottle 6–8 days after the initial roller bottle cell plant. Particle counting and size analysis utilized an Elzone particle size analyzer model with a 48-μm orifice.

An in situ immunostaining procedure was used. The medium was aspirated from the culture vessel (T-flask or roller bottle) using vacuum. The culture vessel was then rinsed three times with PBS with 1% BSA. After the final rinse with PBS, a fixing solution of 5% acetic acid, 5% water, and 90% methanol was added to the culture vessel and exposed to all surfaces for 15–30 min. The methanol is then aspirated from the culture vessel with vacuum. The culture vessels are then rinsed three more times with PBS, and stored with a PBS overlay at 4–8 °C until stained. Immunostaining of the fixed bottles was carried out by a dual antibody method. First, 2–3 mL of a 1:500 dilution of goat antivaricella antiserum in PBS with 1% BSA was added to the culture vessels, covering the entire growth surface of the T-flask and a 3- to 4-cm-wide strip along one side of the roller bottle. The vessels were then placed on a rocker platform and rocked gently at room temperature for 1–2 h to allow binding of the primary antibody. The culture vessels were then rinsed three times with PBS to remove unbound antibody, and 3 ml of a 1:500 dilution of the anti-goat antibody was added. The vessels were again incubated at room temperature with gentle rocking for 30–45 min. Unbound secondary antibody was then removed by three PBS rinses. Then, 10 mL of peroxidase substrate solution was added to each culture vessel and the vessels were incubated at 37 °C until foci of infected cells appeared. The peroxidase solution was then aspirated from the vessels with vacuum and the vessels again rinsed three times with PBS. The stained areas were left under a PBS overlay, and the vessels were stored at 4–8 °C. Infectious foci were counted using a microscope at 10× magnification.

Varicella plaque assay was conducted in the following manner: MRC-5 cells were grown in 60-mm plates with 5 mL/plate of BME with 10% FBS, 0.2% glutamine, and 0.05% neomycin; 10 plates were prepared per sample with 5 plates per dilution. The plates were then incubated at 35.5 °C with a 3% CO_2 gas environment for 2 days. Before addition of the samples, the cell growth medium was removed and 5 mL/plate of MEM with 2% FBS, 0.2% glutamine, and 0.05% neomycin was added to each plate. Diluted virus samples of 0.1 mL were added to each plate. Samples were diluted to ensure a plaque counting range of 15–80 plaques per plate. The plates were mixed well and incubated for 7 days at 35.5 °C with a 3% CO_2 gas environment. Following incubation, the medium was removed by aspiration and 2 mL of 0.2% Coomassie blue stain in 100% ethanol containing 1% v/v glacial acetic acid was added to each plate. After 15 min at room temperature, the stain was removed and the plate was rinsed with cold water. The plates were inverted to dry. Plaques were then counted in each plate using a light box to assist in visualizing the plaques.

Results. In the first study, the kinetics of virus-infected cell sedimentation and attachment were studied at three rotation rates: 0 (T-flask stationary culture), 1/4 rpm (roller bottle culture), and 1/2 rpm (roller bottle). A monolayer of MRC-5 cells was established on the surface of the T-flasks and roller bottles. Following growth of these cells to confluence, varicella-infected MRC-5 cells in nutrient medium were added to the T-flasks or roller bottles and rotated at 0, 1/4, and 1/2 rpm. Samples of the supernatant were collected at various times from 0 to 36 h and were measured for infected cell number remaining. At the same time intervals, flasks and roller bottles were sacrificed and stained with a varicella-specific monoclonal antibody marker to determine the number of infectious foci on the cell monolayer. Infectious foci appear when an infected cell has attached to, fused with, and infected a cell attached to the roller bottle surface followed by infection of neighboring cells. Thus, the disappearance of infected cells from the supernatant could be correlated to the appearance of infectious foci on the cell monolayer (where it is assumed that one infected cell equals one infectious focus).

The infectivity of varicella-infected cells degrades exponentially at culture temperatures. To optimize the use of this material and to provide for as synchronous an infection as possible, the time that the infected cells remain in solution is to be minimized. Figure 15 demonstrates that as the rotation rate is reduced the fraction of infected cells remaining in the supernatant decreases at a given time. This finding is further supported by the increased appearance of infectious foci on the cell monolayer (Fig. 16) as the rotation rate is decreased, thus establishing the correlation between number of infected cells disappearing from the supernatant with the increase in infectious foci. Additionally, a mass balance was performed to demonstrate that as a function of time the appearance of infectious foci equaled the initial number of cells in the supernatant minus the intrinsic degradation rate in solution (degradation rates were determined from independent experiments).

In the second study, lower rotation rates were used to further optimize the roller bottle rotation rate for the infection of the cell monolayer. Rotation rates lower than 1/8 rpm were not selected because the cell monolayer remains without nutrient medium coverage for too long, resulting in poor cell growth and viability. Thus, the following three rotation rates were selected in the second study:

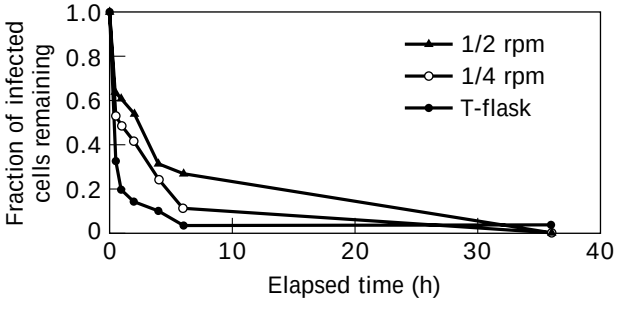

Figure 15. Fraction of cells remaining in the supernatant as a function of roller bottle rotation rate (rpm).

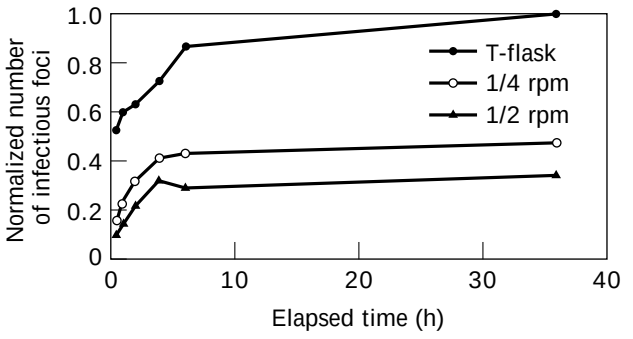

Figure 16. Quantity of infectious foci on the cell monolayer as a function of rotation rate (rpm).

0 (T-flask stationary culture), 1/8 rpm (roller bottle culture), and 1/4 rpm (roller bottle). In Figure 17, the disappearance of infected cells correlates with a decrease in rotation rate, further supporting the hypothesis.

In the final study performed, cell growth rates and final cell densities were determined as a function of roller bottle rotation rate to evaluate if rotation rate was a critical parameter in achieving high cell densities once the cells attached to the culture vessel surface. Two rotation rates were evaluated in this study: 1/4 and 1/2 rpm. Higher cell numbers were achieved when higher rotation rates were utilized (Fig. 18). The higher cell densities as rotation rate is increased may be attributed to improved transport of nutrients, gases, and waste products to and from the bulk

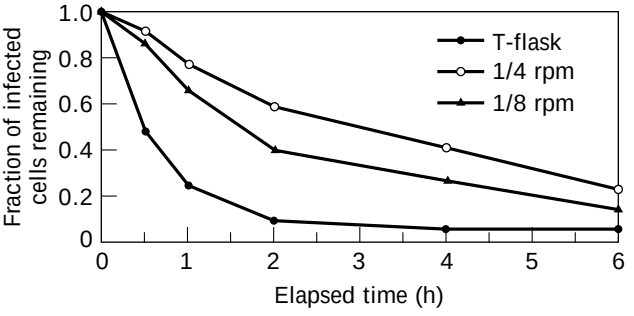

Figure 17. Fraction of infectious foci on the cell monolayer as a function of rotation rate, for lower rotation rates.

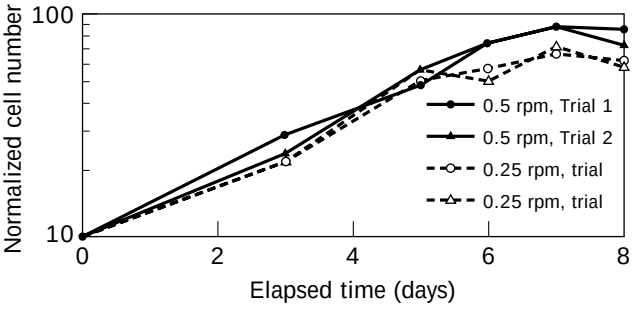

Figure 18. Cell growth rates and final cell densities as a function of rotation rate.

solution to and from the cell monolayer. The results of this experiment pointed to the need to further optimize the cell proliferation steps of the process. These studies were carried out, and the resulting process has shown much greater productivity (data not shown).

The liquid flow modeling shows good qualitative agreement with the experimental data. In both cases, the settling dynamics are nonlinear, in which the rate at which particles are removed from the suspension starts out high and decreases thereafter. In addition, the model correctly predicted that decreases in rotation rate resulted in improved sedimentation of cells onto the cell monolayer.

IMPROVING THE PERFORMANCE OF ROLLER BOTTLES

Using Unsteady Rotation to Enhance Settling

Comparison of Figure 3 and Figure 12 indicates that incomplete settling is caused by the strong recirculation present in the flow, which in two-dimensional cuts of the flow field causes the flow to behave as sets of nested closed loops. When a particle is in the lower part of the flow (below the stagnation point), it falls through loops toward an outer loop. However, if the particle does not reach the wall, it then moves to the upper part of the flow and then falls toward an inner loop. The combination of these two effects causes the particle to move up and down in an closed orbit. In fact, without Brownian motion a particle can exhibit only one of two phenomena: settle to the bottom of the bottle or move in a closed orbit.

Intuitively, such closed orbits can be disrupted by perturbing the flow in a time-dependent manner, perhaps resulting in enhanced settling. This hypothesis was tested by examining settling in time-periodic flows, which are the simplest and most easily controllable time-dependent flows. There are different ways of introducing time periodicity into the flow. A simple approach is to reverse the flow direction periodically. For the creeping flow used in this study, transient effects that occur when the flow reverses direction are negligible because inertial terms in the Navier–Stokes equations are very small; therefore, the periodic flow can be simulated using two identical steady flows that are mirror images of each other, each one acting for a predetermined amount of time in an alternating fashion.

Although mixing of passive tracers will not improve at all in such a periodic flow because the tracers would simply move back and forth along the same streamlines, settling of heavy particles is greatly enhanced by periodic reversal of the direction of rotation. The settling behavior of particles depended strongly on the value of the flow period T, defined as the total displacement of the bottle wall (measured in dimensionless units, where one unit is equal to half the depth of the liquid) between a pair of reversals (i.e., a flow period). For example, if the bottle completes a rotation between reversals, the flow period is two total rotations and one obtains a value of $T = 25.13$. For some values of T, complete settling can be achieved in short times even for a much smaller settling velocity than those studied for steady flow.

The particle settling rate in the periodic flows was studied by placing 6,540 particles uniformly in the flow domain.

As before, particles that hit the wall were considered to be settled at the wall. Two small values of settling velocity were studied, $V_s = 0.002$ and 0.005. The particles were followed for 30 periods for each case, and the fraction of particles suspended in the flow was plotted against time. The results for $V_s = 0.005$ are shown in Figure 19, which demonstrates that the settling processes for all values of T are linear. At small values of T, $T < 25$, almost all particles settle very fast, and the smaller the value of T, the faster the settling. However, at $T = 25$, almost no settling occurs, and the same behavior is observed for $T = 50$. The particle settling rate increases from small T to $T = 25$ and then decreases until $T = 35$. The settling rate for $T = 35$ and 40 are about the same during most of the flow process, except at the later stage when settling in the $T = 40$ case continues at a linear rate while settling in the $T = 35$ case slows down. Therefore, the fastest settling is achieved at small T or between $T = 35$ and $T = 40$. Of those two conditions, the latter is preferable because for $T < 25$, the bottle does not complete a rotation between reversals, and therefore some regions of the bottle wall never touch the liquid. Such a condition would lead to drying and lysis of the cell monolayer in such regions of the bottle wall and therefore to reduced process efficiency.

Using Rocking Motion to Enhance Axial Mixing

As mentioned, the flow patterns revealed by simulations suggest slow fluid mechanical mixing, especially in the axial direction. This expectation was confirmed experimentally by using a pH indicator (bromothymol blue) and an acid–base neutralization to study mixing behavior (29). The experiments were carried out on an apparatus that consisted of a set of rollers whose rotation speed and direction were accurately controlled by a computer (Fig. 20). To achieve flows within the creeping regime, glycerin was used as the working fluid. The glycerin initially was mixed with the indicator and 0.5 mL 1 M NaOH, causing the glycerin to turn a deep blue color. With the roller bottle on the apparatus, approximately 20 mL of glycerin was then removed from the bottle with a syringe and mixed with 1.0 mL of 1 M HCl, turning the fluid yellow. This fluid was then injected back into the roller bottle near the back wall (the bottom of the bottle when upright) with a syringe and carefully mixed with the surrounding fluid at the base of the bottle using a specially modified spatula.

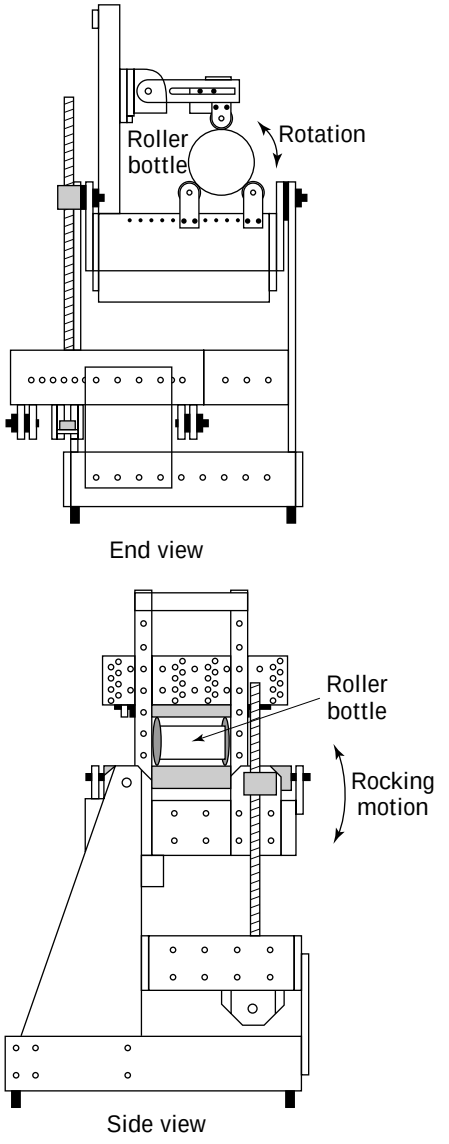

Figure 20. Experimental apparatus used to investigate mixing enhancement by introduction of rocking motion.

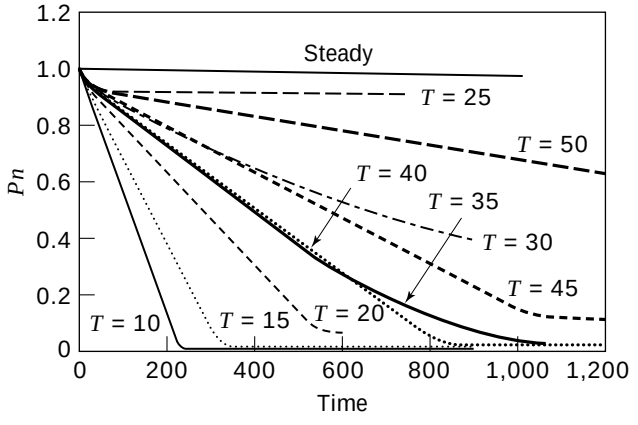

Figure 19. Fraction of particles (Pn) suspended in the flow as a function of time for varied period lengths. The settling velocity for all figures was the same, $V_s = 0.003$ U.

After the acidic glycerin was injected back into the roller bottle, the mixer was turned on and the bottle was rotated at constant speed. Figure 21a–c shows the results of this experiment. The initial condition is shown in Figure 21a, mixing after 32 revolutions in Figure 21b, and 64 revolutions in Figure 21c. These figures clearly reveal the effect of the symmetry plane located in the center of the bottle. After 32 revolutions, mixing within each half of the bottle is complete. This mixing results from the axial motion of fluid caused by the end-wall effects. However, even after 64 bottle revolutions, mixing is minimal between the two halves of the bottle; neutralization of the base on the right-hand side will occur only through the action of diffusion.

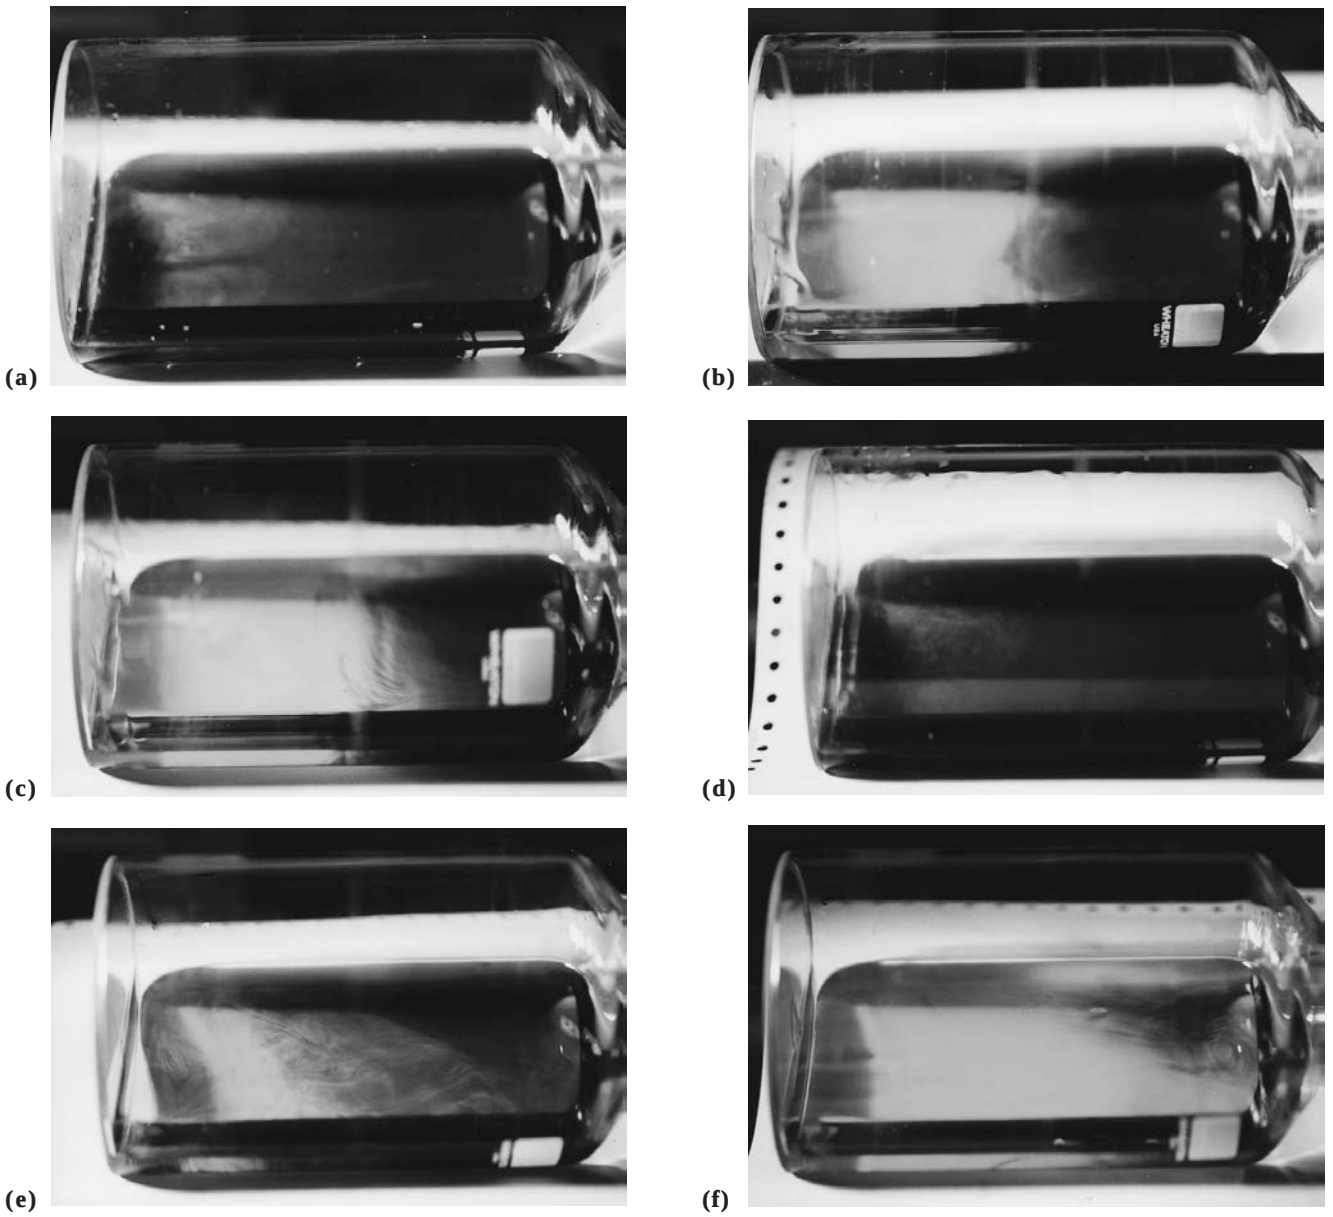

Figure 21. Results from mixing experiments performed (**a–c**) without rocking motion, corresponding to (**a**) the initial condition, (**b**) 32 revolutions, and (**c**) 64 revolutions; (**d–f**) with rocking motion at amplitude of 12 degrees, frequency equal to 1.6 revolutions per rock, corresponding to (**d**) the initial condition, (**e**) 32 revolutions, and (**f**) 64 revolutions; and (**g–i**) with rocking motion at amplitude of 12 degrees, frequency equal to 3.2 revolutions per rock, corresponding to (**g**) the initial condition, (**h**) 32 revolutions, and (**i**) 64 revolutions.

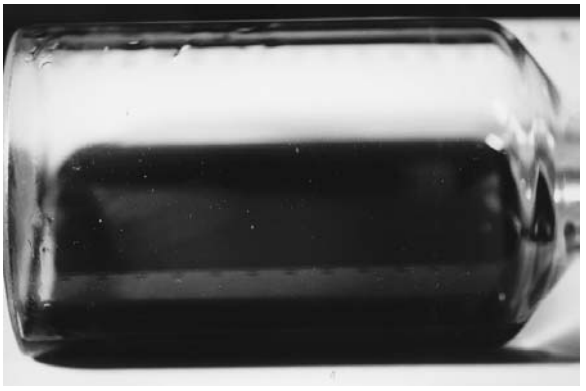
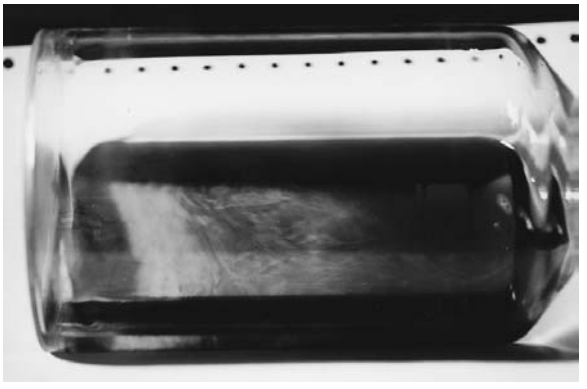
Recent experiments dealing with mixing of dry powders in a rotating and rocking cylinder have shown that a small-amplitude rocking motion in the vertical direction can greatly enhance mixing in the axial direction (30). This approach was implemented here to attempt to enhance mixing in the roller bottle. Two conditions were examined: (*1*) mixing at a rocking frequency of 1.6 bottle revolutions per rocking cycle and (*2*) mixing at a rocking frequency of 3.2 bottle revolutions per rocking cycle.

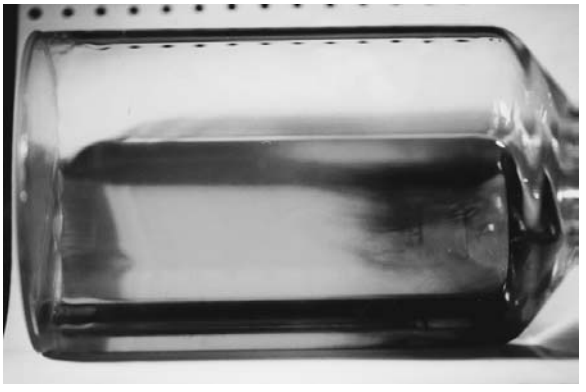
Figure 21d–f represents the effect of rocking on mixing in the system. The roller bottle was rocked approximately 12 degrees at a rocking rate of 1.6 bottle revolutions per rock, and mixing improved substantially in the system as a result of the rocking. Similarly, Figure 21g–i represents mixing for a rocking rate of 3.2 bottle revolutions per rock; rocking indeed enhanced mixing, which is essentially complete after 64 revolutions. Moreover, because rocking disrupts the recirculating flow patterns described earlier, it is also likely to disrupt cyclical cell motions and enhance settling. It is important, however, to realize that if rocking were used to enhance mixing in a cell growth process, the choice of rocking frequency and amplitude should take into



(g)



(h)



(i)

Figure 21. Continued.

account the need to keep the cells submerged in the nutrient medium as uniformly as possible. If an integer number of revolutions per rocking cycle were chosen, then the cells at the top of the bottle when the rocking reached its maximum angle of inclination would always be the same and would be exposed to nutrients for a substantially shorter fraction of time than those at the bottom. The rocking frequencies of 1.6 and 3.2 revolutions per rocking cycle were chosen because these frequencies should keep the cells fairly uniformly exposed to the nutrients, although the cells closer to the neck of the bottle will still be exposed less to the nutrients.

CONCLUSIONS

The three-dimensional flow in a roller bottle was simulated using a finite-volume method and used to study the particle settling behavior in the bioreactor. From the steady flow simulations of cell motion in two-dimensional cuts of the velocity field, it was shown that a large number of particles in the flow remain trapped in circulating loops and never reach the walls of the roller bottle. Only for large settling velocities (i.e., $V_s = 0.2\,U$) do most particles reach the bottle walls. Thus, in many situations, poor mixing and settling of cells could occur.

It was shown that settling could be enhanced by destroying the closed-orbit motion of the cells. A simple time-dependent flow that periodically reversed the rotation direction was an effective approach for this purpose. Particles were found to settle faster for small values of the flow period T, but such short periods are undesirable because such conditions fail to wet the entire bottle wall, which is essential to keep the cell monolayer intact and viable. Longer periods were also shown to be effective for enhancing settling, and nearly optimal values were identified.

Major limitations in mixing performance in the axial direction were caused by the presence of a vertical plane of symmetry at the center of the bottle. Such limitations, however, can be readily overcome by introducing a small-amplitude vertical rocking motion that disrupts the plane of symmetry, leading to much faster and complete axial mixing. The frequency of such motion was shown to have a significant effect on mixing rate. Additional work is needed to identify optimum values of frequency and amplitude.

OUTLINE

INTRODUCTION

To optimize fermentation processes, that is, to ensure maximum growth and/or productivity, the fermentation conditions should be controlled and maintained at their optimum values. However, the media for fermentations and other bioprocesses are very complex in nature. These are often multiphase systems. The liquid phase contains soluble nutrients (e.g., sugar, proteins, vitamins, salts, and products of metabolism such as amino acids, alcohols, and organic acids). Furthermore, there may be a solid phase of suspended material (insoluble substrate/product, carrier materials, etc.). The gas phase is in equilibrium with dissolved gases in the medium. Analysis of any of these compounds by traditional techniques is tedious and time-consuming and cannot provide on-line information of the process. Recently, the increasing demand of high-value products has focused interest on well-controlled, optimized processes. This has initiated the development of new on-line measurement techniques (1–3). The ideal situation would be to have specific probes that can operate in situ during the fermentation. However, at present there is only a limited number of such probes available for measuring pH, dissolved oxygen, and carbon dioxide. There is still no suitable technology for operating biosensors containing a biological macromolecule. In the last few years research on biosensors for bioprocess control has been growing. These sensors offer the ability to measure concentrations of various biomolecules, as well as biological parameters, very specifically using immobilized enzymes or cells or other biochemical/biological entities. Unfortunately, these sensors are inactivated by steam sterilization (4). Because sensor technology is not yet sufficiently advanced to permit this type of monitoring, the majority of analysis is still carried out outside of the bioreactor, a process requiring sampling and sample-handling strategies. This review highlights the importance of sampling and sample handling and the techniques used.

STRATEGIES FOR SAMPLING

For analysis of any bioprocess, off-line or on-line sampling is a prerequisite and is the basis for the final analytical result. The following strategies/criteria are important when designing a sampling device (5).

1. The sterility of the process must be maintained during sampling.
2. The delay between sampling and analysis may result in changes in the composition of the sample. Precautions must be taken to prevent or compensate for that.
3. The analysis must be accurate and reproducible.
4. When constructing the sampling and sample treatment unit, the selection of material must be governed by compatibility criteria such that the process being monitored is not negatively influenced.
5. Protein adsorption and cell colonization on the sampling and sample-handling device may lead to an imparted mass transport and formation of unwanted immobilized catalytic activities that may severely influence the composition of the sample before analysis can be carried out.

Considering these parameters, a sampling system for on-line monitoring of fermentation processes must meet the following criteria.

1. The system can take representative samples from fermenter but should not disturb the fermentation process.
2. The system should be sterilizable and provide a sterile barrier to avoid contamination.
3. Separation of cells, solids, or macromolecules should be carried out with as short a delay as possible within the sampling devices (6).

There are many different types of sampling units available to achieve these goals (7). This review highlights a detailed description of some of the sampling devices used for on-line monitoring of bioprocesses, especially when biosensors are used in the analytical step. It should, however, be stressed that the sampling and sample handling as described here will be applicable when setting up any kind of analysis to monitor a bioprocess. Figure 1 presents a schematic description of different sampling modes.

NATURE OF THE SAMPLE

The character of the reaction mixture to be sampled determines the choice of sampling method. Different kinds of analytes require different sampling protocols.

Volatile Compounds and Compounds Present in Gaseous Phase

Volatile compounds may be present in the head space of a fermentation or be dissolved in the liquid medium. At equilibrium, the concentration in the head space reflects that in the liquid. The composition of the gas phase is usually less complex than that of the aqueous phase; therefore, when the metabolites are volatile, it is probably simpler to monitor the concentration in the gas phase. The risks of infection of the fermentation are lower when sampling from the gas phase. This has made it attractive to use analysis of the gas phase when monitoring industrial fermentations.

There are two main modes described in the literature for the sampling of gases and volatile compounds:

1. Analysis of the outlet gases or of the headspace gases.
2. Analysis of the volatile gaseous compounds dissolved in the culture medium.

A sampling method is applied that is based on a technology for supplying oxygen to bioprocesses that are disturbed by bubbling oxygen. Oxygen is supplied in a tubing made of hydrophobic material. The oxygen penetrates the walls of the tubing and is released to the cultivation broth. Similar phenomena can take place for gaseous compounds with an opposite concentration gradient (8). Tubings made from materials that are permeable to organic solvent molecules are immersed in the fermentation broth, and an inert gas that flows through the lumen of the tubings transports the solvent molecules to an analyzer (e.g., a gas-sensitive semiconductor sensor placed downstream of the tubing) (9,10).

Recently a new approach for monitoring carbon dioxide during fermentation was reported based on a piezoelectric crystal (11). A change in the oscillation frequency of the crystal occurs due to selective sorption of a gaseous compound to the surface, and the change in frequency is directly proportional to the mass deposited. Fast response, simple use, and low cost may lead to a more extensive use of this technique. More details on sampling of gases during fermentations are described in the literature (12,13).

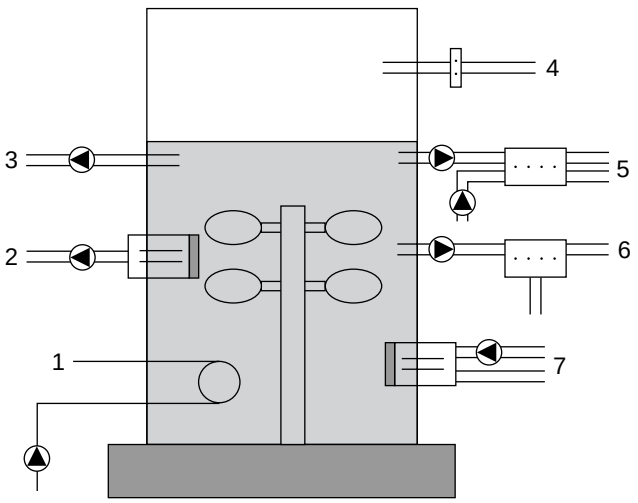

Figure 1. Schematic presentation of different modes of sampling from a bioreactor. The different concepts are (1) dialysis, (2) a membrane unit for removing a particulate-free sample from the turbulent liquid around the impeller, (3) direct sampling, (4) sampling of headspace, (5) sampling and filtering the sample outside the fermenter using a receiving buffer to catch the permeate, (6) sampling with filtering where the permeate is collected, (7) a membrane dialysis probe with the receiving buffer being pumped through the unit.

Analysis of Nonvolatile Compounds

Analytes Dissolved in the Liquid Medium. Automatic sampling, either continuously or by a frequently repeated procedure, is a prerequisite for on-line or "at-line" monitoring. The sampling system normally serves also as a sterile barrier between the bioreactor and the analytical system. Different analytical systems can be used. Flow injection analysis (FIA) is a common and convenient way to carry out the analysis (14). The samples are heterogeneous, with compounds dissolved in the medium, some forming complexes with other constituents, some not fully soluble, some particulate, and so forth. Manual sampling and off-line analysis are still in practice; however, they result in delays in analysis, risks of infection, and less reproducible sample handling (15). Sampling can be done using sampling units mounted either inside or outside the bioreactor. Several systems of both kinds have been reported recently (16,17). The advantages and disadvantages of internal and external sampling modules are presented in Table 1.

Table 1. Advantages and Disadvantages of Internal and External Sampling Modes

Mode of sampling	Advantages	Disadvantages
In situ modules	Short answering time, simple design, less contamination, suited for coupling on on-line analyzers	Problem of long-term stability, not exchangeable, adhesion of microorganisms and fouling, positioning is crucial, size limitation
External modes	Exchangeable, suited for coupling of on-line analysers	Complex design, longer answering time, fouling, shear stress

Direct Sampling. Direct sampling from a bioreactor is possible through a catheter with a small inner diameter. It is possible to connect this sample stream directly to a FIA system or any other analytical device. However, for precise measurements, the metabolic activity in the sample must be stopped immediately after sampling, otherwise unwanted reactions may take place during the period after sampling but before analysis. If a deactivation is carried out with addition of an inhibitory agent (18), one has to examine the possibility of interference from the reagent on the analysis (19).

One device that addresses these challenges is the coaxial catheter unit (20,21), which is connected to the bioreactor for direct sample withdrawal. It consists of two concentrically placed tubings, an inner and an outer (Fig. 2); the outer protrudes beyond the inner a few millimeters. The sampling is done via the inner tubing. An inhibitor is fed into the space between the tubings, and the broth plus the inhibitor are mixed in the small mixing zone at the tip of the catheter. Inhibition thus takes place at the moment of sampling. A major advantage of the direct sampling system is that a complete sample is obtained, and it is therefore possible to measure the biomass concentration on-line (22) and even perform analysis on intracellular compounds (23,24). The coaxial catheter has not yet been used for sample withdrawal from cultures of filamentous fungi and highly viscous fluids. This method is so far limited to studies of unicellular organisms.

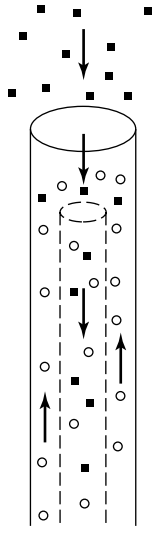

Figure 2. The coaxial catheter. The unit consists of two concentrically placed catheters, the inner being a few millimeters shorter that the outer. Sample is sucked into the inner and is transported away for analysis. The space between the two catheters is used to transport an inhibitor solution toward the tip of the coaxial catheter, where it is mixed with the sample and then withdrawn. If the inner catheter sucks at, for example, double the rate of the inhibitor feed, one volume inhibitor is mixed with one volume of sample and then transported to analysis.

Membrane-Based Sampling Techniques. The sampling system acts as an aseptic barrier between the bioreactor and the analytical equipment. The basic idea behind this type of sampling device is to utilize a membrane for separation during the sampling process. In most cases separations based on differences in size are carried out. The membrane-based sampling techniques can also be applied to cultures of filamentous fungi and in other viscous media. The major disadvantage of the membrane module is clogging of the membrane, mainly due to deposition of proteins on the membrane surface. Reviews on membrane modules are present in the literature (3,25,26).

When using a membrane sampling module, there are three types of separation forces that can be utilized: pressure-driven difference, concentration difference, and electrical potential difference. Applying any of these forces, transport over the membrane will occur and may serve several purposes:

1. Cells are removed from the sample, thus stopping the metabolic activity.
2. Compounds that may interfere with the analysis are retained.
3. Membrane sampling acts as a barrier between the analytical system and the bioreactor.

The details of four major types of membrane separation processes, used in combination with FIA, are presented in Table 2.

Membrane modules can be categorized into two groups: those placed in a recycle loop connected to the bioreactor (filtration outside the reactor), and those placed in situ (as with dialysis filtration). When the membrane unit is placed outside the reactor, fermentation broth is usually pumped through the membrane unit and then recycled to the fermentor. Some characteristics both pro and con of such a device are listed in Table 3.

What is special with the external loop membrane unit is that upon passage of the fermentation broth through the loop, special conditions may prevail. Thus, oxygen limitations may be severe, and, damaging shear forces may appear. This type of device is thus less suited to dealing with high-cell-density fermentations of aerobic cells or with

Table 2. Membrane Separation Procedures Used for Sampling

Mode of separation	Particles separated	Driving force
Filtration	Water and dissolved species	Gravity
Microfiltration	Water and dissolved species (possible to separate unicellular organisms)	Pressure difference
Ultrafiltration	Water and salts (separates biologicals, colloids, and macromolecules)	Pressure difference
Electrodialysis	Charged molecules and ions	Electrical potential
Dialysis	Low molecular weight species	Concentration difference

Table 3. Advantages and Disadvantages in Using a Membrane Unit Placed Outside the Bioreactor

shear-stress-sensitive cells. The great advantage to using an external membrane is the greater flexibility. Thus, a membrane may be easily replaced when needed.

There are two basic modes of operation: the permeate may be collected and used for analysis, or alternatively, a receiving buffer is pumped through the unit on the collection side of the membrane to collect substances passing the membrane. It is important that analyte collection is carried out under sterile conditions. This is usually secured by intermittent sterilization (27–29).

The membranes used for external filtration are made of a variety of materials (e.g., nylon, polypropylene, acrylnitril copolymer, cellulose acetate, cellulose nitrate, polyvinylpyrroliden fluoride) and are available in different pore sizes. Normally, membranes with pore sizes of 0.2 μm are preferred because they guarantee the separation of medium from the biomass and other suspended material (30). Sampling units with external filters are available commercially. The Bio-Pem (B. Braun, Melsungen, Germany) consists of a chamber (vol. 175 mL) containing a magnetically stirred rod. The stirrer ensures a tangential flow across the membrane, which is placed in the bottom of the chamber (31). This unit was successfully used for sample withdrawal during a cultivation process involving unicellular microorganisms but was found unsuitable for sampling cultures of fungi. A major draw back of the Bio-Pem is the large dead volume in the membrane module, which may cause substrate depletion in the loop as well as high response times. An alternative method involves a cross-flow filtration module in which the dead volume is less, resulting in a much shorter response time ($<$10 s). This module is applied efficiently in fed-batch penicillin fermentations on complex media (32) and for wastewater treatment (33).

There is still another unit based on a planar membrane (Fig. 3). The membrane is clamped between two metal blocks, which are then screwed together. During filtration, the incoming broth (feed) is pumped into grooves in the upper block, and the filtrate is collected in the lower chamber. The broth is separated into two streams: the particular-free filtrate (permeate), which passes the membrane, and the particulate-enriched retentate, which is returned to the fermentor. The filtrate is then led to an injection loop for later injection into the analytical system. After passing the loop, two possibilities arise: the filtrate is either returned to the bioreactor or sent to the waste collector. The latter would quickly empty a small fermentor. To avoid this, the filtrate can be recycled to the fermentor, but this increases the risk of contamination. Placing a sterile barrier (e.g., a microfilter) between the injection loop and the bioreactor reduces the risk (34). This may be acceptable in microbial fermentations, but in certain types of processes, such as human cell line production, such a strategy cannot be applied because such cells are very slowly growing and must be cultivated during long time periods and at the same time have a high value. An alternative approach is called discontinuous filtration. The filtrate line is closed between injections and opened shortly before the injection to flush the tubings and the loop (35).

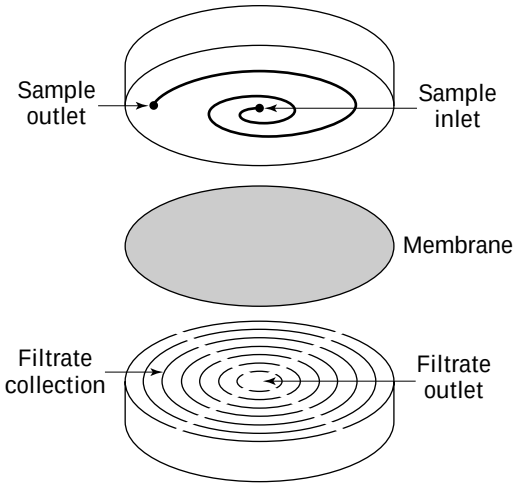

Figure 3. Schematic presentation of the flux membrane dialysis module. The membrane is mounted between the two holders, and sample is introduced on one side. The filtrate is collected and transported for future analysis.

There are several units with planar membranes available on the market. These units have been used for different applications. The A-SEP TM module (Applicon, Schiedam, The Netherlands) has been used for monitoring acetate and phosphate during *Escherichia coli* fermentations (36), utilizing a standard 47-mm-wide 0.45-μm MF membrane. The Minitan TM system (Millipore, Bedford, Mass.), using two membranes, has been employed for the determination of glucose in *Candida rugosa* cultivations

(37), followed by several others for the determination of glucose, diols, and ethanol (38,39).

Membrane filters may also be available in the form of hollow fibers of different diameter and porosity (Fig. 4). Depending on the intended application, the cartridge contains different numbers of hollow fibers. In accordance with the cross-flow filtration principle, the medium is pumped at high velocity (1 m s^{-1}) through the fiber. A pressure is applied, and the filtrate is collected on the outer side of the fibers. It is also possible to pump the broth on the outer side of the fiber(s) and collect the filtrate inside (40). However, depending on the membrane geometry, this latter may be less attractive. When dealing with anisotropic membranes it is advisable to apply the complex medium to the smooth side of the membrane.

A range of different applications are described in the literature. A stainless steel module with only one fiber inside has been reported (41). The fiber had an inner diameter of 5.5 mm and a length of about 200 mm. The dead volume of the module was 2.5 cm^3; and it was successfully used for sampling in conjunction with determination of ammonium, glucose, and phosphate. Reports on the use of several in-house built hollow-fiber modules can be found in the literature, covering vastly different applications in mammalian cell culture (42), lignocellulose hydrolysate fermentations (43), and biodegradation of naphthalene sulphonic acid (44). Systems are also available commercially from Bio-FIO (Glasgow, U.K.) and used for monitoring different types of fermentation components (45,46).

Despite the potential complications associated with operating an external loop filtration system, it remains a popular approach. The great advantage is that when membrane clogging occurs, it is possible to intervene without ruining the fermentation.

In dialysis, a membrane is used to separate a complex solution from a more well defined solution. Pores in the membrane allow exchange of small molecules between the two liquid volumes. The driving force is concentration difference. The different modes of dialysis originate from whether the donor and acceptor phases are stagnant or moving. In equilibrium dialysis both are stagnant and, at equilibrium, the concentration in both phases will be the same of those molecules able to pass the membrane. In continuous dialysis, compounds passing the membrane are continuously removed. This results in a larger concentration gradient, and a higher flux is maintained.

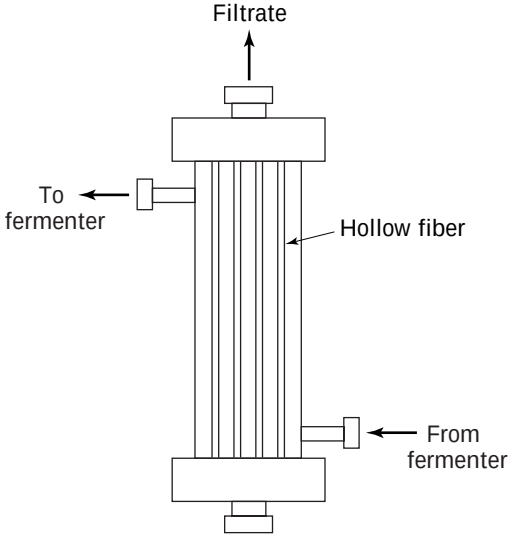

Figure 4. Schematic presentation of the hollow-fiber modules for sampling. A perfusion buffer is passed through the lumen of the fibers, and the fermentation broth is introduced on the shell side of the unit.

The membranes used for dialysis are classified according to their molecular weight cut-off. Most dialysis membranes are made from cellulose materials, but because many organisms are able to hydrolyze cellulosic materials, this limits their applicability. There are several sampling units that incorporate dialysis membranes. They are usually placed in the fermentor, and a receiving dialysis carrier buffer is circulated on the permeate side of the membrane. The carrier buffer is thus pumped into the bioreactor and, after having received the dialysate molecules, removed again. The major problem associated with this approach is the deposition of cells and fouling of the membrane on the fermentor side. The accumulated layer of cells may reduce the mass transfer from the fermentor to the accepting solution and also cause decreases in concentration of metabolites passing through the membrane because they run the risk of being metabolized by the cell layer before entering the dialysis membrane. To help reduce fouling it is possible to place the dialysis probe into the zone of the fermentor where the impeller creates the greatest turbulence (47).

Another means of obtaining similar results, but with fewer design restrictions, is to construct a dialysis probe that besides containing the membrane unit also has a stirring function, so that a high tangential liquid flow is generated over the membrane. This approach was used by Mandenius et al. (48) in constructing a system for use in dense particulate suspensions. The membrane is placed in the front of the probe, and membrane fouling is avoided by means of the rotating magnet driven by an electrical motor inside the probe (Fig. 5).

Zabriskie and Humprey (49) developed a dialysis probe situated within one baffle of a stirred fermentor. They were able to take samples for glucose analysis during cultivation of yeast cells on a synthetic medium. The disadvantage of this dialyzer is that it can be used only in this type of bioreactor. Another sampling device was presented by Glaxo Laboratories, Ltd. (50). This unit consist of an elongated support with a milled helical groove. A tubular membrane made of cellulosic materials or polytetrafluoroethylene was fixed to the support using ring seals.

An in situ dialysis membrane module was developed at the University of Hannover and is marketed by Advanced Biotechnology Corporation (ABC). The module consists of a unit supporting the membrane, and one or more extension units. The membrane module is usually inserted through a standard 19- or 25-mm port in the top of the bioreactor or, alternatively, through a 25-mm port below the liquid surface. When inserted from the top of the bioreactor, one or more extension tubes are needed to place the membrane below the liquid surface. Liquid passing the

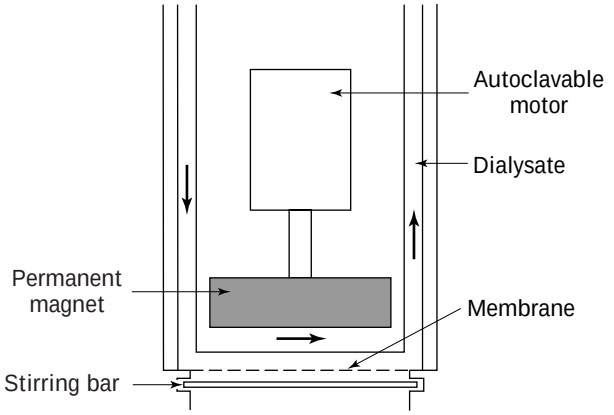

Figure 5. Cross section of the dialysis probe. The stirring bar is rotated by the rotating magnetic field when the motor is on. Receiving solution is pumped over the inner side of the membrane where dialysate is received and removed for analysis *Source*: From Ref. 48.

membrane is collected in 16 grooves, and these 16 permeate streams are joined in four openings placed evenly along the membrane holding unit. Through these four openings the permeate enters the central channel (10 mm i.d.), and a continuous sample stream to the analyzer leaves the unit from the top of the probe (51).

Gibson and Woodward (52) have also described an internal dialysis module, based on the same principle but without a stirrer. Ethanol and glucose could be sampled with this unit, and the results from the subsequent analyses agreed well with the on-line data.

Another modified technique is the microdialysis used for continuous in vivo sampling, which has been described in reviews (3,53,54). The microdialysis sampling unit is a probe, and it is a miniaturized form of a dialysis unit. It is manufactured in several different configurations, one is seen in Figure 6.

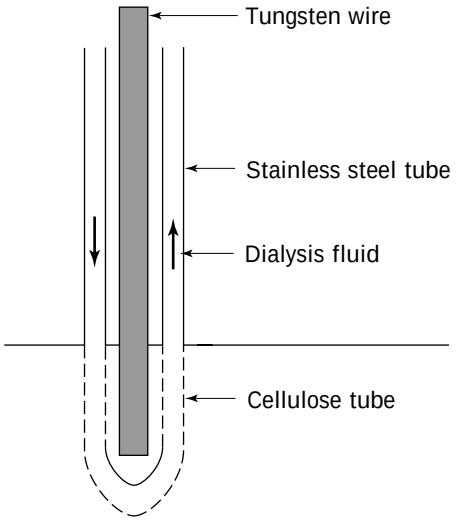

Figure 6. The microdialysis unit.

Typical flow rates of the perfusion liquid are 0.5–25 μL/min, and to avoid pulses in the flow, a peristaltic pump or preferably a syringe pump should be used. Due to its ease of operation and the general approach, the number of applications increases rapidly. It can easily be coupled on-line to a number of separation and detection techniques. This technique was used in fermentation processes for the production of ethanol, penicillin, and so on (55). However, the slow flux of liquid and thus the long response time from an analysis based on this sampling technique, compared with the conventional sensing devices, should be considered.

The major problem in dialysis units is the fouling and clogging by macromolecules on the membrane surface. This can be overcome by adding molecules that compete for the binding site of the protein, adding a displacer (56), changing the pH (57), or pumping the solution tangentially over the membrane surface. An excellent review on dialysis for flow injection analysis has been published (26).

MODES THAT AVOID OR AT LEAST REDUCE THE NEED FOR SAMPLE TREATMENT

As already noted a major concern in sample handling is clogging. Quite often packed-bed systems are used, and then particulate matter constitutes a major obstacle. In these cases, particulate matter has to be removed prior to analysis. However, with the introduction of expanded-bed chromatography, it is possible to handle large-scale chromatographic processes without separating out the cells (58). This made it tempting to investigate the possibility of using the same approach in an analytical system.

Enzyme-based analysis was studied using glucose oxidase immobilized to Streamline® particles. These particles are characterized by being of heterogeneous size and density distribution, such that when used in an expanded bed, a stable expanded bed can be obtained. Glucose was monitored using this technique (59). A more challenging issue is whether the same system would allow binding reactions to take place. If so, one should be able to run immunoassays in whole broth and maybe even in cell homogenates. Assays of human serum albumin in the presence of increasing amounts of heat-killed yeast cells was used as a model system. Antibodies against albumin were present on the Streamline® (60). The assays seemed successful, and therefore the model was also studied to see if the intracellular enzyme β-galactosidase could be quantified in a cell suspension or a cell homogenate. The results were so encouraging that it is safe to say that this technique allows binding assays without the preceding separation of particulate matter from the sample.

PRETREATMENT OF SAMPLES

Another vital part of the analysis is the pretreatment of the samples. This includes dilution, centrifugation, extraction, and filtration, depending on the nature of the samples. Certain samples can be analyzed without pretreatment; however, for complex samples extensive clean-up is required before introduction into the flow system. This topic has been discussed in several reviews (61,62). The

reproducibility and rapidity of flow injection analysis promotes its applicability for on-line pretreatment of samples with less manual intervention (63–65) (Fig. 8). Additionally pretreatment steps by FIA are rapid. The pretreatment and analysis, including chemical conversion, usually require less than a minute. Furthermore, when samples are toxic or pathogenic, FIA offers the advantage of removing, or at least minimizing, human exposure. An excellent review on sample pretreatment by FIA was published by Clark et al. (66) and includes a description of the theoretical background of sample pretreatment.

Disintegration of Cells

Monitoring levels of intracellular compounds has so far been possible only via off-line analyses. However, after the recent development of an on-line disintegration system that can be used together with expanded-bed adsorption in a flow system, a new possibility seems to have emerged. The important issues are that the whole broth is taken and treated and after that the whole homogenate can be processed in, for example, a binding assay.

The whole broth is introduced into an FIA system where it first passes an expanded bed containing Streamline® with immobilized lysozyme. On passage of *Micrococcus lysodeiticus* cells it has been proven that a high degree of disintegration is achieved, as judged from the amount of protein released (23). When adding a subsequent step involving sonication using a flow cell, the disintegration is even more efficient. The experimental set-up is shown in Figure 7. A culture of *E. coli* was studied and its level of β-galactosidase production was monitored. The detection step consisted of an expanded bed containing Streamline® with immobilized antibodies to β-galactosidase.

Upon introduction of the whole broth, homogenization takes place by treatment in the two units; and afterward liberated enzyme is trapped by the immunosorbent. The enzyme is quantified by reading the amount of *o*-nitrophenol liberated after passing a pulse of *o*-nitrophenyl-β-galactopyranoside over the sorbent. After the assay the immunocomplex is broken and the system is ready for another assay (24).

Centrifugation

Centrifugation is commonly used for separating cells and particulate materials from the fermentation broth. It is possible to include a small-scale centrifuge in an FIA system, with recycling of the sample to the reaction vessel (67).

Liquid–Liquid Extraction

Liquid–liquid extraction is based on the partitioning of the analytes between an aqueous and an organic phase and is widely used for gas chromatographic analysis. Integrating this technique into FIA is difficult because it is difficult to automate, laborious, and expensive. Solid-phase extraction (SPE) is based on sorption of analytes in solution to a sorbent packed in a cartridge or reactor, typically the size of a precolumn (10–20 $\times$ 2–4.6 mm in length and i.d., respectively) (68). While the analyte is trapped into the packing material, compounds with little or no affinity for the sorbent pass through the column. After washing the column to further remove the interfering substances, the analytes are then desorbed and eluted by a small volume of an appropriate solvent. Recently, Vreuls et al. (69) demonstrated the coupling of on-line SPE to gas chromatography. A precolumn packed with mixed anion/cation exchange materials was used on-line in a flow system for removal of ionic substances in aliquots of a filtrate from fermentation.

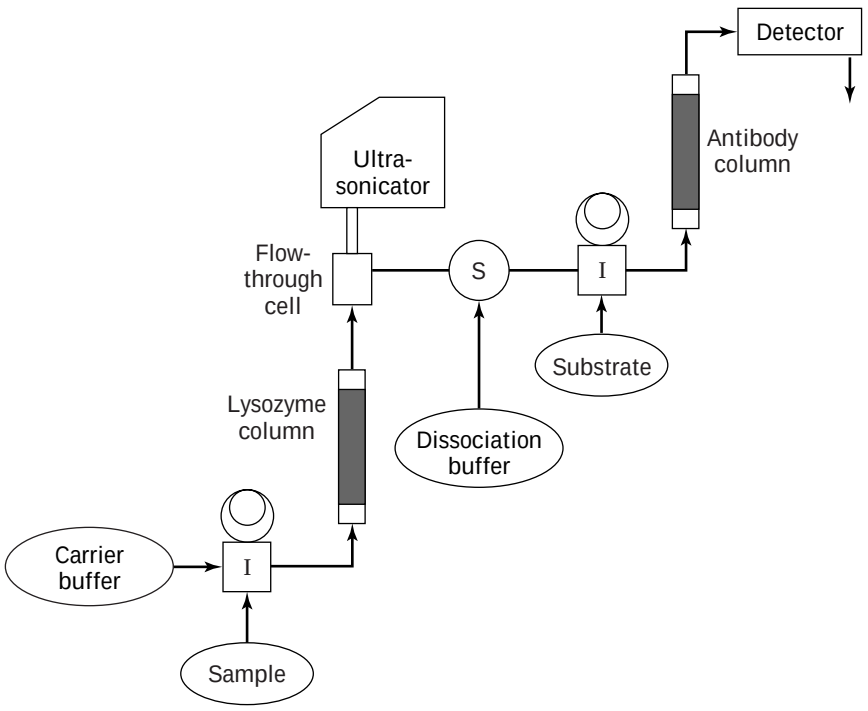

Figure 7. Schematic presentation of a complete flow system, including an expanded flow column with immobilized lysozyme and ultrasonicator flow cell. An expanded column with immobilized antibodies is also included for the subsequent ELISA.

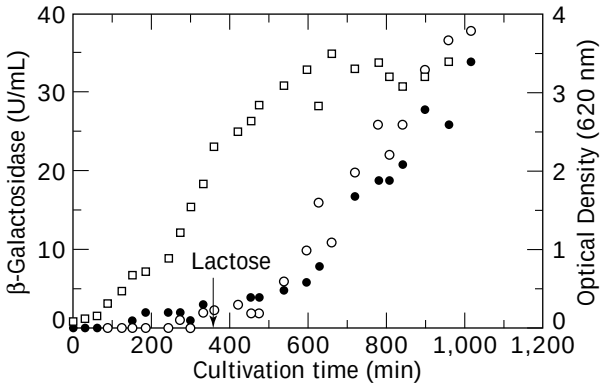

Figure 8. Monitoring of a shake-flask experiment. On-line (●) and off-line (○) *β*-galactosidase activity and o.d. (□) measurements. At the arrow the inducer lactose was added.

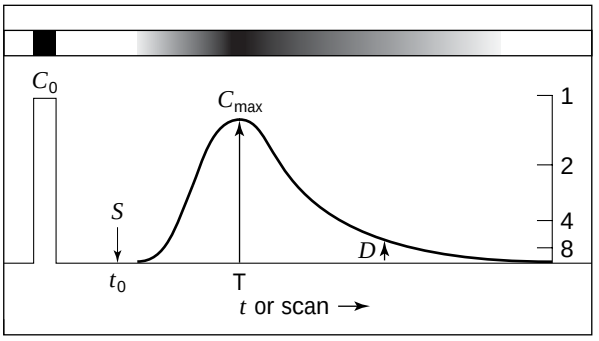

Figure 9. In addition to peak height a dispersed sample zone yields an infinite number of vertical readouts. The initial concentration, C_0, is injected at time t_0, and the pulse appears as a continuum of concentrations as exemplified by the peak. At time T, C_{max} is the highest value read, but a reading could be done anywhere along the peak (e.g., a diluted value at point D).

Preconcentration Techniques

If the analyte concentration is less than the concentration range of the detection method, the sample must be concentrated. Most of the manual pretreatment methods are time-consuming and expensive. Microcolumns with ion exchange materials can be used to significantly reduce the volume of the analyte by adsorbing the sample into a solid support in the column and by a further elution (70).

Dilution of Samples

If the analyte concentration is more than that of the detectable range of the analytical system, the sample must be diluted. The same goes for a sample in which inhibiting or otherwise disturbing substances are present in high concentrations. Manual dilution is used for off-line analysis. On-line dilution is now widely applied for fermentation processes (66) and includes the use of gradient dilution, zone sampling, and cascade dilution.

In the gradient dilution, an originally homogeneous sample zone disperses during its movement through the FIA conduit. The zone undergoes a change from an initial plug shape with a concentration C_0, to an exponentially modified gaussian shape with a maximum concentration in the zone of C_{max}. If the peak maximum does not lie in the calibration range of the measurement, the zone can be made at a time on the profile that yields a decreased response. By selection of measurement times longer than the time of peak maximum (T in Fig. 9), an element with a decreased concentration is measured, yielding a proportionally decreased absorbance. This measurement is reproducible from sample to sample and can be calibrated.

In zone sampling a small portion of the sample zone injected into a second flowing stream results in dilution (71,72). In cascade dilution the sample volume is reduced through stream splitting using differential pumping coupled with a true dilution by merging with a subsequent carrier stream.

Sample Injection

Sample handling and pretreatment can be achieved by using many techniques in FIA. The method of injection is equally important. The purpose of sample injection in FIA is to deliver a well-defined sample bolus reproducibly into a continuously flowing carrier stream. Ruzicka and Hansen (73) described that changing the injected sample volume is a powerful way to change the dispersion. An increase in peak height and sensitivity of measurement is best achieved by increasing the volume of the injected sample solution. Conversely, dilution of overly concentrated sample material is achieved by reducing the sample volume.

There are two methods of injection: time-based injection (a sample loaded for a precise time at a given flow rate) and volume-based injection (the sample fills a geometrically defined volumetric cavity). This well-defined sample bolus is then inserted into the carrier stream. Volume-based injections are performed using rotary valves, commutators, and hydrodynamic injections. A detailed methodology used for injection has been published (74).

Calibration of Sampling System

For any kind of analysis, whether it is on-line or off-line, the system needs to be calibrated to ensure that the compound of interest is being measured reliably. It is easy to calibrate an off-line system. However, the continuous systems described so far commonly have no possibility for calibration and recalibration on-line without disrupting the monitoring procedure. Thus, any changes occurring in the sample during the recalibration, are not registered (5). Another important limitation is the fact that the calibration solution and the sample solution are usually not treated in the same manner.

In-line calibrating systems are used in medical monitoring. Attempts were made for in-line calibration during fermentation with *E. coli* using a double-lumen catheter. The calibration was done by closing the sample inlet from the fermentor and substituting it with a sample of known analyte concentration (20) (Fig. 10). A further development of this technology was the use of the coaxial catheter for sampling. In on-line monitoring of glucose and lactate in blood, the calibration solution was introduced as a pulse

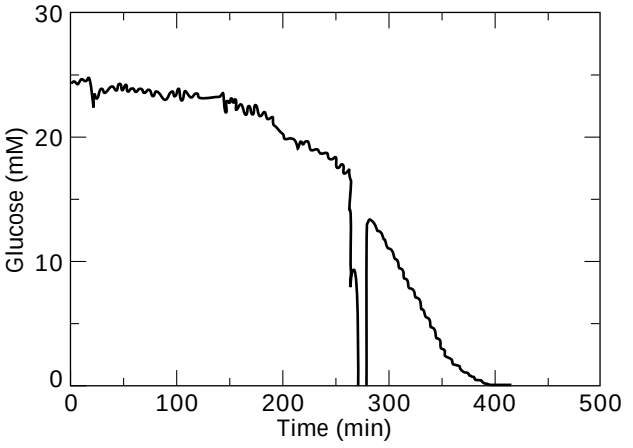

Figure 10. Monitoring of glucose in batch cultivation of *Escherichia coli*. After approx. 270 min a calibration solution is introduced, and the reading is back approx. 10 min later. *Source*: From Ref. 20.

in the heparin stream fed via the outer space in the coaxial catheter. This led to an on-line monitoring of the process without having to interrupt the reading (Fig. 11). Furthermore, by introducing the calibration solution at the tip of the sampling catheter, the whole system is calibrated. Thus a more true calibration value is obtained (75,76).

CONCLUSION

Sampling and sample treatment are extremely important when applying good analytical technique to the monitoring and control of biotechnological processes. Too often much effort is spent on developing a sensitive assay, but very little or no concern has been given to sampling and sample handling. The examples given in this article clearly demonstrate that many good techniques can be applied. Which method to use will be governed by the system studied, the equipment available, and also the earlier experience of the researcher.

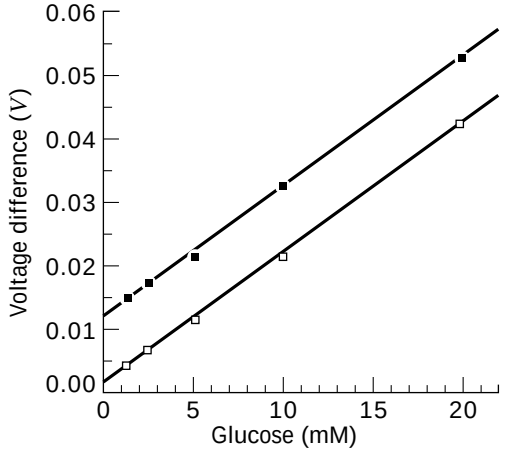

Figure 11. On-line outlet signal (V) as a function of glucose concentrations (mM); (■) glucose standard solution with added internal standard (5 mM), $y = 1.14 \times 10^{-2} + 2.05 \times 10^{-3}\,x$, $r^2 = 1.000$; (□) glucose standard solution, $y = 1.09 \times 10^{-3} + 2.04 \times 10^{-3}\,x$, $r^2 = 1.000$.

OUTLINE

INTRODUCTION

The scale-up of a biotechnological process developed in the laboratory often presents problems that, owing to the many parameters involved and their complexity, do not permit any generalized solution. As a result, criteria for scale-up have always been developed on the basis of specific processes. The main problem in all considerations of scale-up is that no strictly defined criteria exist for conducting biotechnological processes and, hence, their scaled translation. Of the biological and physical factors important in scale-up, generally valid relationships can be established only for the latter. Thus in the following, the experimentally proven physical fundamentals of scale-up for conventional stirred-tank reactors are brought together in a way that reflects their importance in practical operation. Such considerations have been published in the past but were based on the scientific knowledge available at that time (1–5). This article is an updated short version. For further information about scale-ups of fermentation processes and extended literature see Ref. 5.

SCALE-UP METHODS

Balance Equation

A scale-up using a solution of the complete equations for momentum, energy, and mass balances is exceedingly difficult to determine for a complex microbiological process. Thus for a scale-up on the basis of mathematical models, there are still no practicable equations available at present that take into account the kinetics and transport processes in the stirred-tank reactor. Nonetheless, the application of simplified balance equations is often helpful in order to understand the processes involved (6,7).

Dimensional Analysis

Dimensional analysis, introduced successfully into chemical technology and already a classical method of scale-up, is also helpful when dealing with biotechnological processes. Using it, a number of dimensionless quantities (π-quantities) are derived from the relevant process-influencing quantities, which using the mathematical interrelationships of the similarity principle, provide criteria for scale-up (see also Refs. 8 and 9). The invariance of all dimensionless π-quantities relevant to the problem provides the simplest rule for scale-up, but the rule is dependent upon complete similarity. Whereas physical processes often do behave similarly upon change in scale, similarity in the presence of a chemical or microbial process is often unattainable. Even for purely physical processes, a complete similarity can often not be attained. As shown in the section "Performance Characteristics of the Stirred-Tank Reactor," the translation rule Re = idem (idem means that the numerical value of Re is held constant in scale translation) is valid for the energy input in scaling-up stirred-tank reactors, without formation of vortices. But if, nonetheless, a vortex should form, as in unbaffled vessels, then both the Reynolds number and the Froude number must retain their numerical value. From the definition of Re and Fr, it immediately becomes obvious that the requirements Re = idem and Fr = idem cannot be fulfilled because $n \cdot d^2$ = idem cannot equal $n^2 \cdot d$ = idem.

Because it is rarely possible to maintain all dimensionless characteristic quantities at the same numerical value, it becomes necessary to restrict oneself to partial similarities in which only some of the π-quantities remain fixed. To achieve this, the rate-determining step of the reaction for the complex microbial system must be known. That means that from the many process parameters, such as nutrient requirements, physicochemical conditions of growth, or transport processes, the limiting (or inhibiting) quantities have to be determined by careful analysis. Problems then arise when there is a shift in the effect of the individual limiting factors when the scale is altered. Such an approach to scale-up, in which each rate-determining step, both of the microbial reaction and of the transport processes, is mathematically correlated, has been put forward from time to time (for example, see Ref. 10) and has also been introduced highly successfully (11–14).

Maintenance of Identical Operating Conditions

A further simplification of the scale-up criteria, which follows from accepting the notion of partial similarity, is the maintenance of identical operating conditions (usually assuming that there is geometrical similarity). The most common examples of scale-up rules that have been published in the specialized biotechnological literature are based on this concept; extrapolation is often performed ac-

Table 1. Effects of Different Criteria in Linear Scaling-Up by a Factor of 5

		Scale-up criterion			
	Laboratory scale	P/V (kW/m^3)	n (s^{-1})	$n \cdot d$ (m/s)	Re
Diameter D (m)	1	5	5	5	5
Specific power input P/V (kW/m^3)	1	1	25	0.2	1.6×10^{-3}
Power input P (kW)	1	125	3125	25	0.21

Reynolds number	1	8.55	25	5	1

Source: From Ref. 20.

cording to empirical rules of thumb that are still used today in the fermentation industry. Typical examples of this are the following:

- Identical volumetric power input P/V
- Identical mixing time or adaption of the mixing time to different stirred-tank reactor sizes according to purely empirical translation rules
- Identical tip speed of the agitator
- Identical volumetric mass transfer coefficient k_La
- Identical Reynolds number, Re

In fact, according to Ref. 15, about one third of plants employed the translation rules P / V = idem and k_La = idem, and about 20% used the tip speed of the stirrer (i.e., assuming shear stress). Another 20% of industrial plants employ a scale-up on the basis of mixing time and Reynolds number. The remainder scaled-up on the basis of a limiting or inhibiting substrate or product component—most commonly on the basis of the concentration of dissolved oxygen.

A scale-up founded on a single operating condition has diverse effects on the other operating quantities, as shown in Table 1 (see also Refs. 16–19). Using a linear scaling factor of 5 (corresponding to a volume scaling factor of 125) each column shows the change in the operating quantity that results from the respective scale-up criterion. Table 1 shows that it is not possible to simultaneously fulfill several of the scale-up criteria mentioned (20).

PHYSICAL FUNDAMENTALS OF SCALE-UP CONDITIONS

Performance Characteristics of the Stirred-Tank Reactor

The stirring power, P, which produces the three-dimensional flow field can be calculated from the dimensionless power number or Newton number:

$$Ne \equiv \frac{P}{\rho \cdot n^3 \cdot d^5} \tag{1}$$

From considerations of the similarity principle, the formal correlation of the performance characteristic for a given geometry is described by

$$Ne = f(Re, Fr, Q) \tag{2}$$

where the Froude number is $Fr \equiv n^2 \cdot d/g$, the Reynolds number is $Re \equiv n \cdot d^2/\nu$, and the dimensionless gasflow number is $Q \equiv q_G/n \cdot d^3$.

Power Input in Nongassed Systems of Newtonian Fluids. In systems that have no gas input ($Q = 0$) and no vortex formation (as is effectively the case in a vessel with baffles), the effect of the Froude number is negligible. The performance characteristics of the nongassed system of Newtonian fluids, which is then solely a function of the Reynolds number (21–23) is depicted in Figure 1 for a selection of stirrers. The geometrical arrangement and the working range of the stirrers have been standardized in some countries (e.g., DIN 28131 in Germany). Except for the helical and anchor stirrers which extend right to the wall, stirred vessels are equipped with baffles to avoid vortex formation. The reduction in the number of baffles from 4 to 3 or 2 generally lowers the energy input by 10 or 20% (23). In a completely turbulent system (a condition fulfilled with most stirrers at $Re > 10^4$), the performance characteristic is independent of the Reynolds number, that is, Ne = constant. If the scale-up considerations are based on a constant volumetric power input, $P/V \sim P/d^3$ = idem, then the following is valid for the scaled translation:

$$n^3 \cdot d^2 = \text{idem} \tag{3}$$

Power Input in Nongassed Systems of Non-Newtonian Fluids. In many fermentation broths, for example, those containing polysaccharides or mycelium-forming microor-

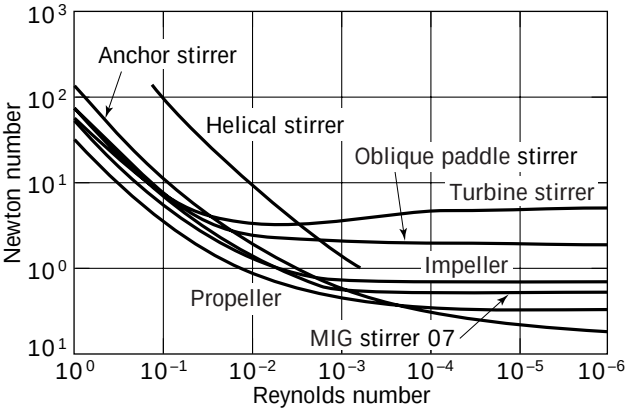

Figure 1. Performance characteristics of some types of stirrer with Newtonian fluids.

ganisms, non-Newtonian flow behavior is encountered: there is a complicated nonlinear relationship between the shearing stress, τ, and shear rate, $\dot{\gamma}$. For non-Newtonian fluids, the viscosity property can be defined only in the form of an apparent viscosity

$$\eta_a \equiv \frac{\tau}{\dot{\gamma}} \tag{4}$$

A number of models have been put forward to describe the non-Newtonian flow behavior. The most efficacious originate from the Ostwald-De Waele law for pseudoplastic fluids

$$\tau = K' \cdot \dot{\gamma}^{m'} \tag{5}$$

and from Herschel–Bulkley law for plastic fluids

$$\tau = \tau_0 + K'' \cdot \dot{\gamma}^{m''} \tag{6}$$

In order to determine the energy input in such fluids, the approach adopted by Metzner and Otto (24) and Metzner et al. (25) has proved itself. According to this concept, there is a direct proportionality between the rate of shear and the rotational speed of the stirrer

$$\dot{\gamma} = K \cdot n \tag{7}$$

whereby the apparent viscosity, η_a, is obtained from the rheological flow curve of the fluid involved. The coefficient K depends only slightly on the rheological behavior of the fluid but mainly on the stirring system, for example, $K \approx 11$ to 13 for turbine agitators and $K \approx 15$ to 25 for anchor agitators (15,26). In Figure 2 the performance characteristic of the turbine stirrer for pseudoplastic fluids is plotted versus the Reynolds number which has been modified by η_a (24,27).

A similar performance characteristic was measured by Sanchez et al. (28) and Velasco et al. (29) for a single and a dual Rushton turbine when mixing a mycelial broth under nonaerated conditions. As with Newtonian fluids, a constant Newton number is attained here at sufficiently high Reynolds numbers (i.e., the performance characteristic is independent of the viscosity). Whereas this independence of the viscosity is unequivocally valid in a nongassed system, considerable dependence on the viscosity occurs in a gassed system of non-Newtonian fluids, as is illustrated in a following section.

The apparently simple approach advocated by Metzner and Otto (24) is made more complicated by the fact that the rheological behavior of fermentation broths often changes drastically during the fermentation, as is shown in Figure 3 for a decrease of the apparent viscosity during the cultivation of *Cellulomonas uda* grown on printed newspaper (26).

Power Input in Gassed Systems at Low Viscosities. In gassed systems of aqueous-like fluids, a decrease in the stirring power input can be observed with increasing gas flow. This decrease is caused by gas cushions that form behind the stirrer blades and diminish the rotational resistance of the stirrer. The effect was first studied by Oyama and Endoh (30); the results are shown in Figure 4. Since then a series of measured values have been published; particularly extensive are the measurements made by Zlokarnik (31) and Judat (32). Judat (32) gives a relationship valid for a turbine stirrer in a turbulent region of flow ($Re > 10^4$) in water. This relationship is also applicable, in a somewhat modified form, to large vessels of up to $V = 900$ m^3:

$$Ne_G = Z \frac{Ne_0 + 187QFr^{-0.32}(d/D)^{1.53} - 4.6Q^{1.25}}{1 + 136Q(d/D)^{1.14}} \tag{8}$$

Here $Ne_0 \approx 4.9$ is the Newton number of the turbine stir-

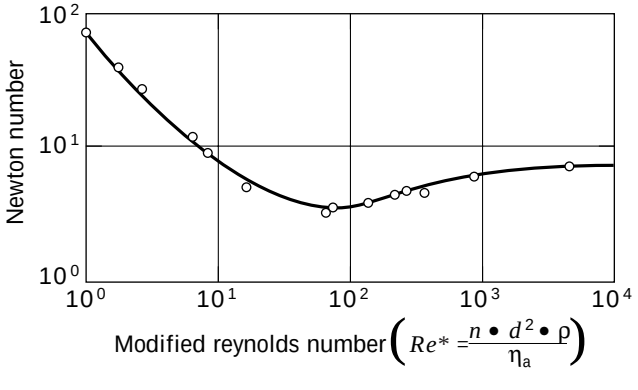

Figure 2. Performance characteristic of turbine stirrer with pseudoplastic fluid.

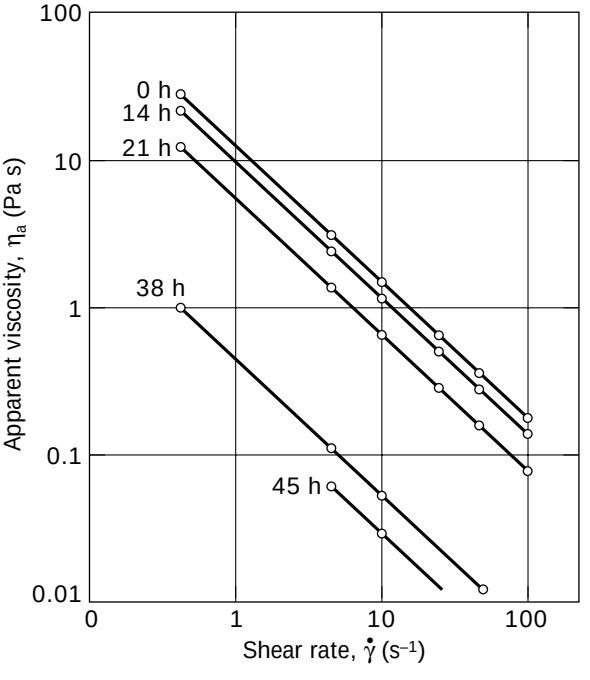

Figure 3. Time course of changes in apparent viscosity in the fermentation of cellulose.

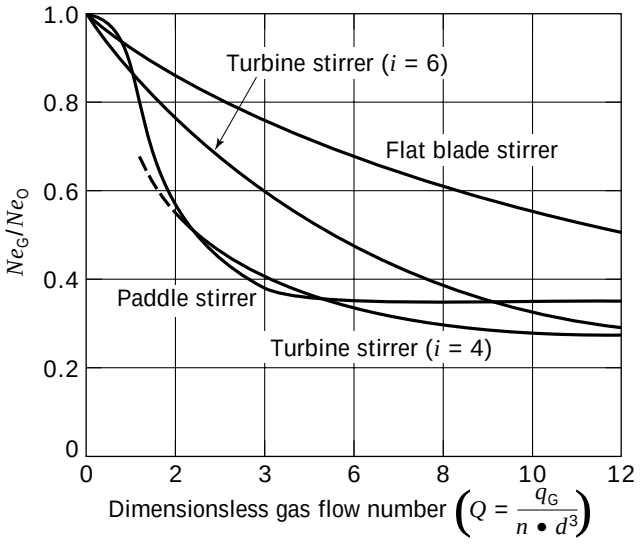

Figure 4. Power input of several types of stirrer in Newtonian fluids, dependent on the gas throughput.

ring in a turbulent region of flow without gassing, and Z is the number of stirrer blades. Equation 8 is valid for $Re > 10^4$, $Fr \leq 0.07(d/D)^3$, $0.2 \leq d/D \leq 0.42$, and $h/d > 0.75$.

Detailed investigations with other types of stirrers and multiple impellers were carried out by Schlueter and Deckwer (33). Their experimental results were well described by equation 8 with a maximum deviation of only 30%. Further investigations are necessary to describe properly the power input in stirred vessels if the impeller position is varied and multiple stirrer arrangements are used.

The influence of the Reynolds number on the power input in a gassed system has been studied by Zlokarnik (31) and is given, for the turbine stirrer, by

$$\frac{Ne_G}{Ne_0} = 1 + [(3.9Re^{0.12} + 6 \cdot 10^{-12}Re^{3.45}) \cdot (0.22Q^{0.1} + 6.25Q^3)]^{-1} \quad (9)$$

which is valid for $Q < 0.05$ and $800 \leq Re \leq 10^4$. Ne_G is the Newton number of the turbine stirrer gassed with Q at $Re > 10^4$.

Power Input in Gassed Systems of Newtonian and Non-Newtonian Fluids at Higher Viscosities. Whereas the influence of the gas on the energy input in aqueous-like fluids is about the same for the different types of stirrer, each stirrer type displays a very different effect when the viscosity increases. Detailed measurements on this have been published by Hoecker and Langer (34) and Hoecker (35). To illustrate the results, the form completely equivalent to equation 2 was chosen,

$$Ne = f(Q, Fr, Ga) \quad (10)$$

with the Galilei number

$$Ga \equiv \frac{Re^2}{Fr} = \frac{d^3 \cdot g}{\nu^2}$$

With turbine stirrers, a decrease in the power input is observed with increasing viscosity (Fig. 5). As in the correlation of the power input for nongassed systems of non-Newtonian fluids, the results with sparging can also be expressed by introducing an apparent viscosity, η_a, as results from the approach taken by Metzner and Otto (24) (i.e., equations 4 and 7). As Figure 5 shows, even the results for Newtonian glycerine–water solutions and for pseudoplastic carboxymethylcellulose–water solutions can be expressed by the same form of curve (34). With viscoelastic polyacrylamide–water solutions (Figure 5b), the decrease in the power input with viscosity is even more pronounced than with Newtonian and pseudoplastic fluids; this can probably be traced back to the development of orthogonal tension in viscoelastic fluids, which tends to damp the turbulence. The illustration of the performance characteristic for turbine stirrers in aqueous glycerine solutions in terms of the gas flow in Figure 6 clearly shows that at high viscosities a decrease in power input with the gas throughput hardly makes itself felt, but rather the Froude number exerts a more marked effect (34,35). The slight influence of the dimensionless gasflow number is due to the formation of gas cushions behind the stirrer blades, which is independent of the gas throughput.

The relationship given in equation 9 to calculate the influence of the Reynolds number on the power input with gassed turbine stirrers is roughly applicable to non-Newtonian fluids, too. In Figure 7 the results obtained by

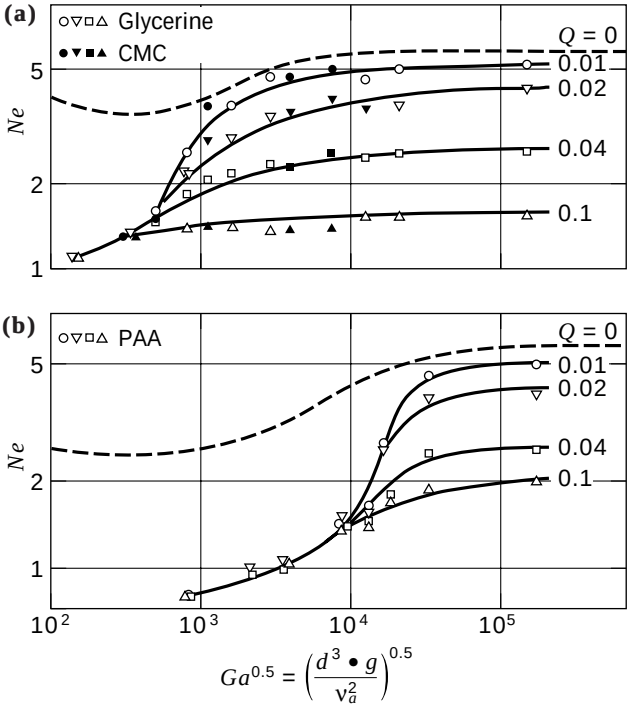

Figure 5. Power input with turbine stirrer ($d/D = 0.33$) in (**a**) Newtonian (glycerine) and pseudoplastic (CMC) and (**b**) viscoelastic (PAA) fluids.

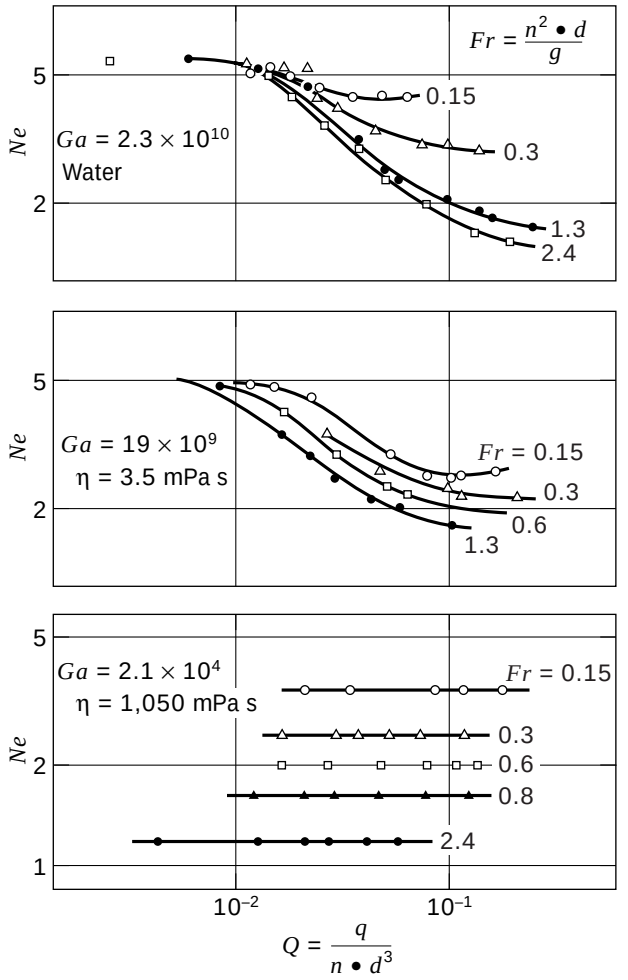

Figure 6. Power input with turbine stirrer ($d/D = 0.33$) in glycerine–water solutions.

Hoecker and Langer (34) are depicted for water, glycerine, carboxymethylcellulose (CMC), and polyacrylamide (PAA) solutions, plotted as $Ne \cdot f(Re, Q)$ corresponding to equation 9 as a function of $Q(1 + 38(d/D)^5)$. The dotted curve shows the results obtained by Zlokarnik (31). From the values taken from the line of the curve, the performance characteristics can be calculated exactly enough from Figure 7 with $Ne = Ne_G/f(Re, Q)$ with equation 9; this is the case for Newtonian and pseudoplastic fluids in the region $Ga > 10^6$ ($Re > 10^3$) and for viscoelastic fermentation broths with $Ga > 10^9$ (34,36).

Completely different behavior from that seen with a turbine stirrer is observed with a multistage impulse countercurrent (MIG) agitator: In Figure 8 the results obtained by Hoecker and Langer (34) and Hoecker (35) are plotted and are analogous to those in Figure 5. Here a decrease in the power input comparable in magnitude to that with the turbine stirrer cannot be established; this is due to the less marked formation of gas cushions with a MIG agitator. Because the interference multistage impulse countercurrent (INTERMIG) and the oblique arm paddle stirrer both exhibit hydrodynamic behaviour similar to that with a MIG stirrer, this result is to be expected in these cases, too.

Dispersing Capacity of the Stirrer

The dispersing capacity of a stirrer is limited by the so-called flooding point, which gives the maximum gas throughput that can be distributed by the stirrer, $q_{G,max}$. If this maximum gas throughput is exceeded, the stirrer is completely "flooded" by the gas, and the circulatory flow provided by the agitator breaks down. This flooding point exists in the transitional zone leading to turbulent flow and is particularly marked in the turbulent flow region. It manifests itself in a sudden decrease in the power input and mass transfer capacity. In the turbulent area of flow ($Re > 10^4$) the measured data can be correlated using the dimensionless form

$$Q = f(Fr, d/D) \tag{11}$$

Judat (32) reports that the flooding point for turbine stirrers for $Re > 10^4$ and $0.2 \leq d/D \leq 0.42$ is

$$Q_{max} = \frac{0.21Fr^{2.1d/D}}{[(d/D)^{-1} - 2.04]^{1.3}} + \frac{0.14Fr^{7.54d/D}}{[(d/D)^{-1} - 2.25]^{1.5}} \tag{12}$$

The flooding characteristic for different stirrers is depicted in Figure 9 (32). Because these results have all been acquired in laboratory experiments, comparison measurements must be carried out in order to achieve a dependable scale-up. A model to describe the flooding characteristic of stirrers by means of dimensional analysis was suggested by Zehner (37).

For fermentation processes that require low rotational speeds of the stirrer at high sparging rates or at very high gas throughput, Breucker et al. (38) made an interesting observation. For different types of turbine, propeller, or INTERMIG stirring systems they showed that sparge rings near the wall prevent the introduced gas flow from flooding the impeller. In the rotational speed range in which the stirrer is normally flooded, flooding did not occur. This extension of the operation range results in greater safety in vessel design. From the observations available for media of higher viscosity and for non-Newtonian fluids, conservative design considers the dispersing capacity of the agitator as lower than with Newtonian fluids.

Mixing Time Characteristics of Stirred-Tank Reactors

The mixing time is commonly defined as the time necessary to reduce concentration differences in the volume in question to a minimum. The mixing time should thus always be related to the method of measurement used and the degree of homogenity desired. From theoretical considerations of similarity, the mixing time characteristic in the case of Newtonian fluids (with negligible density and viscosity differences) is given by

$$n \cdot \theta = f(Re) \tag{13}$$

with the dimensionless characteristic mixing number $n \cdot \theta$.

In Figure 10 the mixing time characteristics of some types of agitator are illustrated. Those conditions of geometry (which deviate from the German norm DIN 28131) are given in the diagram. In the range of turbulent flow

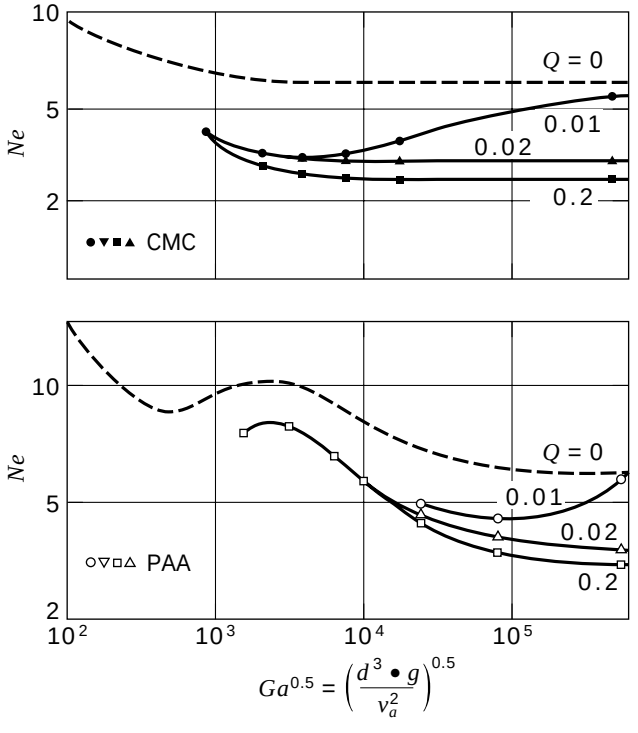

Figure 8. Power input with MIG stirrer (d/D = 0.6, 3 stirrers, H/D = 2), substance systems as in Figure 5.

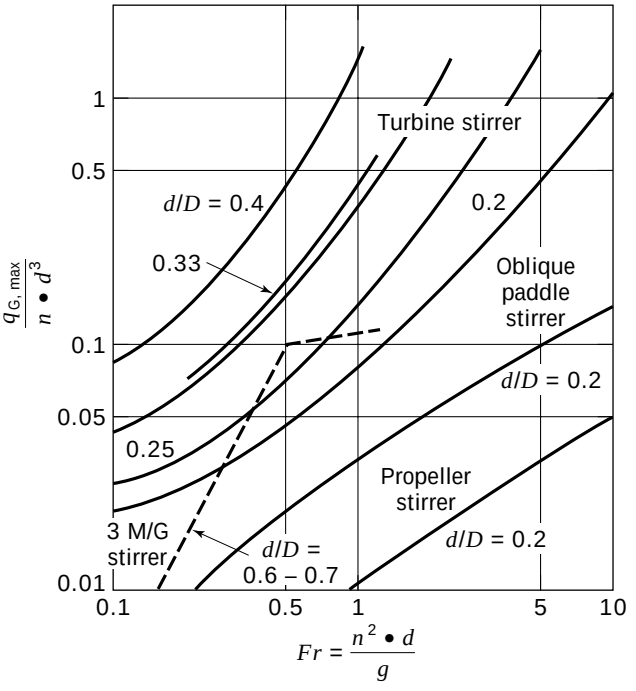

Figure 9. Dispersing capacity of several types of stirrer, $Re > 10^4$.

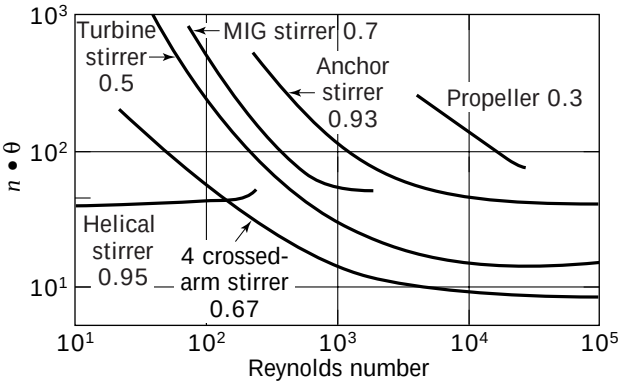

Figure 10. Mixing time characteristics of several types of stirrer in Newtonian fluids.

($Re > 10^4$) the characteristic mixing number is practically independent of the Reynolds number (39–41). Figure 11 shows a plot of the power input that is required to achieve those mixing times in the turbulent region given in Figure 10. The characteristic dimensionless numbers used in this diagram, which were formulated by Zlokarnik (42) on a theoretical consideration of similarity, permit the stirring power input to be determined for a given mixing time, or vice versa (43). For the most favorable conditions of geometry and operation, the stirring power input required in the region of turbulent flow (Ne = constant, $n \cdot \theta$ = constant) is obtained from the relationship

$$\frac{P \cdot \theta^3}{\rho \cdot D^5} = 300 \qquad (14)$$

For a scale-up with P/V = idem there is, from equation 14, a corresponding increase in the mixing time in the region of turbulent flow by

$$\frac{\theta}{D^{2/3}} = \text{idem} \qquad (15)$$

for example,

$$\frac{\theta}{V^{2/9}} = \text{idem} \qquad (16)$$

A scale-up on the basis of constant mixing times (θ = idem) requires, according to equation 14, an increase in the power input by

$$\frac{P/V}{D^2} = \text{idem} \qquad (17)$$

which leads to required energies that cannot be defended either on a technical or an economic basis. Bearing in mind the need for an economical stirring power input, it is indeed meaningful to allow an even longer mixing time when scaling-up than that given by equation 16.

The influence of non-Newtonian flow behavior on the mixing time characteristics can be derived from Figure 12

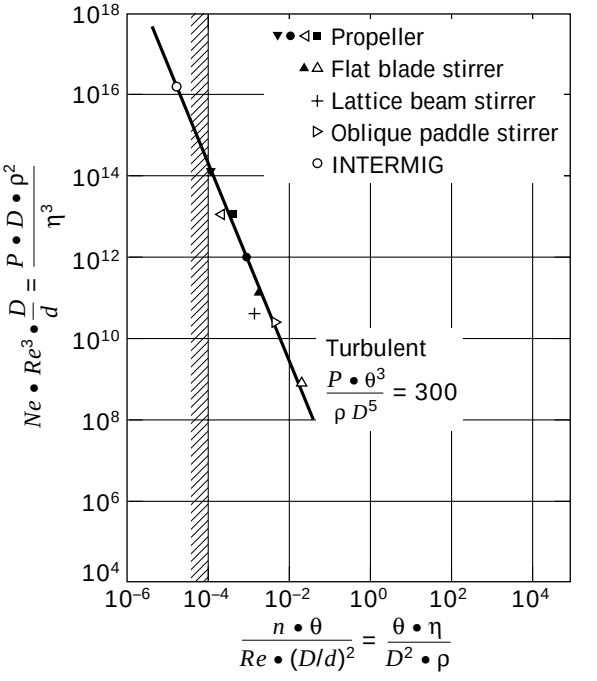

Figure 11. Power input to obtain given mixing times with favorable geometrical and operating conditions.

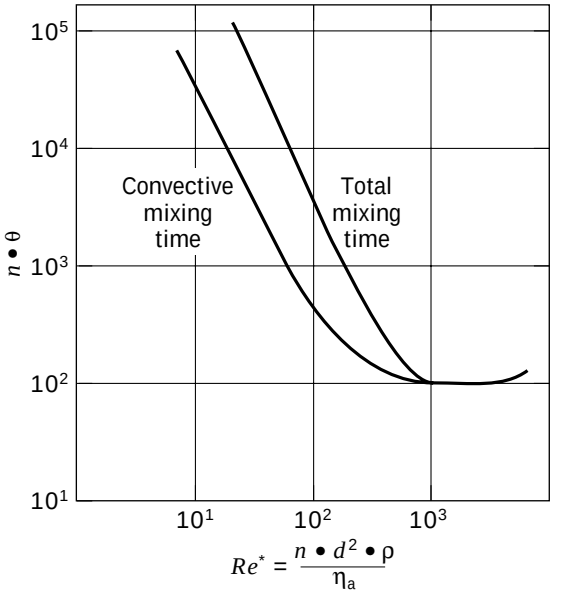

Figure 12. Mixing time characteristics in non-Newtonian fluids (crossed-arm stirrer in CMC solution).

(44). The Reynolds number here has again been modified by the apparent viscosity, as determined according to the method of approach used by Metzner and Otto (24) (equations 4 and 7).

For pseudoplastic fluids Opara (44) observed that in the laminar flow region, about 95% of the liquid is distributed very rapidly by convection, whereas the remainder is

mixed very slowly by diffusion. This convective mixing time corresponds roughly to the mixing time in Newtonian fluids (Fig. 10). The total mixing time in non-Newtonian fluids can be as much as a factor of 10 longer than the convective mixing time.

Mass Transport between Gas and Liquid Phase

Apart from the stirring power, mixing time, and dispersing capacity of the stirrer, mass transfer between gas and liquid is often the prime influence during an aerobic fermentation. The oxygen demand of the aerobic culture has to be the same as the oxygen transfer rate (OTR = $\dot{n}_{O_2}$) in the steady-state condition

$$\dot{n}_{O_2} = \frac{\dot{N}_{O_2}}{V} = k_L a (c^*_{O_2} - c_{O_2})_{av} \tag{18}$$

In this, it has been assumed that because oxygen is such a poorly soluble gas, the overall rate of mass transport is determined essentially by the mass transfer resistance in the liquid phase. In fact the transport coefficient in the gas phase is larger than that in the liquid phase by a factor of 100. The liquid-phase mass transfer coefficient, k_L, multiplied by the interfacial exchange area per unit volume, a, is termed the *volumetric mass transfer coefficient*.

The averaged concentration difference at the phase boundary $(c^*_{O_2} - c_{O_2})_{av}$ in the whole reaction vessel is, in the case of an ideally mixed liquid phase and complete segregation of the gas phase, equal to the logarithmic mean concentration

$$(c^*_{O_2} - c_{O_2})_{av} = \frac{c^*_{O_2,in} - c^*_{O_2,out}}{\ln\left(\dfrac{c^*_{O_2,in} - c_{O_2}}{c^*_{O_2,out} - c_{O_2}}\right)} \tag{19}$$

In stirred tank reactors the average concentration difference can be calculated from equation 19 with sufficient accuracy.

Mass Transfer in Aqueous Fluids. Many equations have been published for the calculation of the volumetric mass transfer coefficient, $k_L a$, in low-viscosity aqueous fluids (see Ref. 5). Regardless of the measuring system used, these equations give differences in the $k_L a$ value of up to a factor of 10. In particular, the influence of the coalescence behavior of the fluid system on $k_L a$ has not been elucidated. Consequently the $k_L a$ values found with the model system of sulfite oxidation in water must be viewed critically when applying such values to fermentation broths.

Theoretical considerations of the similarity of mass transfer between gas and liquid phase made by Zlokarnik (45) led to the formal relationship

$$k_L a = f\left(\frac{P}{V}, \frac{q_G}{V}, \ \ldots\right) \tag{20}$$

with a gas throughput per unit volume q_G/V. However, Judat (46) showed, by evaluating a series of published $k_L a$ values, that in order to fit the measured data better, the gas throughput related to the cross-sectional area of the reactor (i.e., the superficial gas velocity)

$$u_G = \frac{q_G}{A} \tag{21}$$

should be taken as the characteristic gassing quantity. This finding is in agreement with the empirical equation of the type

$$k_L a = K_1 \left(\frac{P}{V}\right)^{\alpha} u_G^{\beta} \tag{22}$$

which was compiled by Moo-Young and Blanch (3) for coalescent and noncoalescent aqueous solutions; their findings are listed in Table 2 (SI units, i.e., $k_L a$ in s^{-1}, P/V in W/m^3, and u_G in m/s). According to Van't Riet (47), differences of up to 35% arise in the $k_L a$ values in coalescent and noncoalescent systems. Van't Riet (47) gives the following correlations for low-viscosity fermentation broths from a series of published data (SI units as in equation 22):

$$\text{Coalescing medium:} \quad k_L a = 0.026\left(\frac{P}{V}\right)^{0.4} u_G^{0.5} \tag{23}$$

$$\text{Noncoalescing medium:} \quad k_L a = 0.002\left(\frac{P}{V}\right)^{0.7} u_G^{0.3} \tag{24}$$

In modifying the dimensionless quantities proposed by Zlokarnik there follows, for the calculation of the volumetric mass transfer coefficient, $k_L a$, the functional relationship

$$k_L a \left(\frac{\nu}{g^2}\right)^{1/3} = \left(\frac{P}{V \cdot \rho \cdot (g^4 \cdot \nu)^{1/3}}, \frac{u_G}{(g \cdot \nu)^{1/3}}, Sc, \sigma^*, S_i\right) \tag{25}$$

In this, $Sc \equiv \nu/\mathcal{D}$ is the Schmidt number, $\sigma^* \equiv \sigma/\rho(g \cdot \nu^4)^{1/3}$ is the dimensionless surface tension, and S_i represents characteristic quantities that are intended to describe the coalescence behavior of the fluid system but whose composition, as already mentioned, still remains largely unclear, though Breucker et al. (38) found that qualitatively the mass transfer coefficient for the noncoalescing system is up to a factor of 4 higher than for coalescing systems at comparable conditions. In the absorption of oxygen in fermentation broths, σ^* and Sc are practically determined only by the viscosity. The surface tension itself changes only very slightly and is not significant. The diffusion coefficient of aqueous solutions exhibiting Newtonian flow behavior can be correlated with the viscosity. On the other hand, the diffusion coefficient in non-Newtonian aqueous solutions is independent of ν and has the same value as water (48,49).

In the mass transfer of gases other than O_2, the Schmidt number and surface tension must also be considered in some cases. However the transport of CO_2, which is also of interest in fermentations, can be calculated without much error by using the same $k_L a$, owing to the very slight differences in diffusion coefficients between O_2 and CO_2. Indeed the overall transport rate is greater for CO_2 because it is 40 times more soluble in water than O_2.

Table 2. Sorption Characteristics of Aqueous Systems for Turbine Stirrers

Liquid	K_1	α	β	Range of validity P/V (kW/m^3)	Range of validity u_G (cm/s)

0.1N	–	0.63	0.62	0.03–18	0.1–0.5
Water	0.0275	0.42	0.43	0.44–10	0.37–1.11
Electrolyte solution (Na_2SO_4 + KOH)	0.017	0.52	0.43	0.44–10	0.37–1.11

Note: $Z = 6$, $d/D = 0.33$; according to Equation 22. For more information see Ref. 5.

By evaluating published data, Judat (46) proposed a correlation that for aqueous systems covers the entire region of technical interest:

$$k_L a\left(\frac{\nu}{g^2}\right)^{1/3} = \frac{9.8 \cdot 10^{-5}\left(\frac{P}{V \cdot \rho(g^4 \cdot \nu)^{1/3}}\right)^{\alpha}}{(B^{-\beta} + 0.81 \cdot 10^{-0.65/B})^{1.05}} \qquad (26)$$

The dimensionless gassing number is here given by

$$B \equiv \frac{q_G/D^2}{(\nu \cdot g)^{1/3}} \qquad (27)$$

The exponents are given as $\alpha = 0.42$ and $\beta = 0.6$. Although the exponents are dependent on the fluid system, the addition of the exponents, $\alpha + \beta \approx 1$, is approximately valid for all substances. Henzler (4) used this circumstance to evaluate the experimental results available with a relationship of the form

$$k_L a\left(\frac{\nu}{g^2}\right)^{1/3} = K_2\left(\frac{P}{V \cdot \rho(g^4 \cdot \nu)^{1/3}}\right)^{\alpha}\left(\frac{u_G}{(g \cdot \nu)^{1/3}}\right)^{\beta} \qquad (28)$$

Taking into account $\beta \approx 1 - \alpha$, the simplified form was derived:

$$\frac{k_L a}{u_G}\left(\frac{\nu^2}{g}\right)^{1/3} = K_2\left(\frac{P}{V \cdot u_G \cdot \rho \cdot g}\right)^{\alpha} \qquad (29)$$

which reflects the measured values with almost the same accuracy as equation 26.

In Figure 13 the sorption characteristics according to equation 29 are given for water and aqueous salt solutions. The results were obtained in reactor volumes of between 2.51 and 900 m^3. They lie close together, independent of the vessel volume. Equation 29 can thus be taken as a translation rule in scale-up on the basis of the oxygen transfer. In Table 3 the constant K_2 and exponent α are given for coalescent and noncoalescent fluid systems for turbine stirrers having $d/D = 0.14 - 0.5$.

Mass Transfer in Fluids of Higher Viscosity. For fluids of higher viscosity, in particular those with non-Newtonian flow behavior, there have been few systematic investigations published that deal with the determination of the volumetric mass transfer coefficient, $k_L a$. Figure 14 shows a plot of several sorption characteristics for millet pulp, aqueous glucose solutions, and aqueous CMC solutions using the same correlation (equation 29) as for low-viscosity fluids (4,35,49). Thereby the translation rule given by equation 29 is confirmed for all fluid systems, even though the viscosity and the diffusion coefficient change by a factor of 1,000 and 30, respectively. To illustrate the experimental results for non-Newtonian fluids it is necessary, however, as with the determination of the power input, to calculate the apparent viscosity with equations 4 and 7 according to the concept of Metzner and Otto (24).

In Table 3 all sorption characteristics compiled by Henzler (4) are shown. Because these sorption characteristics are valid only for the particular rheological behavior and coalescence properties of each system, such properties have to be measured in the fermentation medium before an exact calculation of the mass transport is possible. Perez and Sandall (50) proposed the following correlation to calculate the volumetric mass transfer coefficient for pseudoplastic non-Newtonian fluids according to an approach of Sideman et al. (51):

$$k_L a\left(\frac{d^2}{\mathcal{D}}\right) = 21.24 Re^{111} Sc^{0.5}\left(\frac{\eta_a \cdot u_G}{\sigma}\right)^{0.447}\left(\frac{\eta_G}{\eta_a}\right)^{0.694} \qquad (30)$$

The range of the flow behavior indices according to equation 5 is $m' = 0.916 - 1.00$ and $K' = (0.009 - 0.04)$ Pa $\cdot$ s$^{m'}$ with a vessel diameter of $D = 0.1524$ m. Kawase and Moo-Young (52) showed that the proposed model correlates reasonably well with the relatively wide variety of data measured by different authors for a range of vessel diameters of $D = 0.15 - 0.6$ m and for the flow behavior indices $m' = 0.59 - 0.95$ and $K' = (0.00355 - 10.8)$ Pa $\cdot$ s$^{m'}$.

A completely different correlation for the calculation of the volumetric mass transfer coefficient, $k_L a$, was suggested by Mooyman (53):

$$k_L a = C(270\varphi_G + 135\varphi_G \log(P_a/V)) \qquad (31)$$

Equation 31 expresses the overall transfer coefficient as an enhancement formula dependent on two variables: the gas holdup fraction, φ_G, that is given by

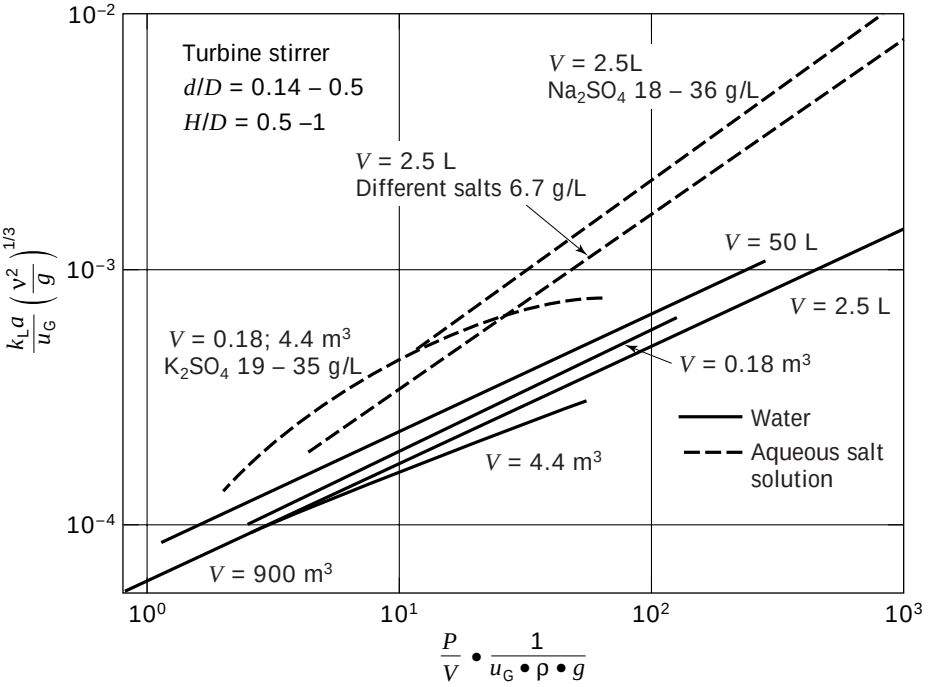

Figure 13. Sorption characteristics of aqueous systems for turbine stirrers.

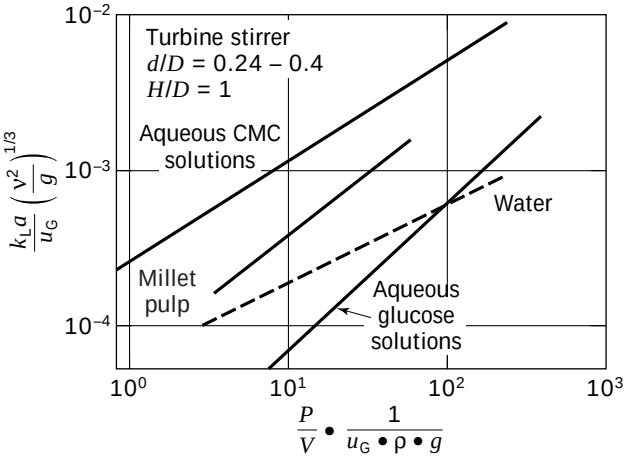

Figure 14. Sorption characteristics for millet pulp, glucose solutions, and CMC solutions.

$$\varphi_G = 0.1\left(\log\left(10.915 u_G \frac{p}{p_{av}}\right) - 0.9\right) \tag{32}$$

and the mechanical plus the adiabatic gas expansion power input per unit of volume, P_a/V; C is a multiplication factor required to correct published or calculated k_La data to actual values observed in industrial fermentations with operating volumes above 250 L (53).

The effects of the suspension of solids on the mass transfer in sparged tank reactors have been investigated by various authors (e.g., Mills et al. [54] and Oguz et al. [55]). Of particular note is the dimensionless correlation developed by Oguz et al. (55) for the k_La in air-sparged agitated tanks containing slurries of different materials:

$$k_L a \frac{V}{q_G} = 2.173 \cdot 10^{-3}\left[\frac{P/q_G}{\rho^{1/3}(\eta_a \cdot g)^{2/3}}\right]^{0.607} \tag{33}$$

The influence of the solid concentration becomes evident

in the calculation of the apparent viscosity of the slurries, which all showed non-Newtonian behavior. Consequently the viscosity was calculated with equations 4 and 7 according to the concept of Metzner and Otto (24). Oguz et al. (55) showed that an increase in the solid concentration leads to an increase of the slurry viscosity that corresponds to a decrease in k_La. The deviation of the measured data from the values calculated with equation 33 was in the range of 12.5%.

For a scale-up on the basis of constant volumetric mass transfer coefficients, there follows from the generally valid equation 29

$$\left(\frac{P}{V}\right)u_G^{(1-\alpha)/\alpha} = \text{idem} \tag{34}$$

for the power input required. The exponent α is approximately 0.67 for noncoalescing aqueous systems as well as for more highly viscous Newtonian fermentation fluids. From equation 34 it follows that

$$\left(\frac{P}{V}\right)u_G^{0.5} = \text{idem} \tag{35}$$

For example, with $u_G \sim q_G/D^2$

$$\left(\frac{P}{V}\right)\frac{q_G^{0.5}}{D} = \text{idem} \tag{36}$$

If surface-active substances, such as chemical antifoam agents, are added to the fermentation medium, the volumetric mass transfer coefficient at the interfacial surface usually drops, and the mass transfer behavior tends toward a coalescing fluid system. In a coalescing fluid system and for non-Newtonian fluids, the exponent α is approximately 0.5. Consequently it follows from equation 29 that

$$\left(\frac{P}{V}\right)u_G = \text{idem} \tag{37}$$

and

$$\left(\frac{P}{V}\right)\frac{q_G}{D^2} = \text{idem} \tag{38}$$

In applying this translation rule (equations 35–38), the dispersing capacity of the stirrer, as given by equation 12, also has to be taken into consideration.

Shearing Stress and Pumping Capacity of the Stirrer

The mixing of the fermentation broth, the distribution and dispersion of the gases, and the suspending of solid constituents of the culture medium and microorganism pellets are effected in the stirred tank by a complex three-dimensional flow field. In only a few isolated cases (those that have a defined flow field) can the shearing stress and the pump capacity of the stirrer be calculated. With turbulent mixing it is possible, however, only to estimate both the longitudinal mixing by the pumping around of the vessel contents, and the shear stress on the fluid caused by the fluctuations in turbulence.

In a theoretical consideration of turbulent flow, Reynolds split up the measured local liquid velocity, u_L, into the sum of a mean (deterministic) velocity, $\bar{u}$, and a superposed stochastic fluctuation velocity, u'. According to this hypothesis, the turbulent Reynolds shear stress produced by the stirrer is proportional to the square of the local fluctuation velocity of the turbulence and is approximately given by the tip speed of the stirrer

$$\tau_R \sim (n \cdot d)^2 \tag{39}$$

With the Reynolds shear stress, τ_R, the effects of the stochastic liquid fluctuation velocity, u', are mathematically seized. τ_R can be interpreted as a virtual shear stress, that is, a consequence of the impulse transport caused by the turbulent motions.

Hoffmann et al. (56) determined the shear stress in stirred-tank reactors by means of a model system consisting of flocculated clay. Their investigations showed that the proportionality between shear stress of the clay floc system and the tip speed of the stirrer is of little influence; this is caused by the distinctness of the length scale of the vortices resulting from the Reynolds shear stress and the size of the relatively small flocs. The clay floc system is suitable for describing the influence of shear stress on tissue cell cultures (57).

Therefore, the model of Cherry and Kwon (58) is proposed for the calculation of shear stress. It is based on Kolmogoroff's theory of local homogenous isotropic turbulence: the length scale of the microeddies in the dissipative area (with laminar flow of the eddies) yields

$$\lambda = \left(\frac{\nu^3}{\varepsilon}\right)^{0.25} \tag{40}$$

where ε is the energy dissipation rate (i.e., the energy input to the system that is completely dissipated by the formation of vortices)

$$\varepsilon = \frac{P}{\rho \cdot V} \tag{41}$$

To employ this model by Cherry and Kwon (58), the particles exposed to shear have to be smaller than 12 times the length scale, λ, a condition that is usually fulfilled in fermentation processes. Under these circumstances the microeddies induced by the energy input or the energy dissipation rate, respectively, cause the shear stress. The particles are put into rotation by the velocity gradients in the microeddies, which are significantly larger than the gradients caused by the liquid fluctuation velocities in Reynolds hypothesis. The pulsating shear stress that acts upon the flocs during the contact with the microeddies leads to

$$\tau = 5.33\rho(\varepsilon \cdot \nu)^{0.5} \tag{42}$$

that is,

$$\tau = 5.33\left(\frac{P}{V}\nu \cdot \rho\right)^{0.5} = K_3\left(\frac{P}{V}\right)^{0.5} \quad (43)$$

The influence of the liquid fluctuation velocities (i.e., the influence of the shear stress caused by the microeddies) has its maximum value if the dimension of the particles is close to the length scale of the microeddies. In Figure 15 the relationship between the experimentally determined shear stress of the clay floc system and the volumetric energy input for different types of stirrers is shown, using a relationship in analogy to equation 43

$$\tau = K_3\left(\frac{P}{V}\right)^{\alpha} \quad (44)$$

The experimentally determined maximum shear stress deviates from the data calculated with the model of Cherry and Kwon (58) by two to six times. This can be explained by the fact that, according to the type of impeller system, there exist areas with increased energy dissipation rates in the reactor in the area close to the stirrer. This effect was not taken into consideration in the model, which uses a mean energy dissipation rate over the entire reactor volume that can be up to 30 times smaller than the maximum value of the energy dissipation rate close to the stirrer (59). Because the main part of the energy input is dissipated near the impeller, the model has to be extended by a supplementary corrective term containing information about the type of stirrer and its geometry (i.e., about the area with increased dissipation rates). By analogy with the work of Liepe (60), who studied the ratio between the maximum and the mean dissipation rate, $\varepsilon_{max}/\varepsilon$, of different impeller systems for dispersion tasks, Hoffmann et al. (56) suggested a corrective function

$$f = f\left(\frac{V}{V_S \cdot Ne}\right)^{\beta} \quad (45)$$

with the effective energy dissipation volume, V_S, that is proportional to the volume of the stirrer ($V_S \sim d^2 \cdot h_B$). The values of V/V_S and Ne are given in Figure 15. By fitting the experimental data, Hoffmann et al. (56) finally determined the following correlation for the calculation of shear stress in stirred-tank reactors:

$$\tau = 0.367\left(\frac{P}{V}\left(\frac{V}{V_S \cdot Ne}\right)^{0.42}\right)^{0.55} \quad (46)$$

Figure 16 shows the calculated shear stress according to equation 46 compared with the experimentally determined data (56). The deviation of the model from the measured data is in a range of up to 30%, which means the model is suitable for a scale-up of the reactor performance on the basis of constant shear stress. In a sparged stirred-tank reactor the shear stress is also dependent on the gas input. Experimental investigations of Henzler and Biedermann (61) showed that there is a qualitative dependency of the shear stress on the pneumatic power input and the type of sparging system. They observed that with constant volumetric power input the shear stress increases with the increasing portion of pneumatic power input and with increasing superficial gas velocity. They described some of

Stirrer		d/D	V/V_S	Ne

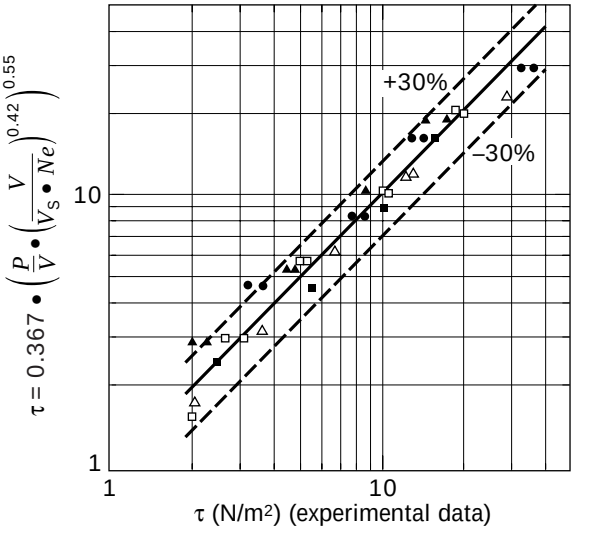

Figure 16. Experimentally determined shear stress compared with calculated data, according to equation 46; for symbols, see Figure 15.

the observed effects causing the increased shear stress, such as the turbulence in the lag zone of rising bubbles, coalescence or dispersion of bubbles close to the sparger, and the bursting of bubbles at the liquid surface (as is observed in bubble columns) (62). Because a model or correlations to describe these effects quantitatively are not yet known, further investigations are necessary to describe the effects of sparging and bubbles on the mechanical shear stress in stirred vessels.

A relationship for the circulating volumetric flow, which is produced by the pumping capacity of the stirrer, can be derived in a manner analogous to the principle that applies to rotary pumps. In this way Van de Vusse (39) calculated the circulating volumetric flow of propellers with the assumption that counterpressure is "zero" and obtained

$$\dot{V} = 0.5 \frac{\pi}{4} n \cdot d^2 \cdot h_S \tag{47}$$

where h_S is the pressure head produced by the propeller. With $h_S \sim d$, the generalized relationship

$$\dot{V} = K_4 \cdot n \cdot d^3 \tag{48}$$

follows from equation 47. K_4 is a constant that is essentially dependent on the type of stirrer (63) (see also Refs. 16, 19, and 64).

Varying details have been published regarding the suspension of solids in stirring apparatuses. Most authors say that in achieving the same suspension result in a larger vessel, the power input can be diminished (43). The circulating volumetric flow given by equation 48 is sufficiently large under the conditions of stirring that generally prevail in stirred-tank reactors so that a uniform distribution of cell pellets and solid constituents in the culture medium is guaranteed. This uniform distribution is supported by the very slight density differences between solid and liquid in the fermentation medium, and the relatively small solid particles and the small fraction of solid material ($d_P < 2$ mm, $\varphi_S < 20\%$) in the fermentation medium. Consequently the suspension process in general takes on no particular significance in scaling up stirred-tank reactors.

Mass Transport Processes in Mycelium Agglomerates

Mycelium-forming microorganisms can build up many morphological forms while submerged fermentation, depending on the conditions of fermentation. Forms include loose hyphae that are distributed homogenously throughout the medium or collect in agglomerates that appear as compact pellets. Whereas the filamentous forms result in highly viscous, non-Newtonian fermentation fluids, the mycelial pellets are usually present in Newtonian fluid systems at a considerably lower viscosity (65). An adequate shearing of the mycelium-forming microorganisms thereby leads to the preferred formation of pellets rather than a filamentous mycelial structure.

Regardless of whether the formation of pellets and compact cell agglomerates leads to fluids of lower viscosity (and thus to more turbulent conditions), problems regarding the oxygen supply to the cells can arise, in particular with large, compact pellets. When the inner and outer mass transport resistances are too large, the danger of autolysis exists, and only the external pellet layer is involved in the biotechnological process.

The effective diffusion coefficient of oxygen in mycelial pellets of *Aspergillus niger* was found to be about $\mathcal{D}_{Pe} = 10^{-4}$ cm^2/s (2). This value is larger by a factor of 10 than the molecular diffusion coefficient, $\mathcal{D}$, in the culture medium. Because the diffusion coefficient determined by Miura (2) also varied with the volumetric power input, this result must be interpreted as indicating that the mycelium forms a loose pellet structure that is penetrated by the turbulent microflow. Thus in such cultures an adequate but not excessive turbulence (i.e., shear stress) is required in order for pellets with a loose structure to form.

Whereas the mass transport inside mycelial aggregates has still not been widely researched, reliable equations exist for determining the mass transfer from fluid to pellet. The mass transfer coefficient k_{Pe} on the surface of the pellet of diameter d_{Pe} can be calculated from the formal relationship

$$Sh = f(Re_{Pe}, Sc) \tag{49}$$

where $Sh \equiv k_{Pe} \cdot d_{Pe}/\mathcal{D}$ is the Sherwood number, $Re_{Pe} \equiv u_{Pe} \cdot d_{Pe}/\nu$ is the Reynolds number formed with the relative velocity between pellet and fluid, and $Sc \equiv \nu/\mathcal{D}$ is the Schmidt number. The relative velocity at the pellet is determined solely by local turbulent fluctuation velocities, u', which are effected by the turbulent eddies of the scale of the pellets. According to the theory of isotropic turbulence put forward by Kolmogoroff, it follows for this velocity that

$$\sqrt{\overline{u'^2}} \sim (\varepsilon \cdot d_{Pe})^{1/3} \tag{50}$$

where ε is the mass-related energy of dissipation calculated with equation 41. Then the Reynolds number, formed with the relative velocity

$$u_{Pe} \sim \sqrt{\overline{u'^2}}$$

is

$$Re_{Pe} = \left(\frac{P}{V} \frac{d_{Pe}^4}{\rho \cdot \nu^3}\right)^{1/3} \tag{51}$$

In Figure 17 the experimental results according to equation 49, from different authors, are shown; the experimental data, following the theory, have been plotted as

$$\frac{Sh - 2}{Sc^{1/3}} = f(Re_{Pe}) \tag{52}$$

The only published equations that are mentioned here are those relationships reported by Liepe and Moeckel (66); with the relative velocity defined here they are given by

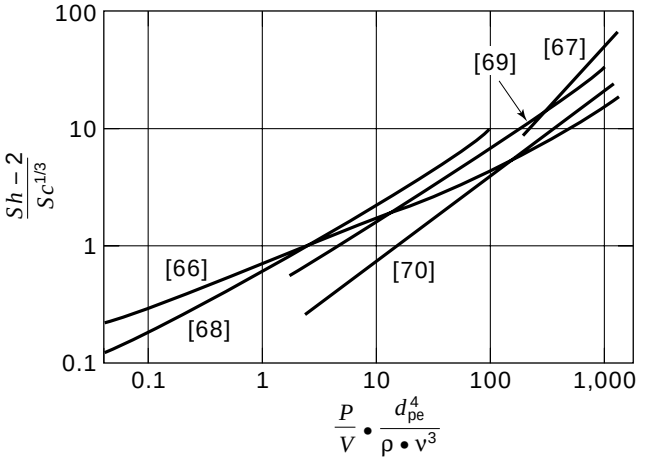

Figure 17. Mass transfer at the pellet surface as dependent on the particle Reynolds number. Numbers in brackets indicate reference.

$$\frac{Sh - 2}{Sc^{1/3}} = 0.35\left(\frac{\Delta\rho}{\rho}\right)^{1/3}\left(\frac{P}{V}\frac{d_{Pe}^4}{\rho \cdot \nu^3}\right) \qquad (53)$$

The curve given by equations 52 and 53 is illustrated in Figure 17, marked according to Liepe and Moeckel (66). Apart from the measurements made by Sicardi et al. (67), all measurements were performed in a nongassed system. Nevertheless the comparison of results shows that the presence of gas has virtually no influence on the mass transfer from fluid to pellet.

SCALE-UP EXAMPLES OF BIOTECHNOLOGICAL PROCESSES BY MAINTENANCE OF IDENTICAL OPERATING CONDITIONS

Scale-Up on the Basis of the Oxygen Transfer Rate

A scale-up of aerobic biotechnological processes is often performed successfully using the criterion of identical oxygen transfer rate (OTR = idem), or the same volumetric mass transfer coefficient (k_La = idem). The reason is that in the aerobic culture of yeasts and bacteria, which have high rates of respiration, the rate-limiting reaction step is often located in the oxygen transfer resistance at the gas–liquid interface. In the fermentation of mycelium-forming microorganisms there arises, under certain conditions, a further limiting mass transport resistance at the surface of or inside the mycelial pellet. That is the reason why a scale-up on the basis of both mass transport resistances is more successful.

Karow et al. (71) took the oxygen transfer rate as a scale-up criterion for the production of penicillin and streptomycin. In Figure 18 the relative penicillin concentrations are shown as a function of the oxygen transfer rate. The results for the production of streptomycin are very similar. The scale-up covers 4 orders of magnitude. At oxygen transfer rates of more than 0.5 mol/(L h) the product yield is maximal and nearly constant. The successful translation from the laboratory to a production scale, performed by

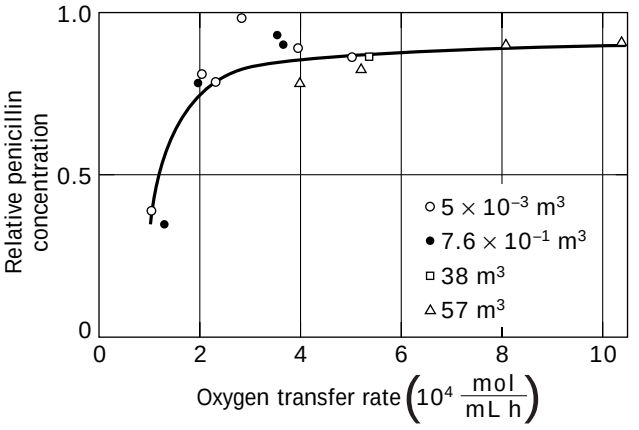

Figure 18. Production of penicillin as a function of the oxygen transfer rate.

Karow et al. (71), was also confirmed by Bylinkina et al. (72) for the fermentation of penicillin and streptomycin. They carried out a scale-up from the 15-L fermentor via a 100-L and 3-m^3 fermentor up to a 63-m^3 production fermentor on the basis of the mass transfer coefficient at the gas–liquid interface. Wegrich and Shurter (73) also described a successful scale-up of penicillin production. The same yields of penicillin were attained in an 8-m^3 fermentor as in a 100-m^3 fermentor. They did not only keep the superficial gas velocity constant but also the volumetric power input of the stirrer. According to equation 37, holding these parameters constant in non-Newtonian fluids corresponds to the scale-up rule k_La = idem.

A further, now "historical," example of scale-up on the basis of the oxygen transfer is shown in Figure 19, in which the production of baker's yeast is depicted (74). Although the oxygen transfer rate in the model system (sulfite oxidation), used as the scale-up criterion, was measured, no significant difference in the production of yeast could be

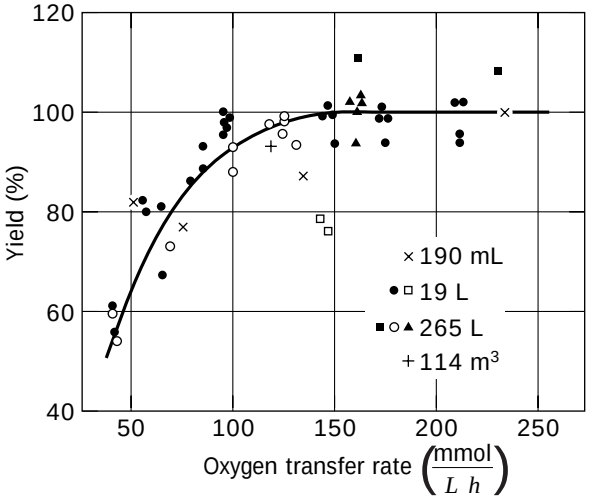

Figure 19. Scale-up of fermentation of baker's yeast based on oxygen transfer rate (sulfite oxidation).

established, which was dependent only on the size of the reactor. Those points plotted in Figure 19 were obtained using shaker flasks with a 190-mL liquid content and in 19-L, 265-L, and 114-m^3 fermentors. Jari (75) was able to show for the production of the primary metabolites alkaline and acid proteases and the secondary metabolites nystatin and fumagillin that a scale-up can be carried out using the same oxygen transfer rate (k_La = idem).

In the bacterial production of vitamin B_{12}, Bartholomew (76) established that the yield at high oxygen transfer rates is negatively influenced by a not very clearly described effect (Fig. 20). Since, moreover, this effect is dependent on the fermentor size, the oxygen transfer rate in this region cannot be used as a scale-up criterion. The dotted curve in Figure 20 applies to the yield only when small-scale equipment is used, and the continuous line represents the yield achieved in a production fermentor. In other words, the production fermentor is oversized. Takei et al. (77) studied protease production by *Streptomyces* sp. in a 0.03-m^3- and a 0.2-m^3-sized fermentor and found the same effect. The productivity of the cells in synthesizing protease is indeed determined by the oxygen transfer rate but is nonetheless diminished at higher oxygen transfer rates by a fermentor size–dependent effect.

In the production of glucoamylase by *Endomyces* sp., the enzyme yield is also not solely determined by the oxygen transport. A scale-up on the basis of identical k_La values also leads to oversizing of the production fermentor. The yields depicted in Figure 21, expressed in relative enzyme activities as a function of the volumetric mass transfer coefficients, were measured in fermentors of 0.06 m^3, 3 m^3, and 30 m^3 (78). In the latter three examples of fermentation described, no adequate scale-up among the fermentor sizes was achieved by using solely the oxygen transfer rate (i.e., the k_La value). The reasons for such deviations can be diverse. For example, in applying the same k_La values as a scale-up criterion, the influence of the surface aeration has to be taken into consideration. Fuchs et al. (79) showed that this effect makes itself felt at fermentor volumes smaller than 200 L.

The translation of the oxygen transfer rate from a laboratory fermentor to a production scale can still lead to

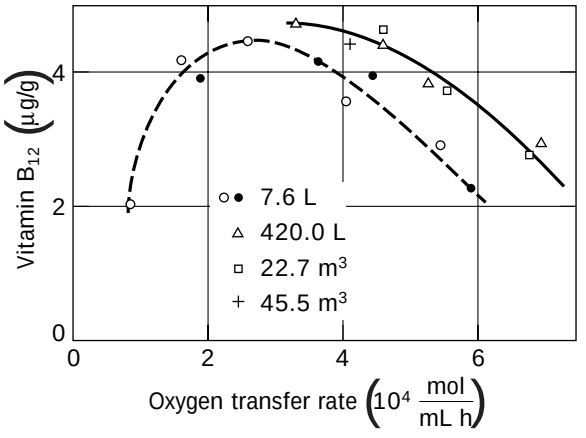

Figure 20. Production of vitamin B_{12} as function of the oxygen transfer rate.

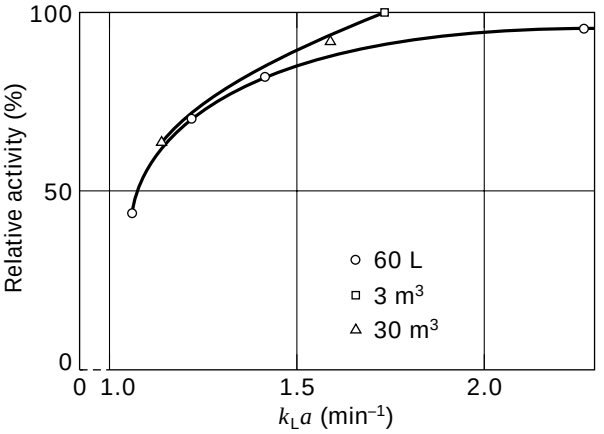

Figure 21. Relative glucoamylase activity as function of the k_La value.

considerable errors for other reasons. Thus, with the same k_La value, the oxygen transfer rate in the production fermentor can be larger than in the laboratory fermentor because, owing to the higher hydrostatic pressure, the driving force (concentration difference) will be larger. But with the same bubble size (identical rising velocity of the bubbles) the average residence time of the air bubble in the larger apparatus is longer; it is thus deficient in oxygen, and consequently, the positive effect of hydrostatic pressure, just cited, is diminished.

Scale-Up on the Basis of the Volumetric Power Input

One-third of the scale-up translations performed in the fermentation industry use the scale-up criterion "identical volumetric power input," as Margarites and Zajic (15) reported. Apart from the simplicity of the measurement in applying this scale-up rule, the reason for its industrial success probably lies in the fact that almost all hydrodynamic and mass transport phenomena can be correlated using the dissipated energy (and thus using P/V). Nevertheless, or maybe simply because of it, this criterion provides an extremely rough rule of thumb, which permits a scale-up only on an empirical basis.

Maxon (80) studied the influence of the volumetric power input on the production of novobiocin using *Streptomyces niveus*. In Figure 22 the novobiocin concentration produced is plotted against the volume-related power input for three different sizes of stirrer. Above P/V = 1 kW/m^3 the yields of the antibiotic are maximal and largely independent of P/V. Scale-up based on this criterion is not dependable because it has been established that there is a dependance on the diameter of the stirrer. According to Wang and Fewkes (81) a scale-up of this process is possible only owing to the partial similarity of the turbulent shearing stress and the pumping capacity of the stirrer.

In the fermentation of penicillin, the volumetric power input, P/V, was often used in the past as a criterion for scale-up. In Figure 23 the penicillin concentration is plotted as a function of the volume-related stirring power, as described by Gaden (82), who gave P/V values between 1.5

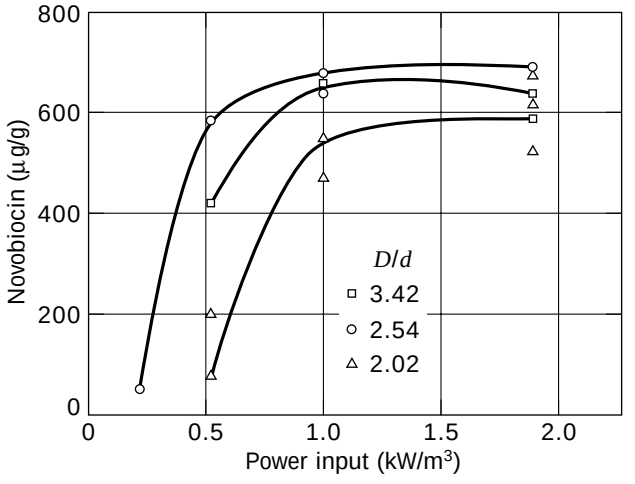

Figure 22. Novobiocin concentration after 115 h of fermentation duration, dependent upon the volumetric power input.

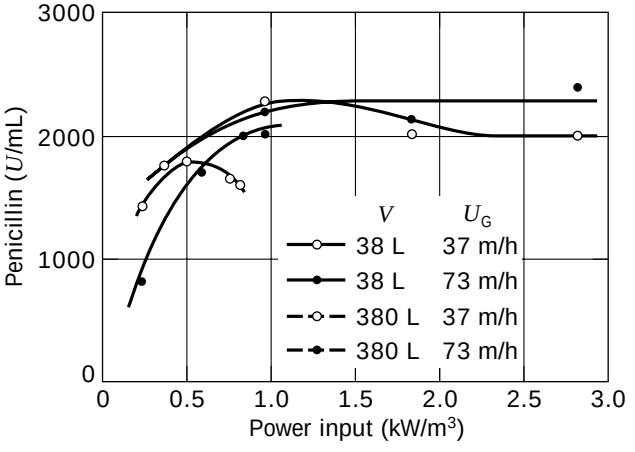

Figure 23. Influence of the volumetric power input on the synthesis of penicillin.

and 3 kW/m^3 as a scale-up rule. Similar results were achieved by Humphrey (83,84), who established a correlation between penicillin production and the volumetric power input and carried out a scale-up at a volume-related stirring power between 1 and 2.5 kW/m^3. Humphrey (84) reports a volumetric power input of 1.5 kW/m^3 for a scale-up of streptomycin production.

NOMENCLATURE

A	Reactor cross-sectional area (m^2)
a	Interfacial exchange area per unit volume (m^2/m^3)
$B \equiv (q_G/D^2)/(v \cdot g)^{1/3}$	Dimensionless gassing number
C	Factor
$c^*_{O_2}$	Saturation concentration of O_2 in fermentation medium (mg/L)
c_{O_2}	Concentration of O_2 in fermentation medium (mg/L)
$c^*_{O_2,in}$, $c^*_{O_2,out}$	Saturation concentration of O_2 at entrance and exit of reactor (mg/L)
D	Diameter of stirred-tank reactor (m)
$\mathscr{D}$	Diffusion coefficient of the liquid phase (m^2/s)
$\mathscr{D}_{Pe}$	Effective diffusion coefficient in mycelial pellets (m^2/s)
d	Diameter of the stirrer (m)
d_P	Diameter of solid particles (m)
d_{Pe}	Diameter of mycelial pellets (m)
$Fr \equiv n^2 \cdot d/g$	Froude number
$Ga \equiv d^3 \cdot g/v$	Galilei number
g	Acceleration due to gravity (m/s^2)
H	Liquid filling height in the reactor (m)
h	Distance between stirrers (m)
h_B	Height of stirrer blade (m)
h_S	Pressure head of the stirrer (m)
i	Number of stirrer blades
K	Proportionality constant
K'	Consistency index [(Pa s)m']
K''	Consistency index [(Pa s)m'']
K_1, K_2, K_3, K_4	Constants
k_L	Liquid-side mass transfer coefficient at gas–liquid interface (m/s)
k_{Pe}	Mass transfer coefficient at mycelium pellet surface (m/s)
k_La	Volumetric mass transfer coefficient at gas–liquid interface (s^{-1})
m', m''	Flow behavior parameters
$Ne \equiv P/\rho \cdot n^3 \cdot d^5$	Newton number
Ne_G	Newton number in gassed reactor at $Re > 10^4$
Ne_0	Newton number without gassing
$\dot{N}_{O_2}$	Oxygen mass flow (kg/s)
n	Rotational speed (s^{-1})
$\dot{n}_{O_2}$	Oxygen transfer rate (mass flow density) [kg/(s · m^3)]
P	Stirring power (kW)
P_a	Mechanical plus adiabatic gas expansion power input (kW)
p	Atmospheric pressure (N/m^2)
p_{av}	Average pressure at half the liquid height (N/m^2)
$Q \equiv q_G/n \cdot d^3$	Dimensionless gassing number
Q_{max}	Dimensionless gas flow number at flooding point of stirrer
q_G	Gas throughput (m^3/s)
$q_{G,max}$	Maximum gas throughput (m^3/s)

$Re \equiv n \cdot d^2/\nu$	Reynolds number
$Re^* \equiv n \cdot d^2 \cdot \rho/\eta_a$	Modified Reynolds number
$Re_{Pe} \equiv u_{Pe} \cdot d_{Pe}/\nu$	Pellet Reynolds number
S_i	Characteristic quantities for coalescence of fluids
$Sc \equiv \nu/\mathcal{D}$	Schmidt number
$Sh \equiv k_{Pe} \cdot d_{Pe}/\mathcal{D}$	Pellet Sherwood number
u'	Turbulent fluctuation velocity of the fluid (m/s)
$\bar{u}$	Mean velocity of the fluid (m/s)
u_G	Gas velocity based on empty cross section area of the reactor (m/s)
u_L	Local liquid velocity (m/s)
u_{Pe}	Relative velocity between pellet and fluid (m/s)
V	Reactor volume (m^3)
$\dot{V}$	Circulating volumetric flow by stirrer pumping (m^3/s)
V_S	Volume stirred up by the stirrer blades (m^3)
Z	Number of stirrer blades
α	Exponent
β	Exponent
$\dot{\gamma}$	Shear rate (s^{-1})
ε	Mass-related energy dissipation rate (kW/kg)
ε_{max}	Maximum energy dissipation rate (kW/kg)
η	Dynamic viscosity (Pa s)
η_a	Apparent dynamic viscosity (Pa s)
η_G	Dynamic viscosity of the gas phase (Pa s)
θ	Mixing time (s)
λ	Length scale of microeddies (m)
ν	Kinematic viscosity (m^2/s)
ρ	Density of fermentation fluid (kg/m^3)
σ	Surface tension (N/m)
$\sigma^* \equiv \sigma/[\rho(g \cdot \nu^4)^{1/3}]$	Dimensionless surface tension
τ	Shear stress (Pa)
τ_R	Reynolds shear stress (Pa)
τ_0	Yield stress (Pa)
φ_G	Gas holdup
φ_S	Solid holdup

OUTLINE

INTRODUCTION

Actinomycetes are an industrially important group of microorganisms, producing, in fermentation, numerous therapeutically relevant natural products. In the pharmaceutical and biotechnology industries, they continue to be the focus of many natural product screening programs, especially in the search for novel antibiotics active against

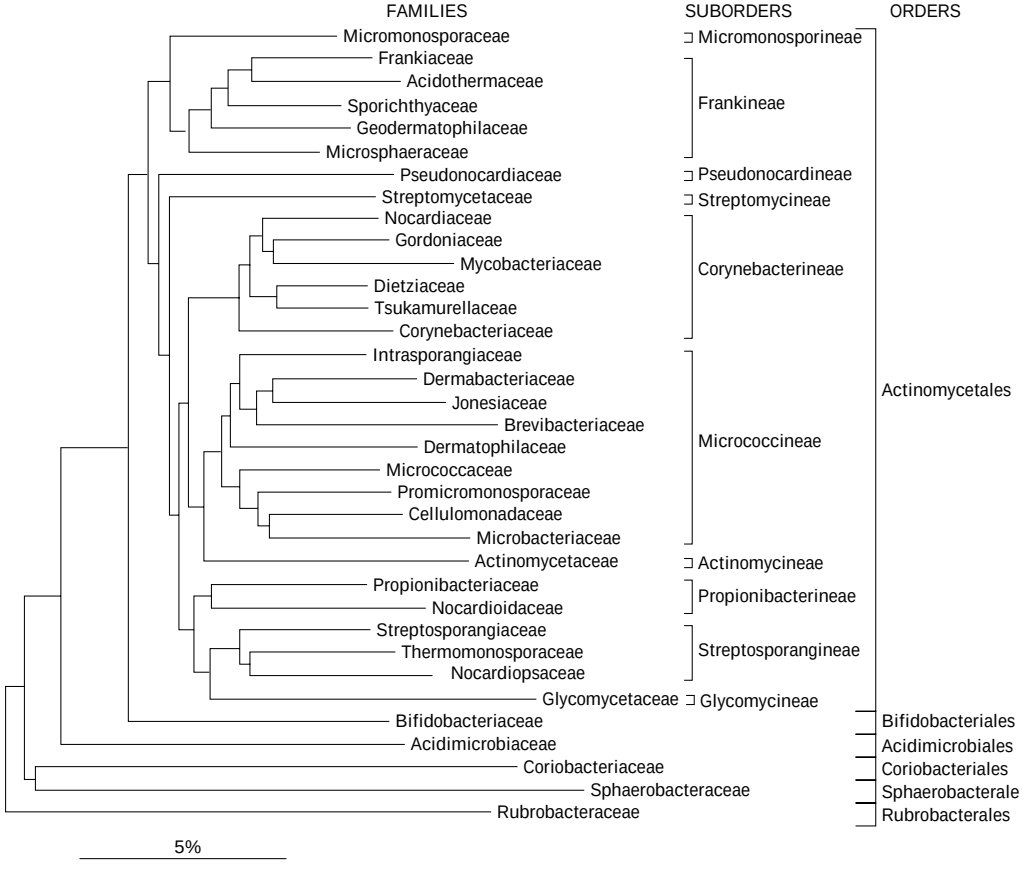

Figure 1. Relatedness of actinobacteria showing the presence of 6 orders and 10 suborders of the Actinomycetales based on 16S rDNA/rRNA sequence comparison. The scale bar represents 5 nucleotide substitutions per 100 nucleotides. *Source*: From Stackebrandt et al. (2).

Table 1. Morphological Characteristics of Members of the Families Streptosporangiaceae, Nocardiopsaceae, Thermomonosporaceae, Pseudonocardiaceae, Micromonosporaceae, and Glycomycetaceae

Family/genus	Substrate mycella	Aerial mycelia	Spore chains	Spores
		Streptosporangiaceae		
Streptosporangium	Branching, nonfragmenting; yellow, brown, orange, red	Present; white, pink to greenish-gray; spore vesicles borne on long or short sporangiophores, singly or clustered	Spore vesicles contain a coiled chain of arthrospores formed by septation of an unbranched, spiral hyphae within an expanded sporangiophore sheath.	Nonmotile; smooth, spherical, oval or rod-shaped
Herbidospora	Branching, nonfragmenting; colorless, tan to yellow-brown	Absent; spore chains, in mass, white	Straight, short chains, 10 to 30 spores, borne on tips of branching sporophores, in clusters, directly from the vegetative mycelium	Nonmotile; smooth, oval
Microbispora[a]	Branching, nonfragmenting; yellow, brown, orange, violet	Present; pink to white; bearing longitudinal pairs of spores often closely arranged along the hyphae, either sessile or on short sporophores	Spores in pairs	Nonmotile; smooth, spherical to oval
Microtetraspora	Branching, nonfragmenting; yellow, brown, orange, violet	Present; white, pink, blue-gray; short, sparsely branched	Spores in chains of 4	Nonmotile; smooth, warty, spherical to oval
Planobispora	Branching, nonfragmenting; colorless or rose	Present; white to light rose; bearing cylindrical to clavate sporangia, singly or in bundles, on short sporangiophores	Longitudinal pairs of spores in sporangia	Motile; peritrichous flagella; smooth, straight to slightly curved
Planomonospora	Branching, nonfragmenting; grayish-yellow, pink, reddish, orange	Present; white to rose; bearing cylindrical to clavate sporangia, sessile or on sporangiophores	Single spore in each sporangium	Motile; peritrichous flagella; straight to curved.
		Nocardiopsaceae		
Nocardiopsis	Branching, fragmenting into rods and coccal elements; yellow, yellowish-brown, olive	Present; white, yellowish-gray; long, moderately branched; straight to flexous, zigzag fragmentation	Fragmenting into long (greater than 50) chains of spores	Nonmotile; smooth, irregular
		Thermomonosporaceae		
Thermomonospora[b]	Branching, nonfragmenting; colorless to pale yellow	Present; white; differentiates into a single, heat sensitive spore	Single, sessile, or on the end of short branched or unbranched sporophores	Nonmotile; smooth to ridged
Actinomadura	Branching, nonfragmenting; colorless to yellow, orange, brown, red-brown, red, violet, gray-green	Present; white, yellow, pink, blue, green, gray; branching, carrying short to long chains of arthrospores	Straight, flexous, hooked, open loops, irregular spirals of 1 to 4 turns	Nonmotile; folded, irregular, smooth, spiny, or warty
Spirillospora[c]	Branching, nonfragmenting; white, pale yellow, pale pink, red to reddish brown	Present; white; bearing spherical sporangia on sporangiophores	Each spore vesicle contains coiled, branched aerial hyphae that differentiate into spores.	Motile, 1 to 7 subpolar flagella; smooth, rod-shaped, curved

Table 1. Morphological Characteristics of Members of the Families Streptosporangiaceae, Nocardiopsaceae, Thermomonosporaceae, Pseudonocardiaceae, Micromonosporaceae, and Glycomycetaceae (continued)

Family/genus	Substrate mycella	Aerial mycelia	Spore chains	Spores
		Micromonosporaceae		
Micromonospora	Branching, well developed; tan to orange, brown, blue-green, purple	Absent or a gray to white bloom	Borne singly, sessile or on short sporophores, in branched clusters	Nonmotile; smooth to warty, oval
Actinoplanes	Branching, nonfragmenting; tan to red, brown, violet	Absent or scanty, sporangia, spherical, subspherical, clavate, irregular, arising from the substrate mycelia, sessile or on short sporangiophores	Within the sporangia	Motile, polar flagella; spherical or short rods
Catellatospora	Branching, nonfragmenting; tan, yellow, mustard gold, orange, reddish brown.	Absent	Short, straight to flexous, branched chains of spores directly from the substrate mycelia	Nonmotile; cylindrical, ovoid, smooth to slightly rough
Couchioplanes	Branching, nonfragmenting; dark blue	Present; branching	Short spore chains in irregular spirals, directly from the substrate mycelia or on short aerial mycelia	Motile, polar flagellation; oval, short rods, smooth
Catenuloplanes	Branching, nonfragmenting; orange, red, brown	Present; sparse, branching	Short spore chains in spirals of 1 to 2 turns, from the substrate or aerial mycelia	Motile, peritrichous flagella; rod-shaped, straight to curved, smooth
Dactylosporangium	Branching, nonfragmenting; orange, rose, or wine.	Absent; sporangia present, borne on short sporangiospores, finger-shaped to claviform	Within the sporangia a single row of 3 to 4 spores	Motile, polar flagella; oblong, ovoid
Pilimelia	Branching, nonfragmenting; pale lemon-yellow, golden yellow, orange	Absent; sporangia present, spherical ovoid, pyriform, cylindrate, borne on sporangiospores	Within the sporangia, in parallel or swirl rows, and as conidia, in chains	Motile, sporangiospores, laterally inserted tuft of flagella; nonmotile, rod-shaped conidiospores
Spirilliplanes	Present, nonfragmenting, branching, yellow to orange	Absent	Short chains of spores arranged in spirals and clusters directly from the substrate mycelia	Motile, oval to short rods, smooth, flagella type not given
		Pseudonocardiaceae		
Pseudonocardia	Zigzag fragmentation and long chains of spore-like structures; mycelial wall with a characteristic electron dense outer layer	Present; white; fragmenting	Spore chains long, 50 or more per chain	Nonmotile; smooth, spiny, irregular
Actinopolyspora	Branching, occasionally fragments; buff	Present; white, with an outer sheath	Long chains of spores	Nonmotile; smooth
Actinosynnema	Fragmenting	Present; form synnemata (dome-like structures)	Chains of arthrospores at the tip of the synnemata	Motile arthrospores (flagellation not given)
Amycolatopsis	Fragments into long chains of squarish to ellipsoid structures	Rarely formed; when present, white; may fragment into chains of spores	Chains of squarish to oval fragments	Nonmotile; oval, smooth, warty
Kibdelosporangium	Zigzag fragmentation	Present; white; sporangia-like structures that do not contain spores but germinate when placed on agar	Long chains	Nonmotile; smooth, irregular

Table 1. Morphological Characteristics of Members of the Families Streptosporangiaceae, Nocardiopsaceae, Thermomonosporaceae, Pseudonocardiaceae, Micromonosporaceae, and Glycomycetaceae (*continued*)

Family/genus	Substrate mycella	Aerial mycelia	Spore chains	Spores
Kutzneria	Branching, nonfragmenting	Present; white, olive gray; branching with globose sporangia	Long chains formed by separation of coiled, unbranched hyphae	Nonmotile; spherical, rod-shaped or oval
Lentzea	Branching, nonfragmenting; yellow to yellow brown	Present; white to whitish-yellow; fragmenting into rod-shaped elements	Chains of rod-like structures	Nonmotile; smooth, rod-like
Saccharomonospora	Branching, rarely fragments; beige, lilac, green	Present; white becoming green; with an outer sheath	Single densely packed, on the aerial mycelia	Nonmotile; oval, smooth, warty
Saccharopolyspora	Fragmenting; spores often present	Present; white, pink to brownish gray, often sparse; with an outer sheath	Long and short chains	Nonmotile; spore sheath ornamentation hairy, spiny, smooth
Saccharothrix	Zigzag fragmentation; yellow to yellow brown	Present; white to yellowish-gray, zigzag fragmentation	Chains of ovoid to irregular elements	Nonmotile; smooth, ovoid
Streptoalloteichus	Branching, bearing spore-like vesicles containing one to several spores	Present; spore chains in clusters and sclerotia	Spore chains on the aerial mycelia, sporangiospores on the substrate mycelia	Motile sporangiospores by a single long polar flagellum
Thermocrispum	Branching, nonfragmenting; yellow to light brown	Present; white; aggregating into clusters that fragment into rod-like structures	Chains of rod-like structures	Nonmotile; smooth, rod-like
		Glycomycetaceae		
Glycomyces	Branching, nonfragmenting; pale yellow to tan	Present; white; forming spores	Short chains	Nonmotile; square-ended
		Genera of Uncertain Affiliation		
Actinobispora	Branching, nonfragmenting; bearing paired spores; light orange	Present; white; sparse; bearing paired spores	Longitudinal pairs	Nonmotile; smooth, spherical
Actinocorallia	Branching, nonfragmenting; ivory to pale yellow	Absent	Coralloid sporophores arising from the substrate mycelia bearing long chains (30+) of spores	Nonmotile; smooth, cylindrical
Actinokineospora	Branching, nonfragmenting; (on agar); colorless to yellow brown	Present; white; bearing chains of spores in a sheath	Irregularly curved; less than 50 per chain	Motile, peritrichous flagella; smooth, ovoid to squarish
Planotetraspora	Branching, nonfragmenting; ivory	Present; whitish gray; cylindrical sporangia on short sporangiophores	Single row of 4 spores per sporangium	Motile, a single polar flagellum
Thermobispora	Branching, nonfragmenting; yellow to yellow brown	Present; white; monopodially branched; bearing pairs of spores	In longitudinal pairs on the aerial hyphae	Nonmotile; smooth, spherical to oval

[a] *Microbispora bispora* has been removed from the genus to form a new, thermophilic single species genus, *Thermobispora* (7).
[b] The genus *Thermomonospora*, as defined by Kroppenstedt and Goodfellow (8), contains two species, *T. curvata* and *T. formosensis*.
[c] The genus *Spirillospora* was last placed in the family Streptosporangiaceae (9) based on 16S rDNA but has now been moved to the family Thermonomosporaceae (2).

Table 2. Cell Wall Types and Corresponding Whole-Cell Sugar Patterns of Aerobic Actinomycetes Containing *meso*-Diaminopimelic Acid

Cell Wall		Whole-cell sugar pattern		
Type	Distinguishing major constituents	Type	Diagnostic sugars	Representative genera
II	Glycine	D	Xylose, arabinose	*Micromonospora*
III	None	B	Madurose[a]	*Actinomadura*
		C	None	*Nocardiopsis*
IV	Arabinose, galactose	A	Arabinose, galactose	*Amycolatopsis*

Source: According to Lechevalier and Lechavalier (13).
[a]Madurose is 3-*O*-methyl-D-galactose.

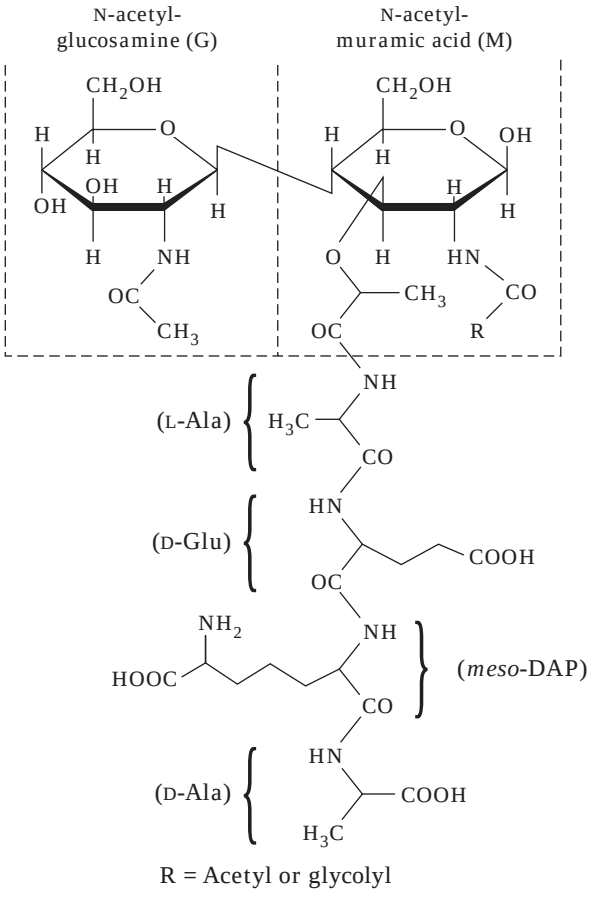

Figure 3. Complete structure of a single subunit of the peptidoglycan showing the linkage between the two amino sugars that make up the glycan strand and between muramic acid and the four amino acids in the peptide. Also indicated is the position of acetyl/glycolyl on muramic acid. *Source*: Modified from Suzuki et al. (15).

highly resistant, infectious Gram-positive pathogens. In an actinomycete-based natural product screening program, the organisms must be isolated from the environment, grown in pure state, preserved, and fermented, and the fermentation products must be tested for biological activity. Essential to this process is a knowledge of actinomycete ecology, taxonomy, and physiology, all of which contribute to the isolation of new strains with the potential of producing novel compounds.

Actinomycetes are Gram-positive, filamentous bacteria with a mol % G + C content of DNA greater than 50%. They can be divided into two broad groups: the fermentative organisms that are found in the natural cavities of man and animals and the larger group of oxidative organisms found in soil (1). The majority of oxidative soil actinomycetes can be further subdivided into two large groups based on the isomer of diaminopimelic acid in the peptidoglycan: the streptomycetes, containing LL-diaminopimelic acid (DAP) and the remainder containing *meso*-DAP. Further subdivisions to family, genus, and species relies on analysis of actinomycete morphology, determination of chemical constituents of cell walls and whole cells, biochemical characteristics, and resistance patterns. Sequence data generated from the analysis of small subunit RNA (16S) have been applied to the understanding of actinomycete phylogeny as well as molecular identification. A new hierarchical classification based on 16S rDNA/rRNA sequences (Fig. 1), proposed by Stackebrandt et al. (2), will be followed as phenotypic data are presented. Aerobic, saprophytic, filamentous actinomycetes containing *meso*-DAP in their cell

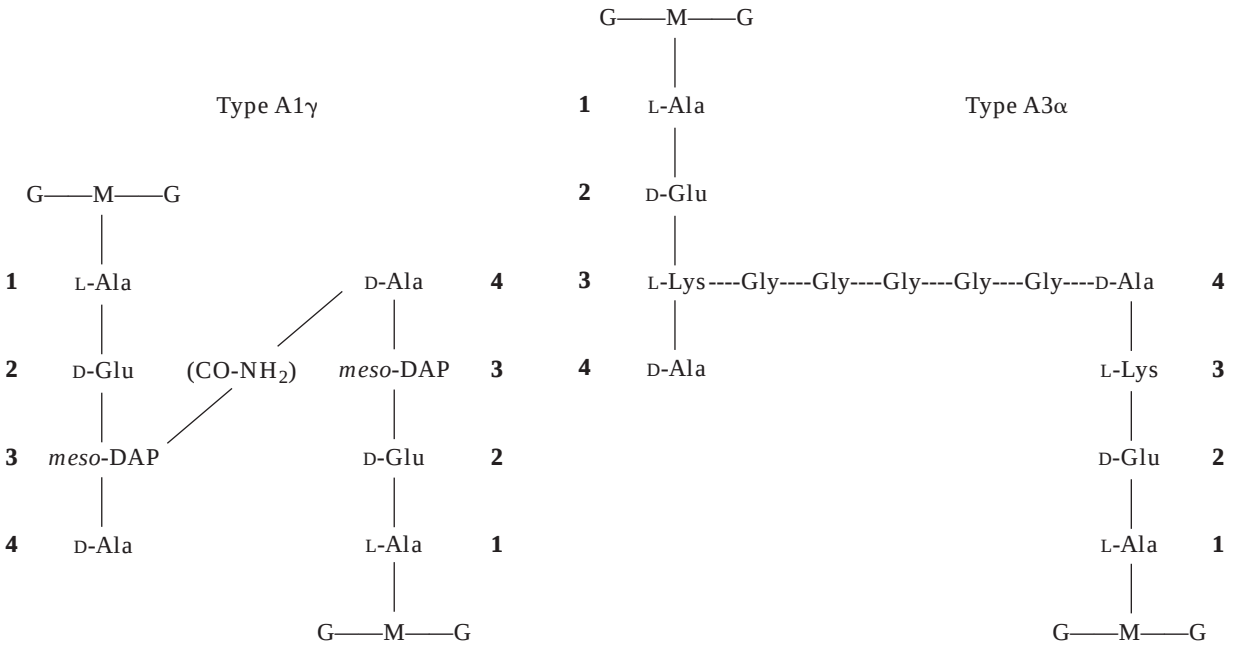

Figure 4. Example of a directly cross-linked *meso*-DAP–containing peptidoglycan of type A (cross-linkage between positions 3 and 4 of two peptide subunits), 1 (no peptide bridge), and γ (*meso*-DAP in position 3), and an example of cross-linking through a peptide bridge, A (as above), 3 (the bridge is an oligopeptide), and α (L-lysine in position 3. Ala, alanine; Dap, diaminopimelic acid; G, *N*-acetylglucosamine; Glu, glutamic acid; Gly, glycine; Lys, lysine; M, *N*-acetyl- or *N*-glycolylmuramic acid. *Source*: Modified from Suzuki et al. (15).

walls, which have not been placed in any of the actinomycete families defined by 16S rDNA sequence data, including Actinobispora (3), Actinocorallia (4), Actinokineospora (5), Planotetraspora (6), and Thermobispora (7) will also be described. The suborders Actinomycineae, Micrococcineae, Corynebacterineae, Propionibacterineae and Frankineae (2) will not be discussed in this article.

IDENTIFICATION OF NONSTREPTOMYCETE ACTINOMYCETES

Morphological Characterization

Meso-DAP–containing soil actinomycetes have a complex morphology. When grown on agar, a substrate mycelia forms that may penetrate the agar and that can bear spores, sporelike structures, or sporangia. Aerial mycelia may arise from the substrate mycelia and can be branching. The aerial mycelia may be in a sheath or in a sporangium and may fragment into motile or nonmotile spores. Morphological characteristics can be observed by growing the organisms on minimal media, for example, water agar (crude agar, 15 g; tap water, 1,000 mL), dilute Bennett's agar (agar, 15 g; glucose, 1 g; pancreatic digest of casein, 0.2 g; yeast extract, 0.1 g; beef extract, 0.1 g; distilled water, 1,000 mL), or dilute yeast–dextrose agar (agar, 15 g; yeast extract, 1 g; dextrose, 1 g; tap water, 1000 mL). After 7–28 days of incubation at 28 °C, plates can be examined directly under a light microscope using a long working distance, 40× objective. Detailed morphological analysis, such as spore and sporangiophore ornamentation, location and attachment of flagella on motile spores, and sporangial structures and spore formation within the sporangia will require either scanning or electron microscopic observations. In some cases, actinomycetes can be identified to genus based on their characteristic morphology (Table 1).

Chemical Characterization

Although the majority of actinomycetes readily form morphological structures, many do not, making preliminary identification based on this characteristic impossible. The laboratories of Huber and Mary Lechevalier at the Waksman Institute, Rutgers University, New Jersey, pioneered the extensive use of chemical markers to delineate genera of actinomycetes. The first large-scale, systematic application of chemical criteria to taxonomy focused on the analysis of cell-wall and whole-cell sugars and amino acids. Representatives of all the described actinomycete genera were analyzed, and distinct patterns were discerned (11,12) (Table 2). In conjunction with the data generated by Schleifer and Kandler (14) delineating the mode of cross-linking between subunits of the Gram-positive peptidoglycan (Figs. 2 to 4), a clearer understanding of the relationship of wall structure to wall chemotype was obtained (15) (Tables 3 and 4). The presence of either glycolyated or acetylated muramic acid in the cell wall (17,18) and lipids such as mycolic acids (19), phospholipids (20), menaquinones (21), and fatty acids (22,23) resulted in additional taxonomic discrimination. Phospholipid patterns are presented in Table 5, and the structure of typical ac-

Table 3. Peptidoglycan Classification

Position of cross-link	Peptide bridge	Amino acid at position 3
	Peptidoglycan A	
Cross-linkage between positions 3 and 4 of two peptide subunits	1. None	α-L-Lysine β-L-Ornithine γ-*meso*-DAP

[b]All cell wall preparations contain major amounts of alanine, glutamic acid, glucosamine, and muramic acid.
[c]From Schleifer and Kandler (14).

tinomycete fatty acids and the patterns obtained from their analysis are presented in Tables 6 and 7. Chemotaxonomic markers aid in the identification of actinomycetes to the genus level. Further discrimination to the species level can be achieved using physiological tests, including utilization of various carbon and nitrogen sources; hydrolysis of complex carbohydrates and macromolecules; and resistance to chemicals, including antibiotics (24,25). Sequence analysis, particularly of the 16S rDNA, may play a significant role in future definitions of actinomycete species. However, because of the highly conserved nature of small subunit RNA, very high similarity levels (greater than 97%) among related strains will be observed. In order to delineate species within these groups, DNA–DNA reassociation may be required (26).

The chemotaxonomic characteristics for each genus of the families described in the next section are presented in Table 8.

CHARACTERISTICS OF ACTINOMYCETE FAMILIES

Streptosporangiaceae

Streptosporangiaceae (9,27) are aerobic, Gram-positive, non-acid-fast, chemoorganotrophic actinomycetes that form stable substrate and aerial mycelia. Aerial mycelia

may carry chains of two or more spores or be differentiated into sporangia (spore vesicles) containing one, two, or more spores. Spores are either motile or nonmotile. Cell walls contain *meso*-DAP and N-acetylated muramic acid, but lack characteristic sugars; whole cells contain madurose. The peptidoglycan is of the A1γ type, having a cross-linkage between positions 3 and 4 of adjacent peptide subunits, with *meso*-DAP at position 3 of the peptide stem (14). Lipid profiles contain saturated, *iso*- and *anteiso*-fatty acids; major proportions of tetrahydrogenated menaquinones, with nine isoprene units saturated at sites III and VIII; and glucosamine-containing polar lipids. Mycolic acids are absent. The mol % G + C content of the DNA ranges from 66 to 74.

Nocardiopsaceae

Nocardiopsaceae (28,29) are aerobic, Gram-positive, non-acid-fast, chemoorganotropic actinomycetes that form well-developed, branching substrate mycelia that may fragment into coccoid to bacillary forms. Aerial mycelia are long and moderately branching, with zigzag fragmentation into irregular spores. The family is defined on the basis of chemotaxonomic markers because the morphological characteristics are the same for the genus *Saccharothrix* (family Pseudonocardiaceae). Cell walls contain *meso*-DAP, N-acetylated muramic acid, and no characteristic sugars. The peptidoglycan is A1γ. Lipid profiles contain phosphatidylcholine and phosphatidylmethylethanolamine; major portions of variably saturated menaquinones with 10 isoprene units; *iso*-branched, *anteiso*-branched, and 10-methyl-branched fatty acids; and high levels of octadecanoic acid. The combination of 15 to 20% *anteiso*-C17:0 (14-methylhexadecanoic acid) with 20 to 25% 10-methyl-C18:0 (tuberculostearic acid) or its precursor, oleic acid, is diagnostic and unique among bacteria. Mycolic acids are absent. The G + C content of the DNA is 64 to 69 mol %. The family contains only one genus, *Nocardiopsis*.

Thermomonosporacea

Thermomonosporacea (8) are aerobic, Gram-positive, non-acid-fast, chemoorganotrophic actinomycetes producing branched substrate mycelia bearing aerial mycelia that differentiate into single or short chains of arthrospores. Cell walls contain *meso*-DAP, N-acetylated muramic acid, and no characteristic sugars. The peptidoglycan type is

Source: From Kroppenstedt (23).
Note: + = 1.5%; + + = 5–15%, + + + = 15–25%, + + + + = 25%; (V) = variable, usually less than 2% for one component.

A1γ. Whole cells contain madurose. Lipid profiles contain mixtures of straight- and branched-chain fatty acids; hydrogenated menaquinones with nine isoprene units; and major amounts of phosphatidylglycerol, phosphatidylinositol, and phosphatidylmannosides, some strains contain minor amounts of phosphatidylglycerol. The G + C content of the DNA is mol % 66 to 72.

Micromonosporaceae

Micromonosporaceae (10,30,31) are aerobic, Gram-positive, and non-acid-fast, forming nonfragmenting, branching substrate mycelia that, in the genus *Micromonospora*, form nonmotile spores, singly either sessile or on short sporophores. Aerial mycelia are rarely formed, but when present are scanty. Sporangia, which may be present and can contain two to five or numerous spores, are formed on sporangiophores arising directly from the substrate mycelia. Globose, subglobose, or rod-shaped spores are formed in the sporangia or in chains arising from the substrate mycelia. In water the spores become motile by means of polar or lateral tufts of flagella. Cell walls contain *meso*- or 3-hydroxy-DAP, or both. The peptidoglycan is of the A1γ type; glycine is the first amino acid (acetate in *Pilimelia*) in the stem peptide attached to a glycolated muramic acid. Whole-cell hydrolysates contain arabinose and xylose. Lipid profiles have saturated, *iso*-, and *anteiso*-fatty acids, and diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, and phosphatidylinositol as characteristic phopholipids; menaquinones are of varying lengths. Mycolic acids are absent. The mol % G + C content of the DNA ranges from 71 to 73.

Pseudonocardiaceae

Pseudonocardiaceae (32,33) are a heterogeneous grouping of organisms based on 16S rDNA/rRNA sequence data. Aerobic, Gram-positive, mesophilic or thermophilic, and chemoorganotrophic, one genus is halophytic. Heterogeneous morphologies include stable or fragmenting substrate and aerial mycelia; single or short chains of nonmotile spores on both the aerial and substrate mycelia; sporangial-like bodies not containing spores; and long chains of interwoven spores with motile spores at the tip. The peptidoglycan contains *meso*-DAP and is acetylated; many genera contain arabinose and galactose in their cell walls and whole cells, others do not. Rhamnose in combination with galactose in whole-cell hydrolysates appears to be diagnostic for some genera. Lipid profiles include mono-methyl-branched, straight-chain saturated and unsaturated, and hydroxy fatty acids and are genera specific; tetrahydrogenated menaquinones with 8, 9, or 10 isoprene units; phospholipid patterns II, III and IV are represented; mycolic acids are not present. The mol % G + C content of the DNA ranges from 64 to 79.

Glycomycetaceae

Glycomycetaceae (34) are aerobic, Gram-positive, non-acid-fast, and chemoorganotrophic, forming stable substrate mycelia and aerial mycelia that fragment into short chains of square-ended spores. The cell wall contains *meso*-DAP and glycine and N-glycolated muramic acid; the whole-cell sugar pattern is xylose and arabinose. The peptidoglycan is A1γ. Lipid profiles contain diphosphatidylglycerol and phosphatidylinositol; nitrogenous phospholipids are not found, nor are mycolic acids; tetra- and hexahydrogenated menaquinones with 10 isoprene units predominate. The mol % G + C content of the DNA is 71. The family contains only one genus, *Glycomyces*.

SCREENING ACTINOMYCETES FOR NATURAL PRODUCTS

Isolation from Natural Habitats

Studies have been performed (35–38) to discover appropriate conditions for isolating various groups of actinomycetes from natural habitats, thereby enhancing diversity and increasing the chances of discovering novel natural products. A testing paradigm was described by Horan (39) that evaluated the effect of soil type, media

constituents, and selective pressure on the isolation of actinomycetes. Resistance to antibiotics and physiological data, derived from taxonomic analysis of the various species of actinomycetes, formed the basis for the choice of selective pressures (antibiotics) and soil isolation media constituents. Soil samples were suspended in distilled water and serially diluted. The suspensions plated onto the surface of agar media containing various carbon and nitrogen sources and antibiotics, including the antifungal agent nystatin at 50 μg/mL. Resulting colonies were isolated to purity and identified microscopically to either genus or broad morphological group. Antibiotics in the agar medium had the most profound effect on the types of actinomycetes isolated, followed by soil type and media constituents. Novobiocin and spectinomycin at 20 μg/mL selectively enhanced the isolation of micromonosporae: up to 90% of isolates belonged to this group. Rifamycin (15 μg/mL), rosaramicin (10 μg/mL), everninomicin (10 μg/mL), and gentamicin (5 μg/mL) significantly reduced the streptomycete population, allowing diverse, *meso*-DAP containing actinomycetes to proliferate. Pretreatment of the soil sample, particularly air drying for 48 hours before plating, and rifamycin in the agar positively affected the isolation of nocardioform (fragmenting aerial and substrate mycelia) actinomycetes. Table 9 summarizes selective isolation techniques for non-streptomycete actinomycetes.

Growth and Fermentation of Isolates

Organisms are isolated from soil plates using sterile toothpicks, streaked onto the surface of a rich medium, usually American Type Culture Collection (ATCC) medium 72 (53); and grown at 28 °C for 5 to 7 days. Isolated colonies are transferred to broth (ATCC medium 172) in 25-mm tubes containing 10 mL of media. After 3 to 5 days' incubation at 28 °C on a rotary shaker at 200 to 250 rpm, the tubes are removed. Sterile glycerol is added to a final concentration of 10%, and 3 mL aliquots are distributed into sterile vials. The contents of a frozen vial are used as the inoculum that initiates the fermentation process. One milliliter of a thawed suspension is added to 10 mL of germination medium in a 25-mm tube stoppered with a Morton closure, and the tube is incubated for 3 to 5 days at 28 °C and shaken (200 to 250 rpm) on rotary shaker. After incubation, 1 mL of the germination tube growth (G1) is transferred into 10 mL of fermentation medium in 25-mm tubes and incubated as above. For primary screening, large numbers of diverse actinomycetes should be fermented in me-

Table 9. Methods for the Isolation of Actinomycetes from Natural Habitats

Genus	Habitat	Method
Streptosporangium *Kurtzneria*	Soil, possibly slightly acidic	Air dry soil, plate on AV agar containing penicillin G (0.8 μg/mL) and/or polymyxin (4 μg/mL) or gentamicin (2–5 μg/mL) (38,40)
Microbispora and *Microtetraspora*	Soil	Air dry soil, dry heat 120 °C/h, treat with 1.5% phenol, plate on AV, MGA-SE, and HV agars alone or on minimal media with rubromycin or streptomycin without phenol treatment (9,41)
Dactylosporangium, *Planobispora*, *Planomonospora*, *Spirillospora*	Soil	Baiting using organic substrates including grass, centrifugation for motile spored organisms, and plating on egg white agar containing nystatin (50 μg/mL) (42–44)
Herbidospora	Soil and plant material	Plant samples desiccated at 28 °C for 1 week, ground in blender with water, suspension incorporated into yeast extract agar containing nystatin and cyclohexamide; pour plates incubated 28 °C >2 weeks (45)
Thermonomonospora	Soil, mesophiles; overheated substances, bagasse, compost, fodders and manure, thermophiles	Sample heated to 100 °C, dilution plate onto media containing rifamycin (12 μg/mL) and/or kanamycin (25 μg/mL) (8,35)
Actinomadura	Soil	Air dry soil, dilution plate on media containing rifamycin (15 μg/mL), mefoxitin (10 μg/mL), or gentamicin (2–5 μg/mL) (38,39)
Micromonospora	Soil, lake muds, sediments	Air dry soil, dilution plate on soluble starch-yeast extract agar plus novobiocin (20 μg/mL), spectinomycin (20 μg/mL), or gentamicin (5–50 μg/mL) (39)
Actinoplanes *Couchioplanes* *Dactylosporangium*	Soil, sediments	Air dry soil, dilution plate on water agar, colloidal chitin agar or HV agar containing 0.1% potassium tellurite (30), or novobiocin (25 μg/mL) (27), or baiting and centrifugation (42)
Pilimelia	Soil, rarely encountered	Baiting using hair (30)
Catenuloplanes	Soil	Dilution plating on starch-casein agar plus nalidixic acid (25 μg/mL), kanamycin (12.5 μg/mL), cefsulodin (5 μg/mL), and kabicidin (6.25 μg/mL) (46)
Spirilliplanes	Soil	Dry heat 120 °C/h, dilution plating onto HV agar (10)
Amycolatopsis	Soil	Dilution plate on AV agar plus vancomycin (1–10 μg/mL) and polymyxin B (5 U/mL) (38); some species isolated from human specimens (47)
Saccharomonospora	Soil, thermophilic strains isolated from leaf litter, manure, compost	Isolate using Anderson Sampler, sedimentation chamber with penicillin G and polymyxin (5 μg/mL) added to half-strength nutrient agar (35)
Saccharopolyspora	Soil and decaying plant material	Dilution plate on yeast extract (1 g/L), glucose (1 g/L), agar (15 g/L) plus novobiocin (5 μg/mL) (A. Horan, unpublished data)
Kibdelosporangium	Soil	Ampicillin (4 μg/mL) and nalidixic acid (10 μg/mL) in complex medium incubated at 43 °C (48)
Saccharothrix	Soil	AV or starch-casein agars plus penicillin G (5–10 μg/mL) and nalidixic acid (15 μg/mL) or starch-casein-nitrate agar plus rifamycin (10 μg/mL) (38,39)
Streptoalloteichus	Soil, arid	Dilution plate on ISP-2 or Bennett's agars plus gentamicin or kanamycin (10 μg/mL), incubate 43 °C (49)
Thermocrispum	Municipal waste and mushroom composts	Dilution plate and Anderson Sampler, TSA plus rifamycin (10 μg/mL), erythromycin and oleandomycin (100 μ/mL), novobiocin (15 μg/mL), 50 °C (50)
Glycomyces	Soil	Dilution plate on Czapek-sucrose agar plus novobiocin (25 μg/mL) and streptomycin (15 μg/mL) (30)
Actinocorallia	Soil	Dilution plate on colloidal chitin-vitamin agar plus kabicidin (10 μg/mL) (4)
Actinokineospora	Soil, fallen leaves	Dilution plates plus kanamycin and/or nalidixic acid (50 μg/mL) or baiting and centrifugation (5,51)

Note: Detailed selective procedures are not reported for the following general: *Nocardiopsis*, *Actinoploy spora* (not isolated from a natural habitat, appeared as a contaminant), *Catellatospora*, *Pseudonocardia*, *Actinobispora*, and *Planotetraspora*. *Lentzea* has been isolated from human specimens (52).
[a]All media contain nystatin at 50–100 μg/mL.

dia that support the production of a wide variety of secondary metabolites. More than one medium is often used, three to four are optimal. The fermentation is harvested after 4 to 6 days and can either be extracted with solvent (butanol, methyl isobutyl ketone, or ethyl acetate) or filtered (paper or 10,000 mw cutoff filters). The extract or filtrate is tested for secondary metabolite production using biological activity or chromatography. Primary fermentations of wild-type strains, under the conditions outlined, can yield from 0.01 μg/mL to as much as 400 μg/mL of

Table 10. Methods for the Production of Actinomycete Secondary Metabolites

Parameter	Example 1 (54): saccharocarcins by *Saccharothrix aerocolonigenes*	Example 2 (55): megalomicin by *Micromonospora megalomicea*
Germination medium (per liter)	Glucose, 10 g; trehalose, 10 g; hydrolyzed casein, 5 g; soy flour, 5 g; yeast extract, 5 g; calcium carbonate, 2 g; tap water	Dextrose, 1 g; potato starch, 24 g; beef extract, 3 g; tryptone, 5 g; yeast extract, 5 g; calcium carbonate, 2 g; tap water
Germination conditions	G1 48 hr at 28 °C, 250 rpm; G2 48 h at 28 °C, 250 rpm	G1 72 h at 35 °C, 300 rpm
% inoculum	10	5
Fermentation medium (per liter)	Dextrin, 30 g; molasses, 10 g; soluble starch, 5 g; tap water	Dextrose, 10 g; starch, 20 g; yeast extract, 5 g; casein hydrolysate, 5 g; calcium carbonate, 4 g; tap water
Fermentation conditions	5 days at 30 °C, 250 rpm	60–70 hr at 31 °C, 300 rpm
Extraction procedure	Whole broth with ethyl acetate	Adjust whole broth to pH 9.5 and extract with ethyl acetate

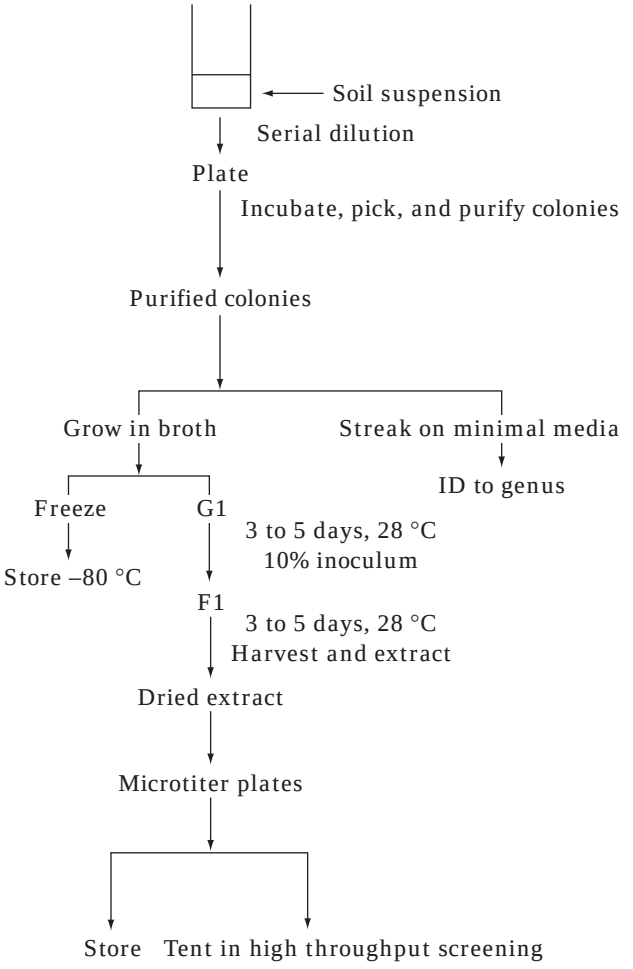

Figure 5. Outline of the primary screen process.

product. Examples of the production of secondary metabolites by two different genera of actinomycetes are presented in Table 10.

The advent of high throughput screening has resulted in a dramatic increase in the number of samples assayed, including natural products, with a concurrent decrease in the time required to test samples. In addition, an assay's lifetime has also decreased because all available samples can be tested in a relatively short time span (one month). For natural products to effectively compete with synthetic compounds and combinatorial libraries for available assay slots, a readily available source of samples is required. High throughput screening requires small amounts of test sample; a 10-mL fermentation results in enough extract for as many as 100 assays. Many natural product screening programs have addressed the issue of sample availability by developing libraries of extracts stored in 96-well microtiter plates. For each extract that is stored, the corresponding producing culture must also be preserved and its location catalogued. The nonstreptomycete actinomycetes described in this section can be stored at −80 °C in 10% glycerol for many years. However, data on the stability of natural product extracts stored over a period of years as well as the ability of preserved nonstreptomycete actinomycetes to maintain productivity have yet to appear in the literature. Figure 5 outlines the steps in a typical primary screen. Once activity has been detected in an extract or filtrate, the producing culture is fermented in a large enough volume to isolate enough material for characterization and structure elucidation. Many of the secondary metabolites produced by the *meso*-DAP containing actinomycetes are listed in Table 11.

SUMMARY

Nonstreptomycete actinomycetes continue to be a source of novel, therapeutically relevant natural products. Procedures described to effectively isolate a wide variety of genera rely on (*1*) collecting ecologically and geographically distinct soil samples, (*2*) using selective pressures (incorporating antibiotics and other chemicals into isolation media) that suppress streptomycetes while allowing diverse genera to survive, and (*3*) incorporating media constituents that favor the growth of rare actinomycetes. Evaluating the effectiveness of soil isolation procedures in obtaining diverse nonstreptomycete actinomycetes can quickly be achieved by identifying isolates macro- and microscopically. More definitive identification currently re-

Table 11. Secondary Metabolites Produced by *meso*-DAP-Containing Actinomycetes

Genus	Secondary metabolites[a]
Streptosporangium	Anthracyclines (figaroic acids, fragilomycins, carminomycin, carborubicin, sibiromycin; ansamycins (ansamitocin); bleomycins (platomycins, victomycin); glycopeptides (A-84575); macrolides (aculeximycin); peptides; phenazines; sugars (sporacuracins, 21906A); selenomycin; WS79089
Microbispora	Peptides (cochinmicins); phenazines; EV22 (SCH31828)
Microtetraspora	Amino acid containing (azaserine); talisomycin B; kistamicins; pyralomicins; macrolactam (fluvirucins); Bu-2313
Planobispora	Peptides; GE 2270
Planomonospora	Peptides (sporangiomycin); polyene
Thermomonospora	Naphthaquinone (SCH38519)
Actinomadura	Anthracyclines (akrobomycins, barminomycins, benanomicins, carminomycins, pradimicin, rubeomycins, rubstomycins); ansamycin (rifamycins); amino acid containing (madumycin); anthraquinones (oxanthromicin, maduramycin); indolocarabozole (AT2433); nucleosides (chloropentastatin, adenosine, coformycin, pentostatin); macrolactam (SCH38516, SCH38518, fluvirucin); macrocyclic lactone (kijanimicin); prodigiosins; polyethers (cationomycin, hidamicin, kijimycin); peptide related (formestin, luzopeptin, parvodicin), sugar containing (veractamycins, esperamicins); tetracyclin related (ES-119, SCH33256, SCH36969)
Spirillospora	Peptide macromolecular (Spirillomycin); polyene.
Micromonospora	Aminoglycosides (gentamicin, fortimicin, kanamycin, neomycin, sagamicin, sisomicin, verdamicin, G-52, G-418, Jl20); anthracyclines (daunorubicin, sibanomicin); anthraquinone (dynemicin); ansamycins (halomycins, rifamycins); benzodiazepine (sibanomicin); macrocyclic lactones (antlermicin, tetrocarcins); macrolides (clostomicin, erythromycin, juvenimicin, megalomicin, mycinamicin, izenamicin, rustmicin, primycin, rosaramicin); nucleosides (astromycin, dapiramicin); orthosomicins (everninomicins); peptides and amino acid containing (actinomycin, bottromycin, chalcidin, micromonosporin, 68-1147, glycine, negamicin); pigments (genistein, rubradirin, nocardiorubin); sugar containing (calicheamicin); xanthone (citreamicins); LL-E-19085
Actinoplanes	Glycopeptides (actaplanin, teicoplanin, ramoplanin); macrolides (lipiarmycin); peptides and amino acid containing (gardimycin, mycoplanecin, planothiocin, taitomycin, azetidine, azaserine, plauracins, virginiamycin, thristreptone); orthosomicin (SE737/74D); polyenes (octamycin, SE293); quinone (purpuromycin); chuangxinmycin; A/15104Y
Couchioplanes	Polyene (67-121)
Catenuloplanes	CP-54715
Dactylosporangium	Aminoglycosides (dactimicin, G-367); macrolides (clostomicin, tiacumin); orthosomicins (SF-2107); peptide containing (capreomycin, SF-2329); polyether (AC-7230, CP44161); quinone (DK-7814); tetracycline (SCH34164)
Pseudonocardia	Glycopeptides (azureomycins, boxazomycins, helvedardins); peptide (41043); polyene; quinones
Actinosynnema	Ansamycins (macbecins, C-33196); β-lactams (nocardicins)
Amycolatopsis	Ansamycins (rifamycins, kanglemycin); glycopeptides (avoparcin, vancomycin, orienticins, decaplanin, ristocetin, balhimycin); macrocyclic lactones (quartromycins); macrolides (A-59770); quinones (benzathrins, epoxyquinomicins, azicemicins); sugar (efrotomycin type); tetracycline (cetocycline); octacosamicins
Kibdelosporanglum	Glycopeptides (aridicins, kibdelins, decaplanin, A-80407); cycloviracins
Kutzneria	Chloramphenicol; glycoside macrolides (sporaviridins)
Saccharomonospora	Glycopeptide (AB-65)
Saccharopolyspora	Aminoglycosides (nebramycin, destomycin, saccharocin, sporaricin); alkaloids (hatomamicin); cinodines (coumamidines); lactones (belactins, nodusmicin); macrolides (erythromycin, sporeamicin); peptides (vanoxonin); CL307-24
Saccharothrix	Alkaloids (tetrazomine); glycopeptides (galacardins); indolocarbazoles (staurosporin, K-252a, rebeccamycins, SCH43228); macrolides (kayamycin, sekothrixide, N-814-103 factors); macrocyclic lactones (saccharocarcins); peptides (dopsisamine, madumycin, polynitroxin, nocamycin, sandramycin); polyether (portmicin); sugar (LL-C-19004); phosphonothrixin; karnamicins; tetrazomine
Streptoalloteichus	Aminoglycosides (kanamycins); bleomycins (talisomycins); siderochelin
Thermocrispum	Undescribed antifungal antibiotic (50)
Glycomyces	Amino acid containing (azaserine); LL-D05139
Actinocorallia	Peptide (azaserine related)

Note: Secondary metabolites not reported from *Herbidospora, Catellatospora, Pilimelia, Spirilliplanes, Actinopolyspora, Lentzea, Actinobispora*, and *Planotetraspora*.

[a]Data from Actinomycetes Antibiotic Data Base, Technomics Inc., C. P. O. Box 882, Tokyo, 00-91, Japan.

quires extensive chemical analysis of cell-wall and whole-cell components. Future identification of actinomycetes from natural habitats will rely on molecular approaches, particularly sequencing the gene encoding the small subunit of RNA (16S). This gene is a likely target because it is relatively small (1.5 kb), many actinomycete-type strains have been sequenced, and the data are readily available on-line for comparison to soil isolated, unknown strains. Numerous isolates can be fermented in small volumes. The fermentations are extracted or filtered, and the resulting samples are stored for testing against novel targets using high throughput screening methodologies. And so the quest for new metabolites with therapeutic potential from new organisms continues.

OUTLINE

INTRODUCTION

Definition of Natural Product Antibiotics

The field of natural products owes its origins to the discovery of penicillin and its ability to kill bacteria. Since Fleming's original discovery in 1928 of the antibacterial effects of *Penicillium chrysogenum* and Flory and Chaim's efforts more than a decade later to bring that discovery to production, the field of natural products has undergone enormous changes.

Vuillemin first introduced the concept of antibiotic activity in 1889, using the term *influences antibiotiques* (antibiotic influences) to describe negative interactions between plants and animals (1). Waksman later coined the term *antibiotic* to describe "a chemical substance derived from microorganisms which has the capacity of inhibiting growth, and even destroying, other microorganisms in dilute solutions" (2). Natural product antibiotics are almost universally secondary metabolites, compounds generally produced at low growth rates or after growth has ceased, nonessential for growth of the producing organisms in pure culture, and typically possessing unusual structures not found in primary metabolites of central metabolism. Although natural product antibiotic biosynthesis is not essential to the producing organism in pure culture, these compounds are critical to the producing organisms in their natural environment, both for survival and competitive advantage (3).

In more recent years, the term *antibiotics* sometimes has been used more broadly to define anti-infective agents, essentially in line with Waksman's definition, as well as *bioactive natural products*. This latter group includes immunomodulatory agents, statins, antitumor drugs, antiparasitic compounds, insecticides, and other bioactive natural products, many of which also possess weak antibacterial or antifungal activities. Indeed, the immunosuppressive drug cyclosporin was originally discovered in an antifungal screening program. Additionally, the biosynthesis of bioactive antibiotics is often very similar to that of other bioactive natural products. As a result, cyclosporin, a weak antifungal antibiotic but an excellent immunosuppressive agent, is usually included in discussions of other peptide antibiotics. Similarly, when reviews are written about macrolide antibiotics, other bioactive natural products such as tacrolimus (formerly called FK-506) and rapamycin, both of which are immunosuppressive agents (4), are typically included in discussions with erythromycin, a bacteriostatic antibiotic; avermectin, a potent antiparasitic compound; and tylosin, an agricultural feed additive.

This certainly makes sense because all these bioactive natural products possess similar modes of biosynthesis.

An extensive table including all marketed antibiotics (both natural product-derived and chemosynthetic) as well as all other marketed bioactive natural products, as of December 1996, was recently compiled for the book entitled *Biotechnology of Antibiotics* (5). Additionally, a recent review by Shu (6) highlighted most of the recent important discoveries in the field of natural products, ranging from new antifungal activities to natural products active as neuromodulators. Thus, this review will focus on natural product anti-infective and antitumor agents.

Overview of the Natural Product Antibiotics Field

Cragg et al. (7) published in 1997 a well-cited review of the natural products field in which they analyzed the percentage of natural products in various fields. Of 520 new approved drugs between 1983 and 1994, 55.6% were chemically synthesized drugs, 24.4% were semisynthetic compounds, 5.8% were unmodified natural products, 8.8% were chemically synthesized drugs patterned after natural products, and 5.4% were "biologics" (e.g., recombinant proteins) (7). Thus, approximately 40% of all newly approved drugs over that period were derived from natural product leads. In breaking down the categories, however, natural products dominated the antibacterial markets (63% were derived from natural product leads) and the anticancer market, in which 61% of the new drugs were derived from natural product leads. Natural product leads also strongly contributed to the antihyperintensive market (48% were derived from natural product leads) and the anti-inflammatory market, in which one-third of the new drugs approved between 1983 and 1994 were derived from natural product leads. According to Cragg et al., however, natural products did not contribute in the period of 1983–1994 to newly approved drugs in the antifungal, analgesic, anxiolytic, antihistamine, antidepressant, cardiotonic, or hypnotic fields (7).

Strohl (5) conducted a similar analysis of bioactive natural products with antibiotic activities, identifying a list of 252 natural and synthetic compounds used clinically and agriculturally in the United States with selected compounds included from other countries. Thus, although this analysis was not all-inclusive, it represented the majority of commercially important antibiotics and antimetabolic drugs. Of those compounds identified, 75 (30%) were natural products, another 75 (30%) were semisynthetic compounds derived from natural products, and the remaining 40% were chemically synthesized compounds (5).

The discovery of new, novel natural products continues to rise dramatically (5). Based on an analysis of papers published in *Journal of Antibiotics*, Bérdy (8) indicated that about 11,900 antibiotics and bioactive natural products had been discovered through 1994, with increasing rates of discovery every year through 1990. He projected that the total of new, novel natural product structures discovered by the year 2000 would top 16,000 (8). The annual rate of new natural product descriptions published is now more than 500 per year, up from 200 to 300 per year 20 years ago (5,8). Nevertheless, there is the widespread perception in both the scientific literature and the popular press that the discovery of new natural products and natural product antibiotics is on the wane (5). This anomaly, however, can easily be explained. Because most new natural product drugs still are concentrated in the fields of anti-infectives and anticancer drugs, and natural product leads have been around long enough in both the anti-infectives and anticancer areas, the law of diminishing returns is most prevalent in these fields. For example, from 1962, when nalidixic acid was developed as the first quinolone antibiotic, to 1996, no new classes of clinical natural-product-derived antibacterials have been introduced to the market. In 1993, only one new natural product antibiotic was approved by the Food and Drug Administration for use in the United States, none in 1994, and only a few in 1995 and 1996. Overall, from 1980 to 1990, the worldwide discovery of more than 4,600 new bioactive natural products was published, yet only 20 new natural-product-derived drugs (3 natural products and 17 semisynthetic products) were commercialized in that period. Finally, in the period spanning from World War II to 1975, approximately 1.6% of all natural product antibiotics reported (either by publication or patent) were eventually commercialized. Since 1975, this number has dropped to about 0.11%. Thus, fewer antibiotics are being commercialized from an increasingly larger pool of isolated candidate compounds. These data suggest that the Golden Era of antibiotics, generally recognized as having begun shortly after World War II ended, lasted nearly 30 years before the law of diminishing returns caught up to it. Another major contributing factor for the dearth of commercialized natural product antibiotics from 1975 to the present is that the U.S. government, academic researchers, and pharmaceutical companies alike turned their efforts toward the defeat of cancer and heart disease, believing that infectious diseases were under control (5,9).

On the other hand, in pharmacological areas in which natural products are making new inroads, many discoveries of bioactive natural products have resulted in compounds that are still in preclinical or clinical trials. Since the late 1960s, Umezawa and colleagues in Japan showed interest in discovering non-anti-infective bioactive natural products, particularly in the area of protease inhibitors (10). Although researchers in U.S. pharmaceutical companies showed interest in developing natural products as bioactive molecules in areas other than the anti-infective and anticancer markets (i.e., whole cell assays), many viewed the Japanese mechanism-based assay approach more as a curiosity than a serious discovery effort. It was not until the publication of Merck's patent and paper in *Proceedings of the National Academy of Science* (11) in 1980 on lovastatin as a remarkable inhibitor of hydroxymethylglutaryl-CoA reductase, and ultimately an outstanding cholesterol-lowering drug, that the inclusion of natural products in mechanism-based screens was considered seriously.

Since that time much has changed, and although some pharmaceutical companies have minimized natural product screening efforts because of the perceived cost-to-benefit ratio, others have sought to expand the scope of natural products in their screening programs. As evi-

denced by publications in journals such as *Journal of Antibiotics*, patent applications, and clinical trial candidates (6), it has now become apparent that natural products can significantly augment synthetic chemical approaches for the discovery of new drug entities in a wide range of pharmacologically important areas. The two most significant recognized drawbacks of natural products in a broad-based screening program are the inclusion of crude extracts (which usually include salts, proteins, fatty acids and other potentially interfering materials) in in vitro assays (e.g., receptor-based, enzyme inhibition, or protein–protein interaction assays) and the time it takes to turn a crude-extract hit into a chemical structure. Despite these drawbacks, natural products now have been found to contribute to significant leads in most therapeutic areas (6).

The sources of natural products are also likely to change. Bérdy (8) showed that of the 11,900 antibiotics that had been discovered through 1994, approximately 6,600 (55%) were produced by *Streptomyces* spp. The remainder of producing organisms included the filamentous fungi, which produced 2,600 (22%); nonactinomycete bacteria, which produced 1,400 (12%); and non-*Streptomyces* strains of actinomycetes, which produced 1,300 (11%) (8). In the broader pharmacological field, it is widely recognized that a great percentage of pharmacologically derived products in use today are derived from or patterned after plant products (6). It can be expected that in the future a wider range of microorganisms, including well-known but underused groups such as the filamentous fungi, myxobacteria, bacilli, and pseudomonads, will contribute to the pool of natural products in larger ways (5).

Market for Natural Product Antibiotics

The total world sales for prescription pharmaceuticals was estimated in a September 1998 news release to be $308 billion. In a recent report of the 200 most-prescribed medicines in the United States (12), natural products accounted for 10 of the top 35 prescribed drugs (Table 1). All the top-prescribed natural products or semisynthetic drugs derived from natural products are anti-infective agents except for three statins: simvastatin, lovastatin and pravastatin. Although it is difficult to identify the entire contribution of natural products to the world pharmaceutical market economy, it should easily total more than $30 billion, including the natural-product-derived anti-infective agents (>$20 billion), the natural-product-derived anticancer agents (in which the anthracyclines and taxanes alone represent more than $3 billion in market size), the statins (with a market size estimated at more than $6 billion and rising at a rate of more than 20% annually), and the large pool of plant-derived natural products or compounds patterned after plant products.

The total world market for anti-infective agents in 1996 was reportedly $23 billion (13). The 1995 U.S. anti-infectives market alone was greater than $8 billion, with cephalosporins (45%), penicillins (15%), fluoroquinolones (11%), tetracyclines (6%), and macrolides (5%) comprising the majority of sales. Of these top-selling anti-infective agents, only the fluoroquinolones lack the distinction of being natural products, and even they are patterned after the original quinolone, nalidixic acid. Thus, in deference to their origins, antibacterial drugs are still natural products, semisynthetic compounds derived from fermentation products, or patterned after natural products.

The world antifungal market in 1995 was approximately $3 billion. Although this represents a much smaller market than the antibacterial market, the antifungal market is projected to grow at 20% annually. This rapid growth in antifungals unfortunately is driven by the dramatic increase in life-threatening fungal diseases, mostly as a result of opportunistic fungal pathogens infecting immunocompromised patients.

The antiviral market was $1.8 billion in 1995, and the projected 1998 market is $3 billion. Although the top product in 1995 was acyclovir (50% of the market [14]), more than 17 million people were infected with HIV, a number that is expected to reach 30 to 40 million by year 2000 (14). Because of the development of successful new anti-HIV drugs such as the HIV-proteinase inhibitors, it is expected that the antiviral market should increase substantially within the next few years.

Biogenesis of Natural Product Antibiotics

Since the discovery and elucidation of the structure of penicillin, there has been an enormous effort placed into finding new natural product antibiotics, particularly those of the antibacterial, antifungal, and anticancer therapeutic classes. Natural product antibiotics, for the most part, fall into several major classes of structures, as shown in Table 2, based on the precursors from which they are assembled and the mechanisms of assembly. Precursors common for the synthesis of natural products include short chain acyl-CoAs such as acetyl-CoA, malonyl-CoA, and propionyl-CoA, which are used to synthesize polyketides; activated amino acids, which are used to build peptides and β-lactams; various pyrimidines, which are the building blocks for nucleoside natural products; isoprene units, which form the basis of terpene, alkaloid, and substituted steroid natural products; and sugars and amino sugars, which are the building blocks for aminoglycosides as well as for the sugar moieties that decorate a wide variety of natural products. Many natural products result from the fusion of moieties arising from two or more different biogenic classes. For example, 6-deoxyerythronolide B (DEB), the macrolide backbone of erythromycin, is synthesized by a type I modular polyketide synthase, but the molecule is not biologically active until the sugars desosamine, attached at C-5, and cladinose, attached at C-3, are added. Several other macrolides, including spiromycin and tylosin, have this same characteristic. Similarly, anthracyclines are comprised of the aglycone portions, derived from the activity of a type II iterative polyketide synthase system, and daunosamine, a 2,3,6-trideoxy-3-aminohexose synthesized from TDP-glucose (15). Glycopeptides such as vancomycin also contain core units derived from the activity of a nonribosomal peptide synthetase that are decorated by sugar units to make bioactive molecules. An exaggerated example of this is the antifungal compound pradimicin, which is synthesized by a type II iterative polyketide synthase and then decorated both with sugar moi-

Table 1. Ranking of Natural Product Pharmaceuticals as Prescription Medicines in the United States (1997)

Natural product[a]	Brand name	Company	Rank[b]
Amoxicillin	Trimox	Apothecon	1
Azithromycin	Zithromax	Pfizer	9
Amoxicillin-clavulanate	Augmentin	SmithKline Beecham	14
Simvastatin	Zocor	Merck	15
Clarithromycin	Biaxin	Abbott	24
Amoxicillin	Amoxil	SmithKline Beecham	25
Cephalexin	Cephalexin	Teva	26
Penicillin V (K^+)	Veetids	Apothecon	32
Amoxicillin	Amoxicillin	Teva	33
Pravastatin	Pravachol	Bristol-Meyers Squibb	34
Cephalexin	Cephalexin	Apothecon	54
Lovastatin	Mevacor	Merck	57
Cefprozil	Cefzil	Bristol-Meyers Squibb	58
Cefuroxime	Ceftin	Glaxo Wellcome	72
Erythromycin	Ery-Tab	Abbott	82
Neomycin/polymyxin B/HC	Neomycin/polymyxin B/HC	Schein	122
Mupirocin	Bactroban	SmithKline Beecham	130
Cefaclor	Cefaclor	Mylan	139
Doxycycline	Doxycycline	Zenith	168
Amoxicillin	Amoxicillin	Warner-Chilcott	184
Clarithromycin	Biaxin suspension	Abbott	192
Cefixime	Suprax	Wyeth-Ayerst	196

eties and D-amino acid moieties (16). Other molecules, such as the rifamycins, contain a unique building block such as 3-amino-5-hydroxybenzoic acid (AHBA), which is used as the primer with which to initiate the synthesis of the macrocycle (17). Thus, many natural products are derived from mixed biogenic origins. For more detailed information on specific antibiotics, recent books edited by Vining and Stuttard (18) and by Strohl (19) cover the biogenesis and biosynthesis of virtually all the major classes of antibiotics and bioactive natural products.

ANTIBACTERIAL AGENTS

Introduction

The most widely prescribed, best known, best characterized, and perhaps also the most widely disparaged natural products are the antibacterials. After the discovery of penicillin by Fleming in 1928 and its subsequent development as a drug during World War II, the pharmaceutical industry and well-known academics such as Waksman of Rutgers University worked feverishly to discover new antibacterials that would eliminate bacterial infections of all kinds. The natural product antibiotics gramicidin (1939), streptomycin (1944), chlortetracycline (1948), chloramphenicol (1948), cephalosporin C (1948), neomycin (1949), oxytetracycline (1950), erythromycin (1952), tetracycline (1953), vancomycin (1955), rifamycins (1959), lincomycin (1962), pristinamycin (1962), and nalidixic acid (1962), the predecessor to fluoroquinolones, were all discovered by 1962 (22). No new, truly novel classes of natural product antibacterial drugs have been marketed since then. Even in the cases of modern synthetic antibacterials, all successful synthetic antibacterials have been biomimetically derived from natural product structures (the best example being the fluoroquinolones, which are based on nalidixic acid). There are new classes of candidate antibacterials, such as the oxazolidinones (23), which are not derived from natural products, but these have yet to break into the market, in part because of associated toxicities exhibited by this class of compounds. The targets for these drugs, including cell wall biosynthesis, protein biosynthesis, and nucleic acid biosynthesis, all have been targeted many times over by analogues of them, as well as by other compounds, both synthetic and naturally derived. As we enter the 21st century, there is a critical need for new, potent antibacterials to which resistance is not easily gained.

Needs and Markets

With the emergence of new infectious diseases as well as the emergence of bacterial strains resistant to existing antibiotics, there is an enormous challenge to pharmaceutical companies, researchers, and governments to develop new methods for treating existing infectious diseases and those emerging as new health threats. As recently reviewed by Strohl (5), there are several reasons for the need to develop new antibiotics, preferably with novel structures and activities.

First and foremost, pathogenic bacteria are acquiring or developing resistance to existing antibiotics and classes of antibiotics in direct correlation with the use of those antibiotics to treat them (24). As Julian Davies stated, "it is frightening to realize that one single base change in a gene encoding a bacterial β-lactamase can render useless $100 million worth of pharmaceutical research effort" (25). Although this is an oversimplification of the problem, it

Table 2. Biogenic Classes of Natural Product Antibiotics

Biogenic class and subclass[a]	Example compounds or groups	Example activities
	Nonribosomal peptide synthetases	
Diketopiperazines	Gliotoxin	Antibiotic
Cyclic peptides	Cyclosporin	Immunosuppressive
	Gramicidin	Antibacterial
Depsipeptide	Enniatin, valinomycin	Ionophores
Lipopeptides	Echinocandins	Antifungal
Glycopeptides	Vancomycin	Antibacterial
	Bleomycins	Antitumor
β-Lactams	Penicillins, cephalosporins	Antibacterial
Lantibiotic	Nisin	Antibacterial
Peptidolactones	Actinomycin D	Antitumor
Phosphinopeptide	Bialaphos	Phytotoxic
	Polyketides	
Type I modular		
Macrolides	Erythromycin, tylosin	Antibacterial
Pentacyclic lactones	Avermectin, milbemycin	Insecticidal acaricidal
Ascomycins	Tacrolimus	Immunosuppressive
Ansamycins	Rifamycin, ansatrienins	Tuberculostatic, antibacterial
Polyenes	Nystatin, amphotericin B	Antifungal
Polyethers	Monensin	Growth promotants
Type I iterative		
Statins	Lovastatin, pravastatin	Cholesterol-lowering
Type II iterative		
Tetracyclines	Oxytetracycline	Antibacterial
Anthracyclines	Doxorubicin, aclarubicin	Cytotoxic antitumor
	Aminoglycosides	
Aminoglycosides	Streptomycin, kanamycin	Antibacterial
Aminocyclitols	Spectinomycin	Antibacterial
Cyclitol	Kasugamycin	Antibacterial
	Isoprenoids	
Steroidal	Squalamine	Antitumor, antibacterial
Sesquiterpene	Artemisinin (Qinghao), epolone	Antimalarial
Diterpene	Paclitaxel (Taxol)	Antitumor
Triterpene	Fusidic acid	Antibacterial
Indole alkaloid	Vinblastine	Antitumor
	Others	
Lincosamides	Lincomycin, clindamycin	Antibacterial
Chorismic acid-derived	Chloramphenicol	Antibacterial
Amino acids	Cycloserine	Antibacterial
Quinolones	Nalidixic acid, fluoroquinolones	Antibacterial
Nucleosides	Nikkomycins, polyoxins	Antifungal
Mitosanes	Mitomycin C	Antitumor, cytotoxic
Oligosaccharides	Everninomycin, avilamycin	Antibacterials

Source: Data from Refs. 5, 18–21.

succinctly sums up the problem with the development of antibiotic resistance by pathogenic bacteria. The most critical reason for the development of new antibiotics is the race to remain a step ahead of antibiotic-resistance development, which has proceeded at an alarming rate (26). Even since the earliest use of antibacterial agents, the emergence of resistance to the drugs used has been observed. For example, within 4 years after the introduction of penicillin during World War II, several strains of penicillin-resistant bacteria were isolated from infected patients (27). After the war, outbreaks of dysentery in Japan, caused by sulfonamide-resistant *Shigella* spp., presented a serious health hazard to the recovering population. Within just a few years after introduction in 1950 of the newly developed antibiotics, streptomycin, tetracycline, and chloramphenicol to help quell the problem, resistance to each of these antibiotics was observed (28). By 1969, 69% of shigellae were resistant to sulfonamides, streptomycin, tetracycline, and chloramphenicol (28). Thus, in fewer than 20 years, nearly 70% of all *Shigella* spp. in Ja-

pan became resistant to four antibiotics to which there was minimal resistance before their use (28). Widespread antibiotic use has resulted in the rapid spread of multidrug resistant pathogens, and it has become both a local and global health hazard of epidemic proportions. The incidence of methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE; particularly by *Enterococcus faecium* and *Enterococcus faecalis*), and β-lactam-resistant *Streptococcus pneumoniae* are among the most serious problems, but are by no means the only ones (29). The incidence of nosocomial infections (i.e., hospital-acquired) is on the rise, and of those, an increasingly greater percentage of the infectious agents (typically MRSA and VRE) are drug-resistant (30). The U.S. Centers for Disease Control and Prevention (CDC) estimates that of the 40 million hospitalizations in the United States each year, 2 million patients (5%) contract nosocomial infections, and that as many as 58,000 of them (0.15%) die of them (31). Unfortunately, VRE are nearly untreatable with current antibiotics, with the possible exceptions of the experimental drugs Synercid or teichoplanin, which have been used successfully to treat some cases of VRE (32). The mortality rate of patients infected with multiple-drug resistant enterococci is 70%, making this a serious health care problem (32).

Second, new pathogens are evolving at an alarming rate. For example, today there are more than 30 new infectious diseases (e.g., AIDS, Ebola, Legionnaires disease, hantavirus, Lyme disease, and food-borne *E. coli* O157:H7 infections) that were unknown 20 years ago (5,33). Third, even with the development of remarkable anti-infective drugs with outstanding biological activities, there are still certain pathogens that naturally defy even the best efforts to defeat them. Perhaps the best example of this is our current inability to treat successfully *Pseudomonas aeruginosa* infections resulting from cystic fibrosis (5).

Finally, many potentially important antibiotics have associated toxicities that limit their use. The best example of this is gentamycin and other aminoglycosides, which are limited in effectiveness because of their associated nephrotoxicity and ototoxicity (5). Thus, critical challenges lay ahead for the entire anti-infectives field, many of which may be met by the discovery and development of new natural product leads.

There are three critical needs in the antibacterial market. First, new parenteral drugs that can successfully treat MRSAs and VREs are absolutely required. This need will grow dramatically in the coming years as the once-rare incidence of vancomycin-resistant *S. aureus* strains, the single greatest worry of infectious disease experts (34), expands. Second, even with a seemingly crowded pediatric market, there is still a critical need (and market place) for an orally absorbed, pediatric-safe (which eliminates fluoroquinolones, which are not considered safe for children) antibacterial agent that can successfully treat upper respiratory tract infections (primarily otitis media caused by β-lactam resistant streptococci, moraxellae, and *Haemophilus influenzae*) and that is not compromised by β-lactam, aminoglycoside, or MLS (macrolide-lincosamine-streptogramin) resistance or degraded by extended spectrum β-lactamases (35).

The pediatric antibacterial market, which has grown sharply since the early 1980s, has become one of the most important anti-infective markets today. Pediatric antibacterials typically are prescribed for middle-ear infections (otitis media) caused by *H. influenzae*, *Moraxella* spp., and *Streptococcus pneumoniae*. By the year 2000, it is expected that the U.S. pediatric market alone will be $2.2 billion, with annual increases of approximately 15%. The current leading pediatric antibacterials are amoxicillin, Augmentin (amoxicillin plus clavulanic acid), azithromycin, and clarithromycin. It is expected that the ketolides may make a significant impact on this market. The final critical need is for a new tuberculocidal drug. Antibiotic resistance in *Mycobacterium tuberculosis* is considered to be a major growing problem. Currently, a combination treatment with isoniazid and rifamycin (both tuberculostats) is the method of choice, but many strains of *M. tuberculosis* have recently been found that are resistant to one or both of these antibiotics, and approximately 14% of all tuberculosis cases reported today involve *M. tuberculosis* strains that are resistant to one or more antibiotics (36). The problem facing doctors today is that there is no proved, effective alternative yet on the market to treat isoniazid- and rifamycin-resistant *M. tuberculosis* (36).

Antibiotic-Resistant Bacteria

Antibiotic resistance is a major clinical problem that will only get worse with time. In the case of bacteria, resistance can be mediated by several different types of mechanisms, including modification of the target to make it unsusceptable to the antibiotic, enzymatic modification of the antibiotic to render it inactive, exclusion of the antibiotic by modification of membrane permeability, active export of the antibiotic, and bypass of the critical physiological mechanisms or structures inhibited by the antibiotic. Resistance to some these mechanisms, encoded by chromosomal mechanisms, is attained at a rate of 1×10^{-8}, and others are obtained at much higher frequencies through horizontal plasmid transfer.

Plasmid-encoded TEM- and SHV-type β-lactamases are the most common mechanisms responsible for β-lactam resistance in Gram-negative bacteria (37). These β-lactamases have generally broad substrate specificities for penicillins as well as some first- and second-generation cephalosporins and are responsible for much of the resistance to β-lactams observed in the clinics. It is well documented that as new β-lactams have been developed to resist plasmid-borne β-lactamases, the β-lactamases themselves have evolved (25,37). In an extraordinary example of natural directed evolution, TEM- and SHV-type β-lactamases recently have been found containing specific point mutations, all falling in close proximity to the active site cavity, which confer resistance to third-generation cephalosporins and monobactams (37).

Vancomycin has long been the last line of defense against antibiotic-resistant bacteria, particularly MRSAs and β-lactam- and aminoglycoside-resistant enterococci. Just a little over a decade ago, it was thought that microorganisms would never become vancomycin resistant because of its unusual mechanism of action (38). This illusion

was shattered, however, when VREs were reported in England and France in 1987 (39). VREs now are being discovered at an alarming rate, with no new last line of defense substitute firmly entrenched on the market (40).

Not all clinically significant antibiotic resistance is plasmid- or transposon-mediated. *S. pneumoniae*, the primary causative agent in pediatric otitis media and pneumonia as well as bacterial meningitis and bacteremia, remained sensitive to penicillin for many years. Recently, however, an alarming number of penicillin-resistant *S. pneumoniae* strains have recently been isolated from infected patients, correlating with the use of penicillins to treat them (41). These penicillin-resistant *S. pneumoniae* were not found to produce *β*-lactamases, the common plasmid-borne mechanism for resistance. Instead, they had incurred chromosomal mutations giving rise to altered penicillin-binding proteins (PBPs), the target for penicillin activity (41). This discovery has a touch of irony, because *S. pneumoniae* is the bacterium with which plasmid-mediated transformation was first observed. Similarly, the Oxford strain of *S. aureus*, isolated 50 years ago, is sensitive to nearly every antibiotic tested against it (42). The staphylococci, however, acquired resistance to aminoglycosides very quickly, and by 1992, 32% of *S. aureus* strains tested were found to be resistant to methicillin, the drug of choice to treat staphylococcal infections, up from 2% in 1975 (42). Like pneumococci, MRSAs have altered PBPs, giving them a resistance mechanism that cannot be countered easily. Thus, vancomycin has become the drug of last resort to treat MRSAs. Ever since *Enterococcus faecalis* was shown to transfer vancomycin resistance to *S. aureus* in the laboratory in 1992 (43), one of the greatest fears of health professionals universally has been the emergence of vancomycin-resistant, methicillin-resistant staphylococci (44). Recently, such doubly resistant, nearly untreatable strains have appeared in sporadic cases, confirming the greatest fears of infectious disease professionals (45).

A new mechanism of antibiotic resistance recently was discovered in meropenem-resistant *Pseudomonas aeruginosa* strains (46). *P. aeruginosa* is an opportunistic pathogen that contributes to nosocomial infections, eye infections, and opportunistic infections of burn patients and those with cystic fibrosis. The mechanism was found to be based on the alteration of outer membrane proteins, causing a reduction in permeability of several antibiotics, including meropenem, through the outer membrane (46). This is a significant finding, because carbapenems (e.g., imipenem) have been considered the antibiotics of choice for the treatment of opportunistic pseudomonads.

β-Lactams

As is well known, the discovery of penicillin was the genesis of modern pharmaceutical efforts to produce antibiotics, the magic bullets that at one time were thought to cure the world of disease. *β*-Lactams function by binding to PBPs, especially transpeptidases, that normally function in peptidoglycan biosynthesis. Because peptidoglycan is novel to bacteria, these drugs specifically act on a bacterial target. Since bacteria cannot grow in normal environments without their cell wall, inhibition of cell wall biosynthesis results in killing of the bacteria; thus, all *β*-lactams by definition are bacteriocidal drugs.

The total antibacterial market tops $20 billion annually, with nearly all the top-selling antibacterial drugs being natural products, semisynthetics derived from natural products, or compounds patterned after natural products. Even more than a half century after the first widespread use of penicillin during World War II to treat bacterial infections, *β*-lactams as a whole still make up 60%, or more than $12 billion worth, of the total antibacterial market. The commercial *β*-lactam antibiotics are comprised of many types of several different classes, ranging from penicillin G to the monobactam biomimetic drug, aztreonam (Table 3).

The natural product *β*-lactams can be separated into five separate biogenic subclasses (47): penams (e.g., penicillins), cephems (cephamycin C, cephalosporins), clavams (clavulanic acid, clavamycins), carbapenems (thienamycin), and monobactams (aztreonam) (Table 4). The ring structures of the various *β*-lactams differ from the classical penicillin core as follows: cephems have an expanded 6-membered ring containing a double-bond but retaining the sulfur atom; clavams have an oxygen atom replacing the sulfur of penicillins, and they tend to differ at C-2 and C-6; in carbapenems, the sulfur is replaced by a carbon and a double bond is present; and the monobactams are monocyclic (48).

β-Lactams of the penicillin, cephamycin, and cephalosporin subclasses share a common biogenic origin, i.e., the condensation of three activated amino acids, L-*α*-aminoadipate, L-cysteine, and L-valine by aminoadipyl-cysteinyl-valine (ACV) synthase (*pcbAB* gene products) to form the tripeptide *δ*-L-(*α*-aminoadipyl)-L-cysteinyl-D-valine (ACV), which is then cyclized by the enzyme isopencillin N (IPN) synthase (*pcbC* gene product) to form isopenicillin N (49). ACV synthases comprise a subset of a larger class of nonribosomal peptide synthases, which have been characterized in detail, both biochemically and molecularly (49,50). Both ACV synthases (49,50) and IPN synthases (49) of all *β*-lactam producers are highly conserved, indicating common ancestral origins. IPN is either directly converted to penicillin G via IPN acyltransferase (*penDE* gene product), or via IPN epimerase (*cefD* gene product) to penicillin N, which is converted via deacetoxycephalosporin C (DAOC) synthase (*cefE* gene product; also called expandase because it expands the 5-membered ring of penicillins to the 6-membered ring of cephalosporins) to deacetoxycephalosporin C (DAOC) (49).

The clavam *β*-lactamase inhibitor, clavulanic acid, is produced by *Streptomyces clavuligerus*, which also produces cephamycins (49). Interestingly, the biogenesis of the bicyclic nucleus of clavulanic acid occurs via a completely different mechanism than does the biosynthesis of other *β*-lactams (49,51). In *S. clavuligerus*, the clavulanic acid biosynthesis genes are just downstream of the cephamycin C biosynthesis genes (51).

Not all *β*-lactam-producing taxonomic groups of organisms synthesize all subclasses of *β*-lactams, as depicted in Table 4. Filamentous fungi, for example, produce *β*-lactams only of the penam and cephem classes, whereas various actinomycetes produce *β*-lactams of all subclasses

Table 3. Important Clinical and Experimental β-Lactams

Subclass	Drugs on market[a]
Penicillins	Ampicillin, *amoxicillin*, bacampicillin, cloxacillin, floxacillin, mezlocillin, nafcillin, oxacillin, penicillin G, penicillin V
Penicillinase-resistant penicillins	*Methicillin*, dicloxacillin
Antipseudomonal penicillins	Carbenicillin indanyl, piperacillin, *ticarcillin*
First-generation cephalosporins	Cefadroxil, cefazolin, *cephalexin*, cephalothin, cephapirin, cephradine
Second-generation cephalosporins	*Cefaclor*, cefmetazole, cefonicid, cefotetan, *cefuroxime*
Third-generation cephalosporins	Cefamandole, *cefixime*, cefoperazone, cefotaxime, cefpodoxime proxetil, *cefprozil*, ceftazidime, *ceftibuten*, ceftizoxime, ceftriaxone
Oxycephams (third generation)	Flomoxef, latamoxef
Fourth-generation cephalosporins	*Cefepime*
Cefam	*Cefoxitin*
Carbacefem	*Loracarbef*
Carbapenems	*Imipemen/cilistatin*, meropenem, MK-826, panipenem (Japan only)
Monobactams	Aztreonam
Clavams (β-lactamase inhibitors)	*Clavulanate*, sulbactam, tazobactam
Penicillins/β-lactamase inhibitors	*amoxicillin/clavulanate (Augmentin*), ampicillin/sulbactam (Unasyn), pipericillin/tazobactam (Zosyn), ticarcillin/clavulante (Timentin)

[a]Compounds in italics are most important commercial antibiotics.

Table 4. Biogenic Classes of β-Lactams

		β-Lactams produced by[a]		
Subclass	Example compounds	Fungi	G^+ bacteria	G^- bacteria
Penams	Penicillin G	*Penicillium, Aspergillus*	—	—
Cephems	Cephalosporin C	*Cephalosporium*	—	—
	DAOC[b]	—	—	Various strains
	Cephabacins	—	—	*Lysobacter*
	Cephamycin C	—	*Streptomyces, Nocardia*	—
Carbapenems	Thienamycin	—	*Streptomyces cattleya*	*Serratia, Erwinia*
Monobactams	Aztreonam[c]	—	*Nocardia*	*Pseudomonas*
Clavams	Clavulanic acid	—	*Streptomyces*	—
	Clavamycins	—	*Streptomyces*	—

Note: See Cohen and Aharonowitz (47) for more information. Dash means not produced by this group.
[a]Example taxonomic groups are given by genus names rather than an exhaustive listing of producing organisms.
[b]DAOC = deacetoxycephalosporin C.
[c]Example given is the biomimetic synthetic compound of the class.

except the penams and cephalosporins of the cephem subclass. The cephems in general are produced by the taxonomically widest range of microorganisms, including filamentous fungi, Gram-negative bacteria (e.g., lysobacters), and actinomycetes. The cephem products accumulated by each group differs, however, likely indicating evolutionary branches in terms of enzymes present. The Gram-negative bacteria, *Flavobacterium* sp. SC 12.154 and *Lysobacter lactamgenes* accumulate a 7-formylamino analogue of cephalosporin called cephabacin (49,52), an unusual natural β-lactam structure that is highly resistant to β-lactamases (49). The actinomycetes *Streptomyces clavuligerus* and *Nocardia lactamdurans* produce cephamycin C, which is formed from DAOC by the enzymes (gene names in parentheses) DAOC hydroxylase (*cefF*), deacetylcephalosporin C (DAC) *O*-carbamoyltransferase (*cmcH*), cephalosporin 7-α-hydroxylase (*cmcI*), and 7-α-hydroxy-*O*-carbamoyldeacetoxycephalosporin C methyltransferase (*cmcJ*) (49). The filamentous fungus, *Cephalosporium acremonium*, on the other hand, converts DAOC to cephalosporin C in two steps: DAOC hydroxylase (*cefF*), and DAC acetyltransferase (*cefG*) (49).

As is well known, penicillin was the first widely used clinical antibiotic. The first oral penicillin, used primarily to treat Gram-positive bacteria, was the fermentation product phenoxymethylpenicillin (penicillin V), still sold today under the name Veetids (5). Second-generation penicillins include the aminopenicillin group of ampicillin, amoxicillin, and bacampicillin, which exhibited much better gastrointestinal tract absorption and possess longer half lives. These aminopenicillins also exhibit greater activity against Gram-negative bacteria at the expense of activity against Gram-positives. Unfortunately, these penicillins are highly susceptible to β-lactamases. Development of β-lactamase inhibitors such as clavulanic acid, sulbactam, and tazobactam, however, have greatly extended the use of these broad-spectrum penicillins (47,49). In fact, Augmentin (oral amoxicillin/clavulanic acid), Unasyn (injectable ampicillin/sulbactam), Timentin (injectable ticarcillin/clavulanic acid), and Zosyn (injectable pipericillin/ta-

zobactam) are widely used antibiotics. Carbenicillin indanyl, the first oral antipseudomonal β-lactam, and ticarcillin, a potent parenterally administered drug, are third-generation penicillins (53). The development of antipseudomonal fluoroquinolones, however, has rendered carbenicillin indanyl obsolete. Pipericillin, azlocillin, and mezlocillin are parenteral fourth-generation penicillins that have not found wide usage clinically (53).

First-generation cephalosporins typically inhibited Gram-positive bacteria other than the enterococci. Second- and third-generation cephalosporins typically inhibit Gram-negative bacteria at the expense of activity against Gram-positives. A new fourth-generation parenteral cephalosporin, cefepime (Maxipime), possesses activity against both Gram-positives and Gram-negatives (54). Additionally, cefipime penetrates bacteria well, is not susceptible to β-lactamases, and has a lower propensity to induce β-lactamases (55). Unfortunately, this broad-spectrum cephalosporin does not effectively treat either VREs or MRSAs (54). Ceftriaxone was very recently approved as a one-time-only injectable for treatment of pediatric otitis media. The concept behind the development of this drug is that the greatest problem, and reason for failure, with treatment of otitis media is patient compliance; the option of a one-time-only injectable removes this as an obstacle.

Carbapenems are very broad spectrum, β-lactamase-resistant β-lactams that contain a carbon atom instead of a sulfur atom in the 5-membered ring (47). Imipenem/cilistatin (Primaxin) was the first clinical carbapenem antibiotic, developed in the mid-1970s and made available commercially since 1986, as a synthetic biomimetic analogue of the natural product thienemycin (56). Imipenem is administered with cilistatin, an inhibitor of human renal dehydropeptidase, to protect the antibiotic from enzymatic degradation. Imipenem has broad-spectrum activity against Gram-negatives and anaerobic bacteria and moderate activity against Gram-positive bacteria (53). Unfortunately, imipenem also is limited by potential renal toxicity (56). Meropenem (Merrem) (57) is a new carbapenem antibiotic approved in 1996 for use as a broad-spectrum injectable antibiotic for treatment of intra-abdominal infections and for pediatric bacterial meningitis. The advantage of meropenem over imipenem is that meropenem is stable in the presence of renal dehydropeptidase, thereby bypassing the need for cotherapy with cilistatin (53). A third carbapenem called panipenem is available in Japan but not in the United States (58). Merck currently has a new, very potent, broad-spectrum, long-acting carbapenem, MK-826, in phase-II clinical trials (59). This new carbapenem drug candidate has been demonstrated to be highly resistant to β-lactamases, including plasmid-encoded extended spectrum β-lactamases (ESBLs) (59). Nevertheless, certain rarely pathogenic bacteria (particularly *Acinetobacter baumannii*) contain specific carbapenem-degrading enzymes known as carbapenemases (60), which may, through horizontal gene transfer, enter the broader pathogen field in the future.

An interesting new parenteral β-lactam drug candidate has recently been described. The new Glaxo-Wellcome experimental compound, GV129606, called a trinem, is a highly potent antibacterial with efficacy against Gram-positives, Gram-negatives, aerobes and anaerobes alike, plus marked resistance to extended spectrum, clinically relevant β-lactamases (61). This compound may mark a new path to be followed in the β-lactam field.

Macrolides

The macrolide antibiotics are a group of compounds produced by actinomycetes via type I modular polyketide synthases (62). The core aglycone of the prototype macrolide, erythromycin, is synthesized by the huge multifunctional enzyme, 6-deoxyerythronolide B synthase (DEBS), which consists of three, multidomain subunits, each subunit with a molecular weight around 300,000 Da. The macrolide chain is synthesized by a set of enzymatic functional domains within the proteins in a linear, stepwise fashion. Interestingly, the enzymatic active sites are arranged in the polypeptides in the same order as their apparent function (62).

Although macrolides theoretically can have ring sizes ranging from as few as 6-membered to over 30-membered, most of the clinically relevant macrolides possess 14-membered or 16-membered rings (Table 5). Current clinical antibacterial macrolides are mostly derived from erythromycin, although a wide variety of biologically active macrolides are used for several purposes across several therapeutic areas (Tables 5 and 6).

The macrolide antibiotic, erythromycin, was first discovered in 1952, the year the double-helical structure of DNA was first announced. Macrolides, which are bacteriostatic agents, inhibit bacterial protein synthesis by structure-based mechanisms: 14-membered macrolides such as erythromycin block translocation of peptidyl-tRNA, whereas 16-membered macrolides inhibit peptidyl-transfer reactions (64). There are apparently additional interactions of macrolides of both groups with ribosomes, but even after 30 years of research, these are not fully understood (64). Resistance to macrolides is most often via the MLS resistance mechanism, which is based on mechanism of action. MLS resistance, conferred by several different genes, results in methylation of adenosine-2058 of 23S rRNA. MLS-I resistance, exemplified by the *tlrD* gene, is result of monomethylation, whereas MLS-II (*ermE* -type) is the result of dimethylation (65).

Erythromycin itself is a poorly soluble, acid-labile molecule that nevertheless has enjoyed a long history of successful use. Erythromycin has been an important orally active antibiotic for many years. The efforts for years in the macrolide field have been aimed at developing new drugs that are acid-stable, possess a longer half-life, have broader ranges of activity, and are not subject to MLS resistance mechanisms. Recently, several semisynthetic macrolides arising from modifications of erythromycin, including clarithromycin (Biaxin) the 15-membered azalide, azithromycin (Zithromax), and most recently, dirithromycin (Dynabac), have made significant contributions to the antibacterials market. Among them, these macrolides represent more than $2 billion in market share.

The most exciting research area in antibacterials today may be the discovery of ketolides, erythromycin-analogue macrolides in which the L-cladinose at the 3-position of

Table 5. Clinical and Experimental Macrolides of Interest as Sorted by Ring Size

Compounds	Ring size	Comments
Spinosad (spinosyns)	12	New insecticidal (esp. against lepidopterans) drugs from Dow AgroSciences
Methymycin	12	Antibacterial; produced by same PKS and gene cluster as picromycin (63)
Clarithromycin	14	Biaxin; 6-*O*-methylerythromycin; acid stable form available in 1-day dosing
Dirithromycin	14	Dynabac; approved in 1995 as orally available, single dose/day formulation
Erythromycin A	14	Original 14-membered macrolide antibacterial agent
Flurithramycin	14	8-Fluoro-erythromycin
Galbonolides	14	Group of 14-membered antifungal macrolides
Ketolides	14	HMR3004 and HMR3647 are new, experimental, 3-oxo-semisynthetic macrolides
Oleandomycin	14	Antibacterial compound used as agricultural feed additive
Picromycin	14	Synthesized from same PKS and gene cluster as methymycin (63)
Roxithramycin	14	9-[*O*]-(2-Methoxyethoxy)methyloxime] derivative of erythromycin
Rustmicin	14	Experimental 14-membered ring antifungal agent of the galbonolide group
Troleandomycin	14	Acid-stable acetylated ester of oleandomycin; antibacterial
Azithramycin	15	Zithromax; Orally active azalide; semisynthetic analogue of erythromycin
Avermectin	16	Veterinary use; also use to treat human onchocerciasis (river blindness)
Doramectin	16	Mutational biosynthetic analogue of avermectin; antiparasitic
Epothilone	16	Experimental myxobacterial antitumor drug; targets microtubule formation
Ivermectin	16	Semisynthetic analogue of natural product avermectin; antiparasitic
Josamycin	16	Used in both human and veterinary treatments
Midecamycin A_1	16	Antibacterial agent
Milbemycin	16	Used in Europe as antiparasitic agent
Miocamycin	16	Acetylated ester of midecamycin gives oral bioavailability
Rokitamycin	16	Propionyl ester of leucomycin A5; active against macrolide-resistant Gram-positives
Spiramycin	16	Used in France as antibacterial agent
Tylosin	16	Veterinary use as antibacterial feed additive
Soraphen	18	Myxobacterial macrolide patented as an agricultural antifungal agent
Ascomycin	23	Also called FK-520 and immunomycin; immunosuppressive compound
Tacrolimus (FK-506)	23	Immunosuppressive agent
Rapamycin	31	Immunosuppressive agent

erythromycin has been replaced by a keto moiety. The ketolides are particularly interesting because they do not induce MLS-resistance mechanisms in pathogenic organisms. This is critical because MLS resistance is typically not constitutive. The two leading ketolide drug candidates, RU64004 (also known as HMR 3004) and RU66647 (also known as HMR 3647), have been shown to be potent inhibitors of Gram-positive bacteria, particularly the pneumococci, including those that show marked resistance to other macrolides such as erythromycin and azithromycin (66). The ketolides, however, show poor activity against Gram-negative bacteria.

Recently, a series of new, 14-membered macrolide antifungal compounds known collectively as galbonolides was discovered (67), of which one, rustmicin, has been investigated in more detail (68). The data indicate that rustmicin and, by extension, possibly the other galbonolides appear to interact with the α-mannan of the cell wall by a potentially novel mode of action (68). Several years ago, interest was sparked when a macrolide known as FK506 (Tacrolimus) was found to possess significant immunosuppressive action (69). Additional compounds of interest in this area included rapamycin, which is expected to be approved soon, and immunomycin, which was dropped because of a narrow efficacy-to-toxicity window (69). Both the milbemycins and avermectins have been used for several years as antiparasitic drugs (70). Ivermectin has been used and approved to treat human diseases such as river blindness and intestinal threadworm. Additionally, macrolides such as tylosin have long been important as animal-feed additive growth promotants in the agricultural area (71).

During the past few years, interest in macrolides as bioactive natural products has grown significantly in areas other than the anti-infective area. As shown in Table 6, there currently is active experimental interest in macrolides in multiple therapeutic areas, including antibacterial, antifungal, antiparasitic, anticancer, immunosuppressive, neuroimmunophilin, gastrointestinal, respiratory, and agricultural areas.

There are five human therapeutic areas in which macrolides have not been used clinically, but in which there is currently considerable interest. An acid-catalyzed breakdown product of erythromycin, called motilide, has been shown to be a potent agonist of the motilin receptor, but it is unstable. Abbott has the lead drug candidate in this area, ABT-229, a 12-deoxyerythromycin homologue possessing modification in the sugars, which is stable and has reasonably high potency (74). It has recently been demonstrated that tacrolimus (formerly FK506) and rapamycin possess additional activities other than those related to immunosuppression. Both tacrolimus and rapamycin have been demonstrated to promote neuron cell growth under conditions in which they can still bind the FK-binding protein in the absence of the second ligand (calcineurin or RAFT, respectively) (73). The macrolide, roxithramycin, currently an investigational drug for treatment of asthma (75), potentially has multiple modes of action for this indication, including inhibition of glycoconjugate secretion to

Table 6. Therapeutic Areas in which Macrolides Are Being Studied as Potential Bioactive Molecules

Therapeutic area	Example macrolides	Comments
Antibacterial	Erythromycin analogues	Traditional area of strength based on erythromycin (64)
Antifungal	Rustmicin, galbonolides	New activities of interest; interaction with mannans (67,68)
Antiparasitic	Avermectin, doramectin	Avermectin recently approved for human use in U.S. (70)
Anticancer	Epothilone	Tubulin stabilizer activity similar to Taxol (72)
Immunosuppressive	Tacrolimus, rapamycin	Substitutes for cyclosporin (69)
Neuroimmunophilin	Rapamycin and analogues	Stimulation of neuronal growth (73)
Motilin receptor	Motilide, ABT-229	Treatment of gastroesophageal reflux disorder (74)
Respiratory	Roxithramycin	Antiasthmatic by multiple potential mechanisms (75)
Agricultural	Tylosin	Antibacterial and growth promoting feed additive (71)

increase mucous clearance; clearance of *Chlamydia pneumoniae*, a possible causative or implicated agent in asthma; suppression of T-cell cytokines interleukins 2, 3, and 4; and inhibition of cholinergic neuroeffector transmission in airway smooth muscle cells. Finally, a macrolide produced by the myxobacterium, *Sorangium cellulosum*, was found to possess tubulin-stabilizing activity similar to Taxol (72), a $1 billion per year anticancer drug. Several companies and research laboratories have shown strong interest in trying to develop epothilone analogues as potential antitumor drugs.

Streptogramins

For more than 25 years, pristinamycin, a combination of two antibiotics, pristinamycin I_A (a peptidic macrolactone belonging to the streptogramin B group) and pristinamycin II_A (a polyunsaturated macrolactone belonging to the streptogramin group A) (76), has been used in Europe as a drug to combat severe infections caused by both Gram-positive and Gram-negative bacteria, without development of resistance against it (76). Each component of pristinamycin is bacteriostatic with poor efficacy, but the combination is bacteriocidal with good potency against a broad range of bacteria (76). The usefulness of pristinamycin, however, has been limited because of its poor solubility (77). In February 1996, however, Rhône-Poulenc Rhorer introduced Synercid, a new variation on pristinamycin. A mixture of the two water-soluble, semisynthetic streptogramins, quinupristin (RP57669) and dalfopristin (RP54476) (78), Synercid (RP 59500) is currently in phase III clinical trials worldwide and is currently available in the United States and Europe in an emergency-use program. More than 700 patients have received Synercid in this program. In one study, 70% of 115 patients with VRE infections were successfully treated (i.e., infection cleared) with Synercid (5). Synercid has been found to be bactericidal for most Gram-positive bacteria, but bacteriostatic for *Listeria monocytogenes* (78). In one study, 96% of all staphylococci tested were sensitive to Synercid in vitro (76), suggesting that this drug may become the "vancomycin of the future," a drug of last resort for use against severe bacterial infections. One hopeful aspect concerning Synercid is that it is unaffected by classical rRNA-methylase-conferred MLS resistance mechanisms, the most common resistance mechanisms found in staphylococci (79). Other MLS resistance mechanisms such as acetylation or hydrolysis of streptogramins still affect these compounds, however, so they are not completely impervious to bacterial resistance mechanisms (79). A recent study showed that Synercid at 2 μg/mL inhibited nearly 99% of vancomycin-resistant *E. faecium* clinical isolates tested in the United States (80), giving rise to hopes that Synercid will help to contain the growing VRE problem.

Tetracyclines

The tetracyclines are among the earliest of antibacterial antibiotics to be discovered, with chlortetracycline being discovered in 1948. The natural tetracyclines are produced by various species of actinomycetes; *Streptomyces aureofaciens* produces both chlortetracycline and tetracycline, the production of each which can be optimized by specific fermentation conditions (81), *Streptomyces rimosus* produces oxytetracyclines, and dactylocyclines are produced by *Dactylosporangium* spp. and *Actinomadura brunnea* (81).

Tetracyclines function as antibiotics by inhibiting protein translation, specifically by disrupting codon-anticodon interactions of tRNA and mRNA at the acceptor site of the ribosome. Because they inhibit protein synthesis, tetracyclines, like macrolides, are bacteriostatic. Tetracyclines are widely used not only in human health, but also in animal health programs; perhaps the widest current use of chlortetracycline and oxytetracycline is as prophylactic drugs in the fish husbandry industry (81).

Bacteria typically develop resistance to tetracyclines by acquiring a plasmid- and transposon-borne resistance gene (*tetA*) encoding an efflux pump (81). Thus, tetracycline resistance is one of the primary resistances observed as being transmitted horizontally among different groups of bacteria. Additionally, a second mechanism, mediated by TetM, gives resistance by inhibition of the interaction of the tetracyclines with the ribosome. This, unfortunately, has led to the diminution of use of the classical tetracyclines for most human health indications. Some of the more modern tetracyclines, such as minocycline, are important for treating MRSAs (81).

The most exciting advance in the tetracycline area has been the development of the glycylglycine tetracyclines (81). Two new semisynthetic glycylglycines, *N*,*N*-dimethylglycylamido-9-aminominocycline (DMG-MINNO) and 9-amino-6-demethyl-6-deoxytetracycline (DMG-DMDOT), have been developed by Lederle for their very broad spec-

trum of activity against Gram-positive, Gram-negative, aerobic, and anaerobic bacteria (54). Their spectrum includes, perhaps surprisingly, bacteria as widely disparate as mycoplasmas, MRSAs, VREs, *Neisseria* spp., *Haemophilus* spp., and *Moraxella* spp. Most importantly, glycylglycine tetracyclines bind the ribosome more tightly than traditional tetracyclines so that TetM, which mediates ribosomal resistance mechanism, cannot interfere with their activity, and they are not substrates for the TetA-mediated efflux mechanisms (81). Thus, there currently is no effective resistance mechanism yet known for these modified tetracyclines. For more information, Hunter and Hill (81) have recently described the tetracyclines in detail.

Glycopeptides

Vancomycin was first isolated in the early 1950s, making it another of the group of long-standing, well-known antibacterial drugs. For a long time, vancomycin was not used to a significant degree, but as the incidence of infections with drug-resistant organisms increased, the use for vancomycin became significantly greater. Because vancomycin is absorbed poorly by the gastrointestinal tract, it is rarely used as an oral drug. Instead, its primary use today comes as a parenteral drug as the last line of defense against many potentially lethal pathogenic bacteria, including MRSAs and antibiotic-resistant *Enterococcus faecium*. In 1987, however, after 30 years of vancomycin being on the market, resistant strains of *E. faecium* (VREs) were finally observed (39). The increased incidence of vancomycin resistance, especially in *S. aureus*, is of enormous concern (44).

Little more than a decade ago, resistance to vancomycin was unheard of and totally unsuspected, because its mechanism of action was so different from that of any other antibiotic class. Nevertheless, resistance to vancomycin and other glycopeptides was discovered and is on the rise. Vancomycin and other glycopeptides exert their activity by inhibiting peptidoglycan biosynthesis, making them potent bacteriocidal drugs. Peptidoglycan consists of a sugar backbone to which pentapeptide chains are attached. The terminal residues of the pentapeptide chain are D-alanine residues, which are critical to processing the peptidoglycan matrix as it is built. Vancomycin and other glycopeptides bind, through multiple hydrogen bonding, to the terminal D-alanine residue of the pentapeptide chain and prevent both transglycosylation and transpeptidation (82). Resistance occurs when a bacterium contains special genes (*vanAHXY*) that allow for incorporation of a D-lactic acid residue in place of the terminal D-alanine residue of the peptidoglycan pentapeptide chains, rendering the peptidoglycan unrecognizable to vancomycin binding. Two genetically distinct forms of resistance have emerged, although both operate by the same mechanism. VanA-mediated resistance gives high-level resistance to both vancomycin and teichoplanan, whereas VanB-mediated resistance is restricted to vancomycin (82). A recent study of clinical VRE isolates in the United States showed that 72% possessed the VanA phenotype, whereas only 28% possessed the VanB phenotype (80).

There are several relatively new analogues of vancomycin on the market to combat vancomycin resistance. Teichoplanan has been around for several years, but its use is restricted to Europe so far. Ramoplanan, another glycopeptide that has been around for a few years, is currently in phase II clinical trials at BioSearch Italia. Eli Lilly has developed a new chlorobiphenyl analogue of vancomycin, LY333328, that is considerably more potent than vancomycin (83). Moreover, LY333328 appears not only to inhibit bacterial growth, but to kill existing bacteria, which may give it a distinct clinical advantage over other existing antibiotics. LY333328 is very potent against VRE in vitro (84), giving hope for treatment of vancomycin-resistant pathogens.

Aminoglycosides

Aminoglycosides are not widely used in clinical therapy in the United States because of their relative toxicity profile as compared to other available antibacterials and to the rapid development of plasmid-borne resistance mechanisms through pathogen populations. Streptomycin and neomycin were first described in 1944 and 1949, respectively, so this group of antibacterials has a rich history. An incredible amount of knowledge about the biosynthesis, the genes, and the molecular mechanisms for regulation of aminoglycoside production is now known, and Piepersberg, the architect of much of this effort, has coalesced this enormous wealth of information in a recent review (85). One new aminoglycoside worth mentioning is the development in Japan of arbekacin, a new aminoglycoside that has potent activity against methicillin-, gentamycin- and tobramycin-resistant *S. aureus* strains (86). The incidence of methicillin-resistance in Japan has risen to nearly 60%, and only vancomycin and the newly developed arbekacin are approved for treatment of these strains. The new aminoglycoside is apparently effective because the widely distributed resistance mechanism, a bifunctional aminoglycoside phosphotransferase (APH[2″])-6′-acetyltransferase (AAC[6′]) which confers resistance to other aminoglycosides such as gentamycin and tobramycin, is relatively ineffective at modifying the new drug (86). It is probable that within a few years, APH(2″)-AAC(6′) will evolve so that it will be able to modify arbekacin.

Other Antibacterial Compounds and New Activities of Interest

Several new antibacterial drugs recently have been introduced to the market or in clinical trials that hold hope for containing the problems of newly emergent pathogens and increased resistance to existing drugs. Several of these are listed in Table 7. A comparison of the minimal inhibitory concentrations (MICs) to kill 90% of *S. pneumoniae* treated in vivo (MIC_{90}s, in μg/mL) was made of several of the new antibacterials with the following results (in order of efficacy) (87): ketolides (new macrolides containing keto groups at C-3), 0.016 to 0.25; everninomicins (novel oligoglycoside from marine organism), 0.06 to 0.25; glycylglycines (modified tetracyclines), 0.12 to 0.5; new fluoroquinolones (e.g., sparfloxacin and trovafloxacin), 0.12 to 0.5; oxazolidinones (new class of chemosynthesized antibacterials), 0.5 to 1.0; and new streptogramins (e.g., Synercid), 0.25 to 2.0. These can be compared to MIC_{90}s for the ex-

Table 7. Newly Approved and Experimental Antibacterial Agents

Compound or drug	Class[a]	Comments
Azithromycin	Azalide	New 15-membered macrolide containing a nitrogen in the ring; approved for pediatric use against otitis media
Trovafloxacin	Quinolone	New very broad-spectrum, high potency quinolone (Pfizer)
Mupirocin	Pseudomonic acid	The pseudomonad product, which inhibits bacterial isoleucyl tRNA synthetase, was recently approved in the U.S. as a topical drug
Cefepime	Cephalosporin	Fourth generation very broad spectrum cephalosporin; has potency of cefotaxime against Gram-positive bacteria and of ceftazidime against Gram-negative bacteria
Oxazolidinones	Chemically made	Two new oxazolidinones are being tested as potential broad-spectrum antibiotics for use against VRE and staphylococci (Upjohn)
Synercid	Streptogramins	Now in phase III clinical trials; combination of quinupristin (RP57669) and dalfopristin (RP54476), both semisynthetic streptogramins
Ziracin (SCH27899)	Everninomycin	Although discovered in 1979, everninomycins were not pursued because of their narrow spectrum; now Ziracin is a leading clinical candidate for treatment of VRE and staphylococci
PA 1648	Ansamycin	Rifampin-derivative being developed that has excellent activity against *Mycobacterium tuberculosis* and *M. avium–M. intracellulare* complex, the most common opportunistic bacteria infection of AIDS patients (PathoGenesis)
Meropenem	Carbapenem	New, safer penem with better activity against Gram-negative bacteria
Rifapentine	Ansamycin	FDA approved in 1998 for treatment of pulmonary tuberculosis
MK-826	Carbapenem	Long-acting, stable, broad-spectrum carbapenem now in phase II clinical trials (Merck)
Trinem	Novel β-lactam	New, broad-spectrum β-lactam being tested that is resistant to β-lactamases (Glaxo-Wellcome)
LY333328	Glycopeptide	New chlorobiphenyl vancomycin analogue with improved potency over vancomycin; currently in phase II clinical trials (Eli Lilly)

[a]Natural product class, except where noted.

isting drugs on various (and variably resistant) strains of *S. pneumoniae*: amoxicillin-clavulanate (Augmentin), 0.06 to 1.0; cefuroxime (semisynthetic cephalosporin), 0.12 to 2.0; cefpodoxime (semisynthetic cephalosporin), 0.25 to 2.0; and cefixime (semisynthetic cephalosporin), 0.5 to 16 (87). As important as MICs are a low MIC does not alone make a good drug. The other critical factor is the development of antibacterials that can be taken orally in once-per-day doses to increase patient compliance. Thus, the time for a particular drug dose to maintain in vivo efficacy above MIC ($T > MIC$) value is also critical to dial into the structure of newly developed drugs (87).

Most of the new antibacterials on the market are modified analogues of existing, well-known classes of antibacterials: azithromycin and clarithromycin, as well as the new experimental ketolides, are based on modifications to the erythromycin core structure; trovafloxacin and sparfloxacin are new fluoroquinolones; cefepime is a new cephalosporin; meropenem and MK-826 are new carbapenems; trinem is a novel β-lactam; LY33328 is a new glycopeptide; and Synercid is comprised of two new streptogramins. Only the oxazolidinones, a chemical synthesis class, represents a new, novel class of antibacterials.

Pharmacia-Upjohn is testing two new oxazolidinones for their ability to treat multiple-drug-resistant strains of *Mycobacterium tuberculosis* (23). These new chemically synthesized antibiotics inhibit protein synthesis in a manner different from natural product protein synthesis-inhibitory antibiotics, have novel structures unrelated to structures of other antibiotics, and have a wide spectrum of activity (23). Experiments have shown that, at least in in vitro tests, pathogens do not form resistance against these antibiotics at significant frequencies.

Mupirocin (Bactroban) was approved in 1997 by the U.S. FDA for use as a topical agent, especially against nasal MRSA. Mupirocin has been used in the U.K. since 1985 and is currently approved in 90 countries. Produced as pseudomonic acid by *Pseudomonas fluorescens*, mupirocin is interesting because of its novel mode of action; it inhibits bacterial protein synthesis specifically through its binding to isoleucyl tRNA synthetase (88). Unfortunately, mupirocin-resistant MRSA have emerged, which is not surprising since the target is a single enzyme.

Ziracin is an interesting, if still-evolving story. The everninomycins have been known since the early 1960s as bacterial protein synthesis inhibitors, but they have attracted little attention for many years (89). Ziracin, an aromatic moiety-containing oligosaccharide, was first isolated in 1979 from a marine actinomycete, *Micromonospora cabonacea* (89). At that time, the everninomycin was not pursued because of its relatively narrow spectrum of being potent against only Gram-positive bacteria. With the increased resistance of Gram-positive bacteria to existing drugs, interest in the everninomycin, Sch27899, was revived. Now, Sch27899 is in clinical development as a novel antibacterial. The problem is that a similar everninomycin, avilamycin (MaxusG), has been used for several years in the European Union as a feed additive in the agricultural market. Recently, avilamycin-resistant isolates of *E. faecium* have been found in broiler chickens that are cross-resistant to Ziracin (90). This discovery is of great concern, potentially cutting short the effectiveness, and certainly the life span, of Ziracin if it is ever marketed (90).

ANTIFUNGAL AGENTS

The need for new antifungal drugs has never been greater for a variety of reasons. Fungal infections fall into two ma-

jor categories, those that are localized, dermal, and mostly annoyances, such as ringworm, athlete's foot, and nail infections (onychomycoses), and those that are disseminated and life threatening. Life-threatening, disseminated fungal diseases have risen dramatically during the past few decades, making this an important area for new drug development. Typically, life-threatening fungal infections occur in patients with impaired defenses, such as patients with AIDS; with other debilitating diseases; who are under treatment with immunosuppressive drugs (usually after organ transplants, to prevent tissue rejection); who are receiving chemotherapy; or with severe burns. Additionally, with the potentially broader use of immunosuppressive drugs for other indications such as arthritis, the potential for fungal infections may be expanded.

The most important pathogenic fungi are *Candida albicans* (disseminated candidiasis), *Candida* spp., *Aspergillus fumigatus* (systemic aspergillosis), *Cryptococcus neoformans* (disseminated cryptococcosis leading to meningoencephalitis), *Pneumocystis carinii* (*P. carinii* pneumonia [PCP]), *Histoplasma capsulatum* (histoplasmosis), and *Coccidioides immitis*, the final example being a fungal pathogen very rich in chitin (91). The most important fungal pathogens associated with immunocompromised patients, such as those with AIDS or receiving immunosuppressive therapy, are *P. carinii*, *C. neoformans*, and *Candida* spp.

The current antifungal drugs and leading clinical candidates are listed in Table 8. Current potent antifungal drugs have problems that make them less than optimal for clinical use. For example, amphotericin B, the antifungal drug of choice in life-threatening cases, causes acute toxicity, resulting in it not being well tolerated in a large percentage of patients, although it is efficacious against PCP (92). Azoles (e.g., clotrimazole, fluconazole, ketoconazole), which target membrane ergosterol synthesis, are static in vitro; they stop fungi from growing but do not kill them. Such agents, which depend on the immune system to clear the existing fungal infection, are used in immunocompromised patients but, because they do not clear the infections, require lifelong therapy to prevent recurrence. Additionally, *Aspergillus* spp. are naturally resistant to azoles, preventing their use in typically aggressive systemic aspergillosis infections that result in high mortality rates. Finally, the incidence of azole-resistant fungi is increasing, particularly among *Candida* spp. such as *C. glabrata* and *C. krusei*.

Because most of the current antifungal drugs suffer from either toxicity (amphotericin B) or the limitations of being static in vitro and increasing resisted by target populations (azoles), there is a critical need for new antifungal agents that act against new targets. Azoles target lanosterol demethylase, a P450 enzyme involved in the synthesis of ergosterol (93), a sterol found in fungal cell membranes but not mammalian cell membranes. Antifungal polyenes, including amphotericin B, nystatin, candicidin, and faerifungin, also target the cell membrane of fungi, but in this case by the formation of transmembrane pores and other membrane-associated effects (94). Although polyene antifungal agents are typically fungicidal, they also are not generally well tolerated by a large majority of patients, making them drugs used as last resorts.

Drug resistance in fungi, which more closely resembles drug resistance in tumor cells, is inherently different from drug resistance in bacteria. First, there is no evidence for plasmid-borne drug resistance mechanisms in fungi, so resistance is limited to chromosomal and nontransferable resistance genotypes. Most fungal drug resistance is effected

Table 8. Clinical and Lead Experimental Antifungal Drugs

Antifungal drug	Type	Comments
Amphotericin B	Polyene (NP)	Clinical; broad-spectrum antifungal agent
Atovaquone	Substituted naphthoquinone (CS)	Clinical; used for *P. carinii* infections
Clotrimazole	Oral fluconazole (CS)	Clinical; for vaginal candidiasis and dermal use
Fluconazole	Bis-triazole (CS)	Clinical; Orally active, relatively broad spectrum
Flucytosine	Flurocytosine	Clinical; for cryptococcal meningitis and candidiasis
Itraconazole	Triazole (CS)	Clinical; used for histoplasmosis and blastomycosis
Ketoconazole	Triazole (CS)	Clinical; broad spectrum
LY303366	Lipopeptide echinocandin (NP)	Phase II clinical trials (Eli Lilly)
Miconazole	Azole (CS)	Clinical; oral, parenteral, and topical; broad spectrum
MK-0991	Lipopeptide pneumocandin (NP)	Phase III clinical trials (Merck); broad spectrum
Natamycin	Polyene (NP)	Clinical; for aphthalmic treatment
Nikkomycin Z	Nucleoside dipeptide (NP)	Phase I clinical trials; chitin synthesis inhibitor
Nystatin	Polyene (NP)	Clinical; orally active and broad spectrum
Pentamidine isethionate	Aromatic diamidine (NP)	Clinical; for *P. carinii* infections
Pradamycins	Benzonaphthacene quinone (NP)	Phase I clinical trials
Rustmicin	Macrolide (NP)	Unusual target; plasma protein interactions
Sordarin analogue	Unusual natural product (NP)	Experimental compound
Sulconazole nitrate	Imidazole (CS)	Clinical; for topical treatment
Sulfanilamide	Sulfonamide (CS)	Clinical; for topical vulvovaginitis
Terbinafine	Allylamine (CS)	Clinical (Lamisil); orally active; for nail fungal infections
Thiabendazole	Benzimidazole (CS)	Clinical; for treatment of worms and fungi
Trimetrexate	Diaminoquinazoline (CS)	Clinical; for treatment of *P. carinii*

Notes: This list may not represent all clinical or experimental antifungal drugs. Generic names are used. NP = natural product; CS = chemically synthesized.

by changes in membrane permeases, leading to exclusion of the drugs, induction of membrane-bound efflux mechanisms, modifications of activases required for the activation of some antifungal drugs into their active forms, and site-specific mutations of target enzymes. Degradation of antifungal drugs by target organisms (e.g., similar to the action of β-lactamases) or modification of antifungal drugs to inert forms (e.g., aminoglycoside phosphotransferases) has not been observed thus far.

With the sequencing of the entire *Saccharomyces cerevisiae* genome, a study was conducted to search for novel targets, unique to fungi or different enough in fungi, which might be used to develop new antifungal agents with novel mechanisms of action (95). Of 6,000 genes analyzed, only a dozen or so potential targets were identified, including chitin synthetase, β-1,4-glucan synthetase, tubulin, elongation factor 2,*N*-myristoyl transferase, acetyl-CoA carboxylase, inositol phosphoryl ceramide synthase, membrane ATPase, mannosyl transferase, tRNA synthetases, lanosterol dehydrogenase, lanosterol synthase, and squalene epoxidase.

The most widely considered new targets for fungicidal activity are all involved with cell wall biosynthesis or structure. Yeast cell walls, which make up 15 to 25% of the cell dry weight, are typically comprised of β-1,3- and β-1,6 glucan polymers (about 50%), α-mannan (highly glycosylated mannoproteins; about 50%), and chitin (about 2%). Although different species of fungi contain different percentages of these components in their cell walls, the major constituents are typically present (93). Thus, the biosynthesis or structural integrity of β-1,3-glucans, β-1,6-glucans, and α-mannans represent potential excellent targets. The pneumocandins and echinocandins, novel lipopeptides produced by *Glarea lozoyensis* and similar fungi, inhibit the synthesis of β-1,3-glucans (96). Two new drug candidates, Merck's MK-0991 and Eli Lilly's LY303366, are semisynthetic lipopeptide echinocandin derivatives that specifically target the Rholp dissociable subunit of the heterodimeric transmembrane 1,3-β-(D)-glucan synthase (92,93,96). Because there is apparently only a single gene that is responsible for the synthesis of this subunit, this is considered an excellent target. The pneumocandin experimental drug, MK-0991, has been shown to possess efficacy against *Aspergillus fumigatus, C. albicans, H. capsulatum*, and *P. carinii* (but not against *Cryptococcus neoformans*), suggesting that this would make an outstanding potential broad-spectrum candidate for disseminated, life-threatening fungal diseases, particularly in immunocompromised patients (92).

Other targets of interest that have been pursued recently include chitin and sphingolipid biosynthesis. Fungi contain three chitin synthetases (CSI, CSII, CSIII) that catalyze the synthesis of the polymer from individual units of UDP-*N*-acetylglucosamine. The leading antifungal chitin biosynthesis-inhibitor drug candidate is nikkomycin Z, a nucleoside dipeptide substrate analog of UDP-*N*-acetylglucosamine which competitively inhibits chitin synthases (91). Although nikkomycin Z is effective in vitro against *C. albicans, C. immitis*, and other fungi with relatively high chitin contents, it does not kill *Saccharomyces cerevisiae* (92,94). The polyoxins, also peptidyl-nucleoside natural products, also inhibit chitin synthase, but none of these has been developed yet as a clinical candidate. Rustmicin (also called galbonolide A), a 14-membered macrolide produced by *Micromonospora chalcea*, inhibits inositol phosphoceramide synthase at pM levels, resulting in the loss of all complex sphingolipids and the accumulation of ceramide (68). Although rustmicin was reasonably efficacious in a murine cryptococcosis model, it suffers from severe in vivo instability, brought about by serum protein binding, and by being an excellent substrate for *S. cerevisiae* efflux pump Pdr5 (68). The pradamycins are D-amino-acid-substituted benzonaphthacene quinone glycosides that appear to act by binding to the saccharide moieties of the mannoproteins in fungal cell walls, leading to a loss of intracellular potassium that results in gross morphological changes (6). Another unusual antifungal compound is sordarin, which exerts antifungal activity via inhibition of the elongation step in protein synthesis (6,97). Glaxo-Wellcome has developed a semisynthetic sordarin, GM237354, that possesses a broad spectrum of activity and high in vivo potency (6).

ANTICANCER AGENTS

The search for natural product anticancer agents began in the late 1950s and became a reality with the discovery in 1964 of daunorubicin, a cytotoxic, antitumor drug of the anthracycline class with efficacy against a wide variety of solid tumors and leukemias (15). Five years later, doxorubicin, the 14-hydroxy analogue of daunorubicin, was discovered at Farmitalia (15). Doxorubicin, which showed a wider range of efficacy for treatment of various cancers, has been a mainstay in chemotherapy for more than 25 years. It was shown recently that doxorubicin as well as many other cytotoxic antitumor drugs (e.g., etoposide) act by trapping topoisomerase II with DNA in what has been referred to as the cleavable complex, resulting in multiple DNA strand breaks (15). Another class of anthracyclines, exemplified by aclarubicin (aclacinomycin A), were recently shown to inhibit by a different mechanism of action, by inhibition of topoisomerae II–DNA interaction (15).

Table 9 shows a list of the major antitumor drugs derived from natural products. Other natural product antitumor chemotherapy agents used for several years, but more restrictively than doxorubicin, include mithramycin, discovered in the early 1950s; the mitomycins, first described in 1956; bleomycin, described by Umezawa in 1965; and the vinca alkaloids, vinblastine and vincristine, which were first described in the period of 1958–1962. In all these cases, the mode of action is cytotoxicity through drug-DNA interactions. With the ultimate desire to get away from cytotoxic drugs that are detrimental to all cells and not just cancerous cells, these cytotoxic natural product antitumor drugs are considered to be drugs of the past and not of the future.

Interest in natural product antitumor drugs was renewed, however, with the discovery of taxanes from the pacific yew tree. Paclitaxel (Taxol), a complex diterpenoid alkaloid, was discovered as a potential antitumor agent in 1971 (98), and it has taken nearly three decades to bring

Table 9. Clinical and Lead Experimental Natural Product-Derived Anticancer Drugs

Anticancer drug	Type	Comments
Aclacinomycin A	Anthracycline	Produced by *Streptomyces galilaeus*; used in Japan and France
Bleomycin	Glycopeptide	Produced by *Streptomyces verticillus*
Carminomycin	Anthracycline	Produced by *Actinomadura carminata*; used in Russia
Dactinomycin	Acylpeptidolactone	Produced by *Streptomyces parvulus*
Daunorubicin	Anthracycline	Produced by *Streptomyces peucetius*
Docetaxel	Taxane	Taxotere; recently approved for treatment of ovarian cancer
Doxorubicin	Anthracycline	Adriamycin; Produced by *S. peucetius* subsp. *caesius*
Epothilone	Substituted macrolide	Produced by *Sorangium cellulosum*; experimental only
Idarubicin	Anthracycline	Synthetic (mimetic), orally available analogue of doxorubicin
Irinotecan	Camptothecin	Approved in 1996 for metastatic colon and rectal cancers
Mitomycin C	Cytotoxic drug	Produced by *Streptomyces caespitosus*
Mitoxantrone	Anthracenedione	Biomimetic compound
Paclitaxel	Taxane	Produced by *Taxus* spp. (yew trees); approved for use in 1994
Pentostatin	Nucleoside analogue	Produced by *Streptomyces antibioticus*
Plicamycin	Polyketide	Mithramycin; Produced by *Streptomyces argillaceus*
Tenipocide	Podophyllotoxin	Cytotoxic antitumor drug
Topotecan	Camptothecin	Semisynthetic; from *Camptotheca acuminata* (Chinese tree)
Vinblastine sulfate	Vinca alkaloid	Produced by *Catharanthus roseus* (periwinkle)
Vincristine sulfate	Vinca alkaloid	Produced by *Catharanthus roseus* (periwinkle)
Vinorelbine tartrate	Vinca alkaloid	Semi-synthetic vinblastine analogue

it to the market. One of the unique features that helped move the taxanes from experimental drugs to clinical candidates was the finding that they acted as tubulin stabilizers, a novel mode of action (99). Docetaxel (Taxotere) and paclitaxel (Taxol) have excellent activity against ovarian and breast cancers. Additionally, Taxol and semisynthetic taxanes may be efficacious against a wide range of tumors. Thus far, the greatest impediment to the development of these drugs on a large scale was that they are only found at levels of about 0.01% (w/w) in the bark of several related yew trees, *Taxus brevifolia* (Pacific yew, an endangered species), *Taxus baccata*, *Taxus cuspidata* (Japanese yew), and others (100). Moreover, the chemical synthesis of paclitaxel is very difficult, requiring more than 30 steps. Thus, paclitaxel is currently made semisynthetically from 10-deacetylbaccatin III, produced by the needles of the Himalayan yew (100). Other novel antitumor drugs developed in recent years include irinotecan (Camptosa) and topotecan (Hycamptin), both which are inhibitors of topoisomerase I.

FUTURE DIRECTIONS IN NATURAL PRODUCTS DRUG DISCOVERY

Several approaches are being taken to address the issues of MRSA, VRE, other antibiotic-resistant bacteria, newly emerging infectious diseases and related problems. One approach is the use of genomics to help to identify new targets amongst bacteria and fungi. As mentioned previously, sequencing of the yeast genome helped to identify about a dozen unique targets for new antifungal drugs. It appears that the incidence of fungal resistance to new drugs targeted against single, critical enzymes, such as glucan synthase, is very low. Similarly, it is hoped that genomic analysis of bacteria is as useful in identifying new targets for novel antibacterials. Unfortunately, there is a significant difference between bacteria and fungi and between bacterial infections and fungal infections that must be considered. First, any single-site bacterial target for which single mutations can render resistance cannot be seriously considered because of the high frequency of mutations (10^{-8}) that occur in bacteria (77). Second, many resistance mechanisms are passed horizontally among bacterial populations by plasmid- and transposon-mediated transfer, which renders many antibiotics useless. Even the fluoroquinolones, which for years were thought to target only DNA gyrase, are now known to target at least two separate enzymes (101). This is critical, too, because single mutations in bacterial gyrases have been shown recently to yield resistance to several fluoroquinolones (102). What is the best answer? Although there is probably no single best answer for all resistance problems, the clear-cut best approach is still to inhibit cell wall biosynthesis, preferably with a novel mechanism of action or at several sites. Alternatively, inhibition of systems or processes, such as protein or nucleic acid synthesis, again at multiple sites, appears to be back in vogue. The conundrum, however, is that protein synthesis inhibitors are bacteriostatic agents, which in recent years have been thought not to be desired. Nevertheless, the newer macrolides, dirithromycin, clarithromycin, and azithromycin, all protein synthesis-inhibiting bacteriostats, are effective drugs.

The Pharmaceutical Research and Manufacturers of America organization announced that as of September 1998, 136 new anti-infective drugs were currently in advanced stages of development by 78 different companies. Of these, 27 compounds are antibacterials, 31 are antivirals, 12 are antifungals, 42 are vaccines, and 24 are in the "other" category, but still relating to anti-infection indications. As described throughout this review, there are unmet needs in all fields of antibiotics. The wealth of new

drugs on the horizon bodes well for the future of antibiotics of all classes.

OUTLINE

INTRODUCTION

The specialized process of secretion in mammalian cells is directed through membrane-enclosed compartments composed of vesicles. Each compartment is unique to ensure specificity and directionality for the secretion process. The compartments are maintained by mechanisms of selective targeting of newly made proteins to their correct vesicle. As proteins destined for the cell surface transit the different compartments, they attain their final conformation through a maturation process that involves protein folding facilitated by molecular chaperones, covalent modification of the polypeptide backbone, and assembly into higher-order structures.

PROTEIN TRANSLOCATION INTO THE ENDOPLASMIC RETICULUM

Targeting to the Endoplasmic Reticulum

All proteins destined for the cell surface, the extracellular space, or intracellular organelles such as lysosomes or the Golgi apparatus are first translocated across the membrane of the endoplasmic reticulum (ER). In mammalian cells the process of protein transport across the ER membrane occurs in the majority of cases while the polypeptide is being translated, which is called cotranslational translocation. In contrast, in yeast, translocation can occur either cotranslationally or after translation of the polypeptide is complete, that is, posttranslational translocation. Proteins that are targeted for transport across the ER must contain a signal that directs the process. Most secretory proteins contain an amino-terminal set of amino acids that compose the signal that directs cotranslational translocation of the protein across the ER membrane. The signal peptide is exposed as the polypeptide emerges from the 60S ribosomal subunit and mediates association of the nascent polypeptide with the cytosolic face of the ER. Although the exact amino acid sequence of signal peptides is not conserved for a given protein across species, its general character is very conserved. The signal sequence may be approximately 30–60 amino acids in length and is composed of three regions: (*1*) an amino terminal segment of variable length that has a net positive charge, (*2*) a central hydrophobic core of 6–15 residues, and (*3*) a C-terminal region that often has a helix-breaking amino acid residue such as glycine proline or serine (1). In yeast, the more hydrophobic the character of the signal peptide, the more likely the transport process occurs by a cotranslational mechanism.

The signal recognition particle (SRP) is a complex of six polypeptides and one 7S RNA molecule that targets substrates for cotranslational translocation (for review see Ref. 2). The 300-nucleotide RNA component is very conserved across all species and is homologous with the highly repetitive Alu DNA family. The mechanism by which cotranslational translocation occurs was elucidated using in vitro studies of protein import into canine pancreatic microsomes, because they are efficient at directing SRP-dependent translocation. Analysis of the SRP has identified subcomplexes that perform different functions. SRP54 (the number refers to the molecular weight of the protein) binds the signal sequence and targets it to the ER membrane. SRP54 contains a stretch of methionine residues that provide a flexible surface, much like bristles of a brush, for interaction with the variable hydrophobic stretches of amino acids in different signal peptides. After interaction with SRP54, translation elongation pauses by a subcomplex of SRP9 and SRP14. This pause helps ensure proper targeting to the ER membrane before significant portions of the polypeptide are synthesized and begin to fold.

After SRP binds the signal sequence of the nascent chain–ribosome complex, it targets the complex to the ER translocation machinery (Fig. 1). The SRP receptor (SRPR) on the ER membrane is composed of two subunits SRα and SRβ and receives the nascent polypeptide after release from SRP. SRP then recycles back to the cytosol. Both SRP54 of the SRP and each of the SRP receptor subunits are GTPases. SRP and SRPR reciprocally stimulate each others' GTPase activity. SRP in the GTP-bound form promotes high-affinity association with SRPR (4). Subsequent transfer of the signal to the translocation apparatus depends on GTP binding by SRα (5). For recycling, SRP must be released from SRPR, a process that requires GTP hydrolysis by SRP54 (6). The nascent chain–associated complex (NAC), an ER-localized protein complex, ensures fidelity of cotranslational targeting to the translocon in the ER membrane by binding nascent polypeptides that lack signal sequences, preventing their targeting to the ER membrane, and preventing free ribosomes from interacting with the ER membrane (7–9). In addition, some polypeptides also require the translocating chain–associated membrane protein (TRAM) for translocation. TRAM can be cross-linked to the signal peptide of some secretory proteins (10). The signal-containing polypeptide inserts into the membrane, and the polypeptide threads through the protein channel, composed of Sec61α, into the lumen of the ER as an extending loop.

Translocation into the ER

The proteins that are required for translocation in vitro and in vivo have been identified through genetic studies in yeast. The most important protein is Sec61p (40 kDa), a protein predicted to span the ER membrane a number of times; it is the primary subunit of the protein translocation channel (11). Sec61p is part of a heterotrimeric complex with Sbh1p and Sss1p, which are the yeast homologues of mammalian Sec62β and Sec61γ (12). In addition to the Sec61p complex, another complex, Sec62p, Sec63p, Sec71p, and Sec72p, is required for posttranslocational translocation in yeast. Sec63p has a luminal region homologous to the J-domain that is highly conserved in the DnaJ protein family, a protein family that stimulates the ATPase activity of Hsp70 family members. The yeast homologue of BiP, Kar2p, is required for posttranslational translocation, probably through its ATPase activity, which is regulated by the J-domain of Sec63p. In mammalian cells, purified SRP, SRPR, and Sec61p are the only proteins required for cotranslocational translocation (12). TRAM is required for only a subset of precursors and stimulates translocation of others.

The role of resident proteins in the lumen of the ER was studied by selectively solubilizing and reconstituting microsomal translocation activity into proteoliposomes (13). Alkaline extraction at pH 9.5 releases a class of luminal proteins that is essential for completion of polypeptide translocation (14). Among the proteins released are the stress proteins BiP/GRP78, GRP94, protein disulfide isomerase, calreticulin, and peptidyl prolyl *cis-trans*-isomerase enzymes (cyclophilin and FKBP). These studies demonstrated that BiP/GRP78 was required for translocation in these yeast-derived proteoliposomes. However, experiments in mammalian systems have not provided compelling evidence that BiP/GRP78 is required for translocation. In addition, expression of an ATPase-defective BiP only prevented the secretion of selective proteins, supporting the view that the BiP ATPase activity is not absolutely required for the secretion of all proteins (15).

Proteins that become integral membrane proteins pose a unique problem for the translocation machinery. Type I transmembrane proteins contain a cleavable N-terminal signal peptide and an internal transmembrane domain. They are oriented such that their amino terminus is in the extracellular space. For these proteins, a span of hydro-

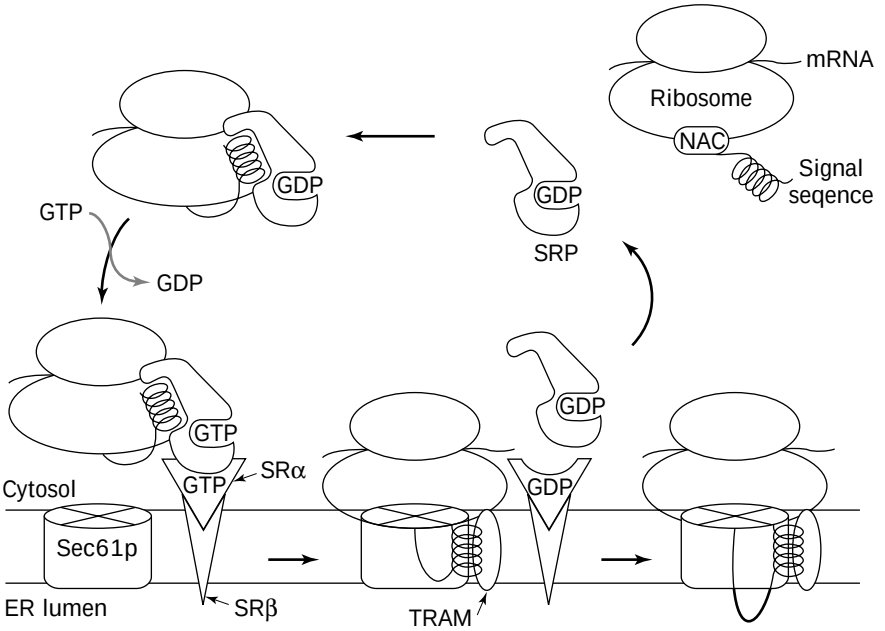

Figure 1. SRP-dependent cotranslocational translocation into the ER. SRP binds to the signal sequence of a nascent polypeptide emerging from the 60S ribosome to form a targeting complex in which elongation is arrested. SRP in the targeting complex then binds SRP receptor (composed of SRα and Srβ subunits) in the ER membrane. After GTP binding, SRP interacts with SRP receptor to result in formation of the ribosome-translocon junction, and translation elongation resumes. GTP hydrolysis stimulates the dissociation of SRP from SRP receptor so they can be recycled. As the nascent chain grows, the translocon pore allows passage of the nascent protein across the membrane. In most cases, the signal sequence is removed on the luminal side of the ER membrane by signal peptidase (not shown). *Source*: Reprinted from Ref. 3, with permission.

phobic amino acids (called the stop-transfer sequence) anchors the polypeptide in the lumen of the ER. In type II transmembrane proteins the carboxy terminus of the protein is in the extracellular space. The topology of type I and type II membrane proteins is determined by the charge distribution of polar amino acids flanking the signal-anchor domain (16). The side of the signal anchor that has more positively charged flanking residues remains intracellular, likely reflecting interactions with the negatively charged phospholipid bilayer. For multiple-spanning transmembrane proteins, each transmembrane domain displaces the prior one from the protein conducting channel where it moves laterally into the lipid bilayer. During the process of translocation, the channel is always gated, either by the ribosome on the cytoplasmic side or by BiP/GRP78 on the luminal side (17).

The cleavage site for signal peptidase is marked by small amino acids (alanine or glycine) in the 3- and 1-positions, relative to the cleavage site. Insertion into the ER membrane involves the formation of a loop structure with the amino terminus remaining in the cytoplasm and the growing carboxy terminus being continuously translocated across the membrane through Sec61p, a protein-conducting channel (18). Cleavage of the signal sequence by the signal peptidase (19,20) then releases the mature amino terminus into the lumen of the ER and is required for translocation of proteins into the secretory pathway.

The transport of a polypeptide across the ER membrane requires energy. GTP is used in the cycling of SRP and SRPR. The energy in cotranslational translocation is derived from the process of translational elongation. For posttranslational translocation, ATP is required for both function of Hsp70 in the cytosol and BiP function in the lumen of the ER. Depletion of intracellular ATP can block the secretion of some proteins, presumably by preventing dissociation of proteins from BiP (21). An ER ATP transporter has been characterized (22), and studies have directly detected ATP in the lumen of the ER by directing firefly luciferase expression to be localized in the ER (23). It is possible that increases in the intraluminal concentration of ATP will increase the secretion capacity in mammalian cells.

POSTTRANSLATIONAL MODIFICATIONS WITHIN THE SECRETORY PATHWAY

Protein translocation into and transport through the secretory pathway in eukaryotic cells is accompanied by a multitude of covalent modifications that occur on the polypeptide backbone. The sequence of posttranslational modifications that occur on a polypeptide is carefully regulated both temporally and spatially; specific modifications occur only within vesicles of the ER or Golgi compartment (Fig. 2). In many cases these modifications are required for proper polypeptide folding and secretion. In addition, posttranslational modifications can affect the half-life of the protein in the plasma and may be required for functional activity of the polypeptide. The mechanisms that direct posttranslational modifications recognize specific structural determinants within the polypeptide backbone. The efficiency of these modifications is determined by the specific host cell enzymatic machinery, the availability of substrates and cofactors, as well as structural properties of the polypeptide. To evaluate the role of posttranslational modification in protein function, investigators have studied proteins treated with chemicals or enzymes to remove modifications, proteins synthesized in the presence of inhibitors of specific modification reactions, proteins expressed in either different cell types or in cell mutants with defects in specific enzymatic machinery required to perform modifications, or proteins engineered through recombinant DNA technology that contain mutations that prevent modifications. The interpretation of results utilizing different strategies needs to be qualified to consider secondary effects due to the approach utilized. As a consequence, it is desirable to utilize several independent approaches to confirm the importance of any specific modification.

Protein Folding and Catalysts of Protein Folding in the ER

Analysis of protein folding in vitro has identified several key steps that occur during spontaneous refolding of a protein upon dilution from a denaturant. First, the polypeptide chain collapses into a compact shape to bury hydrophobic structures; this coincides with formation of secondary structures. Then native tertiary structures form as the protein passes through kinetically defined intermediates; this process may take several minutes. The partially folded intermediate is called the molten globule. Finally, the rate-limiting step lies close to the native folded state and involves formation of hydrogen bonds and disulfide bonds. Although proteins can fold into correct tertiary conformations in vitro (25), additional factors such as protein chaperones assist protein folding in vivo. Molecular chaperones compose a group of unrelated proteins that mediate the correct assembly of other proteins but are not themselves components of the final folded structure. Some molecular chaperones actually catalyze protein folding, whereas others maintain proteins in a folding-competent state and prevent protein aggregation.

A number of protein chaperones bind and stabilize partially folded polypeptides. One of the most well studied members of this family is the immunoglobulin binding protein (BiP) that is the same as the glucose-regulated protein of 78 kDa (GRP78) within the lumen of the ER (26). BiP is a member of the heat shock protein family, which exhibits a peptide-dependent ATPase activity (27), and for which expression is induced by the presence of abberently folded protein or unassembled protein subunits within the ER (28,29). Polypeptide release from BiP and transport out of the ER requires high levels of intracellular ATP (21); however, not all proteins require functional BiP for secretion (15). Intensive investigation into the role of BiP in protein folding has led to two different, but not mutually exclusive, functions for BiP. One hypothesis is that BiP assists protein folding by maintaining proteins in a conformation where they are folding competent, (30,31). This model is supported by the transient association with polypeptides destined for secretion (32–35) and an ATP dependence for proper folding and disulfide bond formation (36). In

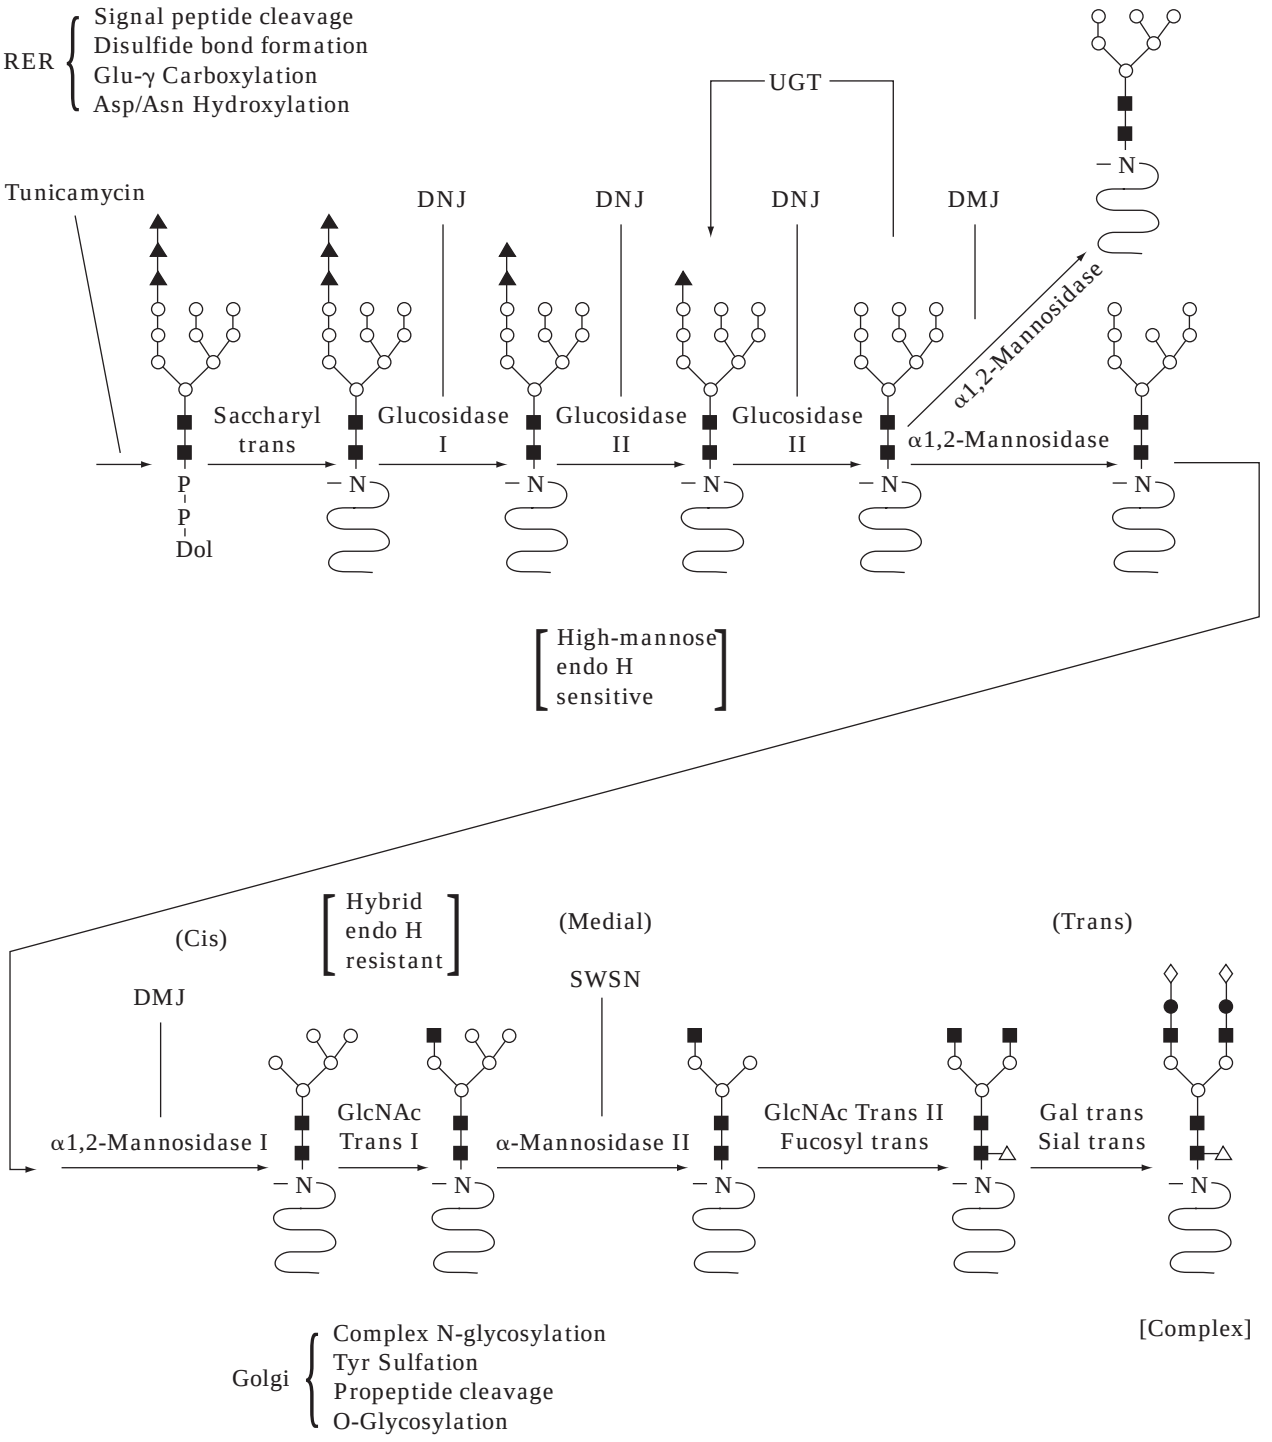

Figure 2. Posttranslational modifications within the secretory pathway. The posttranslational modifications that occur within the rough endoplasmic reticulum (RER, top) and the Golgi compartment (below) are shown. In addition, the sequence of oligosaccharide processing of N-linked oligosaccharides is shown, including the enzymes responsible and the known inhibitors (DNJ, deoxynojirimycin; DMJ, deoxymannojirimycin; SWSN, swainsonine). The point at which N-linked oligosaccharides become resistant to endoglycosidase H is shown. Sugars: ▲, glucose; ○, mannose; ■, *N*-acetylglucosamine (GlcNAc); △, fucose; ●, galactose (Gal); ◇, sialic acid (Sial) trans, transferase. UGT, UDP-glucose:glycoprotein glucosyltransferase. *Source*: Adapted from Ref. 24, with permission.

contrast, other studies (37–40) suggest that these proteins act as a retention mechanism for quality control to prevent aberrantly folded proteins from exiting the secretory pathway. However, despite many efforts to date, there is no direct demonstration that BiP binding to protein substrates actually catalyzes protein folding (41).

Disulfide bond formation occurs in the oxidizing environment of the ER. The tripeptide glutathione (γ-glutamyl, cyteinyl, glycine) is the major thiol-containing molecule in eukaryotic cells and prevents disulfide bond formation in the cytosol and catalyzes their formation in the ER. Glutathione is in equilibrium between a reduced form (GSH) and an oxidized form (GSSG). In the ER the ratio of GSH to GSSG is 5:1, an optimum for formation of disulfide bonds. In contrast, the ratio is 50:1 in the cytosol (42). Oxidized glutathione is reduced by glutathione reductase in a reaction that uses NADPH as a cofactor and occurs in the cytosol. One identified catalyst of protein folding is protein disulfide isomerase (PDI), which exchanges disulfide bonds on substrates and ensures proper disulfide bond formation, and exchange occurs prior to exit from the ER (43). PDI is also the β-subunit of prolyl hydroxylase, which catalyzes posttranslational hydroxylation of proline residue in pro-α-collagen. PDI is a soluble protein of the ER and is the most effective catalyst of protein folding known. PDI does not change the intermediates in the folding reaction but increases the kinetics of the overall process. Proper pairing of disulfide bonds is essential for transport through the ER, and pairing does not always occur in a sequential order.

Another rate-limiting step in protein folding is proline isomerization. Proteins that catalyze isomerization around peptidyl-prolyl bonds are peptidyl-prolyl isomerases (PPIases). There are two classes of these enzymes, based on their different substrate specificities and sensitivities to cyclophilin or FK506. Cyclophilin binds to cyclosporin A, a PPIase that has broad specificity. FK506 binds to FKBP, a PPIase that has narrower specificity with preference for hydrophobic residues in the P1 position. There are some very specific PPIases, one of the best studied is NinaA, a PPIase of the ER that specifically folds rhodopsins 1 and 2. *Drosophila* that have mutations in NinaA lack proper visual responses.

Asparagines and Serine/Threonine-Linked Glycosylation

High-mannose-containing oligosaccharide structures are added to asparagine residues of glycoproteins as an obligatory event for the folding and assembly of many newly synthesized polypeptides (44). This is an essential process in eukaryotic cells (45). The presence of oligosaccharides may be required for the efficient transport of individual glycoproteins through the secretory pathway (33,46), to increase the plasma half-life, or for the biological activity of glycoproteins. The luminal enzyme oligosaccharyltransferase catalyzes the transfer of a preassembled high-mannose-containing oligosaccharide core structure [glucose $(Glc)_3$mannose $(Man)_9$*N*-acetylglucosamine $(GlcNAc)_2$] from a dolichol pyrophosphate precursor onto asparagine acceptor sites within the consensus sequence Asn-X-Ser/Thr, where X can be any amino acid except proline. The mammalian oligosaccharyltransferase is a heterotrimeric transmembrane complex of ribophorin I, ribophorin II, and the oligosaccharyltransferase, which has been purified and molecularly cloned (47). The utilization of a particular consensus site for N-linked oligosaccharide attachment is determined by the structure of the growing polypeptide. As a consequence, proteins expressed in heterologous cells most frequently exhibit occupancy of N-linked sites very similar to that of the native polypeptide (48). To date there is no evidence that the N-linked oligosaccharide addition machinery can be saturated at high expression levels of glycoproteins.

After addition of the high-mannose-containing oligosaccharide core structure, trimming begins with the removal of the three terminal glucose residues, which is mediated by the action of glucosidases I and II (Fig. 2). Glucosidase I removes the terminal α1-3-glucose, and glucosidase II subsequently removes the two α1-2-glucose residues. Glucose trimming is required for binding to the protein chaperones calnexin and calreticulin within the lumen of the ER (49) (Fig. 3). Calnexin (IP90, p88, or CNX; an integral transmembrane protein) (50) and calreticulin (CRT; an ER luminal protein) (51) are homologous lectin-binding protein chaperones that transiently and selectively bind to overlapping sets of newly synthesized glycoprotein folding intermediates, thereby preventing their transit through the secretory pathway. Prolonged association with CNX and/or CRT is observed when proteins are unfolded, misfolded, or unable to oligomerize. CNX and CRT bind most avidly to monoglucosylated forms of the N-linked core structure and promote folding, delay oligomerization, and prevent degradation of some glycoproteins (52). In contrast, interaction with CNX correlates with intracellular degradation of some glycoproteins (53). Removal of the third glucose from the oligosaccharide core structure correlates with release from CNX and CRT and transport to the Golgi apparatus. It is proposed that the selective binding of unfolded glycoproteins to CRT and CNX is mediated by reglucosylation of the deglucosylated N-linked oligosaccharide. This reglucosylation activity is performed by a UDP-glucose:glycoprotein glucosyltransferase (UGT). The activity of the UGT is activated by unfolded protein (54). Thereby, only unfolded, mutant, or unassembled proteins are subject to reglucosylation. Reglucosylated proteins can rebind CNX and/or CRT and in this manner; unfolded proteins are retained in the ER through a cycle of CNX/CRT interaction, glucosidase II activity, and UGT activity. Inhibition of glucose trimming by inhibitors of glucosidase I and II, such as deoxynojirimycin or castanospermine, can inhibit this cycle and the secretion of some proteins. Because glucosidase inhibitors are fairly nontoxic and can inhibit the secretion of HIV envelope glycoprotein gp160, they have been used in the treatment of AIDS (55). Subsequent to glucose trimming in the ER, at least one α1-2-linked mannose is removed by an ER α1-2-mannosidase prior to transport out of the ER. Transit out of the ER is the rate-limiting step in secretion for the majority of proteins and may vary from 15 min to days, depending upon the rate at which a polypeptide attains a properly folded conformation.

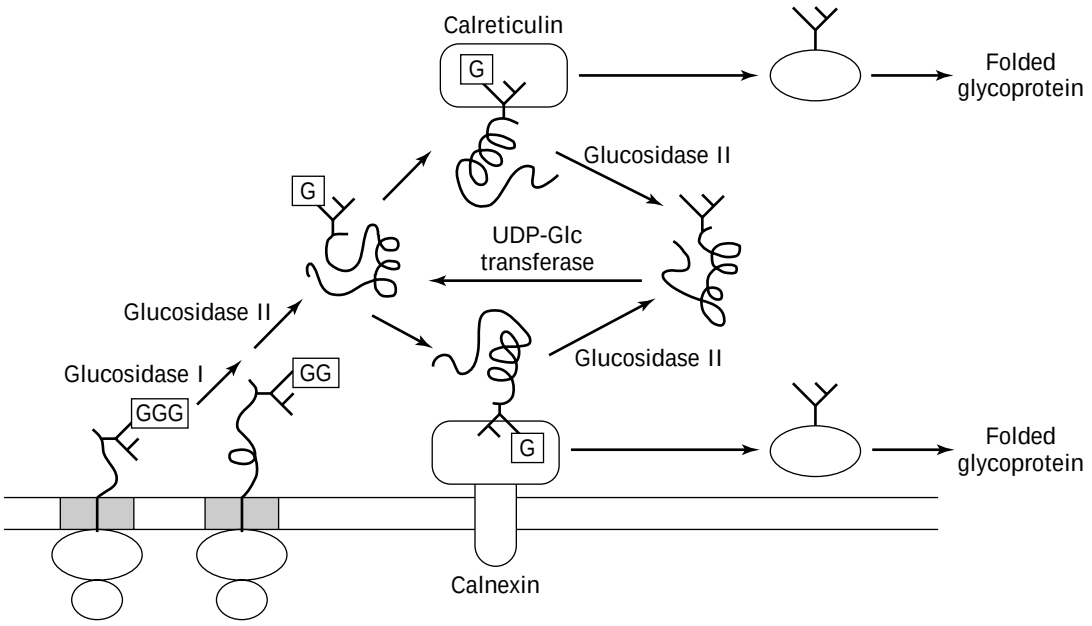

Figure 3. Role of calnexin/calreticulin and UDP-glucose:glycoprotein glucosyltransferase in the recognition and retention of unfolded glycoproteins in the ER. As a protein is cotranslationally translocated into the lumen of the ER, high-mannose core oligosaccharides are attached to asparargine residues. Subsequently, the glucose residues on the core-N-linked oligosaccharides are trimmed by the action of glucosidases I and II to expose a monoglucosylated core oligosaccharide that is a ligand for calnexin (a transmembrane protein) and/or calreticulin (a luminal ER protein) binding. After further action by glucosidase II, the glycoprotein is released from calnexin and calreticulin interaction. Unfolded glycoproteins are recognized as a substrate for the UDP-glucose:glycoprotein glucosyltransferase to form a monoglucosylated ligand to promote another round of calnexin and/or calreticulin binding. Folded glycoproteins bypass reglucosylation and are subsequently transported to the Golgi compartment. *Source*: Adapted from Ref. 44, with permission.

A sequential series of additional carbohydrate modifications occur that are separated spatially and temporarily as the protein transits through the *cis*, *medial*, and *trans* Golgi compartments. Mannose residues are removed by Golgi mannosidases I and II, and then *N*-acetylglucosamine, fucose, galactose, and sialic acid residues are added. These reactions are catalyzed by specific glycosyltransferases that modify the high-mannose carbohydrate to complex forms. Also within the Golgi apparatus, O-linked oligosaccharides are attached to the hydroxyl of serine or threonine residues through an O-glycosidic bond to *N*-acetylgalactosamine. Serine and threonine residues subject to glycosylation are frequently clustered together and contain an increased frequency of proline residues in the region, especially at positions -1 and $+3$, relative to the glycosylated residue (56). Galactose, fucose, and sialic acid are frequently attached to the serine/threonine-linked *N*-acetylgalactosamine. O-glycosylation occurs in the Golgi complex concomitant with complex processing of N-linked oligosaccharides.

The role of N- and O-linked oligosaccharide addition in glycoprotein function can be studied by using specific enzymatic inhibitors, glycosidases, and mutant cell lines (24). N-linked glycosylation is most easily evaluated by using specific glycosidases. The acquisition of resistance to endo-β-*N*-acetylglucosaminidase (Endo-H), which cleaves high-mannose and some hybrid-type oligosaccharides at the GlcNAcβ1-4GlcNAc linkage to leave a single GlcNAc residue attached to the asparagine (57), is frequently used to monitor movement of the protein from the ER to the medial Golgi apparatus. Resistance to Endo-H occurs in the medial Golgi following action of GlcNAc transferase I and mannosidase II. Peptide-*N*4-(*N*-acetyl-β-glucosaminyl)-asparagine amidase (N-gly) removes all N-linked oligosaccharides, regardless of the complexity of their structure, to leave a free aspartic acid residue (58). Also of use are a number of inhibitors that are specific for selective steps in the N-linked oligosaccharide processing pathway (see Fig. 2). In addition, a number of cell lines have been isolated that are defective in specific steps in oligosaccharide processing (59).

There are no specific inhibitors that can be used to study the requirement for O-linked glycosylation. It is possible to inhibit O-glycosylation, as well as complex modification of N-linked oligosaccharides, by depletion of the divalent metal ion manganese from the secretory pathway, and this may be used as an indication of whether O-linked sugars are present on the polypeptide (60). Of greater utility is a mutant cell line, ldlD, that is deficient in the UDP-galactose and UDP-*N*-acetylgalactosamine-4-epimerase and cannot synthesize Gal or GalNAc under normal growth conditions in the presence of glucose (61,62).

Finally, it is possible to enzymatically remove O-linked glycans with endo-α-*N*-acetyl-D-galactosaminidase (*O*-glycanase) that cleaves the Galβ1-3GalNAc disaccharide unit linked to serine or threonine residues (63). Sialic acid residues on the Gal or GalNAc will inhibit *O*-glycanase cleavage and therefore need to be removed by prior digestion with neuraminidase.

Glycosylphosphatidylinositol Anchor Addition

The addition of glycosylphosphatidylinositol (GPI) to many cell-surface-associated proteins occurs in order to anchor the protein in the lipid bilayer. The addition of GPI anchors occurs in the ER. A signal in the carboxy terminus of the polypeptide substrate contains a hydrophobic sequence of 17–30 amino acids followed by a spacer of 5–10 amino acids and a cleavage/attachment site. The attachment site must be an amino acid with a small side chain. The reaction is catalyzed by GPI:protein transamidase. This activity is defective in individuals with paraxysmal nocturnal hemoglobinuria. This disease results from a defect in the cell surface expression of inhibitors of complement-mediated cell lysis (such as decay accelerating factor). As a consequence, hemolytic anemia occurs because blood cells are unprotected from complement-mediated lysis.

Gamma-Carboxylation of Glutamic Acid Residues

The precursor of the vitamin K–dependent coagulation factors and a number of bone proteins and growth factors contain a propeptide that directs γ-carboxylation of up to 12 glutamic acid residues at the amino terminus of the mature protein (64). The propeptides of these proteins exhibit amino acid conservation within the γ-carboxylase recognition site and the site for cleavage of the propeptide. NMR structural analysis identified that the propeptide is an amphipathic α-helix with the carboxylase recognition site N-terminal to the helix (65).

The vitamin K–dependent γ-glutamyl carboxylase enzyme converts glutamate residues to γ-carboxyglutamate Gla residues. In the presence of CO_2, O_2, and vitamin K hydroquinone (KH_2) the enzyme is able to carboxylate a peptide containing glutamic acid residues, yielding a Gla-containing peptide, vitamin K epoxide, and H_2O (66). The vitamin K epoxide formed is subsequently reduced to regenerate KH_2 by either a thiol or the enzyme vitamin K epoxide reductase. The bovine (67) and human (68) cDNAs encoding the vitamin K–dependent γ-glutamyl carboxylase were isolated and demonstrate that the protein is a single-chain polypeptide of 94,000 kDa that spans the membrane 3 to 5 times. The overexpressed protein product directed increased carboxylation activity in vitro using isolated microsomes from transfected mammalian or insect cells and a synthetic peptide substrate (67,69). The ability to express γ-carboxylase activity from the cloned cDNA has permitted identification of the propeptide binding site between residues 50 and 225 (70) and the γ-carboxylase active site for glutamate binding within 218 residues of the amino terminal (71), whereas the vitamin K–reactive site is in the carboxy terminus of the protein (72). Vitamin K epoxidase activity is also catalyzed by the enzyme, and the carboxy terminus of the enzyme is required for this activity.

High-level expression of the vitamin K–dependent plasma proteins in transfected mammalian cells is limited by the ability of the mammalian host cell to efficiently perform γ-carboxylation of amino-terminal glutamic acid residues and also to efficiently cleave the propeptide (73,74). Analysis of factor IX expressed in CHO cells revealed that the protein had a much lower specific activity compared with the natural human plasma–derived protein. The reduced specific activity was attributed to both the limited ability of CHO cells to cleave the propeptide of factor IX and its ability to efficiently perform γ-carboxylation (67,73). Overexpression of the γ-carboxylase cDNA yielded increased activity in microsomal fractions when measured in vitro using small substrates (67). However, overexpression of the γ-carboxylase did not improve γ-carboxylation of factor IX when coexpressed in transfected mammalian cells (67). These results suggest that the amount of carboxylase protein is not a limiting factor to direct vitamin K–dependent γ-carboxylation in vivo. Several possibilities exist for the inability of the overexpressed γ-carboxylase to improve γ-carboxylation in vivo. First, the overexpressed γ-carboxylase may be mislocalized within the secretory pathway. It is possible that another protein, such as a protein chaperone, may be required to utilize a more complex protein substrate as opposed to a small peptide substrate. It is possible that another cofactor, possibly reduced vitamin K, is limiting for factor IX carboxylation in vivo. Further information on the mechanism of γ-carboxylation reaction in vivo is required in order to elucidate the rate-limiting step for γ-carboxylation in vivo.

β-Hydroxylation of Amino Acids: Aspartic acid, Asparagine, Lysine, and Proline

Proline and lysine residues are hydroxylated in procollagen by prolyl-3-hydroxylase and prolyl-4-hydroxylase. Prolyl-4-hydroxylase acts on prolines if the amino acid sequence is G-X-P, where X is any amino acid. This reaction requires O_2, Fe^{2+}, ascorbic acid, and α-ketoglutarate. This modification is important for stability of the collagen triple helix. Vitamin C deficiency results in scurvey because of reduced proline hydroxylation to form a stable collagen triplex.

A number of proteins that contain epidermal growth factor (EGF) domains, such as blood coagulation factor IX, have an aspartic acid or asparagine that is β-hydroxylated (75). This modification occurs by posttranslational hydroxylation of aspartic acid and/or asparagine within the ER. The β-hydroxylase has been molecularly cloned and characterized to some extent in recent years (76,77). β-Hydroxylation does not require the propeptide, vitamin K, or concomitant γ-carboxylation. A consensus β-hydroxylation site within EGF domains (Cys-X-Asp/Asn-X-X-X-X-Phe/Tyr-X-Cys-X-Cys) was proposed (75). Hydroxylation of both aspartic acid and asparagine is catalyzed by aspartyl β-hydroxylase, requires 2-ketoglutarate and Fe^{2+} (78,79), and is inhibited by agents that inhibit 2-ketoglutarate-dependent dioxygenases (80). It is interesting that only 0.3 mol/mol of plasma factor IX is modified by β-hydroxylation at Asp64, and this same amount of β-hydroxylation occurs

in recombinant factor IX expressed at high levels in CHO cells (80). Thus, the low efficiency of β-hydroxylation appears to be a consequence of the factor IX polypeptide backbone and independent of the cell type used for expression.

Sulfation of Tyrosine Residues

Sulfate addition to tyrosine as an *O*4-sulfate ester is a common postranslational modification of secretory proteins that occurs in the trans Golgi apparatus (81) and is mediated by tyrosylprotein sulfotransferase that utilizes the activated sulfate donor 3′-phosphoadenosine 5′-phosphosulfate (PAPS) (82,83). Although the enzyme has been biochemically characterized (83), to date the enzyme has not been molecularly cloned. This modification occurs on many secretory proteins including a number of proteins that interact with thrombin, such as hirudin (84), fibrinogen (85), heparin cofactor II (86), α2-antiplasmin (87), vitronectin (88), bovine factor X (89), factor V, and factor VIII (90–92). Comparison of all known tyrosine sulfation sites yielded a consensus sequence that is primarily characterized by a large number of acidic amino acid residues. The consensus tyrosine sulfation site has three aspartic acid and/or glutamic acid residues near the sulfated tyrosine (± 5 amino acids), a turn-inducing residue within $+7/-7$, and the absence of cysteine or N-linked glycosylation sites within 7 residues of the sulfated tyrosine (81). Although tyrosine sulfation modification is found on many proteins that transit the secretory apparatus, there are few examples where this modification is required for secretion or functional activity of the molecule; for example, tyrosine sulfation in the hormone cholecystokinin is required for its biological activity (93). However, tyrosine sulfation can modulate the biological activity, binding affinities, and secretion of specific proteins (81). For example, tyrosine sulfation at the carboxy terminus of hirudin increases its binding affinity to the anion binding exosite of thrombin (94,95).

The most direct method to measure sulfation of a particular protein is to measure incorporation of [^{35}S]-sulfuric acid into protein as it is synthesized in cultured cells as described in Ref. 24. [^{35}S]-Sulfuric acid will not be incorporated in cysteine. Sodium chlorate is an inhibitor of ATP sulfurylase, the first of two enzymes involved in the synthesis of 3′-phosphoadenosine 5′-phosphosulfate (PAPS). PAPS is the donor for sulfation of both tyrosine and carbohydrate residues in intact cells (96). Analysis of proteins synthesized in the presence of sodium chlorate can provide a useful means to study the role of tyrosine sulfation.

Proteolytic Processing of Precursor Polypeptides

Early studies demonstrated that the budding yeast *Saccharomyces cerevisiae* gene product Kex2 could cleave mammalian precursor polypeptides after paired basic residues (97), suggesting that a human homologue of Kex2 may be the protease required for propeptide processing. Kex2 is a membrane-bound Ca^{2+}-dependent subtilisin-like serine protease that cleaves substrates, such as alpha mating factor, within the *trans*-Golgi compartment (98,99). A computer search identified a human homologue of Kex2 upstream of the c-*fes*/*fps* protooncogene and was subsequently named furin (fes/feps upstream coding region) or PACE, an acronym for "paired basic amino acid cleaving enzyme." The cDNA was subsequently cloned and shown to encode a protein that could cleave pro-vWF (100,101), pro–nerve growth factor (102), proalbumin (103), complement pro-C3 (104), and pro–factor IX (73) after pairs of basic amino acids. PCR-based cloning strategies subsequently identified over a half dozen members of this subtilisin-like serine protease family (105). Expression of some of these enzymes (PC1/PC3, PC2, and PC4) is restricted to neuroendocrine tissues, and the activities are likely responsible for processing of neuropeptides and endocrine hormones (106,107). In contrast, furin/PACE and PACE4 are ubiquitously expressed, but to a greater extent in the hepatocyte (108,109), and are likely candidates for processing of many other proteins including coagulation factors.

Propeptide cleavage occurs in the trans Golgi compartment just prior to secretion from the cell. The activity of the propeptide processing enzymes is uniquely regulated where a calcium-dependent induced autocatalytic activation occurs within the trans Golgi compartment to activate these proteases to their active form (110–113). In the process of activation, a propeptide is cleaved away from the zymogen. The specific localization of propeptide processing to the trans Golgi compartment ensures that the propeptide is associated with the mature polypeptide as proteins transit the secretory compartment.

Characterization of the amino acid requirements around the propeptide cleavage site has identified that both the P1 and P4 arginine are important for efficient processing mediated by furin/PACE and PACE4 (114,115). Cotransfection experiments were performed to test whether these enzymes could process pro–factor IX and or pro-vWF. Whereas both furin/PACE and PACE4 were effective at enhancing pro-vWF processing, only furin/PACE was capable of improving pro–factor IX processing. Thus, it appears that different members of this class of enzymes recognize and process overlapping sets of substrates. Overexpression of furin/PACE in transfected cells (103) as well as in transgenic animals (116) improves the ability to yield fully processed proteins. Recombinant factor IX is produced by coexpression with furin/PACE to ensure complete processing of the propeptide.

VESICULAR PROTEIN TRANSPORT

Transport vesicles are the intermediates for the trafficking of proteins between compartments of the secretory pathway (117). The principal mechanism of transport vesicle formation is through cytosolic coat proteins that bind to specific sites on the membrane (118). Interactions between these coat proteins and the cytosolic tails of membrane proteins play a fundamental role in sorting cargo into vesicles (119,120). Binding of coat proteins to the membrane induces the configuration of the membrane into a coated bud. Membrane fission at the neck of this bud releases the vesicle. The most well-characterized coat protein is the clathrin coat that is responsible for endocytic vesicle formation

at the plasma membrane. Two additional types of coat components mediate vesicle formation and fusion within the secretory pathway. COP II (*co*at *p*rotein) components are required for the formation of vesicles that export cargo from the ER. COP I components were identified as coat proteins that form Golgi-derived transport vesicles (121,122) (Fig. 4).

Protein transport through the secretory pathway begins at the ER. Secretory proteins leave the ER in vesicles that bud from a specialized region of the ER. Protein transport between the ER and the intermediate compartment occurs in both directions. Retrograde transport from the intermediate compartment to the ER was first demonstrated for ER-resident proteins. If such proteins are erroneously incorporated into transport vesicles and leave the ER, they are efficiently recycled by retrograde transport. COP I–coated vesicles mediate the recycling of ER-resident proteins from intermediate compartments back to the ER, and COP II–coated vesicles mediate the export from the ER. The interaction of COP I and COP II components with the cytosolic tail domains of secretory transmembrane and ER-resident transmembrane proteins is likely to play an important role in sorting cargo into transport vesicles (119,120). Recently studies have used green fluorescent protein fused to vesicular stomatitis virus glycoprotein to visualize protein trafficking between the ER and Golgi compartments in living cells. The results demonstrate that the COP II–coated vesicles that are derived from the ER membrane have their coat proteins replaced by COP I and then move in a manner that depends on microtubules to the Golgi complex (Fig. 4). In addition, the vesicles are more elongated (appearing more like tubules) and are juxtaposed to microtubules that probably guide their movement (122,123).

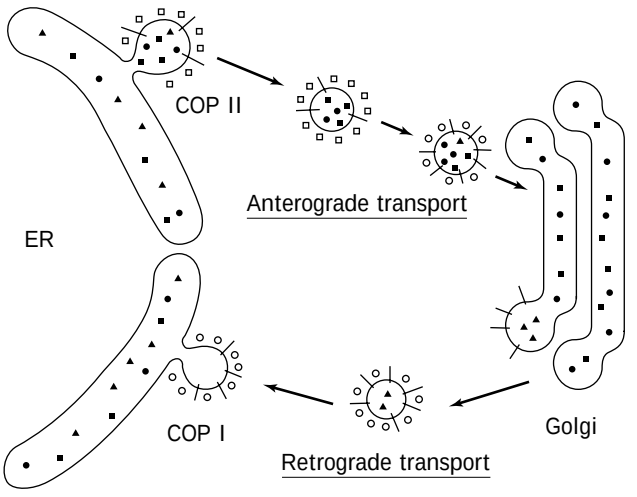

Figure 4. Proposed roles of COP I and COP II in vesicle traffic between the ER and cis Golgi. COP II vesicles transport normal cargo, some escaped ER resident proteins, and some anterograde targeting membrane proteins from the ER to the intermediate compartment where the COP II coat is exchanged for a COP I coat. The COP I–coated vesicle then fuses with the cis Golgi compartment. COP I vesicles are also shown mediating retrograde transport to the ER for escaped ER proteins.

Secretory proteins pass through the Golgi in the cis to trans direction. As proteins pass through the Golgi compartments they are modified by sequence of glycosylation and deglycosylation steps (124). Best understood is the modification of N-linked glycans in the Golgi. Initial trimming of mannose residues is followed by attachment of *N*-acetylglucosamine (GlcNAc), which is followed by more trimming of mannose residues and attachment of more GlcNAc. Mannose trimming and GlcNAc addition occur in cis and medial Golgi compartments. Although each Golgi subcompartment differs from its neighboring compartments in the specific set of enzymes contained within it, this separation is not complete. The same enzymes may even have different localization in different cell types. Golgi enzymes are not restricted to just one cistern. When the distributions of two different Golgi enzymes were determined relative to each other in the same samples, both were found spread out over several cisternae. The maximum concentration of each enzyme was in different in different compartments, but their distribution showed considerable overlap. Furthermore, Golgi enzymes seem to be in flux. Experiments with yeast demonstrated that a Golgi enzyme that is predominantly localized in the early Golgi was modified by late-acting Golgi enzymes (125). In a similar study using mammalian cells it was shown that an enzyme that was localized in the medial Golgi could be modified by an enzyme in the cis Golgi, even after the medial Golgi enzyme had reached its localization (126). These results indicate that Golgi enzymes must be efficiently recycled from late to early Golgi compartments and move again forward with the secretory flow. Golgi enzymes are not immobile in Golgi cisternae, but rather are freely diffusable.

Two models are proposed to explain protein transport through the Golgi: the vesicular transport model and the cisternal maturation model (127–129). The vesicular transport model assumes several distinct subcompartments that exchange cargo by vesicular transport in the anterograde and retrograde direction. The cisternal maturation model proposes that cisternae form de novo by fusion of ER-derived transport vesicles. These ER-derived transport intermediates would acquire Golgi enzymes by fusion with Golgi-derived retrograde transport vesicles from the cis-most compartment of the Golgi stack. At the same time, resident Golgi enzymes would move by retrograde transport in the trans to cis direction, from cisternae that formed earlier to more recently formed cisternae. Ultimately, cisternae would emerge on the trans face of the Golgi stack and disperse into vesicles of the constitutive and regulated secretory pathways and into transport vesicles to endosomes and lysosomes. Both models were first formulated shortly after the Golgi apparatus was characterized by electron microscopy, and which one best describes the Golgi has been controversial ever since.

Fusion of the vesicle membrane with its target membrane requires the cytosolic protein NSF (NEM-sensitive factor for fusion). NSF interacts with another cytosolic protein, SNAP (soluble NSF attachment protein), and SNARE (SNAP receptor) membrane proteins (130). It is the interaction of vesicle SNARE (v-SNARE) with target SNARE (t-SNARE) that is thought to play an important role in

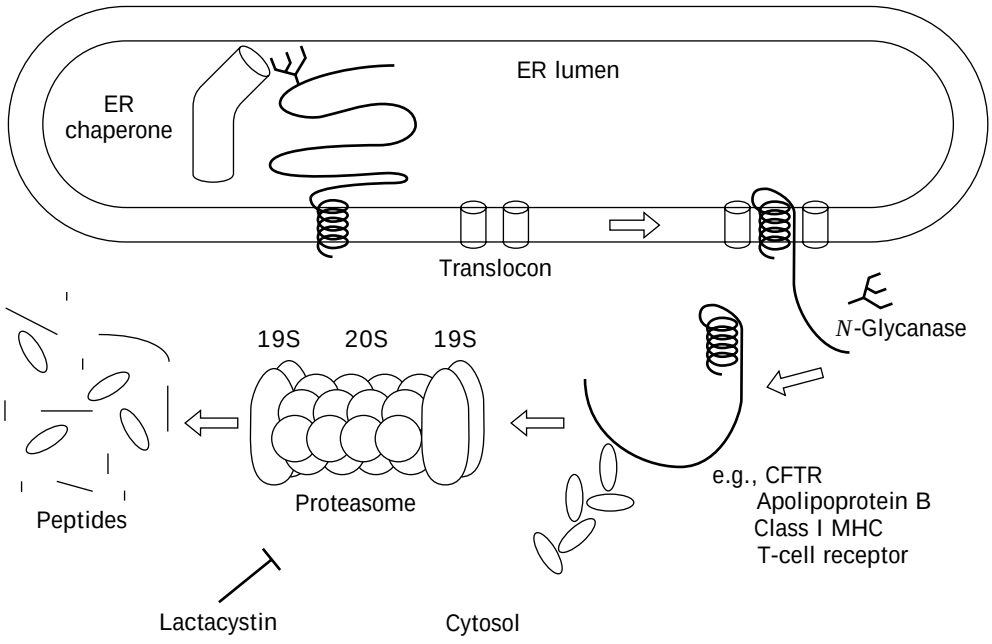

Figure 5. Degradation of ER-associated proteins. A putative ER chaperone facilitates association of a protein, with the Sec61 translocon. Reverse translocation from the lumen to the cytosol occurs with subsequent deglycosylation by *N*-glycanase. The protein may be subject to modification by ubiquitination and eventual targeting to the proteasome. Soluble proteins of the ER may also be degraded by reverse translocation through the Sec61 translocon, or alternatively they may associate with transmembrane proteins, such as CNX, that mediate their degradation. *Source*: Adapted from Ref. 141, with permission.

controlling the specificity of the vesicle fusion reaction. The precise role of NSF in this reaction is unclear. NSF action disrupts a v-SNARE/t-SNARE complex (131). This disruption could be what mediates the rearrangement of SNAREs that is required during fusion (132). These results therefore support the hypothesis that NSF directly mediates vesicle fusion. However, in yeast NSF mutants, vesicles accumulate in the cytosol, and this observation lends support to a model in which NSF is required for vesicle docking (133). Consistent with this hypothesis is that although yeast vacuole fusion is NSF dependent, the NSF action in this process precedes the docking of the membranes (134). These results indicate that NSF acts by activating the SNAREs for vesicle docking, rather than being involved in fusion itself. Small GTP-binding proteins of the rab family, as well as other proteins such as p115/Uso1p, are likely to be involved in further control of vesicle docking and fusion (135–138).

Mammalian cells constitutively transport proteins within vesicles from the ER to the plasma membrane, where they fuse through exocytosis. There are also specialized secretory cells, for example neuroendocrine cells, that store granules and release them upon appropriate stimulation through a regulated secretory pathway. Different proteins are sorted to the regulated secretory granules in different cell types through a common mechanism. The sorting process involves selective protein aggregation into clathrin-coated vesicles at the trans Golgi network. The aggregation occurs at pH 6.5 with 1 mM Ca^{2+}.

PROTEIN RETENTION AND DEGRADATION IN THE ER

A protein within the ER has several possible destinations that include transport to the Golgi compartment, degradation, and retention in the ER. What determines the fate of any particular polypeptide? For resident proteins of the ER, there are two primary mechanisms that ensure that proteins do not exit the ER compartment (139). Soluble luminal proteins of the ER, such as BiP and PDI, contain a carboxy-terminal tetrapeptide, with the consensus sequence KDEL, that is necessary and sufficient for preventing secretion of the polypeptide. A KDEL receptor, that is, a transmembrane-spanning protein, binds KDEL-containing proteins that leave the ER and retrieves them to the ER from the intermediate compartment. For transmembrane-resident proteins of the ER, there is a signal within the cytosolic domain that mediates retrieval from the intermediate compartment by COP proteins. Type I transmembrane-resident ER proteins contain a dilysine motif in the carboxy terminus (i.e., cytosolic tail). For type II transmembrane proteins, a diarginine motif in the amino terminus mediates the interaction with COP proteins. COP I vesicles then retrieve these proteins to the ER from the intermediate compartment.

As mentioned earlier, for many years investigators searched for signals that direct protein transport out of the ER. Although it is now known that specific short sequences exist that facilitate export from the ER, it appears now that the majority of polypeptides have retention signals

that prevent their export. As a polypeptide folds, these retention signals become buried within the polypeptide, and thus, the polypeptide can transit to the Golgi compartment. A variety of polypeptides that recognize and bind unfolded proteins have been identified, including BiP/GRP78, CNX, and CRT, which were discussed earlier. These protein chaperones play a fundamental role in preventing unfolded proteins from exiting the ER compartment.

Proteins that are unable to attain their native conformation are targeted for degradation. A nonlysosomal pathway has been identified in the degradation of these proteins (140,141). The discovery that lactacystin, a fungal metabolite that specifically binds and inhibits the cytosolic 26S proteasome, inhibits the degradation of many ER-associated proteins pointed to the involvement of the cytosolic proteasome in the degradation of ER-localized proteins. There are now a number of examples of ER-associated proteins, such as the cystic fibrosis transmembrane conductance regulator, the T-cell receptor, factor VIII, class I MHC molecules, and so forth, that are degraded by this pathway (53,142–146). Insight into the mechanism of degradation was obtained by studying how human cytomegalovirus (HCMV) evades the immune system (Fig. 5). HCMV encodes two gene products, US2 and US11, that are able to dislocate ER MHC class I proteins to the cytosol (146,147). This dislocation occurs through the Sec61 protein conducting channel (148). Once in the cytosol, the class I molecules are deglycosylated by an *N*-glycanase and are then polyubiquitinated. The ubiquitinated protein is then degraded by the cytosolic 26S proteasome. How are unfolded proteins identified to be degraded? The answer to this question is unknown, but present data suggest that CNX may be involved in this quality control decision. Proteins that are destined to be degraded are bound to CNX but not to CRT (53,143,149,150). CNX is a transmembrane protein that is in close proximity to the Sec61p translocon. It is speculated that CNX may mediate the transfer of unfolded proteins in the lumen of the ER to the proteasome.

Cell damage
Shear damage
Shear protection
Shear rate
Shear stress

OUTLINE

INTRODUCTION

Susceptibility to hydrodynamic and mechanical shear forces affects performance of cultured cells of animals, plants, microalgae, and cyanobacteria. In addition, hydromechanical forces affect or otherwise damage some commercially relevant mycelial fungi, filamentous bacteria, microbial flocs, and biofilms. In specific cases, intense shear fields may also damage the larger bioactive molecules such as enzymes. This article details the shear sensitivity of the major types of biocatalysts and the approaches available for mitigating the damaging effects. Methods for estimating shear rate and shear stress are discussed for various configurations of bioreactors operated in process-relevant conditions.

Depending on its intensity, a shear field may be stimulatory, inhibitory, or outright destructive. Intense shear fields will disintegrate even the most robust of microorganisms (1). Lesser levels of turbulence impact upon cellular morphology (2,3), biochemistry and physiology (4), floc size (5), and attachment and detachment from surfaces (6,7). These influences of shear stresses are reflected in the industrially important aspects of production rate, productivity, product spectrum, and characteristics. Among the most susceptible to shear effects are the animal cells, plant cells, and cells of some microalgae and cyanobacteria. Shear-associated problems have the greatest economic impact in the animal cell culture industry because it is among the largest ones based on shear-sensitive cells and because of the high-value nature of most cell-culture-derived products (8). Damaging consequences of intense shear fields are also well documented for other microorganisms. For example, shear effects may alter characteristics of extracellular microbial polysaccharides by affecting the secretery process in some bacteria (9,10). Considerations of shear stress levels are also important in design and operation of biomedical devices such as dialysis machines, heart-lung machines, and transfusion filters. Shear stresses associated with implanted devices such as artificial heart valves can have medically significant implications. Increasingly, shear-sensitive human cells are being used to regenerate damaged tissue in vitro for later implanting or grafting. In other instances, susceptibility to shear may be beneficial, for example, during recovery of intracellular material by mechanical disruption (1,11,12). Some of the factors that determine shear sensitivity are summarized in Table 1.

SHEAR FORCES IN BIOREACTORS

Substantial information exists on the effects of hydrodynamic forces on cells in defined flow geometries such as viscometers and capillaries (5,13–18), but little is known about shear fields in bioreactors (19–21). Whereas selection of more shear-tolerant cell lines can be helpful, successful culture of shear-sensitive biocatalysts requires attention to bioreactor design and operation.

Table 1. Factors Determining Shear Sensitivity

1. Type of cell and species
2. Composition and thickness of cell wall when present
3. Size and morphology of cell
4. The intensity and nature of shear stress, whether turbulent or laminar, or associated with interfaces (e.g., during bubble rise and rupture)
5. Growth history, both short-term (e.g., starvation) and long-term adaptation
6. Growth environment (pH, temperature, agitation intensity, light in photosynthetic cultures)
7. Growth medium (trace elements, vitamins, carbon and nitrogen sources)
8. Growth rate
9. Growth stage
10. Type and concentration of shear-protective agents if present

The magnitude of the fluid mechanical forces is often expressed as shear stress, τ, or shear rate, γ. These quantities are related; thus, in laminar newtonian flow,

$$\tau = \gamma \mu_L \tag{1}$$

where μ_L is the viscosity of the fluid. Shear rate is a measure of spatial variation in local velocities in a fluid. Cell damage in a moving fluid is sometimes associated with the magnitude of the prevailing shear rate or the associated shear stress, but these quantities are neither easily defined nor easily measured in the relatively turbulent environment of most bioreactors. Moreover, shear rate varies with location within a vessel. Attempts have been made to characterize an average shear rate or a maximum shear rate in various types of bioreactors and process flow devices, as discussed later for the more common cases.

Bubble Columns and Airlift Bioreactors

Expressions for mean shear rate in bubble columns have been summarized by Chisti (21), Chisti and Moo-Young (19), and Shi et al. (22). These expression generally correlate the average shear rate with the superficial gas velocity; thus

$$\gamma = k U_G^a \tag{2}$$

where the parameter a equals 1.0 in most cases, but the k value has been reported variously as 1,000, 2,800, 5,000 m^{-1}, and so forth (20). The enormous disagreement among various authorities is obvious in Figure 1, where the shear rate calculated according to several available equations is shown as a function of the superficial aeration velocity in air–water system in a bubble column.

Equation 2 has also been applied to airlift bioreactors, using the superficial gas velocity in the riser zone as a correlating parameter; however, that usage is incorrect (19). A more suitable form of equation 2 for airlift reactors is

$$\gamma = \frac{k U_{Gr}}{1 + \dfrac{A_d}{A_r}} \tag{3}$$

where U_{Gr} is the superficial gas velocity in the riser, A_r is the cross-sectional area of the riser, and A_d is the cross-sectional area of the downcomer. In addition to the already-noted discrepancies (Figure 1), equations 2 and 3 have other significant flaws. The shear rate should depend also on the momentum transfer capability of a fluid, that is, on the density and the viscosity of the fluid, but equations 2 and 3 show no such dependence. Indeed, it is well known that the bubble size in a turbulent field depends on the viscosity and the density of the fluid as well as on the specific energy input rate. It is therefore reasonable to assume that correlations that express the shear rate as a function of U_G (or U_{Gr}) alone are incomplete (19). Furthermore, correlations such as equation 2 have generally been based on observations of phenomena at solid–liquid interfaces (e.g., heat transfer from coils or jackets), and their extension to phenomena at the gas–liquid interface or the bulk fluid is absurd at best. Shear stress and, hence, shear rate at walls of riser and downcomer zones of an airlift device are readily calculated using methods developed for pipes and channels, as discussed in a later section.

Another equation for estimation of an "effective" shear rate in airlift reactors is

$$\gamma = 3.26 - 3.51 \times 10^2 U_{Gr} + 1.48 \times 10^4 U_{Gr}^2 \tag{4}$$

which was developed for $0.004 < U_{Gr}\ (m\ s^{-1}) < 0.06$ (22); the shear rate range covered was 2–35 s^{-1}. Equation 4 was developed in an external-loop airlift reactor. First, the effect of viscosity on the induced liquid circulation velocity in the downcomer was established using Newtonian glycerol solutions at various gas flow rates. The maximum Reynolds number in the downcomer was about 3,200, or barely in the turbulent regime. In a second step, pseudoplastic media were used in the reactor, and the effective viscosity (μ_{ap}) of these fluids in the circulation loop was determined as being equal to the viscosity of the Newtonian glycerol solutions, when the two systems were at identical aeration rates and liquid circulation rates. The effective viscosity and the known values of K and n were used in the power law equation to calculate the prevailing shear rate:

$$\gamma = \left(\frac{\mu_{ap}}{K}\right)^{1/n-1} \tag{5}$$

The calculated shear rates were correlated with the superficial gas velocity in the riser, as noted in equation 4 (22). Although written in terms of the superficial gas velocity in the riser, equation 4 may usefully be expressed in terms of the specific power input in the reactor, as recommended elsewhere (19).

Because the procedure employed by Shi et al. (22) equated the viscosity-associated reduction in the liquid cir-

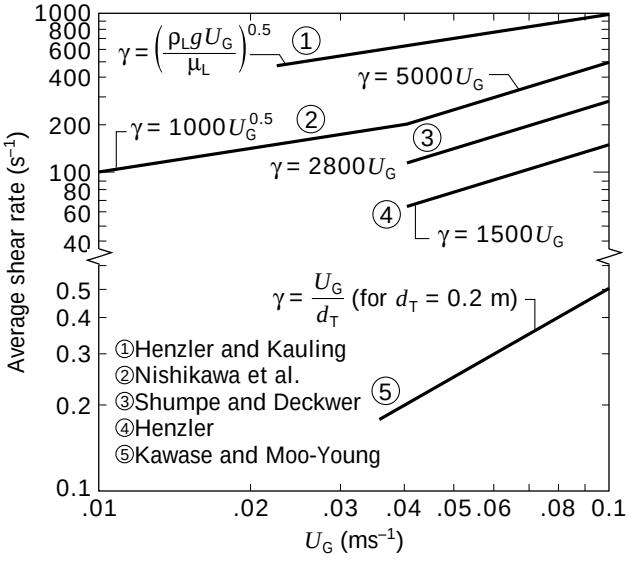

Figure 1. Average shear rate in air–water system in a bubble column according to various sources. *Source*: Based on Ref. 21.

culation velocity in different fluids, it gave in some sense a shear rate in the vicinity of the interface between the fluid and the walls of the reactor; shear rate in the bulk flow, which is the quantity of interest in most cases, was not quantified. Furthermore, the method of analysis used (22) applies strictly to a laminar flow regime, quite unlike the flow situations encountered in most practical operations.

Compared with bubble columns, equation 4 yields quite low values for shear rates in airlift reactors, as noted by Shi et al. (22). In such comparisons, care needs to be taken to ensure that the devices are being compared at identical values of specific power inputs (19,21). Although Shi et al. (22) did not adhere to this criterion, the specific geometry of the reactor they used was such that the error was small. Unlike what Shi et al. (22) concluded, equation 4 is not suitable for correlating mass transfer from gas bubbles or suspended solids because it does not give shear rates at gas–liquid or particle–liquid interfaces. Similarly, the usefulness of the shear rate calculated using equation 4, for correlating survival of fragile biocatalysts, remains questionable. An alternative, mechanistic approach to quantifying the bulk shear rate in various zones of airlift bioreactors has been advanced by Molina Grima et al. (14). Because the hydrodynamic environment in various zones of airlift reactors tends to be quite different, characterization of shear rate by a single global value is not sensible. The overall shear rates can be deceptively low even though damaging levels may be experienced in the high-shear zones (14); hence, the approach of Molina Grima et al. (14) is preferred.

Yet other attempts at characterizing the hydrodynamic forces relied on measurement of noises associated with events such as bubble formation at the sparger, bubble disengagement at the surface, and liquid flow over the baffle into the downcomer (23). Spectra of acoustic signals were measured in water, a salt solution, and aqueous glycerol media in a bubble column and split-cylinder airlift reactor (23). Because several events occur simultaneously in bubbling reactors, there were substantial ambiguities in assignment of the noise signals to specific events. The practical significance of the results was unclear even though the intended aim was to somehow relate the data to damage of fragile cells that has been reported by others in such reactors. Yet other work (24) examined the structure of turbulence in water and power law solutions ($K = 0.0194$ Pa $s^{0.973}$ and 0.0596 Pa $s^{0.958}$) in an external-loop airlift reactor. The reactor achieved complete gas–liquid separation and there was no gas in the downcomer. Measurements of local root mean square velocity fluctuations as an indicator of turbulence intensity showed a slight decrease from the center of the riser to the wall. These measurements were at a constant gas velocity of 2.05×10^{-2} m s^{-1}. The magnitudes of the velocity fluctuations were similar for all media; however, the velocity fluctuations were much lower in the gas-free downcomer than in the riser despite similar values of Reynolds numbers in the two zones. Based on measurements of one-dimensional energy spectra in the center of the riser (24), turbulence could not be considered isotropic, particularly in power law fluids. Other substantial evidence for the absence of isotropic turbulence in airlift and bubble column reactors has been documented (25,26).

Stirred-Tank Fermenters

The local velocity at a fixed position in any vessel fluctuates around a mean value; hence, the shear rate fluctuates. The extent of fluctuations is position dependent. In stirred tanks with radial-flow impellers such as Rushton turbines, the velocity fluctuations are greatest near the impeller tip and decline rapidly as one moves radially outward from the tip. Elsewhere in the vessel, the velocity fluctuations are reduced yet further. The time-averaged mean shear rate generated by a six-bladed Rushton turbine agitating a Newtonian fluid in a baffled vessels of diameter d_T is given as (27)

$$\gamma_{av} = 4.2N\left(\frac{d_i}{d_T}\right)^{0.3}\frac{d_i}{W} \tag{6}$$

where W is the width of the impeller blade, d_i is the impeller diameter, and N is it's rotational speed. The time averaged maximum shear rate value is 2.3-times γ_{av} (27). Another expression for the maximum shear rate at Rushton turbine blades is (28)

$$\gamma_{max} = 3.3N^{1.5}d_i\left(\frac{\rho_L}{\mu_L}\right)^{1/2} \tag{7}$$

which applies to Newtonian and non-Newtonian liquids when $100 \leq (Nd_i^2\,\rho_L/\mu_L) \leq 29{,}000$. The uncertainty in the coefficient (equation 7) is said to be $\pm 20\%$. For non-Newtonian fluids, μ_L in equation 7 is the zero shear viscosity. A different equation has been proposed by Wichterle et al. (28):

$$\gamma_{max} = N(1 + 5.3n)^{1/n}\left(\frac{N^{2-n}d_i^2\rho_L}{K}\right)^{1/1+n} \tag{8}$$

Equation 8 provides the maximum shear rate on a Rushton turbine blade. An average shear rate expression applicable to a broader range of impellers and media is (29):

$$\gamma_{av} = k_i\left(\frac{4n}{3n+1}\right)^{n/n-1}N \tag{9}$$

where n, the flow index of a fluid, equals 1.0 for a Newtonian liquid. In equation 9, k_i is an impeller-dependent constant. Some typical k_i values are noted in Table 2. The various shear rate correlations discussed here are compared in Figure 2 for water in a standard stirred tank (30) agitated

Table 2. The k_i Values for Use in Equation 9

Impeller	k_i
Six-bladed disc turbines	11–13
Paddle impellers	10–13
Propellers	~10
Helical ribbon impellers	~30

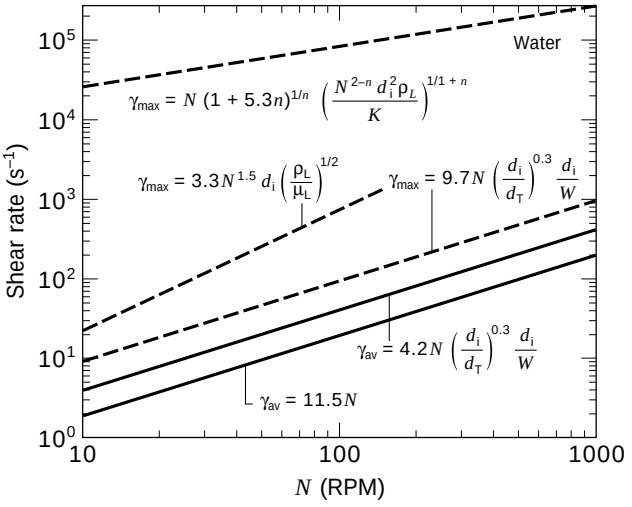

Figure 2. Comparison of the various shear rate correlations for water in a standard stirred-tank agitated with a 0.1-m-diameter six-bladed Rushton turbine. The dashed lines are for the maximum shear rate; the solid ones are for the average shear rate. See text for additional details.

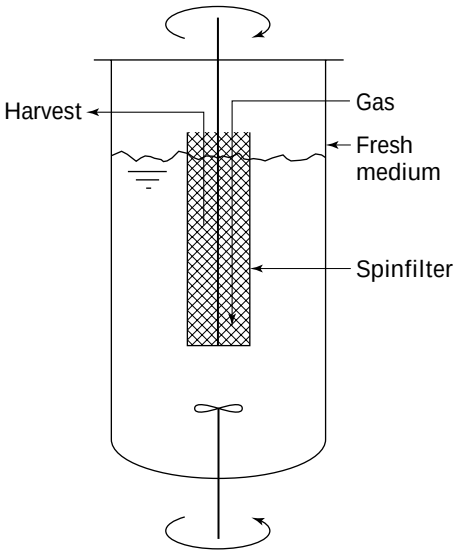

Figure 3. Perfusion culture with spinfilter for hydrodynamics-based cell retention in bioreactors.

with a 0.1-m diameter six-bladed Rushton turbine. For some contexts, the shear rate around a rising bubble may be approximated as the ratio of the terminal rise velocity to the bubble diameter (or radius); hence,

$$\gamma_{av} = \frac{2U_B}{d_B} \tag{10}$$

In air–water, under conditions typical of bubble columns and airlift reactors, the bubble rise velocity is about 0.2 m s^{-1}, and the bubble diameter is about 0.006 m. Thus, the interfacial shear rate approximates to 67 s^{-1} if the interface is nonmobile. Lower shear rates are expected at circulating interfaces.

Spinfilter

Spinfilters—rotating cylinders made of wire screen with openings that are significantly bigger (e.g., 25 μm) than the cells—are used to retain suspended animal cells in perfusion culture continuous bioreactors. Most of the cells are kept on the upstream side of the wire mesh by a hydrodynamic mechanism that depends on rapid rotation (e.g., 500 rpm) of the cylindrical screen (Fig. 3). The spent, largely cell-free medium is withdrawn from the zone within the rotating screen. Shear stresses associated with rotation of spinfilters do not generally damage animal cells (31). Sometimes the cell-free zone within the confines of the screen is also used for submerged aeration.

Other Flow Devices

Bioreactors and process vessels are where much of the shear-sensitive material is processed; however, at least part of the processing usually requires transfer of material between vessels. Transfer is accomplished through pipework, and centrifugal pumps are sometimes used. Methods of estimating shear stress levels in these devices are briefly summarized next.

Pipes, Tubings, and Flow Channels. ***Newtonian Fluids.*** In developed laminar flow of a Newtonian fluid through a straight tube of diameter d, the wall shear rate is given as

$$\gamma_w = \frac{8U_L}{d} \tag{11}$$

where U_L is the mean flow velocity. For rectangular channels of height h, the maximum or wall shear rate in developed laminar flow is

$$\gamma_w = \frac{6U_L}{h} \tag{12}$$

where U_L is again the mean flow velocity.

The wall shear stress (i.e., the maximum value) in a flow channel such as the riser of an airlift reactor is related to the pressure drop (ΔP), the length L of channel, and the hydraulic diameter (20); thus,

$$\tau_w = \frac{d}{4L}\,\Delta P \tag{13}$$

Consequently, in turbulent flow, the wall shear stress is

$$\tau_w = \frac{1}{2}\,C_f\rho_L U_L^2 \tag{14}$$

where ρ_L is the liquid density and C_f is the Fanning friction factor. The latter is related with the Reynolds number as follows:

$$C_f = 0.0792\left(\frac{\rho_L U_L d}{\mu_L}\right)^{-0.25} \quad (15)$$

where d is the hydraulic diameter of the flow channel or pipe. From equations 14 and 15, the wall shear stress can be shown to depend on Newtonian viscosity of the fluid: $\tau_w \propto \mu_L^{-0.75}$ (14). Use of equations 11 and 12 and others given later that are similar presupposes that the liquid velocity is known. This is normally the case in pipes and channels; however, with airlift vessels the induced liquid circulation rate will often need to be estimated using available methods (20,21,32).

Non-Newtonian Power Law Fluids. Methods for calculation of wall shear stress in laminar and turbulent flow of power law fluids with and without dispersed gas, have been discussed by Chisti (21) and Chisti and Moo-Young (33). For a non-Newtonian pseudoplastic medium flowing through a tube such as the riser or the downcomer of an airlift bioreactor, the flow is laminar when (34)

$$Re \leq 2300\,\frac{3n+1}{4n} \quad (16)$$

where the Reynolds number is calculated using the equation

$$Re = \frac{8U_L^{2-n}d^n\rho_L}{K\left(\frac{6n+2}{n}\right)^n} \quad (17)$$

In the laminar regime, the wall shear stress for flow of a gas-free liquid has been expressed as (35)

$$\tau_w = \frac{8\rho_L U_L^2}{Re} \quad (18)$$

When the flow is turbulent (i.e., the Reynolds number exceeds the value calculated with equation 16), the wall shear stress in a gas-free liquid is (34,35)

$$\tau_w = \frac{0.316n^{0.121}\rho_L U_L^2}{8Re^{2/n(x-1)+2}} \quad (19)$$

In presence of a gas, the shear stress is a complex function of τ_w, the gas holdup, the properties of the liquid (ρ_L, K, n), and the superficial velocities of the gas and the liquid phases, as discussed elsewhere (21,33). In equations 16–19, d is the channel diameter, U_L is the superficial liquid velocity, K is the consistency index, and n is the flow behavior index. The parameter x in equation 19 is given as

$$x = 0.70n^{-0.591} \quad (20)$$

as reported by Chisti and Moo-Young (33) based on data of Sokolov and Metkin (34).

Submerged Jets. Submerged jets are encountered wherever a pipe or nozzle discharges a fluid beneath the surface of the same fluid in a larger reservoir. For example, culture broth recirculating from a tank to an ultrafiltration module and back to the tank could form a submerged jet. If the cross-sectional area of the discharge nozzle is less than about 25% of that of the reservoir, the wall effects can be neglected and the jet is said to be "free." In a stable submerged turbulent jet, the maximum shear stress occurs in the direction of discharge, six to seven nozzle diameters downstream from the orifice. This shear stress is given as

$$\tau_{max} = 0.018\rho_L u_o^2 \quad (21)$$

where u_o is the velocity at the orifice.

Centrifugal Pumps. Centrifugal pumps are commonly employed in bioprocessing; hence, a knowledge of the shear rate in these devices is essential to assessing their suitability for a given use. The shear rate in a Newtonian fluid adjacent to the rotating impeller of a centrifugal pump depends on the radial position. The local shear rate at any position has been expressed as

$$\gamma = 6.30NRe_L^{0.5} \quad (22)$$

where the local Reynolds number at the local diameter d_L is

$$Re_L = \frac{Nd_L^2\rho_L}{\mu_L} \quad (23)$$

Equation 22 is based on theoretical considerations, but it has closely correlated measured shear rate data over the range $10^2 \leq Re_L \leq 2 \times 10^6$ in a centrifugal pump with the impeller rotating in a standard volute casing (36). Over the approximate impeller rotational speed range of 0.01–100 s^{-1}, the shear rate values ranged over 1–10^5 s^{-1} in aqueous electrolyte solutions (36).

As a general guideline, centrifugal pumps may be used to transfer most low-viscosity microbial broths and enzyme solutions so long as gas–liquid interfaces are rigorously excluded. Centrifugal pumps should not be used for animal cells, biofilm supporting particles, soft immobilized enzyme supports, suspensions of nematodes and protozoa, protein precipitates, and plant cells. These pumps will be satisfactory for some microalgae but not for others.

Shear Rate in Isotropic Turbulence

Irrespective of the bioreactor configuration, a turbulence field is deemed isotropic when the size of the primary eddies generated by the turbulence-producing mechanism is a thousandfold or more compared with the size of the energy-dissipating microeddies. The length scale of the primary eddies is often approximated as the width of the impeller blade or the diameter of the impeller in a stirred tank. In bubble columns and airlift bioreactors, the length scale of primary eddies is approximated as the diameter of the column (or the riser tube), or the diameter of the bubble issuing from the gas sparger.

Shear stress, shear rate, the dimensions of microeddies, and other characteristics of flow are linked ultimately to the energy input and dissipation rates in the fluid. The local shear rate in the vicinity of an eddy in an isotropically

turbulent field may be estimated as the ratio of the velocity and the length of the eddy; hence,

$$\gamma_i = \frac{u}{l} = \frac{\mu_L}{\rho_L l^2} \tag{24}$$

where ρ_L and μ_L are, respectively, the density and the viscosity of the fluid. The mean length, l, and the velocity, u, of the microeddies are related with the energy dissipation in the turbulence field; thus,

$$l = \left(\frac{\mu_L}{\rho_L}\right)^{3/4} E^{-1/4} \tag{25}$$

and

$$u = \left(\frac{\mu_L E}{\rho_L}\right)^{1/4} \tag{26}$$

where E is the rate of energy dissipation per unit mass of fluid. In most cases, all the energy input to the fluid is dissipated in fluid eddies, and E equals the rate of energy input. Equations 24–26 apply when local isotropic turbulence prevails.

Energy dissipation rate in bubble columns and airlift vessels is a function of the superficial aeration velocity (20,21); thus

$$E = gU_G \text{ (bubble columns)} \tag{27}$$

and

$$E = g\frac{U_{Gr}}{1 + \frac{A_d}{A_r}} \text{ (airlift bioreactors)} \tag{28}$$

Methods for calculating the specific energy dissipation rate in stirred vessels have been discussed elsewhere (30,37). The energy dissipation varies greatly from the mean value in a stirred tank. The maximum energy dissipation occurs in the vicinity of the impellers. This maximum value can be calculated using the equation

$$E = \frac{\mathrm{Po}N^3 d_i^2}{\rho_L} \tag{29}$$

where Po is the power number, d_i is the diameter of the impeller, and N is the rotation speed (s^{-1}). In developed turbulent flow in stirred vessels, the power number is generally constant for a given type of impeller and tank geometry. For single-phase pipe flow, the specific energy dissipation rate is

$$E = \frac{U_L \Delta P}{\rho_L} \tag{30}$$

where ΔP is the pressure drop per unit length, and U_L is the mean flow velocity.

Generally, if the dimensions of the biocatalyst particle are much smaller than the calculated length, l, of the microeddies, the particle is simply carried around by the fluid eddy; the particle does not experience any disruptive force. On the other hand, a particle that is larger than the length scale of the eddy will experience pressure differentials on its surface, and if the particle is not strong enough it could be broken by the resulting forces.

In addition to turbulence within the fluid, other damage-causing phenomena in a bioreactor include interparticle collisions; collisions with walls, other stationary surfaces, and the impeller; shear forces associated with bubble rupture at the surface of the fluid; phenomena linked with bubble coalescence and breakup; and bubble formation at the gas sparger. Some of these aspects are discussed elsewhere in this article. Summarizing, several possible shear rate values may be calculated for a given situation in a bioprocess device. Not every calculated value is appropriate or relevant to the problem at hand. For pneumatically agitated bioreactors, when the turbulence characteristics in the bulk fluid are the relevant ones, the preferred approach is to use equation 24 for shear rate in the vicinity of eddies. The same applies to mechanically stirred tanks. In some cases, the relevant shear rate may be that at the interface of a rising bubble unless turbulence is so intense that bubbles do not rise freely. Other situations would be controlled by the bubble rupture events, as discussed later. In yet other cases, the fluid eddy shear rate and the maximum shear rate at the impeller will need to be taken into account. Factors such as the frequency of passage of a sensitive biocatalyst through high-shear regions may need consideration.

RESPONSE TO SHEAR

Response to shear has been characterized using various indices, including growth rate (38–40); cell viability (41); regrowth potential (42); release of intracellular material (38,43,44); changes in oxygen uptake rate, ATP, productivity of metabolites, and biochemical composition of the cells; and alterations in morphology of cells and cell aggregates (2,42,44).

Most studies of shear response of cells have utilized batch culture with or without aeration. Such cultures contain cells at different stages of growth; hence, the size and metabolic state of cells are nonuniform. In contract, continuous culture is time-consuming (38), differs substantially from the culture methodologies that are typically employed commercially, and, through natural selection, the cells in continuous culture adapt to shear fields, hence, masking the effect of shear. For example, Wu et al. (45) noted for insect cells that the beneficial effect of shear-protective agents (serum, methyl cellulose, Pluronic F68) were not as important as the effect of passage number. Similar results have been alluded to for plant cells (38). To overcome problems associated with cell growth and adaptation to shear, Zhang et al. (43) recommended the use of erythrocytes for comparative evaluation of the hydrodynamic environment in bioreactors. A nongrowing, well-defined, and shear-susceptible cell population such as that provided by erythrocytes can help identify suitable regimes of operation of a given reactor. In addition, shear-

damaging potential of different bioreactor configurations can be assessed on a common basis using cells such as erythrocytes. Specific information on shear susceptibility of animal, plant, and various microbial cells is discussed in the following sections.

Bacteria, Yeasts, and Mycelial Microfungi

Yeasts, bacteria, and mycelial microfungi are generally quite robust and not easily damaged under typical processing conditions; however, even the most robust cells are broken when subjected to suitable combinations of high stress and exposure time (1). Often, genetically modified strains of an otherwise robust microorganism are less shear tolerant (1,10,46–48). With microorganisms, the composition of the growth medium and the specific growth rate used for the culture are known to influence the robustness of the cell (1). Cells grown in fully defined media that may lack one or more components essential to synthesis of a normal cell wall are often less robust (1). Growth at a higher specific rate will often produce weaker cells (1). When the shear field is insufficiently intense to damage cells, it may still affect product formation and characteristics (9,10). In one case, properties of a shear-sensitive polymer were affected, but not the producing bacterial cells (10). Cells experiencing physiological stress (e.g., starvation) are more susceptible to shear-stress-related damage (44).

Reports cited by Märkl et al. (44) document increasing release of intracellular material from mycelium of *Rhizopus javanicus* and *Mucor javanicus* as the stirrer speed increased. Increasing release of nucleotides was noted with increasing speed of agitation, or with increasing agitation time at a constant agitation speed. Effect of Rushton turbine tip speed on performance of a process for converting cellulose to protein-enriched microbial biomass were clearly demonstrated by Moo-Young et al. (39). The process utilized the filamentous microfungus *Neurospora sitophila* for the conversion. Increasing impeller tip speed from 2.35 m s^{-1} to 3.29 m s^{-1} reduced the specific protein production rate and the final yield (Fig. 4). In addition, a distinct lag phase was observed at the higher agitation rate (Fig. 4) when the inoculum grown in a more quiescent environment was transferred to the fermenter. At the highest tip speed shown in Figure 4, the specific protein production rate was only 55% of that at the lowest tip speed. Similarly, the yield of crude microbial protein was reduced to ~67% of the value obtained at the lowest agitation speed used (39). Further work revealed that agitation-associated damage could be reduced substantially by replacing the Rushton turbines with axial flow hydrofoil impellers (40); thus confirming that different types of impellers generate very different shear fields at identical tip speeds. For equal or lower power draw, hydrofoil impellers are typically better bulk mixers than Rushton turbines (30,37).

In *Penicillium chrysogenum* fermentations performed in turbine-impeller-agitated vessels with working volumes of 0.005–1 m^3, operated at impeller tip speeds of 2.5–6.3 m s^{-1}, the specific penicillin production rate and the mean length of the main hyphae were lower at high agitation intensities (2). High agitation speeds affected the fungal

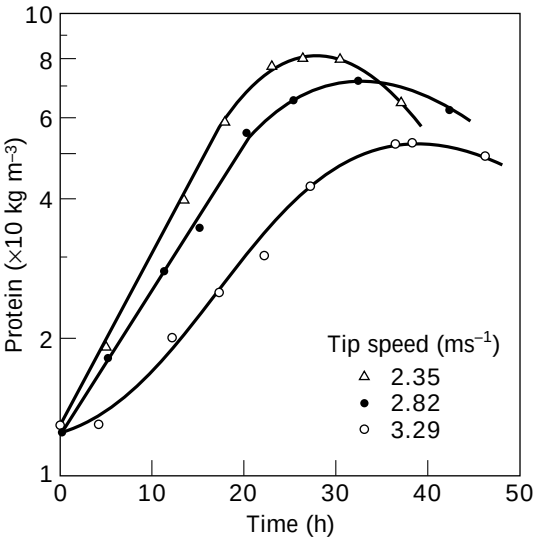

Figure 4. Effect of Rushton turbine tip speed on protein production by the mold *N. sitophila*. *Source*: From Refs. 39 and 40.

morphology, promoting mycelial fragmentation and a greater frequency of branching (2). The behavior of the fermentation at various scales correlated poorly with the impeller tip speed, but correlation was superior in terms of a parameter that took into account the frequency of passage of the culture through the intensely agitated zones around the impellers (2). This behavior suggests that the degree of hyphal damage in stirred bioreactors depends on a combination of the shear intensity in the impeller zone and the cumulative time of exposure of the microbial solids to the shear field.

Sometimes, especially with certain mycelial microfungi, the biomass yield may not be affected by agitation rate, but the cell morphology and production of metabolites may be influenced greatly. Using different strains of citric acid–producing *Aspergillus niger*, Ujcova et al. (3) showed that the yield of citric acid first increased with increasing agitation rate, presumably because of improved oxygen supply, but the yield declined because of cell damage if the agitation speed was increased further. The yield maxima occurred at different agitation rates for different strains, and the sensitivity to agitation differed among strains. Other morphological effects of nondamaging shear levels include changes in growth form, whether pelletlike or pulplike; changes in the degree of branching; the extent of entanglement; and whether growth occurs in filamentous or spherical cell form in certain dimorphic species.

Evidence suggests that even a supposedly robust cell such as *Saccharomyces cerevisiae* (1,11) is susceptible to mechanical shear damage in fermenters (49,50). In one study, *S. cerevisiae* suspended in isotonic saline lost viability at increasing rate over a 25-h period as the agitation speed of the paddle impeller was increased (50). At 1.43 m s^{-1} impeller tip speed, >90% of the cells were dead over the course of 25 h. In contrast, at 0.66 m s^{-1} tip speed, only about 15% of the cells died over the same period (50). Excessive shear has been alleged to also influence the pro-

ductivity of ethanol in fermentations employing *S. cerevisiae* (49).

Among methane bacteria, *Methanobacterium thermoautotrophicum* with rodlike cells that exceeded 2 μm in length was highly resistant to shear stress (44). In contrast, and surprisingly, the relatively smaller (<2 μm) spheroidal cells of *Methanococcus vanielii* were quite sensitive to shear stresses (44). Supplementing the medium with carboxymethyl cellulose viscosity enhancer increased the extent of the cell damage (44). Failure to provide an essential nutrient, selenium is this case, also enhanced shear susceptibility of the culture (44). Although many authors have successfully correlated cell damage with the tip speed of the impeller, Märkl et al. (44) believe that power input per unit culture volume is a superior correlating parameter that is also suitable for comparing the cell damage effects of mechanically stirred and other nonmechanically agitated bioreactors. A constant power input per unit culture volume has also been suggested as a bioreactor scale-up criterion for fragile biocatalysts (44). This recommendation notwithstanding, average power input alone cannot be a universally satisfactory determinant of cell damage; as noted in an earlier section, the maximum shear rate and the frequency of passage (or cumulative exposure) through the high-shear zone need to be taken into account, especially when the shear rate in a given device is strongly position dependent. Several studies confirm that frequency of passes through a high-shear environment have a clear impact on biocatalyst survival (1,2,11,12,16,20,51). Effects of variously intense shear fields on microbial cells are further discussed by Thomas (5,52), Prokop and Bajpai (53), and Chisti and Moo-Young (1). Shear effects on microbial flocs and pellets are treated in a separate section of this article.

Microalgae and Cyanobacteria

Cell fragility has been referred to as the key problem of culture of microalgae in photobioreactors (54); however, the real situation is not quite that bad. Among microalgae, the sensitivity to shear varies greatly with the species. Algae such as *Dunaliella* are indeed extremely fragile, but many other species will tolerate high levels of turbulence and sparging with gas. Thus, gas-sparged airlift devices are commonly used to circulate algal cultures through the solar receivers of photobioreactors (20,55–57). Similarly, relatively low-shear positive displacement rotary pumps have been successfully employed. High-shear centrifugal pumps have also been used; however, at least in some cases, the centrifugal pumps are known to be more damaging than the other fluid-moving systems. In one case, for otherwise equivalent conditions, replacement of the centrifugal pump with a positive displacement device doubled the productivity of *Porphyridium cruentum* (54), a producer of phycoerythrin and polyunsaturated fatty acids. Irrespective of the method used to circulate the culture, the culture flow velocities through tubular solar receivers typically range over 0.3 to 0.5 m s^{-1} in tubes up to 0.06 m in diameter. These conditions have been used with a variety of algae.

In cultures of *Haematococcus pluvialis*, a producer of astaxanthin, early onset of the stationary phase has been associated with turbulence-induced deflagelation of the cells (54). Fragility of species such as *H. pluvialis* depends also on the phase of growth; thus, tailoring the bioreactor operational regime to the growth phase can improve overall productivity (54). The stationary phase red cysts of *H. pluvialis* are significantly more robust than the green vegetative cells (54). The cyanobacterium *Spirulina*—a healthfood and source of the food colorant phycocyanin—is another species that is susceptible to damage by excessive shear forces. The marine alga *Dunaliella* is particularly fragile: the cell lacks a ridged wall; only a thin cytoplasmic membrane encloses it. *Dunaliella* is a good source of natural β-carotene; hence, it is commercially useful. The cell also produces glycerol. Silva et al. (58) showed that *Dunaliella* was susceptible to damage by gas bubbles as well as by turbulence in the liquid. Supplementing the culture with carboxymethyl cellulose or agar improved cell survival.

In one study with *Dunaliella tertiolecta*, culture in a bubble column was quite successful, but when the bubble column was converted to an airlift device by inserting a vertical baffle, the productivity declined (59). Under conditions that were earlier identified as optimal, no growth was observed in the airlift reactor, whereas good growth occurred in the bubble column. Microscopic examination showed significant disruption of the cells in the airlift device (59). This was associated with the hydrodynamic stresses generated as the culture flowed over the upper edge of the baffle into the downcomer (59). This effect could have been avoided, or at least minimized, by hydrodynamic smoothing of the upper and lower parts of the baffle to prevent flow separation (20). In the bubble column, the growth was sensitive to aeration rate: growth rate increased with increasing superficial gas velocity until a velocity of about 0.6 m min^{-1}. Further increase in aeration rate reduced growth, apparently because of hydrodynamic stresses in the fluid (59). Under nongrowth conditions (no light), the specific death rate in the bubble column was shown to increase with superficial gas velocity for velocities exceeding 0.6 m min^{-1} (59). At a fixed aeration velocity ($U_G = 1$ m min^{-1}), the specific death rate decreased with increasing height of the culture fluid in the column (59), probably because the specific power input and, hence, the turbulence intensity declined (20). Similar behavior has been reported with animal cells in bubble columns (60–64).

For otherwise fixed conditions, increasing the number of aeration nozzles (i.e., decreasing the gas jet velocity) caused a marginal reduction in the specific death rate of *D. tertiolecta* (59). This led to the conclusion that the events at the gas sparger did contribute to cell death (59), although the effect was minimal. Unlike Suzuki et al. (59), others (56,57) have quite successfully cultured various microalgae in pilot-scale airlift devices. Continuous culture of the green alga *Chlorella pyrenoidosa* in a rectangular airlift device with multiple light-emitting diodes was reported by Matthijs et al. (65). With a relatively robust photosynthetic organism such as *Chlorella*, increasing turbulence within limits improves productivity in photobioreactors because of enhanced fluid interchange between the dimly lit interior and the better-illuminated exterior parts of a photobioreactor.

In addition to an organism's morphology, the biochemical composition of the cell wall has been associated at least qualitatively with the cell's susceptibility to hydrodynamic stresses. The microalga *Chlorella vulgaris*, which is shear tolerant, has a thick (100–200 nm) cell wall composed of cellulose, pectin, and sporopollenin (44). The somewhat more sensitive alga *Chlorella reinhardii* has only glycoproteins in its relatively thin (40 nm) cell wall (44), whereas a highly sensitive cell wall defective mutant of *C. reinhardii* is devoid of cell wall (44). Similarly, the cyanobacterium *Synechococcus*, with a murein-containing cell wall, and the methane bacterium *M. thermoautotrophicum*, with a pseudomurine-containing wall, are noticeably more resistant than methane bacteria such as *Methanococcus vanielli*, which has a protein-based wall.

Although earlier work with the mold *M. javanicus* showed a reduced extent of damage to mycelia as the viscosity was increased at constant agitation rate, and similar reports exist with animal cells (66,67) and the halotolerant alga *Dunaliella* (58), Märkl et al. (44) observed an opposite effect: with a highly shear-sensitive strain of *C. reinhardii*, even slight increase in viscosity enhanced cell damage (44). The viscosity was increased by adding carboxymethyl cellulose to the culture broth. With a relatively less shear sensitive strain of *C. reinhardii*, increasing the viscosity reduced the impeller agitation speed at which the damaging effects were first discerned (44). Apparently, at least with the less sensitive strain, supplementing the medium with the viscosity enhancer caused the cells to grow in clumps, and aggregation supposedly was an effective shield against cell damage (44). Increasing shear damage with increasing culture viscosity has been seen before with a protozoan (68). These apparently contradictory results are easily explained: whether changes in viscosity increase or reduce shear damage depends on the peculiarities of the mechanism causing the damage. For a given impeller tip speed, increasing viscosity will not affect the tip speed–associated shear rate, but the turbulence will be reduced; hence, the shear rate in the fluid should be lower. However, the shear stress around a particle may increase if the fluid eddy length scale remains comparable to the dimensions of the particle. In other cases, increased viscosity may reduce both shear rate and shear stress: only eddies that are larger than the particle may survive and there may be little or no relative motion between the fluid and the particle. In yet other cases, the frequency of passage through high-shear zones may decline with increasing viscosity.

Plant Cells

Cultured plant cells are a potential source of numerous high-value compounds, although few production processes have been commercialized (13,69). Low culture productivities continue to be the primary limitation. Investigational culture in large bioreactors has been carried out since at least 1959. A variety of reactors have been used, including bubble columns, airlift devices, stirred vessels, rotary-drum reactors, and immobilized cell systems (13). Airlift bioreactors have proven especially effective for large-scale culture of heterotrophic, photomixotrophic, and photosynthetic plant cell suspensions (20,70). Relatively low values of pneumatic power inputs have given satisfactory results during cultivation of plant cells. For example, Fischer and Alfermann (70) obtained good results with about 13 W m^{-3} specific power input during culture of *Chenopodium rubrum* cells in a concentric draft-tube airlift device. Similarly, Ballica and Ryu (71) obtained maximum biomass and product yield at an approximate power input value of 35 W m^{-3}, also in a draft-tube airlift reactor, while culturing *Datura stramonium* cells. In the latter case, power inputs above ~60 W m^{-3} caused large declines in biomass and product yields. The size of the cell aggregates declined with increasing specific power input (71). Reinhard et al. (72) described culture of *Digitalis lanata* in a 300-L airlift bioreactor for producing β-methyldigoxin.

Plant cells in suspension tend to be large: 20–50 μm in diameter and 100–500 μm in length. The cells have a cellulose-based wall. Most of the cell's volume is taken up by a vacuole that may occupy >95% of the available space. The fluid in the vacuole is much less viscous than the cytoplasm; hence, a cell with a large vacuole is likely to be less resistant to certain types of deformations than one with a smaller vacuole. Cells frequently occur as aggregates of up to a hundred cells. The aggregates settle easily. Plant cells grow slowly, with doubling times of the order of 20–100 h. Cells may secrete extracellular polysaccharides, producing non-Newtonian broths. Also, the biomass concentration may be high, up to 70 kg m^{-3}. Heterotrophically growing plant cells require oxygen, but demands are low, of the order of 10^{-6} kg O_2 kg^{-1} cell s^{-1}. Critical dissolved oxygen concentration generally tends to be ≤20% of air saturation. The polysaccharide-containing cultures tend to foam a lot when aerated. Also, excessive aeration may reduce productivity by stripping carbon dioxide and other essential volatiles produced by the cells themselves (5,69).

As has been demonstrated with some microorganisms (1), the composition of the culture medium, the culture conditions, and the specific growth rate of a cell may affect the wall strength of plant cells also. For otherwise identical conditions, agitation intensity is reported to influence the composition of plant cell walls. Thus, the relative amounts of pectin, cellulose, and hemicellulose in walls of *Catharanthus roseus* were affected by the intensity of agitation in one case (73). In another case cited by Doran (13), the mass ratio of cell wall relative to the whole cell increased with increasing intensity of shear, suggesting adaptation of the cell to the prevailing environment even over short periods. Even though the turbulence level may be insufficient to affect individual cells, aggregates may be affected; hence, a shear-related metabolic response may occur due to altered cell–cell interactions (69).

Based on laminar flow viscometric measurements, a critical shear stress level of 80–200 N m^{-2} has been suggested for *Morinda citrifolia* cells. Whereas for *Daucus carota*, a shear stress level of 50 N m^{-2} has been associated with cell damage. In another study, carrot cells in a laminar flow Couette viscometer lost the ability to grow and divide in the shear stress range of 0.5–100 N m^{-2} (53). The intracellular enzyme activity was impaired at shear stress levels above 3,000 N m^{-2}, but significant lysis did not occur until a shear stress level of 10,000 N m^{-2} was applied over a prolonged period (≥1 h) (53). In contrast to behavior in

laminar flow, the cells were quite sensitive to turbulent impeller agitation. Impeller tip speeds of ~1.1 m s^{-1} lysed a significant proportion of the cells within 40 min (53).

In studies with *Perilla frutescens* cell suspensions, Zhong et al. (74) noted that the cell viability declined with increasing shear rate (constant exposure time) or increasing shear time at constant rate of shear in a concentric cylinder shearing device. A constant shear rate of about 140 s^{-1} produced a noticeable loss of viability within 20 min. At higher shear rate of ~860 s^{-1}, less than 75% of the cells were viable after 20 min (74). In marine propeller–agitated fermenters, the impeller tip speed affected the specific growth rate and the yield of the cells (74). Tip speeds >0.6 m s^{-1} reduced the specific growth rate and the cell biomass yield (74). In other cases, impeller tip speeds as low as 0.35 m s^{-1} have extensively lysed certain plant cells.

With *M. citrifolia* cells subjected to 25–350 N m^{-2} turbulent shear stress in a capillary, the viability decline followed first-order kinetics in which the rate constant increased with the applied shear stress (75). The culture was circulated through the capillary by a peristaltic pump, which also contributed to cell damage (75). The specific death rate constant was linearly related with the cumulative energy dissipated (75). Cell aggregates subjected to shear were reduced in size. For the same species, damage was reported when cells grown in a quiescent environment were subjected to turbulent jet flow through 1- and 2-mm nozzles (51). Cells lost viability with increasing number of passes through the nozzles. The viability loss was first order in the number of passes (51). For a fixed number of nozzle passes, increased nozzle flow velocity enhanced the death rate constant. Similarly, the maximum and the mean aggregate size were reduced when the suspension was subjected to jet flows (51). The average aggregate size was lower for higher jet velocities. The average energy dissipation rates in the jet ranged over 10^3–10^5 W kg^{-1} (51).

Meijer et al. (38) assessed the hydrodynamic stress sensitivity of *C. roseus, Nicotiana tabacum, Tabernaemontana divaricata,* and *Cinchona robusta* in a 3-L Rushton turbine-stirred vessel. Effects of stress were quantified in terms of culture growth rate, respiration rate, and release of organic compounds from the cells. Cultures of *C. roseus* carried out at 0.59 m s^{-1} and 2.36 m s^{-1} impeller tip speeds showed identical behavior in terms of biomass growth rate and glucose consumption rate; hence, hydrodynamics-associated stress was concluded to not affect the cells over the ranges examined (38). Similarly, *N. tabacum* was little affected by differences in agitation rate, although the growth rate and the final yield were noticeably greater at the lower agitation speed. Cells of *C. robusta* responded differently: at 0.59 m s^{-1} impeller tip speed the cells grew and there was little release of intracellular protein; however, at 2.36 m s^{-1}, there was no growth and the specific protein concentration increased with culture time, indicating leakage from damaged cells (38). The *T. divaricata* cells also were damaged at 2.36 m s^{-1}, but less than the cells of *C. robusta*. The damage to *T. divaricata* was reduced at a lower impeller tip speed of 0.59 m s^{-1}. In separate experiments, cells of *N. tabacum* that had earlier withstood higher shear stress levels were shown to be more susceptible to damage after a prolonged period (10 days) of starvation (38). This effect is similar to that noted with other cells (44).

Table 3 is a summary of the damage thresholds levels—either impeller tip speed or the specific power input due to aeration—noted for various plant cell suspensions in stirred fermenters and airlift bioreactors. The studies just referenced clearly affirm that the susceptibility to shearing forces varies a great deal with cell line. Moreover, for the same cell line, cultivation history (e.g., prolonged starvation) and age of cell affect the cell's response to shear fields (38,44,69), which is consistent with similar findings for microorganisms (1). That plant cells adapt to shear fields is also well known: cells cultured in high-shear environments better withstand hydrodynamic forces after many generations.

Protozoa

Midler and Finn (68) provided a clear demonstration of shear-related damage to cells of the large (~80-μm cell diameter) ciliated protozoan *Tetrahymena pyriformis*. Lysis correlated with impeller tip speed. Agitation at impeller tip speeds approximately ≥0.5 m s^{-1} destroyed most of the cells. In a Couette viscometer, the critical shear stress level when lysis first occurred was ~24 N m^{-2} (68). Eighty percent of the cells lysed within the first minute when exposed to shear stress levels of 10^3 N m^{-2}. The extent of damage increased with shear stress level and exposure time. At a given shear rate, increasing the broth viscosity made the protozoan more susceptible to shear damage, implying that the damage was associated with shear stress rather than shear rate (68). The cells were more sensitive to turbulent shear stress: an average turbulent shear stress of ~10 N m^{-2} lysed over half the population within 10 min. In contrast, in laminar flow, similar levels of damage occurred at shear stress levels of almost 300 N m^{-2}. Note that *T. pyriformis* cells are larger than most animal cells, but smaller than most cultured plant cells.

Animal Cells

Animal cells are the most shear-susceptible of biocatalysts. Animal cells are relatively large—typically 10–20 μm in diameter—and they lack a protective cell wall. Osmotic

Table 3. Damaging Threshold Values of Impeller Tip Speed or Specific Power Input for Some Plant Cells

Stirred fermenters	Impeller tip speed (m s^{-1})
Catharanthus roseus	≥2.36
Nicotiana tabacum	~2.36
Cinchona robusta	<2.36
Daucus carota	<1.10
Tabernaemontana divaricata	~0.59
Perilla frutescens	0.60
Others	≤0.35
Airlift bioreactors	**Power input (W m^{-3})**
Chenopodium rubrum	≥13
Datura stramonium	~60

shock is often sufficient to lyse animal cells. Other than blood cells, most normal animal cells are anchorage dependent. Cancerous cells, hybridomas, and established lines will normally grow in suspension. Because of these distinct growth characteristics, two types of culture methods are employed in industrial practice: free suspension culture, in which cells are freely suspended in a nutrient broth; and microcarrier culture, in which anchorage-dependent cells grow on surfaces of solid carriers that are suspended in a culture fluid. Irrespective of the culture method, the suspending fluid is invariably directly sparged with air or other gas mixture to supply the cells with oxygen. Although other aeration alternatives are available (see MASS TRANSFER article), direct sparging with a gas is likely to remain the dominant method of providing oxygen to animal cells (76). Both stirred tanks and airlift devices have been successfully employed for commercial processing of animal cells (77–79). Anchorage-dependent cells may also be cultured on surfaces of large static particles held in packed beds (80,81), but this method is uncommon. Devices used in generation of implantable tissue typically grow normal cells supported on stationary surfaces or within a static matrix of gel or woven fabric (82). The supporting surface may be flat or variously shaped.

Cells in bioreactors are subject to two main kinds of fluid mechanical forces: (*1*) those due to turbulence within the liquid, and (*2*) forces associated with the gas–liquid interface. The latter category includes effects of bubble formation, rise, and rupture. In addition in microcarrier culture, collisions among carriers and carrier–impeller (or carrier–wall) interactions may play a role. Furthermore, in tall bioreactors cells may be subjected to substantial changes in hydrostatic pressure as they circulate with the fluid. Cells in tissue regeneration bioreactors experience the same kind of forces as occur in flow past a flat plate, wall, or other submerged object. The specific considerations relevant to the various culture methodologies are treated in the following sections.

Resistance to shear stress is determined at least partly by the cytoskeletal structure of the cell. The cytoskeleton determines a cell's mechanical properties, shape, and movements such as occur during phagocytosis. The cytoskeleton is made of protein filaments, mainly of actin. The filaments interact closely with the cell membrane by anchoring to specific membrane proteins. A cell exposed to mechanical forces undergoes cytoskeletal reorganization. Cytoskeleton-mediated stress signal transmission to intracellular organelles (Fig. 5) has been associated with various biochemical, physiological, and gene-level responses in vascular cells (4). Some cells are known to have surface stress receptors (e.g., Ca^{2+} ion channels) that have been implicated in biochemical responses (4,83,84) independent of cytoskeletal mediation (Fig. 5). Cytoskeletal properties are known to affect the shear tolerance of hybridomas. Effects of turbulence on the cytoskeleton and other biological responses have been treated by several authors (4,53,85). Work cited by Al-Rubeai et al. (86) suggests that inhibitors of actin polymerization decrease a cell's resistance to shear forces, whereas inducers of polymerization make the cells more robust. Thus, supplementing the culture medium with actin polymerization inducers may be one way of improving performance of bioreactor-cultured animal cells, so long as the requisite production biochemistry is not adversely affected.

Plasma membrane fluidity (PMF), which is a measure of the degree of packing of the membrane and its constituent's freedom to move about laterally through the bilayer membrane, to rotate about their major axes, and to oscillate in the plane of the membrane, is another factor that appears to influence shear susceptibility of cells (41). Increasing membrane fluidity correlates with increasing shear sensitivity (41). PMF increases with increasing temperature and can be manipulated in both directions using various additives. In studies with a freely suspended mouse–mouse hybridoma in a laminar shear stress Couette flow device, conditions that yielded higher membrane fluidity produced more fragile cells (41). For example, cells sheared at elevated temperatures showed greater loss of viability than unsheard controls at the same temperature (41).

Shear Effects in Bubble-Free Environments ***Suspended Cells.*** Freely suspended cells in bubble-free bioreactors are not damaged by mechanical agitation even at intensities much greater than the ones used in typical processing. Exceptions occur in extensional or elongational flow in certain high-shear devices even when the flow is laminar. Extensional or elongational flow occurs whenever the cross-sectional area of the flow channel reduces (e.g., at an orifice on the wall of a tank or at the entrance of a capillary connected to a larger reservoir). The fluid elements undergoing extensional flow stretch and thin. Suspended particles also experience elongational forces in the direction of flow, and compression perpendicular to the flow streamlines. Drops subjected to extension flow can rupture. Similarly, extensional flow through orifices of high-pressure homogenizers contributes to rupture of even the very robust microbial cells (1). Rupture of erythrocytes at entrances to capillaries is well known (87). Shear effects on suspended erythrocytes are discussed in detail in a later section.

For a hybridoma line, Born et al. (88) reported that exposure to laminar shear stress (208 N m^{-2}) in unaerated flow in a cone-and-plate viscometer led to substantial loss in cell count and viability within 20 min. At a constant 180-s exposure, increasing shear stress over 100–350 N m^{-2} linearly enhanced cell disruption, with >90% of the cells being destroyed at 350 N m^{-2} stress level (88). Shear stress levels associated with bubble rupture at the surface of a bioreactor may range over 100–300 N m^{-2} (13). These values are remarkably consistent with shear rates that damaged hybridomas in *unaerated* laminar flow experiments (88).

For a suspended mouse myeloma line in turbulent capillary flow, McQueen et al. (18) noted a threshold average wall shear stress value of 180 N m^{-2} when lysis first commenced. Although the flow caused lysis, it had no effect on viability (18), suggesting that cells at various growth stages were equally affected. The sudden flow contraction at the entrance to the capillary may have contributed to cell lysis, but the residence time in the capillary also had an effect at otherwise constant average wall shear stress level. The rate of lysis was first order in cell number. Above

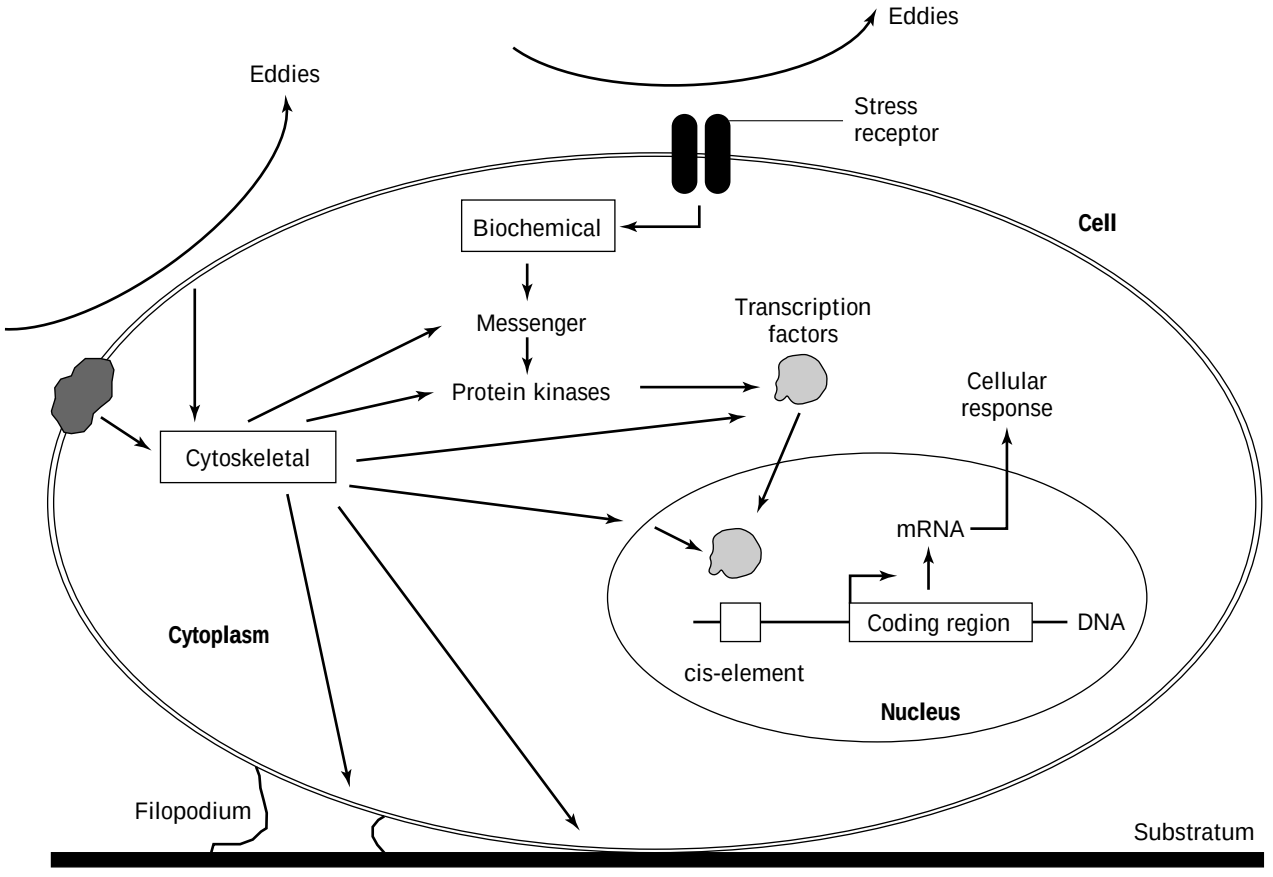

Figure 5. Stress signal transmission and transduction via cytoskeletal and biochemical routs in an anchored cell. *Source*: Adapted from Ref. 4.

the threshold shear stress value, the specific lysis rate increased with increasing level of shear stress (18). The growth rate and the DNA synthesis rate of the cells exposed to the shearing environment were unaffected when the surviving cells were returned to a normal quiescent growth environment (18). In other studies cited by McQueen et al. (18), the shear stress threshold for damage has been reported as 0.87 N m^{-2} for a mouse hybridoma and 1.5 N m^{-2} for insect cells. Higher shear sensitivity of another mouse cell line relative to a human carcinoma has been reported (16).

For human cervical carcinoma HeLa S3 and mouse abdominal fibroblast L929, Augenstein et al. (16) observed lysis of suspended cells in turbulent flow through stainless steel capillaries. Cell death could be correlated with the average wall shear stress level or the power dissipation within the capillaries. The L929 line was more sensitive than the human cell. Control experiments showed that the positive displacement pumps used to circulate the cells through capillaries contributed little to cell lysis (16). Average wall shear stress levels of 0.1–2.0 $\times$ 10^3 N m^{-2} were sufficient to induce cell inactivation for the two lines. According to Shiragami (17), the mean shear stress acting on cells suspended in capillary flow is 4/3 the shear stress at the capillary walls, so long as the ratio of the cell's diameter to that of the capillary is <0.08.

For a hybridoma examined by Shiragami (89), the specific rate of monoclonal antibody production in a surface-aerated spinner flask depended on the agitation speed. In a 250-mL spinner vessel an agitation rate of $\sim$180 rpm gave the highest specific antibody production rate. The specific productivities were reduced at higher or lower values of agitation speed. The increased antibody production with increasing agitation was associated supposedly with enhanced secretion in a more turbulent environment (89). Oxygen transfer effects may have better explained the observations (see MASS TRANSFER), but no data were reported on this aspect.

Damage to murine hybridomas was observed by Jan et al. (31) in stirred tanks equipped with marine impellers agitated at sufficiently high speeds that vortexing occurred and gas entrained into the medium. Even at these high speeds, damage could be prevented by baffling the tank, which suppressed vortex formation. Usually though, vortexing is not a problem in large-scale cell culture. Unbaffled, marine impeller–stirred tanks were successfully used by Chisti (78) in industrial culture of several hybridoma lines. Effects of agitation on hybridoma culture in the absence of sparging or surface entrainment were further examined by Smith and Greenfield (90). Culture growth was unaffected by agitation intensity (100 or 600 rpm) in the RPMI medium supplemented with fetal bovine serum

(10% vol/vol). However, in PFHM II medium supplemented with either Pluronic F68, fetal bovine serum, or bovine serum albumin, and agitated at 600 rpm (impeller tip speed = 1.6 m s^{-1}, power input = 1 kW m^{-3}) the results were different: the agitation intensity did not affect the exponential growth rate, but once growth had ceased, the decline phase was substantially faster than in control experiments (90).

A certain level of hydrodynamic shear is generally beneficial to culture processes, especially in intraparticle immobilized culture where mass transfer limitations can be severe. In producing engineered tissue of smooth muscle cells/polymer matrices (biodegradable 2-mm-diameter fibers of polyglycolic acid assembled into a nonwoven matrix), Kim et al. (82) noted that seeding of the matrix under agitation led to significantly higher intramatrix cell densities than when cells were seeded under static conditions. Moreover, the higher cell densities were attained more rapidly than the lower densities of static culture. In addition, the relative rates of synthesis of elastin and collagen were significantly greater in seeded matrices cultured with agitation than in ones grown statically (82). A lower possible supply of oxygen or other nutrient may have reduced the performance of static seeding methodology. In view of the above referenced studies and similar others, sufficiently intense fluid mechanical forces other than those associated with aeration do affect cells.

Adherent Cells. Quite low shear stress levels, for example, between 0.25 and 0.6 N m^{-2} in laminar flow (91), can interfere with the process of cell attachment to surfaces; however, once the cells are attached and spread out, they may tolerate higher stresses. Laminar shear stress of the order of 0.5–10 N m^{-2} may remove adherent cells from surfaces (92), but even lower values (e.g., 0.1–1.0 N m^{-2}) are known to affect cellular morphology, permeability, and gene expression (92). Sublethal shear stress levels cause no obvious physical damage but are known to produce various biochemical and physiological responses (4,83,84). In studies with rat aortic endothelial cells anchored on the internal walls of glass capillaries, laminar shear stress was shown to affect the cytosolic pH because of preferential leakage of certain ions out of the cells into the buffer saline (84). This reversible permeability enhancement occurred even at stress levels as low as 0.05 N m^{-2} applied over short durations ($\sim$2 min). Similar effects were noted with human aortic endothelial cells but not with human skin fibroblasts or rat intestinal epithelial cells exposed to shear stress levels of up to 1.34 N m^{-2} (84). With rat aortic cells, the flow-induced cytosolic acidification could be maintained for at least 30 min at 1.34 N m^{-2} shear stress level, but the cytosolic pH returned to unstressed levels within about 15 min when the sustained shear stress was $\leq$0.027 N m^{-2} (84).

In studies with anchorage-dependent cells attached to the flat glass walls of a rectangular flow channel, Shiragami and Unno (93) observed increased activity of lactate dehydrogenase (LDH) in cells that had been exposed to a steady-state shear stress of 0.5 N m^{-2} for 12 h: the activity was fourfold greater relative to controls. The LDH activity correlated with the transmission of energy from the fluid to the attached cells (93).

In vivo hemodynamic forces have been implicated in various physiological and pathophysiological processes (4). Atherosclerotic lesions in humans tend to develop in zones of flow separation (4) such as regions of arterial branching and sharp curvature. Arteries adapt to chronic changes in blood flow, increasing in circumference under high flow and declining under reduced flow (4). Shear stress signals transmitted throughout the vascular cell via cytoskeletal and biochemical elements result in changes to structure, metabolism, and gene expression (4).

Shear effects need to be considered also in perfusion devices that retain cells over long periods in continuous culture (94). Shear effects on adhering erythrocytes and leukocytes are treated separately.

Erythrocytes and Leukocytes. Mammalian erythrocytes, or red blood cells, are among the best studied of animal cells. Properties of erythrocytes and other blood cells are relevant to various pathologies and biomedical processes. Erythrocytes and leukocytes, being suspended cells in vivo, likely experience the kind of stresses encountered in bioreactors and various other industrial processing devices; hence, these cells may provide a broad general insight into mechanical behavior of other cells of mammalian origin. The normal lifetime of a human erythrocyte in circulation is 121 days. The normal daily destruction rate is about 2 $\times$ 10^{11} cells (87). Some cells lyse during circulation; most are destroyed in the spleen. Aging cells resist deformation more than the younger ones. All cells unable to deform in the 3-μm openings of the splenic circulation are delayed and ultimately phagocytized (87).

Erythrocytes are highly deformable cells that orient in laminar flow so that least possible surface area of the disc-shaped cell is perpendicular to the flow. The cytoplasm of erythrocytes is a viscous Newtonian fluid (95). The cell membrane behaves as an elastic solid: the cell deforms but almost instantly recovers its shape when the deforming force is removed. The membrane has little resistance to bending but substantially resists increase in area (95). Erythrocytes suspended in turbulent isotonic saline (viscosity $\sim 1 \times 10^{-3}$ Pa s) have been observed to undergo elongation and deformation; however, the cell appears to be less vulnerable to turbulent shear stress than a cell at the same stress level in a viscous suspending medium (87). Based on measurements in turbulent jets, a critical lytic shear stress level of 4,000 N m^{-2} has been reported for very brief exposures ($\sim 10^{-5}$ s) (87). Measurements on erythrocytes of different mammals reveal that the critical shear stress increases dramatically as the cell volume declines.

According to Blackshear and Blackshear (87), "Areal change occurs when the cell membrane is subjected to stress; hemolysis occurs when the area increases by approximately 6.4 percent." Hemolysis is associated at least in part with physical factors and flow, which produce the hemolysis threshold strain in membranes of erythrocytes (87). Once the threshold strain is exceeded, membrane pores open and the membrane eventually tears (87). A briefly (e.g., 10 ms) imposed uniaxial tension of 0.058 N m^{-1} is a sufficient criterion for lysis (87). When the cell is subjected to biaxial stress, a tension of about 0.029 N m^{-1}

may produce lysis. In viscometric stress for prescribed periods, time to lysis declines as the imposed stress is increased. However, it has been conclusively shown that shear stress alone is not a sufficient predictor of hemolysis rate or thresholds (87); cell shape and tumbling also play a role. Membrane shear appears to be far lower when the cells are suspended in higher-viscosity media in viscometric studies.

Erythrocytes allowed to adhere to a glass surface and then subjected to a fluid shear commence movement when the fluid shear force exceeds about 10^{-11} N (95). During this process the cell gradually moves downstream, but the membrane may remain attached to the surface (95). The membrane can be deformed permanently when the deforming force persists for more than a few minutes (95). Shear elasticities of nonnucleated mammalian red cells are generally similar, but elasticities are about an order of magnitude greater for cells of nucleated species. Small amounts of thiol reagents are known to decrease the elongation of human red cells suspended in a shear field (95), presumably by producing some sort of cross-linking. Potentially, this methodology may improve survival of any fragile cell with a significant amount of cross-linkable protein in the membrane. Other additives may render the cell more susceptible to shear damage. Certain chemical lysins and some antigen–antibody reactions cause perforation of the cell membrane and leakage of intracellular material (87). Cholesterol enrichment or depletion of the human erythrocyte membrane does not affect its viscosity.

Hemolysis of red cells is known to occur intravascularly in vivo as well as in various in vitro flow systems (87). A number of studies have correlated hemolysis to flow in pumps, valves, heart–lung machines, blood dialyzers, and transfusion filters. In flow through tubes, wall roughness of the scale of erythrocyte correlates with hemolysis (87). Bubbles trapped in surface imperfections appear to aid lysis. In flow through tubes, hemolysis correlates with the shear rate and the surface-to-volume ratio (87). This type of lysis occurs at shear stress thresholds lower than the ones required to produce lysis in a fluid shear field. Wall contact–associated lysis has been observed to depend on the chemical nature of the wall material. Lysis may decline with time as surfaces become passivated by prolonged contact with plasma proteins (87).

In capillaries of ~1 mm in diameter, an upper limit on the mean tube velocity of 6 m s^{-1} has been suggested for capillaries with sharp-edged entrances, and blood with a viscosity of 4×10^{-3} Pa s (87). This corresponds to a Reynolds number of 1,500 inside the capillary and an average wall shear rate of about 4,800 s^{-1}. Velocities as high as 17 m s^{-1} may be employed inside capillaries with carefully flared entrances (87). As with other animal cells, erythrocytes subjected to bubbling are susceptible to bubble rupture–associated damage, as shown in Figure 6 for porcine erythrocytes. The normalized cell number (Fig. 6) declined more rapidly in a sparged airlift bioreactor in comparison with cells in a surface-aerated shake flask (43). In surface-aerated shake flasks, increasing shaker platform speed over 100–400 rpm increased the specific cell lysis rate (Fig. 7). The slight decline in lysis rate at 100 rpm (Fig. 7) was associated with improved surface aeration

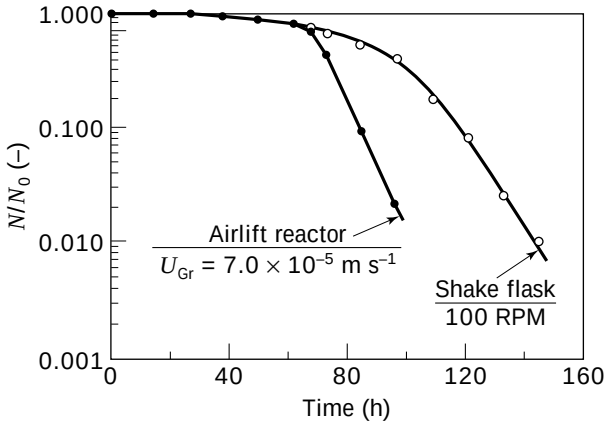

Figure 6. Survival of suspended porcine erythrocytes in a sparged airlift bioreactor and a surface aerated shake flask. Normalized cell count (N/N_0) is plotted as a function of time. *Source*: From Ref. 43.

relative to static flask. Because erythrocytes do not multiply in vitro, the effects of cell-damaging forces are not masked by growth-associated adaptation, changes in cell size, and stages of growth; hence, suitably chosen erythrocytes provide a well-defined cell population for comparative assessment of the damaging potential of various hydrodynamic environments (43).

In comparison with erythrocytes, the cytoplasm of leukocytes has markedly different rheological properties (96), but the properties of the leukocyte membrane are similar to those of the red cell membrane. Leukocytes adhering to vascular endothelium detach when the shear stress is between 26.5 and 106.0 N m^{-2} (96). According to work cited by Prokop and Bajpai (53), a shear stress level of 60 N m^{-2} applied over 10 min should lyse about one-fourth of a leukocyte population. In another study, sublethal shear stresses of 10 and 20 N m^{-2} applied over 10 min in a Couette viscometer affected the biochemical response of human T cells relative to unsheared controls (83). It seems,

therefore, that cells in vivo in circulation are apparently more shear resistant than ones studied in vitro.

Microcarrier Culture. Both stirred-tank and airlift bioreactors (97) may be used for suspended microcarrier culture. Microcarrier-supported cells likely experience hydrodynamic forces of greater magnitude than do freely suspended cells. This is because in highly agitated or aerated systems, the length scale of fluid eddies can be of the same order as the dimensions of microcarriers, resulting in high local relative velocities between the solid and the liquid phases (15,78,98). Furthermore, the carriers have greater inertia than free cells; hence, collisions among microcarriers and between the impeller and microcarriers likely damage attached cells. Similarly, fluid eddy impact and shear stress forces on a high-inertia particle are greater than on free cells.

Resistance of a cell to rupture by impact (i.e., burst resistance) is a possible measure of the cell's survivability in the culture environment. Measurements of burst force are potentially useful also for comparative assessment of cell strength and in establishing culture conditions that give rise to more robust cells. It may eventually be possible to correlate the sensitivity to shear of a cell to its resistance to mechanical rupture (99). Burst strength may be directly relevant in microcarrier culture where impact-associated damage is likely; however, in view of the cytoskeleton-mediated pressure signal transmission to internal parts of a cell, a more likely scenario is that the force required to cause impact-associated damage is far lower than the rupture threshold. This issue notwithstanding, resistance to rupture of a mouse hybridoma grown in serum-containing continuous culture has been measured by squeezing single cells between flat surfaces of micromanipulator arms (100). The bursting strength increased with cell size (101). The bursting force correlated with the initial cell diameter as follows:

$$S = 0.2d_c - 0.1 \times 10^{-6} \tag{31}$$

where the intercept was not significantly different from zero (100). The cell diameter ranged over $\sim(10–17) \times 10^{-6}$ m. Other similar data (101) have been correlated (99) as follows:

$$S = 0.27d_c - 0.86 \times 10^{-6} \tag{32}$$

where the burst strength S is in newtons, and the hybridoma cell diameter, d_c, is in micrometers. The calculated bursting tension had a mean value of $(1.8 \pm 0.5) \times 10^{-3}$ N m^{-1}, which was essentially independent of cell size (100). Because the bursting tension was size independent, the bursting pressure fell with increasing cell diameter. At $(0.8 \pm 0.3) \times 10^{-3}$ N m^{-1}, the calculated mean compressibility modulus of the cells was roughly independent of cell diameter (100).

Sinskey et al. (102) advanced the concept of an integrated shear factor (ISF)—a measure of the strength of the shear field between the impeller and the spinner vessel walls—to correlate shear damage to mammalian cells. The ISF was defined as

$$\text{ISF} = \frac{2\pi N d_i}{d_T - d_i} \tag{33}$$

or, effectively, the laminar shear rate between the impeller tip and the walls. For a range of stirred vessels (0.25–2.0 L, $0.032 \leq d_i$ (m) ≤ 0.085), cell damage occurred once the ISF value exceeded about 18 s^{-1} during culture of microcarrier-supported human fibroblasts (103). Damage could be correlated also with the impeller tip speed, but unlike the ISF, the damaging value of the tip speed depended on the size of the culture vessel (103).

Relying on the earlier work of Nagata, Croughan et al. (103) arrived at the following expression for a time-averaged shear rate:

$$\gamma_{av\cdot T} = \frac{112.8 r_i^{1.8}(r_T^{0.2} - r_i^{0.2})(r_c/r_i)^{1.8}}{r_T^2 - r_i^2} \tag{34}$$

where r_i and r_T are the impeller and the tank radii, respectively. The radius r_c of the formed vortex zone would need to be estimated using Nagata's expression:

$$\frac{r_c}{r_i} = \frac{Re_i}{1{,}000 + 1.6Re_i} \tag{35}$$

The impeller Reynolds number in equation 35 is calculated as follows:

$$Re_i = \frac{N d_i^2 \rho_L}{\mu_L} \tag{36}$$

Equation 34 was developed for unbaffled stirred tanks operated in the turbulent regime (103). For human fibroblasts on microcarriers in various stirred vessels, cell damage occurred when the time-averaged shear rate exceeded about 2.5 s^{-1} (103). For chicken embryo fibroblasts, also on microcarriers, the damage threshold was 6 s^{-1} time-averaged shear rate (103). Cell damage correlated also with the Kolmogoroff eddy length scale (l): for human fibroblasts the cell damage occurred when the length scale declined to approximately below 125 μm, whereas for the chicken embryo cells damage was observed when the l-value declined to below 100 μm (103).

Analyzing data from several sources, Croughan et al. (103) further showed that the specific death rate correlated with the average energy dissipation rate per unit mass; thus,

$$k_d \propto E^m \tag{37}$$

where m was 0.72, 0.76, and 0.82, respectively, for microcarrier-supported Vero cells, similarly supported human fibroblasts, and a freely suspended protozoan. For attaining a more homogeneous shear field in stirred culture vessels (i.e., for the minimum value of the maximum-to-average shear rate ratio) Croughan et al. (103) noted an optimal vessel geometry corresponding to $r_i/r_T = 0.74$.

In microcarrier culture, collisions between microcarriers and interactions between carriers and internals of a reactor are other possible causes of cell damage, particu-

larly in stirred bioreactors (15,104,105). Cherry and Papoutsakis (98,104,105) advanced the concept of "severity of collision" to account for at least some of the damage to cells in suspended microcarrier culture in stirred vessels. Severity of collision combined collision frequency and energy of the impact. Two collision severities were defined: a turbulent collision severity (TCS) for turbulence-associated particle-to-particle impacts, and an impeller collision severity (ICS) for particle-to-impeller collisions; thus,

$$\mathrm{TCS} = \left(\frac{E\rho_L}{\mu_L}\right)^{3/2}\left(\frac{\pi^2\rho_S d_p^5 \varepsilon_S}{72}\right) \tag{38}$$

and

$$\mathrm{ICS} = \frac{9\pi^4\rho_S n_B N^3 d_t^4 d_p^4}{512 V_L} \tag{39}$$

where E is the energy dissipation rate per unit liquid mass, ρ_S and d_p are the density and diameter of the microcarriers, ε_S is the volume fraction of the carriers, n_B is the number of impeller blades, N and d_i are the impeller rotational speed and diameter, and V_L is the volume of the liquid in the vessel. Improved cell growth was observed with smaller microcarriers, as predicted by equations 38 and 39. The specific cell death rate increased with increasing values of TCS and ICS (104,105); however, the influence of hydrodynamic forces on culture performance correlated also in terms of the ratio of Kolmogoroff eddy scale to bead diameter: the specific death rate declined as l/d_p increased. As culture viscosity was raised, damage to cells declined in conformance with equation 38 and in agreement with interpretations based on the l/d_p ratio (105).

Unlike in stirred tanks, animal cell microcarriers suspended in airlift bioreactors under typical operating conditions do not significantly interact with each other or with the walls of the vessel (106); instead, the microcarrier particles follow the laminar streamlines of the fluid (106). Consequently, in airlift reactors at least, the effects of particle–particle or particle–wall collisions on monolayers of cells may be disregarded. Observations of Ganzeveld et al. (106) spanned microcarrier loadings of up to 30 kg m^{-3}, with carriers of 150–300 μm diameter, and 1,030–1,050 kg m^{-3} density. The observations covered a power input value of up to 33 W m^{-3}, which is about the upper limit for cell culture in pneumatically agitated bioreactors. These results applied to a split-cylinder airlift bioreactor with an aspect ratio of 7.6, which would not normally be exceeded in large-scale cell culture systems. As an additional design constraint, the Reynolds number in the riser and the downcomer should not exceed about 3,000, or the flow will be more chaotic (106).

Numerical analysis of forces exerted by laminar flow on anchorage-dependent cells attached to flat surfaces suggests that shear stress between 0.25 and 0.6 N m^{-2} is sufficient to detach round cells, but much higher values are needed to dislodge spread out cells (91). These observations are relevant to microcarrier culture where, during inoculation, the round cells must first attach to microcarriers before spreading on the solid surface. During proliferation, bead-to-bead transfer of cells may also require a level of turbulence that is not so high as to hinder the reattachment process, yet not so low that bead-to-cell encounters are few.

Typically, the shear rate values in airlift bioreactors range over 250–4,000 s^{-1} for operational conditions that are relevant to animal cell culture (14). These shear rates are substantially lower than the $\sim 10^5$ s^{-1} that would be needed to damage cells if a 100-N m^{-2} shear stress value (13,88) is taken as the threshold of mechanical damage. However, based on the shear stress data of Olivier and Truskey (91), during the process of attachment of cells to microcarriers, shear rate levels of 250–600 s^{-1} may well be detrimental. Thus, during initial attachment of cells, the reactor would need to be operated at reduced aeration rates—a practice that is well established through empirical experience, but previously explained only intuitively (14).

Under conditions typical of microcarrier culture in airlift bioreactors, the specific energy dissipation rates are different in different zones of the vessel. The specific energy dissipation rates increase in the following order: downcomer < riser < bottom, for any fixed value of the aeration rate (14). The dissipation rates in all zones decline with increasing loading of microcarriers; however, the prevailing shear rates are not particularly sensitive to the density or the diameter of microcarriers within the ranges that are relevant to anchorage-dependent cell culture. In one case, typical shear rates ranged over 250–4,000 s^{-1} in microcarrier-containing systems, but much higher values, up to 12,000 s^{-1} could occur in solids-free media (14). These values compare favorably with shear rates of $\sim 10^5$ s^{-1} that have been reported as the threshold of damage to cells. Cells in airlift bioreactors would experience a substantial increase in the riser shear rate only when the fluid eddy length–to–microcarrier diameter ratio declines to ~ 1 (14).

Hydrostatic Pressure As the scale of operation increases, suspended animal cells will inevitably experience substantial hydrostatic pressure changes as they move with fluid elements in a large bioreactor. At least for hybridomas, artificially imposed pressure cycling of up to 1.2 atm (18 psig) has shown no harmful effect (79). This level of pressure fluctuation will be encountered in bioreactors that are about 12 m tall; hence, for a 2:1 aspect ratio, an animal cell culture vessel could be scaled up to about 340 m^3. If, as recommended for airlift and bubble column bioreactors (20,21), an aspect ratio of 5:1 is employed, a maximum vessel volume of about 50 m^3 should be feasible. Suspension cell culture vessels in current commercial use do not generally exceed 10 m^3, or about 20% of the feasible volume based on hydrostatic pressure considerations.

Bubble-Associated Damage That sparging damaged cells has been known since the 1960s; however, the specific events responsible for the damage—whether bubble formation at the sparger, bubble detachment, rise through the fluid, or events at the disengagement surface—and the mechanism(s) of damage remained unclear until recently.

The growth rate, viability, and antibody productivity of a mouse hybridoma in a surface-aerated stirred vessel were not affected by the agitation rate, but damage occurred when gas was sparged through the culture (107). In surface-aerated operation, the average and the maximum shear stress values varied over the respective ranges of 0.001–0.4 N m^{-2} and 0.06–6.4 N m^{-2}. Subsequent work showed that bubbles larger than 5 mm were significantly less damaging to cells than smaller bubbles (108). Furthermore, placing the sparger below the impeller enhanced cell damage, presumably because the impeller-associated bubble breakup gave rise to the more damaging smaller bubbles (108).

Cell lines differ tremendously in sensitivity to aeration as was demonstrated by Handa et al. (109). At constant aeration rates in geometrically identical bubble columns, smaller diameter bubbles (0.2 mm in diameter) were shown to be significantly more damaging to a hybridoma than larger bubbles (1.62 mm in diameter). In industrial-scale culture of several hybridomas, Chisti (78) preferred yet larger bubbles (10–20 mm diameter) for aeration. Similarly, Tramper et al. (63) observed that smaller bubbles were more damaging to insect cells than larger ones. However, the effect of bubble size may not be prevalent across cell types. Thus, in another study, baby hamster kidney (BHK-21) cells were not sensitive to the size of gas bubbles (110). Over a superficial gas velocity range of (0.42–8.5) $\times$ 10^{-4} m s^{-1}, higher velocities led to faster decline in cell viability of a hybridoma (109), which is consistent with other similar observations (61).

In commercial stirred-tank culture of several hybridoma lines at up to 0.3 m^3, Chisti (78) employed submerged aeration with bubbles of 0.01–0.02 m in diameter. Because of high rise velocities and mobile interfaces, such bubbles did not carry many attached cells to the surface. In contrast, during aeration with sintered metal spargers that produced slower rising bubbles of ~0.002–0.003 m in diameter, the cells were rapidly carried into a persistent foam layer at the top by a froth flotation mechanism (78). The foam produced by larger bubbles collapsed soon after the bubble rose to the surface. The reactors employed were agitated by magnetically coupled agitators with support bearings submerged in the culture. Reactors with submerged mechanical seals were also used. No loss in culture performance occurred relative to roller bottles. The impeller tip speeds >1 m s^{-1} produced no ill effects. Under typical operating conditions, the length scale of the microeddies was about 130 μm, or about 10-fold greater than the dimensions of the cells (78).

Based on energetics of bubble-associated damage to freely suspended cells, Wang et al. (111) concluded that the principal determinants of cell damage were the cell–bubble encounter rate, the rate of bubble breakup within the fluid, and the bursting rate at the surface. Cell death correlated linearly with specific gas–liquid interfacial area, with the proportionality constant being 0.0125 m h^{-1} for a murine hybridoma (111).

Using an elegant mechanistic analysis, Tramper et al. (62,63) related the first-order rate constant for cell death due to all causes to aeration rate in a bubble column; thus,

$$k_d = \frac{24QV_k}{\pi^2 d_B^3 d_T^2 h_L} \tag{40}$$

where k_d is the first-order death rate constant, Q is the volumetric aeration rate, h_L is the height of fluid, d_T is the column diameter, and V_k is a hypothetical killing volume associated with the bubbles. The latter is actually the total volume of fluid associated mainly with the bubble wakes; the cells entrapped in the circulating wake are carried with the bubble to the surface where most of the damaging events take place. According to equation 40, the specific cell death rate is proportional to the frequency of bubble generation, or $6Q/\pi d_B^3$. Alternatively, because at hydrodynamic steady state the bubble generation frequency equals the frequency of rupture at the surface, the death rate may be interpreted as being dependent on the frequency of bubble rupture and the killing volume associated with the bubbles.

Based on equation 40, the death rate constant should decline with increasing height of fluid, as experimentally confirmed: for otherwise fixed conditions, increasing liquid height in bubble columns improved survival of insect cells (62,63), myelomas, and hybridomas (60,64,110), supporting the view that cell death occurred predominantly in the bubble disengagement zone at the surface (109,110). For a myeloma grown in serum-supplemented medium, the minimum culture height that provided a performance equivalent to that of surface aerated flasks, was ~0.7 m, corresponding to a bubble column aspect ratio of ~14 (64). The 0.05-m diameter column was aerated through a sintered disc sparger (150- to 250-μm pore size). The aeration rate was 5 mL min^{-1} (64), corresponding to a specific power input of about 0.42 W m^{-3}.

If bubble rise were to predominantly contribute to cell death, then the specific cell death rate should be independent of the height of fluid (112). Because this is contrary to experimental observations, the rise events may be disregarded as principal contributors to cell damage (112). Whereas, if gas entry at the sparger contributed predominantly to cell damage, then at a given gas flow rate in the reactor, decreasing the number of sparger holes should enhance the specific cell death rate constant (112). In bubble columns, Jöbses et al. (112) noted that increasing the sparger hole gas velocity over 0.6–2.5 m s^{-1} at a constant volumetric gas flow in the reactors had no effect on the first-order rate constant for cell death; hence, events at the sparger could be disregarded as contributing to cell damage. This process of elimination identified bubble breakup at the culture surface as the principal cause of damage to suspended cells in sparged bioreactors such as bubble columns (112). Equation 40 applies also to airlift devices (61), especially ones in which gas is not carried into the downcomer. Because most agitated tanks used in animal cell culture operate at quite low mechanical power inputs and the impeller does not usually serve as a bubble breaking device, equation 40 should provide a lower limit on k_d also in such tanks.

Using a hybridoma culture van der Pol et al. (60) showed that the first-order death rate constant increased with increasing $1/d_T^2$ in bubble columns, as expected from equation 40. Equation 40 suggests that cell damage in-

creases in direct proportion to the superficial gas velocity in the column, or in direct proportion to the specific power input. Note that increasing liquid level at constant aeration rate in a column of fixed diameter decreases the specific power input (14,20,21). Equation 40 further suggests that for a given V_k, larger bubbles should be less damaging than smaller ones. This agrees with substantial empirical evidence (62,63,78,108,110,113).

That the death rate increases linearly with increasing aeration rate has been proven (62,63,113). Also, the killing volume, V_k, has been shown to be independent of the aeration rate and the height of fluid, so long as the bubble diameter is not affected (62,63). The killing volume apparently depends on bubble diameter, increasing with diameter but in such a way that the ratio V_k/d_B^3 declines as the bubble diameter increases. This has been confirmed by Wu and Goosen (113) using *Spodoptera frugiperda* insect cells in bubble columns that were sparged with bubbles of different mean diameters while maintaining a constant volumetric gas flow rate. Increasing bubble diameters reduced the specific death rate, as shown in Figure 8. In view of the numerous contrary observations, analyses suggesting lesser cell damage with smaller bubbles are clearly flawed.

The dimensionless specific killing volume, or $6V_k/\pi d_B^3$, in equation 40 depends on the concentration of serum in the culture medium. Van der Pol et al. (60) showed that the dimensionless killing volume declined as the serum concentration was raised over the range 0–2.5% (vol/vol); the dimensionless killing volume in the absence of serum was ~2.7-fold that at 2.5% serum in a hybridoma culture (60). This and other similar observations (61) at least partly explain the well-known protective effect of serum. Cell-protective effects of other proteins may be similarly explained. Serum-free media with 1 g protein L^{-1} (equivalent to supplementing the medium with 2% vol/vol serum) are commercially used in sparged airlift culture vessels (79).

Why rupture of larger bubbles is less damaging to cells than breakup of smaller ones has become clear through analyses of mechanics of rupture (114,115). Numerical simulations and experimental observations of bubble rupture at an air–water interface confirm that smaller bubbles rupture much more violently than larger ones (114,115). A bubble reaching the surface rises to different heights above the flat liquid surface before rupturing. For a bubble that is stationary at the surface, a part is always submerged below the flat surface of the liquid. The degree of submergence is generally greater for smaller bubbles. During rupture, the liquid drains from the film between the raised liquid surface and the bubble (116,117). As the film thins, a hole develops in the center of the dome, and the film rapidly retreats into the bulk liquid. The rupture of the film and consequent elongational and accelerational flow have been postulated to damage cells in the film and those adhering to the bubble cavity (116). A cell on the surface of a rupturing film would apparently not experience any motion until struck by the torroidal ring of fluid at the receding edge of the film (116). The force experienced by the cell will depend on the film thickness at the instance of rupture (116). Rupture of thinner films is likely to be less damaging than the breakage of a thicker film. Once the bubble ruptures, fluid rapidly accelerates and moves down the interior walls of the bubble cavity. The flow from around the walls impacts at a stagnation point located immediately below where the bubble had been. The high pressure produced by the impacting streams forces a jet of fluid upward into the gas phase above the liquid surface. A second opposing jet is forced into the fluid below the stagnation point. Intense accelerational flows around the bubble cavity and formation of liquid jets occur mostly during rupture of small bubbles. Bubbles larger than about 6 mm rupture much less violently.

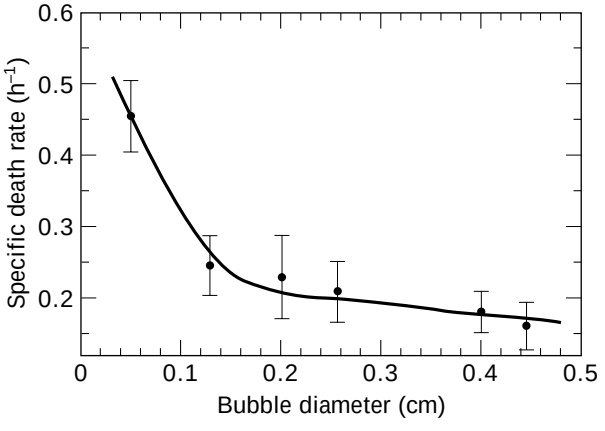

Figure 8. Effect of bubble diameter on the specific death rate of *S. frugiperda* insect cells in bubble columns aerated at a constant volumetric gas flow rate of 10 mL min^{-1}. *Source*: Adapted from Ref. 113.

According to Boulton-Stone and Blake (114), "one of the most important factors determining the motion following film rupture, in terms of the energy released, is the height of the top of the bubble above the equilibrium free-surface" of the liquid. Bubbles rupturing from a lower position beneath the equilibrium surface of the liquid release more energy because of their higher internal pressure. The energy is released as high-speed liquid jets. Bubbles larger than about 6 mm bursting at the surface do not form significant jets (114) which is consistent with numerous observations dating from 1950s and earlier. When a jet is produced, the speed of the jet declines as the size of the rupturing bubble increases: for example, for air bubbles rupturing on water, a maximum jet speed of 6.4 m s^{-1} has been calculated for rupture of a 1-mm bubble; for rupture of a 6-mm bubble the maximum jet speed declines to 0.94 m s^{-1} (114). In addition to a liquid jet rising into the atmosphere above the liquid, a second liquid jet moves down into the fluid from the region that had been below the base of the bubble. The maximum pressure produced during bursting of bubbles of various sizes declines with increasing bubble diameter, as illustrated in Figure 9. The maximum energy dissipation rate occurs just beneath the bubble immediately before the jet forms (114). The calculated maximum energy dissipation rates for the smallest bubbles are equivalent to a stress of about 10.4 N m^{-2} (114). The maximum energy dissipation rates decline with increasing bubble diameter, as depicted in Figure 10.

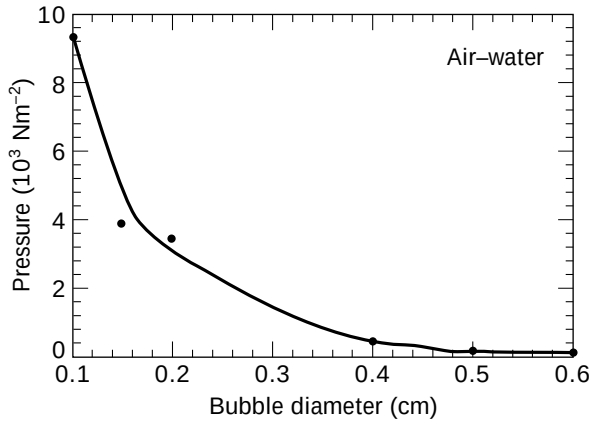

Figure 9. The maximum pressure produced during bursting of air bubbles of various sizes on the surface of water. *Source*: Adapted from Ref. 114.

Even a violent bubble rupture event would be inconsequential if there were no cells in the vicinity. Unfortunately, cells attach to rising bubbles, and the fluid behind bubbles is especially rich in cells. That some animal cells will attach to rising bubbles has been shown with *Trichoplusia ni* and *S. frugiperda* insect cells (116,118). The cells adhered to rising microbubbles (diameter $\leq$3 mm) of the type used commonly in froth flotation. Hydrophobic interactions are apparently responsible for cell attachment—a mechanism observed also with ore particles attaching to bubbles during foam flotation. Although, very small bubbles are generally not suited to aeration of cell cultures (78), larger bubbles also transport cells to the surface, but not predominantly as adhering cells. Instead, the cells are trapped in the circulating wake carried behind large bubbles. The fluid associated with the wakes is known to be richer in particles than the bulk fluid.

More than 95% of the cells in the liquid ejected as jet during rupture of bubbles have been shown to be nonviable even when the cells in the bulk culture contained fewer than 10% dead cells (115). Clearly, the cells carried in the bubble wake are destroyed by the rupture event. Based on simulations of rupture of bubbles with diameters of 0.77 mm, 1.70 mm, and 6.32 mm, Garcia-Briones et al. (115) calculated maximum energy dissipation rate values (W m^{-3}) of 9.52×10^7, 1.66×10^7, and 9.40×10^4, respectively. Comparing these values with energy dissipation rates that have damaged cells in various unaerated flow devices (capillaries and viscometers), Garcia-Briones et al. (115) noted that values of the order of 5.81×10^2 W m^{-3} did not damage the cells significantly, whereas appreciable damage occurred when the energy dissipation rate exceeded about 2.25×10^4 W m^{-3}. Clearly, therefore, a 6.32-mm bubble still has a significant potential to damage cells, and a smaller bubble would produce instantaneous damage. For example, in gas-free capillary flow in experiments reported by Augenstein et al. (16), more than 80% of the cells died within 0.3 s of exposure to energy dissipation rates of about 4.80×10^7 W m^{-3} (115). Interpreting data from several sources, Garcia-Briones et al. (115) further note that average energy dissipation rates of the order of 2,990–29,000 W m^{-3} have generally produced a significant decline in growth rate in impeller-agitated bioreactors. These dissipation rates are average values; the cells probably experienced much higher local energy dissipation rates in the vicinity of the impellers.

If stable foam is not allowed to form, and relatively large bubbles (diameter $\approx$ 10–20 mm) are used for aeration so that the energy dissipated during rupture remains below the cell damaging threshold, then the cells carried in the wake will not be damaged or removed into a foam layer. For bubbles of a given size, the volume of the circulating wake can be reduced by increasing the viscosity of the culture broth. Small increases will reduce the rise velocity of the bubbles, and the circulation in the wakes will be slowed down. Consequently, slight enhancements in viscosity could reduce the transport of particles in the wake. This may indeed be one explanation of why viscosifying additives have been frequently observed to reduce cell damage. Also, for a given volumetric aeration rate, use of larger bubbles reduces bubbling frequency; hence, the frequency of bubble rupture is reduced.

Based on the studies reviewed, several important observations can be made regarding freely suspended animal cells in sparged and agitated bioreactors: (*1*) the aeration rate should be kept as low as possible; (*2*) the mean bubble size should larger than 7 mm, preferably about 10–20 mm; (*3*) the location of the sparger should be such that the rising bubbles do not interact with any impellers; (*4*) with small airlift and bubble column reactors the aspect ratio should be about 14; however, in larger columns where the sparged portion of the cross section can be a small fraction of the total cross-sectional area, more realistic aspect ratios of about 6 or 7 are satisfactory; and (*5*) when an impeller is used, the average energy dissipation (input) rate should remain below about 1.0×10^3 W m^{-3}. Observations (*1–5*) are consistent with industrial practice (78). The sole purpose of the impeller should be to suspend the cells and mix the fluid gently so that the oxygen transferred from the bubbles is distributed throughout the vessel. Consistent with this purpose, the impeller should be of a kind that

does not produce excessively high local rates of energy dissipation. For example, relatively large axial flow hydrofoils are the preferred impellers (30,78). In addition, a suitably selected additive such as Pluronic F68 should be used whenever feasible.

Mitigation of Shear Damage Various approaches have been used to reduce bubble rupture–associated damage to cells. Some common approaches are the use of cell protective additives as noted here; compartmentalization of the culture into cell-free and cell-containing zones, with sparging confined to cell-free regions (80,81); use of bubble-free oxygenation through microporous or diffusion tubing made of silicone rubber or other polymer; use of liquid oxygen vectors such as perfluorocarbons; and surface aeration (see MASS TRANSFER). Alternatives to bubbling are suited typically only to specific cases; direct sparging remains the predominant method of aeration of cell cultures, and it is not likely to be displaced in the foreseeable future (76).

One adaptation of submerged aeration is the "bubble bed" bioreactor, which can substantially reduce surface rupture of bubbles in short-term batch culture (119). The bubble bed device (Fig. 11) is similar to a concentric draft-tube airlift bioreactor, but a downward pumping axial flow impeller located in the draft tube circulates the fluid. The downward liquid flow in the draft tube is sufficiently fast that gas bubbles injected into the draft tube cannot escape; hence, the bubbles do not rupture at the surface of the culture. Pure oxygen or oxygen-enriched gas is used to reduce the needed gas injection rate to very low values. The gas holdup in the downcomer increases during batch operation, and a noncirculating bed of bubbles develops. The cross-sectional area of the draft tube increases downward (Fig. 11) so that the superficial velocity of the liquid declines as it moves down; consequently, the downflowing liquid cannot drag the bubbles out of the draft tube and into the bubble-free annular zone. According to Sucker et al. (119), the cell growth and antibody production in bubble bed devices is comparable to values obtained in surface-aerated spinner flasks even when the sparged culture in the bubble bed units is not supplemented with serum, Pluronic F68, or other protective additives.

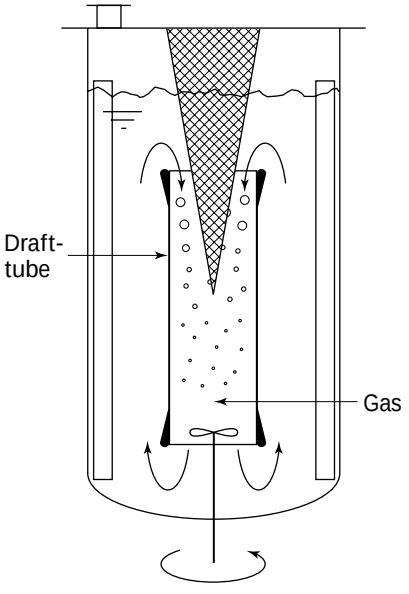

Figure 11. A bubble bed reactor.

Shear Protectants. Bubble-associated damage can be significantly reduced by adding shear-protective substances to the culture medium. Many additives have been examined for shear-protective function (120). Some of the protective additives are noted in Table 4. The protective effect depends on the properties of the specific additives, the concentration used, the type of cell, and the mechanism(s) of protection. Some common protective agents and their mechanisms of protection are treated next.

Serum. A concentration-dependent protective effect of fetal calf serum, horse serum, and others, has been widely observed in aerated and bubble-free suspension cultures of many types of animal cells (41,60,61,66,110,120–122). Typically, protection increases with increasing serum concentration until about 10% (vol/vol) serum. In one study reduction in fetal calf serum level from 2.5% to 0% substantially increased the death rate constant of a hybridoma in aerated culture (60). Investigations revealed that serum had no long-term biological effect, but only a direct nonspecific physical protective effect (60). Thus, cells growing in low-serum medium were immediately protected upon transfer to a medium with 2.5% serum. A physical protective effect of serum has been claimed to originate in its ability to reduce plasma membrane fluidity (41,121). According to Martens et al. (61), serum has an immediate physical protective effect, but also a physiological protective effect that takes longer to become effective. The latter finding concurs with the results of Michaels et al. (122). In bubble-free experiments in a Couette viscometer (shear rate = 5,000 s^{-1}, shear stress = 5 N m^{-2}), prolonged exposure of cells to fetal bovine serum (FBS) reduced their shear sensitivity in laminar flow studies (122); however, shorter (30–120 min) exposure to FBS did not affect shear tolerance of cells. Based on these results, the protective effect of FBS was claimed to have both physical and biological (biochemical) origins (122).

The precise nature of the physical protective effect of serum is not clear. Supplementation with serum enhances the viscosity of the culture medium, but the effect is small (92,123). Nevertheless, Croughan et al. (66) and others (67,104) have associated the observed protection to the turbulence-dampening effect of serum. In contrast, other evidence suggests a lack of relationship between the amount of protection afforded by the serum and enhance-

Table 4. Media Additives Associated with a Cell-Protective Effect

Serum	Pluronics

Derivatized celluloses (e.g., methyl cellulose)	Polyvinyl pyrrolidone
Derivatized starches (e.g., hydroxyethyl starch)	Polyethylene glycols
Dextrans	

ment of viscosity (124,125). In addition to dampening turbulence, the serum proteins may coat the cells so that the fluid eddies no longer penetrate to the vicinity of the cell membrane (66). In one study, increasing the concentration of fetal bovine serum over 0–10% (vol/vol) reduced plasma membrane fluidity of a hybridoma line, making the cells more resistant to shear damage (41,121).

Pluronic® F68. Another well-known shear protectant is the nonionic surfactant polyol Pluronic® F68, a block copolymer of poly(oxyethylene) and poly(oxypropylene). Highly pure Pluronic F68 is added to cell culture media, typically at 0.5–3 kg m^{-3} (92,109,110,112,120,122). The protective effect of the surfactant is concentration dependent, increasing with concentration but leveling off at ~0.5 g L^{-1} (Fig. 12).

The protective effect of Pluronic F68 is commonly associated with its ability to suppress attachment of cells to bubbles (110): in the presence of the surfactant, fewer cells are carried to the surface where much of the cell damage occurs in aerated culture. However, evidence exists for other protective mechanisms. For example, a cell-protective effect of Pluronic F68 has been observed even in unaerated culture (41,112). In one case this effect was observed in a strongly agitated culture sample (112). Although no bubbles were present, a deep vortex was drawn into the fluid by the marine impeller used. Extensive cell damage occurred, but the damage was significantly reduced when the culture was supplemented with Pluronic F68. Based on these observations, Jöbses et al. (112) concluded that the protective effect of Pluronic F68 was due to its direct influence on cells and to some effect of the surfactant on the gas–liquid interface. One possible explanation for the protection observed by Jöbses et al. (112) in the absence of the bubbles follows: the damage may have been occurring at the rapidly moving surface of the vortex (126), and supplementation of the culture with Pluronic F68 may have reduced the surface adherent tendency of the cells; hence, fewer cells may have attached to the surface during its formation at the periphery of the vessel.

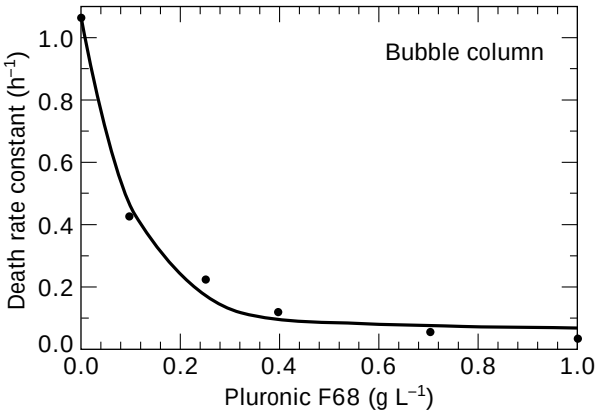

Figure 12. Cell protective effect of Pluronic® F68 in a bubble column. The specific first-order cell death rate constant is plotted as a function of the concentration of Pluronic F68 in the medium. All data were obtained at a constant specific power input of ~40 W m^{-3}. *Source*: Adapted from Ref. 112.

Using flow cytometry, Al-Rubeai et al. (86) showed that leakage of a positively charged dye, fluorescein diacetate, from murine hybridomas increased with rising intensity of agitation, suggesting a possible link between the permeability of the cell membrane and the shear rate. However, because intense agitation was accompanied by entrainment of gas bubbles into the culture (86), the observed leakage could not be conclusively associated with fluid turbulence. The authors noted that for otherwise fixed agitation conditions, the leakage of the dye reduced when the culture medium was formulated with 1% Pluronic F68. The protective effect of the surfactant was apparently linked at least partly with its biochemical association with the cell membrane. The agitation- and vortex-associated hydrodynamic forces were reported to also affect the antigen receptors embedded in the membrane of the hybridoma (86). The number of active surface receptors declined with increasing intensity of agitation and the accompanying increase in the size of the vortex; however, the viability of the cells was unaffected. Pluronic F68 had a protective effect on the receptors.

Pluronic F68 is known to reduce the plasma membrane fluidity (PMF) of cells, and this has been suggested as a possible mechanism of protection (41,121). Other additives that affect PMF also affect a cell's shear tolerance. For example, in one case cholesterol enrichment of the culture medium reduced membrane fluidity and enhanced the shear resistance of hybridomas, whereas supplementing the culture with benzyl alcohol increased PMF and made cells more shear sensitive relative to controls (41,121).

Other protective mechanisms speculated for Pluronic F68 include its stabilizing action on the gas–liquid interface and consequent slower film drainage during bubble rupture (110), improved nutritional transport because of a reduced cell–fluid interfacial tension, and incorporation of the surfactant into the cell membrane accompanied with membrane stabilization (127,128). Although the protective effect of Pluronic F68 is said to be solely due to physical factors (122), the surfactant is known to produce physiological and biochemical effects in at least some cases. Growth suppressing and stimulatory effects of Pluronic F68 have been seen even in some static cultures. Such effects are sometimes associated with impurities in Pluronic F68 samples. Pluronic F68 affects the permeability of some cells. Exposure of *Saccharomyces cerevisiae* to 0.2% (wt/vol) Pluronic F68 for 30 min at 20 °C made the cells more permeable, and they became susceptible to otherwise nonlethal doses of certain antibiotics (129). The mean activity of alcohol dehydrogenase in permeablized cells was more than 3.5-fold of that in normal cells. Although Pluronic F68 could permeablize the yeast cells, it did not inhibit growth or affect cell viability relative to controls when added to culture media at up to 1% (wt/vol), which was the highest concentration tested (129).

Other data suggest that the cell-protective effect of Pluronic F68 may not be quite general (43). For porcine erythrocytes suspended in isotonic buffer, Zhang et al. (43) noted that addition of Pluronic F68 actually increased cell lysis in agitated environments relative to results in the surfactant-free medium. Whether Pluronic F68 incorporates into an erythrocyte's membrane is not known; how-

ever, cholesterol enrichment or depletion of erythrocyte membrane is reported to not affect membrane viscosity and presumably, therefore, fluidity. In addition to Pluronic F68, several other pluronics are known to have a shear-protective capability.

Poly(ethylene glycol). Poly(ethylene glycol) (PEG) supplementation of the medium has a protective effect on some cells but not on others. In one study (129) that employed different PEGs with molecular weights of 400–35,000 Da in the concentration range of 0–2 kg m^{-3}, the polymer had a protective effect in sparged cultures when the molecular weight and the concentration exceeded 1,000 Da and 0.25 kg m^{-3}, respectively. The extent of protection afforded depended on the molecular weight and the concentration used. Under the best conditions, the PEG supplementation reduced the first-order cell death rate constant to 0.5% of the value in the PEG-free medium (130). The PEG additives affected the surface tension of the culture medium; however, in extreme cases the surface tension varied only between $\sim 60 \times 10^{-3}$ and 70×10^{-3} N m^{-1} (130). The pattern (but not the magnitude) of variation in surface tension with addition of PEG was similar to the pattern of change in the death rate constant. This led the authors to suggest that the presence of PEG at the gas–liquid interface was somehow related to the protective mechanism.

Michaels et al. (122) showed that, in sparged bioreactors, supplementing the culture medium with Pluronic F68, fetal bovine serum (FBS), or PEG (8,000 Da, 1 kg m^{-3}) protected cells irrespective of whether the CRL-8018 hybridomas were grown in the presence of the additive, or the additive was added after the damaging levels of agitation were imposed.

Composite Particles and Cell Aggregates

Microbial Biofilms on Suspended Particles. Gas–liquid–solid three-phase suspension reactors are increasingly being used in wastewater treatment (20,131). The suspended solid phase (usually sand, glass beads, or carbon particles) supports a biofilm of waste-degrading microorganisms (132). The hydrodynamic environment of such systems must be tailored to control the biofilm thickness without dislodging it altogether (20). Biofilm slurry reactors are conceptually similar to microcarrier-supported suspension culture of animal cells, but there the similarity ends. Unlike animal cell microcarrier suspensions, the biofilm reactors are much more turbulent, the solids loading is generally higher, the density difference between the solid and the liquid phase is much greater, and the biofilm is typically four or five times thicker than the monolayer of cells on microcarriers.

In studies of degradation of naphthalene-2-sulfonate by *Pseudomonads* immobilized as biofilms on sand particles suspended in an external-loop airlift bioreactor, Wagner and Hempel (133) noted that at solids loadings of 20–30 kg m^{-3}, only about 15–20% of the particles were covered with biofilm, but high solids loadings were necessary to control the film thickness at 75 ± 10 μm by providing a high-attrition environment (133). These observations were for particles about 200 μm in diameter, covered with a biofilm ~ 75 μm thick, suspended in the reactor under fairly turbulent conditions (230–440 W m^{-3} specific power inputs). Even when oxygen limitation is not an issue, diffusion of other substrates limits the useful thickness of microbial biofilm to less than 400 μm in most wastewater treatment operations (131).

The development of microbial biofilms on static surfaces and carriers suspended in airlift bioreactors has been investigated quite extensively (6,7,132,134–140). In one case, 21 carriers were tested at a constant carrier loading of 125 kg m^{-3} (132). The superficial gas velocity was constant at 0.038 m s^{-1}. The hydraulic retention time of wastewater was one or two hours. Based on the tests, carrier diameter and surface roughness were the major factors that influenced biofilm formation (132). Smaller particles, 0.1–0.3 mm in diameter, tended to show better biofilm development. This was said to be due to more frequent collisions among larger particles, causing biofilm detachment (132); however, with larger particles, a greater *severity* of collisions would have been a better explanation (20). For equal mass loadings of solids in two systems, the system with larger particles should have fewer particles per unit volume and, therefore, a lower frequency of particle–particle collisions. Cell disruption experiments in agitated slurries of glass beads confirm this (11). The explanation for the impact of surface roughness on biofilm formation lay in the fact that a rough surface provided many relatively protected, low-shear sites where microbial colonies could take hold in the process of gradually spreading over the whole surface. Based on the criteria of surface roughness, particle size, cost, and the requirement of a high-density carrier for ease of separation, basalt (ρ_S = 2,900 kg m^{-3}) was the best carrier (132).

Irrespective of carrier type, biofilm formation is favored at relatively high dilution rates when any detached cells are rapidly washed out (132,136). Tijhuis et al. (136) have shown that during start-up at high dilution rates, the concentration of bare carriers declines as an increasing number are covered with the biofilm. The total amount of the biomass in the reactor increases, but the amount per carrier remains constant until most of the carriers are covered. With few bare carriers remaining, the extent of abrasive loss of film declines, and the film thickness begins to increase until a stable thickness is reached (136). These observations suggest that varying the reactor operation to suit different stages of film development may be worthwhile (20).

In other similar work, detachment of biomass from nongrowing biofilms supported on carriers suspended in four configurations of draft-tube sparged internal-loop airlift reactors was examined (139). The superficial aeration velocity in the riser varied over the approximate range 0.03–0.09 m s^{-1}. The detachment of biomass from biofilm-covered carriers in the presence of bare solids was dominated by collisions between bare carriers and the covered particles (139,140). The concentration of bare solids and the particle roughness strongly influenced the detachment rate (139). For otherwise identical conditions, biofilm detachment due to bare carriers increased in the following order: glass, sand, basalt. The glass particles were the most round and smooth; the basalt carriers were the

roughest. Whereas biofilms develop more easily on rough surfaces (132), once developed, the film is readily damaged by biofilm-free rough carriers. Gjaltema et al. (139) observed that a "change in flow regime from bubbling to slug flow considerably increased the detachment rate." This change apparently occurred at a U_{Gr} value of $\sim$0.06 m s^{-1}. The "slug flow" regime noted by Gjaltema et al. (139) was more likely the highly chaotic churn turbulent regime in which particle-to-particle collisions are more frequent and severe than in the bubble flow regime. The bottom clearance of the draft tube had no effect on detachment rate (139), but only a small range of the A_d/A_b ratios was investigated. The volume fraction of carriers was 3.3–3.8%, and other properties were: basalt, d_p = 0.32 mm, ρ_S = 3,010 kg m^{-3}; sand, d_p = 0.31 mm, ρ_S = 2,606 kg m^{-3}; and glass, d_p = 0.28 mm, ρ_S = 2,887 kg m^{-3} (139). Another similar study focused on the effects of particle shape, structure, and concentration on biofilm detachment (140).

Strategies for development of biofilms with nitrification activity on carriers suspended in draft-tube sparged internal-loop airlift reactors were investigated by Tijhuis et al. (141) and van Benthum et al. (138). The development of the nitrifying films was similar to what had been reported for heterotrophic biofilms (134–137); however, the nitrifying films were more robust (141). This suggests that biofilms formed by different microorganisms can have markedly different physical properties and strength of attachment to substrate (20); hence, the operating regime of the reactor and, in extreme cases, the design peculiarities are likely to be affected.

In further studies of the dynamics of biofilm detachment from carriers suspended in airlift reactors, Tijhuis et al. (135,137) noted that the common assumptions of uniform growth and detachment of biomass over the surface of the film under fixed hydrodynamic conditions were inconsistent with observations. Instead, nonuniform local detachment of biofilm with formation of cracks and fissures on the surface and rapid filling of the spaces formed with new growing biomass was proposed as a more realistic picture of film dynamics (135).

During development of mixed bacterial biofilm on a static glass surface in a rectangular turbulent flow cell, Stoodley et al. (7) noted that parts of the biofilm sloughed off at a wall shear stress level of 1.32 N m^{-2}. In the region of detachment, pieces of the biofilm were still attached to the surface, suggesting that the glass-to-biofilm bond was stronger than the biofilm structure (7). Relative to the clean flow cell, the pressure drop through the channel was higher in presence of the biofilm (7), presumably because a patchy development of the film increased the effective surface roughness.

Flocs and Agglomerates. Microbial flocs are encountered in several commercially relevant processes, especially in wastewater treatment and beer fermentation with autoflocculating yeasts. Similarly, agglomerates of protein precipitates form during certain recovery operations. The size of flocs and agglomerates often needs to be preserved or increased during processing. Stable size of aggregates and flocs, and whether the flocculated mass further increases in size or breaks up, depends on the level of turbulence in the suspending fluid. Turbulent stress levels below about 0.75 N m^{-2} are generally too mild to break aggregates (142). Physical disruption of aggregates commences at stress levels of $\sim$2.6 N m^{-2}, and especially when the stress level exceeds about 5 N m^{-2} (142). In a turbulent field, aggregates may deform or breakup because of the influence of instantaneous velocity differences acting on different parts of the floc (143). Also, turbulent drag forces originating from the local motion of the fluid relative to the aggregate may contribute to fragmentation (142). The shear force across the aggregate due to instantaneous velocity difference is related to the energy dissipation rate in the fluid and the size of the aggregate (142); thus,

$$F_s = \frac{\pi}{4}(\rho_L \mu_L E)^{1/2} d_F^2 \tag{41}$$

The dynamic pressure fluctuations acting on opposite sides of the floc create a normal stress. Assuming that the eddy size is in the Kolmogoroff microscale range and that the particle dimensions are similar to those of the eddies, the normal force can be expressed as follows (142):

$$F_n \propto \left(\frac{E}{\mu_L}\right)\rho_L^2 d_F^2 \tag{42}$$

The turbulent drag force acting on an aggregate may be calculated using the expression (142)

$$F_D \propto \frac{C_D}{2}\left(\frac{d_F}{2}\right)^3 (\Delta u d_F)^2 \rho_L \tag{43}$$

where Δu is the difference in velocities of the particle and the fluid, and C_D is the drag coefficient. For low-density particles in the Stokes regime ($Re < 1$), the drag coefficient equals $24/Re$, where Re is the Reynolds number, or $(\rho_L \Delta u d_F)/\mu_L$. Reynolds shear stresses (i.e., turbulent stresses associated with the fluctuating component of the mean velocity) may be calculated using the equation (144)

$$\tau = 0.37\rho_L\left(\frac{E\rho_L}{\mu_L}\right)d_p^2 \tag{44}$$

which applies to stresses around a spherical particle. Reynolds stresses are independent of viscosity.

The maximum stable size of the aggregate in a turbulent field can be established by a force balance on a particle: at stable size the instantaneous turbulence force accelerating the particle just equals its mechanical strength (142). In the inertial subrange of turbulence when the eddy size is greater than the Kolmogoroff scale (l),

$$d_{F\ max} \propto \left(\frac{\rho_L \sigma_M}{\mu_L}\right)^{1/3} E^{-1} \tag{45}$$

whereas in the viscous subrange of turbulence when the eddy size is $\leq l$, we have

$$d_{F\ max} \propto \left(\frac{\sigma_M \mu_L}{\rho_L^2 E}\right)^{1/2} \quad (46)$$

where σ_M is the mechanical strength of the aggregate. In practice, the maximum stable floc size has correlated with the energy dissipation per unit mass of fluid,

$$d_{F\ max} \propto \Gamma E^{-m} \quad (47)$$

where the coefficient Γ depends on the nature of the particle, and m is usually between 0.2 and 0.4 (145).

In stirred tanks, the maximum floc size for particles of uniform composition has been theoretically and experimentally correlated with the rotational speed of the impeller (143); thus,

$$d_{F\ max} \propto N^{-1.5} \quad (48)$$

which applies to particles smaller than the microscale of turbulence. The dependence shown in equation 48 can be expressed in terms of the energy dissipation per unit mass; hence,

$$d_{F\ max} \propto E^{-0.5} \quad (49)$$

Expression 49 is consistent with that reported by Thomas (143), but the exponent on E is somewhat stronger than the values noted by Gregory (145) (see equation 47). In precipitation vessels, shear rate values of $\sim 80\ s^{-1}$ appear to be a damaging threshold for soya protein precipitate particles of 20–30 μm initial size (5). Particles exposed to approximate shear rates of $\geq 80\ s^{-1}$ over 10–12 min would be reduced to 5–8 μm. The shear rate numbers were calculated from the specific energy dissipation rates in the vessels, as follows:

$$\gamma = \left(\frac{\rho_L E}{\mu_L}\right)^{0.5} \quad (50)$$

Protein precipitates are easily damaged by pumping. Moyno screw pumps, centrifugal pumps, and gear pumps all damage precipitates to similar levels (5). Peristaltic pumps are apparently the only suitable ones.

Fragmentation of mycelial pellets of the molds *Lentinus edodes* and *Aspergillus niger* in a standard Rushton turbine stirred tank was examined by Taguchi et al. (145). Two types of pellet fragmentation patterns were noted: (*1*) decrease in diameter by erosion of surface, and (*2*) direct rupture of the spherical pellet. The rates of these processes were expressed as

$$-\frac{dd_p}{dt} = k_j (N d_i)^{5.5} d_p^{5.7} \quad (51)$$

for pellet surface erosion, and

$$-\frac{dN_p}{dt} = k' N_p = \alpha (d_p^{3.2} N^{6.65} d_i^{8.72})^{5.5} N_p \quad (52)$$

for rupture of the particle. In equations 51 and 52, d_p is the pellet diameter at time t, N is the rotational speed of the impeller, d_i is the impeller diameter, N_p is the concentration of unbroken pellets at time t, and k_j, k', and α are constants. Clearly, the rates of pellet erosion and rupture depend strongly the agitation intensity–associated factors (i.e., on N and d_i) and the dimensions of the pellet.

In submerged stirred-tank culture of the filamentous fungus *Aspergillus awamori*, Cui et al. (147) correlated the pellet size with the specific energy dissipation rate; thus,

$$d_p \propto E^{-0.16} \quad (53)$$

The E values varied over 0.2–5.7 W kg^{-1} (146), whereas the pellet diameter ranged roughly over 1–2 mm. The length of the "hairy" hyphal extensions from the well-defined surface of the denser pellet also correlated with the specific energy dissipation rate (147); thus,

$$L_h = 1.17 \times 10^{-4} E^{-0.25} \quad (54)$$

where L_h (m) is the length of the hairy extensions.

Bioactive Proteins

Enzymes are not generally susceptible to the shear rates that are commonly encountered during processing including high-shear operations such as cell disruption (1). Exceptions occur when shear stresses are applied in the presence of gas–liquid interfaces, at which proteins tend to unfold (1,8,148). Also, membrane-associated proteins are more prone to shear damage (1). In addition to processes such as high-pressure homogenization, high-shear processing of proteins occurs during liquid–liquid emulsification, which is used to produce microencapsulated proteins for drug delivery systems (149). Effects of extremely high shear rate levels ($>10^5\ s^{-1}$) on recombinant human growth hormone (rhGH) and recombinant human deoxyribonuclease (rhDNase) were examined by Maa and Hsu (149). The rhGH and rhDNase had respective molecular masses of 22.13 kDa and 32.74 kDa. The shearing was done at a controlled temperature of 20 °C. The aggregation and the bioactivity of the two proteins were not significantly affected at shear rates greater than $10^5\ s^{-1}$ applied over 60 min in the absence of gas–liquid interfaces (148,149). Thermodynamic properties of the proteins were determined before and after shearing using scanning microcalorimetery (SM). Alterations in secondary and tertiary structure of a protein are manifested in its scanning calorimetery data. The SM thermograms of rhDNase were not significantly affected by shearing; however, for rhGH, the SM indicated possible conformational changes (149). The silver-stained SDS-PAGE gels of rhGH showed no significant differences in the high molecular weight region, but low molecular weight fragments were observed in the sheared sample, which suggested some clipping of rhGH in the intense shear field. No significant changes were noted in the SDS-PAGE gels of sheared and unsheared rhDNase (148). If a globular protein's molecular weight is assumed to indicate it's size, the rhDNase molecule should be larger by a factor of approximately $(32.74/22.13)^{1/3}$, or 1.14, relative to the rhGH. It seems therefore that the molecular size is

not the sole determinant of a protein's susceptibility to damage; the specific structure or morphology also appear to play a role.

The damaging effect of shear in presence of gas–liquid and solid–liquid interfaces may be reduced by supplementing the protein solution with a surfactant. Added surfactants tend to reduce gas–liquid interface–induced aggregation and precipitation of rhGH (148). Proteins also adsorb on hydrophobic solid surfaces. Adsorption of insulin at hydrophobic surfaces, accompanied by denaturation, is well known. Similarly, tPA is known to adhere to solid surfaces (150), but the surface adherent tendency is reduced in presence of surfactants such as Tween-80 (polyoxyethylene sorbitane monooleate) added at 0.01% typical concentration (150). Shear susceptibility of proteins is further discussed elsewhere (5,151).

CONCLUDING REMARKS

Biocatalysts, especially molds, filamentous bacteria, certain microalgae, and plant and animal cells are susceptible to damage by hydrodynamic and mechanical forces encountered in bioprocessing. Typically, recombinant strains are more prone to shear damage than equivalent wild types. Extent of damage depends on the cell and the specific damaging mechanism operating. Often, the damage may be reduced by one or more of several approaches: adaptation of cells, supplementing culture media with shear-protectants, modification of processing operations and equipment, and other methods. In many cases, the mechanisms of protection and damage are not entirely clear, but multiple mechanisms seem to operate. As noted throughout this monograph, some sound guidance is available for engineering and operation of fragile culture processes; nevertheless, a priori quantitative prediction of culture behavior is not reliably possible. Empirical approaches must continue to be relied upon in engineering practice.

NOMENCLATURE

A_b	Cross-sectional area under the baffle or draft tube (m^2)
A_d	Cross-sectional area of the downcomer (m^2)
A_r	Cross-sectional area of the riser (m^2)
a	Parameter in equation 2
C_D	Drag coefficient
C_f	Fanning friction factor
d	Diameter or hydraulic diameter (m)
d_B	Bubble diameter (m)
d_c	Cell diameter (μm)
d_F	Floc diameter (m)
d_{Fmax}	Maximum stable diameter (m)
d_i	Impeller diameter (m)
d_L	Local diameter (m)
d_p	Microcarrier or particle diameter (m)
d_T	Tank or column diameter (m)
E	Energy dissipation rate per unit mass (W kg^{-1})
F_D	Turbulent drag force on a particle (N)
F_n	Normal force on a particle (N)
F_s	Shear force across the aggregate due to instantaneous velocity difference (N)
g	Gravitational acceleration (m s^{-2})
h	Channel height (m)
h_L	Height of liquid (m)
ICS	Impeller collision severity defined by equation 39 (kg m^{-2} s^{-3})
ISF	Integrated shear factor defined by equation 33 (s^{-1})
K	Consistency index (Pa s^n)
k	Parameter in equation 2 (m^{-1})
k'	Constant in equation 52 (s^{-1})
k_d	Death rate constant (s^{-1})
k_i	Constant in equation 9
k_j	Constant in equation 51 ($s^{4.5}$ $m^{-10.2}$)
L	Channel length (m)
L_h	Length of hairy extensions from pellet surface (m)
l	Mean microeddy length (m)
m	General exponent
N	Rotational speed (s^{-1}) or cell concentration (m^{-3})
N_o	Initial cell concentration (m^{-3})
N_p	Concentration of unbroken pellets at time t (m^{-3})
n	Flow behavior index
n_B	Number of impeller blades
Po	Power number
ΔP	Pressure drop (Pa)
Q	Volume flow rate of gas (m^3 s^{-1})
Re	Reynolds number
Re_i	Impeller Reynolds number defined by equation 36
Re_L	Local Reynolds number defined by equation 23
r_c	Radius of the vortex zone defined by equation 35 (m)
r_i	Impeller radius (m)
r_T	Tank radius (m)
S	Burst strength (N)
TCS	Turbulent collision severity for particle-to-particle collisions (kg m^{-2} s^{-3})
t	Time (s)
U_B	Bubble rise velocity (m s^{-1})
U_G	Superficial gas velocity (m s^{-1})
U_{Gr}	Superficial gas velocity in riser (m s^{-1})
U_L	Average liquid velocity (m s^{-1})
u	Mean velocity of the microeddies (m s^{-1})
Δu	Difference in velocities of the particle and the fluid (m s^{-1})
u_o	Jet velocity at orifice (m s^{-1})
V_k	Dimensionless hypothetical specific killing volume

V_L Volume of liquid (m^3)
W Width of the impeller blade (m)
x Parameter in equation 19

Greek Symbols

α Constant in equation 52 ($s^{35.575}\ m^{-65.56}$)
Γ Coefficient in equation 47
γ Shear rate (s^{-1})
γ_{av} Average shear rate (s^{-1})
$\gamma_{av\cdot T}$ Time averaged shear rate (s^{-1})
γ_i Isotropic turbulence shear rate defined by equation 24 (s^{-1})
γ_{max} Time averaged maximum shear rate (s^{-1})
γ_w Wall shear rate (s^{-1})
ϵ_S Volume fraction of microcarriers or solids (−)
μ_{ap} Effective or apparent viscosity (Pa s)
μ_L Viscosity of liquid (Pa s)
π Pi
ρ_L Density of liquid (kg m^{-3})
ρ_S Density of microcarriers or solid (kg m^{-3})
σ_M Mechanical strength of aggregate (N m^{-2})
τ Shear stress (N m^{-2})
τ_w Wall shear stress (N m^{-2})

Solid-state fermentation
Transport phenomena

OUTLINE

INTRODUCTION

Solid-state fermentation (SSF) involves the growth of microorganisms on moist solid substrates in the absence of free water. The absence of free water makes the system quite different from submerged liquid fermentations and makes SSF superior for the production of some products. However, compared with submerged liquid fermentation, relatively little is known about how to design and operate bioreactors for large-scale SSF processes.

Despite this, there are commercially successful large-scale SSF processes for the production of soy sauce koji and other traditional fermented foods, citric and gluconic acids, and fungal enzymes such as cellulases, amylases, lipases, and pectinases (1,2). In addition, fungal spores have been produced by SSF for use in steroid transformations and as inocula for production of blue-vein cheeses (2). Composting is another SSF application that is widely practiced, although composting is different from other SSF processes, because self-heating of the fermenting substrate is desired in composting processes, whereas avoidance of overheating is a key problem in most SSF processes.

In addition to these commercial processes, over the last 20 years there has been a growing interest in other SSF applications (2), including the following:

- Upgrading of solid wastes from agriculture and food processing for use as fermented animal feeds. In some cases the microorganism is used to enrich the protein content; in other cases it is used to degrade toxic substances in the waste.
- Production of fungal spores for use as mycopesticides. SSF is superior for the production of fungal spores because most fungi do not sporulate well in liquid culture, and even when they do, spores produced in SSF tend to be more robust.
- Production of other enzymes such as dehairing enzymes, fungal rennets, beta-glucanases and xylanases.
- Biopulping of woodchips during the production of paper.
- Production of various other products such as gibberellic acid, aroma and flavor compounds, antibiotics, and ethanol.

Unlike the situation with submerged liquid fermentations, there is no systematic framework guiding the design and operation of large-scale bioreactors for SSF. As a result, there has been relatively little success in developing successful large-scale processes for these newer SSF products, although large-scale bioreactors have been used to

make soy sauce koji. Intermediate-scale processes can be carried out using tray fermentations, but such operations are quite labor intensive. Mathematical models of bioreactor operation will be key tools in the development of strategies for the design and operation of large-scale SSF bioreactors. This article summarizes the current state of development of modeling of SSF processes.

AIMS OF THIS ARTICLE

This article addresses the importance, to the development of large-scale SSF technology, of understanding and modeling microbial growth kinetics and transport phenomena, which combine to determine the overall performance of a solid-state bioreactor. Transport phenomena are of special importance in SSF due to the unavoidable heterogeneity of SSF systems. Good reactor performance will be achieved only through an understanding of these transport phenomena and how they interact with the microbial growth kinetics. Mathematical models represent a convenient, concise, and powerful way of describing these phenomena and their interactions and provide a sound foundation for process development, control, and optimization. They can also guide us in learning where the problems are and how to attack them.

The main message of this article is that modeling of phenomena in SSF and of the performance of SSF bioreactors has not yet progressed to a stage where it can be usefully applied to industrial applications. In fact, it was only in 1990 that the first model was proposed for SSF bioreactor operation (3). Although advances have been made since then, currently we still do not have mechanistic models of SSF that are able to make accurate predictions based fully on independently determined parameter values. To date the focus has been on appropriate model structures. Relatively little attention has been given to parameter estimation, with many parameters being borrowed from other systems, systems that often involve different substrates, organisms, and cultivation systems. As a result, none of the models has been properly validated against experimental data, and although the models are now being used to predict improved operating conditions, they have not yet been used to improve operation of actual bioreactors. In most cases some of the model parameters have been estimated by adjusting them to enable the model to fit the experimental data. Furthermore, although the ultimate aim of SSF processes is to produce useful products industrially, to date models have focused on growth. In fact, in some cases the main aim has been to predict temperatures rather than growth itself.

The aim of this article is to draw together the basic principles from the work that has been done so far, to show the general concepts that underpin all models, to identify the features that will make models most useful for application in industrial processes, and thereby to provide a foundation for continued progress in the modeling of SSF.

ORGANIZATION AND SCOPE

Filamentous fungi are the most important group of microorganisms used in SSF, and most processes are aerobic. Most of the work discussed in this article addresses this type of system, although other systems are mentioned as appropriate.

The article begins by describing the biological and transport phenomena occurring in an SSF bioreactor and identifying the various phenomena that can potentially limit the kinetic performance of the bioreactor:

- Microbial growth phenomena
- Local transport phenomena (occurring at the level of a single particle)
- Bulk transport phenomena (occurring at the level of the whole bioreactor)

Current models of SSF address the influence of either local or bulk transport phenomena on growth and are therefore labeled as microscopic or macroscopic models. The general aims and usefulness of these two types of models are discussed. The mathematical expressions appropriate for describing the three types of phenomena that may be incorporated into these models are discussed in turn.

Readers interested in modeling of SSF processes are urged to consult the original references because no attempt has been made to present the complete models of individual workers. The original articles do that better than we could hope to do. Rather we have organized this article around the ways in which the various kinetic and transport phenomena have been handled. Therefore, where we present equations, these have been separated from the author's discussion of their underlying assumptions and the notation and units they have used.

DESCRIPTION OF KEY FEATURES OF SOLID-STATE FERMENTATION

Growth in an SSF bioreactor results from and is influenced by processes operating at different scales (Fig. 1): microbial processes and local and bulk transport processes. Figure 1 also highlights some of the complex interactions between these phenomena during SSF. This article addresses the approaches that have been made to modeling the various phenomena shown in Figure 1, and the interactions between the various phenomena. Thermodynamic phenomena, such as the ability of solid substrates to absorb heat and the ability of gases to carry water vapor, also affect the overall bioreactor performance; however, these phenomena are not addressed in this article.

In developing a mathematical model, it is important to identify the processes occurring before attempting to describe them mathematically. This focuses attention on the processes that are potentially rate limiting. An understanding of the rate-limiting processes facilitates development of strategies to overcome the limitation, although SSF processes can be difficult to optimize because the limiting step might be different under different conditions, and at different stages of an SSF process the growth rate may be limited by different phenomena. Therefore this section provides a qualitative description of our current understanding of the phenomena occurring in SSF.

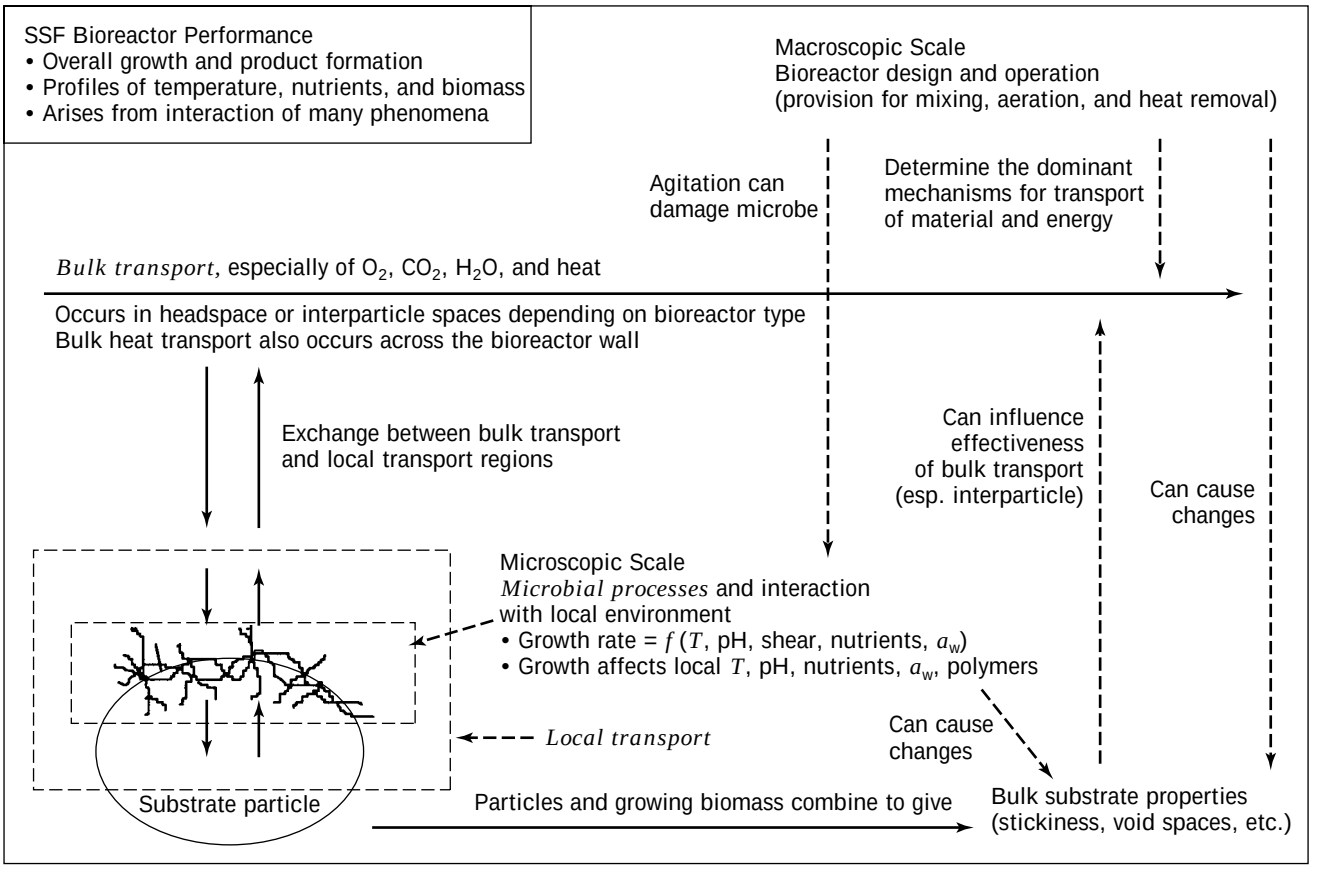

Figure 1. An overview of the microscopic and macroscopic processes that combine to determine the overall performance of an SSF bioreactor. This diagram describes transport processes in general terms and does not identify all the individual mass and heat transfer processes occurring. Although the diagram represents an SSF bioreactor, it is not drawn to scale. The nature and extent of the local and bulk transport regions depend on the particular bioreactor and how it is operated.

The Physical Nature Of Solid-State Fermentation Systems

From a macroscopic viewpoint, up to four subsystems are apparent (Fig. 2), depending on the bioreactor type: the material from which the bioreactor is constructed, a headspace containing gases, the solid particles themselves, and the interparticle gas phase entrapped between the solid particles. It is often appropriate to think of the solid particles and interparticle gas as a pseudohomogeneous "substrate bed."

From a microscopic perspective the system is considered in greater detail. The description focuses on the region near an individual particle and can include (Fig. 3) the following:

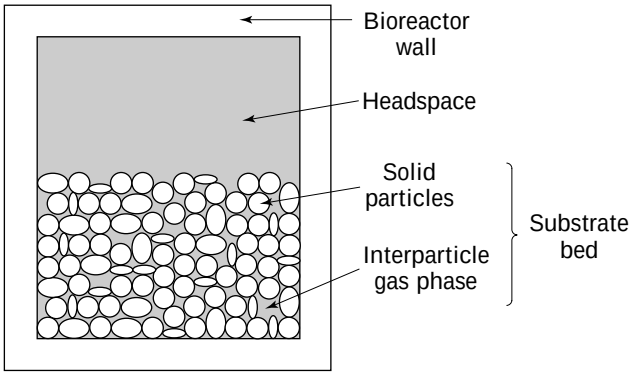

Figure 2. Subsystems within a solid-state fermentation bioreactor.

- The biomass, the majority of which is concentrated as a layer at the particle surface. Part of the fungal mycelium is immersed in the liquid film at the surface, but many hyphae extend into the gaseous region. These aerial hyphae may support films or droplets of water. Other hyphae may penetrate into the substrate particle. In contrast, yeasts and bacteria form a compact moist layer on the particle surface.
- The solid matrix, which provides the physical support for the liquid and biomass phases, and which may or may not be degraded during the fermentation.
- A liquid phase consisting of a stagnant liquid film at the substrate surface and the moisture inside the particle. This phase may be continuous, depending on the internal structure of the substrate particle.

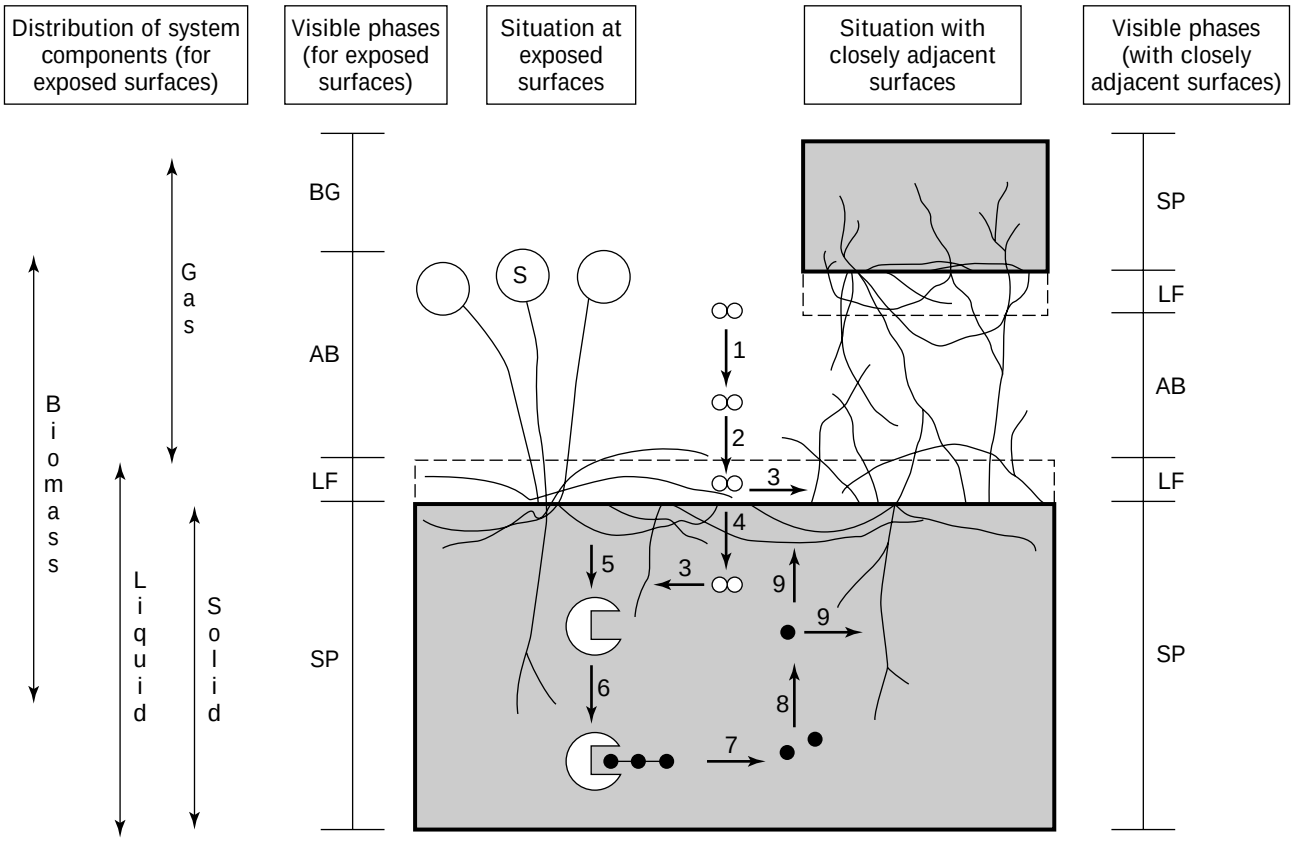

Figure 3. Structure of SSF systems at the microscopic scale and local mass transport processes. The example is for growth of a filamentous fungus, such as *Rhizopus* sp., on a starchy substrate. The diagram represents a cross-sectional view near the surfaces of the substrate particles and indicates the difference between substrate particles exposed to the bulk gas phase and substrate particles that are packed closely together. Simplifications, such as the absence of penetrative hyphae, and the liquid film as the only site of O_2 uptake, have been used in modeling studies. ∞, oxygen; ●, glucose; ●—●—●, starch; S, sporangium; SP, substrate particle; LF, liquid film; AB, aerial biomass; BG, bulk gas. The processes occurring are 1, bulk transport of oxygen; 2, diffusion of O_2 through stagnant gas regions and diffusion across the gas–liquid interface; 3, uptake of oxygen by hyphae; 4, diffusion of oxygen through the liquid phase of the substrate; 5, release of glucoamylase from the hyphae; 6, diffusion of glucoamylase through the solid substrate particle; 7, hydrolysis of starch by the glucoamylase; 8, diffusion of the released glucose through the solid substrate particle; 9, uptake of glucose by the hyphae.

- A gaseous phase. Although this gas phase is continuous, it may be conceived as comprising up to three regions. First, the aerial hyphae of the biomass are surrounded by regions of stagnant gas, and there will be a stagnant gas film adjacent to the liquid film. Second, there may be a stagnant gas region above the biomass region (i.e., part of the interparticle space). Third, there may be a mobile region in which there is bulk flow. The locations and extents of the stagnant and mobile gas regions will depend on whether the substrate bed is agitated and how it is aerated. For example, in static packed beds the interparticle spaces are filled with a network of hyphae, but there is still bulk gas flow through parts of this region. On the other hand, in tray bioreactors, the gas phase within the substrate bed is relatively stagnant, although there may be some free convection due to thermal gradients.

The Processes Occurring During Solid-State Fermentation

Aufeuvre and Raimbault (4) described the changes in morphology during growth of the filamentous fungus *Aspergillus niger* in a packed bed bioreactor, on a granular substrate prepared from cassava flour. Initially, the spores used as inoculum are spread across the substrate surface. During the germination period of about 8 h, the spores swell and then extend germ tubes across the substrate surface. These germ tubes extend for up to 50 μm before branching begins. Branching of these germ tubes then rapidly leads to a loose covering of hyphae across the whole surface. As branching continues, the hyphal density increases, and it is soon impossible to distinguish individual mycelia. The network of hyphae increases in thickness, so that many hyphae are not in contact with the substrate surface. Some hyphae form together into multihyphal filaments, which can extend up to 80 μm above the substrate

surface. These filaments form bridges between the substrate granules and bind the whole bed of substrate particles together into a single compact mass.

This description addresses only the features of the growth process that can be seen with a microscope. Many less obvious processes are occurring and influencing growth (Fig. 3). The growth activities of the microbe are determined by the local environment experienced by the microbe, especially the local temperature, pH, water activity (a_w), oxygen concentration, and nutrient concentrations. In turn, growth processes also affect the local environment, for example, hydrolytic enzymes are secreted, carbon and nitrogen substrates are absorbed into the mycelium, oxygen is consumed, and various products are excreted. In addition, waste metabolic heat is released by the microorganism. Therefore the temperature, pH, water activity, and oxygen and nutrient concentrations in the local environment are affected by the microorganism. This induces the transport processes, which tend to equilibrate chemical potential and temperature throughout a material. Within solid particles and within stagnant gas regions, mass transfer is limited to diffusion and the exchange of gases (O_2, CO_2, and water vapor) at gas–liquid interfaces, and heat transfer is limited to conduction, free-convection, and evaporation of water at the gas–liquid interface. These dissipative processes can be relatively slow compared with the rate of the microbial processes, leading to the establishment of local concentration and temperature gradients around the microbe.

The purpose of a bioreactor is to maintain an optimal local environment for the desired microbial activity, within the limits of physical and economical constraints. In SSF the ability to control the local environment is largely limited to manipulating either the bulk gas flow or agitation of the substrate, or both, providing oxygen for aerobic processes, removing carbon dioxide and evaporated water, and removing heat. Almost nothing can be done during the fermentation to prevent nutrient concentration gradients within individual substrate particles, because it is not possible to have bulk mixing below the scale of the substrate particles. This is an intrinsic consequence of the physical form of SSF systems.

Given that control of the environment is achieved by manipulating the bulk phases, the rate of removal of heat and the rate of supply of oxygen can be maximized by minimizing gradients within the bulk gas phase and minimizing the thickness of the stagnant gas film that separates the bulk gas phase from the local environment. Different reactor types enable this to be achieved to different extents. In bioreactors with bulk flow of air past the solids, due either to forced airflow or to mixing of the substrate bed, gases diffuse from the stagnant gas regions into the bulk flow and are carried away. Heat can be removed by convection and by evaporation of water into this air. Evaporative heat removal can be maximized by aerating with dry air, but this will tend to dry the substrate. Depending on the bioreactor operation there might be significant gas concentration gradients and temperature gradients in the bulk air phase across the bioreactor. Plug flow of gas (and maybe substrate) will tend to favor macroscopic gradients, whereas mixing of the gas phase and of the substrate bed will tend to minimize such gradients. In bioreactors without bulk flow of air past the solids (i.e., trays), mass transfer and heat transfer occur mainly by diffusion and conduction, respectively. In addition to heat and mass transfer within the bioreactor, there are also heat transfers between the substrate bed and the bioreactor wall, the headspace gases and the bioreactor wall, and the bioreactor walls and the surroundings (Fig. 1).

During microbial growth in SSF, growth activities and the aeration and agitation strategies can affect the bulk substrate properties, which in turn can influence the bulk transport processes, as indicated in Figure 1. For example, in an unstirred packed bed, fungal mycelia grow in the interparticle spaces and can significantly increase the pressure drop through the bed, affecting airflow patterns within the bed (5). Microbial activities on the substrate may decrease the strength or increase the stickiness of the particles, leading to compaction or cohesion of particles when the substrate is agitated, thereby eliminating interparticle spaces and preventing bulk transport to or from the microbes within the bed.

In conclusion, there can be significant profiles of temperature, nutrients, and biomass at both the microscopic scale (looking at a single particle with a microbe growing on it, as shown in Fig. 3) and the macroscopic scale (looking across the bioreactor as a whole, as shown in Fig. 1). The success of transport processes at both these scales in dissipating thermal and concentration gradients determines how readily the local conditions can be maintained near the optimal state for the desired microbial activity. Therefore, the overall performance of an SSF bioreactor arises from the interaction of biological growth kinetics, local transport processes, and bulk transport processes. The next section discusses the nature of models of SSF in general terms, whereas the remaining sections address how the underlying phenomena have been described in mathematical models of SSF processes.

Approaches to Modeling Solid-State Fermentation

A fully mechanistic description of the bulk and local transport processes occurring within SSF (Figs. 1 and 3), when combined with the growth kinetics, would lead to a very complex model of the system. Models of SSF to date have focused on either local or bulk transport phenomena, and therefore it is convenient to classify the models as being either microscopic models or macroscopic models. Microscopic models concern themselves with growth at the level of individual particles, whereas macroscopic models describe overall bioreactor performance. Both types of models have a role to play in the development of SSF technology. However, in the future, models should be developed that integrate mechanistic descriptions of both local and bulk transport phenomena, although this will depend on further advances in computing power and methods for constructing and solving complex dynamic models. Such models will describe performance under a wide range of operating conditions. This trade-off between the power of the model and the ease of model solution should be kept in mind. As well, the purpose of the model and the ability to estimate parameters should be considered when develop-

ing models that incorporate both microscopic and macroscopic phenomena. Because microscopic and macroscopic models are currently developed separately, the modeling work usually has related but different aims.

Microscopic models combine local transport phenomena (Fig. 3) and the effect of the local environment on growth, in an attempt to identify the mechanisms by which these may control the growth rate and the total amount of growth that occurs during SSF. For example, due to the absence of mixing at the microscopic scale, diffusive phenomena within the substrate particle can limit the growth rate (6). Microscopic models tend to consider the biomass in more detail than do macroscopic models, and it may be appropriate to describe variations in hyphal density in space, or the presence of differentiated forms of biomass. However, for the modeling of bioreactor performance, it is not appropriate to describe the extension and branching of individual fungal hyphae. Models incorporating these growth phenomena are powerful tools for fundamental studies aimed at understanding the mechanisms of fungal growth but are not discussed in this article.

Macroscopic models attempt to describe the performance of the whole bioreactor (Fig. 1). Such models may be developed to contribute to various aspects of bioreactor development such as design, operation, scale-up, control, and optimization. The main aim is to describe growth, although this may require prediction of temperature or nutrient or oxygen concentrations, or properties of the substrate bed. Their level of sophistication is in keeping with the ability or lack of ability to measure fermentation parameters such as biomass, nutrient concentrations, gas concentrations, temperature, and pH. Macroscopic models should describe the phenomena controlling the bioreactor performance, but current macroscopic models simply combine bulk transport phenomena with empirical descriptions of microbial growth. They do not address local transport phenomena, because of the complexity that these introduce. Simple empirical descriptions of growth may subsume biological and local transport limitations on growth but conceal the mechanisms of the limitation. Therefore, current macroscopic models are most useful for determining whether bioreactor performance is limited by gas or heat exchange, and guiding bioreactor design and operation to overcome any such limitations.

Several other characteristics of SSF lead to common features of models:

- The vast majority of SSF processes are batch processes, and the few continuous processes involve plug flow systems rather than well-stirred vessels. Therefore dynamic models are most useful for describing SSF. Steady-state models are usually not appropriate.
- The presence of mass and thermal gradients means that in most cases it is desirable to include spatial coordinates in addition to the temporal coordinate. Unfortunately this makes the equation sets more complicated to set up and solve.
- Balances are commonly set up over more than one of the subsystems shown in Figure 2.
- Depending on what is expected to limit growth, either heat or mass transfer may be described. Models incorporating both of these transport phenomena will be most flexible in describing what controls the rate of growth under a wide range of operating conditions.
- Due to the complexity that transport phenomena introduce into problems, plus the difficulties of measuring biomass and metabolic states, the majority of models for SSF are unstructured and nonsegregated, although some do have very simple structure or segregation.

The remaining sections discuss the various expressions that have been used within models of SSF to describe microbial, local transport, and bulk transport phenomena in SSF.

MODELING OF MICROBIAL PHENOMENA

This section addresses microbial phenomena and how models of SSF have treated these phenomena. It focuses on studies of either SSF itself or similar systems involving overculture on solid nutrient media. Overculture occurs when a fungus is inoculated across the whole surface, and therefore the mycelium develops simultaneously from many points. This contrasts with colony growth, where the organism is inoculated at one point, and a colony spreads outward across the surface. The kinetics of colony growth on agar plates are not considered in this article. Note also that the word biomass is used here in the restrictive sense of microbial biomass, and not in the broad sense of agricultural biomass. This distinction is important because many substrates are of agricultural origin.

A word of warning is appropriate about modeling growth kinetics. The basis for expression of the microbial biomass must be clear (e.g., total biomass in the bioreactor, or biomass per kilogram of initial dry substrate, or biomass per kilogram of wet substrate present, etc.), and conservation equations must originally be formulated on a conserved quantity (i.e., absolute amounts of biomass rather than biomass concentrations). This is crucial in SSF because there is a significant decrease in substrate mass due to conversion of dry matter to CO_2, and therefore increases in biomass concentration result from two effects: the increase in the overall amount of biomass, plus the decrease in the overall amount of dry matter. Water transfer between the substrate and gas phases causes further complications if concentrations are expressed on a wet substrate basis. Due to the wide range of ways that different workers have expressed biomass, we have used general equations in which the variables X and S represent absolute amounts of biomass and substrate respectively, whereas the variables C_X and C_S represent concentrations. Rates are expressed as mass or energy per unit time and are represented by the symbol r with a subscript. Readers should refer to original articles to find the units and nomenclature used by the authors.

Substrate-Independent Growth Kinetic Equations

Sangsurasak et al. (7) note that four general shapes of growth kinetic profiles in SSF have been reported. In SSF

models the simplest kinetic expressions describing these profiles relate the growth rate (r_g) directly to the biomass:

- Linear growth kinetics, described by

$$r_g = \text{constant} \tag{1}$$

  where r_g is the rate of growth.
- Exponential growth kinetics, described by

$$r_g = \mu_m X \tag{2}$$

  where μ_m is the observed maximal specific growth rate.
- Early acceleration followed by deceleration, with the rates of acceleration and deceleration being nearly equal, such that the biomass profile is symmetrical by rotation around the transition point. These kinetics are described by the logistic equation

$$r_g = \mu_m X\left(1 - \frac{X}{X_m}\right) \tag{3}$$

  where X_m is the maximum possible amount of biomass.
- Early rapid acceleration, followed by an extended period during which growth decelerates slowly. This profile can be approximated by raising the ratio X/X_m to an exponent n to give the power-law logistic model (8,9)

$$r_g = \mu_m X\left(1 - \left(\frac{X}{X_m}\right)^n\right) \tag{4}$$

This allows the logistic curve to be skewed (i.e., for the rates of acceleration and deceleration to be different). The value of n is a measure of the relative sensitivity of the culture to self-inhibition at high biomass densities (8). For values of n less than 1, the organism is relatively sensitive to self-inhibition, and self-inhibition occurs for quite low values of X. For $n = 1$ the logistic equation is obtained. Finally, for values of n greater than 1 the organism is relatively resistant to self-inhibition, and significant self-inhibition occurs only at values of X close to X_m. The exponent n may have biological significance. The mycelium arising from a spore undergoes a maximum number (k_m) of branching events before growth ceases, and mycelia arising from a large number of different spores have a distribution of k_m values. If n is less than 1 then many of the mycelia have low k_m values, whereas if n is greater than 1 then many of the mycelia have high k_m values (8).

The expressions for both the linear and exponential growth kinetics do not describe any limitation on growth and are of little use for incorporating into models of growth in SSF. On the other hand, the logistic equation (and by extension, its power-law modification) describes a limitation on growth, and for this reason has quite commonly been incorporated into models of growth in SSF (10–12), especially macroscopic models. However, the significance of X_m is not clear. Growth might potentially be limited by the amount of substrate or diffusional limitations, but it can also be limited sterically.

Assumption of symmetric branching enables a simplified description of the mycelial mode of growth and enables the macroscopic parameter μ_m in the logistic equation to be related to the specific growth rate of a segment of biomass just before it is about to divide (μ'_m). The value of μ'_m can be determined from microscopic observation of extending hyphae. After a few branching events the following equation holds (8,9):

$$\mu_m = \mu'_m \frac{(X + X_c)}{2X} \approx \frac{\mu'_m}{2} \tag{5}$$

where X_c is the biomass in one hyphal segment just prior to a branching event. The approximation arises because X_c is small compared with the total biomass. This relationship between the two specific growth rates occurs because, after a few symmetric branchings, the biomass in the actively extending segments of a mycelium comprises approximately half the total biomass. The remaining biomass is in the older section of the mycelium where there are no actively extending hyphal tips. The microscopic growth parameters (X_c and μ'_m) can be determined by image analysis, which might even be used to monitor growth during SSF itself (9). If the effect of environmental parameters on growth and branching is known, some prediction can be made about how the environment will influence macroscopic growth kinetics.

Substrate-Dependent Growth Kinetic Equations

Kinetic expressions that rely only on biomass are simple but lack flexibility in describing different systems because new values for the parameters must be determined for each new system. Another approach is to assume that growth is related to the concentration of a growth-limiting substrate (such as a soluble sugar or oxygen) by the Monod equation (6,13,14),

$$r_g = \mu_m X\left(\frac{C_S}{K_S + C_S}\right) \tag{6}$$

where K_S is the saturation constant for the substrate. The models of Muck et al. (13) and Kaiser (14), which are based on the Monod equation, are relatively complex because they describe composting processes involving several organisms and several substrates. Muck et al. have four microbial groups (fungi and yeasts, each of which is divided into thermophilic and mesophilic subgroups), each with different Monod growth parameters, and there are several substrates that are assumed to be used sequentially.

The substrate concentration in the Monod equation must be the actual concentration that the microorganism experiences, which may not be simple to define due to the presence of both solids and water. Due to the concentration gradients that arise during growth, substrate concentrations at the surface of a substrate where the microorganism is located can be quite low compared with the average concentration (6). Therefore the effect of substrate concentration should be incorporated into kinetic models only if

the growth equations are coupled with local transport equations. Neither Muck et al. (13) nor Kaiser (14) modeled local transport, which limits the usefulness of their models.

Various modifications of simple Monod kinetics have been used by different workers:

- Simultaneous limitation of growth by oxygen according to Monod kinetics and self-inhibition by the biomass according to the logistic equation (15)

$$r_g = \mu_m\left(\frac{C_{O_2}}{K_{O_2} + C_{O_2}}\right)X\left(1 - \frac{X}{X_m}\right) \quad (7)$$

- Simultaneous limitation by oxygen and glucose (16)

$$r_g = \mu_m X\left(\frac{C_{O_2}}{K_{O_2} + C_{O_2}}\right)\left(\frac{C_G}{K_G + C_G}\right) \quad (8)$$

- Self-inhibition of growth by biomass late in growth (according to logistic kinetics) combined with substrate inhibition kinetics (17)

$$r_g = \mu_m\left(\frac{C_S}{K_S + C_S + C_S^2/K_i}\right)X\left(1 - \frac{X}{X_m}\right) \quad (9)$$

where K_i is the inhibition constant for the substrate.

Modeling Effects of Microbial Activities on the Environment

Microbial activities affect the environment in SSF, and the changes in the local environment in turn affect growth. The effect of microbial activities on the local pH and water activity in SSF have received almost no attention, with the exception of Muck et al. (13) who related pH changes to acetic and lactic acid production rates and the buffer index of the solids. This section therefore is restricted to describing how workers have modeled consumption of nutrients (either the carbon source or oxygen), the generation of metabolic heat, and effects of growth on porosity in the substrate bed.

In models that describe the dependence of the growth rate on substrate concentration, it is also important to describe the effect of the growth activities on the substrate (i.e., substrate consumption). Sometimes a constant growth yield coefficient has been assumed,

$$r_s = -\frac{1}{Y_{XS}}\, r_g \quad (10)$$

where Y_{XS} is the observed yield coefficient. The negative sign indicates that substrate is consumed during the growth reaction. However, many workers have assumed that substrate is used for both growth and maintenance and have assumed the relationship

$$r_s = -\frac{1}{Y'_{XS}}\, r_g - m_s X \quad (11)$$

where Y'_{XS} is the true growth yield on the substrate, and m_s is the maintenance coefficient. This equation has been applied both to nutrients within the substrate and to oxygen.

If the particle structure is provided by a macromolecule that is degraded by the microorganism, such as during the utilization of predominantly starchy materials by amylolytic microbes, or the degradation of cellulosic substrates by cellulolytic organisms, then the particle will shrink during the fermentation. This can affect bioreactor performance through effects on bulk transport. For example, a decrease in particle size caused the substrate bed in a packed-bed bioreactor to pull away from the walls, allowing the air to bypass the bed and reducing the availability of oxygen within the bed (18). A simple model for particle size reduction assumes that oxygen is the limiting substrate and that it is consumed at the substrate–biomass interface (19,20). As the fermentation proceeds, the oxygen must diffuse through a biomass layer that increases in thickness, lowering the rate of diffusion and therefore the rate of reaction. Further developments of shrinking-substrate models are necessary because most substrates have complex compositions, and microbes can produce a range of enzymes, often in sequential order according to preferences for different macromolecules.

The generation of large amounts of metabolic waste heat can cause overheating of the substrate, and the kinetics of waste heat generation must be described in models of heat transfer in SSF. The simplest approach is to assume a constant relationship between the rate of production of new biomass and the rate of generation of metabolic heat, r_Q (11,15):

$$r_Q = Y_{QX} r_g \quad (12)$$

where Y_{QX} is the differential yield coefficient for waste heat production during growth. However, if maintenance metabolism is significant, then a growth and maintenance model is appropriate (21),

$$r_Q = Y'_{QX} r_g + m_Q X \quad (13)$$

where Y'_{QX} is the differential yield of heat from the metabolism associated with growth, and m_Q is the maintenance coefficient for heat production.

The rate of metabolic heat production does not have to be directly related to the growth rate. Saucedo-Castaneda et al. (3) related heat generation to the carbon dioxide evolution rate, which in turn was related to the substrate utilization rate by a constant yield,

$$r_Q = Y_{QCO_2} r_{CO_2} = Y_{QCO_2}[Y_{CO_2S}(-r_s)] \quad (14)$$

where Y_{QCO_2} is the differential relationship between heat released and CO_2 evolved (J/g), and Y_{CO_2S} is the yield of carbon dioxide from the substrate (g/g). This equation was indirectly related to the growth equation because logistic growth kinetics were assumed, and substrate consumption was modeled by a growth and maintenance model.

Instead of simply using experimentally determined heat yield coefficients (e.g., Y_{QX}) several workers have applied a bioenergetic approach. Gutierrez-Rojas et al. (17)

proposed a stoichiometric equation for microbial growth on sucrose and estimated the enthalpy change associated with the growth reaction from the enthalpies of formation of the reactants and products. Larroche and Gros (22) considered the energetics of growth in SSF in even greater detail, estimating ATP generation and expenditure during growth. Muck et al. (13) related the rate of energy release to the rate of consumption of each of four substrates (water-soluble carbohydrate, ethanol, lactic acid, and acetic acid), estimating the fraction of the energy of combustion of the substrates that is actually released as waste metabolic heat. Finally, Rodriguez Leon et al. (23) estimated the heat yield coefficient from considerations of the degree of reductance of the substrate and biomass.

The growth of the microorganism into the interparticle voids affects the porosity of the substrate bed according to the relationship (24)

$$E = E_0 - X/(\rho_x W_s V_r) \tag{15}$$

where ρ_x is the wet biomass density (g/cm^3); W_s is the biomass dry matter content (g/g); V_r is the reactor volume, and E_0 is the initial porosity. This reduction in void fraction affects the pressure drop through packed beds (5) and reduces the effective diffusion coefficient within the substrate bed in tray bioreactors (24).

Death Kinetics

Overheating is a common problem in SSF, and several models have attempted to describe both growth and death of microorganisms. To date, death kinetics have largely been assumed to be first order (11,12),

$$r_d = k_d X_v \tag{16}$$

where the specific death rate, k_d, is a function of temperature. The effect of temperature on the parameters in growth and death kinetic expressions will be discussed later. The incorporation of death kinetics into a model divides the population into viable (X_v) and dead (X_d) subpopulations, representing a very simple level of segregation. On the other hand, Sargantanis et al. (21) assumed that their organism was killed instantly when the temperature reached 43 °C. Not all models considering the effect of temperature actually have death kinetics in them; some describe only a decrease in net growth rate with temperature (3).

Effects of Environmental Variables on Growth and Death Kinetics

The effect of the environment on kinetic parameters is quite important because it is difficult to control environmental variables; some may change quite significantly during growth, and some might limit growth. The effect of nutrient concentrations (including O_2) have already been considered. Of most interest here are temperature, water activity, and pH. Of these, temperature has received most attention due to the overheating problems that are commonly encountered in SSF. For bioreactors with large temperature gradients, heat transport equations must be built into the model if growth is to be adequately described.

Regarding the effect of temperature, most attention has been given to the effect of the temperature on the rate constants μ_m and k_d. Simple empirical equations are normally fitted by least squares regression to growth rate data collected between the minimum and maximum growth temperatures. Polynomial expressions (11,14,15) or double exponential expressions (3,17) have been used to describe the variation in specific growth rate with temperature. Arrhenius-type relationships have also been used to describe the effect of temperature on both the specific growth rate and the specific death rate (12),

$$\mu_m = \mu_{mo} \exp\left(\frac{-E_g}{RT}\right) - k_{do} \exp\left(\frac{-E_d}{RT}\right) \tag{17}$$

where R is the universal gas constant, T is the absolute temperature, E_g and E_d are the activation energies for growth and death, and μ_{mo} and k_{do} are rate constants. Least squares regression usually allows an adequate fit of such equations, although the biological significance of the parameters is not clear because the equations are not formulated on any theoretical basis.

Other growth parameters may be expressed as functions of the environmental conditions. Sargantanis et al. (21) expressed not only μ_m but also X_m in the logistic equation as empirically fitted functions of temperature and moisture content. Saucedo-Castaneda et al. (3) expressed the maximum biomass, X_m, in the logistic equation as an empirically fitted fourth-order polynomial function of temperature.

The model of Muck et al. (13) has described the effect of the environment on growth in most detail. In addition to using Arrhenius-type equations to describe the specific growth and death rates, with different parameter values for the different microbial groups, they also described the effect of pH and water activity on growth. However, for both these environmental variables the effects on the specific growth rates of the various microbial groups were incorporated simply by using empirical equations, fitted to experimental kinetic data, to modify the maximum specific growth rate. Gervais and Simatos (25) have addressed the effect of water activity on growth on solid surfaces in greater depth, although they consider the radial extension rates of fungal colonies. The effect of water activity on the overculture situation in SSF has not been addressed.

Modeling Branching, Penetration, and Differentiation

Fundamental phenomena in the growth of filamentous fungi on solid surfaces have received some attention. Some models address extension of the hyphal tip at a very fundamental level, but these models have not been extended to describe morphological development. Others can describe branching and certain aspects of hyphal morphogenesis but have not been extended to describe overall growth kinetics (8). In any case, models describing the extension and branching of individual hyphae describe the system in far more detail than is required in models of bioreactor performance, where only overall mycelial con-

centrations are of interest. However, models describing hyphal phenomena might be useful if they concern themselves with the overall population of hyphae or hyphal tips, and this section addresses such models briefly. The equations are not presented but can be found in the original articles.

The symmetric branching model of Viniegra-Gonzalez et al. (8,9), described earlier in conjunction with the logistic equation, makes many simplifying assumptions about the branching process, essentially that all hyphae branch after reaching a certain length, and the two branches arising are identical. These do not happen in practice but may be approximated on average in the large population of hyphae within a mycelium. As shown in equation 5, on this basis the relationship between some microscopic and macroscopic growth parameters can be derived.

Edelstein and Segel (26) used a modeling approach based on average tip and hyphal concentrations per unit area of substrate surface and describing the generation of tips by branching and the movement of hyphal tips across the surface due to hyphal extension. Growth of tips depended on the local nutrient concentration. This approach avoids the great complexity that would be involved in constructing a model on the basis of intracellular events, tip extension, and branching events, and some of the parameters such as tip densities can be estimated experimentally (27). Laszlo and Silman (28) used a cellular automata approach to model mycelial densities during fungal colony expansion over solid surfaces. In this approach a matrix of small squares is superimposed on a flat substrate surface. Initially, one or more squares are designated as living, to represent an inoculum. The fungus can then grow into adjacent squares, with simple rules based on the number of occupied squares adjacent to a vacant square being used to determine whether that vacant square will be colonized. This approach can give insights into density patterns within fungal colonies (28) but otherwise is of limited usefulness for modeling growth kinetics in bioreactors. Edelstein (29) developed a model describing colony expansion, assuming no nutrient limitations, but based on processes of branching, anastomosis, tip death, and hyphal death. Only the average frequencies of these processes need to be known. Different frequencies for the various processes can lead to very different colony morphologies. These approaches could be adapted to describe growth during overculture in SSF.

Penetration into the substrate is an interesting aspect that has not received much attention, although Jurus and Sundberg (30) gave a qualitative account of the penetration of *Rhizopus oligosporus* into soybeans. More recently Ito et al. (31) observed an exponential decrease in the concentration of hyphae below the surface of the rice in koji. Experimentally they observed that the quality of the koji was strongly correlated with the degree of mycelial penetration: at lower degrees of penetration, the activities of undesirable enzymes was high, leading to poorer quality koji. Although they proposed a mathematical equation to describe the decrease in hyphal concentration with depth, it was simply fitted to the data collected at each time point. A dynamic model describing the increase in concentration of penetrative hyphae as a function of time and distance was not proposed. Such dynamic models might be important because penetration into the substrate has the potential to increase substrate degradation.

Differentiation can be quite important in SSF processes as an essential step in the production of spores or secondary metabolites (32). Georgiou and Shuler (33) modeled growth and differentiation of *Aspergillus nidulans* on a solid medium containing glucose. The model could predict the increases in density of the various types of biomass (vegetative, competent, differentiated, and conidial) during overculture.

MODELING OF LOCAL TRANSPORT PHENOMENA

Local mass transfer processes have the potential to limit the rate of growth in solid-state fermentation. Most of the local transport phenomena occurring in SSF, such as diffusion through porous media and stagnant films, have been well studied in other systems. However, the translocation of nutrients within the fungal mycelium itself is poorly understood. The work done on nutrient diffusion during radial expansion of colonies on agar surfaces will not be described here because SSF usually involves overculture of the organism across the whole surface, for which nutrient diffusion horizontally toward the organism is not important. In overculture the key spatial dimension is the one passing vertically through the substrate (Fig. 3).

This section indicates how modeling of these local transport phenomena has improved our understanding of what controls growth in SSF. Emphasis is placed on the mathematical descriptions of the phenomena. Model predictions about system behavior are mentioned but not discussed in detail. This section concentrates on mass transport phenomena because local heat transfer has not been considered in any mathematical model of SSF to date. Indeed, local heat transport is less likely than local mass transfer to limit SSF performance, although it might have unknown significance, for example, through indirect effects on mass transfer coefficients.

Diffusion and Reaction

Early modeling studies relevant to SSF considered the overculture of microorganisms on solid agar media, with glucose as the substrate (33,34). Two growth periods are predicted: an early period during which the glucose concentration at the substrate surface is relatively high and consequently the microbe grows at its maximum specific growth rate (i.e., exponential growth), followed by diffusion-limited growth during which the glucose concentration at the substrate surface is very low and the growth rate depends on the flux of glucose to the surface. The duration of the exponential growth phase depends strongly on the initial concentration of glucose because this determines how long it takes for the surface glucose concentration to fall to limiting levels. Analytical solutions to the diffusion equation can be obtained for short time periods but cannot describe the whole growth period. In any case, the usefulness of these models is limited because relatively few SSF processes contain a soluble sugar as the major carbon source.

Mitchell et al. (6) proposed and solved numerically a model for growth of *R. oligosporus* in overculture with starch as the carbon source. This allows some insight as to how mass transfer within the substrate itself can limit growth. In the experimental system a membrane filter prevented penetration of hyphae into the substrate. Five steps in the growth process were modeled (these correspond to processes 5 to 9 in Fig. 3):

- Glucoamylase release into the substrate by the fungus located in a plane at the substrate surface; an empirical equation was used
- Diffusion of glucoamylase through the substrate according to Fick's law
- Hydrolysis of starch by the glucoamylase according to Michaelis–Menten kinetics
- Generation of glucose by the glucoamylase according to Michaelis–Menten kinetics and the diffusion of the glucose through the substrate; this is a process of simultaneous reaction and diffusion
- The uptake of glucose by the fungus at the substrate surface according to Monod kinetics based on the surface glucose concentration.

The expression of interest here is that for simultaneous reaction and diffusion. For diffusion in an overculture system in which net diffusion occurs only in the vertical direction, as shown in Figure 3, the balance equation for compound A has the general form

$$\frac{\partial A}{\partial t} = r_a + D_a \frac{\partial^2 A}{\partial z^2} \tag{18}$$

where r_a is the rate of generation of compound A, D_a is the diffusivity of A, and z is the vertical spatial coordinate. This equation, with the appropriate sign on the reaction term, can refer to the generation and diffusion of hydrolysis products within the substrate, or to the diffusion and consumption of nutrients within a biomass layer.

Microscopic models incorporating local transport equations are useful tools for understanding the role of local transport phenomena in limiting growth in SSF. The model of Mitchell et al. (6) predicts a short phase of exponential growth during the early period when the glucoamylase is still near the surface and the surface glucose concentration is much higher than the saturation constant for growth. As the biomass at the surface increases, the increased glucose uptake rate causes the surface glucose concentration to fall below the saturation constant. This is followed by a period of slow deceleration of growth. This kinetic profile has been observed in SSF by several workers. The model is able to explain how such kinetics might arise from interactions among the processes of glucoamylase diffusion, starch hydrolysis, and glucose diffusion.

Recently, Rajagopalan and coworkers have made two extensions to this model. Rajagopalan and Modak (16) incorporated an expanding biomass film of constant density, with simultaneous reaction and diffusion of oxygen from the bulk air above the biomass layer and of glucose from the substrate below the biomass layer. This model suggests that at different times during growth either glucose or oxygen may be limiting, but that overall oxygen limitation might be more important than glucose limitation. They ran simulations under different bulk oxygen concentrations, such as might occur in different positions in a bioreactor, foreshadowing the linking of both local and bulk transport equations in a single model. Rajagopalan et al. (35) then further modified the model to describe a decrease in particle size as glucose is used up. Their predictions agreed reasonably well with the experimental data of Nandakumar et al. (20), who measured decreases in particle size during growth of *Bacillus coagulans* on wheat bran particles. The predictions also confirm the observations of Mitchell et al. (6) that glucoamylase diffusion plays a crucial role. At low diffusivities most of the glucoamylase remains near the surface. This quickly depletes the starch at the surface, leaving much of the enzyme without substrate to act upon. As a consequence, the rate of glucose production within the substrate particle falls, and growth becomes limited by the rate of glucose production in the deeper regions of the particles.

These modeling studies have used homogeneous gel substrates with very high water contents in which diffusion is the major mass transport phenomenon. However, SSF substrates may have high solute concentrations and contain cellular structures. Sorption phenomena may restrict diffusion (25), capillary action may occur, and cell walls may present an impermeable barrier. The mechanisms of mass transport within real solid substrates deserve greater attention.

Film Transfer of Oxygen

Another important local transport process is that of diffusion of oxygen across the stagnant gas film into the thin liquid film at the substrate surface (Fig. 3). If the biomass is assumed to be surrounded by a thin liquid film that offers the major resistance to mass transfer, then the oxygen transfer rate, N, can be expressed as (36)

$$N = K_L a(C^* - C) \tag{19}$$

where C^* is the concentration of oxygen in the bulk gas phase, C is the concentration of oxygen at the biomass–liquid interface, a is the area over which mass transfer occurs, and K_L is the mass transfer coefficient. This equation was used to estimate the overall mass transfer coefficient ($K_L a$) for a packed-bed bioreactor. It can be applied also at the microscopic scale, although it can be difficult to measure local oxygen consumption rates and oxygen concentrations (36).

Alternatively, the biomass film can be assumed to be directly in contact with the gas phase, with the transport resistance residing in a stagnant gas film. In this case the variable C in the above equation is replaced by $HC_{O_2,F}$, where H is Henry's constant, and $C_{O_2,F}$ is the concentration of oxygen in the biomass film. This expression has been used to describe oxygen transfer to the biomass in a tray bioreactor (15). Film transfer of oxygen in SSF needs more attention because significant amounts of fungal mycelium are in direct contact with the air phase and are not immersed in the liquid film at the substrate surface (37).

MODELING OF BULK TRANSPORT PHENOMENA

Recognizing Subsystems within SSF Bioreactors

In developing a model of bulk transport phenomena occurring during SSF, we must consider the level of detail to be modeled and identify simplifications of the model structure. As pointed out earlier, at the macroscopic scale, up to four subsystems can be identified in SSF bioreactors: the bioreactor wall, the headspace gases, the solid particles themselves, and the interparticle gases (Fig. 2). The presence and arrangement of these various subsystems and whether the subsystems themselves are homogeneous or have concentration or temperature gradients depend on the particular bioreactor and how it is operated. Macroscopic models contain transport equations to describe the heat and mass transfer processes within and between the subsystems recognized by the model, and between the subsystems and the surroundings.

It is often convenient to ignore the bioreactor wall in order to simplify the model. This may be appropriate if the wall is maintained at a constant temperature by a cooling system, making the bioreactor wall part of the surroundings. Alternatively, if the resistance to heat transfer between the bioreactor wall and the outside air is much greater than the resistance to heat transfer from the substrate material to the bioreactor, the overall heat transfer coefficient can be assumed to be similar to the outside heat transfer coefficient. This also has the implicit assumption that the energy stored in the bioreactor wall is negligible.

It is usually convenient and appropriate in macroscopic models to lump two or more of the phases together as a pseudohomogeneous subsystem having the mass or volume-averaged properties of the individual phases (Table 1). Most commonly, a substrate bed consisting of the moist solid particles and the interparticle gases is defined as a single subsystem. In the pseudohomogeneous matrix that comprises this system, the temperatures and water potentials of the gas and solid at the same location are assumed to be the same. The validity of this assumption depends on whether the bioreactor operation allows the gas and solid to approach equilibrium. In addition, note that the temperature and water potential of this pseudohomogeneous matrix can vary from position to position.

Depending on how well subsystems are mixed, macroscopic models may only need to describe transfer between subsystems, or they may also need to describe transfer within subsystems. If a subsystem is well mixed, then there will be no thermal and concentration gradients across the subsystem, and there will only be transfer equations to describe the transport between subsystems. Therefore the spatial coordinate does not appear in the transfer equations for such subsystems. For subsystems that are static or poorly mixed, there will also be transfer equations to describe the transfer processes within subsystems. For example, equations incorporating the spatial coordinate may be required to describe solid or gas flow patterns in the bioreactor, and to describe temperature and concentration gradients within the substrate bed. Such models can be used to explore bioreactor design and operation strategies to minimize these gradients.

The Bulk Transport Phenomena Occurring in SSF Bioreactors

Through their interactions with local transport processes, bulk transport processes determine the local environment experienced by the microorganism and therefore influence the performance of SSF bioreactors. Macroscopic models predict bioreactor performance by combining empirical descriptions of growth kinetics with expressions describing bulk transport between and within the subsystems (solid, gas, and bioreactor wall), and between these subsystems and the surroundings. Local transfer mechanisms are currently ignored in these models. Momentum transfer, heat transfer, and mass transfer may be involved, and any of these may potentially limit the performance of an SSF bioreactor. Table 2 indicates the mechanisms for these phenomena in various SSF bioreactor types. Of these phenomena, heat transfer has received the most attention.

Conversely, there is very little information regarding momentum transfer processes, that is, those processes involving material flow and that affect mixing and shear phenomena. Within bioreactors, both mixing of gas molecules within the gas phases in the bioreactor and mixing of solid substrate particles may be important. To date, the mixing of solids in agitated SSF systems has not been studied, and there are only two investigations of gas mixing and flow behavior (40,42). Residence time distributions for gas molecules indicate that operational parameters such as the gas velocity and solids loading affect the presence and extent of stagnant gas regions within the substrate bed and the homogeneity of the headspace gas phase (40,42). Further, such investigations are crucial because these flows underlie the other transport phenomena, such as heat and mass transfer. Due to the paucity of information, current macroscopic models assume ideal flow behavior such as plug flow of gases in packed beds or perfect mixing of the solids and gases in rotating drums.

The flow of solids leads to shear forces due to interactions of the solid substrate particles with each other and with the bioreactor wall. These shear forces are complex and therefore difficult to characterize. Thus, despite their potential to affect substrate characteristics and adversely affect microbial growth, and significant speculation regarding their importance in SSF systems, shear forces are not described in any macroscopic model of SSF.

Heat transfer processes have received attention because overheating due to release of metabolic waste heat is a very significant problem in SSF even at small scales. Rates of metabolic heat production reported in SSF range from about 3 to 330 kJ (kg dry matter)$^{-1}$ h^{-1}. Removal of metabolic heat is more difficult in SSF than in liquid fermentation processes for a number of reasons. First, compared to liquid media, solid substrates have low heat capacities and low thermal conductivities, which means that although less heat is required to raise the temperature of the solid substrate by the same increment, the solid substrate loses heat less readily than liquid media. As well, due to the concentrated nature of SSF systems, biomass concentrations are higher and heat production on a volumetric basis is therefore also correspondingly higher. Heat removal in SSF system occurs by convection, conduction,

Table 1. Subsystems in SSF Bioreactors and Their Simplification

Subsystem and references	Detailed view of the system (macroscopic viewpoint)	Simplification of the system appropriate for modeling	Mixing
Trays: may be stirred (the whole room is the bioreactor) (10,15,24)	Headspace gas (flowing around tray)	Headspace gas	Assume headspace infinite and well mixed, such that one tray represents all trays
	Solid particles (static) Interparticle gas (no forced flow)	Assume the bed consists of a pseudohomogeneous matrix	May be intermittently mixed, but usually not appropriate to assume that the bed is well mixed; gradients will exist
Packed beds and similar stirred reactors (3, 38, 39)	Solid particles (mostly static) Interparticle gas (flowing due to movement within bed)	Assume the bed consists of a pseudohomogeneous matrix	If mixed, usually intermittently; therefore will still have end-to-end gradients within the bed
Rotating drums and similar stirred reactors (21, 40)	Headspace gas (flowing) Solid particles (flowing) Interparticle gas (flow depends on movement within bed)	Headspace gas Assume the bed consists of a pseudohomogeneous matrix	Depending on operation may assume these two subsystems are each well mixed, or may allow for axial variation; if well mixed, may assume that headspace and bed are in equilibrium (i.e., 1 subsystem)
Air–solid fluidized beds (growth in this bioreactor has not yet been modeled)	Solid particles (flowing) Interparticle gas (flowing)	Assume a pseudohomogeneous matrix, with mixing keeping the whole bed homogeneous, and that aeration air is moist so that system is close to moisture equilibrium	Typically well mixed

Note: Subsystems are in addition to the bioreactor wall itself.

and evaporative cooling, with the contributions of each mechanism depending on the bioreactor design and operation.

The important bulk mass transfers in SSF bioreactors involve the gas phase: oxygen supply and carbon dioxide removal for aerobic processes, and the removal of water vapor during evaporative cooling. The transfer processes described by macroscopic models may include transfer across interfaces, diffusion within stagnant gas regions, and convection by bulk gas flow. As noted in Table 1, it may be appropriate to divide the gas phase into a headspace gas phase and an interparticle gas phase. The degree of continuity between these phases depends on the type of bioreactor and how it is operated.

Solid-state bioreactors differ in the types of mixing that they provide and in the relative importance of flow and diffusion processes in the bulk transport phenomena that occur. This section discusses mathematical modeling of bulk transport in tray, packed-bed, and rotating drum bioreactors. Models have not been developed to describe transport phenomena within other bioreactor types. The following sections discuss, for each bioreactor, the approaches to modeling the transport phenomena identified in Table 2. Although these transport phenomena have also been studied in non-SSF systems, the discussion is limited to SSF itself.

Macroscopic Transport Phenomena in Tray Bioreactors

Tray bioreactors often consist of a large number of individual trays incubated within a room in which the temperature and the humidity of the air may be controlled. However, mathematical models of trays usually describe only a single tray, assuming homogeneous conditions within the headspace surrounding the multiple trays in the bioreactor. This single tray comprises either an intact or a perforated tray on which rests a thin layer of static solid substrate. Two distinct gas phases exist in tray SSF systems: the first is the interparticle voids within the substrate itself; the second is the bulk gas phase, which consists of the headspaces above and below the tray.

Heat Transfer in Tray Bioreactors. Only Rajagopalan and Modak (15) have described heat transfer during tray SSFs. In their model, sensible heat transfer occurs in the vertical direction by conduction through the substrate,

$$\frac{\partial T}{\partial t} = \frac{k}{\rho_s C_p}\frac{\partial^2 T}{\partial y^2} + \frac{\Delta H r_g}{C_p} \tag{20}$$

and by convection from the substrate surfaces to the headspaces above and below the substrate bed (the base of the tray was assumed to be open),

$$-k\frac{\partial T}{\partial y} = h(T_0 - T) \tag{21}$$

where T is the temperature of the bed; t is time; k, C_p and ρ_s are the thermal conductivity, heat capacity, and density of the bed, respectively; ΔH is the enthalpy of the growth reaction; y is the spatial coordinate; T_0 is the temperature

Table 2. Important Transport Phenomena within SSF Bioreactors

Bioreactor and subsystem	Heat transport phenomena	Mass transport phenomena	Momentum transport phenomena
All bioreactor systems: the microscopic phenomena within the substrate particle are usually greatly simplified in macroscopic models describing bioreactor performance. Also, as noted in Table 1, the solid and gas subsystems are often assumed to form a single pseudohomogeneous matrix.			
Within the solid particle	This is the site of heat generation by the microbe growing at the surface of the solid particles.	Diffusion of enzymes and nutrients within the solid particle (6, 11, 33, 34)	
Between the solid and gas subsystems within the substrate bed	Conduction, evaporation of water, and free or forced convection (depending on bioreactor operation) from solids to interparticle air	Evaporation of water, and transfer of O_2 and CO_2 between the solid particles and the interparticle air (15)	
After assumption of a pseudohomogeneous matrix	Solid and gas in thermal and moisture equilibrium	Transfer of O_2 and CO_2 between solid particles and interparticle air Transfer of water to maintain saturated air (38,39)	
Trays: the solid particles and interparticle air may or may not be considered as a single pseudohomogeneous substrate bed. The whole room is taken as the bioreactor. Individual trays are assumed to be open at the top and to have perforated bases.			
Transfer across the substrate bed	Conduction (15) and natural convection within the bed, leading to spatial gradients	Diffusion (10, 15) and free convection of gases and water vapor within the bed, leading to spatial gradients	
Involving the tray wall or the headspace gases	Conduction to the tray walls, conduction within the tray wall, and then convection between the tray wall and the headspaces Evaporation and free or forced convection (depending on airflow), between the exposed bed surfaces and the headspace gases	Convection of gases (15) from the exposed bed surfaces into the headspace Evaporation of water from the substrate into the headspace at the exposed bed surfaces	Flow of headspace gases around the trays (15)
At inner surface of the room walls	Convection to the tray room walls Condensation on room walls		
	Packed beds and similar stirred reactors, assumed to be vertical cylinders		
Transport through the pseudohomogeneous matrix	Conduction, convection and evaporation axially along the substrate bed (38,39) Conduction radially within the substrate bed (3,38) Both axial and radial gradients may exist (38)	Convection of air in the axial direction due to the forced aeration of the bed. Although axial O_2 gradients occur, they are usually not as important as the temperature gradients Radial mass transfer should be negligible	Gas flow patterns through the bed (plug flow without dispersion is often assumed) (3,38,39) Pressure drop between the bottom and top of the substrate bed (40)
At the inner surface of the bioreactor wall	Conduction radially between the substrate and the inside surface of the bioreactor wall (3,38)		
	Rotating drums and similar stirred reactors, assumed to be horizontal cylindrical drums		
Transport through the pseudohomogeneous matrix	The role of conduction depends on the degree of mixing; may assume that bed is well mixed (21,41) Convective flow within the bed due to mixing Usually well mixed radially, but axial gradients may exist	The role of diffusion depends on the degree of mixing Convection of gases within substrate voids due to mixing Axial O_2 gradients may occur but are usually not important	Mixing and flow of the solid substrate Shear forces; impact and abrasion due to solids interacting with each other

Table 2. Important Transport Phenomena within SSF Bioreactors (*continued*)

Bioreactor and subsystem	Heat transport phenomena	Mass transport phenomena	Momentum transport phenomena
Between the bed and the headspace	Convection between the substrate bed surface and the headspace (41) Evaporative cooling at the surface of the substrate bed (41) Bulk flows of gases between the interparticle voids and the headspace carry sensible energy	Gas and water vapor exchange between the substrate bed and headspace gases (41). This may involve bulk flows exchanging gas between the headspace and interparticle voids.	Bulk gas flows between the interparticle voids and the headspace
Within the headspace	Convective flow of the headspace gases, carrying sensible energy (41)	Convective flow of the headspace gases (41)	Flow patterns of the headspace gases (41)
At the inner surface of the drum wall	Conduction from the substrate to the drum wall and convection between the headspace gases and the inside surface of the drum wall (41)		Shear forces, impact, and abrasion due to solids interacting with the drum wall
Air–solid fluidized beds, assumed to be vertical cylinders. The aeration air is assumed to be moist so that the bed is close to moisture equilibrium. Growth in these bioreactors has not yet been modeled.			
Within the well-mixed substrate bed	Whole bed well mixed such that there are no thermal or moisture gradients	Whole bed well mixed, such that there are no water vapor, CO_2, or O_2 gradients	Pressure drop across the bed itself, fluidization phenomena Shear, impact, and abrasion due to interactions between particles in the bed
At the inner surface of the bioreactor wall	Convection from the bed to the bioreactor wall		Shear, impact, and abrasion due to interactions between the solid particles and the wall
All bioreactors			
Involving the entry and exit of the airstream	Energy enters and leaves the system in the airstream blown through the bioreactor (3,21,38,41).	Gases and water vapor enter and leave the system in the airstream blown through the bioreactor (21,41)	Pressure drop between air pump and air exhaust
Within the bioreactor wall and between the wall and the surroundings	Conduction through the wall (the room wall for the tray system) and loss to the surroundings, often by free convection to air (21,41) or forced convection to cooling water (3,38)		

Note: These are phenomena that should be considered in the construction of mathematical models of bioreactor performance. As discussed in the text, most models greatly simplify the system by including only the most important transport phenomena or lumping phenomena together. In this table not all phenomena have been mentioned. In some places where transport processes occur in parallel, minor contributors have been ignored. In addition, the importance of the transport phenomena mentioned will depend on how the particular bioreactor is designed and operated. After identifying the phenomena to be modeled, the next task in modeling is to find appropriate expressions to include in the mass and energy balances that describe the system. Expressions that have been used to date in macroscopic models of SSF bioreactors are discussed in the text. Numbers in parentheses indicate references.

of the surrounding air, and h is the heat transfer coefficient between the bed and the surroundings. The model predicted that substrate temperatures would be highest in the center of the tray, and that the incubation temperature and substrate depth were critical to the success of tray SSFs. For a tray bed 6.35 cm high, an incubation temperature of 30 °C produced the greatest total biomass, although the maximum specific growth rate occurred at 40 °C. Likewise, substrate depths of 3 cm and under gave significantly better growth when incubated at 38 °C than when incubated at 40 °C. Simulations involving simultaneous changes of incubation temperature and substrate depth indicate that, as the bed height decreases, the incubation temperature supporting optimal growth increases and overall growth is optimal in trays less than 1 cm high. Clearly, such shallow trays would not be practical at large scales. Gas flow velocity around the trays had little effect on heat transfer between the gas phase and the bed. This model did not

describe evaporative cooling, convective heat transfer through the substrate bed due to free convection, or heat removal through the tray material.

Mass Transfer in Tray Bioreactors. A number of workers (10,15,24) have modeled mass transfer in trays. All of these models describe mass transfer within the interparticle voids; however, only the model of Rajagopalan and Modak (15) describes mass exchange between the interparticle voids and the bulk headspace.

In describing mass transfer within the interparticle voids, all three models consider transfer by diffusion in the vertical direction only. The models consider transfer of either oxygen only (10) or both oxygen and carbon dioxide (15,24). None of the models describes the mass transfer of water. All three models neglect the possibility of convective mass transfer due to thermal gradients within the substrate. The equations used in these models for mass transfer within the substrate bed take the general form of a balance of compound A (either O_2 or CO_2) in the interparticle gas phase,

$$\frac{\partial \varepsilon C_a}{\partial t} = D_a \frac{\partial^2 C_a}{\partial y^2} - R_a \tag{22}$$

where t is time, y is vertical distance within the bed, ε is the porosity, and D_a and C_a are the diffusivity and the concentration, respectively, of A in the bed. In the case where A is oxygen, R_a is the rate of oxygen consumption (10,24) or the rate of oxygen dissolution into a liquid film layer on the substrate particles (15). For film transfer, $R_a = K_a(C_{O_2} - HC_{O_2,F})$, where K_a is an overall gas side mass transfer coefficient, H is Henry's constant for oxygen and $C_{O_2,F}$ is the oxygen concentration in the film liquid. In the case where A is carbon dioxide, the minus sign in front of R_a in the previous equation is changed to a plus sign, and R_a is the rate of carbon dioxide production (15,24).

The porosity in the previous equation is an important term and received further attention within the models of Rajagopalan and Modak (15) and Auria et al. (24). Rajagopalan and Modak (15) calculated D for the oxygen and carbon dioxide gases as

$$D_i^b = \frac{\varepsilon}{\tau} D_i' \tag{23}$$

where ε is the porosity of the substrate bed, τ is the tortuosity factor (taken to equal 1.7), i is the gas (either carbon dioxide or oxygen), and D^b and D' are the diffusivities in the bed and in air. However, the porosity was held constant for any one simulation; therefore porosity changes caused by growth were neglected. Auria et al. (24) used their model to estimate the diffusivity within static beds consisting of *A. niger* growing on beads of ion exchange resin impregnated with a nutrient medium. The diffusivity decreased with increasing biomass concentration, and at high biomass concentrations of 27 mg g^{-1} dry matter, the diffusivities of oxygen and carbon dioxide were less than 5% of their bulk diffusivities in air. The effect of growth on porosity and gas diffusivity deserves further attention.

The tray models of Auria and Rajagopalan are dynamic models. The model developed by Ragheva Rao et al. (10) is different in that it consists of only a single pseudo-steady-state equation. From a balance for oxygen within the bed, they developed an equation for the maximum thickness, H_c, that a tray could be without becoming depleted of oxygen at any depth within the substrate layer during the fermentation,

$$H_c = \sqrt{\frac{2D_e C_{O_2} Y}{\mu_m X_m}} \tag{24}$$

where μ_m and X_m are the maximum specific growth rate (h^{-1}) and maximum biomass concentration (mg cm^{-3}), respectively. Use of μ_m and X_m represents the worst case scenario for which the rate of oxygen demand would be greatest. This model has a number of implications for the design and operation of tray SSFs. First, with the use of perforated rather than unperforated trays, the critical bed thickness, H_c, could be increased by a factor of up to two, depending on the fraction of the area of the underside of the bed exposed to air. Second, greater substrate depths can be used if the air above the bed is oxygen enriched or if the headspace is continually replenished during operation (thereby keeping C_{O_2} as high as possible). This model is one that could be readily applied in practice, requiring only values of the D and kinetic parameters μ_m and X_m, although it has not yet been tested experimentally.

The model of Rajagopalan and Modak (15) goes further than the other models in not only describing diffusion within the bed, but also the convection of gases from the upper and lower bed surfaces into the headspaces. Headspace air is assumed to move horizontally across the substrate surface, being well mixed normal to the flow direction but with no axial dispersion. At the plane of contact with the substrate, gases diffuse into or out of the bed. The balance of oxygen or carbon dioxide at the bed surface is given by

$$\frac{\partial C_a^h}{\partial t} = -v_x \frac{\partial C_a^h}{\partial x} - \frac{D_a}{z} \left.\frac{\partial C}{\partial y}\right|_{y=L} \tag{25}$$

where A is either carbon dioxide or oxygen, x is the horizontal coordinate, y is the vertical coordinate, L is the thickness of the substrate, z is the thickness of the headspace above the bed, C_a^h is the headspace concentration, and v_x is the headspace gas flow velocity. Model simulations showed that substrate depth and porosity greatly affected mass transfer within the bed; however, the gas flow velocity around the trays had little effect on mass transfer between the headspaces and the bed. These predictions can guide design and operation of tray bioreactors.

Combined Heat and Mass Transfer in Tray Bioreactors. Finally, both heat and mass transfer processes may be important at different times during SSFs in trays. Therefore, mathematical models describing these systems will need to describe both transport mechanisms. Currently, only the model by Rajagopalan and Modak (15) does this. The phenomena described by their model are shown in Figure 4.

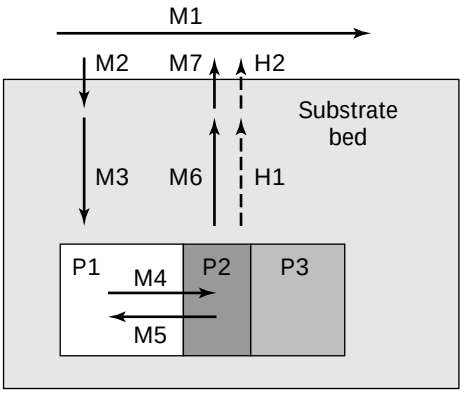

Figure 4. Diagrammatic representation of the tray bioreactor as modeled by Rajagopalan and Modak (15), indicating the three phases within the substrate bed. P1, Interparticle gas phase; P2, thin water film on the surface of substrate particles, which is the location of oxygen consumption, carbon dioxide production, and generation of waste metabolic heat; P3, solid substrate particle. The heat and mass transfer processes occurring are M1, bulk flow of air above the tray surface; M2, transfer of oxygen into the bed; M3, diffusion of oxygen within the bed; M4, transfer of oxygen from the interparticle air phase to the liquid film; M5, transfer of carbon dioxide from the liquid film to the interparticle air phase; M6, diffusion of carbon dioxide within the bed; M7, transfer of carbon dioxide from the bed to the surrounding air; H1, conduction of heat through the bed; H2, convective removal of heat at the bed surface.

The predictions of this model for substrate temperature, biomass, and gas phase concentrations of oxygen and carbon dioxide showed trends similar to those noted experimentally by Rathbun and Shuler (43) during the tempe fermentation of soybeans by *R. oligosporus*. The model predicts that the substrate temperature is the dominant influence on growth in the initial and final stages of the fermentation. During intermediate stages of the fermentation, oxygen has a large effect at the bottom of the bed (in an unperforated tray), whereas temperature effects are more important in the center of the bed.

Macroscopic Transport Phenomena in Packed-Bed Bioreactors

Heat Transfer in Packed-Bed Bioreactors. Heat transfer in packed beds has received most modeling attention because the temperature gradients obtained are more important than the gas concentration gradients, and if aeration satisfies the heat removal requirements it will also satisfy aeration requirements (44,45). In bioreactors of different designs and operated under different conditions, both axial and radial temperature gradients have been observed (45–47). Under some operating conditions, temperatures in the middle of the bed can be over 20 °C higher than the temperature of the inlet air, leading to large variations in growth and product formation across the bioreactor (46).

Saucedo-Castaneda et al. in 1990 (3) modeled radial heat transfer in an experimental packed bed in which *A. niger* was grown on cassava meal. This model was later extended by Sangsurasak to describe both axial and radial heat transfer (38). A general expression for heat transfer in a pseudohomogeneous substrate bed within a cylindrical packed-bed bioreactor, which takes into account the heat transfer processes shown in Figure 5, can be expressed as (38)

$$\rho_b C_{pb} \frac{\partial T}{\partial t} + (\rho_{ma} C_{pma} + \rho_a f \Delta H_v) V_z \frac{\partial T}{\partial z} = \frac{k_b}{r} \frac{\partial T}{\partial r} + k_b \frac{\partial^2 T}{\partial r^2} + k_b \frac{\partial^2 T}{\partial z^2} + r_Q \quad (26)$$

where ρ_a, ρ_{ma}, and ρ_b are the densities of air, moist air, and the bed, respectively; C_{pma} is the heat capacity of moist air; C_{pb} the heat capacity of the bed; f describes the relationship between saturation humidity and temperature; ΔH_v is the enthalpy of vaporization of water; k_b is the thermal conductivity of the bed; V_z is the superficial air velocity; z and r are the axial and radial spatial coordinates; and r_Q is the rate of heat generation from the growth reaction. The factor $\rho_a f \lambda$ arises because the equilibrium assumed between the substrate and air means that the evaporation of water to keep the air saturated as the air temperature increases gives the air a higher apparent heat capacity. This is a simplified approach to handling evaporative cooling,

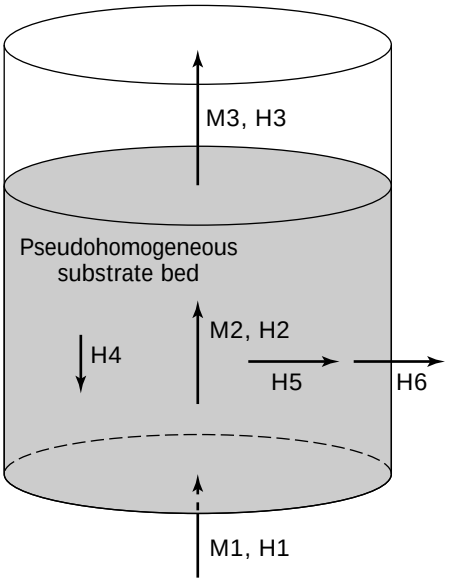

Figure 5. Diagrammatic representation of the packed-bed bioreactor as modeled by Sangsurasak (38). The substrate bed is treated as a single pseudohomogeneous phase. The microbe grows in the bed and releases waste metabolic heat. The heat and mass transfer processes occurring are M1, flow of moist air into the pseudohomogeneous bed; M2, flow of moist air within the bed, with the air being saturated at the bed temperature; M3, flow of moist air out of the pseudohomogeneous bed; H1, bulk transfer of energy into bioreactor with airflow; H2, convective heat transfer within the bed; H3, bulk transfer of energy out of bioreactor with airflow; H4, axial conduction within the bed (opposes the temperature gradient caused by convection); H5, radial conduction within the bed; H6, conduction across the bioreactor wall and convective removal by cooling water.

which can contribute as much as 65% of the heat removal from a packed bed (47).

For thin packed-bed bioreactors of about 6 cm diameter, operated with low superficial air velocities (e.g., 0.01 m s^{-1}), radial conduction is the major heat removal mechanism (3). In this particular case the terms for convection and evaporation and axial conduction can be omitted.

In addition to transfer phenomena within the bed, the other important transfer process is from the outer edge of the substrate bed to the surroundings (the bioreactor wall itself has been assumed to offer negligible resistance to heat transfer). Convective cooling at this boundary has been assumed (3,38):

$$\left.\frac{\partial T}{\partial r}\right|_{\text{wall}} = \frac{ha}{k_b}(T_{\text{surr}} - T_{\text{wall}}) \qquad (27)$$

Overheating problems occur at the top of the column when it is aerated from the bottom because the air reaching higher regions has been prewarmed in the lower regions and therefore does not cool the top as effectively. Even for quite small columns, when they are operated with the cross-sectional airflow rates of 0.01 to 0.025 m s^{-1} that are commonly used in packed-bed bioreactors, temperatures that can cause significant microbial death are predicted. The model of Sangsurasak (38) can be used as a tool in bioreactor design, operation, and scale-up. Sangsurasak used the model to explore strategies for minimizing the overheating problem at large scale. Higher aeration rates and lower height-to-diameter ratios appear to be the best strategies. However, the model has not yet been used in the actual construction of a larger-scale packed bed.

Gutierrez-Rojas et al. (17) used a different approach to modeling heat transfer during growth of *A. niger* in a packed bed on beads of ion exchange resin impregnated with nutrient medium. They defined an "elementary representative volume" of 20 mL, over which scale variations in the process variables were assumed to be negligible. However, they modeled only an individual elementary representative volume, and although their model was able to describe the experimental results obtained in a 20-mL packed bed, it is not able to describe the gas concentration and temperature profiles that occur across larger-scale packed-bed bioreactors (46).

Heat and Mass Transfer in Packed-Bed Bioreactors. The reliance on evaporative cooling means that water balances over the bed are important (45). A combined heat and mass transfer model is required to take these into account. Such a model, considering only gradients in the vertical direction, was proposed by Van Lier et al. (39), who modeled the composting of a mixture of wheat straw and horse manure. The energy balance is similar to that used by Sangsurasak (38), but because a material balance was also done for water, a simplified description of evaporation was not required. The equation was of the form

$$\rho_b C_{pb}\frac{\partial T}{\partial t} + \rho_{ma} C_{pma} V_z \frac{\partial T}{\partial z} = k_b \frac{\partial^2 T}{\partial z^2} - h(T - T_0) - \Delta H_v r_w + r_Q \qquad (28)$$

where h is the heat transfer coefficient for conduction through the side wall to the surroundings at temperature T_0, and r_W is the rate of evaporation of water from the solid phase into the gas phase.

A general mass balance equation for compound A in the gas phase, for example, oxygen or water, can be written in the following form with terms for axial convection, axial diffusion, and exchange with the metabolizing organism attached to the solid phase:

$$\frac{\partial(\varepsilon C_A)}{\partial t} = -V_Z \frac{\partial C_A}{\partial z} + \frac{\varepsilon}{\beta^2} D_A \frac{\partial^2 C_A}{\partial z^2} + r_A \qquad (29)$$

where C_A is the concentration of A at a location, D_A is the diffusivity of A in air, ϵ is the bed void fraction, β is the tortuosity and r_A is the rate of exchange of A with the solid phase. In the water balance Van Lier et al. assumed that the vapor phase remained saturated with water at the local temperature in the bed, and used this equation to calculate the evaporation rate (r_W). Film transfer of oxygen was not incorporated into the equations.

Solution of the equation set was complicated because the porosity and height of the bed changed during the composting process. However, good agreement was achieved between the model predictions and measured temperatures and bed heights. In composting, unlike other SSF processes, some self-heating is desired, and this reduces problems with overheating. Despite this, the aeration rate required to remove excess heat is still about 10-fold greater than that required to supply oxygen (39).

Other Phenomena in Packed-Bed Bioreactors. As air flows through the porous bed in a packed-bed bioreactor, there are viscous and kinetic phenomena (5). Substantial pressure drops can occur in packed-bed bioreactors (5,18,41). To date characterization of this phenomenon has been limited to demonstrating the relationship between pressure drop and the bed void fraction, which decreases as the microbe fills in the interparticle spaces. At high biomass densities, the microorganism can occupy up to 34% of the free interparticular space, reducing the relative permeability of the bed to around 1% of the original value (40). In the future, such considerations could be built into momentum balances to describe how the flow through the bed changes during the fermentation.

Macroscopic Transport Phenomena in Rotating-Drum Bioreactors

Only heat transfer phenomena (and the related mass transfer of water) have been modeled in rotating-drum bioreactors and the related rocking-drum bioreactor (RDBs). As in packed-bed systems, it is likely that in order to achieve adequate heat removal in RDBs, aeration requirements will already be met. Neither of the models developed so far (21,40) describes all of the heat transfer processes mentioned in Table 2.

Sargantanis et al. (21) modeled heat transfer during growth of *R. oligosporus* on corn grit in a rocking-drum bioreactor with a 1.2-L working volume. They described heat removal very simplistically by assuming equilibrium

between the headspace and the substrate bed; in essence, this was a single homogeneous subsystem. The model was useful for determining better operation of their rocking-drum bioreactor system; however, it is not very versatile and can not readily be adapted to describe larger-scale SSFs in RDBs, where the assumption of thermal and moisture equilibrium between the solid substrate and the headspace could be unreasonable, particularly if high aeration rates are used. For such cases a model predicting heat removal in terms of heat transfer rather than equilibrium relationships is likely to be more useful.

Stuart (41) modeled heat transfer in a 20-L rotating-drum bioreactor in which *A. oryzae* was grown on both an artificial gel substrate and on wheat bran. The model is more mechanistic than that of Sargantanis et al. (21) and considers several of the heat transfer processes listed in Table 2. As shown in Figure 6, it simplifies the bioreactor system into three subsystems: the two internal subsystems, the fermenting substrate and the headspace gas, which are contained by the third subsystem, the fermenter wall. Each subsystem is assumed to be homogeneous with respect to composition and temperature in both the radial and axial directions. The model, therefore, does not describe heat transfer processes within any of the subsystems, and the temperature of each subsystem is represented by a single time-dependent value. Stuart (41) neglected water mass transfer within the substrate bed by assuming that water at 25 °C is added to maintain the water activity within this pseudohomogeneous subsystem close to unity. Mass transfer from this bed to the headspace gas is assumed to be limited by the rate at which water vapor in the gas sublayer of the substrate bed diffuses into the bulk headspace gas.

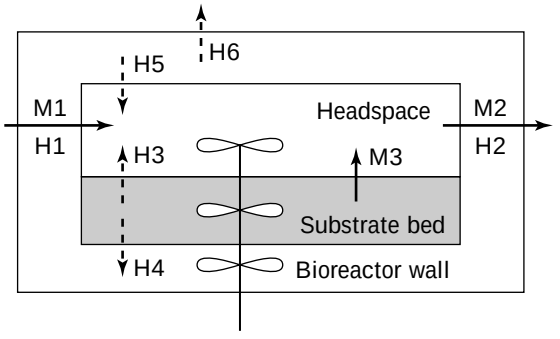

Figure 6. Diagrammatic representation of the rotating-drum bioreactor as modeled by Stuart (41), showing the three subsystems that were assumed. The pseudohomogeneous substrate bed is the site of generation of water and waste metabolic heat during growth. The mixer indicates that each subsystem is assumed to be at the same temperature at all locations within the subsystem. The heat and mass transfer processes occurring are M1, flow of moist air into the headspace; M2, flow of moist air out of the headspace; M3, transfer of water from the substrate bed to the bioreactor headspace; H1, bulk transfer of energy into bioreactor with airflow; H2, bulk transfer of energy out of bioreactor with airflow; H3, convection from the substrate bed to the headspace; H4, conduction from the substrate bed to the bioreactor wall; H5, convection from the bioreactor wall to the headspace; H6, convection from the bioreactor wall to the surroundings.

Three energy balance equations, one for each subsystem, describe heat transfer phenomena within the RDB system, and heat exchange between the RDB system and the surroundings (41). Metabolic heat is generated within the substrate and then dissipated by conduction to the bioreactor wall and by convection and evaporative cooling to the headspace gases. The overall energy balance for the substrate is

$$\frac{d[T_s M(C_{pm} + C_{pw}W)]}{dt} = r_Q - h_{sf}A_{sf}(T_s - T_f) - h_{sa}A_{sa}(T_s - T_a) - (1.2 \times 25)C_{pw}(W_i - W)M - kA_{sa}(C_I - C_B)[T_s C_{pw} + \Delta H_v - (T_s - T_a)C_{ph}] \quad (30)$$

Energy enters the headspace gas with the evaporated water from the substrate and with incoming aeration gases, and through convection from the substrate and from the bioreactor wall:

$$\frac{d[T_a G(C_{pg} + C_{ph}H)]}{dt} = T_i F_i(C_{pg} + C_{ph}H_i) + kA_{sa}(C_I - C_B)T_a C_{ph} - T_a F_o(C_{pg} + C_{ph}H) + h_{sa}A_{sa}(T_s - T_a) + h_{fa}A_{fa}(T_f - T_a) \quad (31)$$

The exiting air flow carries energy out of the headspace and thereby away from the RDB system. During fermentation, the bioreactor wall heats up due to its contact with the substrate. Energy, when it leaves the bioreactor wall, passes either to the surroundings or to the headspace gas inside the RDB:

$$\frac{d(T_f V_f \rho_f C_{pf})}{dt} = h_{sf}A_{sf}(T_s - T_f) - h_{fa}A_{fa}(T_f - T_a) - h_{fe}A_{fe}(T_f - T_e) \quad (32)$$

Thus there are two overall routes by which metabolic heat is removed from the substrate subsystem to the surroundings: with the exiting air stream or as heat lost through the bioreactor wall.

In these equations, T is temperature, M is the mass of dry solid, W is the mass of water per mass of dry solid, G is the mass of dry gas, H is the mass of water per mass of dry gas, V_f and ρ_f are the volume and density of the bioreactor material, respectively, C_P is a heat capacity, r_Q is the rate of production of metabolic heat, h is a heat transfer coefficient, A is an area of heat or mass transfer, k is a mass transfer coefficient, C is a concentration of water at either the interface (subscript I) or within the headspace bulk (subscript B), ΔH_v is the heat of vaporization of water, F is a flow of dry gas either entering (i) or leaving (o) the bioreactor system during aeration. The subscripts S, A, and F denote the three subsystems: the substrate, headspace gas, and fermenter wall, respectively. Combinations of these subsystem subscripts indicate heat or mass transfer between these materials, for example, the subscript combination "SF" represents heat transfer from the substrate

to the bioreactor wall. The other subscript terms denote dry solid matter (m), dry gases (g), liquid water (w), water vapor (h), and the external surroundings (e).

Estimation of the coefficients and areas involved in the heat and mass transfer processes during SSF in RDBs is difficult, Stuart (41) used empirical equations to estimate transfer coefficients and assumed that the substrate and headspace gas subsystems occupy constant volumes throughout the fermentation. Likewise, transfer areas were assumed to be constant and were calculated based on the interfacial areas between the substrate, headspace gas, and the bioreactor wall, when the surface of the substrate bed forms a flat plane. Heat and mass transfer coefficients and interfacial areas of contact urgently require experimental attention in SSF systems.

In order to incorporate evaporative cooling into a model of heat transfer during SSF, water balances must be determined over the substrate and headspace gas subsystems. Stuart (41) assumed that the substrate and headspace gas subsystems each consist of a water component and a dry component. Therefore four material balance equations were written, two equations to describe each subsystem.

- Balance of dry matter in the substrate:

$$\frac{dM}{dt} = r_m \tag{33}$$

- Balance of liquid water in the substrate:

$$\frac{d(MW)}{dt} = -kA_{sa}(C_I - C_B) + r_w + 1.2(W_i - W)M \tag{34}$$

- Balance of dry gas in the headspace gas subsystem:

$$\frac{dG}{dt} = F_i - F_o + r_{dg} \tag{35}$$

- Balance of water vapor in the headspace gas subsystem:

$$\frac{d(GH)}{dt} = F_iH_i - F_oH_o + kA_{sa}(C_I - C_B) \tag{36}$$

In these equations, r_m, r_w, and r_{dg} are the net rates due to microbial metabolism of substrate dry matter consumption, water production, and dry gas production, respectively.

Due to consumption of substrate dry matter during microbial growth in SSF and loss of water from the substrate to the headspace gas, the flow of gases out of the RDB ($F_o[1 + H]$) will often be greater than the air flow into the RDB ($F_i[1 + H_i]$). Because RDBs are open systems and large pressure variations in the headspace are unlikely, ideal gas behavior and a constant pressure within the headspace gas are assumed. This gives an equation (not shown) for the flow of gas out of the bioreactor (F_o) and enables the calculation of C_B (the headspace concentration of water vapor).

This model was used to explore SSF performance in RDBs over a range of scales, operations, and designs. The model predictions of temperature profiles for the substrate, bioreactor wall, and headspace gas agreed reasonably well with experimental results for SSFs in real small-scale RDB systems (41). Model simulations indicate that, whereas at small scales heat removal from the substrate bed through the bioreactor wall is most important, the required contribution of evaporative cooling increases with scale. This requires very high aeration rates with relatively dry air: simulations showed that the aeration rate in air volumes per bioreactor volume per minute (vvm) required to achieve adequate heat removal from the substrate might increase by a factor of 25 over a scale change of 1,000. Such high aeration rates would be costly. Therefore heat transfer through the bioreactor wall should be maximized to minimize reliance on evaporative cooling and to limit the amount of water that needs to be added to the system during the fermentation. At all scales, heat removal from the substrate to the headspace gases by sensible heat transfer was insignificant compared with heat transport from the substrate subsystem by conduction and evaporative cooling. However, sensible heat transfer to the headspace gases was always indirectly important in the model predictions because it affected the temperature of the headspace gases and thereby determined the amount of moisture that the headspace could hold and the driving force for evaporative cooling. This investigation of RDB performance demonstrates how models can be used as tools to explore interactions between important processes occurring during SSFs as well as operation and control options for the design of larger-scale bioreactors. This model, with its mechanistic basis, represents a first step toward developing semifundamental scale-up criteria for SSF in RDBs.

PARAMETER ESTIMATION

As highlighted in the introduction to this article, much more attention needs to be given to the estimation of the parameters involved in models of SSF systems. Models involve four main types of parameters: operational and design parameters, microbial parameters, transport parameters, and thermodynamic parameters. In the modeling work to date, many of these parameters have not been independently determined. In some cases parameters have been allowed to vary to enable the model to fit the experimental data. In other cases parameters have been borrowed from other systems involving different substrates and microorganisms, and even from work done in submerged liquid culture. Even physical parameters may depend on the substrate and its preparation and the bioreactor and how it is operated, making it important for parameters to be measured in the actual system studied. This section describes the work that has been done to determine model parameters in SSF systems.

Operational and Design Parameters

Operational and design parameters come directly from the experimental system being modeled. They include bioreac-

tor geometry, air temperatures and flow rates, and rotation or mixing rates. These parameters are important in optimizing bioreactor performance, but these considerations are beyond the scope of this article. For modeling purposes, these parameters are easy to obtain because they are determined by the operator.

Microbial Parameters

Microbial parameters include specific growth and death rates, saturation constants, yields, activation energies, lag periods, and biomass composition. Ideally these parameters should be measured in SSF systems, although this is difficult for those parameters requiring direct measurement of biomass because it is usually impossible to remove the biomass from the substrate particles. Parameters such as specific growth rates and yields are often based on indirect indicators of growth, such as oxygen uptake or protein content, but the relationship of these indicators to growth can often vary during the growth phase. In other cases, parameter values determined in liquid culture have been used, but due to the different physical environment in SSF, these values may not be appropriate for SSF.

Specific growth rates depend on the particular system used. A wide range of values have been reported, from very low values of 0.05 h^{-1} to values as high as 0.5 h^{-1} (45). In some modeling work the specific growth rate has been used as one of the fitting parameters (3,6). The stoichiometry of growth will also be highly variable, and most models consider overall yields and do not balance elements. Only Larroche and Gros (22) have done detailed stoichiometric analyses (for growth and sporulation of *Penicillium roqueforti* on buckwheat seeds). For the anabolic reactions during biomass production from starch they obtained

$$1.104CH_{1.667}O_{0.833} + 0.087NH_3 \rightarrow CH_{1.882}O_{0.603}N_{0.087} + 0.014CO_2 + 0.109H_2O \quad (37)$$

Because a range of different empirical equations have been used to describe the effect of temperature on growth, the values of the parameters do not have general significance. In any case, these parameters are typically determined by incubating cultures at different temperatures, but with any one culture being held isothermally throughout the whole growth phase. The models of Stuart (41) and Saucedo-Castaneda et al. (3) suggest that the relationships obtained from such experiments may not describe the situation in SSF where the organism is subjected to high temperatures after an initial period at the optimum temperature for growth, because their models could describe their data only if the specific growth rate was maintained unchanged at the value for the optimum temperature as the temperature increased.

Transport Parameters

Transport parameters include heat and mass transfer coefficients, diffusivities, and thermal conductivities. Relatively few efforts have been made to determine these in SSF systems. With respect to mass transfer, Auria et al. (24) estimated the diffusivities of oxygen and carbon dioxide within substrate beds as 2 to 25% of their diffusivities in air, with the values decreasing with increasing biomass content. For transfer of oxygen into the moisture films on substrate surfaces, values of $K_L a$ have been estimated by a sulfite oxidation method to range from 1,140 to 3,050 h^{-1}, with the value increasing with increasing airflow rate (48). For nutrient diffusion within particles, Mitchell et al. (6) estimated the diffusivity of glucose at 37 °C as 8.2×10^{-3} cm^2 h^{-1} compared with a bulk diffusivity in water of 2.5×10^{-2} h^{-1}. However, because they used an artificial gel substrate, this value is not of general applicability. They were not able to measure glucoamylase diffusivity using their experimental system. Diffusion has not been investigated for real SSF substrates containing structures such as fibers and cell walls.

With respect to heat transfer, coefficients for heat transfer between subsystems in SSF bioreactors have typically been estimated from literature values for non-SSF systems. However, because these coefficients can depend strongly on bioreactor design and operation, they need to be determined experimentally for the particular system used. Thermal conductivities of composts varied from 0.25 W m^{-1} K^{-1} at 20% moisture content to 1.0 W m^{-1} K^{-1} at 70% moisture content (39).

Thermodynamic and Physical Parameters

Thermodynamic parameters include enthalpies of vaporization and saturation humidities that are usually straightforward to obtain from thermodynamic databases. However, it may be difficult to estimate other parameters such as the heat capacities of substrates with complex compositions, and therefore experimental measurements should be made. Physical parameters such as substrate densities and bulk packing densities are readily measured experimentally. They vary widely between different systems.

SUMMARY AND NEEDS FOR THE FUTURE

Growth in SSF results from the interaction of three types of phenomena: microbial growth, local transport, and bulk transport. This article has surveyed the ways in which these phenomena have been described in mathematical models of SSF processes. In these models, many simplifications are made, reducing both the complexity of the system and the complexity of the processes occurring within the system. Despite these simplifications and assumptions, the usefulness of the models has been identified. Microscopic models give insights into how diffusion of enzymes, their hydrolysis products, and oxygen can limit growth. Macroscopic models give insights into how interparticle oxygen transport, and more importantly, how heat transport can limit growth within bioreactors.

SSF and traditional liquid culture systems are quite different: compared with liquid culture systems, in SSF systems water availability is more restricted, and diffusional limitations play a greater role. It is these differences that can give SSF advantages over liquid culture in certain cases; the unique SSF environment can stimulate certain products, and the low water content can lead to higher concentrations and therefore higher volumetric productivities and reduced recovery costs. These differences also lead to

some differences in approaches to modelling SSF and liquid culture. Due to the heterogeneity of SSF systems, differential equations must often be formulated and solved for each of several subsystems, and due to the importance of transport processes, many of the equations involve partial differential terms. Also, due to diffusional limitations within substrate particles, it is not simple to measure the substrate concentration experienced by the microbe. For this reason, growth kinetic expressions for the majority of models in SSF will continue to be substrate independent. This is in contrast to liquid culture, where even simple models usually take substrate concentration into account, often assuming a Monod-type relationship. However, in the future, some models will be developed that integrate the microscopic- and macroscopic-scale processes occurring within SSF. These models will give interesting insights into how the interactions among the various phenomena control growth at various stages during SSF.

More work needs to be done in establishing the validity and flexibility of current models. Due to the difficulties of measuring key process parameters in SSF, many of the parameters used in these models have been estimated, or borrowed from other systems. Therefore, more effort is required to measure model parameters in SSF systems. More attention must be paid to microbial physiology. Current expressions describing the effect of elevated temperatures on microbial growth are based on experiments where a number of cultures have been incubated isothermally at a range of temperatures. Better expressions will be developed from experiments that mimic the temporal temperature profiles characteristic of SSF systems. In addition, product formation is usually the main objective of an SSF process. Accurate description of product formation kinetics will require an understanding of how the SSF environment influences microbial product formation.

Our current ability to apply SSF technology at large scale is limited by our relatively poor knowledge of the basic engineering principles underlying SSF bioreactor performance. Rational rules for the design and operation of large-scale SSF bioreactors are crucial to the future commercial success of SSF technology, and mathematical models of bioreactor performance will be essential tools in the development of such rules. The power of the modeling approach is obvious. Modeling is a more cost-effective way of searching for optimal bioreactor designs than building large bioreactors and encountering problems experimentally. It does not replace the need to experiment, but can reduce the experimental program by avoiding poor designs and can guide the program by raising questions about the dominant mechanisms and the key process variables. However, because the models to date have been based on laboratory-scale systems, work needs to be done to confirm that the mechanisms incorporated into the models remain dominant at large scale. Several of the bioreactor designs, such as stirred bioreactors and air solid fluidized beds, have not received any modeling attention. Air solid fluidized beds have the potential to overcome many of the problems faced in other SSF bioreactors, and therefore urgently need modeling attention.

OUTLINE

INTRODUCTION

Solid substrate fermentation (SSF) processes may be defined as four-phase systems. The first, an air phase, is a continuous system that usually flows through a solid bed. The solid second phase consists of a water-insoluble support containing the third phase, a nutrient-rich aqueous solution. This solution is tightly absorbed within the matrix of the insoluble support; some water, however, may exist in a free state in capillaries, although this can never exceed the water-holding capacity of the matrix (1). The fourth phase is the microorganism itself, which grows in or around the support and may grow in the interparticular free space.

SSF has been used by humans for centuries. Traditional uses of SSF systems include the production of fermented foods, pigments, and koji in the Far East. Within the past decade, the production of other, higher-value microbial metabolites such as antibiotics (2,3), biopesticides (4), aromas (5), gibberellic acid (6–9), and bacterial α-amylase (10), to name a few, have been evaluated with highly promising results. Polymeric and insoluble humid agricultural products or by-products are usually employed in SSF processes. These serve a dual functions (*1*) as a source of carbon, energy, nitrogen, and other nutrients and (*2*) as the support for microorganism growth (11). A novel system has been recently developed (12) whereby a solution of nutrients is adsorbed on an inert support.

This type of process has several features that make SSF particularly attractive to industry. One of the main advantages is the use of agroindustrial by-products as raw materials, because these are not only low in cost but are usually very difficult to dispose of properly, given the organic nature of the by-products and the large volumes generated. Differential expression of certain microbial metabolites, which are not expressed in liquid medium (13), is another significant attribute of this culture system, as, for example, in the production of active *Trichoderma* propagules for bio-

logical control programs as well as in bioremediation applications.

Despite certain drawbacks of SSF, higher yields, measured in terms of product per volume, make the process economically viable. Reports of SSF metabolite concentrations 100-fold higher than those obtained from submerged fermentation (14) and biomass concentrations up to 200 g/L have been published. SSF does not need large bioreactors, and downstream processing costs might also be lower. The low energy consumption of SSF bioreactors, which require only occasional agitation of the solid bed, is a further asset from the standpoint of operating costs. Last, but not least, SSF generates less effluent, thereby reducing the environmental impact of the process as well as treatment costs.

In spite of these promising features, few applications of SSF processes are currently utilized in industry. Most SSF research has been carried out only at the laboratory level, where its interest as a fermentation system has been highlighted. Unfortunately, only a few of these processes have been evaluated at pilot or preindustrial levels because of problems inherent to solid substrate cultivation technology:

- Relatively slow rates of production, due to the additional barrier to growth imposed by the solid substrate
- Limited capacity of dissipating metabolic heat generated during cultivation
- Mass transfer problems, in particular, slow diffusion of nutrients from substrate to microorganism
- Lack of readily available, appropriate sensors for monitoring
- Limited research on SSF reactor models, control strategies, and scaling-up procedures

The latter topics are considered in this article in an effort to highlight areas that call for substantial development to bring about widespread industrial acceptance of this unique process.

The production of gibberellic acid by the filamentous fungus *Gibberella fujikuroi* is used throughout to illustrate the technical difficulties in the automation and scaling-up of SSF technology. Gibberellic acid is a biologically active compound, naturally present in plants, which acts as an hormone and regulates many plant growth and development processes. Gibberellic acid is a typical secondary metabolite, which in *G. fujikuroi* is triggered on exhaustion of assimilative nitrogen sources.

This production process presents a real challenge to those involved with automation and scaling. *G. fujikuroi* is a slow-growing filamentous fungus, generates significant amounts of metabolic heat during its exponential growth phase, and is highly susceptible to microbial contamination. Hence, successful advances in this process will boost the industrialization of SSF technology.

AUTOMATION OF SSF BIOREACTORS

Design

This section covers the design and operation of current SSF bioreactors, many of which are still the subject of research and development.

Bioreactor Types. SSF bioreactors may be of static (fixed-bed) or agitated (stirred) design. Tray and packed bioreactors are most commonly used among the former, whereas rotating drums, periodically agitated tanks, and rocking and fluidized-bed bioreactors are examples of the latter. Most SSF bioreactors operate in batch form, although water and nutrients are added periodically in many systems. Very few SSF bioreactors have been designed to operate continuously (15–17), and no industrial continuous processes have been reported.

Tray Bioreactors. Trays, one of the simplest types of SSF bioreactor, have been employed in the Far East for many years. They are readily available commercially (18) from laboratory to industrial scale. The main characteristics of this type of bioreactor follow (11):

1. A set of trays are covered with a thin layer of solid substrate.
2. Trays are kept inside a chamber, normally under controlled environment.
3. Forced air is not commonplace, although trays can be perforated allowing air to circulate smoothly through their bases.
4. In some cases the solid bed is agitated gently, either manually or automatically, using simple mechanical devices.

The main drawback of this type of bioreactor is that it is highly labor intensive, so that automation of large-scale processes is very difficult. Also, because the solid layer in the tray must be thin and the trays cannot be too close to one another, very large chambers are required to achieve industrial levels of production. Industrial applications of this type of reactor include production of mushrooms (*Agaricus bisporus*) and tempeh as well as aseptic production of soy sauce koji mold spore inoculum.

Packed-Bed Bioreactors. Packed-bed bioreactors are normally cylindrical tanks, filled with a solid substrate suspended on a perforated surface through which air is forced. The inlet air conditions (temperature, humidity, and flow rate) are generally regulated. At laboratory scale, the most common types of packed bioreactors are known as Raimbault columns. The latter are submerged in a thermoregulated bath and supplied with saturated air. In larger systems, cooling fluid is forced through double walls, coils, or plates (19) immersed in the solid bed to overcome the difficulty of removing metabolic heat. The main disadvantage of this type of bioreactors is its propensity for heterogeneous growth that hinders scaling up to industrial size.

Plastic bags filled with solid substrate provide a typical example of commercial application of packed bioreactors. The latter includes mushroom cultivation (*Agaricus bisporus, Pleurotus ostreatus*, etc.), production of biopesticides (*Trichoderma harzianum*), tempeh, and koji mold spore inoculum. In addition, biofilters (microbial flora adsorbed to a porous solid support) have recently been developed and commercialized for treating toxic gaseous and liquid streams.

Rotating Drums. Features of rotating drums used as bioreactors (11) include the following:

1. A partially inclined cylinder is filled with substrate up to a predefined level.
2. Smooth cylinder rotation mixes the solid bed; this process is usually enhanced with baffles.
3. Aeration is occasionally provided by means of tubes placed in the free space of the cylinder or in its shaft.

Rotation must be controlled to avoid damaging the microorganisms or causing substrate agglomeration or particle breakup. The control of temperature in this type of bioreactor is very difficult and becomes more difficult when increasing the scale of the reactor. Rotating drums are particularly appropriate for bioremediation of contaminated soils. Klein (16) has described several industrial applications of this technology to kerosene-contaminated soils and to degradation of mineral oil hydrocarbons, chlororganics, and polycyclic compounds. Bioreactor sizes reach 40 m in length and 3 m in diameter, with a treatment capacity of 0.5 to 1 ton/h.

Rocking Bioreactor. Although similar to the rotating drum, the rocking bioreactor cylinder rocks gently instead of performing a complete rotation. It achieves acceptable agitation and mixing without damaging either the microorganism or the substrate. This bioreactor has only been built and tested at a laboratory scale (20).

Fluidized-Bed Bioreactors. This bioreactor is a vertical cylinder inside which the solid substrate rests on a perforated plate. Air forced through the plate at high flow rates suspends the solid in the air, causing the solid–air mixture to behave like a fluid. The main advantage of this type of bioreactors is (11) the high rate of heat transfer and aeration resulting from the enormous solid–gas interface area. Additionally, gases and volatile metabolites are easily removed from the bioreactor, a very good degree of mixture of the solid is achieved, and the absence of mechanical components simplifies the automatic control of the process. These factors permit high yields, reducing the needs for large bioreactors.

Most investigations with this technology have included yeasts, either for cell biomass or ethanol production. Other microorganisms such as filamentous fungi have also been assayed. Even though these cells could be damaged by the vigorous agitation, this system causes less harm than conventional, stirred bioreactors. To our knowledge, this technology has not yet been applied at an industrial scale.

Stirred Bioreactors. Stirred bioreactors are probably the type of SSF bioreactor most widely used at the industrial scale. Here the solid bed is agitated by screws, palettes, or other mechanical devices. Agitation is intermittent and is varied during the process. These bioreactors may be either vertical or horizontal.

- Among vertical bioreactors, the most popular are the Japanese Fujiwara bioreactors (21), which are expensive. These are specifically designed and mostly used for koji production in the Far East and in the United States.
- Among the horizontal type, the best known is the INRA-Dijon bioreactor (22), which is used by some French companies in the production of enzymes (Lyven) and biopesticides (Calliope). This open, rectangular reactor is based on a design for a barley malting process. The solid bed rests on a perforated plate through which air is forced. Agitation is performed by vertical rotating screws mounted on a conveyor that moves them back and forth across the main axis of the tank. The shape and size of the screws must be designed specifically for each substrate and microorganism to minimize abrasion and breakup damage.

In both types, water, nutrients, and preservatives can be added by aspersion over the solid mass. Air can be conditioned at the inlet, and the temperature and pH of the solid may be measured at several places within the tank.

Neither the Fujiwara bioreactors nor the INRA-Dijon bioreactor is designed for a completely aseptic operation. However, results obtained using pilot stirred bioreactors with aseptic operation have been published (23–26). These required a high degree of automation and are described extensively next.

Continuous Countercurrent Bioreactor. The continuous countercurrent bioreactor consists of a ribbon-flighted screw inside a horizontal cylindrical vessel. The screw transports the solid matter backward and forward. Roussos and Pyle (17) evaluated this design for the continuous cultivation of *Aspergillus niger* at a substrate feed rate of 0.5 kg/h in the production of glucoamylase. Regulation of aeration, cooling, and water content was achieved through natural convection. It was shown that the mycelium did not suffer any damage. The general performance of this bioreactor was comparable to that obtained in laboratory-scale batch cultivation. Currently, this kind of bioreactor is used for large-scale soil bioremediation in a manner similar to rotating drums (16).

Critical Operating Conditions. The most critical operating variables in controlling an SSF bioreactor are the bed temperature, pH, and water content of the solid support, because microorganisms can only grow and produce within a relatively small range of these operating conditions. Agitation and aeration of the solid bed are further significant factors. Finally, the concentration of nutrients and metabolic gases affect biomass and metabolite production rates, although these variables are very difficult to control.

Temperature. Significant temperature gradients, to 3 °C/cm, can be observed with almost every type of static SSF bioreactor. Any microorganism generates energy (metabolic heat) during its growth. This heat must be dissipated to avert undesirable solid bed temperature conditions. In certain types of reactor, this requirement may become critical. Keeping laboratory-scale reactors, such as Raimbault columns, in a thermostatic bath overcomes the problem. Controlling the chamber temperature of tray reactors suffices in regulating the solid bed temperature; but only if the solid bed is thin enough. Larger pilot- or industrial-scale reactors require additional cooling techniques. Because of simplicity, the most commonly used cooling method is to force air through the solid bed (27). In extreme cases, very cold air or very high flow rates are required to ensure proper regulation of the solid bed temperature. In these situations, good temperature regulation

may be achieved using refrigerated jackets, cooled coils, or plates (19), although these may diminish the useful volume of the reactor. Evaporative cooling is likely one of the most effective methods; the relative humidity of the inlet air is regulated to control the rate of evaporation from the solid bed, thereby governing the amount of heat removed by the air stream. At some point in the process, however, very dry inlet air may be required, which points out the main drawback of this method; excessive drying of the solid bed requires efficient water content regulation in the control system. Ryoo et al. (20) used the technique successfully in controlling the solid temperature of a rocking laboratory-scale reactor. Fernández et al. (25) reported that evaporative cooling was capable of regulating the solid temperature in a 50-kg pilot-scale reactor. Recent simulation studies (28,29) have established the convenience of regulating the temperature of the solid bed through simultaneously manipulating the relative humidity, temperature, and flow rate of the inlet air.

Water Content of the Solid Bed. Regulation of water activity in the solid bed is crucial because water content directly defines microbial growth and metabolite production rates. Laboratory studies should thus determine the optimal water activity for the rates of both growth and production. The manner in which water activity of the solid bed varies with water content as the result of substrate consumption and subsequent biomass accumulation also needs to be assessed.

Control of water content is difficult because on-line sensors are expensive and unreliable. However, this limitation can be overcome using soft sensors based on secondary on-line measurements such as solid bed weight (22). Periodic samples could also be taken manually and analyzed for water content in the laboratory (25). There are several ways to regulate bed humidity, although the easiest is the direct addition of freshwater to the solid bed. Water may also be supplied through the air stream as fog or vapor. Sato et al. (30) were able to control water content by incorporating particles with high water retention capacity in the solid bed. The method ultimately adopted depends on the type of reactor selected and the way in which control of the solid temperature is managed.

pH. The high buffering capacity of the fermenting bed and the lack of appropriate sensors for solid substrate conditions makes pH control difficult to implement. However, pH regulation could be achieved by selecting supplementary nutrients that can be fed periodically during the cultivation; this is particularly true for the nitrogen source (22).

Agitation. Agitation in SSF reactors accomplishes several functions:

- Maintains homogeneous operating conditions
- Permits uniform distribution of water, nutrients, and preservatives supplied during cultivation
- Renews the air occluded between the particles
- Avoids particle agglomeration, crucial when a filamentous fungus is cultivated

The choice of agitation policy is determined by its main purpose. Normally, several objectives must be considered simultaneously, and it is very difficult to establish a priori how agitation could influence each objective independently. The process engineer also must ensure that the agitation neither harms the active biomass (e.g., mushroom culture) nor the substrate. Consequently, the agitation policy, at this point, is fundamentally empirical. Parameters associated with agitation are speed, sensing, and, for reactors employing intermittent agitation, frequency and duration. In fixed-bed reactors, for example, intermittent agitation could assist in the removal of heat upon the saturation of the other temperature loop control variables. Additionally, stirring could be used when air pressure loss exceeds a certain value. When using these types of reactors, however, it is essential to agitate every time water or nutrients are added.

Aeration. Because most SSF processes involve aerobic microorganisms, oxygen transfer toward the biomass is fundamental (11). Aeration also plays a key role in the removal of metabolic heat, CO_2, and volatile metabolites occluded within interparticular spaces. The following mechanisms are potentially important as relates to mass transfer efficiency between the gas phase and the microorganisms in SSF bioreactors:

- Convection from the bulk of the gas phase toward the interparticular spaces.
- Diffusion through the stagnant gas layer that surrounds the particles.
- Diffusion through the liquid layer that covers the surface of the particles. The high solute concentration of the liquid layer characteristic of SSF processes may significantly affect gaseous diffusion through this layer. To our knowledge, no research has directly targeted this important factor in SSF reactor technology.
- Diffusion inside the porous particles.
- Microbial oxygen consumption and CO_2 production.

Only the first two of these mechanisms could be influenced by either reactor design or operating conditions. Convection in particular is important in packed reactors or in those in which agitation is very slow or infrequent or aeration is very weak. Interparticular oxygen transfer is also retarded in substrates formed by a mixture of fine and thick particles, above all when filamentous microorganisms are cultivated. This situation creates an additional barrier to air circulation. The other mechanisms are fundamentally determined by the characteristics of the substrate (particle size, form, porosity, texture, etc.) and of the microorganism.

Case Study: An Aseptic Pilot Bioreactor for SSF Processes. An SSF general-purpose aseptic pilot reactor of 50-kg nominal capacity that has been built and evaluated for the production of gibberellic acid (GA_3) is now described.

General Features. The structure of the stainless steel reactor encompasses the following parts:

1. A hermetic lid with perforations (for air sampling and nutrient feeding) and an observation window;

the agitation system (motor, double arm, and blades) and the feeding system are mounted on the lid.

2. The principal body has a double-jacket system for sterilization.
3. An air chamber, located in the lower part of the reactor, is used for inlet air homogenization. Air temperature and relative humidity are measured here.
4. A rotating basket 1.15 m in diameter and 0.28 m high has a nominal capacity of 50 kg of wet solid. The basket base contains perforations of 2 mm in diameter with a separation of 3.5 mm.

During reactor operation, the following main steps can be distinguished: (*1*) sterilization, (*2*) substrate loading, (*3*) inoculation, (*4*) cultivation, (*5*) substrate unloading, and (*6*) cleaning. All these steps except cultivation are carried out manually.

Air Conditioning. As shown in Figure 1, the air is forced into the reactor by a fan (a) with a prefilter (b). The speed of the air can be regulated manually between 0.25 and 7 m/s through a purge system (c). An absolute filter (d) ensures the purity of the air, it is able to retain particles larger than 0.3 μm with a minimal efficiency of 99.99%. A heating system (e), with 6-kW electric resistance, can heat the air for reactor sterilization and process needs. In addition, the air can be cooled to 0 °C with fins (f) and a refrigeration system (g). The relative humidity is controlled by vapor addition through a solenoid valve (h) connected to a steam boiler (i) with a working pressure of 5–10 psi.

Agitation. The bed agitation system includes two arms: one contains blades that operate like a plough, and the other has curved paddles that scrape the basket base. Both arms can be manually regulated with cranks, according to process needs. The basket movement is provided by a reducing motor of 1.5 kW that is connected to the basket shaft. An inverter driver controls the rotation speed, achieving a minimum of 5 rpm with a torque of 5,500 Nm. An aseptic water seal ensures that all the inlet air passes through the solid bed. The basket is supported on roller bearings for a uniform and soft movement.

Water and Nutrient Feeding. A set of three sprinklers, mounted on the lid, are used to add water and dissolved nutrients periodically. The solution is based forced into the reactor with a peristaltic pump with a maximum flow of 10 L/min. To distribute the solution over the entire solid bed, the agitation system is turned on each time the solution is fed. The monitoring and control system of this reactor is described later.

Instrumentation and Control

Automation of SSF bioreactors is a complex problem that has yet to be resolved satisfactorily before scaling up the process. In fact, this is why much laboratory-scale research has not yet been scaled up to industrial level (1,6,8). Many of the difficulties complicating the operation and control of SSF bioreactors concern the regulation of temperature and water content in the solid bed. If the high rate of heat generation during the growth period is poorly controlled, overheating of the bed can result. The control of water content is particularly cumbersome. Part of the water is strongly bound to the solid, while the rest may remain free in the capillary areas of the material. Care must be taken to

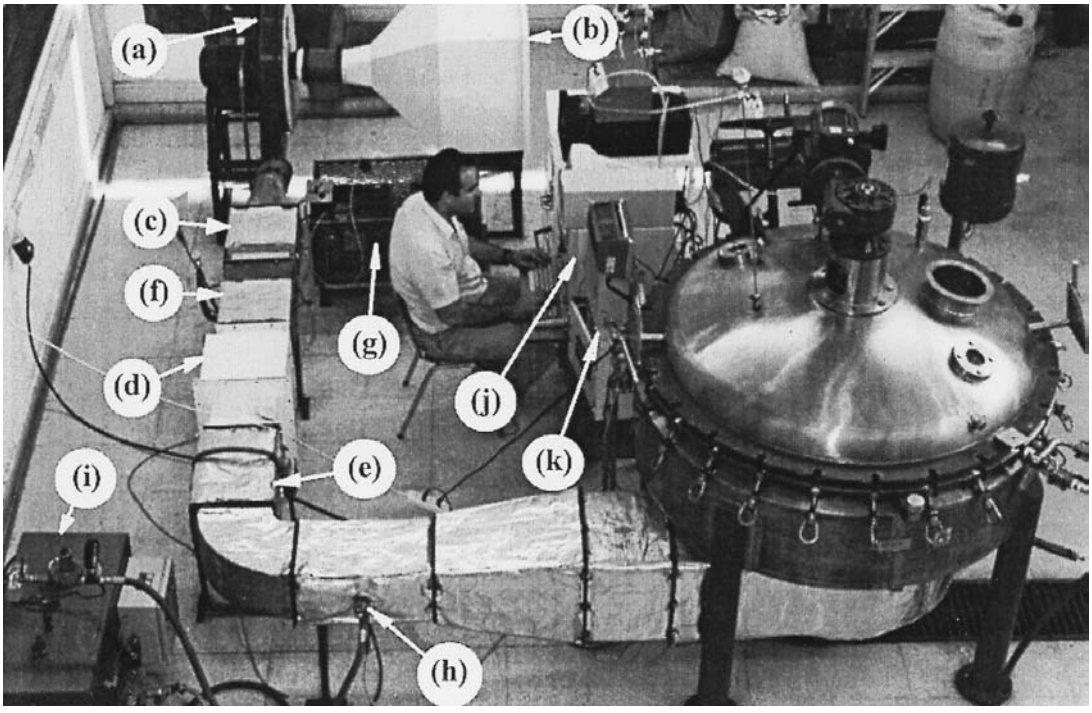

Figure 1. Aseptic pilot solid substrate fermentation (SSF) reactor with its air conditioning system: (**a**) fan, (**b**) prefilter, (**c**) purge system, (**d**) absolute filter, (**e**) heating system, (**f**) fins, (**g**) refrigeration system, (**h**) solenoid valve, (**i**) steam boiler, (**j**) control system, and (**k**) programmable logic controller (PLC).

avoid saturation of the solid matrix, which will lead to anaerobic conditions. The lack of appropriate and inexpensive sensors for monitoring water content on-line results in difficult, slow, and imprecise regulation of water content. The development of new instruments and control strategies specific to SSF processes would unquestionably simplify the development of scalable and economically competitive SSF bioreactor technology.

Instrumentation One of the main limitations of SSF as opposed to submerged fermentation (SMF) bioreactor development is the lack of specific and inexpensive instrumentation enabling proper monitoring and control of the processes. Much of the instrumentation used in SSF bioreactors is associated with measurements of the gaseous phase only. The following section discusses instrumentation commonly used in the monitoring and control of solid substrate bioreactors.

Temperature. The solid bed temperature is a primary control objective because overheating can seriously impair process performance. The temperature of the air stream is an important manipulated variable in many SSF bioreactor control strategies. Several relatively inexpensive and efficient temperature sensors are available, with thermocouples being the most widely used. When two wires of different metals are welded at two junctions and kept at different temperatures, an electric current will flow in the circuit, proportional to the temperature difference. This is the principle behind thermocouples, of which there are of several types, differing with the kind of metals used: J, iron-constantan; T, copper-constantan; K, chromel-alumel; etc. These types are appropriate for different temperature ranges and ambient conditions (reducing or oxidizing). Error limits range from ± 0.5 °C to ± 2.2 °C, depending on thermocouple type and quality. Their main advantages are fast response, shock resistance, small size, probe flexibility, heavy use capability, low cost, and suitability for both high and low temperatures. They must be calibrated periodically.

The electrical resistance of metals changes with temperature. This principle is applied in resistance temperature detectors (RTDs), which are generally more expensive than thermocouples and are suitable over a narrower temperature range; they are however more accurate and do not need periodic calibration. Platinum RTDs are most commonly used.

Air Flow Rate. Differential pressure measurement, with accuracy ranging from $\pm 0.8\%$ to $\pm 5\%$, relies on the pressure drop created as a fluid posses an obstruction (such as a concentric orifice, venturi, or pitot tube), and is therefore proportional to flow rate. The main limitation of these devices is that the energy cost from the loss of pressure can be considerable. A differential pressure transducer is needed to include this measurement in a digital control system.

Another air velocity measurement instrument commonly used is the turbine anemometer. A rotating device is placed in the path of the fluid, where its rotational speed is proportional to the fluid velocity and provides accurate flow measurement over wide ranges. Thermal anemometers, in which a thin wire immersed in the fluid is heated by an electric current, can also be used to measure air velocity. The fluid velocity is related to the heat dissipated from the wire. Full calibration is required for anemometers used for flow rate measurements because velocity depends on the anemometer's transversal position inside the duct.

Relative Air Humidity. Electrochemical sensors are most commonly used for determining relative humidity. Two widely used electronic relative humidity (RH) sensors are the Dunmore element and the Pope cell. The former employs a solid substrate coated with a LiCl solution. The hygroscopic nature of this salt causes it to take up water vapor from the surrounding atmosphere. Dunmore cells, while excellent RH sensors, are normally designed to cover only a narrow range (from 40% to 60% RH). The Pope cell is similar to the Dunmore cell with the substrate being made from sulfuric acid-treated polystyrene. The main advantage of Pope cell is its wide range of response covering from 15% to 99% RH.

Pressure and Differential Pressure. When certain asymmetric crystals are deformed along specific axes, an electrical potential created within the crystals produces an electric current in external circuits. Such devices are called piezoelectric sensors. Cultured quartz is both readily available and reasonably priced for this purpose. In addition, it presents near-perfect elasticity and stability and is temperature insensitive. Instrument response times are of the order of submicroseconds. Differential pressure transducers consist of two chambers connected internally to a rod and externally to high and low pressure measuring diaphragms. When a difference of pressure is encountered the rod is displaced in the oil-filled chambers, producing a signal.

Air Composition. Analysis of exhaust gases is very useful in the monitoring and control of SSF bioreactors (31). Information on the physiological state and respiration rate of the culture can be obtained through continuous measurement of CO_2 and O_2 concentrations in the gas outlet stream. The specific growth rate (μ), biomass concentration, and respiratory quotient (RQ) can also be resolved on-line. Other volatile compounds associated with the metabolite of interest can be measured on-line, facilitating production control and optimization. On-line measurement of CO_2 and O_2 can be performed by gas chromatography or special-purpose gas analyzers. The main advantages of the first method are that many compounds can be monitored with the same instrument and over a wide range of values. Other gas analyzers may be more precise and provide faster response. The several kinds of instruments include paramagnetic analyzers for CO_2, O_2, and ammonia, infrared instruments for CO_2, and electrochemical probes for O_2. Care must be taken to dry the sampling air beforehand and to provide a regulated flow rate entering the instrument to obtain meaningful results.

Solid Bed Water Content. Water content of the reactor bed is very difficult to measure on line. There are no instruments commercially available that can measure water content in solid substrates at levels greater than 80% with good performance and a small error. Conduction and capacitance principles are applied, to good effect, in measuring water content up to 50%. The main problem in measuring high water content in solid substrates, with

instruments based on conductance/capacitance, is that the apparent density varies unpredictably during cultivation, either because of agitation or growth of the biomass. Devices based on infrared (IR) measurements of solid samples yield very good results, but, they are expensive and their application for on-line measurement in aseptic SSF bioreactors is not well developed. A probe that can measure the water activity of a solid medium consists of a chamber which is separated from the medium by a hydrophobic membrane and contains a capacitive device to measure the relative air humidity within it (32).

Control Strategies. Proper regulation of the temperature and water content of the solid bed over several days has long been recognized as crucial to optimum performance (33). The major challenge in temperature control is to overcome the limited dissipation capacity of the metabolic heat generated during the cultivation. Temperature gradients across a bed can be as much as 20 °C, especially during the period of high heat generation. Although agitation of the bed can help in reducing the temperature gradient, in practice this heat cannot be removed by vigorous or frequent agitation, as this often has a negative impact on microbial growth and metabolism. Several methods, linked to reactor type, have been proposed and experimentally tested in attempting to control the temperature of the solid bed. Forced air and the addition of freshwater have been successfully used (27) in controlling the temperature of a packed column (35 cm height × 6 cm diameter). Temperature control has also been achieved with intermittent agitation in a laboratory rotating drum reactor (34) that homogenized the bed and also decreased its compactness. However, agitation can damage the hyphae of filamentous fungi and may alter structure morphology.

The most effective method of controlling bed temperature may be evaporative cooling. In this strategy, the rate of water evaporation from the bed can be modified by manipulating the relative humidity of the inlet air, considerably increasing the rate of heat removal. Applying this principle, good temperature control has been attained at laboratory scale in a rotary drum bioreactor (31) and a rocking bioreactor (20). A further consideration, however, is that freshwater must be supplied to avoid drying of the bed. In a packed bed, the rotation or rocking motion has to be replaced with discontinuous agitation. Our experience with 50-kg and 200-kg aseptic pilot reactors indicates that none of these strategies is sufficient to maintain proper control of the solid temperature (25); periodic agitation of the bed and manipulation of the inlet air temperature are also required. Simulation studies with SSF pilot-scale reactor models have shown that a multivariable algorithm can control solid temperature efficiently by simultaneous manipulation of relative humidity, flow rate, and inlet air temperature (28,29).

Few publications have considered the regulation of solid water content. For example, wet wood pulp particles have been placed in the solid substrate during cultivation of *Aspergillus oryzae* to provide a reservoir of free water (35). However, this practice reduces the effective bioreactor volume. In other works, the water content of the bed has been controlled by manipulating the ambient air temperature (36); the algorithm was based on energy and water balances. While this method was successfully applied in a laboratory bioreactor (20 × 16 cm), it is difficult to scale up to pilot level. Fernández et al. (25) controlled the water content to keep the water activity constant in the solid medium in a 50-kg pilot reactor. As no on-line measurement of water content was available, samples were taken manually to define the addition of freshwater based on a water balance and heuristics.

Carbon dioxide and oxygen in the outlet gas can be controlled by manipulating the inlet air flow rate (31) and pH can be controlled by spraying an acid or base solution over the solid bed (22). Nutrient concentration, can be maintained by spraying a solution directly over the solid bed (37) or into the inlet air (38).

Control Algorithms. Discrete PID and on–off control algorithms are currently used in both pilot and industrial SSF bioreactors. In light of the established process difficulties, these controllers prove difficult to tune and demand manual supervision to ensure effective operation (25).

There are remarkably few reports concerning applications of advanced techniques for controlling SSF bioreactors. The work of Ryoo et al. (20) can be mentioned as an isolated example in which an adaptive algorithm was used to control the temperature of the solid in a rocking reactor by evaporative cooling. These authors also estimated biomass concentration and total dry mass on-line using an extended Kalman filter. Optimizing the addition of nutrients to maximize the production of secondary metabolites in fed-batch SSF reactors remains a challenge, although some attempts have been made to solve the problem empirically (37,38). A short description of a number of advanced control methodologies that have been applied successfully in SMF bioreactors follows. We believe that these techniques can also be useful in the automation of SSF reactors.

Adaptive Linear Control. In essence, an adaptive controller is an on-line algorithm that estimates parameters that are, directly or indirectly, associated with the dynamics of the process. These parameters are then used to "tune" a control law on-line. Several adaptive control algorithms have been described (39,40). These controllers are particularly appropriate for processes that have variable time delays and that exhibit nonlinear dynamic behavior. Many successful applications of adaptive control in biotechnology have been published (41–44). As mentioned, application of this technique in SSF automation has been experimentally assessed by Ryoo et al. (20).

Nonlinear Control. Because real processes present nonlinear dynamics, nonlinear control techniques have attracted the attention of many researchers, both as to the theory and in the development of real-time applications. The employment of adaptive techniques in estimating uncertain or varying model parameters greatly improves the likelihood of using nonlinear control successfully in industrial processes. Several applications of this technique in biotechnology have been reported. Bastin and Dochain (45) have even developed a general methodology for designing nonlinear bioreactor controllers. Successful industrial ap-

plications have been reported by both Pomerleau and Viel (46) and Chen et al. (47).

Predictive Controllers. Paján et al. (28) compared the performance of a dynamic matrix control (DMC) predictive algorithm (48) with that of PID in the control of a simulated fed-batch SSF process and established that employing DMC greatly simplified the design and start-up of the control system. DMC possesses a flexible structure that can be adapted to the process facilities and limitations. In this particular application, the effort devoted to tuning the temperature control loop was significantly reduced and a better closed-loop response was achieved with a DMC algorithm than with a PID one. Real-time application has not yet been described, but the authors believe that this could be on optimal control strategy.

Case Study. To illustrate how the foregoing ideas can be applied to a real SSF process, a control system is now fully described for pilot SSF bioreactors (24,25).

The Process. Two aseptic packed-bed bioreactors (50 kg and 200 kg of total solid nominal capacity) using periodic agitation and forced air were built to scale-up the production of gibberellic acid by the filamentous fungus *Gibberella fujikuroi*. This process is demanding because *G. fujikuroi* is sensitive to high temperatures (above 36 °C) and to contamination by other microorganisms. Because it is filamentous, this fungus is sensitive to mechanical stresses when the solid bed is agitated, and its growth increases bed compactness, which creates a reduction in heat and mass transfer rates. In addition, bed overheating can easily occur as the result of the high rate of metabolic heat generated during the growth period. Finally, the processing time is long, demanding a robust control system.

Monitoring. Variables measured on-line are as follows (Fig. 2):

- Temperatures: in the solid bed and in the inlet and outlet air (K-type thermocouples)
- Relative humidity of the inlet air
- CO_2 concentration in the outlet air
- Air pressure loss throughout the bed
- Inlet air speed

Bed water content was measured off-line every hour.

The following remote commands are available for manipulation:

- Inlet air electric heaters (on–off; 6 kW maximum for sterilization and 3 kW maximum for operation)
- Inlet air cooler (on–off; 6.6 kW capacity)
- Bed agitation speed (regulated between 3 and 15 rpm) for both reactors
- Local screw stirrers (inverted drive) for 200-kg reactor only
- Water addition flow rate (on–off; peristaltic pump, 600 rpm)
- Steam addition (on–off; solenoid valve)

Finally, the inlet air flow rate can be set manually between 50 and 500 m^3/h.

A programmable logic controller (PLC) is used for data acquisition and control of primary actuators (Fig. 2). Operator and control calculation interaction are carried out via an IBM-compatible PC computer linked to the PLC. Project-specific software was developed for the PC with a graphic interface to handle the control systems in either automatic or manual mode (Fig. 3).

Control System. The primary objectives of this control system are to regulate solid bed temperature and to control bed water content according to a varying reference. The secondary objectives are the minimization of temperature gradients within the bed, as well as bed compactness.

Control of the bed temperature is based on evaporative cooling, by manipulating the relative humidity of the inlet air and maintaining its temperature at a low value. During the period of high heat generation, manual operation of inlet air flow rate, inlet air temperature, and agitation is also necessary to avoid bed overheating. The average bed temperature is fed into a digital PID control algorithm to drive the setpoint of the inlet air relative humidity. This, in turn, is controlled with an on–off algorithm with a dead band and hysteresis that commands a solenoid valve adding steam. The inlet air temperature is further controlled with another on–off algorithm with a dead band and hysteresis that manipulates the heaters or coolers, according to process needs.

The water content of the bed is controlled through the periodic addition of freshwater. The reference trajectory of the water content was computed in the laboratory based on water activity studies. A solid sample was taken each hour from the reactor for the laboratory measurement of the water content. The amount of water to be added is determined by the operator using an approximated water balance and their own experience. The bed is agitated at each addition of water.

To keep the bed as homogeneous as possible and to avoid excessive interparticular aerial growth, which would reduce porosity, a periodic agitation policy was established. The degree of homogeneity is defined by the temperature gradient inside the bed, while interparticular aerial growth is estimated by the loss in air pressure through the bed, as suggested by Auria et al. (49); this is a semiautomatic loop that employs heuristic logic. The operator may establish the agitation speed, its duration, and, as for the 200-kg reactor, also its path (left or right, up or down for individual stirrers).

Control Performance. The control strategy adopted here provides efficient operation of an aseptic pilot SSF bioreactor. When the reactor was run manually, it required the constant attention of at least two operators. The current control system, however, requires only one operator, who has relatively little interaction with the process; the system even allows bioreactor operation without direct supervision at certain times. Moreover, the control of bed temperature and water content is more precise than was possible without automation. Although the inlet air conditioning control system exhibits limitations, such as oscillations and offsets (25), these do not influence bed temperature control. The latter loop is critical to the achievement of high biomass and product concentrations.

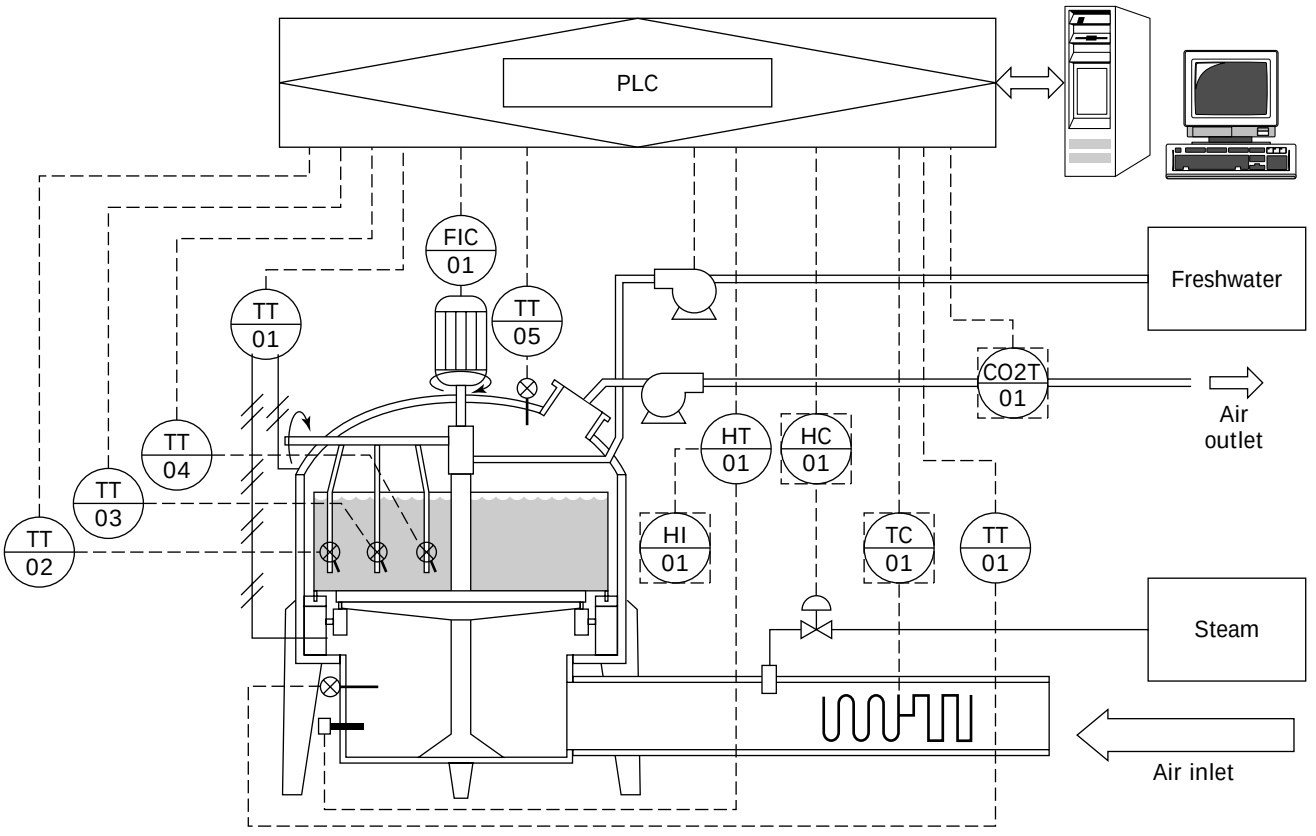

Figure 2. Process and instrumentation diagram (P&ID) of a pilot SSF reactor.

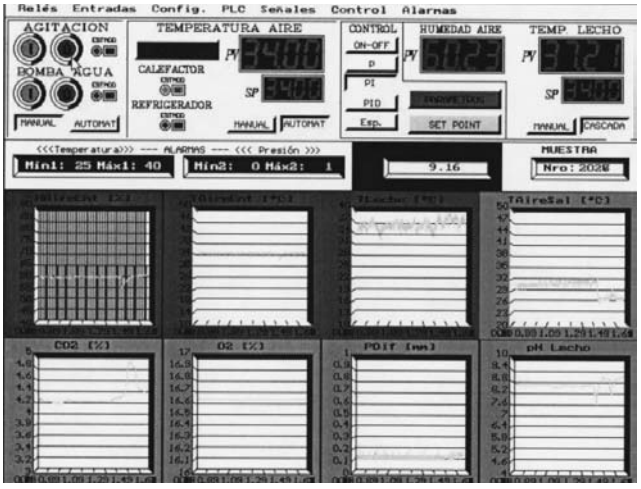

Figure 3. Example of graphics interface for SSF reactor operation.

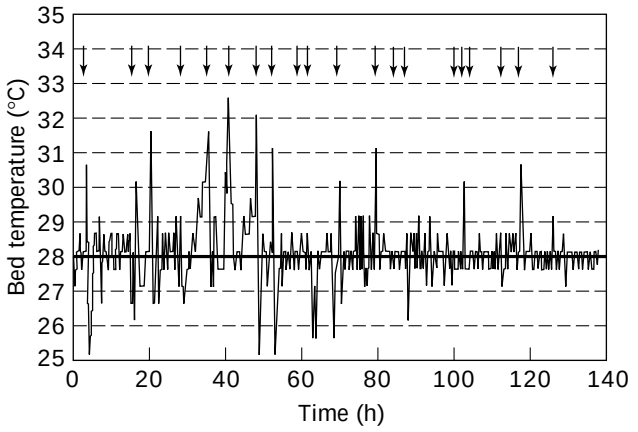

Figure 4. Bed temperature control of a SSF reactor. Agitation time is shown by arrows.

Adequate average bed temperature (Fig. 4) and water content control (Fig. 5) are achieved, although they are not fully automatic. For temperature control, evaporative cooling is insufficient during high heat generation and must be complemented with agitation and direct manual operation of the inlet air temperature and flow rate. Lacking appropriate sensors, control of bed water content is performed manually. Another significant limitation of the current system is that it is difficult to control the temperature gradient of the bed during high heat generation (not shown). However, this is undoubtedly more a limitation of the current agitation system than of the controller. It is also noteworthy that the control strategy was successfully scaled up from a 50-kg reactor to a 200-kg design with only minor adjustments.

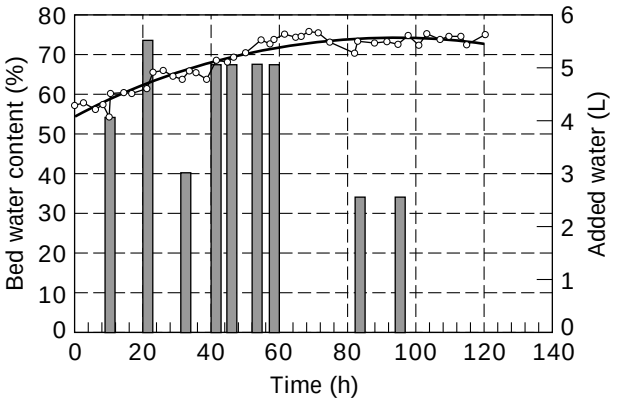

Figure 5. Water content control of a SSF reactor. *Bars* indicate addition of freshwater.

Future Developments. Before scaling the bioreactor up to industrial capacities (2 or 3 tons), a multivariable model-based control algorithm that has already been tested using simulations (29) will be installed in the 200-kg bioreactor to achieve control of the bed temperature. In this strategy, the inlet air temperature, flow rate, and relative humidity will be manipulated automatically considering prespecified priorities.

Research is under way to develop on-line estimators of water content, biomass, and product. Thus, through the addition of freshwater and nutrient solutions, these variables will be controlled automatically in the near future.

Modeling. The first step in modeling is to clearly establish the purpose of the model (50,51). This section mainly covers physical models that may be used in scaling-up, optimization, and control of solid substrate cultivation of filamentous microorganisms; black-box (fuzzy, neural networks, etc.) and microscopic models are purposely excluded. Because industrial SSF processes are carried out in batch or semibatch mode, only dynamic models are discussed.

To simplify matters, it is convenient to divide the modelling of solid state bioreactors into three stages. First, it is necessary to describe *biomass growth* and its relationship with respiratory activity (CO_2 and O_2 evolution). The effect of culture conditions such as temperature, water content, pH, CO_2, O_2, and limiting nutrients on biomass growth must be defined. Then, the *production* and *degradation* rates of the metabolite of interest are studied. Finally, *mass* and *heat transfer* phenomena must be included using appropriate energy and mass balances. This step is critical when it comes to scaling-up from laboratory to pilot and on to industrial reactors.

Biomass Growth. Almost all published work on solid substrate fermentation models considers logistic growth kinetics (27,52,53), which assumes that steric effect is the only limitation for microbial growth:

$$\frac{dx}{dt} = \mu_{\max} \cdot \left(1 - \frac{x}{x_{\max}}\right) \cdot x$$

This model may be useful in describing the evolution of the biomass during the growth phase, although it cannot be applied directly during stationary or lytic phases. If the aim of the fermentation is to produce a secondary metabolite, substrate limitation must be included in the kinetic growth model. The most widely used expression for this is the Monod equation, in which the growth rate decreases steadily after the limiting substrate begins to be depleted. This equation may be derived theoretically assuming that the growth rate is controlled by a single enzymatic reaction. Although real systems are much more complex, the Monod equation fits experimental results well. Many other kinetic equations also can be used to fit experimental results, for example, the Contois, Tessier, and Moser (54). Each of these equations considers a single limiting substrate; multiple substrate models are discussed by Blanch (55). Few SSF models consider growth kinetics other than the logistic equation. For example, Mitchell et al. (56) modeled the growth of *Rhizopus oligosporus* on a solid substrate using the Monod equation with glucose as the limiting substrate, and Gutiérrez-Rojas et al. (57) presented a growing kinetic expression that simultaneously included a logistic model and a substrate-dependent model with substrate inhibition.

Temperature and water content strongly influence biomass growth. Few models consider the effect of water content on the growth kinetic in SSF processes. Sargantanis et al. (52) modeled the dependence of the logistic kinetic parameters on temperature and water content using polynomials. Gervais et al. (58) considered the effect of water activity on the biomass growth rate; this variable better represents the physicochemical state of the water in the fermenting solid substrate. The effect of temperature on biomass growth is modeled in several works using different mathematical expressions, such as polynomials (53,59), the Ratkowsky equation (60,61), the Esener equation (27), and the Arrhenius equation (62).

Other important aspects that have received little research attention include dependence on other environmental variables (pH, CO_2, O_2) and the description of the reduction of biomass activity during the lytic phase. Rajagopalan and Modak (59,63,64) attempted modeling the effect of O_2 concentration on biomass growth using the Monod equation. Sangsurasak and Mitchell (53) and Smits (61) included a death rate in their growth models to describe the reduction of biomass activity. Finally, almost all authors use the Pirt linear growth model (65), which relates biomass with respiration activity. This model assumes that respiration activity is proportional to the biomass growth rate, and that a little respiration activity is still present (maintenance) even after the growth has ceased.

Metabolite Production. Although many authors have presented experimental results on metabolite production in SSF processes (66–68), modeling is in its infancy (54,69).

Heat and Mass Transfer. Many of the experimental systems used in the study of fungal growth on solid substrates are small enough (shake flasks, Raimbault columns, thin trays) to ensure homogeneity of the medium; that is, biomass concentration, temperature, water content, O_2 concentration, pH, and nutrient concentration are approximately equal throughout the solid bed. Because these

systems are small, it is relatively easy to keep environmental variables (temperature, water content, O_2) under control. In larger bioreactors (pilot and industrial scale), the situation is very different; in these, it is extremely difficult to regulate the environmental variables and almost impossible to ensure homogeneity of the solid medium.

Few researchers have developed models aimed at predicting or explaining temporal and spatial dependence of temperature, water content, and O_2. These models can be classified as lumped parameter or distributed parameter and as pseudo-homogeneous or heterogeneous. Lumped parameter models are those that do not consider space distribution. In this scheme, process variables depend only on time and are mathematically described by ordinary differential equations. When space distribution is considered, process variables are described by partial differential equations. Lumped parameter models are used to describe very small bioreactors or stirred bioreactors. Larger static bioreactors should be modeled as a distributed parameter system. Models not explicitly considering distribution inside the solid particles are termed pseudo-homogeneous (70), while models that describe gradients inside the solid particles are called heterogeneous.

An early complete model describing a SSF process that was developed by Raimbault (71) purports that the growth of the filamentous fungus *Aspergillus niger* on amylaceous substrates is limited by the lack of surface and free water. These limitations are specific to the fermentation on solid substrates and hence are not applicable to liquid fermentation. Thus, a physiological base is established to explain the logistic model of growth. Raimbault obtained a global model, based on these principles, to predict the evolution of relevant process variables, such as sugars, biomass, CO_2, O_2, water, and metabolic heat. The determination of the maintenance coefficients for sugars, O_2, and CO_2, and the establishment of a global stoichiometric equation of growth, are significant contributions of this work. This author used small laboratory columns (known as Raimbault columns) specifically designed to minimize temperature and humidity gradients.

Another significant contribution to SSF modeling has been presented by Ryoo (72). The main feature of this lumped parameter model is the incorporation of the latent heat of evaporation in the energy balance. This model also considers the degradation kinetics of the substrate (extruded corn) by the filamentous fungus *Rhizopus oligosporus*. Like Raimbault, Ryoo used a logistic model to describe the fungal growth. The model also includes the evolution of CO_2, water content, and temperature. The growth kinetic parameters are calculated in terms of the water content and temperature of the solid bed. This work was carried out in a 20- $\times$ 25-cm rocking reactor.

More recently, Gutiérrez-Rojas et al. (57) proposed a lumped parameter model for the growth of *Aspergillus niger* on inert support in a Raimbault column. The model describes the evolution of biomass, sugar, water, CO_2, O_2, and temperature. It incorporates several new features:

- Growth kinetic with simultaneous steric and substrate limitations
- A temperature-dependent μ_{max}
- An energy balance that includes conduction, convection, and metabolic heat

Using this model, which did not consider evaporative cooling, the authors concluded that the main growth rate-limiting factor was sugar depletion; water and void spaces remained largely available.

Saucedo-Castañeda et al. (27) applied a distributed pseudo-homogeneous model in describing the evolution of the radial temperature gradient of a cylindrical static packed-bed SSF bioreactor with forced air in laminar regime. The energy balance included metabolic heat generation and heat transfer by two mechanisms, conduction inside the solid bed and convection through the reactor wall. The model was calibrated and validated with experimental data obtained in a reactor of 6 cm radius $\times$ 35 cm height during the growth of *Aspergillus niger* on cassava meal. In this example, conduction presented the largest heat transfer resistance.

A similar model was developed by Rajagopalan and Modak (59) to describe a 6-cm-deep tray reactor without forced air. The model was able to reproduce the trend of experimental observations, such as maximum temperatures at the center of the bed, decrease of oxygen concentration, and increase of carbon dioxide from the top to the bottom of the tray. However, it failed to quantitatively fit the experimental data. The authors argued that this is because the model neglects some observed phenomena, for example, evaporative cooling, loss of moisture, and solid shrinkage. Smits (61) included evaporative cooling in a tray bioreactor model, concluding that evaporation was not significant because the differences in water vapor concentrations between the tray and the environment were small.

A heterogeneous form of their original model was developed by Rajagopalan and Modak (64); that is, oxygen diffusion inside a solid particle is also considered. Assuming a zero-order oxygen consumption rate, they found an upper limit for cell density. In addition, the model predicted that, despite aerobic conditions in the gas phase, anaerobic conditions may exist within the biofilm. The same authors (63) also developed a model for fungal growth over an spherical particle of wheat bran, where the growth kinetics included simultaneous O_2 and glucose limitations, using the Monod equation in both cases. Simulations with this model showed that for a typical tray fermentation, oxygen depletion inside the biofilm is the primary cause of growth rate decline. However, as fermentation proceeds, the depletion of glucose causes growth to halt completely. In contrast, for a highly aerated solid bed of spherical particles, J. Thibault, K. Pouliot, E. Agosin, and R. Pérez-Correa (unpublished), using an oxygen transfer model calibrated with published data, concluded that in this case diffusion of oxygen through the biofilm is the main limiting step for oxygen transfer. Therefore, a direct consequence of this result is that for large bioreactors, optimizing operating conditions (air flow rate, oxygen concentration in the gas phase, bed agitation) is not enough to maximize oxygen availability to the microorganism because this also significantly depends on the thickness and the diffusion coefficient of the biofilm. In our opinion, data resulting from this exciting research subject can

significantly improve the overall performance of SSF technology.

Case Study: Modeling of Fungal Growth and Metabolite Production by *Gibberella fujikuroi*. A homogeneous, lumped parameter model that described the evolution of biomass of *G. fujikuroi* growing on an inert support in a Raimbault column was developed. The lag phase was not incorporated either in the model or with the data used for calibration. The main assumptions are as follows:

- Oxygen transfer resistance is negligible.
- Available nitrogen is the limiting substrate.
- Carbon source is not limiting.
- Temperature and water activity are constant throughout cultivation.

The major novelties of this model are the inclusion of the lytic phase of growth and the production of a secondary metabolite in SSF. A more detailed description of the model is under preparation.

Fungal Growth. The Contois equation is used to model the growth kinetics. Total biomass is determined by the glucosamine method (73). To be consistent with the respiration activity, the model also considers active and inactive biomass. Moreover, it was assumed that biomass lysis occurs.

The active biomass concentration is described by

$$\frac{dX}{dt} = \mu \cdot X - k_d \cdot X$$

where μ is the specific growth rate: and k_d is the death rate. The measured biomass, X_m, includes both active and inactive biomass:

$$\frac{dX_m}{dt} = \mu \cdot X - k_m$$

k_m represents a constant lysis rate. The consumption rate of the nitrogen source, urea, is given by

$$\frac{dU}{dt} = -k \cdot U$$

where k is the conversion rate from urea to available nitrogen for the microorganism, N_l, which can be directly metabolized into active biomass. The following expression represents its evolution during cultivation:

$$\frac{dN_I}{dt} = 0.47 \cdot k \cdot U - \mu \cdot \frac{X}{Y_{X/N_l}}$$

where 0.47 corresponds to the nitrogen content of the urea.

The specific growth rate is then

$$\mu = \mu_m \cdot \left(\frac{N_I}{k_N \cdot X + N_I}\right)$$

The evolution of the carbon source, soluble starch, is given by

$$\frac{dG}{dt} = -\mu \cdot \frac{X}{Y_{X/G}} - m_G \cdot X$$

where m_G is the maintenance coefficient. Finally, the respiration activity is described by the accumulated CO_2 using a standard linear growth model:

$$\frac{dCO_2}{dt} = \mu \cdot \frac{X}{Y_{X/CO_2}} + m_{CO_2} \cdot X$$

The following figures compare experimental data, obtained at 31 °C, with simulations using this model (the parameters are given in Table 1).

Figure 6 shows the expected three growth phases: exponential, deceleration, and lysis. The model reproduces accurately the first and second phases, as well as the trend of the lytic phase. The data of the latter show high dispersion, which makes it difficult to fit it adequately. Urea concentration disappeared before 20 h of cultivation, much earlier than the maximum biomass concentration was reached (Fig. 7). This result supports the assumption that urea is not directly used by the microorganism for growth.

Table 1. Model Parameters

Parameter	31 °C
μ_m (h^{-1})	0.20
k_N (g N_l/g X)	0.55
k_d (h^{-1})	0.022
k_m (h^{-1})	5.0×10^{-5}
$Y_{X/G}$ (g X/g G)	0.35
m_G (g G/g X h)	0.028
$Y_{X/N\,l}$ (g X/g N_l)	4.4
m_{CO_2} (g CO_2/g X h)	0.12
Y_{X/CO_2} (g X/g CO_2)	0.19
β_m (h^{-1})	1.22×10^{-3}
γ (g/g i.s.)	0
K_l (g i.s./g)	996
k_p (h^{-1})	1.0×10^{-6}
k (h^{-1})	0.1330

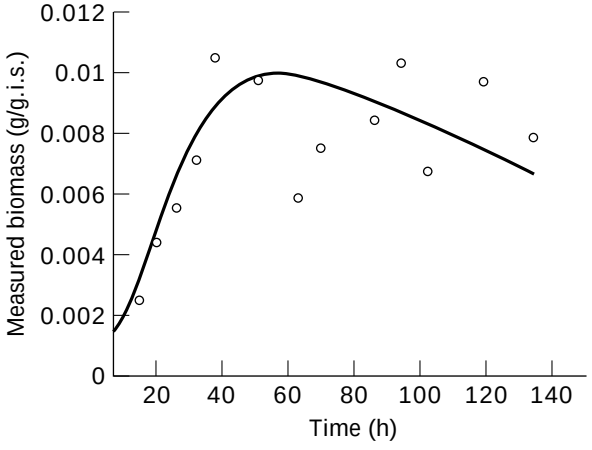

Figure 6. Biomass: measured (*circles*) and simulated (*line*).

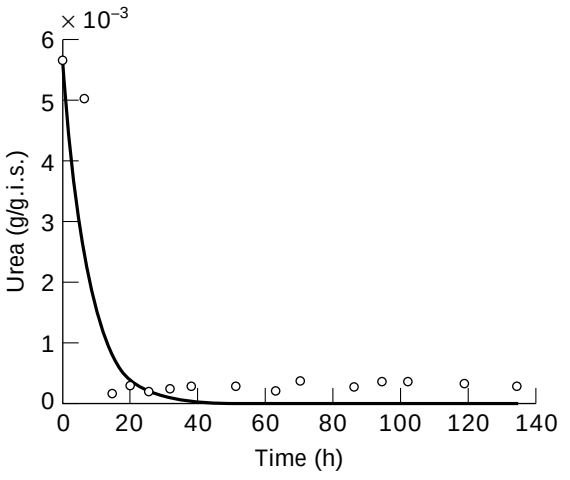

Figure 7. Urea concentration: measured (*circles*) and simulated (*line*).

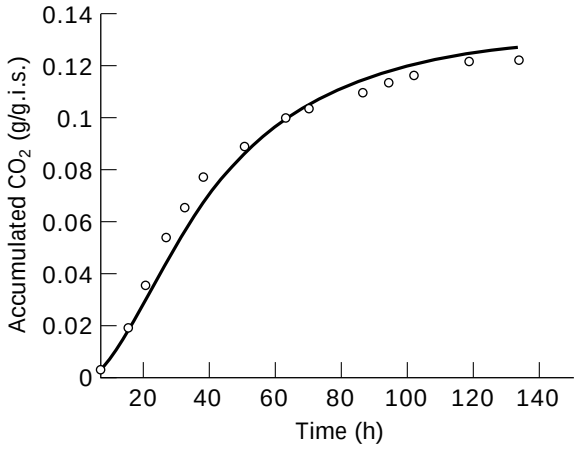

Figure 8. Accumulated CO_2: measured (*circles*) and simulated (*line*).

The model is able to reproduce well the observed decline in biomass respiration activity (Fig. 8). The carbon source is not limiting for growth as seen in Figure 9, because enough starch remains even after growth has stopped.

These figures show that the model is able to describe the complex interaction between active biomass concentration, nutrients, and respiration activity. This model can serve several purposes, such as establishing a fed-batch policy to maximize biomass concentration or developing on-line biomass estimators (74).

Production. The product of interest is a growth hormone called gibberellic acid (GA_3), which is a secondary metabolite; its production starts after nitrogen depletion. GA_3 production in SSF is difficult because it decomposes in water (75), so that if cultivation continues too long, most of the product will be lost. The following model can reproduce this observed behavior:

$$\frac{dP}{dt} = \beta \cdot X - k_P \cdot P$$

where k_p is the degradation rate and $\boldsymbol{\beta}$ is the specific production rates, which depends on the available nitrogen:

$$\beta = \frac{N_I \cdot \beta_m}{\gamma + N_I + K_l \cdot N_I^2}$$

Figure 10 shows the evolution of product concentration. The model fits the experimental data well, so it can be used to developed an on-line GA_3 estimator or a fed-batch policy to maximize product concentration at a given time.

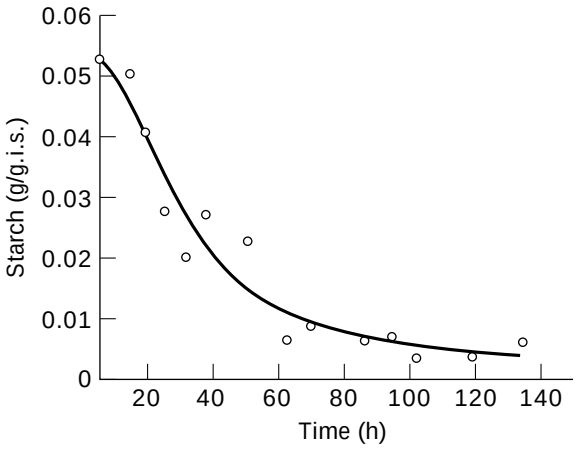

Figure 9. Carbon source evolution: measured (*circles*) and simulated (*line*).

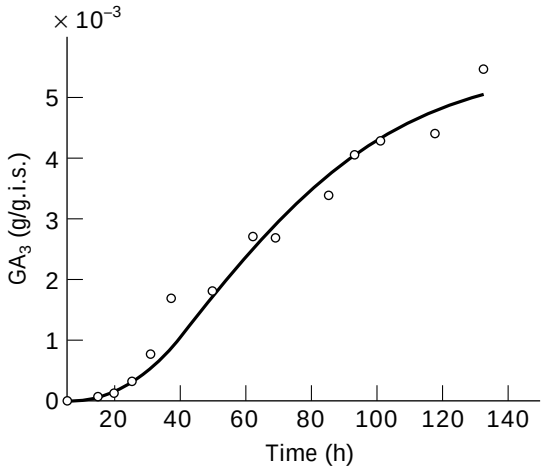

Figure 10. GA_3 concentration: measured (*circles*) and simulated (*line*).

INDUSTRIAL IMPLEMENTATION

To develop a complete SSF process that can be scaled up to industrial level, production must be integrated with the following two critical stages.

Upstream Processing

In SSF processes, supports are normally made from either agricultural products (soybean, rice, wheat, corn) or by-products (wheat bran, sugarcane bagasse, cassava bagasse). These materials are generally supplemented with easily metabolized carbon and energy sources (starch, maltodextrin, molasses, etc.) and other nutrients (urea, calcium, phosphates, etc.). The preprocessing of these substrates, mainly thermal treatment, has a double objective:

- Sterilize the support
- Change substrate physicochemical properties (starch gelatinization, increase porosity, etc.) to favor the support's structural strength and also the degradability and accessibility of its polymeric components (polysaccharides and proteins)

Minimizing the endogenous microbial load present in these substrates to levels compatible with the growth of the microorganism of interest is fundamental to attaining proper cultivation. It is easy to understand that this operation shares a significant part of the production costs when considering the high volumes of solids that are handled in industrial reactors. Lonsane et al. (76) have proposed the use of batch sterilization for 3–6 h at 121 °C, emphasizing that each solid particle must be subjected to 121 °C for at least 60 min. This, however, does not seem feasible for industrial-scale processes.

Traditionally, this stage is performed through prolonged cooking of the support, that is, rice and soybean in the particular case of koji production. For the latter, toasting has been recently been introduced as an alternative to cooking, with encouraging results in terms of productivity (Tomomori, personal communication, 1992). In 1995 Chou and Rwan (77) evaluated the extrusion cooking of rice for koji production. Here, *Aspergillus oryzae* was cultivated on rice extruded at different temperatures and water content levels, and achieved enzymatic yields superior to those obtained with traditional cooking techniques. Extrusion is a technology widely applied in the formulation of foods for human and animal consumption. However, its use in the preprocessing of substrates for SSF has been limited (78,79). Extrusion is essentially a fast process at high temperature in which proteic nutrients, rich in starch, are subjected to considerable heat and mechanical stresses, which modify the structure of the original material (80). Extrusion provides cooked substrates with the following characteristics:

- Elimination or at least significant reduction of the initial microbial load
- Liquefaction and gelatinization of the starch
- Denaturation of proteins and inactivation of antinutritional factors
- Solid form and porosity, which improve microbial growth and resistance to mechanical stresses
- Homogeneous substrate granulometry, increasing interparticular gas mass transfer

Special substrates made from products rich in fiber, such as sugar beet (81) or wheat bran (82), and amylaceous products, have also been developed. Recent results obtained in our laboratory in the production of gibberellic acid by *G. fujikuroi* have demonstrated the benefits of using this treatment. A mixture of wheat bran and starch (80%: 20%) extruded at 160 °C and at 22% humidity achieved a volumetric productivity 25% higher than that obtained when using nonextruded material.

In conclusion, this technique appears particularly appropriate for industrial-level SSF preprocessing. An aseptic support is produced at shorter processing times, with higher productivities and reduced costs. However, the process requires considerable investment. Other promising techniques that are currently being evaluated are sterilization by microwave (83), high voltages, and magnetic fields.

Downstream Processing

Downstream processing is one of the most neglected aspects of SSF processes in spite of its importance from both technical and economical standpoints. Traditional SSF-derived products generally encompass the whole fermented mass (koji, ang-kak, tempeh, etc.), which is, at most, dried (tane koji, for example) to improve keeping quality. However, there is a growing number of products that now require purification and formulation before being marketed. It is worth noting that the usual operations tied to these stages, although well developed for liquid cultivation, cannot be directly applied to SSF. Indeed, it is necessary first to leach the product from the fermented solids.

Following solid substrate cultivation, the fermented mass consists of unused substrate, biomass, spores (when formed), the product of interest, and a series of other cometabolites (76,84). The product in question must be extracted from this mass with an appropriate solvent. Efficiency of leaching depends on a series of factors:

- Effectiveness of the selected solvent
- Solid-solvent proportion
- Product and solvent diffusion
- Solvent retention by the solids
- Time, degree of mixing, temperature, and pH
- Techniques used to separate the leached solution

Among the available separation techniques, the most commonly used are percolation, pulsed extraction in plug flow, multistage countercurrent extraction, hydraulic press, and supercritical extraction. It is imperative to the economic viability of the SSF process that the selected extraction technique maintains the high concentration of the product to the greatest extent possible. Indeed, if the leaching process resulted in the dilution of the product, even at concentrations similar to those obtained by submerged fermentation, one of the main advantages of SSF would be lost. As a result, while common, percolation is not an appropriate technique because the high dilution of the resulting product (1:10 on the average) demands an additional concentration stage (84).

Plug flow pulsed extraction is a variation of percolation (85) in which the solvent is added by pulses through as-

persion of the substrate. With such a flow, the solvent completely wets the solid, achieving optimum solid to solvent proportions (1:2 to 1:3). A further advantage is that this is a simple, low-cost technique that requires minimum supervision. On the negative side, the extraction period is long, which may result in product modification or degradation.

Countercurrent extraction (86) allows adequate product concentration (1:1 solid:solvent proportion). In this system, the solids and the solvent move in opposite direction. Initially, the fresh solvent makes contact with the leached solids then with partially leached solids, contacting increasing concentrations of product. Finally, the enriched solvent contacts fresh solid. The required number of contact stages varies between 2 and 5 (86,87). In spite of the high concentrations achieved, the method presents some limitations in that the operation needs constant attention from trained operators. In addition, the extract obtained can be highly viscous, resulting from the extraction of exopolysaccharides. Extraction by hydraulic press is an efficient operation, although it requires high pressures and a second press to improve efficiency. Moreover, the operation is slow and tedious.

Product extraction with supercritical fluids has been studied for solid-state fermentation; in particular with CO_2 (88). Solvents have greater extraction ability at near-critical temperatures and pressures. This property is being used increasingly in the chemical industry as an alternative to conventional distillation and to other extraction processes. Here, the separation stages are simplified because the products are volatilized or precipitated from the supercritical fluid. However, the capital and operational costs of this process are high, restricting its applicability to high-value products. Once the product is leached from the solids, the extract is similar to a cultivation broth obtained following submerged fermentation. Conventional bioseparation (concentration, purification) and product formulation methods normally used for liquid cultivation processes can then be applied.

Case Study: Production of Gibberellins by Solid Substrate Cultivation of *Gibberella fujikuroi*

All commercially available gibberellins, which are typical secondary metabolites, are produced by liquid cultivation (LC) of the ascomycetous fungus *G. fujikuroi* (88). On exhaustion of the nitrogen source, exponential fungal growth ceases. At this point, secondary metabolism is triggered, with the concomitant biosynthesis of gibberellins. Commercially, the most important resultant product is gibberellic acid (GA_3). Several authors have reported on gibberellic acid production in solid substrate fermentation with higher yields than those obtained from liquid fermentation (6,9,37,89). A flowsheet of a pilot plant (Fig. 11) used for the production of gibberellic acid is presented and discussed.

This process, which has been scaled up from laboratory (12 g) to prepilot level (50 kg) and, recently, on up to a 200-kg reactor (Fig. 12), is carried out in three stages. The first, *upstream*, includes fungal propagation and substrate

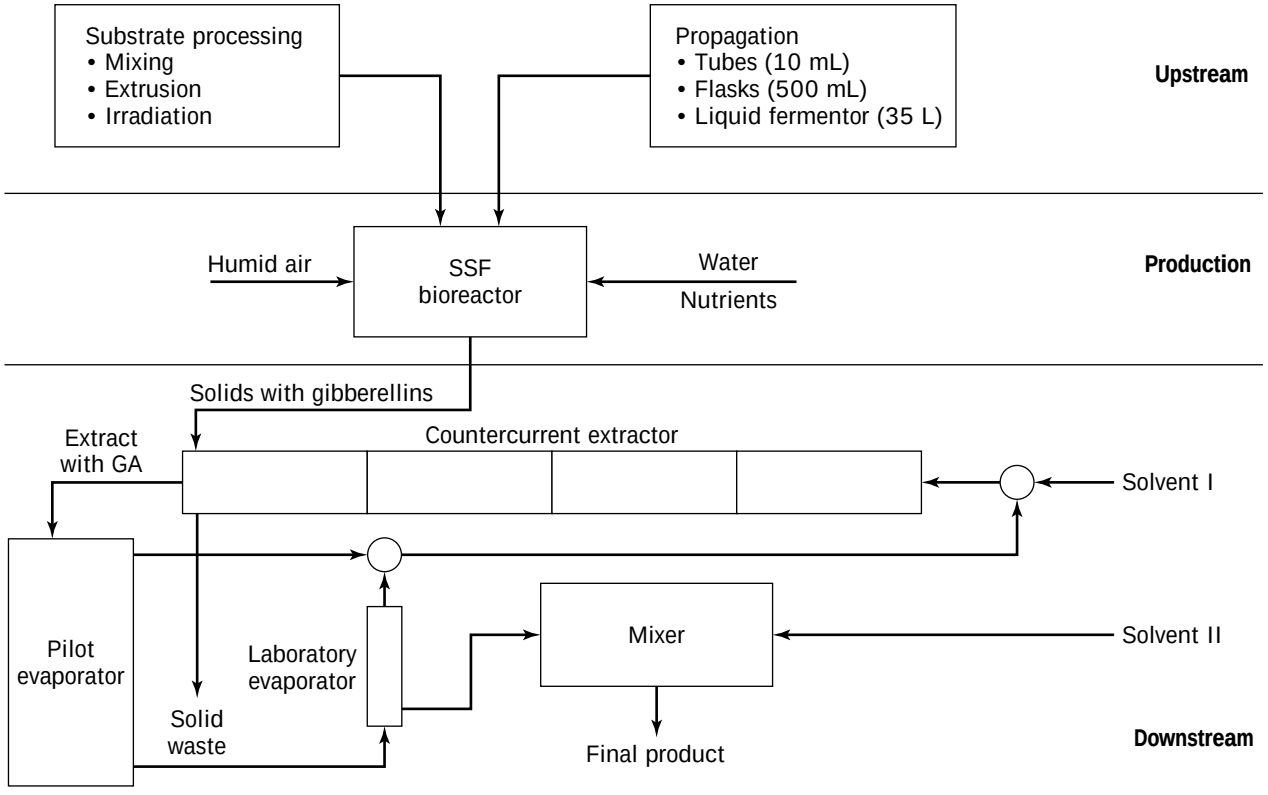

Figure 11. Flowsheet of a SSF pilot plant for gibberellin production.

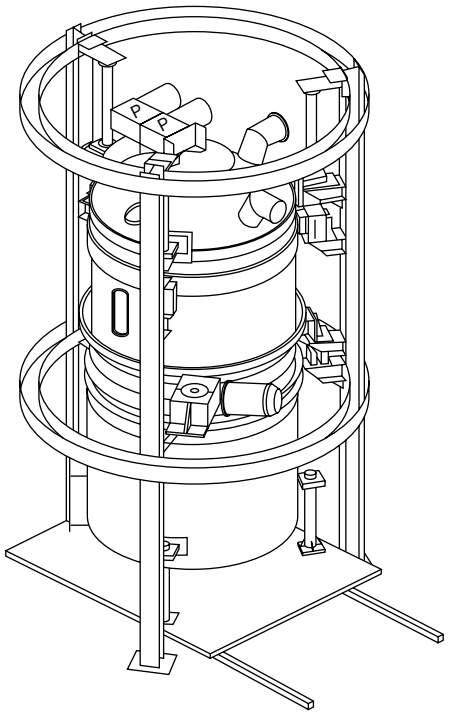

Figure 12. A 200-kg SSF pilot bioreactor.

preparation; second, the *production phase*; and finally, *downstream*, which consists of extraction and formulation. Substrate preparation involves mixing wheat bran with starch, extrusion of the mixture at high temperatures, and gamma ray irradiation. Mycelial propagation of the fungus was achieved in 72 h, from 10 mL up to 35 L. Production is carried out in batch form following a defined sequence: reactor sterilization (3 h), substrate loading (1 h), and inoculation (0.5 h), water content adjustment (0.5 h), cultivation (5 days), unloading (2 h), and bioreactor cleaning (4 h).

Extraction is done in batch form in four countercurrent stages. A primary concentration is then performed in a 15-L batch evaporator followed by final concentration in a laboratory evaporator. The last step is the formulation of the product according to market needs. The results obtained are easily reproducible (Fig. 13), and the economic viability and technical feasibility of the whole process have been demonstrated.

On field evaluation in production-scale vineyards, the product obtained (FITOPLUS) via this process exhibited considerable benefits over commercially available gibberellic acid products. Thompson seedless grapes of superior quality (berry size, reduction in berry loss, berry stalk color, etc.) were consistently obtained when treated with the SSF-derived product. This product has been placed under patent protection for agricultural applications (90).

NOMENCLATURE

G	Starch concentration (g/g i.s.)
k	Urea transformation constant (L/h)

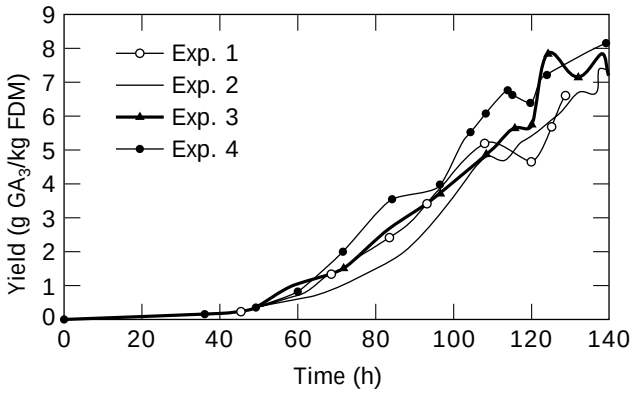

Figure 13. Gibberellic acid production in a SSF pilot bioreactor.

k_d	Biomass death constant (L/h)
K_i	Inhibition constant (g i.s./g)
k_m	Lysis constant (L/h)
k_N	Contois model parameter (g N_I/g X)
k_p	GA_3 degradation constant (L/h)
m_G	Starch maintenance constant (g G/g X h)
m_{CO_2}	CO_2 maintenance constant (g CO_2/g X h)
N_1	Available nitrogen (g/g i.s.)
P	Gibberellic acid (GA_3) (g/g i.s.)
U	Urea (g/g i.s.)
X	Active biomass (g/g. i.s.)
X_m	Measured biomass (g/g. i.s.)
$Y_{X/G}$	Biomass/starch yield coefficient (g X/g G)
$Y_{X/NI}$	Biomass/nitrogen yield coefficient (g X/g N_I)
Y_{X/CO_2}	Biomass/CO_2 yield coefficient (g X/g CO_2)
β	Specific production rate (L/h)
β_m	Maximum specific production rate (L/h)
γ	Parameter in the production rate (g/g i.s.)
μ	Biomass specific growth rate (L/h)
μ_m	Maximum specific growth rate (L/h)

ACKNOWLEDGMENTS

Financial support through the projects Fondecyt 1960360 and FONDEF 2-50, and from DICTUC S.A. and BASF-Chile S.A., is greatly appreciated. The work accomplished would not have been possible without the fruitful and continual discussions with our colleagues Iván Solar, Luciano Chiang, and Héctor Jorquera (Pontificia Universidad Católica de Chile), Gonzalo Acuña (Universidad de Santiago de Chile), Georges Corrieu and Erik Latrille (INRA, France), Paul Molin (ENSBANA, France), Maurice Raimbault (ORSTOM, France), and Jules Thibault (Université de Laval, Canada). Our dedicated postgraduate students undertook most of the experimental and computational work and also contributed several original ideas; our thanks go to Andrés Corona, Armin Ebner, Mario Fernández, Claudio Gelmi, Mauricio González, Harold Paján, Marcial Peña y Lillo, Ariel Rossenblitt, and Daniel Volpe. The skillful technical assistance of Andrea Belancic, Lenka Torres, and Cristián Valenzuela is also acknowledged. The English translation was carefully revised by Alex Crawford.

OUTLINE

INTRODUCTION

Solid substrate fermentations involve microbial modification of a solid, undissolved substrate. This definition includes solid-state fermentations in which microbial cultures grow on a moist solid with little or no free water, although capillary water may be present (1). Examples of this type are seen in mushroom cultivation (2–4), bread making (5,6), and production of cheeses (7). Examples in which the solid substrate is submerged in large amounts of free water are pickling of vegetables (8) and brewing of soy sauce and sake (9,10), as well as bioconversion of cellulosic materials (11,12).

Solid substrate fermentations have been practiced worldwide since ancient times (9,13,14). Bread, sausages, and soy sauce are a few familiar products of solid substrate fermentation. Such fermentations are used in processing coffee and cocoa, as well as in environmentally significant operations: composting, silage production, soil bioremediation, biodesulfurization of coal, and metal recovery from low-grade ores (15). Solid substrate fermentations are employed also in producing enzymes and chemicals and in biotransformations.

Despite long history and widespread use, most solid substrate fermentations are not well understood. Processing is often an art, commonly employing poorly defined, naturally occurring, mixed microbial populations. Mixed cultures are sometimes essential to development of the desired product characteristics, including appearance, aroma, texture, and taste. With few exceptions, fermentations are labor-intensive batch operations. The level of technical sophistication and capital outlay vary a great deal. Solids concentration is generally high, whereas the water content is usually low (16). The product may be highly concentrated in comparison with submerged fermentations. Similarly, water consumption is comparatively lower, but space requirements can be substantial. Solid substrate culture generally requires less power because agitation is not excessive. A low-pressure blower is sufficient for air supply, unlike the higher-pressure compressors required in submerged fermentations (17). Unlike submerged culture, solid-state processes require extensive solids handling, which is difficult; nevertheless, highly mechanized, automated, and continuous processing of solids is being practiced in large *koji* (or molded grain) factories (9,10,18), as well as for other processes. Processing machinery tends to be complex. Hygienic processing practices are followed, but sterility standards that are common in submerged culture production of pharmaceuticals are not attained. Because of fungal spores and product- or microbe-contaminated dust from substrate solids, solid substrate fermentations often pose a greater health risk to operators than do submerged fermentations.

FERMENTATION EQUIPMENT

Solid substrate fermentation devices vary in technical sophistication from the very primitive banana leaf wrappings to highly automated machines used mainly in Japan. Simple fermentation systems (e.g., fermentation of cocoa beans in heaps) are quite effective in some large-scale processes. Commonly used fermentation devices are detailed in the following sections.

Tray Fermentors

One of the simplest and widely used fermentors is a wooden, metal, or plastic tray, often with a perforated or wire mesh bottom to improve air circulation (1,19,20). A shallow layer, usually less than 0.15 m deep, of pretreated (e.g., steamed) substrate is placed on the tray for fermentation. Individual trays or stacks may be located in temperature- and humidity-controlled chambers (Fig. 1) or simply in ventilated areas. A spacing of at least one tray height is usually allowed between stacked trays. Trays may be covered with cheesecloth to reduce contamination (10), but strict monosepticity is not attempted. Inoculation and occasional mixing are done manually, often by hand

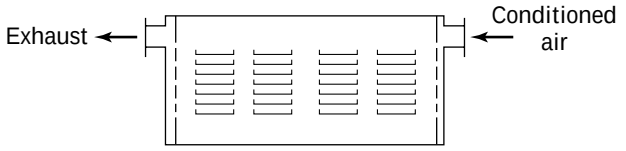

Figure 1. Tray fermentation chamber.

(10). This type of technology is quite common in small- and medium-scale koji operations in Asia. In some cases, filling, emptying, and other aspects of handling (4) of trays may be automated. For example, hinged trays with open ends may be dropped for emptying (19). Despite some automation, tray fermentors are labor intensive, require a large area, and difficulties with processing hundreds of trays limit their scalability (19). In parts of Asia, the bamboo baskets historically used instead of trays (16) continue to be employed.

Static Bed and Tunnel Fermentors

A commercially used modification of the tray fermentor employs a single, larger and deeper, static bed of substrate with forced aeration through the bed (Figs. 2 and 3). The substrate is located in an insulated chamber. In one version of this device, the tunnel fermentor (Fig. 3), the bed of solids may be quite long (1,20), but is usually no deeper than 0.5 m. Tunnel fermentors may be highly automated with mechanisms for mixing (Fig. 3), inoculation, continuous feeding, and harvest of substrate.

Rotary Disk Fermentors

Some large-scale commercial koji-making operations in Japan use a rotary disk fermenter configuration shown schematically in Figure 4 (18). The fermentor consists of upper and lower chambers, each with a circular perforated disk

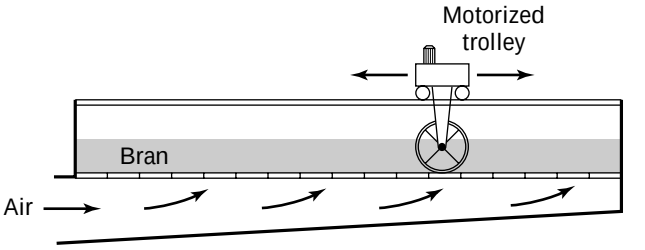

Figure 3. Mechanical mixing of fermenting substrate in a tunnel fermentor.

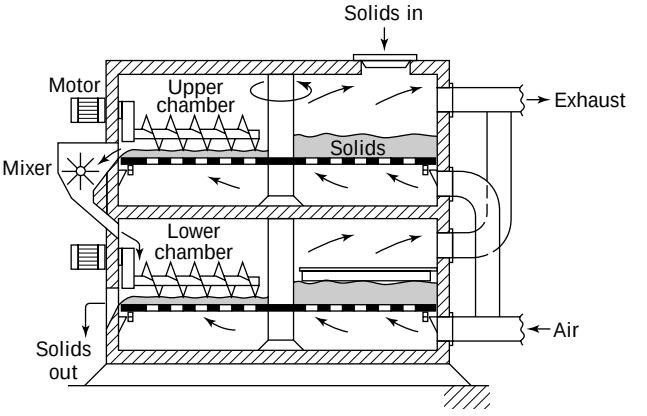

Figure 4. Automatic rotary koji fermentor.

to support the substrate. A common central shaft rotates the disks. Inoculated substrate is introduced in the upper chamber and slowly moved to the transfer screw. The upper screw transfers the partly fermented solids through a mixer to the lower chamber where further fermentation occurs. The mixer breaks up the partly fermented

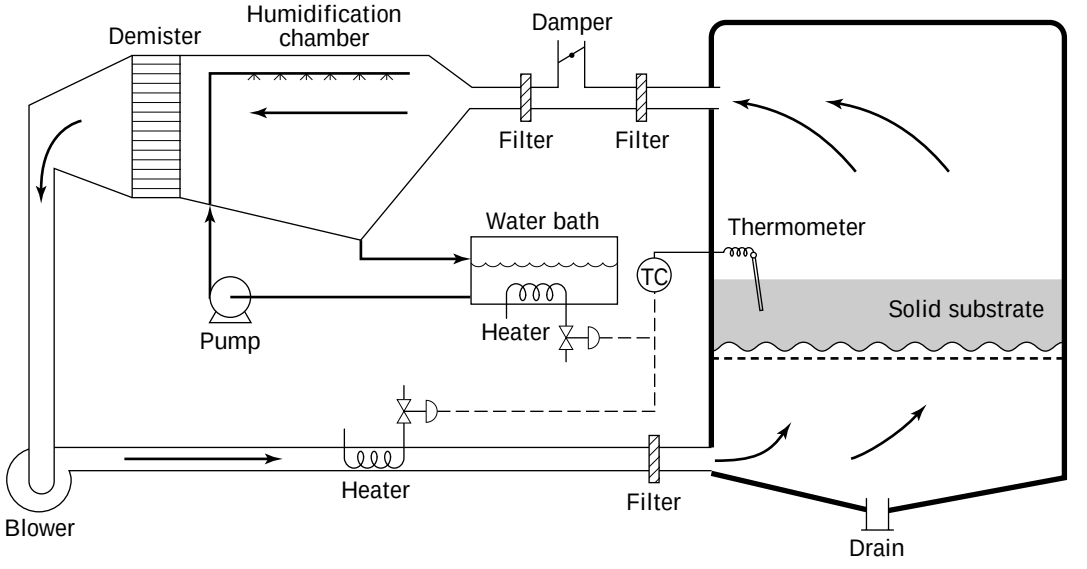

Figure 2. Static bed-type koji fermentor.

substrate–mycelium aggregates halfway through the fermentation process. Fermented substrate is eventually harvested using the lower transfer screw (Fig. 4). Both chambers are aerated with humidified, temperature-controlled air.

A tower fermentor similar in concept to the rotary koji fermentor is used in certain composting operations. The solids are supported on plates or trays that may be perforated. A stack of several tray chambers forms the tower. Mechanical devices mix and move solids down the tower (20–22) in a manner similar to that described for the rotary koji device. The gradually moving bed of solids is aerated either by forced aeration through the solid mass or solely from the surface exposed to the air above the bed.

Rotary Drum Fermentors

Rotary drum fermentors consist of a cylindrical vessel mounted horizontally on rollers and rotated around the long axis (Fig. 5). The rotational speed is commonly 1–5 rpm, but speeds up to 15 rpm are used occasionally. Rotation may be intermittent, and the speed may vary with the fermentation stage. The vessel may have straight or curved internal baffles that aid aeration and temperature control by imparting a tumbling motion to the substrate (23). Sometimes the drum may be inclined, causing the substrate to move from the higher inlet end to the lower outlet during rotation. The amount of substrate that can be processed in a batch operation depends directly on the length of the vessel and the square of its diameter. Aeration is through coaxial inlet and exhaust nozzles (Fig. 5). The air inlet pipe may extend into the vessel and may branch into several arms (19). Air is either supplied by a compressor or may be sucked in by an exhaust fan located at the air outlet (19).

Fluidized Beds

Fluidized-bed fermentors (Fig. 6) are relatively uncommon, but sufficiently promising that large-scale devices are being tested (9). A fluidized-bed fermentor consists of a relatively shallow bed of substrate supported on a perforated plate. Compressed conditioned air is normally used for fluidization, but carbon dioxide or nitrogen may be employed for anaerobic processes. Superficial gas velocity for fluidization is typically 0.24–1 m s^{-1}; the specific value

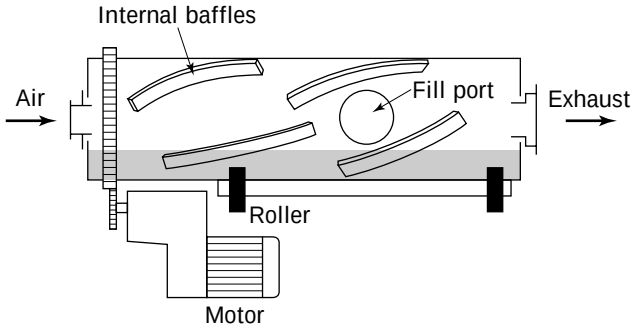

Figure 5. Rotary drum fermentor.

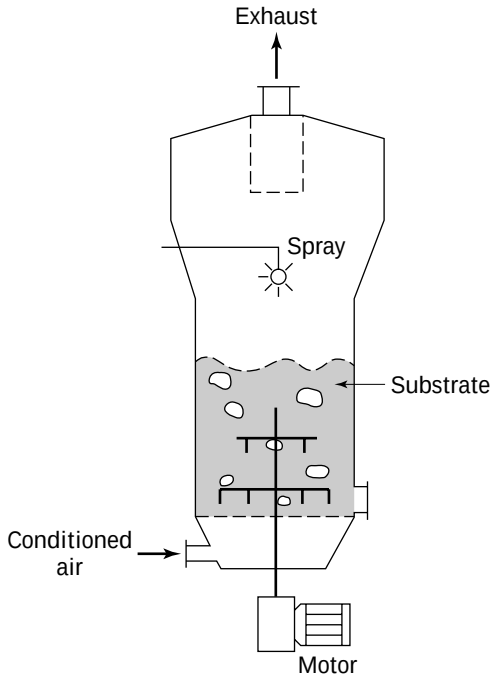

Figure 6. Fluidized-bed fermentor.

depends on the density and the particle size of the substrate. In the upper regions of the fermentor, the cross section is expanded (Fig. 6) to reduce the gas velocity to values that are insufficient to suspend the larger particles. Loss of fines in the exhaust gas is prevented by screens, filters, or cyclonic separators located at the exhaust nozzle. Fluidized beds achieve good aeration, mixing, and temperature control. Intermittent water spray may be necessary to prevent dehydration. A mechanical agitator as in Figure 6 is useful for periodic loosening of clumped solids.

Agitated Tank Fermentors

Helical ribbon-stirred tank fermentors have been employed for solid-state culture of fungi such as *Chaetomium cellulolyticum* on wheat straw (24). Other similar designs have utilized multiple helical screws for agitation of large rectangular tanks. The screws extend into tanks from mobile trolleys that ride horizontal rails located above the tanks (25). Yet another stirred tank configuration is the paddle fermentor. This design is similar to the rotary drum device (Fig. 5), except that the drum is stationary and motor-driven paddles on a concentric shaft provide periodic mixing of the substrate (20). As with rotary drums, the quantity of the substrate in paddle fermentors is generally restricted to less than 50% of the volume of the vessel. Although simpler than the rotary drum, the paddle fermentor is unlikely to be as effective in moving the entire mass of solids.

Continuous Screw Fermentors

A screw fermentor suitable for continuous fermentations is shown in Figure 7. Sterilized, cooled, and inoculated sub-

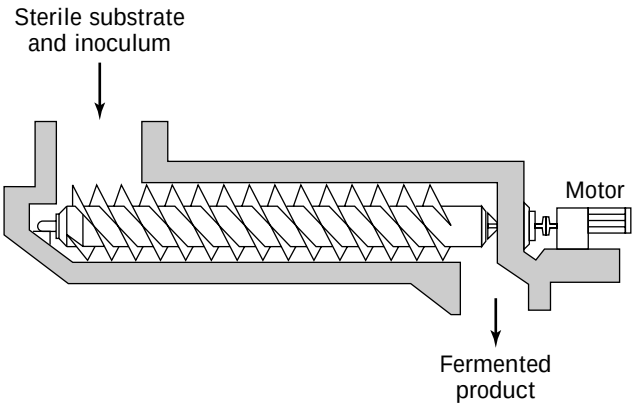

Figure 7. Screw fermentor for continuous fermentation.

strate is fed at the inlet. The screw moves the fermenting solids toward the harvest port. The fermentation time depends on the rotational speed and the length of the screw. Because the device is not aerated, only anaerobic or microaerophilic fermentations may be carried out.

Other Systems

Other miscellaneous types of fermentation devices that are used mostly in small-scale studies have been described by Lonsane et al. (19). Equipment for fermenting undissolved solid substrate slurries is identical to that used in submerged culture processes. Exceptions may be in devices used to feed slurried solids to the fermentor and remove the fermented product. Commonly used slurry fermentors include stirred tanks, bubble columns, and air-lift vessels (26–28). Simple vats are frequently employed in anaerobic slurry fermentations. Fermentors used in various types of composting have been described (14,21,22).

Construction and Cleaning

Modern commercial solid-state fermentors are constructed predominantly of stainless steel, but pressure vessel construction that is the norm for submerged culture processes (29) is not employed. Large concrete or brick fermentation chambers, or koji rooms (Fig. 1), may be lined with steel. Type 304 steel is used typically, but more corrosion-resistant grades such as Typed 304L and 316L are also utilized. Materials of construction have been discussed further by Chisti (29).

Because pressure vessel construction is not used, the fermentors cannot be steam sterilized; however, the design usually allows for atmospheric steaming. Typically, the fermentation chamber and process vessels are washed with alkaline detergent, sanitized with sodium hypochlorite, formaldehyde, or quaternary ammonium salts, and steamed between successive batches (17). Automated clean-in-place methods similar to those noted for submerged culture processes (30) are increasingly employed.

Design and Scale-Up

Design and scale-up of solid-state fermentation equipment relies heavily on empirical experience because the process kinetics and transport phenomena, such as heat transfer, oxygen transfer, and mixing, in these systems are insufficiently understood for more formal approaches to be usefully applied (20). Potentially useful strategies for scale-up have been discussed by Lonsane et al. (31), and Moo-Young et al. (22) have considered aspects of transport phenomena.

ENVIRONMENTAL FACTORS IN SOLID SUBSTRATE FERMENTATIONS

Moisture

Moisture content of the substrate is an important consideration in solid substrate processes. Free water indicates a saturated substrate. The moisture content at which free water is apparent depends on the nature of the solid (Table 1). Many solid substrate fermentations are carried out with little or no free water; typically, the substrate moisture content is 30–80% w/w (1,32). High moisture levels lead to aggregation of substrate particles, poor aeration, and possible anaerobic conditions (24). Steamed rice, a common substrate, becomes sticky when the moisture level exceeds 30–35% w/w. Optimal moisture content depends on the microorganism and the substrate. For the commonly used fungi, the optimal moisture requirement varies between 40% and 80% w/w. For the same organism growing on different substrates, the optimal moisture levels may differ widely; hence, percent moisture by itself is unreliable for predicting growth (32), and water activity is preferred instead. The water activity or relative humidity of the substrate is the ratio of the vapor pressure of water in the substrate to the vapor pressure of pure water at the temperature of the substrate. Water activities below 0.9 do not support most bacterial growth, but yeasts and fungi can grow at water activities of 0.7 and greater. Thus, the low moisture environment of many solid substrate fermentations favors yeasts and fungi. The water activity in a substrate may be determined by hygrometric measurement of relative humidity of a small air space in equilibrium with the substrate.

In addition to affecting growth, water activity affects product formation. The spectrum of products produced and characteristics such as aroma are affected. In some cases, the optimal water activities for growth and product formation differ (32). The optimal water activity depends also on factors such as agitation rate and cultivation temperature (32). Because the water activity depends on the concentration of dissolved solutes, sometimes salts, sugar, or other solutes are added to alter the activity. Different additives may influence the fermentation differently even though the water activity produced may be the same. Furthermore, the fermentation process itself leads to changes

Table 1. Saturation Moisture Content of Some Substrates

Substrate	Percent moisture (w/w)
Maple bark	>40
Rice and cassava	>50–55
Straw	75

in water activity as products are formed and the substrate is hydrolyzed. Oxidation of carbohydrates produces water.

During fermentation the water activity is controlled by aeration with humidified air and, sometimes, by intermittent water spray. Aeration with water-saturated air has commonly been found to increase the moisture content of the substrate. Relative humidity of the aeration gas is typically 60–80%. Ideally, prevention of water loss or gain by the uninoculated substrate would require that the water activity of the aeration gas and the substrate be identical. In practice, water generated during fermentation, and the additional requirement of evaporative cooling, demand aeration gas that is somewhat drier than the substrate. The temperature and humidity of the aeration gas are controlled in the same way as in air conditioning systems: temperature and humidity sensors (hygrometers) in the fermentation chamber provide the necessary data, and cooler air is humidified by water spray or injection of clean steam, and warmed to reduce the humidity to the required value (Fig. 2). Humidity–temperature relationships available in standard psychrometric charts are the basis of control.

Temperature

At 10–30 kg m^{-3}, the maximum microbial biomass concentration in solid-state fermentations is lower than 40–50 kg m^{-3} typically seen in submerged culture (24); but, because there is little water, the heat generation per unit fermenting mass tends to be much greater in solid-state fermentations. Temperature can rise rapidly, again, because there is little water to absorb the heat (i.e., the mean specific heat capacity of the fermenting mass is much lower than that of water). Consequently, temperature control in large-scale fermentations can be particularly difficult. Removal of the metabolic heat sometimes becomes the major limitation, especially because of the poor thermal conductivity of the porous fermenting mass. Cumulative metabolic heat generation in koji fermentations for a variety of products has been noted at 419–2,387 kJ kg^{-1} solids (14). Higher values, up to 13,398 kJ kg^{-1}, have been observed during composting (32). Peak heat generation rates in koji processes range over 71–159 kJ kg^{-1} h^{-1}, but the average rates are more moderate, at 25–67 kJ kg^{-1} h^{-1} (32). Peak metabolic heat production rate during fermentation of readily oxidized substrates such as starch can be much greater than in typical koji processes. For example, in one case, a generation rate of 330 kJ kg^{-1} h^{-1} was observed for *Aspergillus niger* growing on cassava starch. Heat generation during composting has been treated in depth by Stentiford and Dodds (33).

Temperature control during fermentation is obtained mostly through evaporative cooling (34); hence, drier air provides a better cooling effect. Air temperature is controlled. Intermittent spray of cool water is sometimes necessary to prevent dehydration of the substrate. Occasionally, the substrate-containing metal trays are also cooled by a circulating coolant, even though most relatively dry and porous substrates are poor conductors. Intermittent agitation further aids heat removal, particularly in large heaps and piles. Despite much effort, temperature gradients in the substrate do occur, particularly during peak growth. Gradients as steep as 3 °C cm^{-1} have been recorded during rapid growth of *Rhizopus oligosporus* on soybeans in *tempe* fermentations, even though the substrate layer was less than 7 cm deep (35). Similar values were noted in solid-state citric acid production by *Aspergillus niger* (34).

pH

Solid-state fermentations are practiced without pH control (19) other than any adjustments made during substrate preparation. In some nonsterile processes the initial pH may be adjusted to pH 4 or less to suppress bacterial contamination. Unlike most bacteria, yeasts and fungi are generally tolerant of more acidic conditions. Either mineral acids (e.g., 0.2 M hydrochloric acid) or organic acids (e.g., 0.5% w/w acetic acid) may be used for pH adjustments. Other than initial adjustments, the buffering capacity of substrates is relied on to check large changes in pH during fermentation (19). Many substrates are effective buffers. This is particularly true of protein-rich substrates, especially if deamination of protein is minimal. Some pH stability can be obtained by using a combination of urea and ammonium sulfate as the nitrogen source in the substrate. Decomposition of urea produces ammonia that takes up a proton to become NH^{+}_{4}, causing an increase in pH. This effect is countered by ejection of a proton from cells that take up the ammonium ion but incorporate it into proteins as —NH^{+}_{3}. Uptake of ammonium causes rapid acidification. In the absence of other contributing nitrogen sources, an equimolar combination of ammonium sulfate and urea is expected to yield the greatest pH stability. In media that are rich in protein or amino acids, deamination may contribute to pH rise. Attention to stabilizing the pH during fermentation can be particularly important for certain processes. Stability of enzymes and some secondary metabolites is pH dependent, and even though the rate of production may not be affected by changes in pH, the overall process productivity may decline because of destruction of the product. This behavior has been observed in producing pectinases by *Aspergillus niger* cultured on glucose-enriched sugar cane bagasse (36).

PRODUCTION OF ENZYMES

Process Technology

Only extracellular enzymes, those secreted by the microbial cell into the extracellular medium, can be produced by solid-state fermentation technology (37). Predominantly, these are hydrolytic enzymes (38,39), as noted in Table 2. Commercial production of many of those enzymes in the West utilizes submerged culture, but solid-state fermentation persists particularly in Asia where koji-type processing is commonly used. Koji is molded grain that has been used in oriental food preparations for thousands of years (40,41). Koji is a source of fungal enzymes that digest proteins, carbohydrates, and lipids into nutrients used by other microorganisms in subsequent fermentation. Koji

Ribonuclease	*Aspergillus candidus*
Xylanase	*A. niger, A. fumigatus, Aspergillus terreus, Gibberella fujikuroi*

comes in many varieties depending on the mold, substrate, method of preparation, and stage of harvest. Traditional and mechanized koji production has been described by several sources (9,10,18), and concise outlines of food koji processes are given later in this article. In typical processing for enzymes, a suitable solid substrate is mixed with water and mineral salts, heat sterilized/cooked, cooled, and inoculated. Incubation at controlled temperature (20–45 °C) and humidity follows. Subsequently, the fermented substrate is extracted with buffer to yield an enzyme-containing liquor. Further purification and recovery methods are identical to those that have been described for submerged culture processes (17,27,42,43). The crude liquor is filtered or centrifuged to remove suspended solids and concentrated by ultrafiltration. The concentrate may be stabilized and packaged. Extensive purification is uncommon for many bulk enzymes. In some cases, the fermented substrate may be dried at 35–40 °C, and ground before extraction (44).

The commonly used solid substrates include wheat bran, wheat, soybean, rice, barley, oats, and other cereals, but many more substrates have been used occasionally (Table 3). Studies with nutritionally inert substrates (e.g., polyurethane foam) wetted with dissolved nutrients have been reported (45). Two or more substrates are sometimes used in combination. Cereal grain may be used whole or cracked into pieces. Substrate particle size affects the extent and the rate of microbial colonization, air penetration, and carbon dioxide removal as well as the downstream extraction and handling characteristics (19,46). Relatively small particles are preferred because they present a larger surface for microbial action. However, particles that are too small pack together to reduce the interparticle voids that are essential for aeration (46). Similarly, too many fines in a batch of larger particles will fill up the voids. Particle shapes that pack together tightly (e.g., flat flakes, cubes) are undesirable. Lignocellulosic substrates such as straw, sugar cane bagasse, and wood chips are sometimes extensively pretreated to ease microbial colonization and substrate utilization. Pretreatments include size reduction, steaming, steam explosion, solubilization of lignin with organic solvents, acid and alkaline hydrolysis, and irradiation (12,47,48). Most of those pretreatments have proven too expensive for commercial utilization. For cereal substrates, common pretreatments include dehulling, pearling, size reduction, soaking, and cooking or steaming (9,10,18).

Table 3. Solid-State Fermentation Substrates

Animal	Milk solids
Apple pulp	Millet
Bagasse	Newspaper
Banana meal	Nutrient wetted inerts
Barley	Oats
Beet pulp	Orange peel
Buckwheat	Paper pulp
Canola meal	Peanut press cake
Cardboard	Potato starch
Cassava starch	Rice
Coffee pulp	Rice bran
Corn cobs	Rye meal
Corn grits	Sawdust
Cotton seed meal	Sewage sludge
Fish	Soybean
Fruit pulp	Straw
Jerusalem artichoke meal	Sweet potato meal
Lignocellulosic waste	Wheat bran
Logs	Wood chips
Meat	Vegetables

The selection of substrate depends to some extent on the enzyme of interest. Thus, pectinases are often produced using fungi grown on fruit pulp (e.g., apple, avocado), or on a combination of pulp and bran, or bran and fruit juice. Similarly, cellulose-rich substrates such as rice and wheat straw are commonly employed in producing cellulases.

Enzyme production processes rely overwhelmingly on filamentous microfungi (43), the main producer genera being *Aspergillus*, *Mucor*, *Penicillium*, *Trichoderma*, and *Rhizopus*. *Bacillus* species predominate among bacteria used in enzyme production (38,43,44). Examples of pro-

duction from yeasts are few. Some specific enzyme producers are listed in Table 2. Production of β-galactosidase by the yeast *Kluveromyces lactis* grown on corn grits and wheat bran moistened with deproteinated milk whey has been reported (49). Although β-galactosidase is an intracellular enzyme in yeasts and cultivation on solid substrate does not promote secretion, solid-state fermentation has been claimed to be superior to liquid culture for this enzyme (49); however, recovery questions have not been addressed.

Microbial inocula for commercial enzyme production are maintained as pure cultures (17). Routine checks on culture purity, freedom from variant forms, physiological characteristics, and enzyme productivity are used to ensure process consistency (17). The sterile solid substrate is inoculated in one of several ways: by mixing with a liquid suspension culture inoculum; by mixing with solid substrate-grown inoculant; by using a suspension of solid substrate-produced spores in a sterile liquid; or by blowing the solid substrate-produced spores with sterile air going into the fermentation chamber. Aseptic processing practice is observed (17), but fermentations are never entirely contamination free. Fermentations last 1–7 days, and a significant amount of the substrate is oxidized to carbon dioxide and water (17). Thin uncompacted and porous layers of nonadhering solid substrate particles generally ensure good oxygen penetration from the exposed surface. Excessive agitation is not wanted. Occasional turning and mixing improve oxygen transfer and reduce compaction and mycelial binding of substrate particles. Because agitation continually damages the surface hyphae, mixing suppresses often-unwanted sporulation (46). The frequency of agitation may be purely experience based, as in occasional turning of a fermenting cocoa heap, or it may be determined by a temperature controller.

Production of spore inocula requires static conditions. Deep substrate layers and heaps may require forced aeration and agitation. Oxygen supply affects product formation. Depending on the microorganism and the product, both enhanced and reduced productivities have been observed to accompany improved aeration or agitation. Aeration plays an important role in removing carbon dioxide and in controlling temperature and moisture. In some cases, increased concentrations of carbon dioxide have been severely inhibitory, whereas enhanced oxygen partial pressures have improved productivity. If used, forced aeration rates may vary widely; a typical range being 0.05–0.2×10^{-3} m^3 kg^{-1} min^{-1} (1).

Regulatory Considerations

Production of food, medicinal, and medical–diagnostic enzymes must comply with standards of "good manufacturing practices" as established by the U.S. Food and Drug Administration (FDA) or other regulatory agency appropriate to the particular jurisdiction. Safety of enzyme preparations, especially those derived from non-GRAS species (GRAS, generally recognized as safe; i.e., microorganisms such as baker's yeast that have proven to be safe through extended use and have been recognized as such by placement on the GRAS list of the FDA), must be demonstrated to gain marketing approval. Specific requirements vary with the intended use of the product. Freedom from toxins, antibiotics, other contaminants, and unwanted effects may have to be ascertained. Multigeneration feeding trials and studies of teratogenicity may be necessary. Requisite purity, potency, and stability may have to be demonstrated. The quality assurance requirements are similar to those for therapeutic proteins produced by other methods (42,50–52). Enzymes for industrial and household use (e.g., detergent enzymes) also must comply with product safety criteria, although the requirements are less stringent than in food, feed, veterinary, and medical applications.

OTHER PRODUCTS AND APPLICATIONS

Secondary Metabolites

Although solid-state surface culture technology was employed in the earliest attempts at large-scale production of penicillin, submerged culture is now the only method used in commercial production of antibiotics. Nevertheless, promising research on solid-state production methods continues, albeit at a slow pace. Solid-state production of oxytetracycline by *Streptomyces rimosus* grown on corncob has been described (53). Cephalosporins have been produced using *Cephalosporium acremonium*, *Streptomyces clavulgerus*, and *Aspergillus chrysogenum*. *Streptomyces cinnamonensis* has been used to produce monensin, an anticoccoidal agent for poultry. Other potentially antibiotic-producing *Streptomyces* that have been cultured in solid state include *S. badius*, *S. aureofaciens*, and *S. flavovirens* (1). Studies of penicillin production by several strains of *Penicillium chrysogenum* have shown that the best producers in submerged culture are not necessarily the best in solid-state culture (54). Improving productivity demands selection of strains suited specifically to solid-state fermentation.

Solid substrate fermentation for producing gallic acid used in tanning, printing, and other applications has been described (13,14). Koji technology is employed in citric acid production in Japan (16). In producing citric acid by *Aspergillus niger*, Pallares et al. (45) noted that solid-state culture had doubled the productivity (g L^{-1} d^{-1}) of submerged culture, reducing the fermentation time from 14 to 6 days. Medium-impregnated polyurethane foam cubes were used as substrate (45). Productivity was sensitive to substrate particle size; 0.3-cm cubes gave the best results (45). Other products that have been produced by solid-state culture include several mycotoxins (14,46,55) and ergot alkaloids from various fungi, gibberellic acid from *Gibberella fujikuroi* (56,57), and kojic acid (14). In one case involving production of gibberellic acid and proteases, the yield of products was improved by fed-batch strategies (57), but nutrient feeding of solid-state batches other than at start-up remains a rare practice.

Ethanol has been commercially produced by aerobic–anaerobic solid-state fermentation of sweet sorghum grains in Taiwan (24). Production of γ-linolenic acid, a polyunsaturated fatty acid, by *Cunninghamella japonica* grown on rice and millet has been reported (58). The fungus *Monascus purpureus* or *Monascus anka* is used to com-

mercially produce a bright red polyketide pigment for food coloring and flavoring in Asia (41). An additional and developing application of solid-state fermentations is in producing fungal spores for use in a variety of biotransformations (1,14). Use of phytopathogenic and entomopathogenic fungi as herbicidal and insecticidal biocontrol agents promises further applications of solid-state fermentation technology for spore production (14,59–61).

Environmental Remediation

Because of their ability to degrade otherwise persistent toxic organics, white rot fungi—for example, *Phanerochaete chrysosporium*, *Phanerochaete sordida*, and *Trametes versicolor*—are being tested for bioremediation of soils contaminated with polychlorinated biphenyls, pentachlorophenol, and other polycyclic aromatics (62). In the preferred mode of implementation, solid-state cultured fungal carriers such as corncobs, wood chips, and straw are mixed with the soil in situ. Commercial implementation requires, among other factors, the ability to economically and consistently produce large inocula. Solid substrates enriched with nutrients and concentrates of fugal spores, and formulated into pellets, are being developed to improve consistency of performance (62). Other pollution remediation applications of solid-state fermentations are composting (22,33,63), anaerobic digestion for producing methane in slurry fermentations and landfills (64–66), and treatment of gaseous pollutants and vapors in biofilters (65).

Animal Feeds

Solid substrate fermentation methods are used to enrich many wastes and low-grade substrates for animal feed (1,11,12,22,25,46,65,67). One such widely used process is ensiling. Ensiling is used to stabilize and preserve forage crops; any nutrient enrichment is incidental. Typically, crops are ensiled immediately on harvest. An uncontrolled anaerobic primary fermentation by naturally occurring or inoculated (68,69) lactic acid bacteria takes place. Sugars present in the fodder are converted to lactic and acetic acids, causing a drop in pH. A low pH suppresses secondary fermentation by *Clostridia* that leads to butyric acid and spoilage. A good silage should generally have a pH of 4.0 to 4.2 and a butyric acid content of less than 5% of dry weight. A high dry matter content, for example, 20–30% w/w, of biomass at ensiling is preferred because secondary fermentation is difficult to suppress when dry solids are less than 15% w/w. Unlike *Clostridia*, the lactic acid bacteria remain active up to 70% w/w dry matter. Microbiology of silage has been detailed by Whittenbury (70) and Fenlon et al. (68). Silage inoculants have been described by Seale (69). Certain silages may contain animal and food processing waste (e.g., cattle and poultry manure, fish waste, or offal) and grain (e.g., corn), in addition to grass and other fodder crops. Fish silage has been described by Wignall and Tatterson (71); in-depth treatments of silage fermentations have been reported by McDonald (72) and Woolford (73).

PRODUCT RECOVERY FROM FERMENTED SOLIDS

Unless the fermented solids are the desired product, the solids must be further processed to recover the enzyme or other metabolite. Volatile products such as ethanol may be recovered by direct distillation of the fermented mash (24). Most other products require extraction from fermented solids. The solids may be extracted moist or dry (44); moisture content can affect the extraction behavior. Because drying generally improves keeping quality, dried material from several batches can be accumulated for later extraction. The solid cake should be crumbled or otherwise size reduced for improved extraction. Either batch or continuous extraction may be employed. When feasible, continuous extraction with countercurrent flow of solids and solvent allows greater product recovery in a more concentrated solution. A suitable continuous extraction device is the Chisti contactor shown in Figure 8. Leaching machinery developed for the chemical industry can also be potentially adapted for use with fermented solids. A series of mixer-settlers has been used in small-scale extractions (74), but that arrangement is too cumbersome for commercial practice. Between two and five contacting stages are generally sufficient, but a larger number may be practicable with high-value products.

Cumulative contact periods typically do not exceed 50 min. Water, aqueous buffers, or dilute solutions of salts (e.g., 1% sodium chloride) or glycerol (e.g., 1% glycerol) are used to leach enzymes (74). Aqueous solutions of ethyl acetate, acetone, ethanol, or chloroform may be needed for nonprotein products such as most antibiotics and mycotoxins. In one case, aqueous ethanol (10%) was the best solvent for extracting gibberellic acid from fermented wheat bran (74). Pure methylene chloride has been used to extract mycotoxins (1). A suitable solvent must be selected empirically for each application. Factors that affect solvent choice are cost, toxicity, flammability, corrosion effects, disposal issues, solubility and stability of product, solubilities of other solutes, and compatibility with end use. The

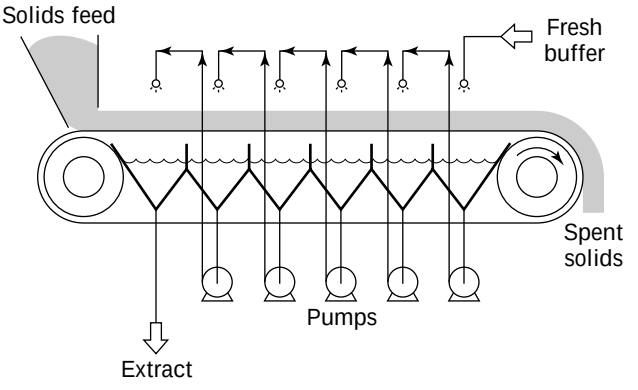

Figure 8. Continuous countercurrent leaching of solids in an extractor. Solids are placed continuously on the stainless steel conveyer mesh (0.6 m wide, 6 m long) that moves at 0.1–0.2 m min^{-1}. Fresh buffer is sprayed at the downstream end of the conveyer; the percolated extract is collected for extracting solids further upstream.

solvent-to-solid ratio generally ranges over 1 to 8; higher values increase the fraction of the product leached at the expense of producing a more dilute solution. Extraction temperature does not normally exceed 30 °C, but enzymes are commonly extracted at lower temperatures (e.g., 4–10 °C) to reduce denaturation, proteolysis, and microbial growth. Extraction performance and stability of the product may depend critically on pH. The pH of greatest stability may not be the same as that required for optimal leaching (75). Enzymes are generally extracted at pH values close to 7; however, to prevent precipitation, the extraction pH must not be the same as the isoelectric pH. Once the product has been extracted into solution, further purification employs the same well-known methods that are used in recovering extracellular products from submerged fermentations (27,42,43).

FERMENTATION-ENRICHED AND FERMENTATION-MODIFIED FOODS

Solid-state fermented foods occur worldwide. In some regions, such foods are the primary source of calories, proteins, and other nutrients for the consumers. Historically, fermented foods arose more by accident than by guided effort; nonetheless, recognition of the numerous advantages of the fermented products led to their established use. In comparison with the unfermented substrate, the fermented material may have one or more of the following characteristics: enhanced flavor, texture, and digestibility; reduced or eliminated undesirable compounds or flavors; protein enrichment or otherwise improved nutritional value; changed physical character; improved keeping quality; fast food quality of easier or quicker preparation; and other economic advantages such as reduced cooking time and hence lower energy demand. Table 4 notes some of the world's significant fermented products. Further details appear in the *Handbook of Indigenous Fermented Foods* (76), as well as other sources (6,8,40,41,77). The contribution of fermented products to the human food supply is likely to remain strong (78), and increasing cross-cultural spread is expected considering the popularity of tempe, tofu, and soy sauce in nonindigenous regions. The following sections discuss a small selection of the important foods as representative illustrations of the solid-state and solid substrate fermentation technologies.

Miso

Miso is a semisolid fermented soybean product that is widely consumed in Japan (18,40,41,79). Similar foods are produced in other parts of Asia (Table 4). In Japan miso is made into soup with added ingredients such as vegetables, meat, and seafood (18). Modern miso is generally produced from protein-rich yellow soybeans, but other varieties can be used. Cleaned soybeans are continuously washed, soaked overnight, drained, and cooked (Fig. 9). Cooking conditions vary. Large plants employ continuous pressure cookers with cooking done at 1.3–2.0 kg cm^{-2} for 2–7 min (18). Cooked beans are ground using a meat grinder with 5-mm-diameter holes (18) before being mixed with separately produced koji for fermentation. Barley koji is used in making "rural miso"; commercial processes employ rice koji (18). Miso koji is made from milled, cleaned, and usually cracked rice that is washed and soaked overnight in water at approximately 15 °C (18). Soaked rice is drained (1 h) and steamed. A horizontal belt steamer (Fig. 10) is commonly used. Steamed rice is unloaded onto a cooling conveyer, where a stream of air is blown through the rice layer to lower the temperature to 35 °C (18). Rice is then inoculated with the starter culture (called *tane-koji* in Japanese) of *Aspergillus oryzae*. Tane-koji is an olive-green, sporulated culture that has been grown on cooked rice mixed with a small amount of wood ash (18). Tane-koji is produced under aseptic and strictly controlled conditions. One kilogram of tane-koji is sufficient to inoculate 1,000 kg of rice (18). Many varieties of tane-koji are available with different capabilities for hydrolyzing proteins, carbohydrates, and lipids (18). An appropriate variety should be selected with regard to the amounts of proteins, oils, and carbohydrates in the mix of miso substrates (18).

Inoculated rice is transferred to a koji fermentor. Either a tunnel fermentor (Fig. 3) or, in larger plants, a rotary fermentor (Fig. 4) is used. The tunnel fermentor is mixed twice during the fermentation, but the rotary machine is mixed only once. Fermentation occurs at 30 °C for 40 h (18). Rice koji is then harvested and mixed with ground beans, salt, and a miso starter. The starter consists of halophilic yeasts, *Zygosaccharomyces rouxii* and *Candida versatilis*, and a halophilic lactic acid bacterium, *Pediococcus halophilus* (18). Fermentation is carried out in wooden vats, or tanks made of stainless steel or fiberglass-reinforced plastic. During fermentation miso is occasionally transferred from one vat to another to maintain homogeneity (18). The fermentation temperature is 25–30 °C (18). Ripened miso is taken out of vats, blended, pasteurized, and packaged. Process variations occur depending on the type of product desired (41).

The miso koji mold, *A. oryzae*, grows well around 30 °C (18), but optimal conditions for spore germination have been found to be 36 °C, ≥97% relative humidity, 0.1% carbon dioxide, and 20% oxygen (18). Optimal conditions for mycelial growth are 35–37 °C, ≥75% relative humidity, <1% carbon dioxide, and 20% oxygen (18). In practice, a lower than optimum temperature (28–30 °C) is used for germination, and 30–35 °C for cultivation in the koji chamber (18), apparently to avoid overheating. Desirable temperatures for production of enzymes are as follows: glucoamylase, 30 °C; α-amylase, 35 °C; protease, 25–30 °C; and carboxypeptidase, 35 °C (18). The optimal moisture level of cooked rice is 36–38%, and the optimal pH is 6.0–6.4 (18). Fermentation pH can be effectively maintained at 6–7 by supplementing the substrate with sodium glutamate or sodium succinate. Controlled pH favors higher-activity proteases (18). The microbiology and biochemistry of miso fermentation are further discussed by Abiose et al. (82).

Sake

Sake is a Japanese alcoholic beverage made from rice (10,40). Rice koji preparations for sake brewing are obtained by methods similar to those described for miso. The amount of tane-koji inoculum is 0.6–1 kg per kilogram of

Table 4. Solid Substrate Fermented Foods of the World

Sufu. A Chinese cheese made from soybean curd (*tofu*) by fermentation with molds such as *Actinomucor elegans* and *Mucor hiemalis* (41).

Idli. Small, white, steamed rice cake made by lactic acid fermentation of a thick batter of coarse-ground rice and fine-ground black gram in India. Idli cakes are moist, soft, and spongy, with a slightly sour flavor. Several varieties are produced. Other similar products of India are *dhokla* and *khaman*.

Dosa. Pancake made with thin pourable fermented batter of fine-ground rice and gram. Important part of diet in South India and Sri Lanka.

Ambali. A cooked product of fermented millet flour batter and rice. India.

Puto. Steamed cake of milled, acid-fermented rice. Similar to idli, but without legume. Important food in Philippines. Several varieties.

Enjera. Very flexible, soft, sour leavened pancake containing many small uniformly distributed gas bubbles. Made from thin, pourable fermented batter of *tef* (*Eragrostis abyssinica*) flour, or other ground grain (corn, sorghum, millet, barley, wheat). Consumed as staple in Ethiopia.

Hopper or ***appa***. Steam-baked product made from acid-fermented dough (rice or wheat flour) formulated into liquidy batter with coconut water. Sri Lanka.

Kisra. Flat bread made from fermented sorghum flour batter in Sudan.

Ogi (also *furah* and other names). Fermented cereal flour (corn, sorghum, or millet) made into a slightly sour gruel. Important source of calories in Nigeria.

Uji (and other names). Suspension of cereal (corn, millet, sorghum) or cassava flour (relatively large particles) in water. Sour-acid fermented either before or after cooking. East Africa.

Mahewu (also *magou* or *mageu*). Suspension of acid-fermented corn flour used as high-calorie beverage/food. More dilute than uji or ogi. Cooked cornmeal in water is fermented after adding a small amount of wheat flour. Product is very slightly alcoholic. Produced in large commercial operations in South Africa. Similar cereal-derived alcoholic beverages/foods occur throughout sub-Saharan Africa.

Sake. Rice wine of Japan, and other similar products: *brem bali* (Indonesia); *mie-chiu* (China); *tapoi* (Philippines); *sato* (Thailand); *yakju* (Korea); and *sonti* (India). See text.

Gari. A dry granular starchy product of West Africa (80,81). Made into staple food by adding hot or cold water. Made from peeled, grated cassava by fermenting in cloth bags while squeezing out the water over 12–96 h. The anaerobic acid fermentation produces a sour taste. Fermented solids are sun dried and lightly toasted in iron pans. A small amount of palm oil may be added during toasting to impart a pale-yellow color. Solids are sieved and sold in markets. Very poisonous varieties of cassava may be used in making gari. Crushing of cassava releases naturally present linamarase, which breaks down the cyanogenic linamarin to reduce the cyanide content. Cyanide produced boils off as hydrogen cyanide gas, indicating the need for good ventilation during processing. Acid pH produced during fermentation enhances the action of linamarase (pH optimum of 5.5). In addition, microbial action may produce enzymes that enhance the breakdown of cyanoglycosides.

Miso. Fermented soybean paste of Japan. Other similar products: *jang* (China); *doenjang* and *kochujang* (Korea); *taucho* or *tauco* (Indonesia); *tao-tsi* (Philippines) (18,40,41,79,82). See text.

Soy sauce. Japanese *shoyu*, and similar products throughout Asia: *chiang-yu* (China); *kan jang* (Korea); *kecap* (Indonesia) (9,40,41,76,79). See text.

Natto. Soaked and cooked soybeans fermented by bacteria, principally *Bacillus natto*, consumed in Japan. Other similar products: *thua-nao* of Thailand; *kinema* of Nepal, Bhutan, Sikkim, and parts of northeastern hills of India; *dagé*, an Indonesian produce made of bacterial fermented peanuts and other oilseeds.

Tempe (or *tempeh*) and similar products: *tempe kedele*, *tempe gembus*, *tempe benguk*, *tempe bongkrek*, *oncom*, or *ontjom*. See text. A Japanese solid food, *hamanatto*, is also made from soy beans fermented by fungi (41).

Dawadawa. Fermented African locust bean (*Parkia filicoidea*) product used as flavoring agent in West Africa (14).

Kenkey (and other similar products). Fermented corn dough used as staple in Ghana (8).

Mawé. Acid-fermented corn dough used in Benin and Togo (8).

Pozol. Fermented corn dough used as staple in parts of Mexico.

Kocho. Unleavened flat bread made from fermented pulp of ensete (*Ensete ventricosum*) or 'false banana' plant (a banana-like plant that does not bear bananas). Used as staple in certain regions of Ethiopia.

Tapai. Malaysian fermented glutinous rice or cassava gratings. Sweet and mildly alcoholic. Used as dessert. Similar products occur elsewhere: *lao chao* in China (41); *tapé ketan* and *tapé ketella* of Indonesia (40); and *peujeum* in Sudan.

Nham. Fermented minced raw pork similar to sausages. Thailand.

Fermented seafood. Usually fish or shrimp pastes, or sauces: *bagoong*, *patis* (Philippines); *ngapi* (Burma); *trassi*, *kccap ikan* (Indonesia); *belachan*, *budu* (Malaysia); *mam*, *nuoc-mam* (Vietnam); *jeotkal* (Korea); *prahoc* (Cambodia); *kapi* (Thailand); *padec* (Laos); *shottsuru*, *shiokara*, *katsuobushi* (Japan); *faseich* (Sudan) (14); *kobi* (Ghana) (14); and fermented fish of Northern Europe.

Balao balao. Fermented rice–shrimp mixture eaten in Philippines. Cooked, somewhat pasty rice is blended with fresh, unshelled, salted shrimps, and fermented for 7–10 days. Shrimp shell becomes quite soft. Product cooked before consumption.

Burong dalag. A fermented fish and rice product of the Philippines.

Fermented milk products. Yogurt; sour cream; cheeses; *ergo* and others (Ethiopia); *kefir*, *koumiss* (Russia); *dahi* (India); *tairu* (Malaysia); *laban rayeb*, *laban zeer*, *laban zabadi* (Egypt); *liban argeel*, *liban khather*, *mast*, *mass taw*, *shenina*, *dabbo* (Iraq).

Kishk. A fermented milk–wheat mixture of Egypt. Stored as dry balls.

Trahanas (and other names). Made from crushed wheat and fermented sheep milk in Greece, Turkey, and Cyprus. Stored as dry biscuits or dry crumbled solids.

Fermented vegetables (8). Sauerkraut (Europe, North America); Chinese sauerkraut *hum choy*; acid-pickled olives and cucumbers; various Indian and Malaysian pickles; various varieties of *kimchi* (Korea); kimchilike products of Thailand and elsewhere.

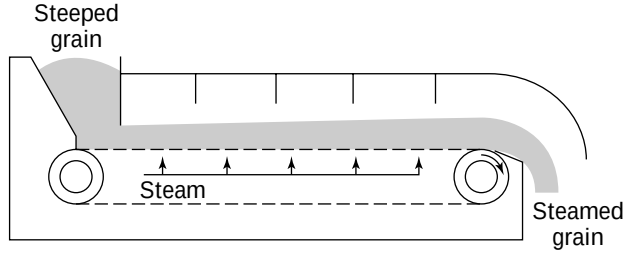

Figure 10. Continuous grain steamer.

the original rice, corresponding to about 2,000 fungal spores for each rice grain (10). The koji used is white because mold growth is arrested before sporulation (10). The unsporulated koji is relatively dry; the rice kernels are relatively hard and unclumped (10). The koji is then used in preparing the sake yeast starter mash, or *moto*. The traditional method of moto making required about a month-long fermentation of koji (300 kg) and water (1 m^3) (10). A succession of microbial populations developed, including lactic acid bacteria that reduced the pH and created an environment in which only the sake yeast, *Saccharomyces cerevisiae*, thrived (10). In modern moto production, fermentation time is reduced by adding lactic acid to water (pH 3.5–3.8) before mixing with koji. A large inoculum of sake yeast and steamed rice is also added. In a few days the starch is hydrolyzed, and fermentation begins. The next step is a *moromi* fermentation; it involves further addition of steamed rice, koji, and water to moto. Three additions are made at 1-day intervals (10). Temperature is lowered at each addition to control contamination because the added materials dilute the acids and alcohol. The temperature of moromi is controlled carefully, and after the final addition the temperature is 7–8 °C (10). Saccharification of starch and fermentation occur simultaneously in moromi (unlike in moto) until the alcohol content reaches nearly 20% v/v (10). Some steamed rice may be added during the final stages of fermentation to produce a sweeter product (10). Once the fermentation has almost ceased, alcohol is added to the mash to bring the concentration to 20–22% by volume (10). Solids are filtered out; the liquid product is further clarified, pasteurized, aged, blended, diluted to 15.0–16.5% v/v alcohol, and packaged (10). Unlike Western beer fermentations, sake mash is very high in solids that help to keep a large amount of yeast in suspension (10).

Beverages similar to sake are also found in China and many other Asian countries (Table 4). Other quite different indigenous alcoholic beverages, some made through solid substrate fermentation, are found in Africa and elsewhere (76). Some of these products are now produced in large industrial operations (77).

Soy Sauce

Soy sauce originated in China, but it is widely produced and consumed throughout Southeast Asia, Japan, and, increasingly, Europe and North America. The history, variety, and production technology of soy sauce have been detailed by Fukushima (9) and others (40,41,76,79). Here, a short description of only the latest, large-scale Japanese production methods is given.

Manufacture of soy sauce (*shoyu* in Japanese) involves a solid substrate koji fermentation, a brine or *moromi* fermentation, and refining steps (40,41,79). In koji making, soybeans or, more usually, defatted soybean flakes or grits are moistened and cooked in continuous pressure cookers (Fig. 9). The latest cooking methods employ a cooking time of 0.25 min or less, at approximately 7 kg cm^{-2} gauge pressure, equivalent to 170 °C (9). Rapid high-temperature cooking reduces loss of proteins and improves the yield of hydrolyzed amino acids in the final product. Cooked beans are mixed with roasted wheat that has been cracked into four or five pieces (9). Wheat roasters operate in a continuous mode at 170–180 °C (9). The ratio of wheat to beans is commonly 1:1, but it varies with the variety of shoyu (9). The mixed substrate is inoculated with a pure culture of *Aspergillus oryzae* (or *A. sojae*). The fungal spore density at inoculation is about 2.5×10^8/kg of wet solids (1). After a 3-day fermentation the substrate mass becomes green-yellow because of sporulation (9). Too long an incubation causes excessive, unwanted sporulation, production of ammonia from deamination of amino acids, and off-flavors in the final product (41). Koji is now harvested for use in the moromi step. Koji production is highly automated and continuous (9,18). Among the largest of koji-making processes is that of Kikkoman Corporation; it produces up to 4,150 kg h^{-1} koji, which is equivalent to processing 1,650 kg h^{-1} raw soybeans and 1,775 kg h^{-1} wheat (9).

Harvested koji is mixed with brine containing at least 20% salt for the moromi fermentation step (9,41). Large outdoor tanks are used for moromi fermentation. A specially selected culture of lactic acid bacteria is added to moromi mash, and the temperature is kept relatively low (15–20 °C) for the first month or so (9). Low temperature

prevents a too rapid growth and attendant rapid decline in pH. A pH drop that is too rapid causes undesirable early arrest of the proteolytic activity of koji enzymes; action of koji glutaminase is also obstructed (9). When the pH of moromi has declined to pH 5, a separately grown culture of the yeast *Zygosaccharomyces rouxii* is added (9). The temperature is then gradually raised to nearly 30 °C until a vigorous alcoholic fermentation occurs (9). On cessation of the alcoholic fermentation, the temperature is again reduced to about 25 °C and maintained there for the last 2 months (9). Aged moromi is filtered using automatic filter presses; the liquor is pasteurized in continuous flow plate heat exchangers and packaged in plastic bottles (9). The production schemes vary a great deal within Japan, and many quite primitive methods are encountered elsewhere in Asia. Chinese practices have been outlined by Wood and Min (41).

Tempe

Tempe (or tempeh) kedele is a fermented soybean product consumed in Indonesia, Malaysia, Singapore, the Netherlands, the West Indies, and, increasingly, the United States and Canada (8,40,41,76). Tempe kedele is made from partly cooked soybeans that are fermented with the mold *Rhizopus oligosporus*. The mold mycelium completely covers, penetrates, and binds the beans into a cake. In addition to the beans, lower-quality tempe varieties may contain solids such as cassava grits, soybean coats, or tofu that are added before fermentation. Freshly fermented tempe is creamy white; it has a mushroomlike flavor that becomes nutty and peppery on deep frying (8,76). Raw tempe does not keep well. Unless consumed within 24–48 h, it should be deep fried, dried, or blanched and refrigerated (76).

Production processes vary a great deal. In typical cottage-level processing in Indonesia, cleaned dry soybeans are washed and partially cooked by boiling for 2.5–3 h. An overnight soaking in clean water follows (8). A bacterial acid fermentation occurs and the pH drops to 4.5–5.3. The beans are now dehulled by rubbing with hands or feet. Hulls float on top and are washed away. Well-drained beans are inoculated using a previous batch of sporulated tempe that may have been sun dried. Alternatively, mold grown and dried on large leaves of *Hibiscus tiliaceus* may be used (8,76). Inoculum densities of 10^7 spores (or 10^7 cfu) per kilogram of wet solids have been reported (1,8). Overinoculation may produce excessive heat that inactivates fungal mycelium; *Bacillus* species proliferate, causing spoilage (8). Similarly, suboptimal inoculum density may cause outgrowth of yeasts and bacteria and again spoilage (8). Inoculated beans are lightly packed in relatively flat packets of *Hibiscus*, banana, or other broadleaves for 30–40 h of fermentation at ambient conditions (76). Similar general schemes are followed in large-scale production processes operated in the United States, Asia, and other countries; exceptions are mechanized processing, better-defined inoculum, and fermentation in perforated stainless steel trays (2- to 3-cm-deep bean layer) or perforated plastic bags (76). Fermentation is nonsterile; the bacterium *Klebsiella pneumoniae* that is invariably present in commercial preparations leads to vitamin B_{12} enrichment of the product (76).

Studies on production of *R. oligosporus* spores (pure culture) for commercial tempe inoculum indicate that viable spore counts of 10^9–10^{10}/kg dry substrate can be obtained on a variety of grains (1). Spores may be freeze-dried, but typically about one-log reduction in viability accompanies drying (1). Freeze-dried spores generally keep for 6 months (1).

Other tempelike products are consumed in Indonesia, including *tempe gembus*, made from waste produced by soybean curd factories; *tempe benguk*, produced using the legume *Mucuna pruriens* instead of soybeans; *tempe mata kedele*, made from soybean hulls; and *tempe bongkrek*, made from coconut press cake. The latter type can be potentially contaminated with the bacterium *Pseudomonas cocovenenans*, which produces lethal toxins (76). *P. cocovenenans* suppresses the growth of the tempe mold; hence, tempe bongkrek must never be consumed if a luxuriant growth of the mold has not developed (76). Formation of bacterial toxins is suppressed below pH 6, and an incubation temperature of 37 °C or higher prevents development of *P. cocovenenans* (76). The mold that is primarily responsible for most tempe fermentations is *Rhizopus oligosporus*, but other *Rhizopus* species, such as *R. oryzae, R. achlamydosporus*, and *R. arrhizus*, as well as non-*Rhizopus* fungi, may be involved (8).

Oncom

Oncom (or ontjom) is another tempelike product made from peanut press cake in Indonesia (41,76). *Rhizopus* species are used to produce the black oncom (*oncom hitam*), whereas the preferred red oncom (*oncom merah*) is produced using *Neurospora* species (76). *Neurospora sitophila*, *N. crassa*, and *N. intermedia* are typical oncom molds (76). In quite different processes, *N. sitophila* has been investigated also for protein enrichment of low-grade substrates such as sugar cane bagasse for animal feed (11).

Sausages

Fermented meat products such as bologna, summer sausage, thuringer, teewurst, dry sausage, pepperoni, and salami are produced by solid-state anaerobic fermentations utilizing acid-forming bacteria, particularly *Lactobacillus*, *Pediococcus*, and *Micrococcus* species. Typically, ground meat is mixed with curing agents and a starter culture at low temperature (-1 °C or less), and placed in cloth or other casings. Fermentation occurs at 20–40 °C. In dry sausage production in the United States, for example, a fast acid fermentation is employed to prevent growth of spoilage microorganisms. The curing mixture is predominantly salt and nitrite. Nitrite reacts with myoglobin in meat to produce the characteristic dark-red color of the product. Either *Pediococcus acidilactici* or *P. pentosaceus* is used for starter, depending on the selected fermentation temperature. Slower fermentation at 24 °C is commonly used in Europe. The curing mixture consists of salt, nitrate, and other spices. Naturally present micrococci and staphylococci convert the nitrate to nitrite for the desired coloring effect. After the lactic acid fermentation, a further incu-

bation period of up to 7 days at low temperature is practiced, with the meat held in 0.2-m-deep layers in metal pans.

Coffee

Coffee, after oil, is the second largest traded commodity, and more than 1.2 billion cups are consumed daily (83). Coffee processing employs a solid substrate fermentation for removing adhering mucilage (mesocarp) from ripe, mechanically pulped coffee cherry. This method is used predominantly only for *Coffea arabica* (84), which supplies the high-quality end of the market (83). Apparently, fermentation is not essential to flavor development, serving merely to remove the mesocarp from the parchment that encloses the bean. Nevertheless, the fermentation needs to be carefully conducted, or off-flavors develop that affect the final cup quality (84). In the preferred mode of fermentation, pulped cherry is placed in concrete or wooden tanks arranged for continuous drainage of the liquors produced (84). An alternative fermentation scheme utilizes under water fermentation with or without continuous water flow (84). The fermentation lasts 20–100 h, depending on factors such as pH, the coffee variety and stage of ripeness, aeration, and concentration of ions (for example, Ca^{2+} enhances the activity of certain enzymes) (84). Once the mucilage has degraded, the solids are washed and graded by water in concrete channels, and dried to produce parchment coffee (84). Milling (dehulling) removes the parchment to yield green beans used in commerce. The well-known coffee grounds are obtained by crushing blended and roasted green beans. Further processing is required to produce the instant varieties of coffee (83).

Cocoa

Cocoa beverages and chocolate are made from fermented cocoa (*Theobroma cacao*) seed or beans (85). Mature cocoa fruits or pods are harvested and split open to release the pulp-enveloped seeds. The pulp ferments as the seeds are piled in 2- to 4-ft-diameter heaps placed on perforated banana leaves that allow drainage of the liquids released (14,85). Alternative fermentation schemes employ perforated wooden boxes and other methods (85,86). The fermentation usually lasts 2–8 days, depending on the cocoa variety. The cocoa mass is turned several times during fermentation to ensure aeration and homogeneity and to avoid clumping (85,86). Turning also discourages mold growth on the better-aerated, exposed parts (86). A succession of microorganisms develop, including yeasts that are followed in turn by lactic acid producers, acetic acid bacteria, and, finally, aerobic spore-forming bacteria (86). The heat developed during the two-stage anaerobic–aerobic fermentation kills the cocoa embryo. Fermentation degrades the pulp, making removal easier, and products of fermentation penetrate the beans, stimulating complex biochemical reactions that are essential to flavor development (85,86). Fermented beans are dried, cleaned, and sold to chocolate processors or marketing organizations.

Mushrooms

The variety of edible mushrooms is tremendous, but only a few types are commercially cultivated. Production of mushrooms, mushroom compost and other substrates, and mushroom spawn utilize solid substrate fermentation methods that are comprehensively described elsewhere (2–4).

SAFETY CONSIDERATIONS

Microorganisms used in solid substrate fermentations have the potential to produce harmful effects in humans and animals. The history of occupational disease in solid-state cultivation is reflected in names such as cheesemaker's lung and mushroom worker's lung (87). Allergenic reactions and immunological hypersensitivity have been associated with exposure to fungal spores, including those of *Aspergillus niger, Aspergillus oryzae, Aspergillus awamori,* and *Aspergillus batatae* in industrial settings (88,89). Conditions such as dermatitis, asthma, vasomotor rhinitis, and itchy skin have been observed among exposed workers (87,88). Exposure to *Bacillus thuringiensis* has produced similar effects in humans (88). *Aspergillus* and *Pseudomonas* species have caused fatal infection in immunocompromised individuals and serious lung infection in cystic fibrosis patients (89). Fatal infections with *Aspergillus fumigatus* in previously healthy adults have been observed (89).

Inhalation of spores of edible mushrooms has long been associated with disease among mushroom growers (87). Allergenic reactions to spores of *Pleurotus* species, *Lentinus edodes* (3), and others have been documented. *Pleurotus* spores survive for several days after inhalation in the human respiratory tract, suggesting the potential for germination in the body (3). Allergenic reactions encountered in cultivation of *Agricus* species are linked to other molds that inhabit the substrate (3). In best-practice cultivation, attention to handling and processing of mushroom substrate and product should accompany ventilation of work areas and the use of personnel protective clothing.

In addition to microbes, fermentation products such as antibiotics and enzymes have been implicated in occupational asthma (87,89). Severe allergenic reactions to *Bacillus subtilis* proteases are well known (89). Under certain environmental conditions, organisms such as *Aspergillus flavus* and *Aspergillus oryzae* are known to produce lethal toxins (89). Specific strains of the blue-veined cheese mold, *Penicillium roqueforti*, also produce mycotoxins under narrowly defined environmental conditions (7). Species of the genus *Claviceps* and some members of other genera produce toxic ergot alkaloids. Some other toxin-producing fungi are noted in Table 5. Potentially, most physiologically active fermentation products can be disruptive to health, and certain products are highly toxic. Aflatoxins are potent carcinogens. For a given fungus, the product spectrum often depends on the fermentation conditions (temperature; pH; moisture content; type of substrate; agitation; metabolic energy source; amounts of oxygen and carbon dioxide; and nature and concentration of micronutrients, metal ions, and other chemicals); hence, evaluations under relevant conditions are essential. In particular, information from submerged culture may be an unsatisfactory indicator of behavior in solid-state fermentation.

Table 5. Toxin-Producing Fungi

Aspergillus alliaceus

Fusarium moniliforme
Fusarium graminearum
Penicillium islandicum
Penicillium roqueforti
Penicillium viridicatum

Handling of the substrate used in solid substrate fermentation requires care. A seemingly innocuous substrate may be contaminated with microbial spores or may generate allergenic dust. Raw material for composting may be heavily contaminated with human and animal pathogens, including eggs of parasites. Hence, certain high temperatures and holding time combinations are essential in composting to ensure destruction of pathogens and parasites. Depending on the composting process and the end use of the product, a uniform maximum temperature of 55 °C maintained for 3–15 days may be considered acceptable (33). Special care in process design and operation may be necessary to prevent recontamination of the final product. Cases of such contamination do occur perennially (e.g., infection from vegetables fertilized with manure; *Listeria* contamination in cheese). Sometimes inadequacies in processing may lead to a dangerous product: cases of cyanide poisoning from consumption of insufficiently processed *gari* occur from time to time in West Africa. Normally, fermentation and other process steps in gari making should substantially eliminate the cyanogenic glycosides (mostly linamarin and lotaustralin) that occur naturally in cassava tubers. Cases of fatal poisonings from consumption of poorly prepared tempe bongkerk have occurred in Indonesia.

Poor operational practice and failings in process and plant design can exacerbate the hazard. Experience suggests the following guidelines for minimizing process risks: (*1*) the number of operators should be kept to a minimum through mechanization and automation; (*2*) personnel–product contact should be minimal to reduce contamination of the product and ensure safety of operators; (*3*) operations should be enclosed and should be designed to minimize generation of aerosols and particulates; (*4*) the applicable GMP standards for food and pharmaceutical products should be followed; (*5*) the environment in and around the process plant must meet acceptable workplace air quality standards, especially for particulates, microorganisms, spores, humidity, and temperature; (*6*) the process equipment and the facility (including the air conditioning system) must be frequently sanitized; (*7*) facility design and operation must eliminate the risk of recontaminating the processed product; (*8*) there should be checks on the quality of the in-process material and the final product; and (*9*) satisfactory disposal of solid, liquid, and gaseous wastes must be ensured.

Operators should be fully informed of risks, and they should be given the training necessary for safe processing. Where required, personnel protective equipment should be provided. There should be adequate supervision, including routine health surveillance. Personnel who are ill, and those with open sores and cuts, should be sent home or moved to other, noncritical work. Attention to protection of peripheral support staff, for example, maintenance and cleaning personnel, is especially important because they may not have the knowledge or training for the potential risks. Thus, for example, trained, regular process operators should clean and sterilize a bioreactor before maintenance work.

The solid substrate fermentation facility should be designed and operated to prevent cross-contamination between dirty and clean areas. This goal requires attention to plant layout; movement of personnel, in-process material, process machinery; and flow of air in the facility. A minimum 12-Pa (0.05-in water gauge) pressure differential is recommended between adjacent clean and dirty areas. Negative pressure with respect to surroundings should be maintained in most solid-state fermentation chambers. Alternatively, the fermentation chamber may be under positive pressure with respect to the adjacent area, but that area should be under negative pressure with respect to other surrounding areas. Most work areas should comply with a relative humidity standard of 40–50%. Relative humidities lower than 40% cause problems with static electricity, whereas values greater than 50% promote corrosion. Between 10 and 15 air changes per hour are recommended for most plant areas. Workspaces for substrate preparation, downstream processing, and fermentation should attain 15–20 air changes per hour. Generally, conditioned air should be supplied at the ceiling level and return at lower wall locations. Preferably, particle counts should not exceed 3.5×10^6 m^{-3} (10^5 per cubic foot) for particles 0.5 μm or larger, and 2.5×10^4 m^{-3} (700 per cubic foot) for particles 5.0 μm or larger. There should be no more than 25 cfu/10 ft^3 of air. Air entering and exiting the fermentation chamber should be filter sterilized with 0.45-μm (or better) absolute filters that are also capable of in situ steam sterilization. A filter maintenance and replacement program should be in place. The practice of sterilizing solid substrate aeration gas by bubbling it through caustic or acid baths is misguided. Admittedly, the standards recommended here are not intended for processes such as composting and mushroom cultivation, but for plants producing foods, food additives, bulk pharmaceuticals, and secondary metabolites. The recommended practices are based on the author's experience. Note that the standards for packaging, sterile processing, and final dosage pharmaceuticals processing areas are significantly higher than the ones given here (90,91).

Much of the indigenous fermented food production in Asia, Africa, and South America is carried out at the cottage- or village-scale level with little consideration for hygienic processing. With few exceptions, even the larger plants do not come close to meeting the minimum standards expected in the developed world. The practices rec-

ommended in this review are for best-case production processes in the developed world where attention to hygiene and safety have transformed the traditional processing methods. Finally, as examples of toxic gari and tempe bongkerk prove, a thorough understanding of the fermentation microbiology and biochemistry is essential if disasters are to be prevented (78). Such knowledge is indispensable to developing large-scale production processes and in gaining increased acceptance of products beyond the regions of origin.

OUTLINE

INTRODUCTION

Soybean, *Glycine max*, is a crop native to Asia. It is not known when soybeans were introduced to the United States. Morse (1) reports that the first written mention of soybeans in the United States occurred in 1804, although there are references dating back to 1770, when Benjamin Franklin sent soybeans home from England (2). It is certain, however, that in the United States soybeans as a crop did not begin to gain popularity until the early 1920s. The primary reason for soybean's increased popularity was a newly developed ability to extract oil from it. Technological advances allowing utilization of soybeans for oil production led to the development of a large soybean industry. Today, the annual soybean crop value is about $14.5 billion. The advent of crushing facilities (continuous expellers) in the 1920s encouraged domestic demand for soybeans, and so for several decades since the 1920s, steady increases in the production and consumption of soybeans have occurred (Table 1) (3).

Economically, meal production today is more important than oil production. One metric ton (MT) of soybeans yields about 180 kg of oil and 800 kg of defatted meal. The unit price of oil is more than twice that of meal; however, a metric ton of soybeans produces meal and oil worth $160 and $80, respectively. The meal usually is the driving force behind soybean price because, on the average, it accounts for approximately two-thirds of the value of the beans (4). Soybean oil, the other direct product of soybean processing, is also important especially in the food industry. Soybean oil has 77% of the edible fats and oils market in the United States (4).

Most soy protein in the form of defatted meal is used as animal feed. Because of an ever-increasing population, however, demand for food protein has increased tremendously in recent years. Many types of soy food products have been developed, mostly from defatted soybean meal. These include soy flour and grits, soy protein concentrate, soy protein isolates, texturized soy proteins, defatted soy flakes, soy meal, full-fat soy flour, and enzyme-active soy flour. Advances in processing technology have resulted in soy protein products that can perform many functions in food while retaining their nutritive value. The development of technologies and processes has pioneered the way for soybean production and utilization. Improving existing and developing new ways to process and utilize soybeans will continue to be necessary if increasing demand for soybean products is to be met. This article reviews major soybean products and commercial processes currently in use.

Table 1. U.S. Production of Soybeans, Soybean Oil, and Total Crop Value from 1925 to 1995

Year	Total soybean production (million Bu.)	Total oil production (million lb)	Total crop value ($ million)
1925	4.9	2.5	11.4
1930	14	14	19
1935	49	105	36
1940	78	533	70
1945	193	1,392	402
1950	299	2,075	738
1955	374	2,827	831
1960	555	4,420	1,185
1965	846	5,800	2,151
1970	1,127	8,265	3,205
1975	1,548	9,630	7,618
1980	1,798	11,270	13,560
1985	2,099	11,617	10,571
1990	1,926	13,408	11,042
1995	2,152	15,155	14,564

VARIETIES AND COMPOSITION

A great number of soybean varieties are grown in the United States. Most differ in agronomic characteristics, so maximum yield under diverse growing conditions can be achieved. Because chemical composition is not considered in the grading standards for trading soybeans, plant breeders have focused plant improvement programs on increasing yield. But in the last few years, new market opportunities for specialty soybeans have led to an increased release of soybean varieties with improved quality traits. Some quality characteristics recently developed in soybeans include lower amounts of linolenic and palmitic acids and higher levels of oleic acid in the oil and reduced or complete elimination of lipoxygenase and lower concentration of trypsin inhibitor in the meal.

Processing and utilization of soybeans have led to the creation of soybean varieties of two types: those processed for production of oil and meal and those processed for direct food use (5). Soybeans used directly for food are generally lighter in color, have clear hilum, and contain more protein and less oil than soybeans used for oil and meal do (2). The most desired characteristics of soybeans for food

include a large seed, high protein content, and high quality at a reasonable price (6). Typical dry weight composition of soybeans is 12 to 25% oil, 35 to 50% protein, 33 to 35% carbohydrate, and 5% ash (6).

PROCESSING SOYBEANS FOR OIL AND MEAL

Soybeans are the dominant oilseed crop among the seven major oilseeds grown in the United States. More than half of the U.S. soybean crop is used by the domestic crushing industry to produce meal and oil. More than 15 billion pounds of soybean oil were produced in 1996 (7). Improved understanding of lipid chemistry and enhanced oil processing technologies were the most vital factors in the acceptance of soybean oil as a food-grade product. Refined, bleached, and deodorized soybean oil is used by a variety of industries, including food processors and industrial concerns, by food service organizations, and by consumers (8). Modern soybean crushing for oil and meal production involves these unit operations: preparation and handling, cleaning, drying, cracking and dehulling, conditioning, flaking, extraction, and product desolventizing.

Preparation and Handling

Conventional preparation and handling of soybeans before extraction consists of cleaning, drying, cracking, dehulling, conditioning, and flaking (9).

Cleaning. Sand, stones, dust, and other foreign material usually are removed by conventional seed conditioners, which consist of a two-deck vibrating screen (5). The upper screen retains the stones and coarser materials but allows the passage of soybeans, and the lower screen retains the soybeans and filters out finer particles. Light trash and hull particles are removed by aspiration, and magnetic separators are used to remove tramp iron (5).

Drying. Drying is conducted to efficiently remove the hulls from cotyledons. Beans are dried to a moisture content of 10% or less. Soybeans are usually dried in countercurrent open-flame grain dryers heated with natural gas or fuel oil (10). Soybean temperature must be raised sufficiently to achieve the desired final moisture of 10%, but it must not exceed 76 °C because discoloration and protein denaturation will occur (10). Dried soybeans are stored in bins for 2 to 5 days of tempering to allow for moisture equilibration by diffusion. The tempering bins also serve as working bins for uninterrupted feeding of processing plants (5). Improvements have been made in reducing fuel and energy costs. Some relatively new drying concepts include microwave vacuum drying and solar drying (10).

Cracking and Dehulling. To break the soybeans into small pieces for dehulling and flaking, cracking is achieved by counter-rotating corrugated rollers (9). To save power and to obtain more uniform granulation with fewer fines in the cracked beans, the corrugation of the cracking rolls was changed some years ago by widening the pitch between the teeth of the corrugated rolls (11). This alteration resulted in cleaner cuts or shearing with less power consumption (11). Cracking rollers usually are 25 cm in diameter and at least 107 cm long, having a processing capacity as great as 500 to 600 MT/day (9). The cracking step is very important in traditional dehulling. The cotyledons of properly dried and cracked soybeans should separate easily from the hulls (12). If the soybeans are too dry, they will pulverize in the cracking rolls and produce excessive fines, which could cause problems in the extractor. If beans are too moist, they tend to mash and not to release the hulls (12).

Conditioning. Cotyledon fragments (meats) are conditioned by heat and moisture to obtain the plasticity required for flaking. The temperature of the meats at the end of conditioning is between 65 and 70 °C (9). Conditioners may be vertical stack cookers or rotary horizontal cookers in which steam or water spray is added to adjust moisture to approximately 11% (12). Effective preheating before flaking decreases power consumption of the flaker (11). Flaking cold beans (25–30 °C) requires a power of about 5 to 6 kWh/ton of soybeans; however, flaking at 55 to 60 °C requires only 3 to 4 kW h/ton (11).

On-line dryers have been developed that combine the drying, dehulling, and conditioning steps into a continuous operation. Soybeans are cracked hot, which decreases the amount of fines produced. Different systems have been designed for this combined operation. The Escher-Wyss system uses a fluid bed dryer-heater to heat and dry soybeans so that the hulls detach from the meat. This is followed by cracking rolls and impactors to break up the soybeans and loosen the hulls. Hulls then are separated by air aspiration and meats are sent to a fluidized-bed conditioner-cooler for final moisture and temperature adjustment (13).

Flaking. Flaking is achieved by passing the conditioned meats between two horizontal smooth rolls. Flaking mills consist of a pair of smooth surfaced rolls with a minimum diameter of 50 cm (12). Rolls usually are 120 cm long and 70 cm in diameter. Pressure between the rolls is generated by mechanical or hydraulic systems, and flake thickness is controlled by the pressure (12). Flaking before solvent extraction is important because (*1*) solvent can flow easier through a bed of flaked particles than through a bed of cotyledon fragments or fine particles and (*2*) pressure generated between the rolls ruptures oil cells and facilitates subsequent solvent extraction (9).

Thickness of the flakes is crucial because solvent and oil diffusion are the rate-limiting steps during hexane extraction. Optimal flake thickness is 0.025 to 0.037 cm; thickness outside this range does not yield satisfactory results. Thicker flakes offer greater diffusion resistance; thinner ones easily crumble, producing fines that hinder hexane penetration into the soy-flakes bed (9).

A common problem in flaking is greater wear at the center than at the ends of the rolls. As the wear progresses, soy flakes at the center of the rolls become thicker than those at the ends. Continued pressure adjustment to correct flake thickness near the center may cause excessive pressure at the roll ends and chipping or pitting of the metal (12).

Improvements in Pre-Extraction Technology. The use of expanders in preparing oilseeds for extraction has been one of the most significant developments in the oilseed industry (13). Expanders produce collets that improve drainage and reduce solvent carryover to the desolventizer toaster. The three main benefits of the expander in oil extraction are (*1*) as great as a 40% increase in bulk density, potentially as great as 40% increase in contact time; (*2*) increase of bed porosity resulting in more rapid drainage rates; and (*3*) additional rupture of oil cells, which substantially increases the oil diffusion rate (14).

Solvent Extraction

The most prevalent solvent extraction method in modern soybean processing facilities is hexane extraction (15). The oil extraction process is basically a process of solid–liquid extraction (5). The transfer of oil from solids to the surrounding oil–solvent solution may be described in three steps: (*1*) diffusion of solvent into the solids, (*2*) oil solubilization, and (*3*) diffusion of oil from the solid particles into the surrounding liquid phase.

The driving force of diffusion is the oil concentration gradient. Although hexane has been the solvent of choice in most commercial extraction plants, other solvents also have been considered (16,17). The properties of an ideal solvent have been discussed in detail by Johnson (17); the most important of these include high-solvent power, nontoxicity, triglyceride selectivity, nonflamability, low specific heat and heat of vaporization, and low cost. The two streams exiting from the solvent extractor are the miscella, or oil-hexane mixture, and the marc, or defatted flakes containing hexane (Fig. 1).

Throughout the world, mechanical extraction often is preferred by small extraction plants, particularly those processing a variety of oilseeds. Screw presses consist of a shaft with an interrupted worm gear rotating in a cage of metal bars separated by small spaces. High pressure forces the oil out between the cage bars as the press cake moves along the shaft. Mechanical extraction can be used for the cold pressing of oils and the production of meal with a high oil content. Advantages are low initial capital cost and no solvent requirement; the efficiency of oil extraction, however, is less than with other methods.

Extraction Equipment. The basic types of commercial oil extractors in use today fall into two main categories: percolation and immersion (15,18). Percolation types are used worldwide and are considered more efficient. Immersion extractors are not commercially used for soybean oil extraction (15).

Four types of percolation extractors are actively marketed at present: the rotary basket extractor (Rotocel), the stationary basket extractor, the horizontal belt extractor, and the continuous loop extractor (12). A description of each extractor is beyond the scope of this article, and an excellent review of commercial extractors has been given by Milligan (19). In percolation extractors, hexane or miscella is pumped over the bed of soy flakes, percolates through the bed, and leaves at the bottom through a perforated plate or mesh screen. Extractors can be classified as deep-bed ($>$ 5 m deep) and shallow-bed ($<$ 5 m deep) extractors. Deep-bed extractors (rotary or stationary basket extractors) have a material bed whose overall length is approximately five times greater than its depth (14). The bed surface area per miscella stage is relatively small, allowing the required miscella flow to permeate the bed completely. The solvent-flakes contact time is maximized, and these extractors can operate with relatively thick flakes. Shallow-bed extractors (horizontal belt and continuous loop extractors) are designed so that overall length of the bed material is 50 times greater than its depth. Bed surface area per miscella stage is large, and contact time between solvent and flakes is not maximized. Shallow-bed extractors operate effectively by using thin flakes, thereby increasing the diffusion rate (14).

Miscella Stripping. Full miscella contains about 30% oil; for every ton of crude oil, therefore, about 2.5 tons of solvent must be removed by distillation (5). The hexane must be efficiently removed and recycled to ensure the oil safety and to conform to environmental regulations (9).

A solvent recovery system consists of a two-stage stripping evaporator and an oil stripping column. Solvent is removed from the miscella by double-effect evaporators and steam stripping. The first stage usually consists of a long-tube vertical evaporator, where the miscella is heated and solvent evaporated using vapors from the desolventizer-toaster (DT) unit at below atmospheric pressure, concentrating the miscella to about 70% oil (12,15). The second-stage evaporator is a rising-film evaporator heated with steam at 10 to 20 psi in which the miscella is further concentrated to 90 to 95%. Vapors generated go to the condenser, and oil goes to the oil stripper, a disk-donut type operating under vacuum provided by steam injection (12,15). Oil flows downward in contact with stripping steam introduced at the bottom. At the end of this operation, the amount of residual solvent is sufficiently low to achieve a flash point of 150 °C. A flash point of 121 °C corresponds to 1,000 ppm of hexane in the crude oil, which is the required level for transfer to the refinery (9).

Desolventizing and Toasting Soybean Meal for Feed. Desolventizing is a key operation in solvent extraction (13). Defatted flakes from the extractor contain about 30% (w/w) hexane, and before they can be processed further for feed they need to be processed through a desolventizer. The meal, which is used usually as livestock feed, must be heated sufficiently to inactivate antinutritional factors such as trypsin inhibitors (9). This process is known as *toasting*. It is carried out commercially in conjunction with desolventizing in a DT unit (9). Hexane-wet flakes leave the extractor at temperatures of about 57 °C. Live steam is injected at the bottom of the DT unit, and the steam that condenses provides the latent heat required for hexane evaporation. The condensed steam raises the moisture level of the flakes to 16 to 24%, facilitating the toasting operation at 100 to 105 °C (20). The residual hexane content of the flakes is less than 500 ppm. The flakes then are hot-air dried to about 10% moisture, cooled to a temperature below 32 °C, and ground and screened to a desired grit size.

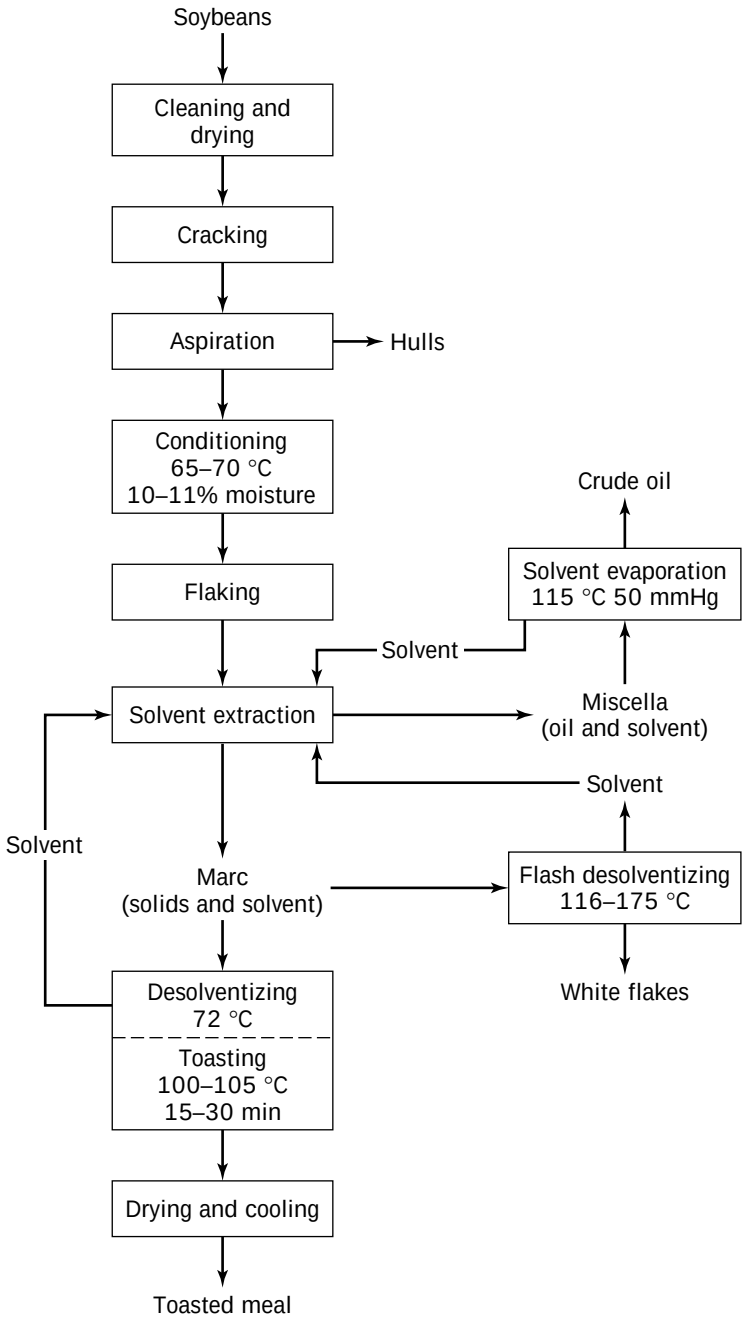

Figure 1. Principal unit operations in soybean oil extraction facilities.

Soybean meal with greater than 50% (w/w) protein, which is produced by grinding toasted flakes, provides greater than 60% of the value of processed products from soybeans. In the United States, meal is used primarily in swine and poultry rations (8). The other components of meal are carbohydrates (30 to 35%), lipids (1%), ash, and moisture.

A predesolventizing step and the use of expanders in flake preparation have marked effects on the desolventizing operation (20). Predesolventizing reduces the amount of hexane going into the DT and the amount of water condensed on the flakes and, consequently, decreases the steam requirements (20). Moisture reduction of the flakes, however, increases the possibility of overheating and decreases the nutritive value of the meal (20). Expanded flakes have higher bulk density and lower residual solvent content than unexpanded flakes do (9).

Desolventizing and Deodorizing Soy Flakes for Food. For food and industrial applications of meal, it is necessary to minimize the heat denaturation of soy proteins and to maintain their water solubility (9). Desolventizing to produce white flakes can be performed (*1*) in steam-jacketed conveyor tubes arranged in a vertical stack; (*2*) by using superheated circulating solvent vapor in a horizontal drum equipped with an agitator/conveyor pipe to facilitate con-

tact between the flakes and the superheated vapor; and (*3*) by using superheated solvent vapor to contact the flakes in a conveyor pipe, where the conveying action results from the velocity of the superheated vapor (20). The last process, also called *flash desolventizing* because of the relatively short residence time of flakes in the apparatus, is the best method for desolventizing white flakes (5). The superheated vapor provides energy for the evaporation of solvent from the flakes. The turbulent nature of the flake-vapor flow permits extremely rapid heat and mass transfer. In seconds, the superheated hexane will flash off the residual liquid hexane, leaving desolventized flakes to be collected in the cyclone (21). Protein denaturation is minimized primarily because of the short heating time. Hexane losses in white flake desolventizing systems are generally higher than those in DT systems (20). After desolventizing, white flakes are deodorized with live steam to remove the remaining hexane. Depending on end use, deodorization conditions can be adjusted to produce flakes with varying protein solubilities, such as with protein dispersibility indices (PDIs) of 10 to 90%.

One negative impact on the environment from the oilseed processing industry is the unrecovered solvent from the oil extraction (14). By November 15, 2000, maximum achievable control technology standards for hexane emissions will be established (23). What the standards will be is unknown; it will not, however, be easy to meet them, even by the most efficient plants (24). The most significant hexane loss points in the extraction plants include desolventizing, meal drying and cooling, vent systems, water and oil carrying solvents, fugitive emissions, and plant shutdowns (24). In most plants, hexane loss is less than half that of 10 years ago. This decrease was accomplished by emphasizing the basic engineering and processing principles upon which most plants were designed and built (24).

Storing and Handling Crude Soybean Oil. Crude soybean oil contains a significant amount of nontriglyceride components that should be removed before bulk storage, handling, and transport (25). Deterioration of oil in storage depends not only on external factors but also on the initial conditions of oil, including moisture content, free fatty acids content, organic impurities, and contamination with molds (25). Crude oil must be stored under specific conditions to avoid oxidation caused by moisture, temperature, air, and metals promoting oxidation (9). To avoid the settling of fines and gums, oil with a moisture content below 0.2% is cooled to 40 °C and stored in stainless steel tanks with agitation. Oil stability can be improved if impurities are removed before storage (9).

REFINING SOYBEAN OIL

Refining freshly extracted oil means less product loss and improved product quality (13). Crude oil contains both insoluble and oil-soluble impurities. Insoluble impurities include seed fragments, excess moisture, and sometimes a waxy fraction appearing in refrigerated oils (9). Oil-soluble impurities include phosphatides, free fatty acids, gummy or mucilaginous material, color bodies, tocopherols, sterols, hydrocarbons, ketones, and aldehydes. The refining process removes those impurities, converting the crude oil into food grade soybean oil (9). Oil refining consists of several major unit operations: degumming, neutralization, bleaching, hydrogenation, and deodorization, each of which is designed to remove one or more specific compounds (Fig. 2).

Crude Oil Clarification

The removal of fines from crude oil is done traditionally by filtration. In integrated facilities, filters are being replaced by centrifugal decanters (13). In facilities with acid and water degumming and when lecithin is not produced, the clarification step is combined with the degumming step by removing both solids and gums in a high-speed decanter (13).

Degumming. The degumming step removes the phospholipids, also referred to as *phosphatides*, *lecithin*, or *gums*, which are the major source of oil phosphorus. Removal of phospholipids is essential in the production of oil with optimal color, flavor, and oxidative stability. Direct mixing of warm oil (70 °C) and soft water (1 to 3%) is the most commonly used method for degumming. Hydrated and insolubilized phospholipids partition to the water phase, and the oil temperature disrupts the possible formation of emulsion (9). Degumming of the oil from undamaged soybeans decreases phosphorus content in crude oil from 500 to 900 ppm to 12 to 170 ppm (9). Soy phospholipids also are extracted, because they are used in the food industry as soy lecithin (a mixture of phosphatidylcholine, phosphatidylinositol, and phosphatidylethanolamine). Because of the limited market for lecithin, a common practice in the United States is to alkali refine crude soybean oil and to dispose of lecithin in soapstock (26). The next important development in the degumming process probably will be the implementation of membrane filtration (13).

Neutralization

Neutralization is the removal of free fatty acids from the oil. Free fatty acids must be removed because they reduce the smoke point of oil, increase foaming, and may impart soapy flavor in foods (9). There are several methods of neutralizing crude soybean oil, alkali refining, Zenith refining, and physical refining are commercially used.

Alkali Refining. Alkali refining, also called *caustic refining*, is the most common method of neutralization and can be performed on crude or degummed oil. It involves adding alkali solution, in-line mixing with oil, centrifugation, in-line washing with water, and a second centrifugation (27). The sodium salt of the fatty acid (soaps), which are produced during neutralization, are removed during centrifugation. Some loss of triglycerides may occur with soaps. A typical level of free fatty acids before refining is 0.3 to 0.7%, and refining lowers this to $<0.05\%$ (9).

Zenith Refining. The Zenith refining process was developed in Sweden in 1960 and consists of degumming with

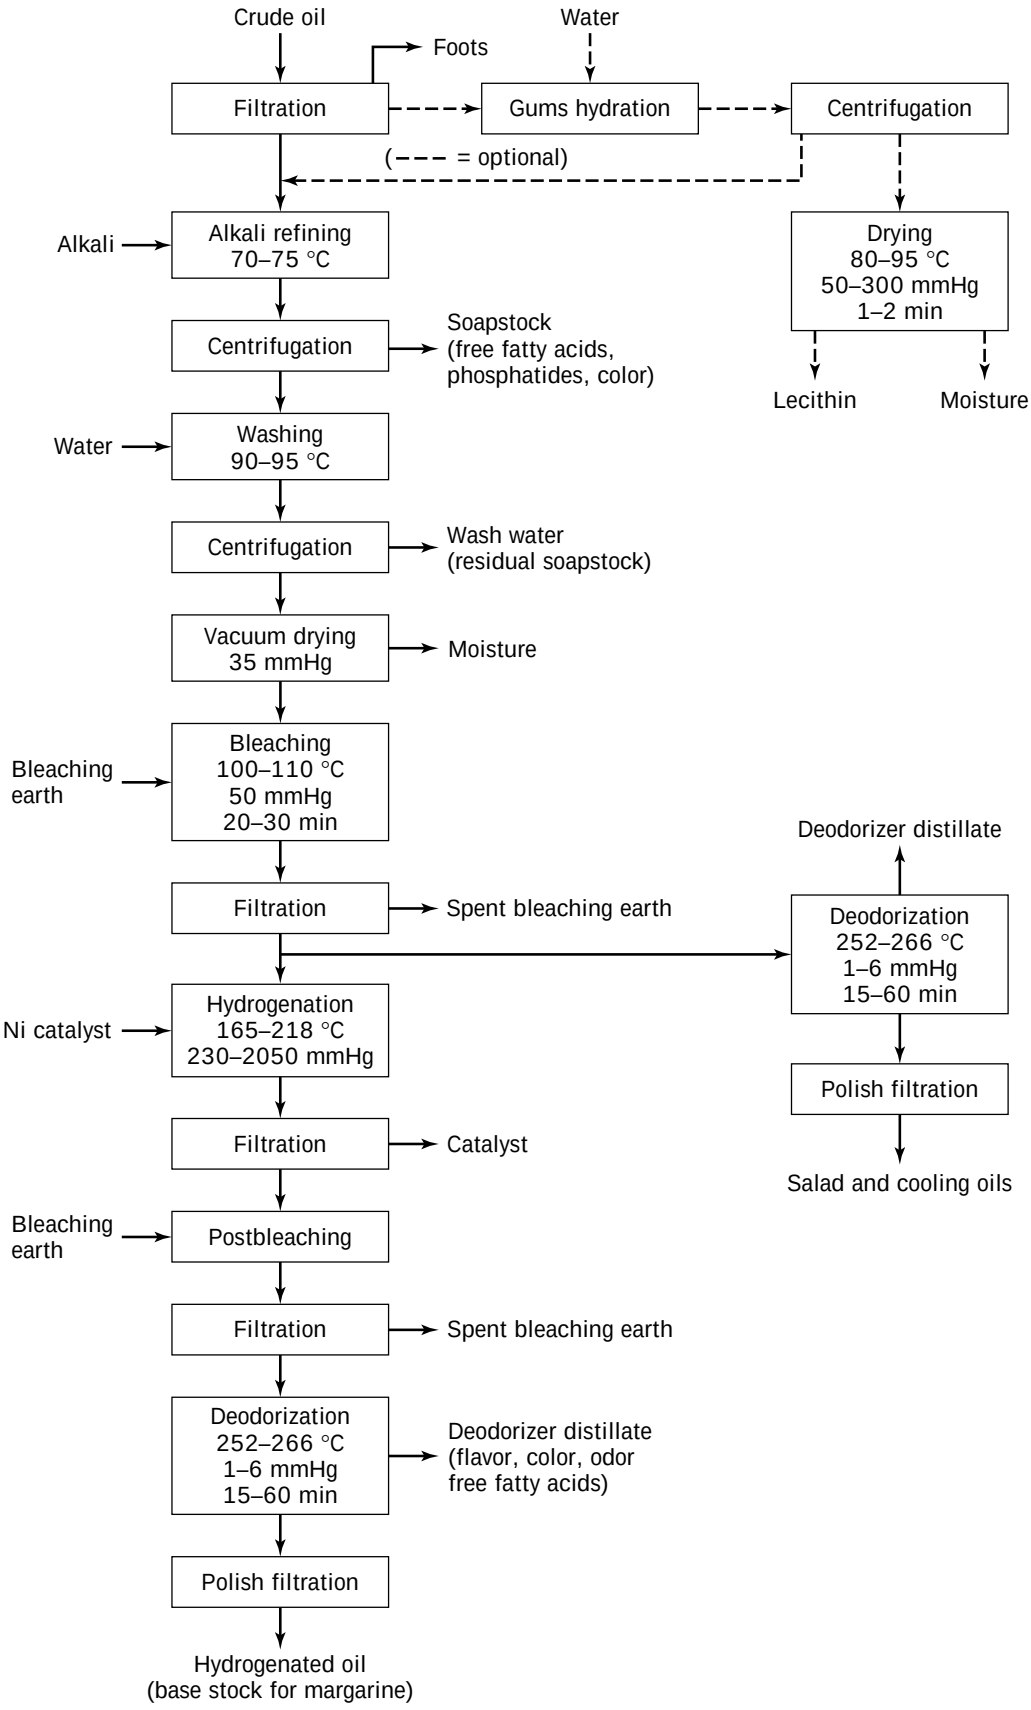

Figure 2. Unit operations involved in soybean oil refining for the production of hydrogenated oil, salad and cooking oils, and optional lecithin production.

0.1 to 0.4% (w/w) of phosphoric acid and alkali refining with a dilute sodium hydroxide solution (0.35 M). The use of dilute alkali obviates washing the oil with water. The neutralized oil contains about 1% water and 50 ppm soap and requires bleaching with citric acid and bleaching earth (27).

Physical/Steam Refining. This process is essentially a deodorization of lecithin-free oil under high vacuum at high temperatures. The process conditions are the same as those used in the deodorization. Physical refining reduces water usage and generates less wastewater than alkali refining does. Because of flavor instability, physically refined oils are not acceptable in the United States (27).

Bleaching

Treatment of refined oil with a bleaching adsorbent removes pigments, metal compounds, residual soap, and trace amounts of prooxidants that were not removed by alkali refining (15). Neutral earth, acid-activated earth, activated carbons, and silicates are used as adsorbents for soybean oil bleaching (28). This process has evolved basically from an open batch system to a continuous process under vacuum with alternating filters for clay removal (13). Typically, neutralized oil is mixed at about 70 °C with an appropriate dosage of earth (0.3 to 0.6%), heated to bleaching temperature (100 to 110 °C), mixed for 20 to 30 min, cooled to 70 to 80 °C, and filtered (28). Bleaching is an important step in enhancing oil appearance, flavor, and stability and in obtaining a light color appealing to the consumer (9).

Hydrogenation

The goal of hydrogenation is to decrease the amount of unsaturated fatty acids and to convert liquid oils to fluid, semisolids, or plastic fats (9,29). Hydrogenation is performed with hydrogen gas in the presence of a nickel catalyst. Reaction conditions differ with the desired product, and the ranges of process temperatures, pressures, and catalyst concentrations are 165 to 218 °C, 0.3 to 2.7 atm, and 0.02 to 0.05%, respectively (29). Hydrogenation increases the oxidative stability by reducing the number of double bonds in fatty acids, which are the sites of peroxide formation and subsequent off-flavor development (9).

Deodorization

The main purpose of deodorization is to remove free fatty acids, odors, and flavor compounds from the oil (13). Deodorization is a steam-stripping process in which good quality water is injected into soybean oil under a strong vacuum (1 to 6 mm Hg) and a temperature sufficiently high (252 to 266 °C) to vaporize undesirable volatile compounds (30). Deodorization is the last step in refining edible oils to be used as ingredients in salad dressings, cooking oil, margarines, shortenings, hard butters for the confectionery industry, and other food products (9).

Winterization

Winterization is the removal of solids that settle out from the oil at temperatures between 4 and 10 °C. The solid fraction (stearine) is separated so that it does not precipitate during refrigeration of salad oils (9). Winterization begins with dry, hydrogenated oil being pumped into a large insulated tank fitted with cooling coils. The temperature is lowered slowly by controlling the amount of propylene glycol circulating through the cooling coils. The rate of cooling must be controlled to promote the formation of larger crystals for easy separation. Crystal formation and growth is determined by nucleation temperature, triglyceride composition, and cooling rate. Commercial winterization is done by cooling the oil from 30 to 35 °C to about 6 °C. The temperature difference between oil and coolant is maintained at about 13 °C to ensure slow cooling. As the final temperature is approached, the cooling rate is decreased further. The cooling process lasts between 12 and 24 h (9). At the end of the cooling period, the external cooling is stopped and the winterized oil is allowed to stand for 6 to 8 h at 6 °C before filtration (15). Typical oil recovery is 75 to 80%.

Industrial Uses of Soybeans

Industrial (nonfood, nonfeed) uses of the two major soybean products, protein and oil, comprise less than 0.5% of total soy protein and about 2.6% of the total soy oil produced in the United States (31). Economically viable industrial uses today of soy protein and oil include paper coatings (protein), wood adhesives (protein), alkyd resins (oil), printing inks (oil), and oleochemicals. Potential uses include plastics and textile fibers from soy protein and soybean-based fuel. The most important current and potential applications of major soybean products are summarized in Table 2. For in-depth review of the industrial uses of soybeans, interested readers are referred to the work of Johnson and Myers (31).

SOYBEAN PROTEIN PRODUCTS

The term *soy protein* is given to processed edible dry soybean products with protein contents greater than 50% (w/w). Typically, food-grade soy proteins are produced from white flakes, which are processed on different lines than those used for producing oil and feed meal (32).

Defatted Soybean Grits and Flour

Grits are obtained by grinding defatted flakes coarsely followed by screening. Grits are sold as coarse (10 to 20 mesh), medium (20 to 40 mesh), or fine (40 to 80 mesh) grade. Soy flour is produced by grinding soy flakes to very fine particles to achieve 97% product pass through a 100-mesh screen. Soybean flour and grits are used in a variety of food products, including soups, sweets, beverages, desserts, bakery goods, breakfast cereals, and meat products.

Soy Protein Concentrates

Soy protein concentrates are prepared by removing soluble carbohydrates and volatile compounds from defatted meal or flour to obtain a product with a protein content of 65 to 75% (w/w). Nondenatured soybean protein is most soluble at pH values between 1.5 and 2.5 and between 7 and 12

Table 2. Current and Potential Industrial Uses of Soybean Products

Product	Main processes	Uses
Adhesives	Alkali dispersion of soy flour, mixing and treatment with other ingredients such as sodium silicate, antifoam, and preservatives	Wood adhesives
Plastics	Mixing of soybean meal with formaldehyde and phenol followed by heating	Potential use for foam cups, food packaging, and other fast-food industry items
Textile fibers	Treatment of soybean meal with alkaline solution and with acid to precipitate protein; dissolving, wet-spinning, recoagulating in reel, and stretching	Blending with other fibers such as cotton, rayon, nylon, wool
Paper coating	Alkali dispersion, mixing with additives	Decorative papers
Paints, varnishes, and coatings	Heating of soybean oil, and mixing with maleic anhydride; esterification of maleinized oil to a polyol	Alkyd resins
Plasticizers	Oxidation of soybean oil with performic acid, peracetic acid, or with hydrogen peroxide in the presence of a strong ion-exchange resin	To improve heat and light stability of plastics
Diesel fuel	Dissolving of 0.1–0.5% (based on oil) sodium methoxide in methanol, and mixing with heated soybean oil (80 °C); vacuum distilling, drying, and blending with diesel fuel, of the ester layer	Interest in biodiesel in cities with air pollution problems
Printing ink	Polymerization of oil by heat, blending the polymerized oil with 1% butilated hydroxitoluene and 6–20% pigments	Lithographic and letterpress newsprint applications

Source: Adapted from Johnson and Myers, 1995 (31).

and least soluble at its isoelectric region of pH 4.2–4.6 (32). Three basic processes have been used to remove carbohydrates (Fig. 3): acid extraction at pH 4.5, 60 to 80% aqueous ethanol extraction, and hot water extraction (33). In all three processes, protein remains insoluble while solubilized carbohydrates are removed by centrifugation. Solids from the acid extraction process are resuspended in water and neutralized to pH 6.8, whereas those from alcohol extraction are flash desolventized before spray drying. The most obvious difference between soybean protein concentrates is the lower ash content of concentrates prepared by acid or hot water extraction, indicating more thorough removal of minerals (32). Figure 3 summarizes basic unit operations and process conditions required to make soy protein concentrate by each of the three methods.

Soy Protein Isolates

Many processing options exist for making soy protein isolates. The preferred approach is to tailor the extraction process so that the isolate is made optimally compatible with the intended consumer product (32). Soy protein isolates are prepared traditionally from defatted soybean meal using aqueous or mild alkali extraction (pH 7 to 10) of proteins and soluble carbohydrates (33). The insoluble residue, mostly carbohydrates, is removed by centrifugation, and soluble protein is then precipitated at the isoelectric point (4.2 to 4.5) of soy proteins (Fig. 4). The precipitated protein is separated by mechanical decanting, washed, neutralized to about pH 6.8, and spray dried to obtain a product with protein content greater than 90% (w/w).

Textured Soy Protein

Textured soy protein products are obtained by thermoplastic extrusion of soy flour or concentrates to obtain a meatlike texture. Flours and concentrates are mixed with water and additives to form a dough and extruded under high pressure and temperature to obtain fibrous texture (33). Processes for textured proteins include thermoplastic extrusion, fiber spinning, direct steam texturization, shaping and heating, enzymatic texturization, and coagulation (34). Texturizing processes differ based on the type of raw protein material used, which can include defatted soy flour, soy protein concentrate, soy protein isolate, or a blend of several products (34). The most popular raw material has been slightly toasted, defatted soy flour.

Textured soy products have been produced with raw materials ranging in PDI from 20 to 70 (35). The PDI is the percentage of total protein dispersible in water under controlled conditions of extraction. During extrusion, the raw material is placed in the feeder and moved to a conditioning section where the food is mixed with 80 °C steam. In the conditioning section, the moisture content is raised to between 10 and 25%. The mixture then is sent to the extrusion cooker, where it is processed under conditions depending on type of raw material, equipment, and desired final product. Processing conditions include pressures of 400 to 1,500 psi and temperatures of 105 to 113 °C (35).

PROCESSING OF WHOLE SOYBEANS FOR FOOD

In the United States, only 3 to 5% of the soybean crop is used for food. This proportion is much larger in other countries, especially those in Asia, where soybeans are a staple of the human diet (8). In Japan alone, about 1 million tons

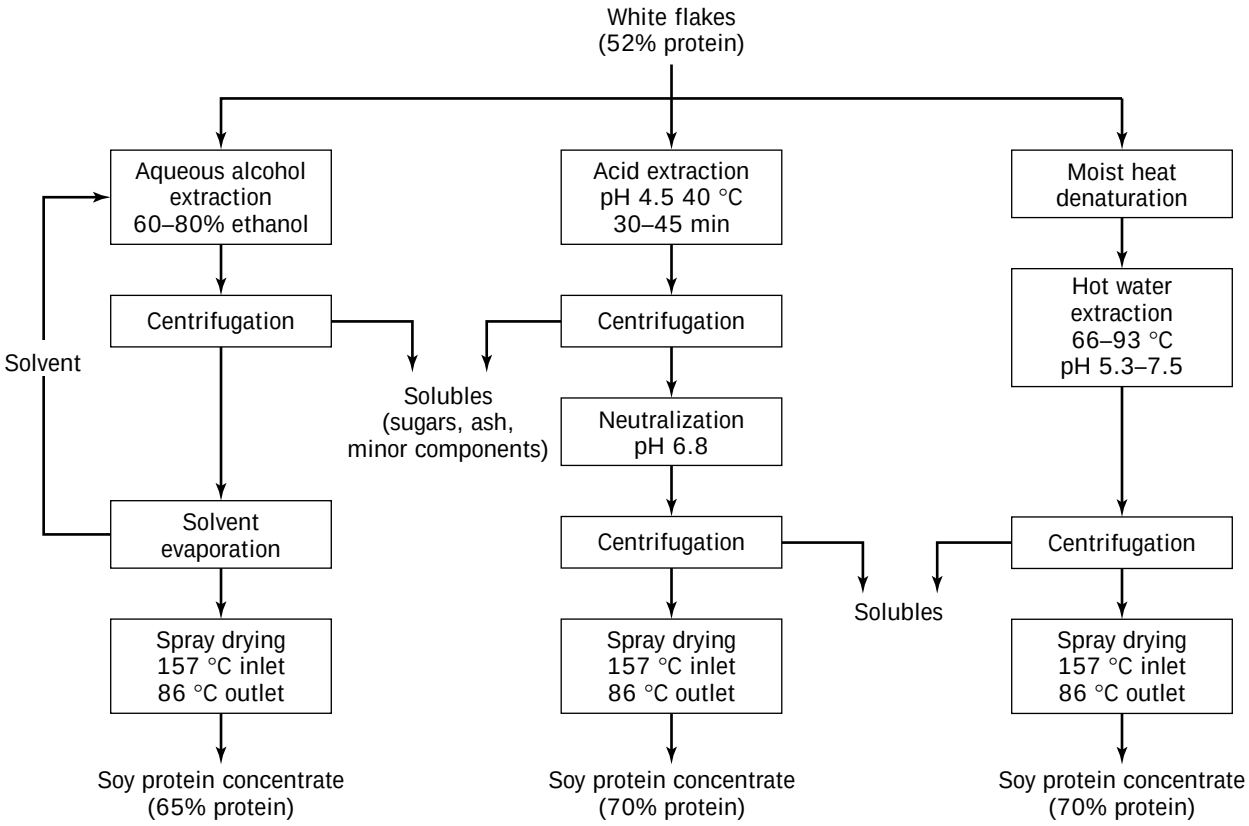

Figure 3. Alternative processes for the production of soy protein concentrates.

of soybeans are used to produce traditional Japanese foods such as tofu, shoyu, and miso (36). Both fermented and nonfermented foods are made from soybeans, and a brief discussion of most important products will be presented next.

Nonfermented Foods

A variety of nonfermented food products are made from whole soybeans. Raw soybeans have an undesirable bitterness and beany off-flavor and are rarely consumed without some sort of processing. In addition, raw soybeans contain several enzymes and antinutritional factors that need to be eliminated or inactivated if soybeans are to be palatable and digestible for humans (5,37). Growing interest in soybean foods in western countries has led to modernization of the manufacturing of traditional products and to the development of totally new products such as tofu-based ice cream and soybean yogurt (5). Soy milk, tofu, toasted full-fat soy flour, and enzyme-active soy flour are among the most important and best known commercial nonfermented food products.

Soy Milk. Soy milk is basically a water extract of soybeans obtained by wet grinding of soaked soybeans and subsequent filtering of solids (Fig. 5). Soy milk quality is related directly to raw soybean quality. Differences among soybean varieties affect not only yield but also important properties such as aroma and taste of soy milk. Soybean standards for soy milk production have been developed in Asian countries, and their use in the selection the raw soybeans have contributed to the consistently good quality of soy milk.

There are many different methods for producing soy milk, and the majority are variations of those described by Nelson et al. (38) (the Illinois method) and by Wilkens et al. (39) (the Cornell method). Both methods were developed primarily to improve soy milk flavor and stability. Regardless of process variations, the basic steps and principles of soy milk preparation are very similar and consist of soaking and grinding the beans and heating the extracted soy milk (Fig. 5). Modern large-scale soy milk plants use several additional steps and more sophisticated equipment. Several new processes have been described by Chen (40), Wilson (41), Kwok and Niranjan (42), and Liu (43).

Cleaning. Cleaning and washing, which remove dirt, dust, and microorganisms from the surface of soybeans, is crucial if contamination of the final product is to be avoided. The precleaning steps also include the removal of foreign material such as straws, stones, metal, weeds and their seeds, and damaged soybeans.

Dehulling. There are arguments in favor of and against dehulling. Most soy milk manufacturers use whole beans because dehulling disrupts the cotyledon tissue and releases the lipoxygenase enzymes, which diminishes the quality of soy milk. In addition, the presence of hulls helps filtration. Dehulling supporters believe that dehulling im-

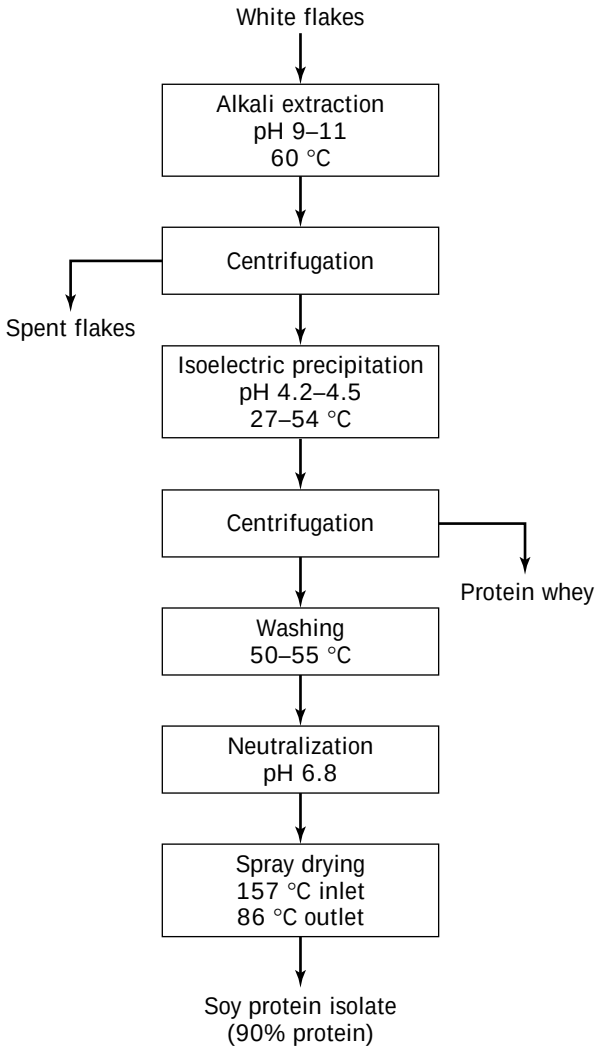

Figure 4. Production of soy protein isolate from white flakes.

proves the flavor and color of soy milk. Dehulling of soybeans is a process that consists of three steps, a heat treatment (93 °C for 15 min) to break the bonds between the hulls and the cotyledon, soybean cracking, and hull aspiration. A final dehulling efficiency of 88% is required for good quality soy milk (40). Most dehulling is done dry, but wet dehulling is also possible.

Soaking. Soybeans are soaked in water at a 1:3 solids-to-liquid ratio. The length of soaking depends on water temperature; the cooler the water, the longer the soaking. Typically, soaking time is 8 to 10 h at 20 °C in the summer and 14 to 20 hours at 10 °C in winter (40). Soybeans can be soaked in circulating water to be rinsed continuously throughout the soaking period. Most commercial soy milk production calls for soaking of soybeans to decrease the energy required for grinding, to achieve better dispersion and suspension of the solids, to increase yield, and to decrease cooking time (40,43).

Increased soaking time increases loss of water-soluble solids. Soaking of dehulled soybeans for 24 h results in a 5% solids loss as compared with a 1.5 % loss for whole (not dehulled) soybeans. Dehulled soybeans reach full hydration much faster than whole soybeans do and require only 2 to 3 h of soaking at 30 °C, or 1 h at 50 °C; whole soybeans require 7 h at 30 °C or 3 h at 50 °C (40). The addition of alkaline salts such as sodium bicarbonate, sodium citrate, or sodium hydroxide to the soaking water has been shown (*1*) to increase the protein and solids recovery, (*2*) to decrease beany off-flavor, (*3*) to inactivate trypsin inhibitors, (*4*) to tenderize soybeans, and (*5*) to affect soy milk quality by increasing soy protein solubility (43).

Fine Grinding. The purpose of fine grinding is to disrupt soybean tissue at both the cellular and the subcellular level and to suspend or to solubilize proteins, lipids, and other solids (43). Soaked soybeans may be ground with hot or cold water by a stainless steel disintegrator (Rietz), hammermill (Fiztpatrick), pin mill, or large blender (Waring) to produce coloid solution that will pass through a 150-mesh screen (40). Grinding in hot water (above 80 °C) inactivates lipoxygenases and prevents the formation of the beany off-flavor. Both very fine and rather coarse grinding are undesirable. Finely ground slurry contains maximum amount of soy protein but makes filtration difficult, thereby lowering soy milk yield. Coarse grinding may not result in the highest solubilization of the soy protein and other soluble solids and will be retained in the okara after the filtration (43). To improve flavor and mouthfeel, insoluble soybean residue is removed from the soy slurry by filtration or centrifugation.

Thermal Treatments. One or more heat treatments are used in soy milk processing. For example, in addition to cooking the slurry, the Illinois method calls for blanching (steaming), whereas the Cornell method calls for grinding the beans in hot water. Commercial processes also require pasteurization or sterilization of milk before packaging. Thermal treatment is one of the most important variables in the processing of soy milk (42). The positive effects of heat on soy milk include inactivation of antinutritional factors and lipoxygenases, increased extraction efficiency, denaturation of soy protein, and increased product shelf life. It is recommended that soy slurry or soy milk be heated for about 30 min at 100 °C to obtain optimal nutritional value and flavor. Heating also is applied to lower viscosity of the slurry to increase recovery of proteins and solids (40–43). Different soy milk processes use different temperature-time regimes during thermal processing. Effects of thermal processing on soy milk have been extensively reviewed by Kwok and Niranjan (42).

Homogenization. Homogenization is an optional step that is used to stabilize the soy milk emulsion and to disperse solids that otherwise may settle on the bottom of the container. Homogenization makes soy milk creamier and more uniform in consistency. For most soy milk products, a single pass at 2000 to 3500 psi and 90 °C through a dairy-type homogenizer is sufficient to obtain a good product. Some soy milk products exhibit a chalky taste caused by relatively large particles (>150 mesh) suspended in the milk (40). Chalkiness may be reduced by increasing the alkalinity of the blanching solution, by adjusting the final pH of soy milk to about 7.5, by decreasing solids content, or by homogenizing at high temperatures and pressures.

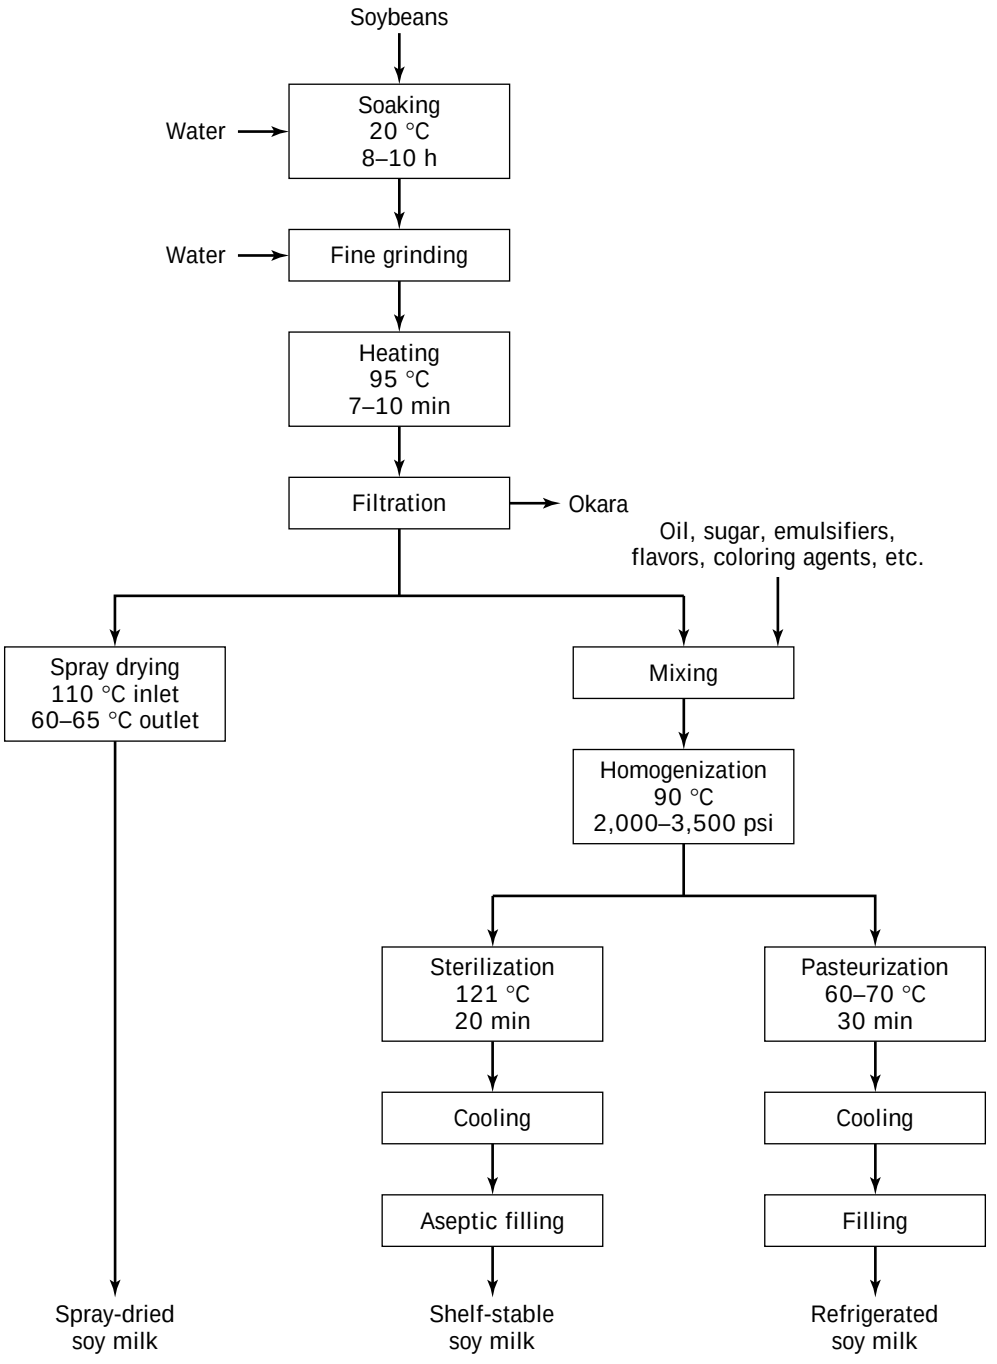

Figure 5. Alternative processing methods for soy milk production.

Pasteurization/Sterilization. After homogenization, soy milk can be pasteurized (75 °C for 15 min) or sterilized (12 °C for 15 to 20 min) and packaged for distribution. Pasteurized soy milk requires refrigeration at 4 °C to maintain a typical shelf life of about 1 week, whereas sterilized milk is shelf stable (Fig. 5).

Tofu. Tofu is a curd that is made directly from soybeans and resembles a soft white cheese. Basically, tofu is water-extracted and salt- or acid-coagulated soy protein gel with water, lipids, and other constituents trapped in its network (43). Typical pressed tofu has a moisture content of about 85% and contains about 7.8% protein, 4.2% lipids, and 2 mg/g calcium. On a dry basis, it contains about 50% protein and 27% oil.

In the United States, the tofu industry has shown steady growth during the past 10 years, partly because of the demand for healthy and low-fat ingredients (44). The quality and yield of produced tofu depend on several factors including soybean variety. For example, the ratio of

the 7S and 11S proteins in soybeans contribute to the textural characteristics of tofu (45). Tofu made from crude 11S protein is significantly harder than that made from 7S protein, and the crude 11S fraction adds to the springiness, chewiness, and gumminess of tofu (43,45). During the preparation of soy extract (milk), water-to-bean ratio, temperature and hardness of water, degree of maceration, extraction time, and grinding equipment affect amount of extracted protein (46).

There are three main steps involved in the making of tofu: preparation of soy milk, coagulation of protein, and pressing and molding (Fig. 6) (43,45,46). The processing steps for preparation of soybean extract are similar to those discussed in the previous section. A greater yield and better quality of tofu was obtained when the bean slurry was filtered before heating (45). The bean slurry is filtered through a cloth sack to separate the undispersible fiber (okara) from the soy milk. The okara normally is washed with hot water, stirred, and pressed again to increase dispersible solids recovery. Previous studies have shown that tofu yield and texture depend on the heating temperature. The texture of tofu produced from soy milk heated below 70 °C is soft and watery, between 70 and 80 °C is good and above 80 °C is hard and uneven (48).

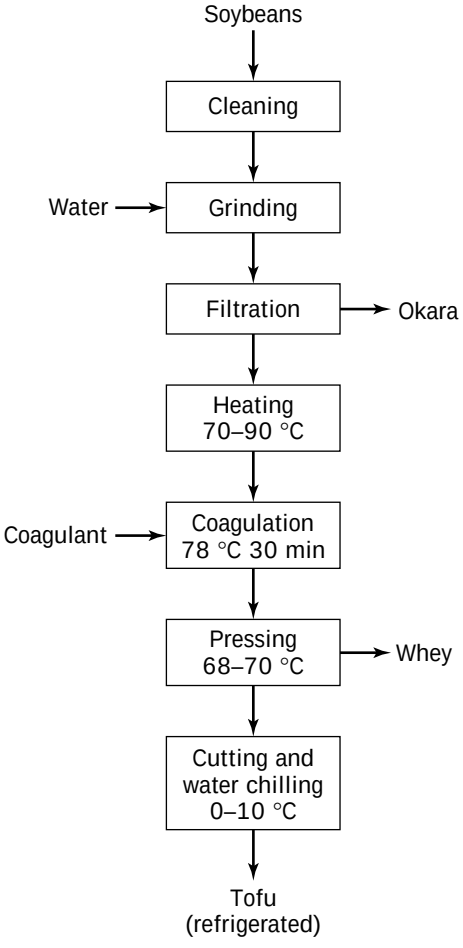

Figure 6. Basic unit operations involved in processing of soy milk into tofu.

Coagulation. Coagulation of soy milk is the most important step in tofu making and the most difficult to control because it depends on the complex interaction of many variables (49,50). Temperature of the soy milk, coagulant amount and concentration, and mode and rate of stirring all affect yield and texture of tofu. The ideal pH for soy milk coagulation is at or near 6. Soy proteins start coagulating near pH 6, and the addition of coagulant should be stopped at that pH (45). The amount and type of coagulant are important in producing reproducible tofu. Insufficient amount of coagulant would fail to coagulate the soy milk, but too much would result in low yield of small, hard aggregates with an uneven texture and a bitter (magnesium chloride) or chalky (calcium sulfate) taste (41). Data indicate that a coagulant concentration of 0.02 to 0.04 M is likely to produce a firm product (45). The characteristics of the five most common coagulants (magnesium sulfate, magnesium chloride, calcium sulfate, calcium chloride, and glucono-*d*-lactone) have been described by Karta (45). Stirring is necessary to keep the coagulant suspended, and the speed of stirring must be sufficient to maintain uniform distribution of the coagulant. A short mixing time is preferred because prolonged stirring may result in breakage of protein aggregates (50). In general, higher speed and shorter mixing time increase tofu yield.

Pressing. The soy protein coagulate (curd) is stirred and transferred to a shallow box for pressing. The purpose of breaking the gel is to disrupt the protein network to release the whey. Part of the whey is separated from the broken curd before transferal to the press box, and the rest is separated during pressing. Degree of curd breakage affects tofu yield and texture. Greater curd breakage generally leads to firmer texture and lower bulk yield. Variations in the pressing step include the amount of pressure and time applied (43). A study by Gandhi and Bourne (51) indicated that increasing the pressure from 0.19 Pa to 0.74 Pa reduced decrease moisture content from 82 to 60% and yield from 2 to 1.2 kg fresh tofu/kg soybeans. It also increased the hardness, chewiness, and gumminess of the final product. The ideal pressing temperature is between 68 and 70 °C; and, from a microbiological quality standpoint, tofu temperature should not fall below 60 °C (41).

Toasted Full-Fat Soy Flour. Full-fat soy flour, with different degrees of heat treatment, may be considered as modern industrial version of oriental soybean powder (5). It is made from dehulled soybeans and used mainly in bakery and dietetic foods. In the preparation of full-fat soy flours, soybeans first are steamed under light pressure for 20 to 30 min to inactivate lipoxygenases (52). Beans then are dried, cracked, dehulled, and ground finely to obtain full-fat soy flour.

Enzyme-Active Full-Fat Soy Flour. Soybeans used for producing enzyme-active full-fat soy flour are dried at low temperatures to minimize protein denaturation (52). Enzyme-active flour is produced by a process similar to that described for full-fat soy flour except that the initial steaming step is omitted. The resulting product is used widely in the food industry for bleaching wheat flour and for conditioning doughs in western-type breads. Enzyme-

active full-fat flour contains several lipoxygenases that bleach the carotenoid content of wheat flour to produce a whiter bread (5). The enzyme-active flour also possesses β-amylase activity, which improves the textural properties of dough. The U. S. Food and Drug Administration permits a maximum of 0.5% (w/w) of enzyme-active soy flour in wheat flour.

Fermented Foods

Fermented soybean food products are consumed commonly in Asian countries and are becoming increasingly popular in human diets in the United States and other western countries. Different procedures are used to produce somewhat similar and yet unique fermented soybean products, whose names differ between countries. This section will focus on manufacturing soy sauce, soy paste, and tempeh because they are representative and the commercially most important fermented products and because their process operations are similar to those of other fermented foods.

Soy Sauce. Soy sauce is a dark-brown liquid extracted from a fermented mixture of soybeans and wheat. Among the fermented soy foods, soy sauce is the most widely accepted, not only in the Far East but also in western countries (47). Depending on the geographic region, there are great variations in processing method and variety of soy sauce. Household production of soy sauce is still popular in some regions, but most soy sauce is made in commercial plants. Regardless of production level and method used, the basic steps and principles involved in soy sauce manufacture are very similar. Based on the method of preparation, soy sauce is divided into three types: fermented, chemical, and semichemical (47,53,54). In fermented soy sauce, proteins and carbohydrates in the raw material are enzyme hydrolyzed very slowly under mild conditions, below 30 °C for longer than 6 months. In chemical soy sauce, protein and carbohydrates are hydrolyzed quickly with hydrochloric acid at greater than 80 °C for 8 to 10 h. Semichemical soy sauce usually involves chemical hydrolysis of the raw material followed by lactic acid or yeast fermentation (47,53,54).

Fermented Soy Sauce. A typical process for the manufacture of a representative Japanese soy sauce (shoyu) generally involves treatment of raw material, koji preparation, brine fermentation, pressing, and refining.

Cleaned soybeans are soaked overnight in water at ambient temperature and then cooked for several hours under pressure. Soybeans are cooled quickly to 40 °C to prevent growth of undesirable microorganisms before fermentation (Fig. 7). Wheat kernels are roasted at 170 to 180 °C for a few minutes and then cracked into several pieces to be able to adsorb moisture from soybeans upon mixing (47,54).

Two fermentations are used in making soy sauce (Fig. 7). The first fermentation is a solid state and occurs during koji preparation, during which various enzymes are produced under aerobic conditions. The second fermentation, known as *brine fermentation*, is mainly anaerobic and begins after the addition of brine to the koji (47,54). The koji is the source of hydrolytic enzymes for converting polysaccharides and proteins into simple sugars, peptides, and amino acids, all of which are utilized by lactic acid bacteria and yeast in the subsequent brine fermentation (53). The soybean-wheat mixture is inoculated with a 0.1 to 0.2% (w/w) culture of *Aspergillus oryzae* or *A. sojae* and allowed to ferment in shallow, perforated vats for 3 to 4 days at 30 °C. Before brine fermentation, mature koji is mixed with 17 to 23% NaCl solution to achieve a final salt concentration of 17 to 19%. Lower salt concentrations allow growth of undesirable bacteria, whereas higher concentrations (greater than 23%) may retard growth of desirable halophilic bacteria and osmophilic yeast. The mash (*moromi*) is kept in large wooden containers or concrete vats fitted with aeration devices.

Temperature is an important factor during brine fermentation. In general, the higher the temperature, the shorter the fermentation time. Fermentation at lower temperatures results in a better product because enzyme inactivation rate is lower. A good quality soy sauce can be produced in 6 months by maintaining the mash temperature at 15 °C for the first month, at 28 °C the next 4 months, and at 15 °C the last month. Occasional stirring is necessary to provide aeration for yeast growth, to prevent growth of undesirable microorganisms, to maintain uniform temperature, and to facilitate CO_2 removal (47,54).

At the end of the fermentation and aging period, matured mash should have a bright reddish brown color, a pleasant aroma, and a salty but palatable taste. Raw soy sauce is commonly removed from the mash by pressing. Filtrate is stored in tanks to separate sediment (on the bottom) and floating oil (47,54). Refining of raw soy sauce consists of pasteurization (60 to 70 °C) and clarification by either sedimentation or filtration. Kaolin, diatomite, or alum may be added to enhance clarification. Heating during pasteurization inactivates enzymes and microorganisms, darkens the sauce, enhances the aroma, and induces formation of flocculants, which also facilitate clarification (47,54).

Chemical Soy Sauce. The chemical process, much simpler, faster, and cheaper than the fermentation process, results in a product lacking some of the fermented soy sauce flavor. Chemically processed soy sauce has a very limited market in Asia. In the western countries, where consumers are unaccustomed to the fermented product, acceptance of chemical soy sauce has been more rapid (54). In the chemical process, raw materials (soybeans and wheat) are hydrolyzed by boiling with 18 to 20% hydrochloric acid for 8 to 16 h (47,54). Hydrolysate is neutralized with sodium hydroxide or sodium carbonate to pH 4.5, pasteurized, and filtered. The resulting product is a clear dark-brown liquid with an approximate concentration of 18% (w/v) NaCl (47,54).

Semichemical Soy Sauce. Chemical soy sauce does not have the taste and flavor of fermented soy sauce. To improve its quality, chemical soy sauce is often blended with fermented soy sauce. A semichemical process has been developed whereby chemical hydrolysis is followed by lactic acid or yeast fermentation. Dilute hydrochloric acid (7 to 8%) is used to partly hydrolyze defatted soybeans, koji is added to the neutralized hydrolysate, and the mixture is inoculated with yeast. Fermentation can be shortened by

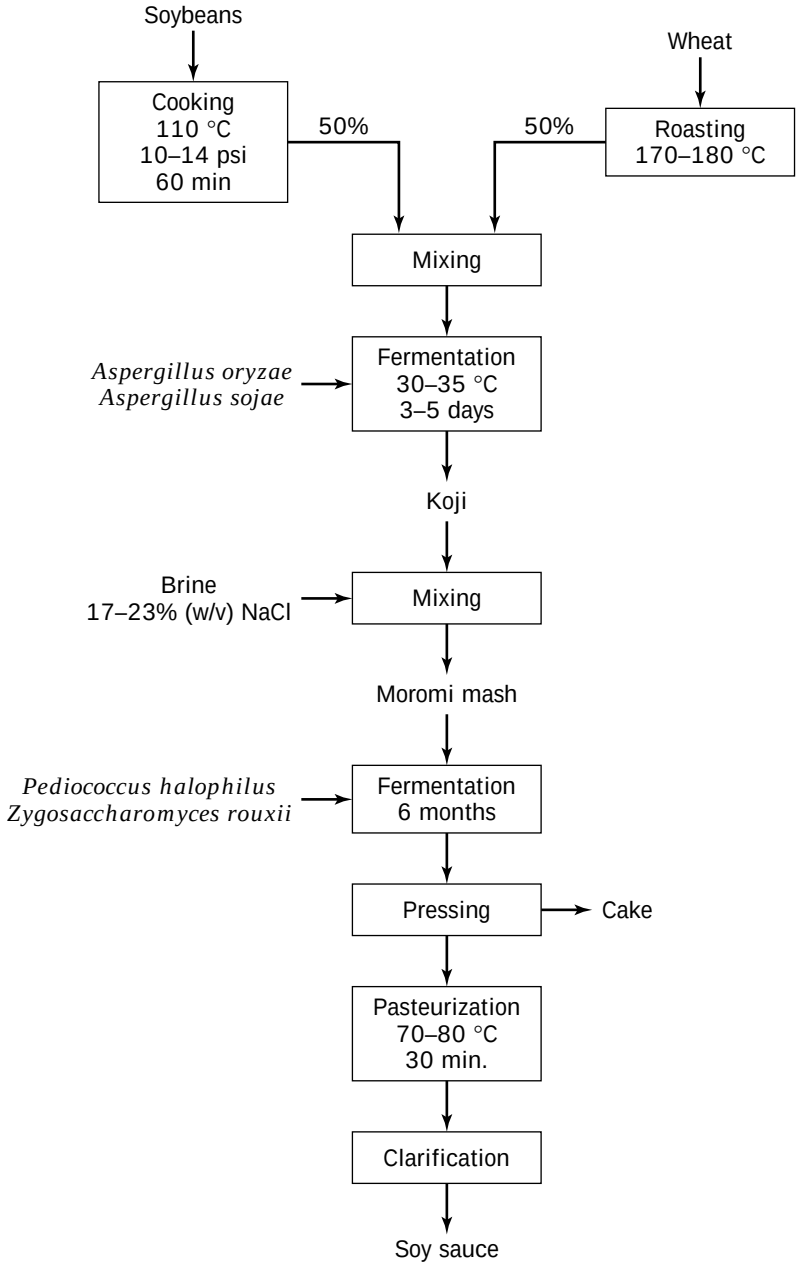

Figure 7. Flow diagram of the unit operations involved in the production of fermented soy sauce.

2 to 3 months, but the product retains some odors characteristic of chemically hydrolyzed beans (47,54).

Soy Paste. Soy paste is one of the most important fermented oriental soy foods. It is known commonly as *jiang* in China, *miso* in Japan, *jang* in Korea, *taucho* in Indonesia, and *taotsi* in Philippines. The process of making soy paste depends on the region, but the basic processes are essentially similar. The production of Japanese rice miso involves five steps (rice koji preparation, soybean treatment, ingredient mixing, fermentation, pasteurization, and packaging) that are very similar to those used in producing soy sauce (47,54). The major differences are that koji for miso is grown only on rice and that, because the whole fermented mixture is pasteurized and packaged for distribution, no pressing and filtering is required, as it is in the soy production. In this section, pertinent processing steps and conditions for making Japanese rice miso will be briefly discussed (Fig. 8).

Rice koji is prepared by soaking polished rice in water at 15 °C overnight or until the grain has a moisture content of 35%. After draining, the rice is cooked in an open cooker for 40 min, cooled to 35 °C, inoculated with a 0.1% (w/w) koji starter with *A. oryzae*, and incubated at 30 °C and 96% relative humidity (RH) for 15 h. After 15 h incubation, rice is spread on trays and maintained at 35 °C for an additional 25 to 30 h (47,54).

Soaked soybeans are steam cooked under pressure (10 to 15 psi) for 20 to 30 min. For white or light colored miso, soybeans are boiled with water at a 1:4 solids-to-water ratio to prevent browning. The advantage of boiling over steam cooking is the retention of soybean color, but the disadvantage is a 10 to 20% solids loss. Batch-type cookers are used widely, but continuous cookers with rotary bulbs and belt conveyers have been used recently in larger factories (47,54).

Pretreated soybeans are mixed with the rice koji and salt and blended in a closed blending container or ground with a sausage-type grinder. The mixture is packed tightly into wood, concrete or steel vats, covered with resin sheets or plates, and allowed to ferment at 30 to 38 °C. Fermentation for sweet miso production lasts between 10 and 15 days and for salty miso—2 and 12 months.

After ripening, miso is blended and, if needed, mashed again through a chopper with a plate cutter with perforations of 1 to 2 mm. The mashed miso is packaged in resin bags or cubic containers. For preservation, miso can be pasteurized or mixed with preservatives such as 2% ethyl alcohol or less than 0.1% sorbic acid (47,54).

Tempeh. Tempeh is a compact, cakelike product made by fermentation of dehulled and cooked soybeans with *Rhizopus oligosporous*. Tempeh is one of the most popular traditional foods in Indonesia and is becoming a popular vegetarian dish in the United States because it serves as a major source of protein, calories, and vitamins (55). A broad range of tempeh preparation methods have been reported; principles are the same, however, regardless of the method. Steinkraus et al. (54) have described a large-scale tempeh production method consisting of size grading, dry dehulling, hydration with optional addition of lactic acid, boiling, and fermentation (Fig. 9).

First, soybeans are cleaned to remove dirt, stones, weed seed, damaged and decomposed beans, and any other matter. Cleaned and graded soybeans are shrivelled slightly by dry heating for 10 min at 93 °C, cooled, and cracked to facilitate hull removal (47). Dehulled soybeans are soaked

Table 3. Principal Processing Steps and Uses of Fermented Soy Food Products

Food product (product description)	Main processing steps	Uses
Natto (cakelike product)	Soaking and cooking, fermenting with *Bacillus natto*	Side dish
Tao tio (soy paste type)	Cooking, fermenting with *Aspergillus* sp., sun-drying	Side dish, flavoring
Kochu chang (soy paste)	Boiling, mashing, fermenting, and drying	Flavoring
Ketiap (soy sauce)	Soaking, cooking, fermenting with *Aspergillus oryzae*, filtrating and washing, concentrating, and bottling	Flavoring
Sufu (soft cheese type)	Cutting, sterilizing, fermenting with *Mucor* and *Antinomucor* sp., brine aging	Side dish

Source: Data adapted from Johnson (1989) and Lui (1997) (47,52).

in water or 0.85% lactic acid solution for 2 h at 25 °C or for 30 min at 100 °C. Addition of lactic acid results in a pH drop to 4.3 to 5.3 and controls contaminating bacterial growth.

Hydrated soybeans are boiled for 60 min, drained, and cooled before inoculation with a pulverized pure *R. oligosporus* starter containing both mycelia and spores. Inoculated beans are spread out on perforated trays and covered with waxed paper to prevent dehydration and excessive aeration. Trays are incubated at 35 to 37 °C and 75 to 78% RH for about 18 h. At the end of the fermentation period, fresh tempeh is harvested, dried, and packaged before storage and shipping (47).

There are other traditional fermented products made from soybeans. Table 3 summarizes some of the best known, their principal processing steps, and their uses. Until now, most have been prepared on a small scale for family or regional consumption. Globalization of the world trade and economy is expected to increase demand for some of those products, whose production, in turn, will require further scale-up and modernization.

CONCLUDING REMARKS

Processing of soybeans into food, feed, and industrial products has experienced significant growth in the past, but new developments and challenges are foreseen. Continuous efforts must be made to further reduce energy consumption and to address safety issues and various environmental concerns such as air pollution, odor control, and waste treatment. New products and associated processing issues will emerge as a result of innovations in agricultural biotechnology. Plant biotechnology progress will not bypass the soybean industry; on the contrary, soy growers and processors will play an important role in capturing added value from new plant traits. For example, the precise alteration of metabolic processes in soybean plant will allow modification of quality, functional properties, and quantity of the protein, oil, and phytochemicals to fit end application. The new traits imparted to soybeans will require better understanding and control of soybean handling and processing to achieve the full impact and capture the added value of improved food and feed products. The ability to transfer new genes into soybeans (transgenic soybeans) will enable their use not only as a source for modified oil and protein but also as bioreactors to produce pharmaceutical proteins and drugs, industrial enzymes, biodegradable polymers, and nutritional supplements. Transgenic soybeans producing novel biomolecules will require significant processing adjustments and, in many instances, dedicated processing facilities. The success of newly derived products from genetically modified soybeans will probably depend on the close interaction or integration of the production, processing, and end application. The developments in processing of genetically engineered soybeans will ultimately affect processing and utilization of commodity soybeans.

OUTLINE

Stainless steels offer an unusual combination of strength, ductility, formability, weldability, corrosion resistance, and amenability to cleaning that makes them uniquely suitable for pharmaceutical and bioprocessing operations. This article discusses the origin and nature of stainless steels, the several groups and many grades of stainless steels, together with the fundamentals of the metallurgical differences. Specific corrosion phenomena that pose potential problems, together with preventive and remedial measures, are presented. I explain the basic nominal workhorse compositions, together with their potential weaknesses, and discuss the possible utilization of other more highly alloyed substitute alloys. Particular emphasis is laid upon measures for quality assurance, postfabrication cleanup procedures, and passivation treatments to ensure improved resistance toward specific types of localized corrosion.

THE NATURE OF STAINLESS STEELS

As a whole, stainless steels and similar chromium-rich alloys are characterized by their *passivity*. Passivity is a condition in which a base metal, such as iron, exhibits the corrosion behavior of a more noble metal or alloy. As described further here, passivity cannot be maintained under some specific conditions.

Steel is an alloy of iron and carbon plus other minor elements and is notorious for susceptibility to rusting. With even minimal corrosion, it is a source of iron contamination and is therefore objectionable in many services. However, when a minimum of 12% chromium (Cr) is alloyed with steel, the resulting metal is generally not susceptible to rusting under ordinary circumstances of exposure to the atmosphere or in substantially neutral aqueous solutions. (Certain exceptions, however, are described further here.) Actually, several types of stainless steels, which are characterized by specific properties, have been developed.

TYPES OF STAINLESS STEELS

The 12% Cr grades of stainless steels are predominantly "martensitic." Martensite is a needlelike structure resulting from heating and quenching iron-base alloys, which gives increased hardness and strength with a concurrent diminution of ductility. (A certain amount of ductility is restored by tempering, i.e., heating to some intermediate temperature.) The martensitic grades are exemplified by Type 410 (UNS S41000) (1) and are characteristically magnetic.

When the chromium is increased to about 17%, the material is magnetic but not amenable to hardening by heat treatment. Such alloys, exemplified by Type 430 (S43000), are classified as "ferritic" and are more corrosion resistant than the martensitic grades by virtue of their higher chromium content, although they have lower strength than heat-treated martensitic grades.

The "workhorse" materials for the process industries, however, are the "austenitic" grades, often loosely called "18-8" stainless steels. When about 8% nickel (Ni) is added to an 18% Cr steel, a face-centered crystal structure called austenite is formed that is characteristically nonmagnetic. (This structure exists only at elevated temperatures with steels and the straight chromium grades.) Austenitic stainless steels, exemplified by Type 304 (S30400) and Type 316 (S31600), have in general a remarkable combination of properties that occasion widespread use in the process industries as compared with the martensitic and ferritic grades, which are used much less frequently.

Stainless steels that contain 18% Cr or more are also alloyed with a lesser amount of nickel (about 5%) to form "duplex" grades, which are about 50:50 austenite and ferrite. This method results in alloys of higher strength than Types 304 (S30400), 316 (S31600), and so forth, with an improved resistance in aqueous environments of high chloride content. The newer duplex grades are exemplified by Alloys 2205 (S31803) and 255 (S32550).

Finally, there are "superferritic" grades such as Alloy 26-1 (S44626) and several "superaustenitic" alloys, exemplified by Alloys 254SMO (S31254) and 6XN (N08367). The superaustenitic grades have superior resistance to localized corrosion such as pitting, crevice corrosion, and stress corrosion cracking (SCC) in chloride-bearing environments. Also, they are as strong as duplex grades by virtue of nitrogen addition.

The compositions of some typical specific grades in these basic categories are given in Table 1, wherein the midrange of major elements is given with the maximum allowable concentration for minor elements. More detailed listings of stainless steel types and compositions are available (2).

CORROSION MECHANISMS

Corrosion of metals is electrochemical in nature, metal ions being formed at anodic sites by oxidation, accompanied by a discharge of electrons through the external (metallic) circuit. At cathodic sites, electrons provide reduction of specific species (e.g., dissolved oxygen, cations) in the electrolyte to complete the reaction equilibrium. This change is most apparent in galvanic (i.e., bimetallic) corrosion in which the anodes and cathodes are different materials (e.g., the galvanic corrosion of steel by contact with copper, or of zinc by contact with steel). However, it also occurs in monometallic corrosion, such as steel in water, wherein discrete local anodes and cathodes of a transient nature provide the reactions.

$$Fe^{\circ} \rightarrow Fe^{2+} + 2e \text{ (anodic)}$$

$$2H^{+} + 1/2O_2 \rightarrow H_2O \text{ (cathodic)}$$

The formation and dissipation of discrete anodes and cathodes cause the general, uniform corrosion typical of base metals.

When a metal or alloy is protected by a superficial layer of a composition different from the substrate (mill-scale on steel; oxide films on copper-, nickel-, or chromium-bearing alloys), anodic sites may be relatively stable at defects in the otherwise protective film, causing a more localized type of attack. This reaction is somewhat analogous to galvanic corrosion, the film acting as a cathode to the more anodic substrate.

CORROSION SUSCEPTIBILITY OF STAINLESS STEELS

The stainless steels in general resist corrosion because of the formation of an invisible oxide film that renders them

passive in oxidizing environments. The semipermanent surface passive film is very thin (about 0.1 nm), analogous to ice on a pond. This passive film of chromic and silicon oxides plus adsorbed oxygen can be increased in thickness by exposing it to oxidizing solutions or by anodic passivation using an electrochemical technique. (Note: Electropolishing is followed by another electrochemical treatment to reform and enhance the passive film following anodic dissolution of the alloy. If the film is solubilized, as by reducing acids such as hydrochloric or dilute sulfuric, stainless steels change from a passive to an active state and are actually less resistant than ordinary iron and steel.) Most applications of stainless steels are in air, aerated water, and other oxidizing media wherein the passive film is retained. It should be noted that stainless steels are *autopassivating*; the film reforms immediately if removed by mechanical means (e.g., abrasion) when the alloy is subsequently exposed to air, water, or other oxidizing environments. They do not demonstrate the active state except under continuous abrasion or conditions of immersion in reducing environments.

Stainless steels are resistant to general corrosion in most applications, with corrosion rates <4–5 mpy. When data are reported showing general corrosion rates of 10, 20, or 50 mpy, this indicates that the alloy is fluctuating between an active and a passive state and should not be used in that specific environment. Unfortunately, despite their passive nature, stainless steels are subject to several forms of localized attack. These are described further for the austenitic grades, which are the primary alloys for bioprocessing applications (3).

FORMS OF LOCALIZED CORROSION

Pitting

Pitting can occur on boldly exposed surfaces in high-chloride environments, such as brackish cooling waters or dilute hypochlorite solutions (e.g., during sanitizing operations). The molybdenum-free alloys such as Type 304L (S30403) are more susceptible to pitting than molybdenum-bearing alloys in chloride-bearing environments, and the problem is combated by specifying successively higher grades, that is, Type 316L, Type 317L (S31703), and the 6% Mo grades as required by the severity of the environment.

Crevice Corrosion

Crevice corrosion is a special form of pitting occurring in physical or mechanical crevices (e.g., flanges, threaded fasteners) or under surface films. When it occurs under calcareous deposits, biomasses, or other foreign material, it is known as “under-deposit corrosion” or UDC. Typically, crevice corrosion is driven by a dissolved oxygen (DO) cell, the oxygen-starved crevice functioning as an anode to the boldly exposed cathodic area where the DO constitutes a cathodic depolarizer. However, the cell can also be driven by dissolved sulfur (DS) or by differences in metal ion concentrations. Crevice corrosion is aggravated by chloride contamination, the chlorides being attracted to the anodic sites and producing a locally low pH (e.g., pH 2) from acid chlorides within the crevice.

Sensitization

When the regular carbon grades such as Types 304 (S30400; 18 Cr–8 Ni–0.08 C maximum) or 316 (S31600) are heated in the temperature range from about 800° to 1,500 °F (as by slow cooling from the annealing process or from thermal stress-relieving treatment, or in the heat-affected zones of welds), carbon migrates to the grain boundaries and precipitates as chromium carbides. This leaves a chromium-depleted zone around each grain and causes a susceptibility to intergranular corrosion (IGA) in many environments. When IGA is observed in the heat-affected zone of welds, it is commonly called by the misnomer “weld decay,” although it is not the weld itself that suffers corrosion. Sensitized areas are also more prone to chloride pitting than are unaffected areas such as those at some distance from welds.

Conventional sensitization by chromium carbide precipitation was originally combatted by addition of stabilizing elements, that is, columbium (niobium) or titanium, to an 18-8 alloy such as Type 304 (S30400). When stabilizing elements are present in concentrations several times the carbon content, it is their carbides that precipitate, thereby avoiding chromium depletion. The stabilized grades such as Types 321 (S32100) and 347 (S34700) are therefore derivatives of Type 304 containing Ti and Cb, respectively, and are still used in some special applications. It should be noted that titanium-stabilized grades such as S32100 require a stabilizing anneal at about 1,800 °F to tie up the carbon in the form of titanium carbides before welding. IGA may occur even in stabilized or low-carbon grades if weldments are carbon-contaminated by oil or grease.

The stabilized grades can themselves become sensitized by multipass welding or cross-welding, causing knife-line attack (KLA); this is caused by a resolubilizing of the columbium or titanium carbides by the heat of welding, followed by slow cooling. This step requires about 1,250 °C (2,300 °F) reheating in 18-8 grades, moving the susceptible area to the fusion zone, and permitting a very narrow band of corrosion immediately adjacent to the weld (KLA). With higher nickel content, the resolubilization temperature drops; Alloy 20Cb3 (N08020) and Alloy 825 (N08825) with nickel contents in the 35% range are more easily sensitized to KLA (about 980 °C or 1,800 °F) than is type 347.

In modern practice, the problems of sensitization have been largely alleviated by use of low-carbon grades (Type 316L, S31603; 17 Cr–12 Ni–2.5 Mo–0.030 C maximum), although sensitization will occur with very prolonged exposure in the sensitizing range (e.g., in long-time service >800 °F or when stainless steel–clad vessels are thermally stress relieved). Modern-day steel-making practice using argon–oxygen decarbonation (AOD) makes very low carbon grades of stainless steels routinely available.

IGA may also occur due to mechanisms other than carbide precipitation. A ferrite phase, if present for any reason, may be selectively attacked by reducing acids such as hydrochloric or sulfuric; its thermal conversion product, sigma phase, is selectively attacked by oxidizing acids (e.g.,

nitric). Chi phase can form in molybdenum-bearing grades (S31603) as the result of prolonged heating in the sensitizing range (e.g., thermal stress relief of clad-steel vessels), producing IGA in alloys of <0.030% carbon in certain aggressive environments.

Selective Weld Corrosion

Selective or preferential attack is sometimes encountered in weldments, particularly in the molybdenum-bearing grades. This can occur either in conventional welds or autogenous welds (i.e., welds made without the addition of filler metal) in some environments. This type of attack is ascribed to microsegregation, which causes a maldistribution of the molybdenum component of the alloy.

Selective weld corrosion is the reason for the cold-work requirement for welded stainless steel condenser tubes (see ASTM A249). Cold-working to minimum requirements before the final anneal allows the weld to recrystallize and homogenize, alleviating the microsegregation.
